Foreword

The 2015 International Conference on Extending Database Technology (EDBT) took place between the 23rd and the 27th of March in Brussels, Belgium. In its 18th edition, EDBT 2015 continued its long tradition of offering an outstanding research venue for the database community where to present and discuss recent contributions.

This year, there were 184 submissions to the research track, 19 to the industrial track, and 25 to the demo track. While these numbers are somewhat lower than in recent editions, the quality of the submissions was very high, which made the job of the Program Committee quite difficult. At the end, the program committee selected for publication 13 demos, 9 industrial papers, and 47 research papers. Of the latter, 5 of them were Vision Papers, shorter papers proposing radically new ideas, which were presented in their own session at the conference.

I would like to take this opportunity to thank all those that have made the 2015 EDBT edition such a success. First and foremost, all the authors of papers submitted to the conference, thereby providing the basis for a strong program, as well as the program committee members for their effort and dedication to study the submissions in detail and engaging in many interesting discussions about the papers, their contributions, their merits, and how to create the best possible program. Special mention should be made of the small committee in charge of deciding the Test of Time Award, in this occasion covering 4 editions of the conference (from 1988 to 1994): Martin Kersten, Christoph Koch, and Guido Moerkotte. They selected the following paper for the award:

> Geo-Relational Algebra: A Model and Query Language for Geometric Database Systems, Ralf Hartmut Güting, University of Hagen, Germany, from EDBT 1988.

I also would like to thank Lucian Popa and Jens Teubner for the great work they have done in running the industrial and demo tracks. Martín Ugarte has done an excellent job with the proceedings, as have Pablo Barceló with the tutorials and Peter Fischer with the workshops. The Conference Chair—Floris Geerts—and the local organizers have also been instrumental in coordinating all the efforts of what is a very complex and demanding endeavor. As a joint EDBT/ICDT Conference, we have four keynote talks, two of which have been proposed by the EDBT community. Thanks go to Christoph Koch and Wolfgang Lehner for their acceptance of our invitation. Finally, Christine Collet and Norman Paton have been instrumental in coordinating the overall effort with the Executive Board of EDBT.

EDBT 2015 Test of Time Award

In 2014, EDBT began awarding the EDBT test-of-time (ToT) award, with the goal of recognizing one paper, or a small number of papers, presented at EDBT earlier and that have best met the "test of time", i.e. that has had the most impact in terms of research, methodology, conceptual contribution, or transfer to practice over the past decade(s). The EDBT ToT award for 2015 will be presented during the EDBT/ICDT 2015 Joint Conference, March 23-27, in Brussels (Belgium). The EDBT 2015 Test of Time Award committee was formed by Martin Kersten (CWI, The Netherlands), Guido Moerkotte (Uni Mannheim, Germany), Christoph Koch (EPFL, Switzerland), all members of the EDBT 2015 PC and chaired by Gustavo Alonso, the EDBT 2015 PC chair.

The committee was charged with selecting a paper or a small number of papers from the proceedings of the following 4 editions: EDBT'88 - Venice, EDBT'90 - Venice, EDBT'92 - Vienna, EDBT'94 - Cambridge.

After careful consideration, the committee has decided to select the following paper, as the EDBT ToT Award winner for 2015:

Geo-Relational Algebra: A Model and Query Language for Geometric Database Systems
by Prof. Dr. Ralf Hartmut Güting, University of Hagen, Germany
Published in the EDBT 1988 proceedings, 506-527

The paper addresses the user's conceptual model of a database system for geometric data. It proposes to extend relational database management systems by integrating geometry at all levels: At the conceptual level, relational algebra is extended to include geometric data types and operators. At the implementation level, the wealth of algorithms and data structures for geometric problems developed in the past decade in the field of Computational Geometry is exploited. The paper starts from a view of relational algebra as a many-sorted algebra which allows to easily embed geometric data types and operators. A concrete algebra for two-dimensional applications is developed. It can be used as a highly expressive retrieval and data manipulation language for geometric as well as standard data. Also, geo-relational database systems and their implementation strategy are discussed.

The committee members unanimously agreed that this paper clearly stands out in terms of relevance, impact, and influence in databases. Of all the papers considered, this is the one that had had the most and longest lasting impact with results that are still relevant today and whose influence can be traced to many real systems and a significant amount of follow up work.

The paper pioneered an important application area well before it became mainstream and did it in a systematic and clean way that has been very influential in both research and practice. Modern commercial systems all support geographic data types that are nowadays used in a wide range of applications and use cases (maps, locations based services, geographic information systems, mobility, etc.).

The selection committee also appreciated very much the cleanliness, completeness, insights, formalism, and systematic treatment of the problem as well as the approach followed by the author in selecting and solving a research problem.

ABSTRACT

Most of previous studies on automatic database partitioning focus on deriving a (near-)optimal (re)partition scheme according to a specific pair of database and query workload and oversees the problem about how to efficiently deploy the derived partition scheme into the underlying database system. In fact, (re)partition scheme deployment is often non-trivial and challenging, especially in a distributed OLTP system where the repartitioning is expected to take place online without interrupting and disrupting the processing of normal transactions. In this paper, we propose SOAP, a system framework for scheduling online database repartitioning for OLTP workloads. SOAP aims to minimize the time frame of executing the repartition operations while guaranteeing the correctness and performance of the concurrent processing of normal transactions. SOAP packages the repartition operations into repartition transactions, and then mixes them with the normal transactions for holistic scheduling optimization. SOAP utilizes a cost-based approach to rank the repartition transactions' scheduling priorities, and leverages a feedback model in control theory to determine in which order and at which frequency the repartition transactions should be scheduled for execution. When the system is under heavy workload or resource shortage, SOAP takes a further step by allowing repartition operations to piggyback onto the normal transactions so as to mitigate the resource contention. We have built a prototype on top of PostgreSQL and conducted a comprehensive experimental study on Amazon EC2 to validate SOAP's significant performance advantages.

1. INTRODUCTION

The difficulty of scaling front-end applications is well known for DBMSs executing highly concurrent workloads. One approach to this problem employed by many Web-based companies is to partition the data and workload across a large number of commodity, shared-nothing servers using a cost-effective, distributed DBMS. The scalability of online transaction processing (OLTP) applications on these DBMSs depends on the existence of an optimal database design, which defines how an application's data and workload is partitioned across the nodes in a cluster, and how queries and transactions are routed to the nodes. This in turn determines the number of transactions that access data stored on each node and how skewed the load is across the cluster. Optimizing these two factors is critical to scaling complex systems: a growing fraction of distributed transactions and load skew can degrade performance by a factor of over ten. Hence, without a proper design, a DBMS will perform no better than a single-node system due to the overhead caused by blocking, inter-node communication, and load balancing issues.

Automatic database partitioning has been extensively researched in the past. As a consequence, nowadays, most DBMSs offer database partitioning design advisory tools. The idea of these tools analyze the workload at a given time and suggest a (near-)optimal repartition scheme in a cost-based or policy-based manner, with the expectation that the system performance can thereby always maintain a consistently high level. It is then the DBA's responsibility to deploy the derived repartition scheme into the underlying database system, which however often posts great challenges to the DBA. On the one hand, the repartition operations should be executed fast enough so that the new partition scheme can start to take effect as soon as possible. However, granting high execution priorities to the repartitioning operations will inevitably slow down or even stall the normal transaction processing on the database system. On the other hand, the repartitioning procedure should be as transparent to the users as possible. In other words, the normal user transactions' correctness must not be violated and the processing performance should not be significantly influenced. Obviously, even skilled DBAs may not be able to easily figure out the best ways of deploying repartition schemes, especially when the workload changes over time

10.5441/002/edbt.2015.02

and has bursts and peaks. As a result, automatic partition scheme deployment satisfying the above requirements is highly desirable. Surprisingly, few previous studies have been devoted to this important research problem.

In this paper, we focus on the problem about how to optimally execute a database repartition plan consisting of a set of repartition operations in a distributed OLTP system, where the repartitioning is expected to take place online without interrupting and disrupting the normal transactions' processing. We propose SOAP, a system framework for scheduling online database repartitioning for OLTP workloads. SOAP aims to minimize the time frame of executing the repartition operations while guaranteeing the correctness and performance of the concurrent normal transaction processing.

SOAP models and groups the repartition operations into repartition transactions, and then mixes them with the normal transactions for holistic scheduling optimization. There are two basic strategies for SOAP to schedule the repartition transactions, which are similar to the techniques used in state-of-the-art database systems' online repartitioning solutions. The first strategy is to maximize the speed of applying the repartition plan and submit all the repartition transactions to the waiting queue with a priority higher than the normal transactions. The second strategy schedules repartition transactions only when the system is idle. Both basic strategies lack the flexibility to find a good trade-off between the two contradicting objectives: maximizing the speed of executing repartition transactions and minimizing the interferences to the processing of normal transactions. As a result, SOAP interleaves the repartition transactions with normal transactions, and leverages feedback models in control theory to determine in which order and at which frequency the repartition transactions should be scheduled for execution.

In the feedback-based method the repartition transactions have the same priority as the normal transactions, hence they will contend with normal transactions for the locks of database objects and significantly increase the system's workload, especially when the system is under heavy loads or resource shortage. To mitigate this issue, SOAP utilizes a piggyback-based approach, which injects repartition operations into the normal transactions. The overhead of acquiring and releasing locks as well as performing the distributed commit protocols incurred by a repartition transaction can be saved if the normal transaction that it piggybacks on will access the same set of database objects.

While the piggyback-based approach consumes less resources, it fails to take use of the available system resources to speed up the repartitioning process. This may leave some resources unused when the system workload is low and there are few transactions to piggyback on. Therefore, SOAP adopts a hybrid approach that is composed by a piggyback module and the feedback module. When the system workload does not use up all the system's resources, we can make use of the available resources to repartition the data before the actual arrival of transactions that will access them, meanwhile the piggyback-based approach will attempt to let the repartition transactions piggyback on the normal transactions when they arrive.

To summarize, we make the following contributions with this work:

- To the best of our knowledge, we are among the first to specifically study the problem of online deploying database partition schemes into OLTP systems.
- We propose a feedback model that realizes dynamic scheduling of the repartition operations.
- We also propose a piggyback approach to execute selected repartition operations within normal transactions to further mitigate the repartitioning overhead.
- We have built a SOAP prototype on top of PostgreSQL, and conducted a comprehensive experimental study on Amazon EC2 that validates SOAP's significant performance advantages.

The rest of this paper is organized as follows. In Section 2, we describe the generic SOAP system architecture, as well as how SOAP realizes online repartitioning for OLTP workloads. In Section 3, we elaborate SOAP's feedback-based, piggyback-based and hybrid approaches of online scheduling repartition operations. Section 4 presents the experiment set-up and experimental results of a SOAP prototype on an Amazon EC2 cluster. We discuss the related works in Section 5 and then conclude in Section 6.

2. SOAP SYSTEM OVERVIEW

In this section, we describe the generic SOAP system architecture, as well as how SOAP realizes online repartitioning for OLTP workloads.

2.1 SOAP System Architecture

Figure 1 shows a SOAP-enabled distributed database architecture providing OLTP services. The clients submit user transactions through a *transaction manager (TM)*, which can be either centralized or distributed.Each submitted transaction will be given a global unique ID by the TM. TM takes care of the processing life-cycle of transactions and guarantees their ACID properties with certain distributed commit protocols and concurrency control protocols. The *query router* maintains the mappings between data partitions and their resident nodes, based on which it routes the incoming transaction queries to the correct nodes for execution. All the submitted transactions will be associated with a scheduling priority and then put into a *processing queue*, where higher-priority transactions will be executed first, while the FIFO policy will be applied to break the tie. The rules of setting priorities are customizable.

The transaction manager, query router and processing queue are common components in most OLTP systems, while SOAP introduces a new component *repartitioner* to coordinate its online database repartitioning for OLTP workloads. In the following subsection, we describe how the repartitioner works.

2.2 Online Database Repartitioning

In this paper, we consider the scenarios where the type of transactions and frequency of OLTP workloads could change over time, so that periodic database repartitioning is required in order to maintain the system performance.

The repartitioner determines when and how the OLTP database should be repartitioned. Its optimizer component periodically extracts the frequency of transactions and their visiting data partitions from the workload history, and then estimates the system throughput and latency in the near

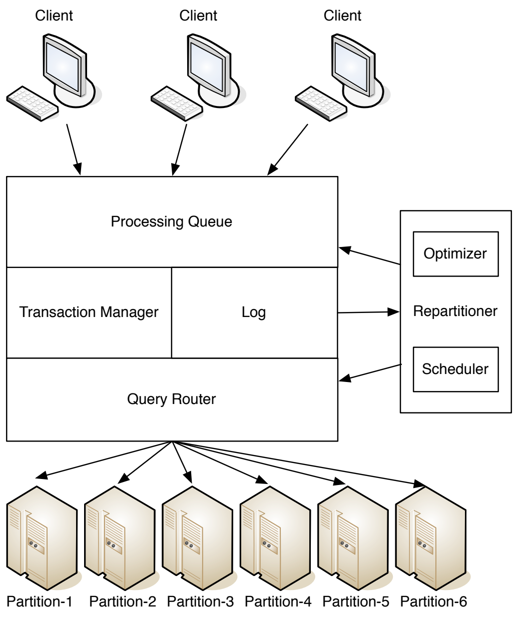

Figure 1: The generic SOAP system architecture

future based on the history. If the estimated system performance is under a predefined threshold, the optimizer will derive a repartition plan in a cost-based manner. The repartition plan could be at the granularity of moving individual tuple or tuples within some ranges or with some hash keys on their attributes. We assume each tuple contains enough information to be positioned by query router. We assume tuple replicas are only made for the purpose of high availability, yet make no assumptions about the replication strategy utilized. Tuple replicas will be distributed over distinct data partitions, and the query router will determine for a transaction which replica of a specific tuple should be visited.

The optimizer will generate three types of repartition operations together with the normal transactions accessing the database objects repartitioned by each of them, i.e. *new replica creation*, *replica deletion* and *objects migration*.

- *New Replica Creation*: insert some new replicas of database objects originally stored in a data partition into an another one containing no other replicas of the same objects.
- *Replica Deletion*: for database objects with multiple replicas, delete the specific replica within one partition.
- *Objects Migration*: relocate some database objects between two partitions; the procedure is realized by first inserting new replicas of them into the destination partition and then deleting the original ones from the source partition.

To execute the repartition operations, the scheduler packages them into repartition transactions using the information provided by the optimizer. The repartition transaction will be scheduled by the repartitioner and submitted to the system at a chosen time. It utilizes a cost-based approach to determine the repartition transactions' execution orders, and leverages a feedback model in control theory to determine at which frequency the repartition transactions should be scheduled for execution. As such, the processing of repartition transactions and normal transactions may be interleaved. In other words, during the database repartitioning, the processing of normal transactions will keep going on, and an online scheduling algorithm, which will be elaborated in Section 3, attempts schedule repartition transaction so that the time frame of executing the repartition operations is minimized while guaranteeing the correctness and performance of the concurrent processing of normal transactions.

The repartitioner accesses the system logs, manipulates the processing queue and updates the mapping information and routing rules in the query router during and after the database repartitioning. With the piggyback-based execution method, the repartitioner may need to modify the normal transactions by inserting additional repartition operations to some of them, and the transaction manager will coordinate the processing of the modified normal transactions.

3. ONLINE REPARTITION SCHEDULING

The scheduling of repartition operations has to be done in an online fashion. Besides the incoming workload is hard to predict, there are many system factors that will cause the system performance to fluctuate over time, such as variations of network speeds/bandwidth, transaction failures, and interferences from other programs running on the same server. Therefore, we study how to implement an online scheduler that can continuously adapt to the system's actual workload and capacity.

3.1 Generating and Ranking Repartition Transactions

In all the subsequent scheduling algorithms, we have to first decide the execution order of repartition transactions and schedule the more "beneficial" ones before those less "beneficial". To achieve this, we need to estimate the cost and benefit of executing such transactions. To estimate the cost of a transaction under different partitioning plans, we follow the approach in [4]. Suppose the cost of running transaction T_i with a repartition plan where all the tuples accessed by T_i are collocated in a single partition is C_i, then the cost of T_i with a plan where T_i has to access more than one partition is $2C_i$.

To estimate the benefit of a repartition transaction, we use the cost model of the data partitioning algorithms, such as [4, 13, 15]. Suppose the cost of an arbitrary normal transaction T_i with partition plan $\mathcal{P}$ is $C_i(\mathcal{P})$, then the benefit of a repartition transaction T_j, denoted as B_j can be defined as $\Sigma_{\forall T_i} f_i(C_i(\mathcal{O}) - C_i(\mathcal{P}))$, where f_i is the frequency of T_i. Finally, we can define the benefit density of T_j as B_j/C_j and then we can schedule the repartition transactions in descending order of their benefit densities.

To package the repartition operations into transactions, there are two simple options: (1) putting all operations into one transaction and (2) creating one transaction for each operation. The first option will create a very large transaction especially when there are a lot of data to be repartitioned. Such a large transaction will be run for a very long time and will significantly increase resource contention. For example, with a 2PL policy, the repartition transaction has to hold the locks of all the data objects involved in the repartition plan until it is committed. This will substantially increase the degree of lock contention with the normal transactions. On the other hand, the second option will not suffer from this problem but it will create a lot of transactions each incurring overhead to the transaction manager. It is desirable to find a good trade-off between this two extremes. In principle, we would like to create small transactions and their overhead can be paid off by the benefit that it will bring to the system. As accurately predicting and quantifying the overhead and the degree of lock contentions that will be introduced by a repartition transaction is difficult, we adopt a simple heuristic here. Roughly speaking, we put the repartition operations that repartition all the objects accessed by a normal transaction into a repartition transaction. In this way, we can ensure that there is at least one normal transaction that will benefit from executing the repartition transaction. Provided that the achieved benefit is greater than the overhead of introducing the repartition transaction, we can ensure that the overhead will be paid off when the repartition transaction is executed. Furthermore, even with this heuristic, there are still many possible ways to combine the repartition operations into transactions. We prefer generating transactions that will have higher benefit densities and, as mentioned earlier, schedule them in descending order of their benefit densities.

Algorithm 1 shows the whole process for the scheduler to generate a ranked list of repartition transactions. Given a new partition plan $\mathcal{P}$ generated by a cost-based repartition optimizer, the scheduler will obtain a list of repartition operations OP_{rep} together with the list of normal transactions that will access the data objects modified by each operation. In line 1-8, we construct a map T_{OP} that maps the ID of a normal transaction t_i with frequency f_i to a group of repartition operations that will modify objects accessed by t_i. In other words, the performance of t_i will be affected by this list of repartition operations.

We then calculate the benefit of executing each repartition operation in lines 9-14. After that, we can calculate the total benefits of each group of repartition operations in T_{op} and store them in another map $T_{benefit}$ with value descending order. Finally, we transform each group of repartition operations into a repartition transaction, and make sure each repartition operation only belongs to one repartition transaction. These repartition transactions will be returned by the algorithm as the output. Furthermore, we calculate the benefit density of each repartition transaction and sort them in descending order. Given a repartition transaction r_i and a normal transaction t_i whose performance will be affected by r_i, T_{Rep} maps the ID of r_i to the ID of t_i and the benefit density of r_i. Such auxiliary information will be used in our subsequent scheduling algorithms.

Algorithm 1: Generating and Ranking Repartition Transactions

```
Data: a list of repartition operations $OP_{rep}$ generated
      by optimizer, new partition plan $\mathcal{P}$
Result: a list of repartition transactions $L_{Rep}$,a map
        $T_{Rep}$ mapping repartition transaction id to a
        affected normal transaction id and the benefit
        density of the repartition transaction
1  Create HashMap $T_{op}$, a mapping from normal
   transaction to the repartition operations that edit the
   objects visited by it
2  for $op_k \in OP_{rep}$ do
3      for Normal transaction $t_i$ accessing the objects
       modified by $op_k$ do
4          if $C_i(\mathcal{O}) - C_i(\mathcal{P}) > 0$ then
5              Insert $op_k$ to $T_{op}$.get($t_i$)
6  for $t_i \in T_{op}.keylist$ do
7      benefit $\leftarrow f_i \frac{C_i(\mathcal{O})-C_i(\mathcal{P})}{T_{op}.get(t_i).size()}$
8      for $op_k \in T_{op}.get(t_i)$ do
9          $op_k.benefit$ += $benefit$
10 Create HashMap $T_{benefit}$, a mapping from repartition
   operation group ID to the total benefit for system if all
   the operations within this group are executed
11 for $(t_i, L_{op}) \in T_{op}.entrySet$ do
12     benefit $\leftarrow$ 0; for $op_i \in L_{op}$ do
13         benefit += $op_i.benefit$;
14     Insert ($t_i$,benefit) to $T_{benefit}$;
15 Sort $T_{benefit}$ with value descending order
16 for $(t_i, benefit) \in T_{benefit}$ do
17     ops $\leftarrow T_{op}.get(t_i)$;
18     for $op_i \in ops$ do
19         if $op_i \notin OP_{rep}$ then
20             Remove $op_i$ from ops; $T_{benefit}.get(t_i) \leftarrow$
               $T_{benefit}.get(t_i) - op_i.benefit$;
21     Remove ops from $OP_{rep}$;
22     Create $r_i$ with ops;
23     $c_i \leftarrow$ Cost($r_i$,$\mathcal{O}$);
24     $cpr_i \leftarrow \frac{T_{benefit}.get(t_i)}{c_i}$;
25     Insert $((r_i, t_i), cpr_i)$ to $T_{Rep}$;
26     Insert $r_i$ to $L_{Rep}$
27 Sort $T_{Rep}$ with value descending order;
```

3.2 Basic Solution

In general, there is a tension between the two objectives in our scheduling: (1) executing the repartitioning queries as soon as possible to improve the current partitioning plan, (2) avoiding interferences to the normal transactions and making the repartition process transparent to the end users. In this subsection, we propose two baseline solutions, each favoring one of the objectives.

Apply-All. This strategy is to maximize the speed of applying the repartitioning plan and submits all the repartition transactions to the waiting queue with a priority higher than the normal transactions. As mentioned earlier, the system will schedule the transactions in descending order of their priorities and hence this strategy is equivalent to pausing the processing of normal transactions and performing the repartitioning queries immediately. Depending on the number of repartition transactions, the normal transactions may need to wait for a rather long time, which is usually unacceptable.

After-All. To minimize the interferences to normal transactions, we can use a lazy strategy where repartition transactions will only be scheduled when the system is idle. We can achieve this by giving all the repartition transactions a priority lower than the normal ones. By doing so, the normal transactions will almost not be affected by repartition transactions and the repartitioning could be done transparently. Due to this advantage, a state-of-the-art approach for online repartitioning adopted this strategy [15]. However, there is a downside of this approach: the repartitioning may be per-

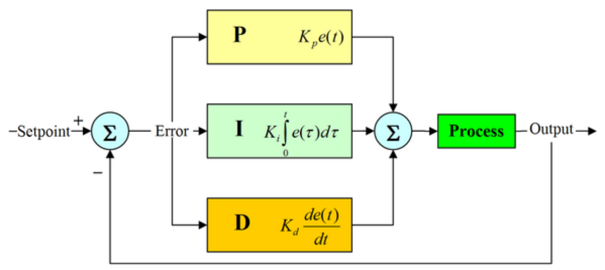

Figure 2: A sample PID controller block diagram

formed too slowly, especially when the system workload is high and there is very little idle time. Under this situation, the high workload could actually be alleviated by adopting the new and better partitioning plan and this strategy fails to take advantage of those.

3.3 Feedback-based Approach

As discussed earlier, the aforementioned basic solutions lack the flexibility to find a good trade-off between the two contradicting objectives. To achieve this, one can schedule some additional repartition transactions on top of those scheduled by the After-All strategy. These additional transactions will be assigned with the same priority as the normal transactions so that they have the chance to be executed faster. We call such transactions as high-priority repartition transactions to distinguish them with those low-priority ones scheduled by the After-All strategy. To limit the impact over the normal transactions, we can limit the number of high priority repartition transactions.

However, such a seemingly simple idea is rather challenging to realize in practice. Note that the number high-priority repartition transactions that we can execute without significant disturbance of the normal transactions heavily depends on the system's current workload and capacity. In reality, the system's workload may have temporal skewness and fluctuations even if it appears to be uniformly distributed for a long period [13]. Furthermore, the system's capacity is also subject to variations caused by external factors, such as external workload imposed on the same server or other virtual servers running on the same physical machine or cluster rack in a cloud computing environment. A desirable solution should be able to detect such short-term variations of system workload and capacity and promptly adapt the scheduling strategy accordingly. To achieve this goal, we model our system as an automatic control system and make use of the feedback control concept in control theory to design an adaptive scheduling strategy.

Control theory deals with the behaviors of complex dynamic systems with inputs and present output values. A controller is engineered to generate proper corrective actions so that system error, i.e. the differences between the desired output value, called setpoint (SP), and the actual measured output value, called process variable (PV), are minimized.

A commonly used controller is the Proportional-Integral-Derivative controller (PID controller). Figure 2 depicts a graphical representation of a PID controller. Let $u(t)$ be the output of the controller, then the PID controller can be defined as follows:

$$u(t) = K_p e(t) + K_i \int_0^t e(\tau)d\tau + K_d \frac{d}{dt} e(t) \qquad (1)$$

where K_p, K_i and K_d are the proportional, integral and derivative gains respectively, and $e(t)$ is the system error at time t. The system error can be minimized by tuning the three gains so that the controller will generate proper outputs. Simply put, K_p, K_i and K_d determines how the present error ($e(t)$), the accumulation of past errors ($\int_0^t e(\tau)d\tau$) and the predicted future error ($\frac{d}{dt}e(t)$) would affect the controller's output.

The system for scheduling repartition transactions can be modeled as a PID controller as follows. We can use the ratio of the total cost of the high-priority repartition transactions to that of the normal transactions as the SP for the PID controller. By stabilizing this ratio, we can constrain the total workload imposed by the high-priority repartition transactions at a desirable level so that they would have limited impact over the latency of the normal transactions and in the mean time maximize the speed of applying the repartitioning plan.

To capture the fluctuations of the system's workload and capacity, we divide the time into small intervals and measure the aforementioned ratio for every interval. The actual ratio that is measured would be the PV of the PID controller and hence the error can be computed as $SP - PV$. The output of the controller is the ratio to be used to calculate the number of high-priority repartition transactions that we should schedule in the coming interval.

To tune the parameters of the PID controller, we take an online heuristic-based tuning method formally known as the Ziegler—Nichols method[19].

Finally, we enforce a limit on the maximum number of high-priority repartition transactions scheduled in each time interval to avoid significant impacts caused by sudden changes of system workload and capacity, which the PID controller will take some time to stabilize its outputs. Putting such a limit is essentially a conservative approach to avoid too much interferences during the period that the PID controller is stabilizing its behavior.

3.4 Piggyback-based Approach

In the feedback-based method the repartition transactions have the same priority as the normal transactions, hence they will contend with normal transactions for the locks of database objects and significantly increase the system's workload.

In this section, we propose a piggyback-based approach, which injects repartition operations into the normal transactions that access the same object. As these transactions would acquire the locks of these objects anyway, we can save the overhead of acquiring and releasing locks as well as performing the distributed commit protocols. Moreover, we can reduce the degree of lock contention by reducing the number of transactions.

The algorithm of this approach is illustrated in Algorithm 2. The algorithm make use of the auxiliary information produced in Algorithm 1. It examines the transaction ID t_i of the incoming normal transaction and check if there exist an repartition transaction r_j in T_{Rep} which t_i can benefit from but are not yet executed. If so, r_j will piggyback onto t_i, injecting the repartition operations in r_j to t_i. These

Algorithm	Workload	HighLoad			LowLoad

Data: a list of repartition transactions $L_{Rep}$, a map
      $T_{Rep}$ from repartition transaction id to an
      affected normal transaction and the benefit
      density of the repartition transaction, incoming
      normal transactions $T_i(k)$ in interval $k$, List of
      all the repartition operations $OP_{Rep}$
Result: Piggybacked normal transaction executed in
        interval $k$
1  Create a map P(k) of all the normal transactions
   piggyback some repartition operations in interval $k$
2  for $t_i \in T_i(k)$ do
3      if $r_j, t_i \in T_{Rep}.keylist$ then
4          ops ← $L_{Rep}.get(r_j)$
5          Insert ops to $t_i$
6          Inert $(t_i, (r_j, t_i))$ to P(k)
7  Submit $T_i(k)$
8  Get Result(k) for any finished transaction
9  for $(t_i \in P(k))$ do
10     if $t_i \in Result(k)$ then
11         if $t_i.success$ then
12             Remove $P(k).get(t_i)$ from $T_{Rep}$
13         else
14             Remove $L_{Rep}.get(P(k).get(t_i).getKey())$
               from $t_i$
15             Resubmit $t_i$
```

repartition operations will share the locks of objects with the normal transactions. This essentially leads to a repartition-on-demand strategy where data will be repartitioned only when they are accessed. After the piggybacked transaction is successfully committed, we will remove the corresponding repartition transaction in T_{Rep}.

The piggyback method will increase the transaction failure rate as the execution times of normal transactions are increased. If too many repartition operations piggyback onto a normal transaction, then the system throughput will be decreased due to unnecessary aborts caused by the failure of the piggybacked repartition operations. Therefore, we need to limit the maximum number of repartition operations that can piggyback onto each normal transaction. This parameter should be tuned at runtime to adapt to the scenarios of different systems.

3.5 Hybrid Approach

While the piggyback-based approach consumes less resources, it fails to take use of the available system resources to speed up the repartitioning process. This may not work well when the system workload is low and there are few transactions to piggyback on. A more desirable approach is, when the system workload is low, we can take use of the available resources to repartition the data before the actual arrival of transactions that will access them, and when the system is a bit congested, we can take advantage of the opportunities to piggyback the repartition operations on the incoming transactions.

In this section, we present a hybrid approach that is composed by a piggyback module and the feedback module. The piggyback module will piggyback the repartition operations on the incoming normal transactions. Then for each interval, the feedback module will measure the actual PV value by counting in both the repartition transactions and those repartition operations piggybacked on the normal transactions. In this way, the feedback module will adapt the number of repartition transactions according to the actual workload of the system. In other words, when there are more incoming normal transactions that more repartition operations can piggyback on, we will reduce the number of repartition transactions and vice versa.

4. EVALUATION

In this section, we will first provide some details of our system implementation and experimental configuration in Section 4.1. The experimental results under different workload conditions are presented and discussed in Section 4.3 and Section 4.2.

4.1 Experimental Configuration

System Implementation and Configuration. We have used PostgreSQL 9.2.4 as the local DBMS system at each data node and JavaSE-1.6 platform for developing and testing our algorithms. We have developed a query router using a lookup table to route each query to its target database objects. We have also implemented a query parser that reads a query and extracts the partition attributes of the target objects, which will be used for query routing and applying our online repartition strategies. For transaction management, we take use of Bitronix[17], an implementation of Java Transaction API 1.1 version adopting the XAResource interface to interact with the DBMS resource managers running each the individual data node and using 2-Phase Commit protocol for distributed transaction commits.

Our evaluation platform is deployed on a Amazon EC2 cluster consisting of 5 data nodes corresponding to 5 data partitions respectively. Each data node runs an instance of a PostgreSQL 9.2.4 server, which is configured to use the *read committed* isolation level and has a limitation of 100 simultaneous connections. Note that higher isolation level will decrease the system concurrency and hence lower the system's capacity. But it will not affect the performance of our algorithms. The node configuration consists of 1 vCPU using Intel Xeon E5-2670 processor and 3.75 GB memory with an on-demand SSD local storage running 64-bit Ubuntu

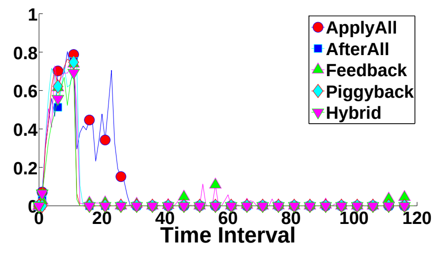
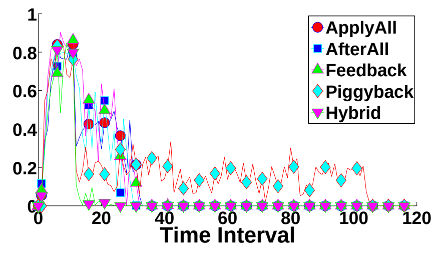
(b) Uniform/High Workload



(c) Zipf/Low Workload



(d) Uniform/Low Workload

Figure 3: Experiment Results for Transaction Failure Rate

13.04. The query router is run on another EC2 instance with the same setting.

Workloads and Datasets. We create a table containing $500,000$ tuples, each tuple has a global unique key field and an integer content field. The size of each tuple is 8 bytes. We generate two types of workload distribution to simulate different sceneries of transaction popularity: a uniform distribution with $30,000$ distinct transactions and a Zipf distribution with $23,457$ distinct transactions. We generate the workload with a Zipf distribution using the parameter $s = 1.16$ so that the workload follows the 80-20 rule. Each normal transaction contains 5 queries. Each query access one unique tuple and is either a read-only or a write query with equal possibility.

We use a Poisson distribution to determine how many normal transactions are submitted to the system during each interval, which is set to be 20 seconds. Each run of the experiment will last for 45 minutes and the normal transactions are submitted to the system at the beginning of each time interval. We generate a high and a low workload as follows. *Lowload* has an average system utilization as 65% before the repartitioning, which is measured by the percentage of time that the system spend on processing the normal transactions. *Highload* simulates a system overloaded situation, where the incoming workload is 30% higher than the system capacity. Under this situation, it is more urgent to adopt the repartitioning plan to reduce the effective incoming load. Furthermore, for each situation, we vary the percentage of tuples α we need to repartition, which varies from 100% to 20%. After the repartitioning, α percent of the normal transactions would be tranformed from distributed transactions to non-distributed transactions.

Algorithm Settings. We compare all the algorithms we discussed in the previous sections. We use two performance metrics for comparison: the system throughput, which is counted as the maximum number of normal transactions that the system can process per unit of time, and the processing latency, which is the time between a transaction is submitted and the time its processing is finished. In order to examine the lock contentions incurred by the various scheduling algorithms, we also collect the failure rate of transactions, which is defined as the number of aborted transactions compared to the total number of transaction submitted to transaction manager.

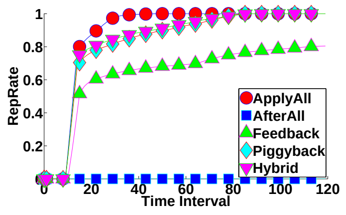
In line with the workload generation, we divide the time into 20 seconds of intervals and run the system for 10 intervals to warm it up before we start the repartitioning. Furthermore, the feedback-based approach uses 20 seconds as the monitoring interval. For the feedback model parameter used in each of the experiment, we have the different SP values which are listed in Table 1. All the experiments will have the same controller parameter $K_p = 1$, $K_i = 0$ and $K_d = 0$.

4.2 Performance Under High Load

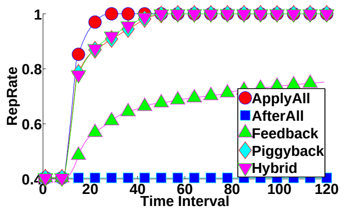
Recall that under the high workload setting, we have set the initial workload to be higher than the system's capacity but it should become lower than the system's capacity after applying the repartition plan as the normal transactions would consume less resources with the new partition plan. Therefore, it is necessary for the system to be able to process the repartition transactions soon.

Zipf workload. The experimental results are presented in Figure 4. As we discussed earlier, ApplyAll would stall all the normal transactions and execute all the repartition transactions before we resume the normal processing. This should result in the fastest deployment of the new partition plan. This is verified by Figures 4a, 4b and 4c. However as one can see from Figures 4d, 4e and 4f and Figures 4g, 4h and 4i, using this approach will experience a period that system has a very low throughput and very high processing latency caused by the stalling of the normal transactions.

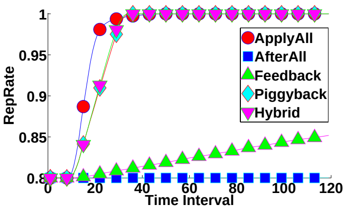
As shown in Figure 4i, the impact on processing latency can actually last much longer than the time needed to perform the repartitioning. This is because a long waiting queue



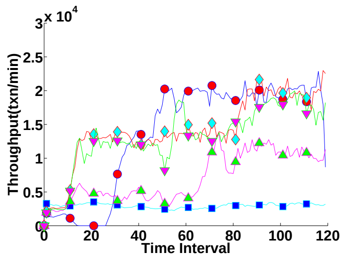
(a) $\alpha = 100\%$



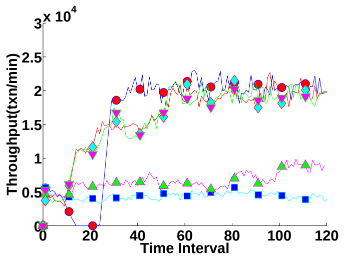
(b) $\alpha = 60\%$



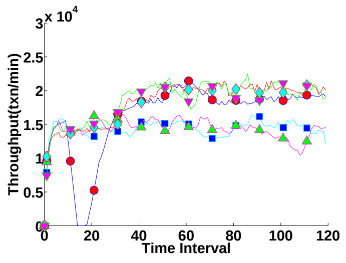
(c) $\alpha = 20\%$



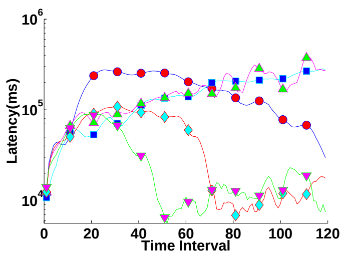
(d) $\alpha = 100\%$



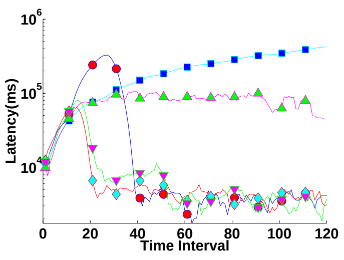
(e) $\alpha = 60\%$



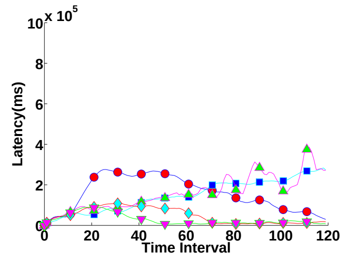
(f) $\alpha = 20\%$



(g) $\alpha = 100\%$



(h) $\alpha = 60\%$



(i) $\alpha = 20\%$

Figure 4: Experiment Results for Zipf High Workload

will be built up during the repartitioning process and hence it needs a longer time to clear the queue. (Note that we have set the initial ratio of workload to system capacity be roughly equal for all α values and we actually submit more normal transactions in the case with a lower α value. Hence the waiting queue will be longer in this case.)

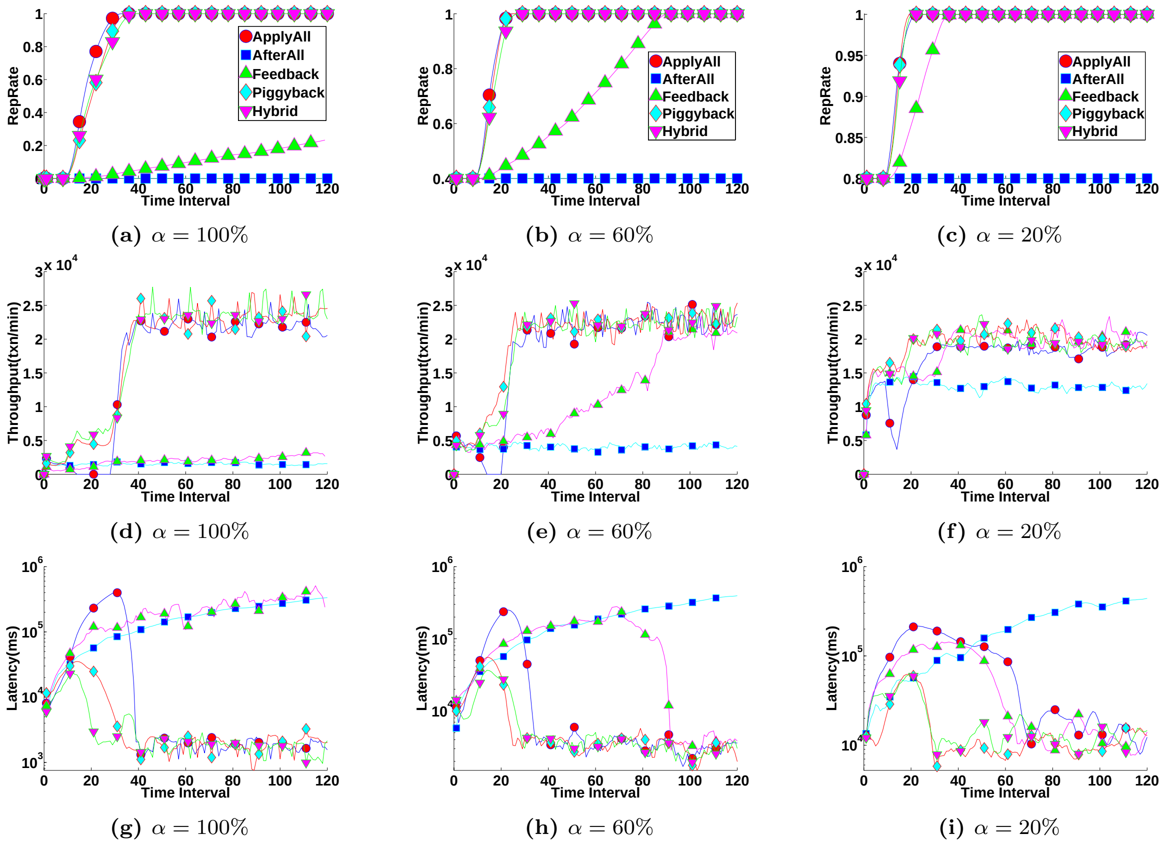
On the contrary, AfterAll basically cannot execute any repartition transactions due to the lack of system idle time, hence it cannot take advantage of the new data partition plan. The Feedback approach will enforce the scheduling of some repartition transactions, hence can make some progress in deploying the new partition plan (Figures 4a, 4b and 4c). Accordingly the system's throughput and processing latency will improve gradually. (Again, we submit more normal transactions in the case with a lower α value. So it takes a longer time to deploy the repartition plan.)

As we analyzed in the earlier sections, the Piggyback approach can effectively reduce the cost of executing repartition operations. This is especially important when the system is under high workload and has little extra resources for repartitioning the data. Furthermore, the high arrival rate of normal transactions provides abundant opportunities for the repartition operations to piggyback. The results in Figure 4 verify our analysis. In comparing to ApplyAll, both Piggyback and Hybrid do not incur any sudden dropping of system performance while is able to quickly execute the repartition plan. It even outperforms ApplyAll at almost all time intervals in terms of both throughput and latency with a lower α value, i.e. fewer tuples to be repartitioned.

Uniform workload. We also perform the experiments with a workload under a uniform distribution. The results are presented in Figure 5. The difference from the workload with a Zipf distribution is that we will not gain a lot of improvement by executing a small portion of repartition transactions.

Similar to the previous experiments, since the workload is more than the system could handle, AfterAll could barely execute any repartition transactions improve the system's performance, while ApplyAll finish the repartition process in 20,12 and 4 intervals, which is proportional to the number of repartition transactions that need to be executed.

For the Feedback method, we set a higher SP value under uniform workload to examine its performance when more repartition transactions are enforced to be submitted to the system. Under $\alpha = 100\%$, we cannot apply enough repartition transactions to stop the queue size from increasing. So even the repartition rate increases a bit in figure 5a, the throughput and latency does not get improved. But under the cases with $\alpha = 60\%$ and $\alpha = 20\%$, since the number of repartition transactions we need to execute is smaller, the system finally finish the repartition in time and make the system able to process all the incoming normal transactions without queuing. In comparing the results in the previous experiments, a higher SP here is actually beneficial when the number of repartitioning transactions is relatively small and Feedback has the chance to finish them in a good time.



(a) $\alpha = 100\%$ **(b)** $\alpha = 60\%$ **(c)** $\alpha = 20\%$

(d) $\alpha = 100\%$ **(e)** $\alpha = 60\%$ **(f)** $\alpha = 20\%$

(g) $\alpha = 100\%$ **(h)** $\alpha = 60\%$ **(i)** $\alpha = 20\%$

Figure 5: Experiment Results for Uniform High Workload

Similar to the Zipf workload, both Piggyback and Hybrid performed the best in all cases. They can achieve a speed that are almost identical to the *ApplyAll* approach.

Transaction failure rate. To further investigate the effect of the algorithms, we also collect the failure rates of transactions. Here we only report the results with $\alpha = 100\%$ since we could experience highest lock contention in these scenarios. The results are shown in Figure 3. We can see from Figure 3a, AfterAll has a very high failure rate during the whole period simply because the system's workload is very high and it fails to apply the repartition plan to quickly improve the system's performance. Furthermore, both the piggyback and hybrid method has a very low failure rate through the whole period, which clearly show the piggyback-based method's advantage of lowering lock contentions. On the other hand, the feedback-based method experiences some failure caused by the extra transactions scheduled by the feedback-based method.

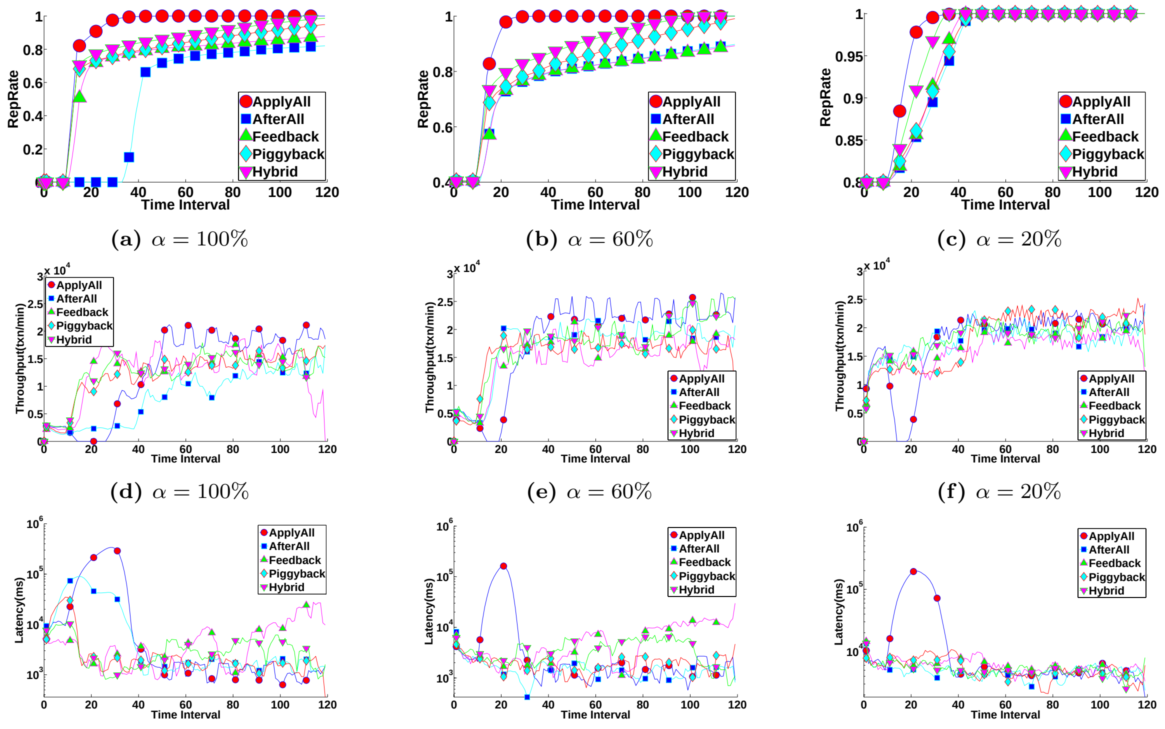
Figure 3b shows the results with the uniform workload. The general trend is similar. But it is interesting to see that the extra failure rate caused by the piggyback strategy lasts longer than the case with Zipf workload. This is because there is not any very hot transaction in this scenario, so we cannot deploy the repartition plan as quickly as in the case with Zipf workload. The mechanism of executing more high-priority repartition transactions with Hybrid causes a higher initial failure rate but it drops more quickly than the piggyback approach. This shows that Hybrid has an edge when there are less transactions to piggyback on.

4.3 Performance Under Low Load

In the low load experiments, we expect the system has more idle time and the repartition process could be done more aggressively to make use of those available resources. For the Zipf workload, since there exist some transactions that have very high frequencies, the resource contention under the same load level will be higher than the Uniform workload. The results are shown in Figure 6 and 7.

Zipf workload. ApplyAll performs similarly as under high load situation. But since there are fewer normal transactions, there are also fewer transactions that are queued up during the repartitioning period and we have a shorter time for the system to achieve its maximum performance after the repartitioning period.

As the system has enough idle time now, AfterAll could submit quite some repartition transactions. In Figure 6a, we can see that it takes some time for the system to have an idle period. It happens that there are three intervals that have a very high workload generated by our Poisson load generator. When the tuples accessed by the high frequency normal transactions are not repartitioned yet, their average execution time will be much higher than normal because of resources contention. We could see that AfterAll does not have this problem in Figures 4b and 4c. AfterAll has the minimum interference to the normal transactions when the system is able to handle the normal transaction load like



(a) $\alpha = 100\%$ (b) $\alpha = 60\%$ (c) $\alpha = 20\%$

(d) $\alpha = 100\%$ (e) $\alpha = 60\%$ (f) $\alpha = 20\%$

(g) $\alpha = 100\%$ (h) $\alpha = 60\%$ (i) $\alpha = 20\%$

Figure 6: Experiment Results for Zipf Low Workload

the situations in Figure 6h and 6i and hence it could be the algorithm that can achieve the lowest average latency.

The Feedback method will add more repartition transactions to the system besides filling the idle period. So we can see in Figure 6g that it partitions the tuples accessed by some high frequency transactions and render the system load decreasing more quickly than AfterAll. Adding the extra repartition transactions will increase processing latency of the normal transactions. This extra latency is a trade-off against the repartitioning speed. In Figure 5d, we can see that Feedback has a higher throughput than AfterAll but with a higher latency before it finishes all the repartition transactions.

The overhead of the piggyback method is proportional to the number of piggybacked transactions. When the workload is low, like the condition in Figure 6f, it may not be able to repartition the database as fast as the other methods. But the overhead on latency is also lower when the workload is low, which is similar to AfterAll.

Hybrid performs very well even under low workload. It always finishes the repartitioning work with a speed that is only slower than ApplyAll and in the meantime keeps the latency overhead less than the Feedback method. Since the repartitioning speed of Hybrid is faster than Feedback, the time period that normal transactions will experienced some extra latency are much shorter.

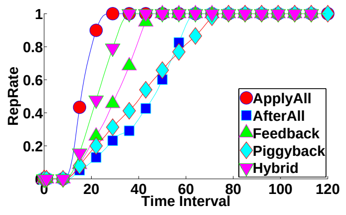
With regard to the failure rate, the trend shown in Figure 3c is very similar to the case with high workload, except that AfterAll has a much lower failure rate in this case. This is because the system's workload is not that high and AfterAll has the opportunity apply the repartition plan to further improve the system's performance.

Uniform workload. The results are reported in Figure 7. In this case, the degree of resource contention among normal transactions is lower than that with the Zipf workload. AfterAll could finish the repartitioning more quickly than with the Zipf load. Since the frequency of each normal transaction is low, the effect of repartition may take some time to get into effect. An interesting phenomenon is that Piggyback in this case works worse than the previous cases. With the uniform and low load situation, there are relatively few transactions to be piggybacked on and hence it take much longer for the piggyback approach to finish the repartitioning.

Furthermore, from Figure 3d, we can find that before the repartitioning is finished, the piggyback approach incurs a higher failure rate. This is because, even though Piggyback does not incur additional transactions, the piggybacked transactions will run longer than normal and this may still increase lock contentions to a certain degree. Given the longer repartitioning period in this case, its overhead on failure rate is more prominent here. On the contrary, Hybrid is able to make use of the available system resources to speed up the repartition and hence do not suffer this problem.

5. RELATED WORKS

Data partitioning for distributed database system is about designing a data placement strategy minimizing the transaction overheads and balancing the workloads. Besides basic algorithms using some static functions, such as range-based or hash-based, to partition the data, researchers have recently been focusing on workload-aware partitioning al-



(a) $\alpha = 100\%$

gorithms that take the transaction statistics as input [4, 13]. These solutions utilize various techniques to model the historical workload information and search for an optimal partition scheme according to a specific objective function. Schism [4] is an automatic partitioning tool trying to minimize distributed transactions. Horticulture [13] further improve this approach by considering temporary skewness of workloads and using a local search algorithm to optimize partition schemes. This work provides a cost model for processing a transaction that considers both the number of partitions the transaction need to access and the overall skewness of data access.

Alekh etc.[8] present an online partitioning method that will partition the data in checkpoint time intervals. They generate partition schemes based on historical query execution logs and automatically update the partition plan when the workload changes. Besides the static partitioning methods, there are also some studies on incremental partitioning. For example, Sword [15] adopts a similar model as Schism [4] and introduces an incremental repartitioning algorithm that calculates the contribution of each repartition operation and the cost of executing it. They also propose a threshold on the number of repartition queries that will be generated for each repartition step and a constrained number of repartition queries will be executed when the system is at a lean period. This approach is similar to our baseline solution *AfterAll*. Some commercial database systems [12, 10] support online partitioning. But all of them require the partitioned data would not be untouched by normal transactions during the partitioning period. Hence this is similar to our *ApplyAll* solution. In our former short paper[1], we briefly presented the basic ideas about the feedback and piggyback algorithms. In this paper, we provide a more thorough analysis of the problem, consider the drawbacks of the piggyback solution and provide more experiment results to illustrate the trade-offs in the piggyback solution. We also propose the hybrid approach that combines the feedback and piggyback algorithm to benefit from the advantages of both algorithms while avoiding the problem of high failure rate in the piggyback solution and the problem of high interference with normal transactions in the feedback solution.

On the other hand, some researches on quality of service (QoS) of OLTP systems, such as [11], have considered the different resources' influence on transaction performance and have attempted to find the bottleneck resource for OLTP transactions and shows an arresting performance improvement. [6] makes use of machine learning methods to predict multiple performance metrics of analytical queries. The solution relies on SQL text extracted from the query execution plans. In [18], the authors addressed predictions of query execution time using the query optimizer's cost model and the generated query plan, which can be used to estimate the transaction execution time in OLTP systems. For distributed systems, the extra cost of network communication will be the new bottleneck, which limits the OLTP transactions performance [3]. It is an important part of execution cost if we want to optimize the transaction performance in a distributed environment.

Live migration of databases [5] focuses on migrating a whole database from one system to another while providing non-stop services and has not considered the scenario of migrating data from multiple nodes to multiple destinations, which however is the common case in our online data partitioning problem and may encounter distributed transactions that update the data at both the source and the destination nodes simultaneously. The authors of [5] provide a solution of combining on-demand pull and asynchronous push to migrate a tenant with minimal service interruption. Their solution is somehow similar to our piggyback approach, where data that needs to be moved will be migrated when the incoming transactions visit it.

Transaction scheduling is an important topic studied in various areas such as Web services and database systems, and there are several works, such as [7, 2]), that tried to find an optimal schedule by considering query execution time, transaction deadline and system workload. Given the transactions' execution time and hard execution deadlines, most of the scheduling problems are NP-Complete [16]. The most common solution is cost-based algorithms [9]. The quality of a schedule highly depends on the cost estimation and how the execution cost each transaction is modeled. [14] is a scheduling and admission control method using a priority token bank in computer networks. They classify jobs into N classes and jobs within each class are treated equally (by using FIFO). This approach is much simpler than cost-based scheduling (CBS).

6. CONCLUSION

In this paper, we studied the problem of online repartitioning of a distributed OLTP database. We identify that the two basic solutions are very rigid and miss the opportunities to find good trade-offs between the speed of repartitioning and the impact on the normal transactions. We then propose to use control theory to design an adaptive methods which can dynamically change the frequency that we submit repartition transactions to the system. As putting the repartition queries into extra transactions may further increase the system's resource contention especially when the system has a high workload, we also proposed a piggyback-based method to mitigate the repartitioning overhead, which however do not perform well when the system has a low workload and there is few transactions to piggyback on. Our hybrid approach intelligently integrates the two approaches and is able to combine their strengths while avoiding their problems. Based on the experiments of running our prototype on Amazon EC2, we can conclude that Hybrid is the overall best approach and achieves a great performance improvement in comparing to the two basic solutions used in most existing systems.

ABSTRACT

Web-based applications face unprecedented workloads demanding the processing of a large number of events reaching to the millions per second. That is why developers are increasingly relying on *scalable cloud platforms* to implement cloud applications. Chariots exposes a shared log to be used by cloud applications. The log is essential for many tasks like bookkeeping, recovery, and debugging. Logs offer linearizability and simple append and read operations of immutable records to facilitate building complex systems like stream processors and transaction managers. As a cloud platform, Chariots offers fault-tolerance, persistence, and high-availability, transparently.

Current shared log infrastructures suffer from the bottleneck of serializing log records through a centralized server which limits the throughput to that of a single machine. We propose a novel distributed log store, called the *Fractal Log Store* (FLStore), that overcomes the bottleneck of a single-point of contention. FLStore maintains the log within the datacenter. We also propose Chariots, which provides multi-datacenter replication for shared logs. In it, FLStore is leveraged as the log store. Chariots maintains causal ordering of records in the log and has a scalable design that allows elastic expansion of resources.

1. INTRODUCTION

The explosive growth of web applications and the need to support millions of users make the process of developing web applications difficult. These applications need to support this increasing demand and in the same time they need to satisfy many requirements. Fault-tolerance, availability, and a low response time are some of these requirements. It is overwhelming for the developer to be responsible for ensuring all these requirements while scaling the application to millions of users. The process is error-prone and wastes a lot of efforts by reinventing the wheel for every application.

The cloud model of computing encourages the existence of unified platforms to provide an infrastructure that provides the guarantees needed by applications. Nowadays, such an infrastructure for compute and storage services is commonplace. For example, an application can request a key-value store service in the cloud. The store exposes an interface to the client and hides all the complexities required for its scalability and fault-tolerance. We envision that a variety of programming platforms will coexist in the cloud for the developer to utilize. A developer can use multiple platforms simultaneously according to the application's needs. A micro-blogging application for example might use a key-value store platform to persist the blogs and in the same time use a distributed processing platform to analyze the stream of blogs. The shared log, as we argue next, is an essential cloud platform in the developer's arsenal.

Manipulation of shared state by distributed applications is an error-prone process. It has been identified that using immutable state rather than directly modifying shared data can help alleviate some of the problems of distributed programming [1–3]. The *shared log* offers a way to share immutable state and accumulate changes to data, making it a suitable framework for cloud application development. Additionally, the shared log abstraction is familiar to developers. A simple interface of append and read operations can be utilized to build complex solutions. These characteristics allow the development of a wide-range of applications. Solutions that provide transactions, analytics, and stream processing can be easily built over a shared log. Implementing these tasks on a shared log makes reasoning about their correctness and behavior easier and rid the developer from thinking about scalability and fault-tolerance. Also, the log provides a trace of all application events providing a natural framework for tasks like debugging, auditing, checkpointing, and time travel. This inspired a lot of work in the literature to utilize shared logs for building systems such as transaction managers, geo-replicated key-value stores, and others [6, 11, 13, 27, 28, 30, 33].

Although appealing as a platform for diverse programming applications, shared log systems suffer from a single-point of contention problem. Assigning a log position to a record in the shared log must satisfy the uniqueness and order of each log position and consequent records should have no gaps in between. Many shared log solutions tackle this problem and try to increase the append throughput of the log by minimizing the amount of work done to append a record. The most notable work in this area is the CORFU protocol [7] built on flash chips that is used by Tango [8]. The CORFU protocol is driven by the clients and uses a *centralized sequencer* that assigns offsets to clients to be filled later. This takes the sequencer out of the data path and allows the append throughput to be more than a single machine's I/O bandwidth. However, it is still limited by the bandwidth of the sequencer. This bandwidth is suitable for small clusters but cannot be used to handle larger demands encountered by large-scale web applications.

We propose **FLStore**, a distributed deterministic shared log system that scales beyond the limitations of a single machine. FL-

Store consists of a group of *log maintainers* that mutually handle exclusive ranges of the log. Disjoint ranges of the log are handled independently by different log maintainers. FLStore ensures that all these tasks are independent by using a deterministic approach that assigns log positions to records as they are received by log maintainers. It removes the need for a centralized sequencer by avoiding log position pre-assignment. Rather, FLStore adopts a *post-assignment* approach where records are assigned log positions *after* they are received by the Log maintainers. FLStore handles the challenges that arise from this scheme. The first challenge is the existence of gaps in the log that occur when a log maintainer has advanced farther compared to other log maintainers. Another challenge is maintaining explicit order dependencies requested by the application developer.

Cloud applications are increasingly employing geo-replication to achieve higher availability and fault-tolerance. Records are generated at multiple datacenters and are potentially processed at multiple locations. This is true for applications that operate on shared data and need communication to other datacenters to make decisions. In addition, some applications process streams coming from different locations. An example is Google's Photon [4] which joins streams of clicks from different datacenters. Performing analytics also requires access to the data generated at multiple datacenters. Geo-replication poses additional challenges such as maintaining *exactly-once* semantics (ensure that an event is not processed more than once), automatic datacenter-level fault-tolerance, and handling un-ordered streams.

Chariots supports multiple datacenters by providing a global replicated shared log that contains all the records generated by all datacenters. The order of records in the log must be consistent. The ideal case is to have an identical order at all datacenters. However, it is shown by the CAP theorem [12, 16] that such a **consistency** guarantee *cannot* be achieved if we are to preserve **availability** and **partition-tolerance**. In this work we favor availability and partition-tolerance, as did many other works in different contexts [14, 15, 20, 23]. Here, we relax the guarantees on the order of records in the log. In relaxing the consistency guarantee, we seek the strongest guarantee that will allow us to preserve availability and partition-tolerance. We find, as other systems have [5, 10, 19, 23, 31], that causality [21] is a sufficiently strong guarantee fitting our criterion [24].

In this paper we propose a cloud platform that exposes a shared log to applications. This shared log is replicated to multiple datacenters for availability and fault tolerance. The objective of the platform's design is to achieve high performance and scalability by allowing seamless elasticity. Challenges in building such a platform are tackled, including handling component and whole datacenter failures, garbage collection, and gaps in the logs. We motivate the log as a framework for building cloud applications by designing three applications on top of the shared log platform. These applications are: (1) a key-value store that preserves causality across datacenters, (2) a stream processing applications that handles streams coming from multiple datacenters, and (3) a replicated data store that provides strongly consistent transactions [27].

The contributions of the paper are the following:

- A design of a scalable distributed *log storage*, FLStore, that overcomes the bottleneck of a single machine. This is done by adopting a post-assignment approach to assigning log positions.

- Chariots tackles the problem of scaling causally-ordered geo-replicated shared logs by incorporating a distributed log storage solution for each replica. An elastic design is built to allow scaling to datacenter-scale computation. This is the first work we are aware of that tackles the problem of *scaling geo-replicated shared logs through partitioning*.

Table 1: Comparison of different shared log services based on consistency guarantees, support of per-replica partitioning, and replication.

The paper proceeds as the following. We first present related work in Section 2. The system model and log interface follows in Section 3. We then present a set of use cases of Chariots in Section 4. These are data management and analytics applications. The detailed design of the log is then proposed in Sections 5 and 6. Results of the evaluations are provided in Section 7. We conclude in Section 8.

2. RELATED WORK

In this paper we propose a geo-replicated shared log service for data management called Chariots. Here we briefly survey related work. We focus on systems that manage shared logs. There exist an enormous amount of work on general distributed (partitioned) storage and geo-replication. Our focus on work tackling shared logs stems from the unique challenges that shared logs pose compared to general distributed storage and geo-replication. We provide a summary of shared log services for data management application in Table 1. In the remainder of this section we provide more details about these systems in addition to other related work that do not necessarily provide log interfaces. We conclude with a discussion of the comparison provided in Table 1.

2.1 Partitioned shared logs

Several systems explored extending shared logs as a distributed storage spanning multiple machines. Hyder [11] builds a multi-version log-structured database on a distributed shared log storage. A transaction executes optimistically on a snapshot of the database and broadcasts the record of changes to *all* servers and appends a record of changes to the distributed shared log. The servers then commit the transaction by looking for conflicts in the shared log in an intelligible manner. LogBase [33], which is similar to network filesystems like BlueSky [34], and RAMCloud [29] are also multi-version log-structured databases.

Corfu [7], used by Tango [8], attempts to increase the throughput of shared log storage by employing a sequencer. The sequencer's main function is to pre-assign log position ids for clients wishing to append to the log. This increases throughput by allowing more concurrency. However, the sequencer is still a bottleneck limiting the scalability of the system.

Distributed and networked filesystems also employ logs to share their state. Blizzard [25] proposes a shared log to expose a cloud block storage. Blizzard decouples ordering and durability requirements, which improves its performance. Ivy [26] is a distributed file system. A log is dedicated to each participant and is placed in a distributed hash table. Finding data requires consulting all logs but appending is done to the participant's log only. The Zebra file system [18] employs log striping across machines to increase throughput.

2.2 Replicated shared logs

Causal replication. Causal consistency for availability is utilized by various systems [10, 19, 19, 23, 31, 32]. Recently, COPS [23] proposes causal+ consistency that adds convergence as a requirement in addition to causal consistency. COPS design aims to increase the throughput of the system for geo-replicated environments. At each datacenter, data is partitioned among many machines to increase throughput. Chariots targets achieving high throughput similarly by scaling out. Chariots differs in that it exposes a log rather than a key-value store, which brings new design challenges. Logs have been utilized by various replication systems for data storage and communication. PRACTI [10] is a replication manager that provides partial replication, arbitrary consistency, and topology independence. Logs are used to exchange updates and invalidation information to ensure the storage maintains a causally consistent snapshot. Bayou [32] is similar to PRACTI. In Bayou, batches of updates are propagated between replicas. These batches have a start and end times. When a batch is received, the state rolls back to the start time, incorporate the batch, and then roll forward the existing batches that follows. Replicated Dictionary [36] replicates a log and maintains causal relations. It allows transitive log shipping and maintains information about the knowledge of other replicas. Lazy Replication [19] also maintains a log of updates ordered by their causal relations. The extent of knowledge of other replicas is also maintained.

Geo-replicated logs. Geo-replication of a shared log has been explored by few data management solutions. Google megastore [6] is a multi-datacenter transaction manager. Megastore commit transactions by contending for log positions using Paxos [22]. Paxos-CP [30] use the log in a similar way to megastore with some refinements to allow better performance. These two systems however, operate on a serial log. All clients contend to write to the head of the log, making it a single point of contention, which limits throughput. Message Futures [27] and Helios [28] are commit protocols for strongly consistent transactions on geo-replicated data. They build their transaction managers on top of a causally-ordered replicated log that is inspired from Replicated Dictionary [36].

2.3 Summary and comparison

The related works above that build shared logs for data management applications are summarized in Table 1. We display whether the system support partitioning and replication in addition to the guaranteed ordering consistency. Consistency is either strong, meaning that the order is either identical or serializable for replicated logs or totally ordered for non-replicated logs. A system is *partitioned* if the shared log spans more than one machine for each replica. Thus, if a system of five replicas consists of five machines, they are *not* partitioned. A system is *replicated* if the shared log has more than one *independent* copy.

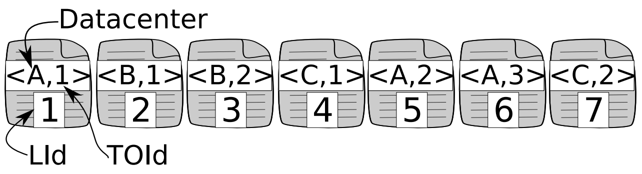

Figure 1: Records in a shared log showing their TOId inside the records alongside the datacenters that created them and the records LIds under the log

Other than Chariots, the table lists four systems that support partitioning. It is possible for these systems to employ replication in the storage level. However, a blind augmentation of a replication solution will be inefficient. This is because a general-purpose replication method will have guarantees stronger than what is needed to replicate a log. The other solutions, that support replication, do not support partitioning. Handling a replica with a single node limits the achievable throughput. The processing power, I/O, and communication of a single machine can not handle the requirements of todays web applications. This is specially true for geo-replication that handles datacenter-scale demand.

Chariots attempts to fill this void of shared logs that have both a native support of replication and per-replica partitioning. This need for both replication and partitioning has been explored for different applications and guarantees, including causal consistency, *i.e.*, COPS [23]. However, geo-replication of a distributed shared log and immutable updating pose unique challenges that are not faced by geo-replication of key-value stores and block-based storage. The paper studies these challenges and design Chariots as a causally-ordered shared log that supports per-replica partitioned log storage and geo-replication.

3. SYSTEM AND PROGRAMMING MODEL

Chariots is a shared log system for cloud applications. The inner workings of Chariots are not exposed to the application developer. Rather, the developer interacts with Chariots via a set of APIs. In this section, we will show the interface used by developers to write applications using Chariots.

System model. Chariots exposes a log of records to applications. The log is maintained by a group of machines called the *log maintainers*. Collectively, these log maintainers persist a single shared log. Each log maintainer is responsible for a disjoint range of the shared log. The shared log is accessed by cloud applications, called *application clients*, through a linked library that manages the exchange of information between the application and the log maintainers. Application clients are distributed and independent from one another. And they share a single view of the shared log. The shared log is fully replicated to a number of datacenters. In our model, we adopt a view of the *datacenter as a computer* [9], an increasingly popular view of computing that reflects the demand of datacenter-scale applications.

Meta information about log maintainers, other datacenters, and the shared log are managed by *meta servers*. Meta servers are a highly-available collection of stateless servers acting as an oracle for application clients to report about the state and locations of the Log maintainers and other datacenters. This model of scale-out distributed computing and centralized stateless highly-available control servers has been shown to perform the best for large-scale systems [17].

Data model. The state of the shared log consists of the records it contains. These records are either *local copies*, meaning that they were generated by application clients residing in the same datacenter, or *external copies*, meaning that they were generated at other datacenters. Each record has an identical copy at each datacenter, one of which is considered a local copy and the other copies are considered external copies. The record consists of the contents appended by the Application client, called the record's *body*, and other *meta-information* that are used by Application clients to facilitate future access to it. The following are the meta-information maintained for each record:

- *Log Id (LId):* This id reflects the position of the record in the datacenter where the copy resides. A record has multiple copies, one at each datacenter. Each copy has a different LId that reflects its position in the datacenter's shared log.
- *Total order Id (TOId):* This id reflects the total order of the record with respect to its host datacenter, where the Application client that created it resides. Thus, copies of the same record have an identical TOId.
- *Tags:* The Application client might choose to attach tags to the record. A tag consists of a key and a value. These tags are accessible by Chariots, unlike the record's body which is opaque to the system. Records will be indexed using these tags.

To highlight the difference between LId and TOId, observe the sample shared log in Figure 1. It displays seven records with their LIds in the bottom of each record at datacenter A. The TOId is shown inside the record via the representation $< X, i >$, where X is the host datacenter of the Application client that appended the record and i is the TOId. Each record has a LId that reflects its position in the shared log of datacenter A. Additionally, each record has a TOId that reflects its order compared to records coming from the same datacenter only.

Programming interface and model. Application clients can observe and change the state of the shared log through a simple interface of two basic operations: reading and appending records. These operations are performed via an API provided by a linked software library at the Application client. The library needs the information of the meta servers only to initiate the session. Once the session is ready, the application client may use the following library calls:

1. Append(in: record, tags): Insert record to the shared log with the desired tags. The assigned TOId and LId will be sent back to the Application client. Appended records are automatically replicated to other replicas.
2. Read(in: rules, out: records): Return the records that matches the input rules. A rule might involve TOIds, LIds, and tags information.

Log records are immutable, meaning that once a record is added, it cannot be modified. If an application client desire to alter the effect of a record it can do so by appending another record that exemplifies the desired change. This principle of accumulation of changes, represented by immutable data, is identified to reduce the problems arising from distributed programming [1–3]. Taking this principled approach and combining it with the simple interface of appends and reads allows the construction of complex software while reducing the risks of distributed programming. We showcase the potential of this simple programming model by constructing data management systems in the next section.

Causality and log order. The shared log at each datacenter consists of a collection of records added by application clients at different datacenters. Ordering the records by causality relations allows sufficient consistency while preserving availability and fault-tolerance [12, 16]. Causality enforces two types of order relations [21] between read and append operations, where $o_i \rightarrow o_j$ denotes that o_i has a causal relation to o_j. A causal relation, $o_i \rightarrow o_j$, exists in the following cases:

- **Total order** for records generated from the same datacenter. If two appended records, o_i and o_j, were generated by application clients residing in the same datacenter A, then if o_i is ordered before o_j in A, then this order must be honored at all other datacenters.
- **Happened-before relations** between read and append operations. A happened-before relation exists between an append operation, o_i, and a read operation, o_j, if o_j reads the record appended by o_i.
- **Transitivity:** causal relations are transitive. If a record o_k exists such that $o_i \rightarrow o_k$ and $o_k \rightarrow o_j$ then $o_i \rightarrow o_j$.

4. CASE STUDIES

The simple log interface was shown to enable building complex data management systems [6, 11, 13, 27, 30, 33]. These systems, however, operate on a serial log with pre-assigned log positions. These two characteristics, as we argued earlier, limits the log's availability and scalability. In this section, we demonstrate data management systems that are built on top of Chariots, a causally ordered log with post-assigned log positions. The first system, *Hyksos*, is a replicated key-value store that provides causal consistency with a facility to perform *get transactions*. The second system is a stream processor that operates on streams originating from multiple datacenters. We also refer to our earlier work, Message Futures [27] and Helios [28], which provide strongly consistent transactions on top of a causally ordered replicated log. Although they were introduced with a single machine per replica implementation, their design can be extended to be deployed on the scalable Chariots.

4.1 Hyksos: causally consistent key-value store

Hyksos is a key-value store built using Chariots to provide causal consistency [21]. Put and Get operations[1] are provided by Hyksos in addition to a facility to perform get transactions (GET_TXN) of multiple keys. Get transactions return a consistent state snapshot of the read keys.

4.1.1 Design and algorithms

Chariots manages the shared log and exposes a read and append interface to application clients, which are the drivers of the key-value store operations. Each datacenter runs an instance of Chariots. An instance of Chariots is comprised of a number of machines. Some of the machines are dedicated to store the shared log and others are used to deploy Chariots.

The value of keys reside in the shared log. A record holds one, or more put operation information. The order in the log reflects the causal order of put operations. Thus, the current value of a key, k, is in the record with the highest log position containing a put operation. The get and put operations are performed as follows:

[1]The terms "read" and "append" are used for operations on the log and "put" and "get" are used for operations on the key-value store.

Algorithm 1 Performing Get_transactions in Hyksos

```
1: // Request the head of the log position id
2: i = get_head_of_log()
3: // Read each item in the read set
4: for each k in read-set
5:     t = Read ({tag: k, LId<i}, most-recent)
6:     Output.add (t)
```

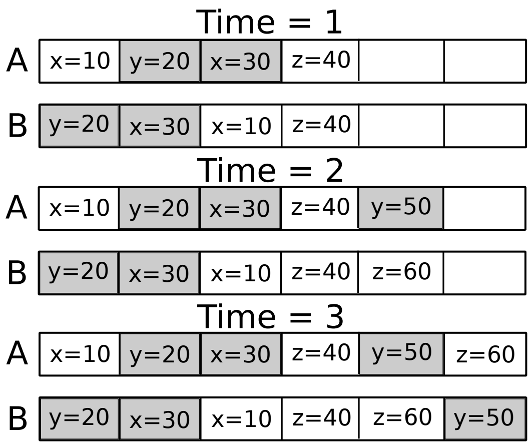

Figure 2: An example of Hyksos, the key-value store built using Chariots.

- Get(x): Perform a Read operation on the log. The read returns a recent record containing a put operation to *x*.
- Put(x, value): Putting a value is done by performing an Append operation with the new value of *x*. The record must be tagged with the key and value information to enable an efficient get operation.

Get transactions. Hyksos provides a facility to perform get transactions. The get_transaction operation returns a consistent view of the key-value store. The application client performs the Get operations as shown in Algorithm 1. First, Chariots is polled to get the head of the log's position id, *i*, to act as the log position when the consistent view will be taken (Line 2). There must be no gaps at any records prior to the log id. Afterwards, the application client begins reading each key *k* (Lines 4-6). A request to read the version of *k* at a log position *j* that satisfies the following: Record *j* contains the most recent write to *k* that is at a position less than *i*.

4.1.2 Example scenario

To demonstrate how Hyksos works, consider the scenario shown in Figure 2. It displays the shared logs of two datacenters, *A* and *B*. The shared log contains records of put operations. The put operation is in the form "$x = v$", where *x* is the key and *v* is the value. Records that are created by Application clients at *A* are shaded. Other records are created by application clients at *B*.

The scenario starts with four records, where each record has two copies, one at each datacenter. Two of these records are put operations to key *x*. The other two operations are a put to *y* and a put to *z*. The two puts to *x* were created at different datacenters. Note that the order of writes to *x* is different at *A* and *B*. This is permissible if no causal dependencies exist between them. At time 1, a Get of *x* at *A* will return 30, while 10 will be returned if the Get is performed at *B*.

At time 2, two Application clients, one at each datacenter, perform put operations. At *A*, Put(y,50) is appended to the log. At *B*, Put(z,60) is appended to the log. Now consider a get transaction that requests to get the value of *x*, *y* and *z*. First, a non-empty log position is chosen. Assume that the log position 4 is chosen. If the get transaction ran at *A*, it will return a snapshot of the view of the log up to log position 4. This will yield $x = 30$, $y = 20$, and $z = 40$. Note that although a more recent *y* value is available, it was not returned by the get transactions because it is not part of the view of records up to position 4. If the get transaction ran at *B*, it will return $x = 10$, $y = 20$, and $z = 40$.

Time 3 in the figure shows the result of the propagation of records between *A* and *B*. $Put(y,50)$ has a copy now at *B*, and $Put(z,60)$ has a copy at *A*.

4.2 Event processing

Another application targeted by Chariots is multi-datacenter event processing. Many applications generate a large footprint that they would like to process. The users' interactions and actions in a web application can be analyzed to generate business knowledge. These events range from click events to the duration spent in each page. Additionally, social networks exhibit more complex analytics of events related to user-generated contents (*e.g.*, micro-blogs) and user-user relationships to these events. Frequently, such analytics are carried in multiple datacenters for fault-tolerance and locality [4, 17].

Chariots enables a simple interface for these applications to manage the replication and persistence of these analytics while preserving the required exactly-once semantics. Event processing applications consist of publishers and readers. Publishing an events is as easy as performing an append to the log. Readers then read the events from the log maintainers. An important feature of Chariots is that readers can read from different log maintainers. This will allow distributing the analysis work without the need of a centralized dispatcher that can be a single-point of contention.

4.3 Message Futures and Helios

Message Futures [27] and Helios [28] are commit protocols that provide strongly consistent transactions on geo-replicated data stores. They leverage a replicated log that guarantees causal order [36]. A single node at each datacenter, call it replica, is responsible for committing transactions and replication. Transactions consist of read and write operations and are committed optimistically. Application clients read from the data store and buffer writes. After all operations are ready, a *commit request* is sent to the closest replica. A record is appended to the log to declare the transaction *t* as ready to begin the commit protocol. Message Futures and Helios implement different conflict detection protocols to commit transactions. Message Futures [27] waits for other datacenters to send their histories up to the point of *t*'s position in the log. Conflicts are detected between *t* and received transactions, and *t* commits if no conflicts are detected. Helios [28] builds on a lower-bound proof that determines the lowest possible commit latency that a strongly consistent transaction can achieve. Helios commits a transaction *t* by detecting conflicts with transactions in a *conflict zone* in the shared log. The conflict zone is calculated by Helios using the lower-bound numbers. If no conflicts were detected, *t* commits. A full description of Message Futures and Helios are available in previous publications [27, 28].

Message Futures and Helios demonstrate how a causally ordered log can be utilized to provide strongly consistent transactions on replicated data. However, the used replicated log solution [36] is rudimentary and is not suitable for today's applications. It only

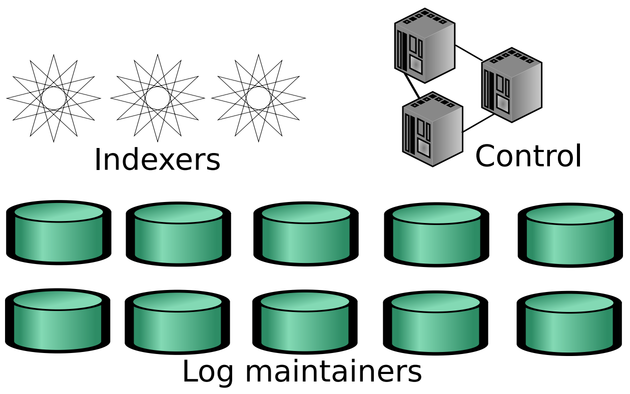

Figure 3: The architecture of FLStore

utilizes a single node per datacenter. This limits the throughput that can be achieved to that of a single node. Chariots can be leveraged to scale Message Futures and Helios to larger throughputs. Rather than a replica with a single node at each datacenter, Chariots would be used to distribute storage and computation.

4.4 Conclusion

The simple interface of Chariots enabled the design of web and analytics applications. The developer can focus on the logic of the data manager or stream processor without having to worry about the details of replication, fault-tolerance, and availability. In addition, the design of Chariots allows scalable designs of these solutions by having multiple sinks for reading and appending.

5. FLSTORE: DISTRIBUTED SHARED LOG

In this section we describe the distributed implementation of the shared log, called the Fractal Log Store (FLStore). FLStore is responsible of maintaining the log *within* the datacenter. We begin by describing the design of the distributed log storage. Then, we introduce the scalable indexing component used for accessing the shared log.

5.1 Architecture

In designing FLStore, we follow the principle of distributing computation and highly-available stateless control. This approach has been identified as the most suitable to scale out in cloud environments [17]. The architecture of FLStore consists of three types of machines, shown in Figure 3. *Log maintainers* are responsible for persisting the log's records and serving read requests. *Indexers* are responsible of access to log maintainers. Finally, control and meta-data management is the responsibility of a highly-available cluster called the *Controller*.

Application clients start their sessions by polling the Controller for information about the indexers and log maintainers. This information includes the addresses of the machines and the log ranges falling under their responsibility in addition to approximate information about the number of records in the shared log. Appends and reads are served by Log maintainers. The Application client communicates with the Controller only at the beginning of the session or if communication problems occur. And Application clients will communicate with Indexers only if read operation did not specify LIds in the rules.

5.2 Log maintainers

Scalability by post-assignment. The Log maintainers are accessed via a simple interface for adding to and reading from the shared log. They are designed to be *fully distributed* to overcome the I/O bandwidth constraints that are exhibited by current shared log protocols. A recent protocol is CORFU [7] that is limited by the I/O bandwidth of a sequencer. The sequencer is needed for CORFU to pre-assign log positions to application clients wishing to append records to the log. In FLStore, we abandon this requirement of pre-assigning log positions and settle for a *post-assignment* approach. The thesis of a post-assignment approach is to let the application client construct the record and send it to a randomly (or intelligibly) selected Log maintainer. The Log maintainer will assign the record the next available log position from log positions under its control.

Design. The shared log is distributed among the participating Log maintainers. This means that each machine holds a partial log and is responsible for its persistence and for answering requests to read its records. This distribution poses two challenges. The first is the way to append to the log while guaranteeing uniqueness and the non-existence of gaps in the log. This includes the access to these records and the way to index the records. The other challenge is maintaining explicit order guarantees requested by the application client. We employ a *deterministic* approach to make each machine responsible for specific ranges of the log. These ranges round-robin across machines where each round consists of a number of records. we will call this number the batch size. Figure 4 depicts an example of three log maintainers, *A*, *B*, and *C*. The figure shows the partial logs of the first three rounds if the batch size was set to a 1000 records.

If an application wants to read a record it directs the request to the Log maintainer responsible for it. The Log maintainer can only answer requests of records if their LIds are provided. Otherwise, the reader must collect the LIds first from the Indexers as we show in the next section. Appending to the log is done by simply sending a record or group of records to one of the Log maintainers. The Log maintainer appends the record to the next available log position. It is possible that a log maintainer will receive more record appends than others. This creates a load-balancing problem that can be solved by giving the application feedback about the rate of incoming requests at the maintainers. This feedback can be collected by the Controller and be delivered to the application clients as a part of the session initiation process. Nonetheless, this is an orthogonal problem that can be solved by existing solutions in the literature of load balancing.

5.3 Distributed indexing

Records in Log maintainers are arranged according to their LIds. However, Application clients often desire to access records accord-

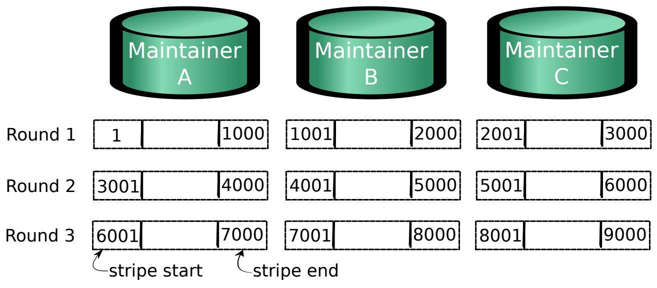

Figure 4: An example of three deterministic log maintainers with a batch size of 1000 record. Three rounds of records are shown.

ing to other information. When an Application client appends a record it also *tags* it with access information. These tags depend on the application. For example, a key-value store might wish to tag a record that has Put information with the key that is written. For this reason, we utilize distributed Indexers that provide access to the Log maintainers by tag information. Distributed indexing for distributed shared logs is tackled by several systems [11, 33, 35]

Tag and lookup model. The tag is a string that describes a feature of the record. It is possible that the tag also has a value. Each record might have more than one tag. The application client can lookup a tag by its name and specify the amount of records to be returned. For example, the Application client might lookup records that has a certain tag and request returning the most recent 100 record LIds to be returned with that tag. If the tag has a value attached to it, then the Application client might lookup records with that tag and rules on the value, *e.g.*, look up records with a certain tag with values greater than i and return the most recent x records.

5.4 Challenges

Log gaps. A Log maintainer receiving more records advances in the log ahead of others. For example, Log maintainer A can have 1000 records ready while Log maintainer B has 900 records. This causes temporary gaps in the logs that can be observed by Application clients reading the log. The requirement that needs to be enforced is that *Application clients must not be allowed to read a record at log position i if there exist at least one gap at log position j less than i.*

To overcome the problem of these temporary gaps, minimal gossip is propagated between maintainers. The goal of this gossip is to identify the record LId that will guarantee that any record with a smaller LId can be read from the Log maintainers. We call this LId the *Head of the Log (HL)*. Each Log maintainer has a vector with a size equal to the number of maintainers. Each element in the vector corresponds to the maximum LId at that maintainer. Initially the vector is initialized to all zeros. Each maintainer updates its value in the local vector. Occasionally, a maintainer propagates its maximum LId to other maintainers. When the gossip message is received by a maintainer it updates the corresponding entry in the vector. A maintainer can decide that the HL value is equal to the vector entry with the smallest value. When an application wants to read or know the HL, it asks one of the maintainers for this value. This technique does not pose a significant bottleneck for throughput. This is because it is a fixed-sized gossip that is not dependent on the actual throughput of the shared log. It might, however, cause the latency to be higher as the the throughput increases. This is because of the time required to receive gossip messages and determine whether a LId has no prior gaps.

Explicit order requests. Appends translate to a total order at the datacenter after they are added by the Log maintainers. Concurrent appends therefore do not have precedence relative to each other. It is, however, possible to enforce order for concurrent appends if they were requested by the Application client. One way is to send the appends to the same maintainer in the order wanted. Maintainers ensure that a latter append will have a LId higher than ones received earlier. Otherwise, it is possible to enforce order for concurrent appends across maintainers. The Application client waits for the earlier append to be assigned a LId and then attach this LId as a minimum bound. The maintainer that receives the record with the minimum bound ensures that the record is buffered until it can be added to a partial log with LIds larger than the minimum bound. This solution however must be pursued with care to avoid a large backlog of partial logs.

6. CHARIOTS: GEO-REPLICATED LOG

In this section we show the design of Chariots that supports multi-datacenter replication of the shared log. The design is a multi-stage pipeline that includes FLStore as one of the stages. We begin the discussion by outlining an abstract design of log replication. This abstract design specifies the requirements, guarantees, and interface desired to be provided by Chariots. The abstract solution will act as a guideline in building Chariots, that will be proposed after the abstract design. Chariots is a distributed scale-out platform to manage log replication with the same guarantees and requirements of the abstract solution.

6.1 Abstract solution

Before getting to the distributed solution, it is necessary to start with an efficient **abstract solution**. This abstract solution will be provided here in the form of algorithms running on a totally ordered thread of control at the datacenter. This is similar to saying that the datacenter is the machine and it is manipulating the log according to incoming events. Using this abstract solution, we will design the distributed implementation next (Section 6.2) that will result in a behavior identical to the abstract solution with a higher performance.

The data structures used are a log and a $n \times n$ table, where n is the number of datacenters, called the Awareness Table (ATable) inspired by Replicated Dictionary [36]. The table represents the datacenter's (DC's) extent of knowledge about other DCs. Each row or column represents one DC. Consider DC A and its ATable T_A. The entry $T_A[B,C]$ contains a TOId, τ, that represents B's knowledge about C's records according to A. This means that A is certain that B knows about all records generated at host DC C up to record τ. When a record is added to the log, it is tagged by the following information: (1) *TOId*, (2) *Host datacenter Id*, and (3) causality information.

The body of the record, which is supplied by the application is opaque to Chariots . To do the actual replication, the local log and ATable are continuously being propagated to other DCs. When the log and ATable are received by another DC, the new records are incorporated at the receiving log and the ATable is updated accordingly.

The algorithms to handle operations and propagation are presented with the assumption that only one node manipulates Chariots, containing the log of records and ATable. In Section 6.2 we will build the distributed system that will be manipulating Chariots while achieving the correct behavior of the abstract solution's algorithms presented here. The following are the events that need to be handled by Chariots:

1. **Initialization**: The log is initialized and the ATable entries are set to zero. Note that the first record of each node has a TOId of 1.

2. **Append**: Construct the record by adding the following information: host identifier, TOId, LId, causality, and tags. Update the entry $T_I[I,I]$, where I is the host datacenter's id, to be equal to the record's TOId. Finally, add the record to the log.

3. **Read**: Get the record with the specified LId.

4. **Propagate**: A snapshot of Chariots is sent to another DC j. The snapshot includes a subset of the records in the log that are not already known by j. Whether a record, r, is known to j can be verified using $T_i[j,i]$ and comparing it to $TOId(r)$.

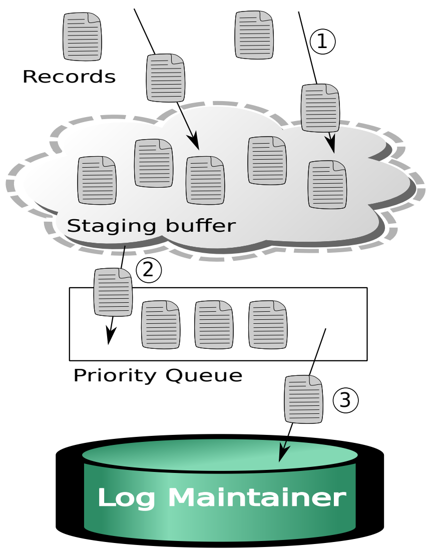

Figure 5: The components involved in adding records in the abstract solution.

5. **Reception**: When a log is received, incorporate all the records that were not seen before to the local log if its causal dependencies are satisfied. Otherwise, add the record with unsatisfied dependencies to a priority queue ordered according to causal relations. This is depicted in Figure 5. The incoming records are all put in a staging buffer (step 1) and are taken and added to the log or priority queue according to their causal dependencies (step 2). Chariots checks the priority queue frequently to transfer any records that have their dependencies satisfied to the log (step 3). Also, the ATable is updated to reflect the newly incorporated records.

Garbage collection. The user has the choice to either garbage collect log records or maintain them indefinitely. Depending on the applications, keeping the log can have great value. If the user choses not to garbage collect the records then they may employ a cold storage solution to archive older records. On the other hand, the user can choose to enable garbage collection of records. It is typical to have a temporal or spatial rule for garbage collecting the log. However, in addition to any rule set by the system designer, garbage collection is performed for records only after they are known by all other replicas. This is equivalent to saying that a record, r, can be garbage collected at i if and only if $\forall_{j \in nodes}(T_i[j, host(r)] \geq ts(r))$, where $host(r)$ is the host node of r.

6.2 Chariots distributed design

In the previous section we showed an efficient abstract design for a shared log that supports multi-datacenter replication. Chariots is a distributed system that mimics that abstract design. Each datacenter runs an instance of Chariots. The shared logs at different datacenters are replicas. All records exist in all datacenters. The system consists of a multi-stage pipeline. Each stage is responsible of performing certain tasks to incoming records and pushing them along the pipeline where they eventually persist in the shared log. Each stage in Chariots is designed to be elastic. An important design principle is that Chariots is designed to identify bottlenecks in the pipeline and allow overcoming them by adding more resources to the stages that are overwhelmed. For this to be successful, elasticity of each stage is key. Minimum to no dependencies exist between the machines belonging to one stage.

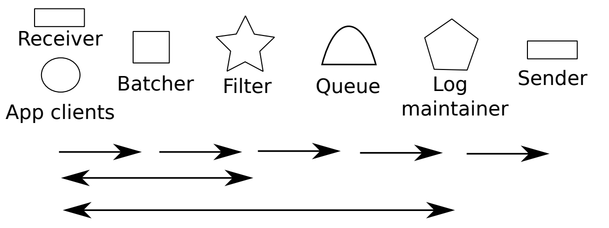

Figure 6: The components of the multi-data center shared log. Arrows denote communication pathways in the pipeline.

Pipeline design. Chariots pipeline consists of six stages depicted in Figure 6. The first stage contains nodes that are generating records. These are Application clients and machines receiving the records sent from other datacenters. These records are sent to the next stage in the pipeline, *Batchers*, to batch records to be sent collectively to the next stage. *Filters* receive the batches and ensure the uniqueness of records. Records are then forwarded to Queues where they are assigned LId. After assigning a LId to a record it is forwarded to FLStore that constitutes the Log maintainers stage. The local records in the log are read from FLStore and sent to other datacenters via the *Senders*.

The arrows in Figure 6 represent the flow of records. Generally, records are passed from one stage to the next. However, there is an exception. Application clients can request to read records from the Log maintainers. Chariots support elastic expansion of each stage to accommodate increasing demand. Thus, each stage can consist of more than one machine, *e.g.*, five machines acting as Queues and four acting as Batchers. The following is a description of each stage:

Application clients. The Application client hosts the application modules. These modules uses the interface to the log that was presented in Section 3. Some of the commands are served by only reading the log. These include Read and control commands. These requests are sent directly to the Log maintainers. The Append operation creates a record that encapsulates the user's data and send it to any Batcher machine.

Batchers. The Batchers buffer records that are received locally or from external sources. Batchers are completely independent from each other, meaning that no communication is needed from one Batcher to another and that scaling to more batchers will have no overhead. Each Batcher has a number of buffers equal to the number of Filters. Each record is mapped to a specific Filter to be sent to it eventually. Once a buffer size exceeds a threshold, the records are sent to the designated Filter. The way records are mapped to Filters is shown next.

Filters. The Filters ensures uniqueness of records. To perform this task, each Filter becomes a champion for a subset of the records. One natural way to do so is to make each Filter a champion for records with the same host Id, i.e. the records that were created at the same datacenter. If the number of Filters needed is less that the number of datacenters, then a single Filter can be responsible for more than one datacenter. Otherwise, if the number of needed Filters is in fact larger than the number of datacenters, then more than one Filter need to be responsible for a single datacenter's records. For example, consider that two Filters, x and y, responsible for records coming from datacenter A. Each one can be responsible for a subset of the records coming from A. This can be achieved by leveraging the unique, monotonically increasing, TOIds. Thus, x can be responsible for ensuring uniqueness of A's records with odd

TOIds and *y* can ensure the uniqueness of records with even TOIds. Of course, any suitable mapping can be used for this purpose. To ensure uniqueness, the processing agent maintains a counter of the next expected TOId. When the next expected record arrives it is added to the batch to be sent to the one of the Queues. Note also that this stage does not require any communication between filters, thus allowing seamless scalability.

Queues. Queues are responsible for assigning LIds to the records. This assignment must preserve the ordering guarantees of records. To append records to the shared log they need to have all their causal dependencies satisfied in addition to the total order of records coming from the same datacenter. Once a group of records have their causal dependencies satisfied, they are assigned LIds and sent to the appropriate log maintainer for persistence. For multi-datacenter records with causal dependencies, it is not possible to append to the FLStore directly and make it assign LIds in the same manner as the single-datacenter deployment shown in section 5.2. This is because it is not guaranteed that any record can be added to the log at any point in time, rather, its dependencies must be satisfied first. The queues ensure that these dependencies are preserved and assign LIds for the records before they are sent to the log maintainers. The queues are aware of the deterministic assignment of LIds in the log maintainers and forward the records to the appropriate maintainer accordingly.

Queues ensure causality of LId assignments by the use of a token. The token consists of the current maximum TOId of each datacenter in the local log, the LId of the most recent record, and the deferred records with unsatisfied dependencies. The token is initially placed at one of the Queues. The Queue holding the token append all the records that can be added to the log. The Queue can verify whether a record can be added to the shared log by examining the maximum TOIds in the token. The records that can be added are assigned LIds and sent to the Maintainers designated for them. The token is updated to reflect the records appended in the log. Then, the token is sent to the next maintainer in a round-robin fashion. The token might include all, some, or none of the records that were not successfully added to the log. Including more deferred records with the token consumes more network I/O. On the other hand, not forwarding the deferred records with the token might increase the latency of appends. It is a design decision that depends on the nature of Chariots deployment.

Log maintainers. These Log maintainers are identical to the distributed shared log maintainers of FLStore presented in Section 5.2. Maintainers ensure the persistence of records in the shared log. The record is available to be read by senders and application clients when they are persisted in the maintainers.

Log propagation. Senders propagate the local records of the log to other datacenters. Each sender is limited by the I/O bandwidth of its network interface. To enable higher throughputs, more Senders are needed at each datacenter. Likewise, more Receivers are needed to receive the amount of records sent. Each Sender machine is responsible to send parts of the log from some of the maintainers to a number of Receivers at other datacenters.

6.3 Live elasticity

The demand on web and cloud applications vary from time to time. The ability of the infrastructure to scale to the demand seamlessly is a key feature for its success. Here, we show how adding compute resources to Chariots in the fly is possible without disruptions to the Application clients. The elasticity model of Chariots is to treat each stage as an independent unit. This means that it is possible to add resources to a single stage to increase its capacity without affecting the operation of other stages.

Completely independent stages. Increasing the capacity of completely independent stages merely involves adding the new resources and sending the information of the new machine to the higher layer. The completely independent stages are the receivers, batchers, and senders. For adding a receiver, the administrator needs to inform senders of other datacenters so that it can be utilized. Similarly, a new batcher need to inform local receivers of its existence. A new sender is different in that it is the one reading from log maintainers, thus, the log maintainers need not be explicitly told about the introduction of a new sender.

Filters. In Chariots, each filter is championing a specific subset of the log records. Increasing the number of filters results in the need of reassigning championing roles. For example, a filter that was originally championing records from another datacenter could turn out to be responsible for only a subset of these records while handing off the responsibility of the rest of them to the new filter. This reassignment need to be orchestrated with batchers. There need to be a way for batchers to figure out when the hand-over took place so that they can direct their records accordingly. A *future reassignment* technique will be followed for filters as well as log maintainers as we show next. A future reassignment for filters begin by marking future TOIds that are championed by the original filter. These future TOIds mark transition of championing a subset of the records to the new filter. Consider a filter that champions records from datacenter *A* in a reassignment scenario of adding a new filter that will champion the subset of these records with even TOIds. Marking a future TOId, *t*, will result in records with even TOIds greater than *t* to be championed by the new filter. This future reassignment should allow enough time to propagate this information to batchers.

Queues. Adding a new queue involves two tasks: making the new queue part of the token exchange loop and propagating the information of its addition to filters. The first task is performed by informing one of the queues that it should forward the token to the new queue rather than the original neighbor. The latter task (informing filters) can be performed without coordination because a queue can receive any record.

Log maintainers. Expanding log maintainers is similar to expanding filters in that each maintainer champions a specific set of records. In this case, each log maintainer champions a subset of records with specific LIds. The future reassignment technique is used in a similar way to expanding filters. In this case, not only do the queues need to know about the reassignment, but the readers need to know about it too. Another issue is that log maintainers persist old records. Rather than migrating the old records to the new champion, it is possible to maintain an epoch journal that denotes the changes in log maintainer assignments. These can be used by readers to figure out which log maintainer to ask for an old record.

7. EVALUATION

In this section we present some experiments to evaluate our implementation of FLStore and Chariots. The experiments were conducted on a cluster with nodes with the following specifications. Intel Xeon E5620 CPUs that are running 64-bit CentOS Linux with OpenJDK 1.7 were used. The nodes in a single rack are connected by a 10GB switch with an average RTT of 0.15 ms. We also perform the baseline experiments on Amazon AWS. There, we used compute optimized machines (c3.large) in the datacenter in Virginia. Each machine has 2 virtual CPUs and a 3.75 GiB memory. We refer to the earlier setup as the *private cloud* and the latter setup as the *public cloud*. Unless it is mentioned otherwise, the size of each record is 512 Bytes.

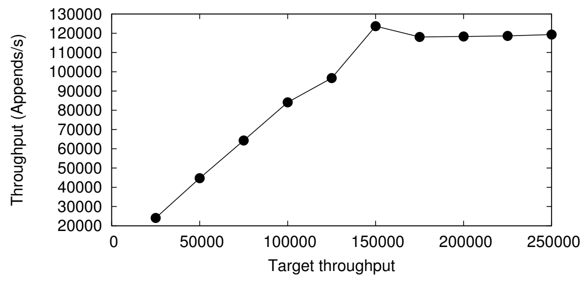

Figure 7: The throughput or one maintainer while increasing the load in a public cloud

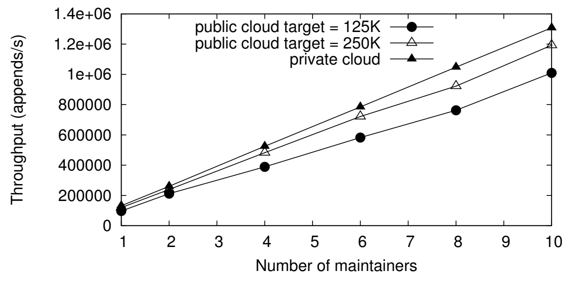

Figure 8: The append throughput of the shared log in a single-datacenter deployment while increasing the number of Log Maintainers.

7.1 FLStore scalability

The first set of experiments that we will present is of the FLStore implementation which operates within the datacenter. Each one of the experiments consists of two types of machines, namely Log maintainers and clients. The clients generate records and send them to the Log Maintainers to be appended. We are interested in measuring the scaling behavior of FLStore while increasing the number of maintainers. We begin by getting a sense of the capacity of the machines. Figure 8 shows the throughput of one maintainer in the public cloud while increasing the load on it. Records are generated with a specific rate at each experiment point from other machines. The rate is called the *target throughput*. Note how as the target throughput increases, the achieved throughput increases up to a point and then plateaus. The maximum throughput is achieved when the target throughput is 150K and then drops to be around 120K appends per second. These numbers will help us decide what target throughputs to choose for our next experiments.

To verify the scalability of FLStore, Figure 8 shows the cumulative throughput of different scenarios each with a different number of maintainers. For each experiment an identical number of client machines were used to generate records to be appended. Ideally, we would like the throughput to increase linearly with the addition of new maintainers. Three plots are shown, two from the public cloud and one from the private cloud. The ones from the public cloud differ in the target throughput to each maintainer. One targets 125K appends per second for each maintainer while the other targets 250K appends per second. Note how one is below the plateau point and one is above. The figure shows that FLStore scales with the addition of resources. A single maintainer has a throughput of 131K for the private cloud, 96.7K for the public cloud with a target of 125K, and 119K for the public cloud with the target of 250K. As we are increasing the number of Log Maintainers a near-linear scaling is observed. For ten Log Maintainers, the achieved append throughput was 1308034 record appends per second for the private cloud. This append throughput is 99.3% when compared to a perfect scaling case. The public cloud case with a target of 125K achieves a throughput that is slightly larger than the perfect scaling case. This is due to the variation in machines' performances. The other public cloud case achieve a scaling of 99.9%. This near-perfect scaling of FLStore is encouraging and demonstrates the effect of removing any dependencies between maintainers.

Machine	Throughput (Kappends/s)
Client	129
Batcher	129
Filter	129
Maintainer	124
Store	132

Batcher	126
Filter	125
Maintainer	123
Store	132

Table 3: The throughput of machines in a deployment of Chariots with two clients and one machine per stage for the remaining stages.

7.2 Chariots scalability

The full deployment of Chariots that is necessary to operate in a multi-datacenter environment consists of five stages. These stages are described in Section 6.2. Here, we will start from a basic deployment of one machine per stage in the private cloud. We observe the throughput of each stage to try to identify the bottleneck. Afterward, we observe how this bottleneck can be overcome by increasing resources. The simple deployment of one machine per stage of Chariots pipeline achieves the throughputs shown in Table 2. The table lists the throughput in Kilo records per second for each machine in the pipeline. Note how all machines achieve a similar throughput of records per second. It is possible for the store to achieve a throughput higher than the client because of the effect of buffering. Close throughput numbers for all machines indicates that the bottleneck is possibly due to the clients. The clients might be generating less records per second than what can be handled by the pipeline.

To test this hypothesis we increase the number of machines generating records to two client machines. The results are shown in Table 3. If the clients were indeed not generating enough records to saturate the pipeline, then we should observe an increase in the throughput of the Batcher. However, this was not the case. The increased load actually resulted in a lower throughput for the batcher. This means that the batcher is possibly the bottleneck. So, we increase the number of batchers to observe the throughput of latter stages in the pipeline. Table 4 shows the throughput of machines with two client machines, two batchers, and a single machine for each of the remaining stages. Both batchers achieve a throughput that is higher than the one achieved by a single batcher in the pre-

Machine	Throughput (Kappends/s)
Client 1	126
Client 2	129
Batcher 1	149
Batcher 2	129
Filter	120

Store	121

Table 4: The throughput of machines in a deployment of Chariots with two client machines, two Batchers, and a single machine for the remaining stages.

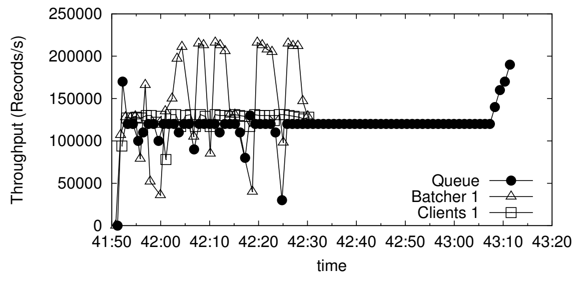

Figure 9: The throughput of machines in a deployment of Chariots with two client machines, two Batchers, and a single machine for the remaining stages

vious experiments. This means that the throughput of the Batcher stage more than doubled. However, now the bottleneck is pushed to the filter stage that is not able to handle more than 130000 records per second. Because the throughput of latter stages is almost half the throughput of the Batcher, they take twice the time to finish the amount of records generated by the clients (10000000 records). The throughput timeseries for one client, one batcher, and the queue are shown in Figure 9. We did not show all the machines' throughputs to avoid cluttering the figure. The Batchers are done with the records at time 42:30, whereas, the latter stages lasted till time 43:10. Note that by the end of the experiment, the throughput of the queue increases abruptly. The reason for this increase is that the although the Batchers had already processed the records they are still transmitting them to the Filter until time 43:08, right before the abrupt increase. The network interface's I/O of the Filter was limiting its throughput. After it is no longer receiving from the two Batchers it can send with a higher capacity to the latter stages, thus causing an increase in the observed throughput. This is also the reason of why in the beginning of the experiment, a higher throughput is observed for some of the stages (*e.g.*, the high throughput in the beginning for the queue). The reason is that they still had capacity in their network's interface I/O before it was also used to propagate records to latter stages. Another interesting observation is the performance variation of the batcher. This turned out to be a characteristic of machines at a stage generating more throughput than what can be handled by the next stage.

Increasing the number of machines further should yield a better throughput. We experiment with the previous setting, but this time with two machines for all stages. The throughput values records are presented in Table 5. Note how all stages are scaling. The throughput of each stage has doubled. Each machine achieves a close throughput to the basic case of a pipeline with one machine per stage.

Machine	Throughput (Kappends/s)
Client 1	130
Client 2	130
Batcher 1	127
Batcher 2	127
Filter 1	127
Filter 2	126
Maintainer 1	125
Maintainer 2	126
Store 1	137
Store 2	137

Table 5: The throughput of machines in a deployment of Chariots with two machines per stage.

Our main objective is to allow scaling of shared log systems to support today's applications. We showed in this evaluation how a FLStore deployment is able to scale while increasing the number of maintainers within the datacenter (Figure 8). Also, we evaluated the full Chariots pipeline that is designed to be used for multi-datacenter environments. The bottleneck of a basic deployment was identified and Chariots overcome it by adding more resources to the pipeline.

8. CONCLUSION

In this paper we presented a shared log system called Chariots. The main contribution of Chariots is the design of a distributed shared log system that is able to scale beyond the limit of a single node. This is enabled by a deterministic post-assignment approach of assigning ranges of records to Log maintainers. Chariots also increases the level of availability and fault-tolerance by supporting geo-replication. A novel design to support a shared log across datacenters is presented. Causal order is maintained across records from different datacenters. To allow scaling such a shared log, a multi-stage pipeline is proposed. Each stage of the pipeline is designed to be scalable by minimizing the dependencies between different machines. An experimental evaluation demonstrated that Chariots is able to scale with increasing demand by adding more resources.

ABSTRACT

Social networks are large graphs that require multiple graph database servers to store and manage them. Each database server hosts a graph partition with the objectives of balancing server loads, reducing remote traversals (edge-cuts), and adapting the partitioning to changes in the structure of the graph in the face of changing workloads. To achieve these objectives, a dynamic repartitioning algorithm is required to modify an existing partitioning to maintain good quality partitions while not imposing a significant overhead to the system. In this paper, we introduce a *lightweight repartitioner*, which dynamically modifies a partitioning using a small amount of resources. In contrast to the existing repartitioning algorithms, our lightweight repartitioner is efficient, making it suitable for use in a real system. We integrated our lightweight repartitioner into Hermes, which we designed as an extension of the open source Neo4j graph database system, to support workloads over partitioned graph data distributed over multiple servers. Using real-world social network data, we show that Hermes leverages the lightweight repartitioner to maintain high quality partitions and provides a 2 to 3 times performance improvement over the de-facto standard random hash-based partitioning.

1. INTRODUCTION

Large scale graphs, in particular social networks, permeate our lives. The scale of these networks, often in millions of vertices or more, means that it is often infeasible to store, query and manage them on a single graph database server. Thus, there is a need to partition, or shard, the graph across multiple database servers, allowing the load and concurrent processing to be distributed over these servers to provide good performance and increase availability. Social networks exhibit a high degree of correlation for accesses of certain groups of records, for example through frictionless sharing [15]. Also, these networks have a heavy-tailed distribution for popularity of vertices. To achieve a good partitioning which improves the overall performance, the following objectives need to be met:

- The partitioning should be *balanced*. Each vertex of the graph has a *weight* that indicates the popularity of the vertex (e.g., in terms of the frequency of queries to that vertex). In social networks, a small number of users (e.g., celebrities, politicians) are extremely popular while a large number of users are much less popular. This discrepancy reveals the importance of achieving a balanced partitioning in which all partitions have almost equal *aggregate weight* defined as the total weight of vertices in the partition.
- The partitioning should minimize the number of *edge-cuts*. An edge-cut is defined by an edge connecting vertices in two different partitions and involves queries that need to transition from a partition on one server to a partition on another server. This results in shifting local traversal to remote traversal, thereby incurring significant network latency. In social networks, it is critical to minimize edge-cuts since most operations are done on the node that represents a user and its immediate neighbors. Since these *1-hop traversal* operations are so prevalent in these networks, minimizing edge-cuts is analogous to keeping communities intact. This leads to highly local queries similar to those in SPAR [27] and minimizes the network load, allowing for better scalability by reducing network IO.
- The partitioning should be *incremental*. Social networks are *dynamic* in the sense that users and their relations are always changing, e.g., a new user might be added, two users might get connected, or an ordinary user might become popular. Although the changes in the social graph can be much slower when compared to the read traffic [8], a good partitioning solution should dynamically adapt its partitioning to these changes. Considering the size of the graph, it is infeasible to create a partitioning from scratch; hence, a repartitioning solution, a *repartitioner*, is needed to improve on an existing partitioning. This usually involves *migrating* some vertices from one partition to another.
- The repartitioning algorithm should perform well in terms of time and memory requirements. To achieve this efficiency, it is desirable to perform repartitioning locally by accessing a small amount of information about the structure of the graph. From a practical point of view, this requirement is critical and prevents us from applying existing approaches, e.g., [18, 30, 31, 6] for the repartitioning problem.

The focus of this paper is on the design and provision of a *practical* partitioned social graph data management system that can support remote traversals while providing an

10.5441/002/edbt.2015.04

effective method to *dynamically* repartition the graph using only local views. The distributed partitioning aims to co-locate vertices of the graph *on-the-fly* so as to satisfy the above requirements. The fundamental contribution of this paper is a dynamic partitioning algorithm, referred to as *lightweight repartitioner*, that can identify which parts of graph data can benefit from co-location. The algorithm aims to incrementally improve an existing partitioning by decreasing edge-cuts while maintaining almost balanced partitions. The main advantage of the algorithm is that it relies on only a small amount of knowledge on the graph structure referred to as *auxiliary data*. Since the auxiliary data is small and easy to update, our repartitioning algorithm is performant in terms of time and memory while maintaining high-quality partitionings in terms of edge-cut and load balance.

We built Hermes as an extension of the Neo4j[1] open source graph database system by incorporating into it our algorithm to provide the functionality to move data on-the-fly to achieve data locality and reduce the cost of remote traversals for graph data. Our experimental evaluation of Hermes using real-world social network graphs shows that our techniques are effective in producing performance gains and work almost as well as the popular Metis partitioning algorithms [18, 30, 6] that performs static offline partitioning by relying on a global view of the graph.

The rest of the paper is structured as follows. Section 2 describes the problem addressed in the paper and reviews classical approaches and their shortcomings. Section 3 introduces and analyzes the lightweight repartitioner. Section 4 presents an overview of the Hermes system. Section 5 presents performance evaluation of the system. Section 6 covers related work, and Section 7 concludes the paper.

2. PROBLEM DEFINITION

In this section we formally define the partitioning problem and review some of the related results. In what follows, the term 'graph' refers to an undirected graph with weights on vertices.

2.1 Graph Partitioning

In the classical (α, γ)-graph partitioning problem [20], the goal is to partition a given graph into α vertex-disjoint subgraphs. The weight of a partition is the total weight of vertices in that partition. In a *valid solution*, the weight of each partition is at most a factor $\gamma \geq 1$ away from the average weight of partitions. More precisely, for a partition P of a graph G, we need to have $\omega(P) \leq \gamma \times \sum_{v \in V(G)} \omega(v)/\alpha$. Here, $\omega(P)$ and $\omega(v)$ denote the weight of a partition P and vertex v, respectively. Parameter γ is called the *imbalance load factor* and defines how imbalanced the partitions are allowed to be. Practically, γ is in range $[1, 2]$. Here, $\gamma = 1$ implies that partitions are required to be completely balanced (all have the same aggregate weights), while $\gamma = 2$ allows the weight of one partition to be up to twice the average weight of all partitions. The goal of the minimization problem is to achieve a valid solution in which the number of edge-cuts is minimized.

The partitioning problem is NP-hard [13]. Moreover, there is no approximation algorithm with a constant approximation ratio unless P=NP [7]. Hence, it is not possible to introduce algorithms which provide worst-case guarantees on the quality of solutions, and it makes more sense to study the typical behavior of algorithms. Consequently, the problem is mostly approached through heuristics [20] [12] which are aimed to improve the average-case performance. Regardless, the time complexity of these heuristics $\Omega(n^3)$ which makes them unsuitable in practice.

To improve the time complexity, a class of *multi-level* algorithms were introduced. In each *level* of these algorithms, the input graph is *coarsened* to a representative graph of smaller size; when the representative graph is small enough, a partitioning algorithm like that of Kernighan-Lin [20] is applied to it, and the resulting partitions are mapped back (uncoarsened) to the original graph. Many algorithms fit in this general framework of multi-level algorithms; a widely used example is the family of Metis algorithms [19, 30, 6]. The multi-level algorithms are *global* in the sense that they need to know the whole structure of the graph in the coarsening phase, and the coarsened graph in each stage should be stored for the uncoarsening stage. This problem is partially solved by introducing distributed versions of these algorithms in which the partitioning algorithm is performed in parallel for each partition [4]. In these algorithms, in addition to the local information (structure of the partition), for each vertex, the list of the adjacent vertices in other partitions is required in the coarsening phase. The following theorem establishes that in the worst case, acquiring this amount of data is close to having a global knowledge of graph (the proof can be found in [25]).

THEOREM 1. *Consider the (α, γ)-graph partitioning problem where $\gamma < 2$. There are instances of the problem for which the number of edge-cuts in any valid solution is asymptotically equal to the number of edges in the input graph.*

Hence, the average amount of data required in the coarsening phase of multi-level algorithms can be a constant fraction of all edges. The graphs used in the proof of the above theorem belong to the family of power-law graphs which are often used to model social networks. Consequently, even the distributed versions of multi-level algorithms in the worst case require *almost* global information on the structure of the graph (particularly when used for partitioning social networks). This reveals the importance of providing practical partitioning algorithms which need only a small amount of knowledge about the structure of the graph that can be easily maintained in memory. The lightweight repartitioner introduced in this paper has this property, i.e., it maintains only a small amount of data, referred to as auxiliary data, to perform repartitioning.

2.2 Repartitioning

A variety of partitioning methods can be used to create an initial, *static*, partitioning. This should be followed by a *repartitioning* strategy to maintain good partitioning that can adapt to changes in the graph. One solution is to periodically run an algorithm on the whole graph to get new partitions. However, running an algorithm to get new partitions from scratch is costly in terms of time and space. Hence, an incremental partitioning algorithm needs to adapt the existing partitions to changes in the graph structure.

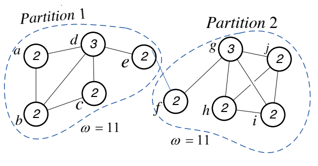
It is desirable to have a lightweight repartitioner that maintains only a small amount of auxiliary data to perform

[1]Neo4j is being used by customers such as Adobe and HP [3].

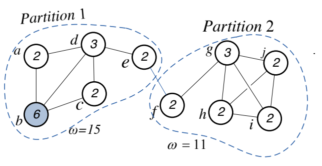
repartitioning. Since such algorithm refers only to this auxiliary data, which is significantly smaller than the actual data required for storing the graph, the repartitioning algorithm is not a system performance bottleneck. The auxiliary data maintained at each machine (partition) consists of the list of accumulated weight of vertices in each partition, as well as the *number* of neighbors of each hosted vertex in each partition. Note that maintaining the number of neighbors is far cheaper that maintaining the *list* of neighbors in other partitions. In what follows, the main ideas behind our lightweight repartitioner are introduced through an example.

Example: Consider the partitioning problem on the graph shown in Figure 1. Assume there are $\alpha = 2$ partitions in the system and the imbalance factor is $\gamma = 1.1$, i.e., in a valid solution, the aggregate weight of a partition is at most 1.1 times more than the average weight of partitions. Assume the numbers on vertices denote their weight. During normal operation in social networks, users will request different pieces of information. In this sense, the weight of a vertex is the number of read requests to that vertex. Figure 1a shows a partitioning of the graph into two partitions, where there is only one edge-cut and the partitions are well balanced, i.e., the weight of both partitions is equal to the average weight. Assuming user b is a popular weblogger who posts a post, the request traffic for vertex b will increase as its neighbors poll for updates, leading to an imbalance in load on the first partition (see Figure 1b). Here, the ratio between aggregate weight of partition 1 (i.e., 15) and the average weight of partitions (i.e., 13) is more than γ. This means that the response time and request rates increase by more than the acceptable skew limit, and the repartitioning needs to be triggered to rebalance the load across partitions (while keeping the number of edge-cuts as small as possible).

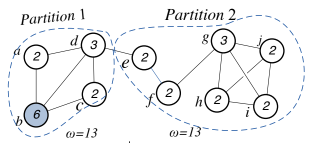
The auxiliary data of the lightweight repartitioner available to each partition includes the weight of each of the two partitions, as well as the number of neighbors of each vertex v hosted in the partition. Provided with this auxiliary data, a partition can determine whether load imbalances exist and the extent of the imbalance in the system (to compare it with γ). If there is a load imbalance, a repartitioner needs to indicate where to migrate data to restore load balance. Migration is an iterative process which will identify vertices that when moved will balance loads (aggregate weights) while keeping the number of edge-cuts as small as possible. For example, when the repartitioner starts from the state in Figure 1b, on partition 1, vertices a through d are poor candidates for migration because their neighbors are in the same partition. Vertex e, however, has a split access pattern between partitions 1 and 2. Since vertex e has the fewest neighbors in partition one, it will be migrated to partition 2. On partition 2, the same process is performed in parallel; however, vertex f will not be migrated since partition 1 has a higher aggregate weight. Once vertex e is migrated, the load (aggregate weights) becomes balanced, thus any remaining iterations will not result in any migrations (see Figure 1c).



(a) Balanced partitioned graph



(b) Skewed graph



(c) Repartitioned graph

Figure 1: Graph evolution and effects of repartitioning in response to imbalances.

The above example is a simple case to illustrate how the lightweight repartitioner works. Several issues are left out of the example, e.g., two highly connected clusters of vertices may repeatedly exchange their clusters to decrease edge-cut. This results in an *oscillation* which is discussed in detail in Section 3.

3. PARTITIONING ALGORITHM

Unlike Neo4j which is centralized, Hermes can apply hash-based or Metis algorithm to partition a graph and distribute the partitions to multiple servers. Thus, the system starts with an initial partitioning and incrementally applies the lightweight repartitioner to maintain partitioning with good performance in the dynamic environment. In this section, we introduce the lightweight repartitioner algorithm behind Hermes. Embedding the initial partitioning algorithm and the lightweight repartitioner into Neo4j required modification of Neo4j components.

To increase query locality and decrease query response times, the initial partitioning needs to be optimized in terms of having almost balanced distributions (valid solutions) with small number of edge-cuts. We use Metis to obtain the initial data partitioning, which is a static, offline, process that is orthogonal to the dynamic, on-the-fly, partitioning that Hermes performs.

3.1 Lightweight Repartitioner

When new nodes join the network or the traffic patterns (weights) of nodes change, the lightweight repartitioner is triggered to rebalance vertex weights while decreasing edge-cut through an iterative process. The algorithm makes use of aggregate vertex weight information as its auxiliary data. Assuming there are α partitions, for each vertex v, the auxiliary data includes α integers indicating the number of neighbors of v in each of the α partitions. This auxiliary data is insignificant compared to the *physical data* associated with the vertex which include adjacency list and other information referred to as *properties* of the vertex (e.g., pictures posted by a user in a social network). The repartitioning auxiliary data is collected and updated based on execution of user requests, e.g., when a new edge is added, the auxiliary data of the partitioning(s) including the endpoints of the edge get updated (two integers are incremented). Hence, the cost involved in maintenance of auxiliary data is proportional to the rate of changes in the graph. As mentioned earlier, social networks change quite slowly (when compared to the read traffic); hence, the maintenance of auxiliary data is not a system bottleneck. Each partition collects and stores aggregate vertex information relevant to only the local vertices. Moreover, the auxiliary data includes the total weight of all partitions, i.e., in doing repartitioning, each server knows the total weight of all other partitions.

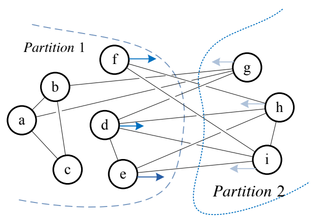
The repartitioning process has two *phases*. In each iteration of the first phase, each server runs the repartitioner algorithm using the auxiliary data to indicate some vertices in its partition that should be migrated to other partitions. Before the next iteration, these vertices are *logically* moved to their target partitions. Logical movement of a vertex means that only the auxiliary data associated with the vertex is sent to the other partition. This process continues up to a point (iteration) in which no further vertices are chosen for migration. At this point the second phase is performed in which the physical data is moved based on the result of first phase. The algorithm is split into two phases because border vertices are likely to change partitions more than once (this will be discussed later) and auxiliary data records are lightweight compared to the physical data records, allowing the algorithm to finish faster. In what follows, we describe how vertices are selected for migration in an iteration of the repartitioner.

Consider a partition P_s (source partition) is running the repartitioner algorithm. Let v be a vertex in partition P_s. The *gain* of moving v from P_s to another partition P_t (target partition) is defined as the difference between the number of neighbors of v in P_t and P_s, respectively, i.e., $gain(v) = d_v(t) - d_v(s)$ ($d_v(k)$ denotes the number of neighbors of v in partition k). Intuitively, the gain represents the decrease of the number of edge-cuts when migrating v from P_s to P_t (assuming that no other vertex migrates). Note that the gain can be negative, meaning that it is better, in terms of edge-cuts, to keep v in P_s rather than moving it to P_t. In each iteration and on each partition, the repartitioner selects for migration *candidate* vertices that will give the maximum gain when moved from the partition. However, to avoid *oscillation* and ensure a valid packing in term of load balance, the algorithm enforces a set of rules in migrating vertices. First, it defines two *stages* in each iteration. In the first stage, the migration of vertices is allowed only from partitions with lower ID to higher ID, while the second stage allows the migration only in the opposite direction, i.e., from partitions with higher ID to those with lower ID. Here, partition ID defines a fixed ordering of partitions (and can be replaced by any other fixed ordering). Migrating vertices in one-direction in two stages prevent the algorithm from oscillation. Oscillation happens when there is a large number of edges between two group of vertices hosted in two different partitions (see Figure 2). If the algorithm allows two-way migration of vertices, the vertices in each group migrate to the partition of the other group, while the edge-cut does not improve (Figure 2b). In one-way migration, however, the vertices in one group remain in their partitions while the other group joins them in that partition (Figure 2d).

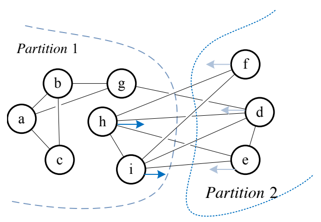
In addition to preventing oscillation, the repartitioner algorithm minimizes load imbalance as follows. A vertex v on a partition P_s is a candidate for migration to partition P_t if the following conditions hold:

- P_s and P_t fulfill the above one-way migration rule.
- Moving v from P_s to P_t does not cause P_t to be *overloaded* nor P_s to be *underloaded*. Recall from Section 2.1 that the imbalance ratio of a partition is the ratio between the weight of the partition (the total weight of vertices it is hosting) and the average weight of all the partitions. A partition is overloaded if its imbalance load is more than γ and underloaded if its weight is less than $2 - \gamma$ times the average partition weight. Here, γ is the maximum allowed imbalance factor ($1 < \gamma < 2$); the default value of γ in Hermes is set to be 1.1, i.e., a partition's load is required to be in range $(0.9, 1.1)$ of the average partition weight. This is so that imbalances do not get too high before repartitioning triggers.
- Either P_s is overloaded *OR* there is a positive *gain* in moving v from P_s to P_t. When a partition is overloaded, it is good to consider all vertices as candidates for migration to any other partition as long as they do not cause an overload on the target partition. When the partition is not overloaded, it is good to move only vertices which have positive weight so as to improve the edge-cut.

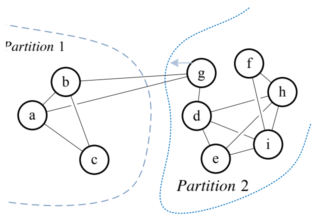
When a vertex v is a candidate for migration to more than one partition, the partition with maximum gain is selected as the target partition of the vertex. This is illustrated in Algorithm 1. Note that detecting whether a vertex v is a candidate for migration and selecting its target partition is performed using only the auxiliary data. Precisely, for detecting underloaded and overloaded partitions (Lines 2, 5 and 11), the algorithm uses the weight of the vertex and the accumulated weights of all partitions; these are included in the auxiliary data. Similarly, for calculating the gain of moving v from partition P_s to partition P_t (Line 10), it uses the number of neighbors of v in any of the partitions, which



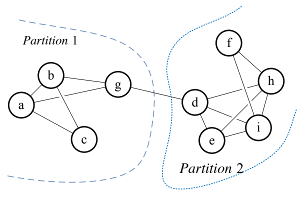
(a) Initial graph, before the first iteration.



(b) The resulted graph if vertices migrate in the same stage (i.e., in a two-way manner).



(c) The resulting graph after the first stage.



(d) The final graph after the second stage.

Figure 2: An unsupervised repartitioning might result in oscillation. Consider the partitioning depicted in (a). The repartitioner on partition 1 detects that migrating d, e, f to partition 2 improves edge-cut; similarly, the repartitioner on partition 2 tends to migrate g, h, i to partition 1. When the vertices move accordingly, as depicted in (b), the edge-cut does not improve and the repartitioner needs to move d, e, f and h, i again. To resolve this issue, in the first stage of repartitioning of (a), the vertices d, e, f are migrated from partition 1 (lower ID) to partition 2 (higher ID). After this, as depicted in (c), the only vertex to migrate in the second stage is vertex g which moves from partition 2 (higher ID) to migration 1 (d).

Algorithm 1 Choosing target partition for migration

```
1: procedure GET_TARGET_PART(vertex $v$ currently hosted in partition $P_s$, the current stage of the iteration.)
2:     if imbalance_factor($P_s - \{v\}$) $< 2 - \gamma$ then
3:         return $(null, 0)$
4:     $target = null$; $maxGain = 0$;
5:     if imbalance_factor($P_s$) $> \gamma$ then
6:         $maxGain = -\infty$
7:     for partition $P_t \in$ partitionSet do
8:         if ($stage = 1$ and $P_t.ID > P_s.ID$) or
9:            ($stage = 2$ and $P_t.ID < P_s.ID$) then
10:            $gain \leftarrow$ Gain($v, P_s, P_t$)
11:            if imbalance_factor($P_t \cup \{v\}$) $< \gamma$ and
12:               $gain > maxGain$ then
13:                $target \leftarrow P_t$; $maxGain = gain$
14:    return $(target, maxGain)$
```

is also included in the auxiliary data.

Recall that the repartitioning algorithm runs on each partition independently, a property that supports scalability. For each partition P_s, after selecting the candidate vertices for migration and their target partitions, the algorithm selects k candidate vertices which have the highest gains among all vertices and proceeds by (logically) migrating these *top-k* vertices to their target partitions. Here, migrating a vertex means sending (and updating) the auxiliary data associated with the vertex to its target destination and updating the auxiliary data associated with partition weights accordingly. The algorithm restricts the number of migrated vertices in each iteration (to k) to avoid imbalanced partitionings. Note that when selecting the target partition for a migrating vertex, the algorithm does not know the target partition of other vertices; hence, there is a chance that a large number of vertices migrate to the same partition to improve edge-cut. Selecting only k vertices enables the algorithm to control the accumulative weight of partitions by restricting the number of migrating vertices. We discuss later how the value of k is selected. In general, taking k as a small, fixed fraction of n (size of the graph) gives satisfactory results.

Algorithm 2 shows the details of one iteration of the repartitioner algorithm performed on a partition P_s. The algorithm detects the candidate vertices (Lines 4-8), selects the *top-k* candidates (Line 9), and moves them to their respective target partitions. Note that the migration in Line 11 is logical. After each phase of each iteration, the auxiliary data associated with each migrated vertex v is updated. This is because the neighbors of v may also be migrated, which would mean that the degree of v in each partition, i.e., auxiliary data associated with v, has changed. The algorithm continues moving vertices until there is no candidate vertex for migration, i.e., further movement of vertices does not improve edge-cut.

Example: To demonstrate the workings of the lightweight repartitioner, we show two iterations of the repartitioning algorithm on the graph of Figure 3 in which there are $\alpha = 3$ partitions and the average weight of partitions is 10/3. Assume the value of γ is $1.\bar{3}$. Hence, the aggregate weight of a partition needs to be in range $[2.\bar{2}, 4.\bar{4}]$; otherwise the partitioning is overloaded or underloaded. Figure 3a shows the

Algorithm 2 Lightweight Repartitioner

```
1: procedure REPARTITIONING_ITERATION(partition $P_s$)
2:     for stage $\in \{1, 2\}$ do
3:         $candidates \leftarrow \{\}$
4:         for Vertex $v \in$ VertexSet($P_s$) do
5:             $target(v) \leftarrow$ GET_TARGET_PART(v,stage)
6:                                 ▷ setting $target(v)$ and $gain(v)$
7:             if target(v) $\neq$ null then
8:                 candidates.add ($v$)
9:         $top\text{-}k \leftarrow k$ candidates with maximum gains
10:        for Vertex $v \in top\text{-}k$ do
11:            MIGRATE($v, P_S, target(v)$)
12:        $P_s$.update_auxiliary data
```

initial state of the graph. The partitions are sub-optimal as 6 of the 11 edges shown are edge-cuts. Consider the first stage of the first iteration of the lightweight repartitioner. Since the first stage restricts vertex migrations from lower ID partitions to higher ID only, vertices a and e are the migration candidates since they are the only ones that can improve edge-cut. Note that if the algorithm was performed in one stage, vertices h and d would be migrated to partition 1 causing the oscillating behavior discussed previously. At the end of the first stage of the first iteration, the state of the graph is as presented in Figure 3b. In the second stage, the algorithm migrates only vertex g. While vertex c could be migrated to improve edge-cut, the migration direction does not allow this (Figure 3c). In addition, such migration would cause partition 1 to be underloaded (its load will be 2 which is less than $2.\bar{2}$). In the second iteration, vertex c is migrated to partition 2. The result of the first stage of iteration 2 is presented in Figure 3d. At this point, the graph reaches an optimal grouping, thus the second stage of the second iteration will not perform any migrations. In fact further iterations would not migrate anything since the graph has an optimal partitioning.

3.2 Physical Data Migration

Physical data migration is the final step of the repartitioner. Vertices and relationships that were marked for migration by the repartitioner are moved to the target partitions using a two step process: (1) Copy marked vertices and relationships (copy step) (2) Remove marked vertices and relationships from the host partitions (remove step).

In the first step, a list of all vertices selected for migration to a partition are received by that partition, which will request these vertices and add them to its own local database. At the end of the first step, all moved vertices are replicated. Because of the insertion-only operations, the complexity of the operations is lower as all operations can be performed locally in each partition, meaning less network contention and locks held for shorter periods.

Between the two steps there is a synchronization process between all partitions to ensure that partitions have completed the copy process before removing marked vertices from their original partitions. The synchronization itself is not expensive as no locks or system resources are held, though partitions may need to wait until an occasional straggler finishes copying. In the remove step, all marked vertices will enter an unavailable state in which all queries referencing the vertex will be executed as if the vertex is not part

of the local vertex set. This allows performing the transactional operations much faster as locks on unavailable vertices cannot be acquired by any standard queries.

3.3 Lightweight Repartitioner Analysis

3.3.1 Memory and Time Analysis

Recall that the main advantage of the lightweight repartitioner over multilevel algorithms is that it makes use of only auxiliary data to perform repartitioning. Auxiliary data has a small size compared to the size of the graph. This is formalized in the following two theorems, the proofs of which can be found in the extended version of the paper [25].

THEOREM 2. *The amortized size of auxiliary data stored on each partition to perform repartitioning is $n + \Theta(\alpha)$ on average. Here, n denotes the number of vertices in the input graph and α is the number of partitions.*

When compared to the multilevel algorithms, the memory requirement of the lightweight repartitioner is far less and can be easily maintained without hardly any impact on performance of the system. This is experimentally verified in Section 5.3.

THEOREM 3. *Each iteration of the repartitioning algorithm takes $O(\alpha n_s)$ time to complete. Here, α denotes the number of partitions and n_s is the number of vertices in the partition which runs the repartitioning algorithm.*

The above theorem implies that each iteration of the algorithm runs in linear time. Moreover, the algorithm converges to a stable partitioning after a small number of iterations relative to the number of vertices, e.g., in our experiments, it converges after less than 50 iterations, while there are millions of vertices in the graph data sets.

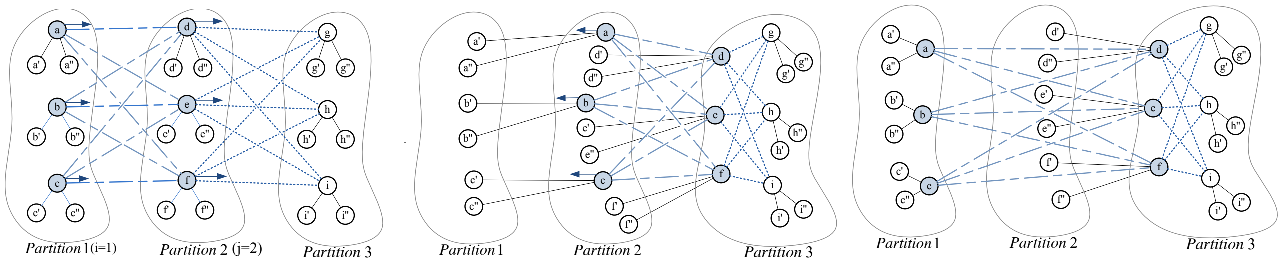
The lightweight repartitioner is designed for scalability and with little overhead to the database engine. The simplicity of the algorithm supports parallelization of operations and maximizes scalability. In the first phase, each iteration is performed in parallel on each server. The auxiliary data information is fully local to each server, thus lines 4 through 9 of Algorithm 2 are executed independently on each server. In the second phase of the repartitioning algorithm, physical data migration is performed. As mentioned in Section 2.2, this part has been decomposed into two steps for simplicity and performance. Because information is only copied in the first step (in which vertices are replicated), it allows for maximum parallelization with little need to synchronize between servers.

3.3.2 Algorithm Convergence

When the lightweight repartitioner triggers, the algorithm starts by migrating vertices from overloaded partitions. Note that no vertex is a candidate for migration to an overloaded partition. Hence, after a bounded number of iterations, the partitioning becomes valid in term of load balance. When there is no overloaded partition, the algorithm moves a vertex only if there is a positive gain in moving it from the source to the target partition. This is the main idea behind the following proof for the convergence of the algorithm.

THEOREM 4. *After a bounded number of iterations, the lightweight repartitioner algorithm converges to a stable partitioning in which further migration of vertices (as done by the algorithm) does not result in better partitionings.*

PROOF. We show that the algorithm constantly decreases the number of edge-cuts. For each vertex v, let $d_{ex}(v)$ denote the number of external neighbors of v, i.e., number of neighbors of v in partitions other than that of v. With this definition, the number of edge-cuts in a partition is $\chi/2$ where $\chi = \sum_{v=1}^{n} d_{ex}(v)$. Recall that the algorithm works in stages so that if in a stage migration of vertices is allowed from one partition to another, in the subsequent stage the migration is allowed in the opposite direction. We show that the value of χ decreases in every two subsequent stages; more precisely, we show that when a vertex v migrates in a stage t, the value of $d_{ex}(v)$ either decreases at the end of the stage t or at the end of the subsequent stage $t+1$ (compared to when v does not migrate). Let $d_k^t(v)$ denote the number of neighbors of vertex v in partition k before stage t. Assume that vertex v is migrated from partition i to partition j at stage t (see Figure 4). This implies that the number of neighbors of v in partition j is more than partition i. Hence, when v moves to partition j, the value of $d_{ex}(v)$ is expected to decrease. However, in a worst-case scenario, some neighbors of v in partition j also move to other partitions at the same stage (Figure 4b). Let $x(v)$ denote the number of neighbors of v in the target partition j which migrate at stage t; hence, at the end of the stage, the value of $d_{ex}(v)$ decreases by at least $d_j^t(v) - x(v)$ units. Moreover, $d_{ex}(v)$ is increased by at most $d_i^t(v)$; this is because the previous internal neighbors (those which remain at partition i) will become external after the migration of v. If $d_j^t(v) - x(v) > d_i^t(v)$, the value of $d_{ex}(v)$ decreases at the end of the stage and we are done. Otherwise, we say a *bad migration* occurred. In these cases,



(a) Original graph (b) After the first stage (c) After the second stage

Figure 4: The number of edge-cuts might increase in the first stage (in the worst case), but it decreases after the second stage. In this example, the number of edge-cuts is initially 18 (a); this increases to 21 after the first stage (b), and decreases to 15 at the end of the second stage (c).

assuming k is sufficiently large, in the subsequent stage $t+1$, v migrates back to partition i since there is a positive gain in such a migration (Figure 4c), and this results in a decrease of $d_i^{t+2}(v)$ and an increase of at most $d_j^t(v) - x(v)$ in $d_{ex}(v)$. Consequently, the net increase in d_{ex} after two stages is $(d_i^t(v) - (d_j^t(v) - x(v))) + (d_j^t(v) - x(v) - d_i^{t+2}(v)) = d_i^t(v) - d_i^{t+2}(v)$. Note that if v does not move at all, d_{ex} increases $d_i^t(v) - d_i^{t+2}(v)$ units after two stages. Hence, in the worst case, the net decrease in $d_{ex}(v)$ is at least 0 for all migrated vertices (compared to when they do not move). Indeed, we show that there are vertices for which the decrease in d_{ex} is strictly more than 0 after two consecutive stages. Assuming there are α partitions, these are the vertices which migrate to partition α [in stages where vertices move from lower ID to higher ID partitions] or partition 1 [in stages where vertices move from higher ID to lower ID partitions]. In these cases, no vertex can move from the target partition to another partition; so the actual decrease in $d_{ex}(v)$ is the same as the calculated gain when moving the vertex and is more than 0. To summarize, for all vertices, the value of $d_{ex}(v)$ does not increase after every two stages, and for some vertices, it decreases. For smaller values of k, after a bad migration, vertex v might not return from partition j to its initial partitioning i in the subsequent stage (since there might be more gain in moving other vertices); however, since there is a positive gain in moving v back to partition i, in subsequent stages, the algorithm moves v from partition j to another partition (i or another partition which results in more gain). The only exception is when many neighbors of v move to partition j so that there is no positive gain in moving v. In both cases, the value of $d_{ex}(v)$ decreases with the same argument as above. To conclude, as the algorithm runs, the accumulated values of $d_{ex}(v)$ (i.e., χ), and consequently the number of edge-cuts, constantly decrease. □

The graph structure in social networks does not evolve quickly and its evolution is towards community formation. Hence, as our experiments confirm, after a small number of iterations, the lightweight repartitioner converges to a stable partitioning. The speed of convergence depends on the value of k (the number of migrated vertices from a partition in each iteration). Larger values of k result in faster improvement on the number of edge-cuts and subsequently achieve partitioning with almost an optimal number of edge-cuts. However, as mentioned earlier, large values of k can degrade the balance factor of partitioning. Finding the right of value of k requires considering a few parameters which include the number of partitions, the structure of the graph (e.g., the average size of the clusters formed by vertices), and the nature of changing workload (whether the changes are mostly on the weight or on the degree of vertices). In practice, we observed that a sub-optimal value of k does not degrade convergence rate by more than a few iterations; consequently the algorithm does not require fine tuning for finding the best value of k. In our experiments, we set k as a small fraction of the number of vertices.

4. HERMES SYSTEM OVERVIEW

In this section, we provide an overview of Hermes, which we designed as an extension of Neo4j Version 1.7.3 to handle distribution of graph data and dynamic repartitioning. Neo4j is an open source centralized graph database system which provides a disk-based, transactional persistence engine (ACID compliant). The main querying interface to Neo4j is traversal based. Traversals use the graph structure and relationships between records to answer user queries.

To enable distribution, changes to several components of Neo4j were required as well as addition of new functionality. The modifications and extensions were done such that existing Neo4j features are preserved. Figure 5 shows the components of Hermes with the components of Neo4j that were modified to enable distribution in light blue shading while the components in dark blue shading are newly added. Detailed descriptions of the remaining changes are omitted as they pose technical challenges which were overcome using existing techniques. For example, as the centralized loop detection algorithm used by Neo4j for deadlock detection does not scale well, it was replaced using a timeout-based detection scheme as described in [10].

Internally, Neo4j stores information in three main stores: node store, relationship store and property store. Splitting data into three stores allows Neo4j to keep only basic information on nodes and relationships in the first two stores. Further, this allows Neo4j to have fixed size node and relationship records. Neo4j combines this feature with a monotonically increasing ID generator such that a) record offsets are computed in O(1) time using their ID and b) contiguous ID allocation allows records to be as tightly packed as possible. The property store allows for dynamic length records. To store the offsets, Neo4j uses a two layer architecture where a fixed size record store is used to store the offsets and

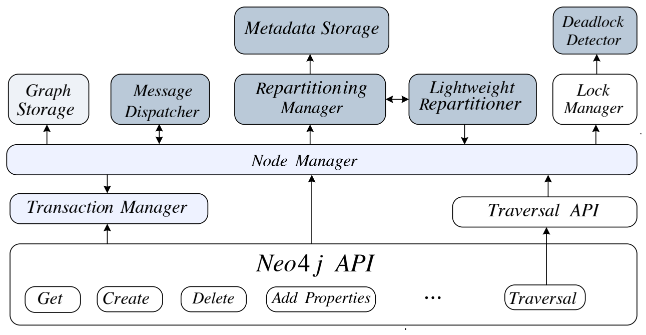


Figure 5: Hermes system layers together with modified and new components designed to make it run in a distributed environment.

a dynamic size record store is used to hold the properties. To shard data across multiple instances of Hermes, changes were made to allow local nodes and relationships to connect with remote ones. Hermes uses a doubly-linked list record model when keeping track of relationships. Such a node in the graph needs to know only the first relationship in the list since the rest can be retrieved by following the links from the first. Due to tight coupling between relationship records, referencing a remote node means that each partition would need to hold a copy of the relationship. Since replicating and maintaining all information related to a relationship would incur significant overhead, the relationship in one partition has a ghost flag attached to it to connect it with its remote counterpart. Relationships tagged by the ghost flag do not hold any information related to the properties of the relationship but are maintained to keep the graph structure valid. One advantage of this is the complete locality in finding the adjacency list of a graph node. This is important since traversal operations build on top of adjacency list.

The storage was also modified to use a tree-based indexing scheme (B+Tree) rather than an offset-based indexing scheme since record IDs can no longer be allocated in small increments. In addition, data migration would make offset based indexing impossible as records would need to be both compacted and still keep an offset based on their ID.

In Hermes, servers are connected in a peer-to-peer fashion similar to the one presented in Figure 6. A client can connect to any server and perform a query. Generally, user queries are in the form of a traversal. To submit a query the client would first lookup the vertex for the starting point of the query, then send the traversal query to the server hosting the initial vertex. The query is forwarded to the server containing the vertex such that data locality is maximized. On the server side, the traversal query will be processed by traversing the vertex's relationships. If the information is not local to the server, remote traversals are executed using the links between servers. When the traversal completes, the query results will be returned to the client.

5. PERFORMANCE EVALUATION

In this section, we present the evaluation of the lightweight repartitioner implemented into Hermes.

5.1 Experimental Setup

All experiments were executed on a cluster with 16 server

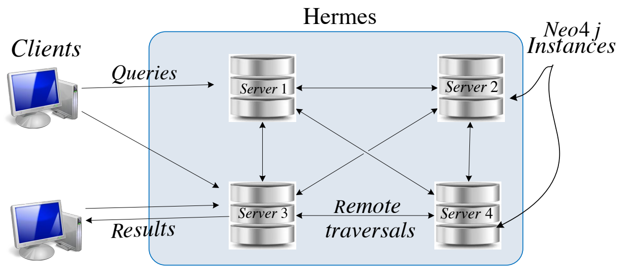

Figure 6: Overview of how Hermes servers interact with clients and with each other.

machines. Each server has the following hardware configuration: 2 AMD Opteron 252 (2 cores), 8 GB RAM and 160GB SATA HDD. The servers are connected using 1Gb ethernet. In each experiment, one Hermes instance runs on its own server.

The experiments are focused on typical social network traffic patterns, which based on previous work [8, 21], are 1-hop traversals and single record queries. We also consider 2-hop queries which are used for analytical queries such as ads and recommendations. Given the small diameters of social graphs (Table 1), queries with more than 2-hops are more typical of batch processing frameworks rather than social graphs where querying most or all of the graph data is required. The submission of traversal queries was described in Section 4.

5.2 Datasets

Three real-world datasets, namely Orkut, DBLP, and Twitter, are used to evaluate the performance of the lightweight repartitioner. We consider average path length, clustering coefficient, and power law coefficient of these graphs to characterize the datasets (Table 1). Average path length is the average length of the shortest path between all pairs of vertices. The clustering coefficient (a value between 0 and 1) measures how tightly clustered vertices are in the graph. A high coefficient means strong (or well connected) communities exist within the network. Finally, power law coefficient shows how the number of relationships increases as user popularity increases.

5.3 Experimental Results

The lightweight repartitioner is compared with two different partitioning algorithms. For an upper bound, we use a member of Metis family of repartitioners that is specifically designed for partitioning graphs whose degree distribution follows a power-law curve [6]. These graphs include social networks which are the focus of this paper.

Several previous partitioning approaches (e.g.[26, 28]) are

	Twitter	**Orkut**	**DBLP**
Number of nodes	11.3 million	3 million	317 thousand
Number of edges	85.3 million	223.5 million	1 million
Number of symmetric links	22.1%	100%	100%
Average path length	4.12	4.25	9.2
Clustering coefficient	unpublished	0.167	0.6324
Power law coefficient	2.276	1.18	3.64

Table 1: Summary description of datasets

compared against Metis as it is considered the "gold standard" for the quality of partitionings. It is also flexible enough to allow custom weights to be specified and used as a secondary goal for partitioning. We also compare the lightweight repartitioner against random hash-based partitioning, which is a de-facto standard in many data stores due to its decentralized nature and good load balance properties. Note that Metis is an offline, static partitioning algorithm that requires a very large amount of memory for execution. This means that either additional resources need to be allocated to partition and reload the graph every time the partitioner is executed, or the system has to be taken offline to load data on the servers. When the servers were taken offline, it took 2 hours to load each of the Orkut and Twitter graphs separately. This long period of time is unacceptable for production systems. Alternatively, if Hermes is augmented to run Metis on graphs, the resource overhead for running Metis would be much higher than the lightweight repartitioner. Metis' memory requirements scale with the number of relationships and coarsening stages, while the lightweight repartitioner scales with the number of vertices and partitions. Since the number of relationships dominates by orders of magnitude, Metis will require significantly more resources. For example, we found that Metis requires around 23GB and 17GB of memory to partition the Orkut and Twitter datasets, respectively; however, the lightweight repartitioner only requires 2GB and 3GB for these datasets. While Metis has been extended to support distributed computation (ParMetis [4]), the memory requirements for each server would still be higher than the lightweight repartitioner.

5.3.1 Lightweight Repartitioner Performance

Our experiments are derived from real world workloads [21, 8] and are similar to the ones in related papers [27, 24]. We first study 1-hop traversals on partitions with a randomly selected starting vertex. At the start of the experiments, the workload shifts such that the repartitioner is triggered, showing the performance impact of the repartitioner and the associated improvements. This shift in workload is caused by a skewed traffic trace where the users on one partition are randomly selected as starting points for traversals twice as many times as before, creating multiple hotspots on a partition. This workload skew is applied for the full duration of the experiments that follow.

Figure 7 presents the percentage of edge-cuts among all edges for both lightweight repartitioner and Metis on the skewed data. As the figure shows, the difference in edge-cut is too small (1% or less) to be significant, and we expect that this very small difference could shift in the other direction depending on factors such as query patterns and number of partitions. However, Figure 7 demonstrates that the lightweight repartitioner generates partitionings that are almost as good as those of Metis.

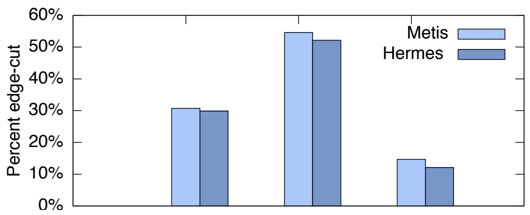

Figure 7: The number of edge-cuts in partitionings of the lightweight repartitioner (as a component of Hermes) versus Metis. Results are presented as a percentage of edge-cuts among the total number of edges.

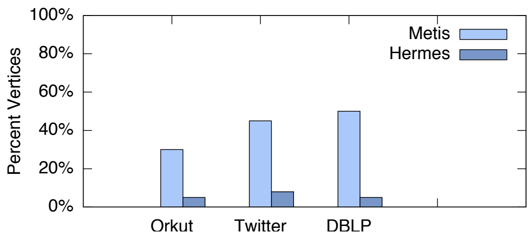
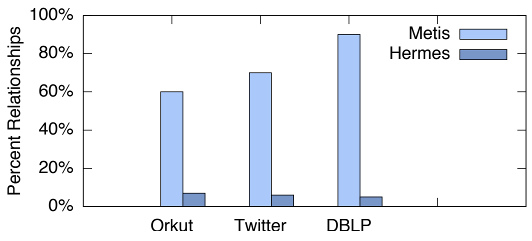


(a) Migrated vertices.



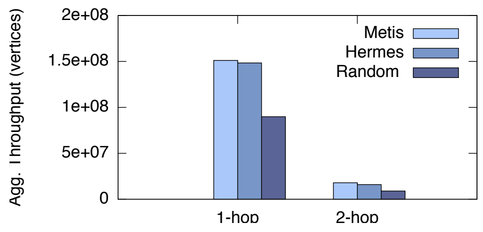
(b) Changed or migrated relationships.

Figure 8: The number of vertices (a) and relationships (b) changed or migrated as a result of the lightweight repartitioner (Hermes) versus running Metis.

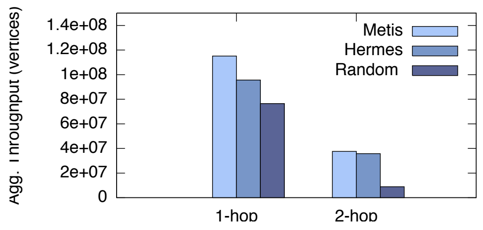
A repartitioner's performance is affected by the amount of data that it needs to migrate. To quantify the impact of migration on performance, the partitions resulting from the lightweight repartitioner and Metis are compared with the initial partitioning. Figure 8a shows the number of vertices migrated due to the skew based on the two partitioning algorithms. The results show a much lower count for the lightweight repartitioner. Figure 8b shows that the lightweight repartitioner requires, on average, significantly fewer changes to relationships compared to Metis. This difference is more extensive in the case of DBLP. The lightweight repartitioner is able to rebalance workload by moving 2% of the vertices and about 5% of the relationships, while Metis migrates an order of magnitude more data.

Overall, both the numbers of vertices and relationships migrated are important as they directly relate to the performance of the system. We note that, however, the relationship count has a higher impact on performance as this number will generally be much higher and relationship records are larger, and thus more expensive to migrate.

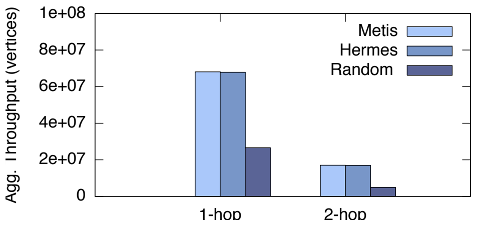
Figure 9 presents the aggregate throughput performance (i.e., the number of visited vertices) of 16 machines (partitions) using the three datasets. In these experiments, 32 clients concurrently submit 1-hop traversal requests using the previously described skew. Before the experiments start, Metis is applied to form an initial partitioning which has a trace with no skew so as to remove partitioning bias by starting out with a good partitioning. Once the experiment starts, the mentioned skew is applied; this skew triggers the repartitioning algorithm, whose performance is compared with running Metis *after* the skew. For Orkut, results show that by introducing the skew and triggering the lightweight repartitioner, a 1.7 times improvement in performance can



(a) Orkut



(b) Twitter



(c) DBLP

Figure 9: Aggregate throughput for the three datasets.

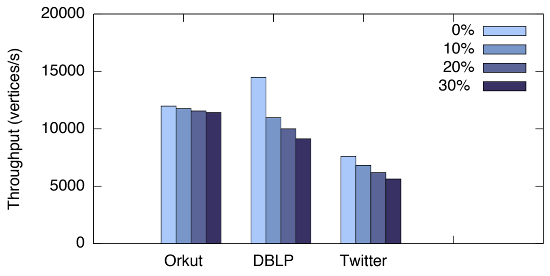


Figure 10: Throughput while varying the write rate.

be obtained over random partitioning while Metis shows a 6% improvement over the lightweight repartitioner. Figure 9b shows the aggregated throughput while running the Twitter dataset. The results show very similar performance for the lightweight repartitioner and Metis. Finally, Figure 9c shows the results related to the DBLP experiments that indicate there is no performance degradation due to the lightweight repartitioner, which benefits from the relatively small changes required by the algorithm. In fact, based on results from Figure 9c, the performance difference is not significant. Interestingly, the DBLP dataset is the only dataset for which the performance differences are not noticeable due to the highly clustered and well partitioned dataset. Given an edge-cut of 15%, the high query locality means that partition skews have little effect on performance as they do not shift workloads towards partition borders.

5.3.2 *2-hop Performance*

The previous section focused on 1-hop traversals . In this section, we conduct 2-hop experiments since they are representative operations used for recommendations, e.g., friend, events or ad recommendations in social networks. Figure 9 shows the aggregated performance of the system running with the three data-sets. The 2-hop experimental results are similar to 1-hop except for the decrease in performance. To analyze why this decrease occurs in the 2-hop case, we observe that the ratio between the number of vertices in the query response versus the number of vertices processed is 1 for both Metis and Random partitioners in case of 1-hop traversal queries, while these ratios degrade to 0.39 and 0.28, respectively, for 2-hop traversal queries. The reason 2-hop traversals return less vertices than what it processes is because some vertices are visited multiple times during a traversal while the query response contains only one copy of the queried vertices. Since social networks exhibit high clustering, a high fraction of processed vertices are accessed multiple times within the same traversal.

5.3.3 *Mixed Read/Write Experiments*

The following experiments test how the system handles mixed traffic workload and evolving social network graphs. The experiments insert data through random write traffic. The lightweight repartitioner in Hermes is then run to improve the quality of partitioning after records are inserted. Results of these experiments are shown in Figure 10 and indicate little performance degradation with increasing write traffic. A 10% write mix (with 90% reads) show a 3% decrease in performance, while 20% writes (80% reads) and 30% writes (70% reads) show 5% and 7% decreases in throughput (vertices per second) performance. The small performance impact of writes is attributed to how B+Trees store information and the monotonically increasing ID generator in Hermes. Since each new record will get the next, highest ID, insertions in the B+Tree always happen in the last page in a sequential manner. This translates to sequential writes to disk and the B+Tree requires caching only the last page to perform insertions. To verify that the quality of the graph is high after the insertions finish, we ran 100% read traffic and compared the throughput with the results for Metis. Results showed that Hermes was able to keep partition quality and system performance within 2% of Metis, which demonstrates the effectiveness and efficiency of Hermes's lightweight repartitioner.

5.3.4 *Sensitivity of Repartitioner Parameters*

Recall from Section 3 that in each iteration of the algorithm, the lightweight repartitioner moves at most k vertices from each partition. Here, we examine how the value of k affects the outcome of the algorithm. We run the lightweight repartitioner with three different values of k (500, 1000, and 2000). The first observation is that the load-balance factor slightly degrades from 1.05 for $k = 500$ to 1.16 for $k = 2000$. This is because, as mentioned earlier, larger values of k result in simultaneous migration of many vertices to partitions which have recently become popular (due to hosting popular vertices). Consequently, we excluded values of k large than 2000 from the experiment as they result in imbalance factor more than the maximum allowed value of $\gamma = 1.1$ (the default value of γ in the system). Next, we verified how

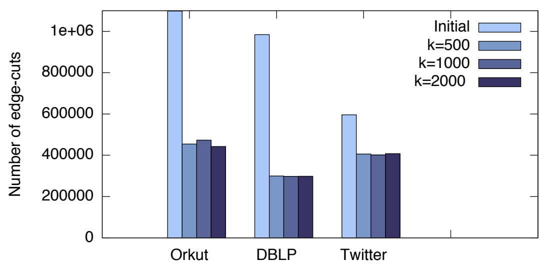

Figure 11: The number of edge-cuts for different values of k. The numbers are scaled by 10^{-2} for Orkut dataset.

many iterations are required for the algorithms to converge. Table 2 shows the number of required iterations for different values of k. As expected, larger values of k result in slightly faster convergence since they move more vertices per iteration. Finally, we considered the quality of partitioning when different values of k are used. As Figure 11 shows, the number of edge-cuts in the final partitioning is almost the same for different values of k, indicating that the quality of partitioning does not depend on this value. To summarize, larger values of k result in faster convergence while increasing the load imbalance; at the same time, the value of k does not have a significant effect on the number of edge-cuts.

6. RELATED WORK

Previous work on graph databases focused on a centralized approach [17, 23, 1]. Some of these systems, e.g., Neo4j, have a high availability mode but this provides limited scalability [2]. HypergraphDB [17] provides a message passing API between server instances, however there is no partition management system and no support for distribution-aware querying. In addition, the focus of each of these systems is different. For example HyperGraphDB focuses more on the flexibility of its storage system, allowing users to store different types of objects. None of these graph databases support data partitioning or distributed graph querying.

SPAR [27] and Titan [5] are middleware that run on top of key-value stores or relational databases to provide on-the-fly partitioning and replication of data. However, SPAR is restricted to keeping only one-hop neighbours local while Hermes can support general remote traversals. Titan uses only static hash-based, random partitioning scheme supported by the underlying key-value store. This is in contrast to the dynamic repartitioning that the lightweight repartitioner in Hermes uses.

Unlike our system, SEDGE [36] focuses on partition replication in which a coarsening stage aggregates nodes which are then matched with nodes in another partition. SEDGE is not designed to handle dynamic workload changes that Hermes is designed for. An approach that performs dynamic replication is described in [24] but it does not involve a system that does on-the-fly partitioning. Horton [29] is a query execution engine built for distributed in-memory graphs. However it only provides a user abstraction, leaving partitioning to existing offline algorithms.

A streaming algorithm using simple heuristics has been proposed in [32] but focuses on improving initial data placement unlike the dynamic repartitioning in Hermes. In [33] an improved heuristic for better partitioning quality is proposed; however, the partition imbalance in the resulting solutions can be significantly impacted. While this approach extends the concept by saving state and allowing future data loads to reuse state from previous runs, the algorithm needs to parse the full dataset again, which can lead to expensive operations and large migrations.

Several Pregel-like [22] systems, e.g., [11, 16], have been proposed. These systems are quite different from Hermes in that they address only in-memory batch processing of graph analytics queries rather than the persistent management of graph data that Hermes is designed to support. In [35], a weighted multi-level partitioning algorithm is proposed which is based on label propagation (community detection technique). The edge-cut decrease in this approach can be small while communities might be detected improperly because of the weighted approach. Their multi-level algorithm does not guarantee communities are preserved over multiple calls of the algorithm and can lead to large migrations similar to Metis.

Some graph partitioning algorithms are experimentally compared in [9]. Among these, DiDiC [14] is the only distributed algorithm that tends to minimize the number of edge-cuts, but the resulting partitions of this approach may not be well-balanced [28, 9].

Ja-Be-Ja [28] embeds a distributed algorithm for balanced partitioning without global knowledge. In this algorithm, the initial partition of each node is selected uniformly at random; this ensures a balanced partitioning. In order to decrease the number of edge-cuts, vertices are swapped between partitions. This will ensure maintaining a balanced partitioning if vertices have fixed, uniform weights; however, this is usually not the case for social networks.

An adaptive algorithm for repartitioning large-scale graphs has the objective of minimizing the number of edge-cuts with respect to certain capacities for partitions [34]. The resulting partitionings might not be balanced if the capacity constraints are maintained. Moreover, it is assumed that vertices have fixed and uniform weights, which is usually not the case for social networks. Additionally, their work is targeted for graph analytics rather than the persistent management of graph data that Hermes is designed to support.

Table 2: The number of iterations after which the lightweight repartitioner converges.

7. CONCLUSION

We presented an online, iterative, lightweight repartitioner designed to increase query locality, thereby decreasing network load and maintaining load balance across partitions. The lightweight repartitioner effectively adapts a partitioning to varying query workloads and the continuous evolution of the graph structure using only a small amount of auxiliary data. We implemented our lightweight repartitioner into Hermes, which we built to extend the open source Neo4j database system to support the partitioning of social network data across multiple database servers. The experimental evaluation of the algorithm on real-world datasets shows that the repartitioner is able to handle changes in query workloads while maintaining good performance. The overhead of the repartitioner is minimal, producing sustained performance comparable to that of static, offline, partitioning using Metis. Our evaluation shows sizable performance gains over random, hash-based partitioning, which is widely used for database partitioning.

ABSTRACT

Handling non-answers is desirable in information retrieval systems. Current e-commerce websites usually try to suppress the somewhat dreaded message that no results have been found. Possible solutions include, for example, augmenting the data with synonyms and common misspellings based on query logs. Nonetheless, this is only achievable if we can know the cause of the non-answers. Under the hood, most e-commerce data sits in some *structured* format. Debugging non-answers in the underlying KWS-S systems is therefore not trivial — non-answers in a KWS-S system could be a problem of the data (e.g., absence of some keywords), the schema (e.g., missing key-foreign-key joins), or due to empty join results from one of possibly several joins in the generated SQL queries. So far, we are unaware of any previous work that explores how to enable developers to debug non-answers in a KWS-S system. In this paper, we take a first step towards this direction by proposing a KWS-S system that can expose non-answers to the developers. Our system presents the developers with the maximal nonempty sub-queries that represent the frontier cause of the non-answers. We outline the challenges in building such a system and propose a lattice structure for efficient exploration of the non-answer query space. We also evaluate our proposed mechanisms over a real world dataset to demonstrate their feasibility.

1. INTRODUCTION

Handling non-answers (i.e., queries that return no results) is now a common practice in information retrieval systems. Current SEO companies and e-commerce websites like Orcale Endeca [21], HP Autonomy [9], and IBM Coremetrics [13] often try to avoid showing the somewhat dreaded "*No results found*!" message when they fail to return any results that can match user's keyword queries. Possible strategies include, for instance, substituting user's original keywords with different keywords from a controlled vocabulary (e.g., synonyms, hyponyms, and hypernyms), or displaying a "*Did you mean*?" style response with spelling corrections. Doing so is critical to helping customers find what they are looking for and improving user experience and ultimately retention.

Nonetheless, implementation of such seemingly simple strategies is not trivial. While users interact with a search box, under the hood most e-commerce data sits in some *structured* format, largely due to maintainablity reasons. To employ strategies such as augmenting the data with synonyms and common misspellings based on query logs, we first need to understand the cause of the non-answers. For example, we need to convince ourselves that a non-answer query is really caused by missing keywords in the data before we decide to add the missing words into the vocabulary; otherwise this action is not helpful. Unfortunately, debugging non-answers in the underlying KWS-S (acronym for KeyWord Search over Structured data) systems is challenging — non-answers in a KWS-S system could be a problem of the data (e.g., absence of some keywords), the schema (e.g., missing key-foreign-key joins), or due to empty join results from one of possibly several joins in the generated SQL queries. So far, we are unaware of any previous work that explores how to enable developers to debug non-answers in a KWS-S system.

In this paper, we take a first step towards systematically exploring non-answers in KWS-S systems, and we focus on seeking the *maximal* partial matches or sub-queries of the non-answers. Similar ideas have been explored in the *unstructured* world. For example, Figure 1 presents the screenshot from buy.com in response to the keyword query "`saffron scented candle`". Although no saffron-scented candles are found, rather than displaying a blank page that shows no results, other saffron-scented products and other scented candles are presented to the user, corresponding to the three sub-queries "`saffron scented`", "`saffron candle`", and "`scented candle`". We believe that this kind of information could also be very helpful for debugging non-answers in KWS-S systems, and our primary goal in this paper, akin to what has been done over unstructured data, is to find results from sub-queries of non-answers, but over *structured* data.

Moving from unstructured to structured data, however, is more complicated than we might have thought. In typical KWS-S systems such as Banks [1, 14], DBXplorer [2], and DISCOVER [11], users enter a set of keywords and the system responds with a multitude of relationships connecting those keywords. In [2, 11, 17, 19] and many other KWS-S systems, this is done by mapping the keyword query to several structured queries (i.e., SQL queries). All of these structured queries are then evaluated, and the tuples corresponding to the queries that produce answers are returned to the user. Sub-queries of a non-answer query in a KWS-S system thus refer to sub-queries of a structured SQL query rather than the original keyword query. Since a KWS-S system can usually generate many SQL queries in response to a single keyword query, naively evaluating all possible sub-queries at runtime could be quite expensive. To efficiently explore the space of sub-queries, our basic idea is to exploit the common sub-queries that are shared by

multiple structured SQL queries. To put things in context, let us consider the following example:

EXAMPLE 1 (NON-ANSWERS IN KWS-S). *Figure 2 shows a toy database that will be used throughout this paper. It contains an* `Items` *table I, a* `Product Type` *table P, a* `Colors` *table C, and an* `Attributes` *table A. The arrows here present the key-foreign-key associations between the tables.*

Consider the keyword query "`saffron scented candle`*". The KWS-S system maps it to two structured SQL queries (R^k here means the keyword k is mapped to the table R):*

(q_1) $P^{candle} \bowtie I^{scented} \bowtie C^{saffron}$, which tries to "find scented candles whose <u>*color*</u> *is saffron."*

(q_2) $P^{candle} \bowtie I^{scented} \bowtie A^{saffron}$, which tries to "find scented candles whose <u>*scent*</u> *is saffron."*

Both q_1 and q_2 return no result tuples with the given database, namely, they are non-answers. In the case of q_1, while every keyword does occur in the database, the join of all the involved tables produces no results. Exposing this information and q_1 can allow the developer or SEO person to add `saffron` *as a synonym of* `yellow`*, thus returning several relevant results to the user. In existing KWS-S systems q_1 would never be exposed.*

As for q_2, its sub-queries, which are $P^{candle} \bowtie I^{scented}$ and $I^{scented} \bowtie A^{saffron}$, do return answers, even though q_2 does not. More specifically, while the merchant does not carry any saffron-scented candles, it does carry scented candles and saffron-scented products that are not candles. Knowing this information may not help return answers to the original query, like in the q_1 case. However, it could be useful for merchandizing purposes. Additionally (like in Figure 1), the partial queries serve as a good alternative to returning nothing.[1]

Inspired by Chapman and Jagadish [5], to explain causes of the non-answers, we report their *maximal* sub-queries that return at least one tuple. To illustrate, in Example 1, our system will display $P^{candle} \bowtie I^{scented}$ and $C^{saffron}$ for q_1, and $P^{candle} \bowtie I^{scented}$ and $I^{scented} \bowtie A^{saffron}$ for q_2. Intuitively, these sub-queries sit on the *boundary* of answers/non-answers and provide the developer with information about the *frontier* causes of the non-answers. Similar notions have been proposed in previous work as solutions to "why not" style questions. For instance, in [5] the authors proposed using *frontier picky manipulations* which are the highest operators in a query tree or the latest manipulations in a workflow that rule out data items interested by the user from the results.

To find the maximal nonempty sub-queries for the non-answers, a naive strategy could be to enumerate all sub-queries and evaluate them (i.e., run the SQL query over the database) to check if they are empty. This is clearly inefficient. Our key observation here is that sub-queries of the non-answers overlap. For example, the q_1 and q_2 in Example 1 share the common join query $P^{candle} \bowtie I^{scented}$. In our experiments, we found that this overlap is significant on real data. Motivated by this observation, we propose a lattice structure that represents all the structured queries that a KWS-S system explores (details in Section 2). This structure is constructed offline and is used to capture the overlap between the sub-queries of each query (Section 2.2). Additionally, it also lends itself to systematic exploration of the sub-queries of non-answer queries. Note that, once we know the status of a query (i.e., if it is empty),

[1]The situation here is a bit more symmetric than that described in this example: given another instance of the tables, it might be q_2 that can be fixed via a synonym, whereas q_1 might be the query where non-answers are explained via maximal sub-queries.

this information can be utilized to determine the status of other queries based on the hierarchical relationships between queries presented in the lattice. For instance, in Example 1, we do not need to run the two SQL queries corresponding to P^{candle} and $I^{scented}$ once we know $P^{candle} \bowtie I^{scented}$ is nonempty — they must both be nonempty as well. This raises the interesting question of in which order we should visit the nodes in the lattice with the purpose of minimizing the number of SQL queries that need to be executed, which is the key to runtime system performance. We studied both *top-down* and *bottom-up* strategies to traverse the lattice structure (Section 2.5), and found that their performance depends on the distribution of the non-answer sub-queries within the hierarchy. Specifically, top-down/bottom-up strategies are more efficient when the maximal nonempty sub-queries are at higher/lower levels of the lattice. With this in mind, we further propose a greedy algorithm based on a scoring function that measures the potential reduction in the search space from examining a certain sub-query (Section 2.5.3). Our experimental results show that, while top-down and bottom-up strategies suffer from certain distributions of the non-answers, the greedy algorithm can perform relatively well in all the cases we tested.

While our proposed framework can efficiently find all the maximal non-empty sub-queries for non-answers, in our experiments we observed that the number of sub-queries is sometimes large. This is actually an inherent problem of KWS-S systems. Existing KWS-S systems usually use ranking functions to present users with only the most relevant results. For instance, Hristidis et al. [10] studied the problem of efficiently presenting the end users with a list of top-k matches. However, such strategies cannot work for the goal of debugging non-answers in KWS-S systems. This is simply because of the nature of debugging, which needs to find the cause of the non-answers no matter how trivial the cause might be. It is akin to debugging a normal computer program, where *all* possible bugs should be reported. Of course, there is a number of possible solutions to alleviate the problem of overwhelming number of sub-queries. For example, one option could be to allow the developer to define various filters or a priority hierarchy on the returned sub-queries. We do not try to explore all of these possible postprocessing techniques in this paper, most of which are application-specific and therefore may not have a uniformly optimal solution. Rather, we focus on an essential foundational task that must be solved before any higher-level postprocessing can be performed: the task of efficiently finding non-answers in response to a keyword query over structured data. It is our hope that our solution for this task provides a building block that can be used in conjunction with future research to build more customized systems.

In the rest of the paper, we start by introducing the system architecture of the proposed system and detailing its components in Section 2. We then evaluate our proposed approaches in Section 3. We discuss related work in Section 4 and conclude in Section 5.

2. EXPLORING NON-ANSWERS

In this section we describe our proposed solution for efficiently determining and explaining non-answer queries. Figure 3 presents the proposed system in its entirety. **Phase 0** is performed offline. In this phase, based on the schema graph of the underlying database, we generate a lattice in which each node is labeled with an uninstantiated SQL query. This structure is designed to exploit the overlap between the queries that are explored by our system. Following this, in **Phase 1** user's keyword query is accepted and used to prune the lattice generated in **Phase 0**. At the end of **Phase 1** each node in the pruned lattice is labeled with an instantiated SQL query with respect to the keyword query. In **Phase 2** we prune the lattice even further by retaining only those nodes that contain answer queries or non-answer queries, with respect to the current keyword query, and their respective descendants. Finally, we traverse the pruned lattice to determine and explain non-answer queries in **Phase 3**. Based on the information obtained, the user can subsequently choose to modify the keyword query as needed. We start by providing a formal problem definition describing the input and output of the proposed system.

2.1 Problem Definition

The input to our system is the keyword query submitted by the user. We convert the keyword query to join networks of tuple sets and candidate networks (see DISCOVER [11] for definitions).

The output of our system contains three parts: (i) answer queries, i.e., candidate networks that return at least one tuple; (ii) non-answer queries, i.e., candidate networks that return no tuples; (iii) additionally, for non-answer queries, we return the *maximal* sub-networks (i.e., subgraphs) that return at least one tuple. This is analogous to the queries in Figure 1, and is meant to provide some insight into the reasons behind the non-answer queries.

More formally, let J be a join network of tuple sets (JNTS) of a keyword query K. Let $q(J)$ be the SQL query corresponding to J and $R(J)$ be the result set of tuples obtained by executing $q(J)$.

Let $\mathcal{C}(K)$ be the set of candidate networks (CNs) generated for K. For each $C \in \mathcal{C}(K)$, we say that C is an *answer query* of K if $R(C) \neq \emptyset$. Otherwise C is a *non-answer query*. We denote $\mathcal{A}(K)$ and $\mathcal{N}(K)$ as the sets of answer and non-answer queries of K.

For each $C \in \mathcal{N}(K)$, let $\mathcal{S}(C)$ be the set of JNTSs that are sub-networks of C. A $J \in \mathcal{S}(C)$ is said to be *maximal* if: (i) $R(J) \neq \emptyset$ and (ii) there is no $J' \in \mathcal{S}(C)$ s.t. J is a sub-network of J' and $R(J') \neq \emptyset$. We use $\mathcal{M}(C)$ to denote the *maximal* JNTSs in $\mathcal{S}(C)$ and $\mathcal{M}(K)$ to denote the set of maximal JNTSs for all the non-answer queries, i.e., $\mathcal{M}(K) = \bigcup_{C \in \mathcal{N}(K)} \mathcal{M}(C)$.

With the above definitions and notation, we can now formally define the input and output of our system as follows:

- **Input**: An unstructured keyword query K.
- **Output**: $\mathcal{O}(K) = \mathcal{A}(K) \bigcup \mathcal{N}(K) \bigcup \mathcal{M}(K)$.

2.2 Offline Lattice Generation (Phase 0)

Phase 0 of the system is performed offline. In this phase we generate a lattice-structure that serves as the starting point for every keyword query. The goal of this structure is to capture all the queries that a KWS-S system explores (i.e., join-queries that contain no projections). Each node in the lattice is labeled with the SQL query corresponding to the node. The base level nodes of the lattice contain the simplest queries — single table queries, one for each table. The next level is generated by joining in tables to each single-table query (avoiding cross products and using the joins that are implicit in the schema graph), and so forth.

Our goal is to cover all queries with up to m joins. Since each relation can appear many times in a single query, we maintain copies $R_1 \ldots R_{m+1}$ of each relation R. In this way we know we can generate all possible m-join queries (including the extreme case where a m-join query contains $m+1$ instances of the same relation). In addition to this we also maintain a copy R_0 of every relation R in the database (explained in the next section).

EXAMPLE 2 (LATTICE). *Consider a database with only two relations $R(a, b)$ and $S(c, d)$. Assume that $m = 1$, namely, we allow only one key-foreign-key join $R.b \bowtie S.c$. As a result, the lattice contains two (i.e., $m + 1 = 1 + 1 = 2$) copies for each relation (except for the special R_0 and S_0).*

Figure 3: System Architecture for the proposed system. (MTN means Minimal-Total Node: see Section 2.4.)

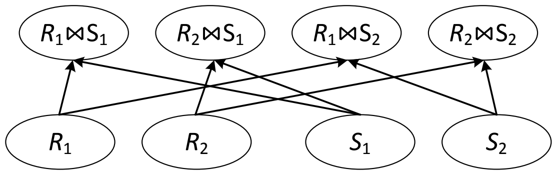

Figure 4: Example lattice with two relations $R(a,b)$ and $S(c,d)$, and a schema graph containing only one key-foreign-key join $R.b \bowtie S.c$.

Let "k_1 k_2" be the user's keyword query. As shown in Figure 4, the generated lattice has two levels. Additionally, each node in the lattice is bound to a SQL query template. For instance, the node $R_1 \bowtie S_2$ corresponds to the template

```
SELECT * FROM R1, S2 WHERE R1.b = S2.c
AND R1.a LIKE '%k1%' AND S2.d LIKE '%k2%'.
```

Note that, the copies here are just conceptual symbols rather than physical replicas. The purpose of introducing the copies is to maintain a 1-1 mapping between lattice nodes and SQL query templates, which reduces the run-time query processing overhead. If, on the other hand, no additional copies were maintained, then the lattice in Figure 4 can be reduced to containing only three nodes R, S, and $R \bowtie S$. While this could reduce the storage overhead, each node in the lattice would correspond to multiple SQL query templates, and the parent-child relationships between the nodes would need to be reconstructed at run-time. This would adversely impact the time required to process keyword queries.

Furthermore, if a node N in the lattice is a descendant of a node N', then the query in N is a sub-query of the query in N'. The lattice structure hence organizes the queries and sub-queries that in a hierarchical fashion. As we will see, this structure has three primary advantages — (i) it allows reuse of evaluated queries; (ii) sometimes, it allows us to infer the outcome of a SQL query without executing it; and (iii) its hierarchical structure allows us to systematically explore sub-queries, which can be used to better understand non-answer queries. Also, since this structure is computed offline, it bypasses the costly candidate network generation phase, which is a part of traditional KWS-S systems.

While offline processing allows us to generate all the combinations of join-queries without taking a performance hit at run-time, this process leaves us with many duplicates. The duplicates are due to the fact that a node in the lattice can be obtained by different extensions of its children. For example, in Figure 4, the node $R_1 \bowtie S_2$ can be obtained by either extending the node R_1 (joining it with S_2) or extending the node S_2 (joining it with R_1). We therefore need to eliminate as many duplicates as possible offline, to avoid expensive graph isomorphism tests at run-time. Eliminating duplicate nodes also helps with reuse. We talk more about reuse in Section 2.5.2.

Algorithm 1: Lattice Generation

```
1  Input: $\mathcal{R} = \{R_1, R_2, ..., R_n\}$, set of instance relations; $SG$,
   schema graph; $maxJoins$, max number of joins
2  Output: $\mathcal{L}$, lattice
3  // Generate the base level $\mathcal{L}_1$
4  $\mathcal{L}_1 \leftarrow \emptyset$
5  foreach $R_i \in \mathcal{R}$ do
6      for $1 \leq j \leq maxJoins + 1$ do
7          $\mathcal{L}_1 \leftarrow \mathcal{L}_1 \cup \{CreateSingleNodeGraph(R_i)\}$
8
9  // Generate higher levels $\mathcal{L}_k$, for $2 \leq k \leq maxJoins + 1$
10 foreach $2 \leq k \leq maxJoins + 1$ do
11     $\mathcal{L}_k \leftarrow \emptyset$
12     foreach Graph $G \in \mathcal{L}_{k-1}$ do
13         foreach $R \in Nodes(G)$ do
14             $\mathcal{G}' \leftarrow ExtendGraph(R, G, SG)$
15             foreach $G' \in \mathcal{G}'$ do
16                 // Offline Pruning 1: detect duplicates
17                 if $G' \notin \mathcal{L}_k$ then
18                     $\mathcal{L}_k \leftarrow \mathcal{L}_k \cup \{G'\}$
19 return $\mathcal{L}$
```

The details of the lattice generation algorithm are presented in Algorithm 1. It works as follows. We first create $maxJoins + 1$ copies for each input instance relation (lines 5 to 7). These constitute the bottom level of the lattice. We then construct the upper levels (lines 9 to 18). When generating the graphs at the level k (i.e., $\mathcal{L}_k$ for $2 \leq k \leq maxJoins + 1$), we check each graph G at the level $k-1$ (i.e., $\mathcal{L}_{k-1}$). For each relation R in G, we look up the schema graph SG to find possible edges that are connected with R. Whenever we find such an edge $e = (R, R')$, for each copy R'_c of R', we create a new graph G' by first copying G and then inserting the edge (R, R'_c) into G'. This is done by calling the function $ExtendGraph$ (line 14). For each such extension G', we then check whether $G' \in \mathcal{L}_k$. If not, G' is added into $\mathcal{L}_k$ (lines 15 to 18). Note that here, to detect the duplicates, we need to test

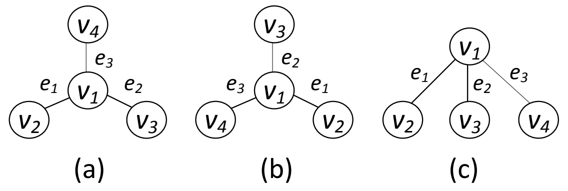

Figure 5: Two isomorphic trees and their canonical form.

the isomorphism between graphs, which is a problem not known as either P or NP-complete. However, since G' is a candidate join-query network, which by definition must be a tree [11], there are efficient algorithms (in linear time) for this special case. We use a variant of the algorithm in [3], by computing a *canonical labeling* for each graph (tree). Two graphs (trees) are isomorphic if and only if they have the same canonical labeling.

Specifically, given a candidate join-query network (tree) T, let $V(T)$ and $E(T)$ be its nodes and edges. For any $v \in V(T)$, the label of v is defined as the relation name R_i associated with v. For any $e \in E(T)$, the label of e is defined as $(R_i.a, S_j.b)$, where $R_i.a \bowtie S_j.b$ is the join associated with e. We further map the labels to integer ID's. Let $id(v)$ and $id(e)$ be the ID's assigned to a node v and an edge e. We compute the canonical labeling of T as shown in Algorithm 2. Example 3 illustrates this.

Algorithm 2: Canonical Labeling

```
1  Input: $T$, a candidate join-query network
2  Output: $l_T$, canonical labeling of $T$
3  GetCode($u$):
4  $l \leftarrow$"[$id(u)$"
5  if $HasChildren(u)$ then
6      $l.Append$("|")
7      foreach $v \in Children(u)$ do
8          $l(v) \leftarrow$"$id(e)GetCode(v)$" // $e = (u, v)$
9      Sort $v \in Children(u)$ with respect to $l(v)$
10     foreach $v \in Children(u)$ do
11         $l.Append(l(v))$
12 $l.Append$("]")
13 return $l$
14
15 Main:
16 $\mathcal{R} \leftarrow \{r | r = \arg\min_v\{id(v) | v \in V(T)\}\}$
17 $L_{\mathcal{R}} \leftarrow \{l_r | l_r \leftarrow getCode(r), r \in \mathcal{R}\}$
18 $l_T \leftarrow \min\{l_r | l_r \in L_{\mathcal{R}}\}$
19 return $l_T$
```

EXAMPLE 3 (CANONICAL LABELING). *Figure 5(a) and (b) show two isomorphic trees. Their canonical form is shown in (c). The corresponding canonical labeling computed by Algorithm 2 is:* $[v_1|e_1[v_2]e_2[v_3]e_3[v_4]]$.

In Algorithm 2, we first define $\mathcal{R}$ to be the set of nodes with the minimum node ID (line 16), and then call *GetCode* to compute the labeling l_r for each $r \in \mathcal{R}$ (line 17). The minimum l_r in lexicographic order is the canonical labeling for T (line 18). The procedure *GetCode* (lines 3 to 13) first puts the ID of the current node u into the labeling. If u has children, it appends a delimiter "|", and then recursively calls *GetNode* to construct the label $l(v)$ of each child node v (lines 7 to 8). The label of v is appended with respect to the ordering of $l(v)$ (lines 9 to 11).

Once the lattice is generated and duplicates are removed, each node is labeled with a SQL query corresponding to the node. Since Phase 0 is performed offline, the SQL query in each node has an uninstantiated "where" clause. More specifically, the join conditions (e.g., `Item`.cid = `Color`.id) in the "where" clause are present, but the keywords (e.g., `Color`.name contains "saffron" OR `Color`.synonym contains "saffron") can be added to it only at run-time, once user's keyword query is available. Keyword query is accepted in the next phase.

2.3 Keyword Based Pruning (Phase 1)

Once the user inputs the keyword query K, we *map* each keyword to a relation using an inverted index over the data. A keyword k_i can be *mapped to* a relation R if k_i occurs in some tuple in R. Recall that we generated copies $R_1 \ldots R_{m+1}$ for each relation R in the database. If k_i maps to R, k_i is bound to one of the copies R_j of relation R. Additionally, we bind the *empty keyword* to the copy R_0 for each relation R in the database.

We do this because relations to which no keywords are bound can still contribute to valid relationships. For example, for the keyword query "red candle", suppose that "red" is bound to the `Color` (C) table and "candle" is bound to the `Product Type` (P) table. While these two tables cannot be directly joined due to the lack of a key-foreign-key association, the `Items` (I) table can be used to form a path between them. The resulting join network is then $C_1 I_0 P_1$, which represents the query "Find all products where product type is *candle* and color is *red*". The I_0 here is used to indicate that no keyword is bound to the `Items` table. This is analogous to a *free tupleset* in Discover [11].

At the base level, all the nodes that contain queries with copies of relations to which no keyword is bound are pruned. Their respective ancestors are also pruned. For the keyword query "red candle", a sample lattice with the `Item` (I), `Color` (C), and `Product Type` (P) relations from the sample database in Figure 2 is presented in Figure 6. Upon using the inverted index "red" is bound to C_1 and "candle" to P_1. C_0, I_0 and P_0 are bound to the *empty keyword* and are not pruned. Only the shaded nodes in the lattice are retained. The remaining nodes are pruned.

In our implementation, we handle cases where keywords can have multiple interpretations by dealing with one interpretation at a time. Additionally, if a keyword does not occur anywhere in the database, the system displays all such keyword(s) and does not investigate the query any further. This is in accordance with "and" semantics for keyword search.

At the end of Phase 0, each node is labeled with a SQL query with an uninstantiated "where" clause. Once we bind keywords to copies of relations, the "where" clauses of the queries in each remaining node in the lattice can then be instantiated. We now have an instantiated, pruned lattice for the keyword query K.

2.4 Finding Answer and Non-Answer Query Nodes (Phase 2)

Once the lattice has been pruned based on keyword query K, the next step is to find nodes that contain queries that correspond to answer queries and non-answer queries. To do this, first we introduce some terminology.

- *Total/Partial Node*: A node can be total or partial. A node N is said to be total if its query contains tables corresponding to every keyword k_i in K. Otherwise N is said to be partial. Since we assume "and" semantics for keyword search, only a total node can contain an answer query. [2]

[2]We further note that totality decreases by moving down in the

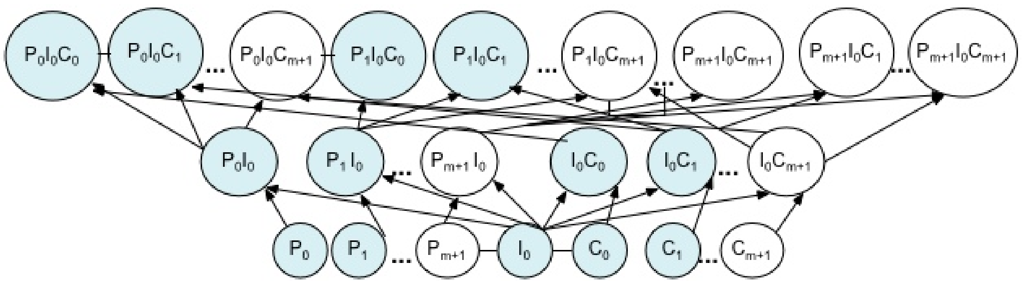

Figure 6: Sample lattice for the query "red candle". The un-shaded nodes are pruned.

- *Alive/Dead Node*: A node N is said to be alive if its query returns at least one tuple upon execution. If the query returns zero tuples, N is said to be dead. Typically a node can be classified as dead or alive only after executing its underlying structured query. As we shall see later in this section, in many cases, using the lattice structure helps us classify a node without actually executing its query.

- *Possibly Alive Node*: This node has not yet been classified as dead or alive. In the beginning, all the nodes in the pruned lattice are possibly alive.

- *Minimal-Total Node (MTN)*: A node N is said to be minimal-total, if N is total and no descendant of N is total. MTNs correspond to candidate networks in KWS-S systems [11], and contain answer and non-answer queries.

In Phase 2, we prune the lattice even further by only retaining MTNs and their descendants. To continue with our example, the node marked $P_1I_0C_1$ is the only MTN in the lattice in Figure 6. (None of the other shaded nodes are total.) We are now left with the task of classifying MTNs as dead or alive and explaining the reason(s) for the dead MTNs. We do this using Maximal Partial Alive Nodes (MPANs).

- *Maximal Partially Alive Node (MPAN)*: A node N is said to be a MPAN of a MTN M if it is both partial and alive, and if there exists no other node $N' \in \mathcal{D}esc(M)$ such that $N \in \mathcal{D}esc(N')$ and N' is alive.

There can be multiple reasons for a non-answer query. For example, the SQL query q_2 in Example 1 for the keyword query "saffron scented candle", where saffron is a scent, could be a non-answer query due to several reasons — the store carries products that are saffron scented but are not candles, they only carry unscented candles, they carry scented candles but none of them are saffron-scented or maybe they only carry products that are neither saffron-scented nor candles. The options that an administrator needs to explore in order to determine why q_2 is a non-answer query can get dauntingly large for manual debugging. Given that each keyword may have multiple interpretations (e.g., saffron could be a color or a scent), this task gets even more daunting.

We display the maximal alive query because we know that all its descendants are alive (i.e., if "find scented candles" returns some result tuples, then both "find scented products" and "find candles" will also return some result tuples). In Example 1, "find scented candles" and "find saffron scented products" are both MPANs of q_2. Collectively they convey that while the store does not carry saffron-scented candles, it does carry scented candles and other saffron-scented products. Notably, since all possible reasons for a non-answer query are sub-queries of the non-answer query, they can be systematically explored using our proposed lattice structure.

In the final phase of our system and in the rest of this section we discuss lattice traversal strategies to efficiently determine dead MTNs and their respective MPANs.

lattice, because the descendant sub-queries of a query q in general refer to fewer tables than q itself. This allows us to speak of *minimal* total nodes as in the following.

2.5 Lattice Traversal (Phase 3)

One approach to classifying the MTNs as dead or alive and finding MPANs is to simply execute the SQL queries for all the nodes in $\mathcal{L}$. However, this may not be necessary. Since each MTN is derived from its descendants, we can use the following two rules to avoid executing many of the SQL queries in $\mathcal{L}$.

Node Classification Rules:
- **(R1)** Node N is alive $\Rightarrow$ All $\mathcal{D}esc(N)$ are alive.
- **(R2)** If any $N' \in \mathcal{D}esc(N)$ is dead $\Rightarrow$ N is dead.

The descendants of a node in the lattice represent sub-queries of the node. R1 says that if a node is alive, all its sub-queries should also return some tuples when executed. R2 says that if a node is dead, all the queries of which it is a sub-query will also return no tuples. Next, utilizing the above two rules we propose traversal strategies that classify MTNs and find MPANs in the lattice.

2.5.1 Bottom-Up/Top-Down Traversal

In the bottom-up (BU) strategy, we classify one MTN at a time and traverse the sub-lattice consisting of the MTN and its descendants from the single-table level up. At each level we evaluate the SQL query corresponding to each node. If a node N is dead (i.e., its SQL query returns no result tuples), all the nodes in $\mathcal{A}sc(N)$, including the MTN, can be marked as dead (by R2). If a node is alive, it is marked as a potential MPAN until one of its ancestors is found to be alive. This process is repeated for all the MTNs until they are all classified as dead or alive and the corresponding MPANs are found.

This strategy performs well when the MTNs and MPANs corresponding to dead MTNs are found at lower levels of the lattice. In this case BU can avoid executing several expensive SQL queries at higher levels of the lattice. For keywords where MTNs and MPANs are found at higher levels, a better approach might be a top-down traversal of the lattice.

Top-down (TD) traversal is similar to BU, except that we traverse the sub-lattice for each MTN from its highest level down to the single-table level. We evaluate the SQL query corresponding to each node at each level. If a node N is alive, all the nodes in $\mathcal{D}esc(N)$ can be marked as alive (by R1). This is done till all the nodes in the lattice are classified and all the MPANs are found.

Algorithm 3: Bottom-Up with Reuse Approach

```
1  Input: $SG$, schema graph; $K = \{k_1, k_2, \ldots, k_N\}$, keyword
   query; $\mathcal{L}$, lattice; $M$, set of MTNs found during Phase 2
2  Output: $A$, set of alive MTNs; $D$, set of dead MTNs; $P$, set
   of corresponding MPANs for each dead MTN
3  GetBaseNodes($K$, $\mathcal{L}$):
4  $baseNodes \leftarrow \emptyset$, $nonKeywords \leftarrow \emptyset$
5  foreach $k \in K$ do
6      $T \leftarrow GetBaseTables(k)$
7      if $T == \emptyset$ then
8          $nonKeywords.add(k)$
9      else
10         $baseNodes.add(\mathcal{L}.GetBaseNodes(T))$
11     if $nonKeywords \neq \emptyset$ then
12         Display $nonKeywords$
13         $baseNodes \leftarrow \emptyset$
14 return $baseNodes$
15
16 Main:
17 $M' \leftarrow M$, $currLevel \leftarrow 1$
18 foreach $m \in M$ do
19     MP[$m$]$\leftarrow$ $GetDescendants(m)$ // potential MPANs
20 $B \leftarrow GetBaseNodes(K, \mathcal{L})$, $curr \leftarrow B$, $next \leftarrow \emptyset$
21 if $B == \emptyset$ then
22     return
23 while $currLevel \leq maxJoins + 1$ and $M' \neq \emptyset$ do
24     foreach $node \in curr$ do
25         $isAlive \leftarrow true$
26         if $node \notin B$ and $execSQL(node).nTuples == 0$ then
27             $isAlive \leftarrow false$
28         if $node \in M$ then
29             $M' \leftarrow M' - node$
30         if $isAlive == true$ and $node \notin M$ then
31             $next \leftarrow next \bigcup \mathcal{L}.GetParentNodes(node)$
32             foreach $m \in M$ do
33                 if $node \in$ MP[$m$] then
34                     $\mathcal{L}.RemoveAllDesc$(MP[$m$],$node$)
35         else if $isAlive == false$ then
36             $MarkAsDead(\mathcal{L}.GetAscNodes(node))$
37             if $node \notin M$ then
38                 foreach $m \in M$ do
39                     if $node \in$ MP[$m$] then
40                         $\mathcal{L}.RemoveAllAsc$(MP[$m$],$node$)
41                         $\mathcal{L}.Remove$(MP[$m$],$node$)
42             else
43                 $P[node]$$\leftarrow$ MP[$node$] // MPANs
44         $curr \leftarrow next$, $next \leftarrow \emptyset$
45     $currLevel \leftarrow currLevel + 1$
```

2.5.2 Bottom Up and Top Down with Reuse

We found that there is usually substantial overlap between the descendants of each MTN. Based on this observation, we modify BU and TD to process all the MTNs and their descendants simultaneously. We find that we can substantially reduce the redundancy in executing SQL queries corresponding to the common descendants of the MTNs. The corresponding algorithms are termed bottom-up with reuse (BUWR) and top-down with reuse (TDWR). The details of BUWR are presented in Algorithm 3. TDWR is very similar to BUWR so we do not elaborate on it any further.

Algorithm 3 works as follows. It first finds the descendants for the MTNs in M, which are all the potential MPANs (lines 18 to 19). It then traverses the lattice $\mathcal{L}$ in a bottom-up manner. For each keyword k, *GetBaseNodes* (lines 3 to 14) collects the base nodes (i.e., tables) in the lattice containing the keyword k. If some keyword is not contained by any base table, then this is reported to the user (lines 11 to 13) and no further exploration is needed (lines 21 to 22). Otherwise, answers and non-answers will be reported to the user by climbing up the lattice $\mathcal{L}$ (lines 23 to 45). For each node $node$ at the current level, the algorithm first checks its aliveness (if not known yet) by executing the SQL query associated with it (lines 25 to 27). If $node$ is alive, and it is not a MTN in M, then we can remove its descendants from candidate MPANs of each MTN $m \in M$, since they must be alive and cannot be MPANs because of the aliveness of $node$ (lines 30 to 34). On the other hand, if $node$ is dead, then all of its ancestors must be dead (line 36). If $node$ is not a MTN, once again we can remove $node$ and its ancestors from candidate MPANs of each MTN $m \in M$, since they cannot be MPANs because of their deadness (lines 37 to 41). Otherwise, $node$ is a dead MTN, and we need to report its MPANs (lines 42 to 43). Note that the MPANs must be those candidates that are still remaining in MP$[node]$. This is because, due to the nature of bottom-up traversal, the aliveness of each member in MP$[node]$ must have been either explicitly (by executing the corresponding SQL query) or implicitly (by using the two node classification rules R1 and R2) checked and hence known before $node$ is examined. After checking all the nodes at the current level, the algorithm can proceed to the next level (line 44). The next level only needs to include the parents of the alive nodes at the current level (line 31), since ancestors of dead nodes must also be dead and therefore can be excluded from further examination.

While we find that these approaches perform well in general, like any bottom-up or top-down approach, they suffer poor performance in certain cases. For example, TD will perform poorly if many MPANs are present at the lowest level in the lattice. On the contrary, BU will perform poorly if many MTNs at higher levels of the lattice are alive. In the rest of this section, we propose a score-based greedy approach, with the goal of avoiding the worst-case performance of both BU and TD.

2.5.3 Score Based Heuristic for Traversal

Given that the main advantage of the lattice structure is reuse amongst MTNs, the goal of this approach is to evaluate nodes in an opportunistic manner with the goal of minimizing the number of evaluated SQL queries. We do this by assigning a score to each unevaluated node in the lattice. This score indicates the amount of reduction in the search space that would result from evaluating this node. In other words, we evaluate the nodes that are most likely to influence the classification of other nodes first. Table 1 summarizes the notation used in the following discussion.

We start by investigating the effect that evaluating a node n_j in $\mathcal{L}$ has on the remaining nodes in the search space $\mathcal{S}(m_i)$ of each $m_i \in \mathcal{M}$. $\mathcal{S}(m_i)$ contains potential MPANs of m_i with unknown status. SQL queries might be required to determine aliveness of the nodes in $\mathcal{S}(m_i)$. Initially, $\mathcal{S}(m_i) = \mathcal{D}esc^+(m_i) = \{m_i\} \bigcup \mathcal{D}esc(m_i)$. Figure 7 demonstrates how n_j and m_i and their descendants could overlap. We next consider the cases when n_j is alive or dead.

- **If the current node n_j is alive** :

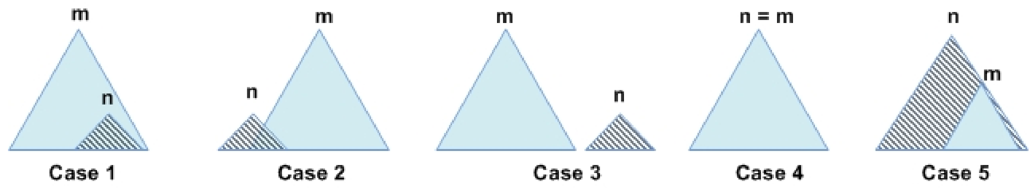

Figure 7: Ways in which a minimal complete node m, an unexplored node n, and their respective descendants may overlap.

Notation	Description
$\mathcal{N}$	$\mathcal{N} = \{n_1 \dots n_q\}$, the set of nodes in the lattice $\mathcal{L}$
$\mathcal{M}$	$\mathcal{M} = \{m_1 \dots m_p\}$, the set of MTNs
$\mathcal{P}(m_i)$	the set of MPANs for each dead $m_i \in \mathcal{M}$
$\mathcal{S}(m_i)$	the search space for each $m_i \in \mathcal{M}$ to find $\mathcal{P}(m_i)$
$\mathcal{D}esc(n)$	the set of descendants of the node n in $\mathcal{L}$
$\mathcal{A}sc(n)$	the set of ancestors of the node n in $\mathcal{L}$
$\mathcal{D}esc^+(n)$	$\mathcal{D}esc^+(n) = \{n\} \cup \mathcal{D}esc(n)$
$\mathcal{A}sc^+(n)$	$\mathcal{A}sc^+(n) = \{n\} \cup \mathcal{A}sc(n)$

Table 1: Notation used in the score-based heuristic

Case 1 ($n_j \in \mathcal{D}esc(m_i)$): If the current node n_j is a descendant of an MTN m_i, then all descendants of n_j are also alive. Since n_j is alive, these alive descendants cannot be maximal (i.e., cannot be in $\mathcal{P}(m_i)$), and thus can be removed from the search space $\mathcal{S}(m_i)$ as well.

$$\mathcal{S}(m_i) = \mathcal{S}(m_i) - \mathcal{D}esc^+(n_j).$$

Case 2 ($\mathcal{D}esc(n_j) \cap \mathcal{D}esc(m_i) \neq \emptyset$ and $n_j \notin \mathcal{D}esc(m_i)$): Let n_k be the root node of the intersection $\mathcal{D}esc(n_j) \cap \mathcal{D}esc(m_i)$. The descendants of n_k can also be removed from $\mathcal{S}(m_i)$ because they cannot be MPANs in $\mathcal{P}(m_i)$.

$$\mathcal{S}(m_i) = \mathcal{S}(m_i) - \mathcal{D}esc^+(n_k).$$

Case 3 ($\mathcal{D}esc(n_j) \cap \mathcal{D}esc(m_i) = \emptyset$): The intersection of the descendants of n_j and m_i is empty. This implies that n_j has no impact on the search space of m_i.

Case 4 ($n_j = m_i$): Here n_j is the MTN. $\mathcal{S}(m_i) = \emptyset$.

Case 5 ($m_i \in \mathcal{D}esc(n_j)$): This case cannot occur because it implies that m_i is not minimal and hence not an MTN.

• **If the current node n_j is dead** :

Case 1 ($n_j \in \mathcal{D}esc(m_i)$): In this case, all nodes in $\mathcal{A}sc(n_j)$ are also dead and therefore can be removed from $\mathcal{S}(m_i)$.

$$\mathcal{S}(m_i) = \mathcal{S}(m_i) - \mathcal{A}sc^+(n_j).$$

Case 2 ($\mathcal{D}esc(n_j) \cap \mathcal{D}esc(m_i) \neq \emptyset$ and $n_j \notin \mathcal{D}esc(m_i)$): No change in $\mathcal{S}(m_i)$.

Case 3 ($\mathcal{D}esc(n_j) \cap \mathcal{D}esc(m_i) = \emptyset$): No change in $\mathcal{S}(m_i)$.

Case 4 ($n_j = m_i$): m_i is the MTN.

$$\mathcal{S}(m_i) = \mathcal{S}(m_i) - \{n_j\}.$$

Case 5 ($m_i \in \mathcal{D}esc(n_j)$): This case cannot occur because it implies that m_i is not minimal and hence not an MTN.

We define $\mathcal{S}^a_{exp}(m_i)$ to be the expected search space of m_i if n_j is alive and $\mathcal{S}^d_{exp}(m_i)$ to be the expected search space of m_i if n_j is dead. Now, if p_a is the average probability that a node in the graph is alive, we define the score for n_j to be:

$$Score(n_j) = \sum_{m_i \in \mathcal{M}} p_a \cdot |\mathcal{S}^a_{exp}(m_i)| + (1 - p_a) \cdot |\mathcal{S}^d_{exp}(m_i)|. \quad (1)$$

Intuitively, this score measures the expected size of the search space given the information that n_j is alive/dead.

We give some further analysis to the score so defined. Let

$$\mathcal{C}over(n) = \{n\} \cup \mathcal{D}esc(n) \cup \mathcal{A}sc(n)$$

be the *coverage* of a node n. We can then express $\mathcal{S}^a_{exp}(m_i)$ and $\mathcal{S}^d_{exp}(m_i)$ more explicitly:

$$\begin{aligned} \mathcal{S}^a_{exp}(m_i) &= \mathcal{D}esc^+(m_i) - \mathcal{D}esc^+(n_j) \\ &= (\mathcal{D}esc^+(m_i) - \mathcal{C}over(n_j)) \\ &\cup\ (\mathcal{D}esc^+(m_i) \cap \mathcal{A}sc(n_j)) \end{aligned}$$

and

$$\begin{aligned} \mathcal{S}^d_{exp}(m_i) &= \mathcal{D}esc^+(m_i) - \mathcal{A}sc^+(n_j) \\ &= (\mathcal{D}esc^+(m_i) - \mathcal{C}over(n_j)) \\ &\cup\ (\mathcal{D}esc^+(m_i) \cap \mathcal{D}esc(n_j)). \end{aligned}$$

Since $\mathcal{D}esc^+(m_i) - \mathcal{C}over(n_j)$ and $\mathcal{D}esc^+(m_i) \cap \mathcal{A}sc(n_j)$ are disjoint, we have

$$\begin{aligned} |\mathcal{S}^a_{exp}(m_i)| &= |\mathcal{D}esc^+(m_i) - \mathcal{C}over(n_j)| \\ &+\ |\mathcal{D}esc^+(m_i) \cap \mathcal{A}sc(n_j)|, \end{aligned}$$

and similarly,

$$\begin{aligned} |\mathcal{S}^d_{exp}(m_i)| &= |\mathcal{D}esc^+(m_i) - \mathcal{C}over(n_j)| \\ &+\ |\mathcal{D}esc^+(m_i) \cap \mathcal{D}esc(n_j)|. \end{aligned}$$

Therefore, according to Equation (1), we have

$$\begin{aligned} Score(n_j) &= \sum_{m_i \in \mathcal{M}} |\mathcal{D}esc^+(m_i) - \mathcal{C}over(n_j)| \\ &+\ p_a \cdot \sum_{m_i \in \mathcal{M}} |\mathcal{D}esc^+(m_i) \cap \mathcal{A}sc(n_j)| \\ &+\ (1 - p_a) \cdot \sum_{m_i \in \mathcal{M}} |\mathcal{D}esc^+(m_i) \cap \mathcal{D}esc(n_j)|. \end{aligned}$$

Based on the above equation, we can see that the score actually takes three factors into consideration:

(1) *the descendants of the MTNs that are not covered by n_j (the 1st summand)*: these nodes must be explored no matter whether n_j is alive or dead;

(2) *the descendants of the MTNs that are ancestors of n_j (the 2nd summand)*: these nodes are explored when n_j is alive;

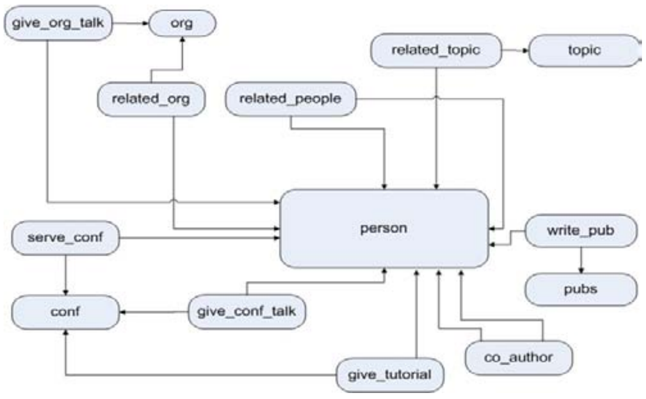

Figure 8: Relational schema for the DBLife dataset.

(3) *the descendants of the MTNs that are descendants of n_j (the 3rd summand)*: these nodes are explored when n_j is dead.

Hence, a smaller score means a smaller expected search space. We then use a simple greedy strategy based on this score to traverse the lattice — each time we pick the node n_j with the minimum score, check its aliveness, and eliminate other nodes from the lattice according to this information as before. This algorithm terminates when all nodes have been classified and the MPANs for all dead MTNs have been found.

The remaining issue is how to determine the probability p_a. We note here that setting p_a affects performance, not correctness. Estimating the probability value p_a accurately requires evaluating all the queries and finding out what percentage of them are empty. However, our experiments show that the simple assumption that p_a = 0.5 works surprisingly well. Nonetheless, it is still interesting future work to explore lightweight estimation approaches for p_a.

3. EVALUATION

In this section we evaluate our proposed approaches. We ran our experiments using PostgreSQL 8.3.6 on an Intel(R) Core(TM) 2 Duo 2.33 GHz system with 3GB of RAM. We implemented all the query processing algorithms in Java, and used JDBC to connect to the database. We further implemented the inverted indexes over the data using Lucene [18]. We evaluated the proposed approach over a 40MB snapshot of the DBLife [7] dataset that has 801,189 tuples in 14 tables (Figure 8). Note that in the DBLife schema, keywords are contained in 5 entity tables, namely, `Person`, `Publication`, `Conference`, `Organization`, and `Topic`. The 9 relationship tables connect the entity tables but do not contain any text attributes.

3.1 Lattice Generation

In Figure 9(a), we look at the number of nodes in the lattice. Having several copies of each table adds to the number of seed tables and consequently to the number of nodes in the lattice. As expected, the number of nodes grows exponentially as the level (and number of joins) increases. It is thus important to have efficient traversal and pruning strategies. Figure 9(a) shows the number of nodes generated and the number of duplicate nodes in the lattice. On average 11.7% of the generated nodes were removed due to duplicate elimination (note that the Y-axis is in log scale).

Next, in Figure 9(b), we look at the time spent in generating the lattice. We vary the level on the X-axis and measure the time taken on the Y-axis. We observe that lattice generation completes in less than 100 seconds, even for a lattice with 7 levels (i.e., 6 joins). We note that this is a one-time cost, and is done offline.

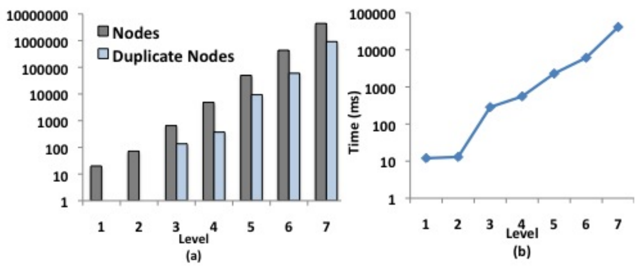

Figure 9: (a) The number of nodes generated in the lattice at each level and the number of duplicates are shown. As expected, the number of nodes in the lattice grows exponentially. On an average 11.7% of the nodes were pruned due to duplicate elimination. (b) The time spent in generating the lattice is shown. We note that the lattice is generated *offline*.

3.2 Keyword Queries

Table 2 lists the keyword queries we used in our following experiments. DBLife has a star schema, with the `Person` table at the center. As a result, queries with many person names (e.g., Q3) often lead to many MTNs. Q7, Q9, and Q10 do not contain any person names and Q8 contains the term "Washington" which occurs in the `Person`, `Publication`, and `Organization` tables. Q4 and Q6 lead to empty queries at the two-table level, but MTNs are found at higher levels as KWS-S explores relationships with more joins.

ID	Keyword Query
Q1	Widom Trio
Q2	Hristidis Keyword Search
Q3	Agrawal Chaudhuri Das

Table 2: Keyword queries

3.3 Keyword Based Pruning (Phase 1) and Finding MTNs (Phase 2)

The next step involves mapping user's keyword query to schema terms and is performed online. This primarily involves lookups over the inverted indexes on the data. For the 10 testing queries, the time to map the keywords to schema terms varied between 7 ms and 66 ms with an average time of 26 ms.

Next, we measured the number of nodes in the lattice that remain in the lattice upon the introduction of keywords. We note that keyword-based pruning reduced the number of relevant nodes by 98% on average. Once the keywords are mapped to schema terms, the next step is to find the MTNs. This process took up to 23 ms for the 10 queries, in a lattice for level = 5. The number of MTNs ranged from 3 to 85.

Figure 10 summarizes these results. It also shows the number of unique descendants for the MTNs. We note that Q3 and Q8 have lower number of unique descendants, allowing higher possibility of reuse, as we will show later. We also computed these statistics for level = 7, and observed that the number of nodes after pruning varied from 277 to 18,904 with an average of 9,226 nodes, a reduction of 94.3% from the 161,440 nodes in the original lattice. The number of MTNs ranged from 35 to 1,418. This shows that even though a large number of lattice nodes are generated, phases 1 and 2 can prune the lattice substantially.

3.4 Comparison of Traversal Strategies

The goal of our traversal strategies is to efficiently determine if an MTN is alive or dead and to find the MPANs for the dead MTNs. We compared the five strategies for lattice traversal from end-to-end. Figure 11 shows the number of SQL queries that needed to be executed by each traversal approach for level = 5. Figure 12 shows the times taken by each approach for the corresponding queries. Note that both BUWR and TDWR perform better than their respective counterparts without reuse. This is especially true for Q3 and Q8, because for these queries, the total number of unique descendants are much smaller than that with duplicates. The number of SQL queries executed for Q3 is shown in Table 4. Q2 leads to only 3 MTNs, all of which are alive (i.e., Q2 has 0 MPANs). One of these 3 MTN queries is a join between the `Person` and `Publication` tables, with the keywords occurring in many tuples. This query takes around 20 seconds to execute. The proposed score-based heuristic (SBH) approach performs well in almost all cases, owing to its opportunistic choice of nodes during the pruning/traversal process. Further, we also note that TD and TDWR perform better than BU and BUWR respectively. Next, we explain the reason for the performance difference.

3.5 Impact of MTN and MPAN Distributions

For the DBLife dataset, we find that as the maximum level of the lattice increases, BU and BUWR generally perform poorly when compared to TD, TDWR, and SBH. This is because even keyword queries that return no answers at lower levels might return answers at higher levels. These answers correspond to relationships with many hops. Since the number of nodes in the lattice grows exponentially as the number of joins increases, TD and TDWR have a better pruning effect than BU and BUWR.

In Table 3, we present the distributions of MTNs and MPANs at levels 3, 5, and 7. Note that as most of the MTNs and MPANs are concentrated at higher levels, TD and TDWR perform better than BU and BUWR. We find that SBH performs well regardless of the distribution of MTNs.

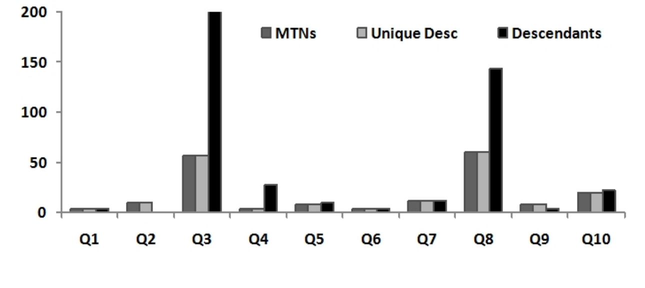

Figure 10: Keyword queries enable substantial pruning of the lattice (98% on an average). The number of MTNs and their descendants and unique descendants are presented to show the extent of overlap between the nodes in the lattice.

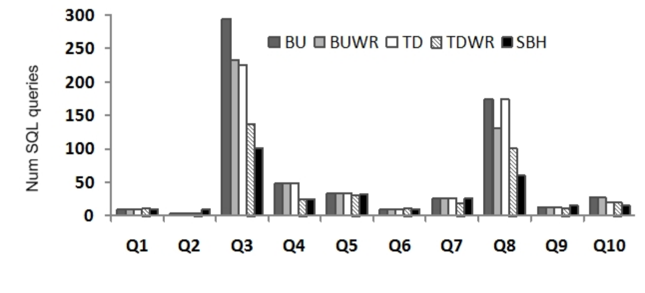

Figure 11: The number of SQL queries generated by the system for each keyword query.

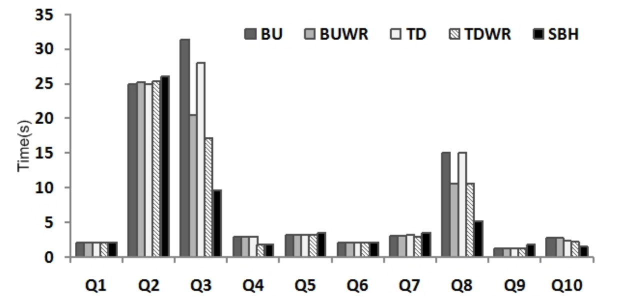

Figure 12: The time taken to execute all the SQL queries for each keyword query.

	MTNs			MPANs		
Q	L3	L5	L7	L3	L5	L7
Q1	1	6	41	0	4	34
Q2	0	3	35	0	0	0
Q3	0	85	1418	0	94	1584
Q4	4	20	144	8	28	130
Q5	4	24	164	2	10	42
Q6	1	6	41	2	4	18
Q7	2	14	92	4	12	70
Q8	0	31	451	0	87	1172
Q9	0	8	40	0	4	4
Q10	0	6	83	0	10	92

Table 3: Distributions of MTNs and MPANs at levels 3, 5, and 7 for the 10 keyword queries (L3 is short for "Level 3", and so forth). Note that most of the MTNs and MPANs are concentrated at higher levels.

3.6 Performance at Higher Levels

We now investigate how the approaches perform as we vary the maximum level of the lattice. Table 4 shows the number of SQL queries executed for Q3 when increasing the maximum level from 3 to 7. As before, we note that the number of SQL queries executed increases as the maximum level is increased. We also note that reuse-based approaches perform better by executing fewer queries — BUWR executes 28% fewer queries than BU, while TDWR executes 52% fewer queries than TD, at level 7. Further, TDWR performs better than BUWR, owing to the presence of a large number of MPANs and MTNs at higher levels of the lattice. Finally, we note that SBH provides substantial reduction (79% reduction compared to BU) in the number of queries executed at higher levels of the lattice.

3.7 Performance Improvement with Reuse

We were interested in investigating the extent of the overlap between the descendants of each MTN. Increased overlap would allow more reuse, decrease the number of SQL queries executed and consequently improve runtime performance. Figure 13 shows the percentage of reuse, i.e., $100 * (1 - \frac{N_u}{N})$, where N_u is the

Level	BU	BUWR	TD	TDWR	SBH
3	0	0	0	0	0
5	294	233	225	136	101
7	5036	3624	3866	1818	1026

Table 4: Number of SQL queries executed in all the traversal techniques for Q3 with lattice level = 3, 5, 7. SBH provides substantial reduction in the number of queries executed at higher levels of the lattice. The approaches with reuse perform better than their respective counterparts without reuse.

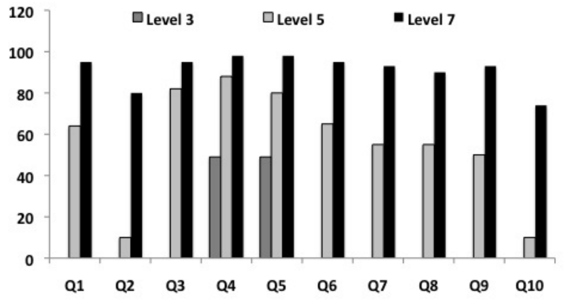

Figure 13: Percentage of reuse for the 10 keyword queries. While reuse is keyword dependent, it increases as the number of joins increases.

number of unique descendants of MTNs, and N is the total number of descendants of MTNs. The percentage of reuse for levels 3, 5, and 7 is shown. As expected, reuse increases as more joins are allowed. At level 3, only queries Q4 and Q5 show some overlap. However, we see substantial overlap between the descendants of the MTNs at levels 5 and 7. Specifically, Q2 and Q10 show a steep increase in overlap from level 5 to level 7. This increase is reflected in the performance of the reuse-based approaches and helps explain the performance of SBH over the other traversal approaches.

3.8 Comparison with Other Alternatives

Our proposed approach is not the unique one that can address the non-answer exploration problem. We therefore further compared our approach with other alternatives. Here we consider a simple indicator that is correlated with the "work" required to diagnose a non-answer. Our intent is to explore a simple quantitative metric that captures the intuition for why we think our approach may be helpful. Specifically, we compare our approach with the following two alternatives:

- *Return Nothing* (RN): Return nothing to the user for non-answers. This is the standard, existing KWS-S approach. To address the "why not" question, a developer would likely repeatedly submit modified queries by removing keywords from the original query. For instance, if the original keyword query were "k_1 k_2 k_3", then a user trying to understand the reason for the non-answer might additionally submit the queries: "k_1 k_2", "k_1 k_3", "k_2 k_3", "k_1", "k_2", and "k_3".
- *Return Everything* (RE): Do not build the lattice and return MPANs of the non-answers. Instead, explore alive descendants at runtime. For each descendant, issue the associated SQL query to determine its aliveness.

RN requires additional user effort to submit more queries. Both RE and our proposed approach remove this burden from the user. Meanwhile, the set of alive descendants returned by RN is both incomplete and redundant. It is incomplete, since only *minimal* alive descendants can be returned by existing KWS-S systems. That is, each leaf node of a candidate network is required to be bound by a keyword. As a result, alive descendants, including some MPANs, that do not satisfy this requirement will not appear in the results and hence are missing. It is also redundant, since some of the alive descendants returned may belong to answers (i.e., alive MTNs) but not non-answers (i.e., dead MTNs). Both incompleteness and redundancy are unsatisfactory for the purpose of debugging non-answers. On the other hand, RE returns the complete set of alive descendants. However, it is still redundant, since the aliveness of some descendants can be automatically inferred based on the aliveness of the others. Compared with RE, with the help of the lattice structure, our proposed approach can rule out this redundancy without sacrificing the completeness.

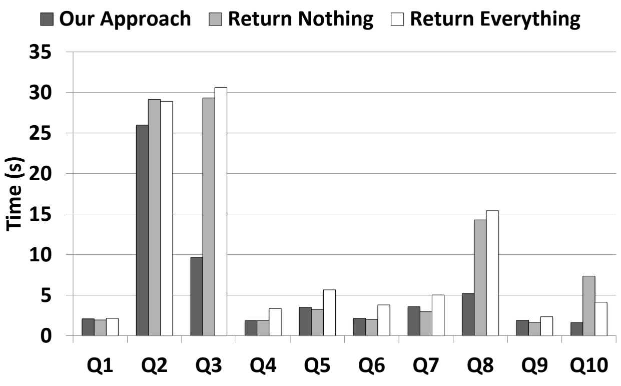

Figure 14: Response time when lattice level = 5

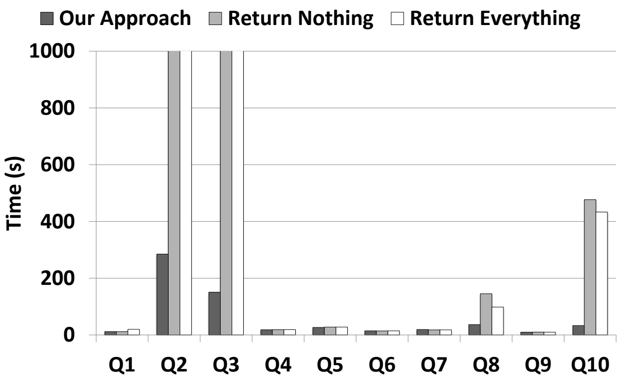

Figure 15: Response time when lattice level = 7

We further tested the system response time when the three approaches were adopted, in terms of the total execution time of the SQL queries issued. Figure 14 and 15 present the results for lattice levels 5 and 7. Our approach substantially reduces the response time for the more complicated queries Q2, Q3, Q8, and Q10, which contain three keywords, while the other queries only contain two. The improvement is more dramatic when multi-way joins (i.e., higher lattice levels) are allowed. For example, the response times are reduced by 84% and 99% for the two most costly queries Q2 and Q3, when the lattice level is 7 (i.e., up to 6 allowable joins).

4. RELATED WORK

Although we are not aware of any previous work that pertains to non-answers in the KWS-S context, the related work for the approaches and ideas presented in this paper is extensive.

Banks [1, 14], DBXplorer [2], and DISCOVER [11] are seminal papers in KWS-S. While Banks operates on a data graph, our paper is geared towards approaches like DISCOVER and DBXplorer, which use the underlying schema graph to explore relationships between the keywords. Several other KWS-S systems have been proposed over the years as well (see Yu et al. [25] for an extensive survey). Notably, Markowetz et al. [19] explored efficient generation and evaluation of candidate networks and briefly mentioned purging dead tuples in their paper about keyword search over streaming data. The Helix system [22] proposed a rule-based method for mapping keyword queries to structured queries. They automatically mined and manually tuned a set of patterns from query logs and mapped each pattern to a template query. A query was mapped to the best template once it arrived at runtime. Our static lattice structure is somewhat analogous to these templates. EASE [16] extensively leveraged offline computation to speed up runtime performance but did not consider the problem of non-answers. KWS-S-F [6] also leveraged offline computation but did not deal with non-answers. In addition, lattice structure has also been used in relaxing selection and join queries in relational databases to help users find more results [15].

We drew inspiration from Why Not [5] and Provenance of Non-Answers [12]. This work addressed non-answers in the context of single SQL queries and did not deal with KWS-S systems. Huang et al. [12] and Herschel et al. [8] provided tuple insertions or modifications that would yield the missing tuples. Chapman and Jagadish [5] tried to find the manipulation that led to a non-answer query. Tran and Chan [24] generated a modified query whose results included the user-specified missing tuple(s). In contrast, in a KWS-S system we cannot rely on user input, given that the user is assumed to be schema agnostic and may not even be aware that the KWS-S system is executing structured queries. Our notion of MPANs is similar to that of a frontier picky manipulation [5] in spirit. However, we feel that MPANs are more suited for the keyword search context; they represent the subset of keywords that would render a dead relationship alive. Work on lineage and provenance including [4, 20] influenced the lattice structure and use of MPANs to explain non-answer queries in KWS-S.

While we focused on pure relational database techniques in this paper, there has also been work on mapping sets of structured tuples to virtual documents and then applying information retrieval techniques to find results that match the keywords (e.g., the EKSO system [23]). However, this idea relies on inverted indices built over materialized views. In typical industry systems, these indices are updated only at some pre-determined time-intervals (mostly, on a nightly basis). This then implies that they may suffer from severe data staleness issues, for in the daily use of a relational database, any changes to the underlying data can impact answers and non-answers to keyword queries almost immediately. Moreover, it actually cannot work for non-answers if only "and" semantics is considered. Using "and" semantics, non-answers would never be displayed to the user. Nonetheless, this raises a very interesting point that there might be an alternative way to deal with the problem: replace "and" semantics by "or" semantics, though it seems to be equivalent to the "Returning Nothing" strategy discussed in Section 3.8 and thus suffers from issues such as incompleteness and redundancy. In fact, Hristidis et al. have considered the "or" semantics in KWS-S systems [10]. However, their focus was to efficiently present the end users with a list of top-k matches for moderate values of k. In contrast, our goal is to enable system developers to debug non-answers so providing top-k matches is insufficient. Nevertheless, this merits further exploration but it is out of the scope of this paper.

5. CONCLUSION

In this work we take a first step towards building a KWS-S system that exposes non-answer queries to system developers for the purpose of debugging the system. Given the exponential complexity of answer generation in KWS-S, exposing and explaining non-answer queries is a time-consuming process. We leveraged offline computation to generate a lattice structure and exploited the overlap between the queries to efficiently determine non-answer queries and their closest alive sub-queries.

While we concentrated on improving the performance of discovering and investigating non-answer queries in the KWS-S domain, this work opens up a couple of interesting directions for future work. For instance, debugging is often an interactive process and it is worth studying how to combine the search for MPANs with user intervention. Meanwhile, pushing user-defined constraints into the search procedure might greatly prune the search space and therefore significantly improve the efficiency. All of these are interesting questions that deserve further investigation.

Elevating Annotation Summaries To First-Class Citizens In InsightNotes

Karim Ibrahim, Dongqing Xiao, Mohamed Eltabakh

ABSTRACT

Most scientific and modern applications generate—in addition to the base data—valuable annotations and metadata information at unprecedented scale and complexity. Such annotations warrant the need for advanced annotation management techniques that not only propagate the raw annotations to end-users, but also mine, summarize, and extract useful knowledge from them. Towards this goal, we proposed the *InsightNotes* system, the first summary-based annotation management engine in relational databases [22]. InsightNotes relies on creating concise representations of the raw annotations, called *annotation summaries*. InsightNotes addresses several unique challenges related to the maintenance, propagation, and zooming of these summaries. However, a key limitation is that the annotation summaries are treated as *propagate-only* (*report-only*) objects that cannot be directly queried or manipulated. This limitation hinders higher-level applications from applying complex processing over both the base data and its attached annotation summaries even within a single query. In this paper, we propose new extensions to InsightNotes for treating the annotation summaries as *first-class citizens*. We address the challenges of: (1) Developing new manipulation functions and query operators specific for the annotation summaries, (2) Designing summary-based index structures and access methods for efficient retrieval and predicate evaluation, and (3) Extending the query optimizer to optimize queries accessing both the data and the annotation summaries. The proposed extensions not only make it feasible to natively query and manipulate the annotation summaries, but also achieve more than two orders of magnitude speedup in query evaluation.

1. INTRODUCTION

Metadata—usually referred to as *"annotations"*— is gaining an increasing importance in most modern database applications as a valuable source of information. Applications in many science domains, e.g., in biology, healthcare, earth sciences, and ornithology, create and manage annotations and metadata information in orders of magnitude larger than the base datasets as reported in [5, 20, 22]. For example, according to the *geneontology.org* website, several biological databases, e.g., Genobase (http://ecoli.naist.jp/GB8/), EcoliHouse (http://www.porteco.org/), and UniProt (http://www.ebi.ac.uk/uniprot), manage annotations in a 10x scale compared to the number of genes and proteins in the database. Moreover, in ornithological databases, e.g., DBRC (http://www.dbrc.org.uk/), and AKN (http://www.avianknowledge.net/), the number of annotations collected from the bird watchers and scientists all over the world is around 200x larger than the number of birds' collection stored in these repositories [1].

It is not only the scale of annotations that poses challenges, but also the need for transparent processing and propagation of annotations, and their combinatorial relationship with the data, e.g., annotations can be attached to single table cells (attributes), rows, columns, arbitrary sets and combinations of them, or even attached to sub-attributes. That is why annotation management has been extensively studied in RDBMSs to address some of these challenges [4, 7, 11, 14, 17, 21]. However, all of the existing techniques have the common limitation of manipulating only the raw annotations, and hence reporting back to end-users 100s of annotations attached to each output tuple. Nevertheless, any advanced processing of mining, summarizing, and extracting useful knowledge from the annotations is entirely delegated to end-users.

As a first step towards addressing the above limitations, we proposed the *"InsightNotes"* system, *a summary-based annotation management engine in relational databases* [22]. InsightNotes is based on integrating data mining and summarization techniques with annotation management in novel ways with the objective of creating concise and meaningful representations of the raw annotations, called *"annotation summaries"*. For example, the R.H.S in Figure 1 illustrates a data tuple with 100s of attached raw annotations, while the L.H.S illustrates the tuple with its attached summary objects using InsightNotes. The summary objects include, for example, Classifier-type objects, e.g., *ClassBird1* and *ClassBird2*, that classify the raw annotations into user-defined classes, Snippet-type objects, e.g., *TextSummary1*, that summarize the attached big articles and report snippets on each, and Cluster-type objects, e.g., *SimCluster*, that group similar annotations into groups and reports only a representative from each group. An overview on the system will be presented in Section 2.

1.1 Case Study: Effectiveness and Motivation

We performed a usability case study to demonstrate the effectiveness of InsightNotes and motivate the new extensions proposed in this paper. We used a small subset of 100 data tuples from the AKN ornithological database, each has a number of raw annotations ranging between 75 to 380. The annotations describe anything related to birds, e.g., color, body shape or weight, certain behavior or sound, eating habits, geographic location, or observed diseases. And then, we asked 20 students to query the data, and an-

Query Semantics	# Qualifying data tuples	InsightNotes Group	Raw-Annotations Group
Q1: Report the *disease-related* annotations attached to birds with name like "Swan*".	5	Time: 47 sec Accuracy: 100%	Time: 21 mins False Positives: 17% False Negatives: 25%
Q2: Aggregate based on the bird's family column, and report the number of behavior-related information on each group.	3	Time: 47 sec Accuracy: 100%	Time: 45 mins False Positives: 18% False Negatives: 34%
Q3: Report the data tuples sorted based on the number of attached disease-related annotations	100	Time: 5.2 mins Accuracy: 100%	-----

Figure 2: Usability Case Study using InsightNotes.

swer the three questions highlighted in Figure 2. These are simple annotation-based analytical queries that scientists or end-users may ask over their datasets. Half of the students use the InsightNotes engine, while the other half uses an existing annotation management engine that reports the raw annotations [11]. We then measured the average time taken by each group (including writing the query) as well as the results' accuracy.

To answer $Q1$, the InsightNotes group needs to submit a single SQL query to get the 5 expected data tuples (similar to the L.H.S in Figure 1). And then, they need to issue another follow-up command, i.e., a zoom-in command, to retrieve the raw disease-related annotations over these tuples. In contrast, the *Raw-Annotations* group will get the 5 tuples along with their raw annotations (similar to the R.H.S in Figure 1). And then, they need to manually read the annotations and extract the desired ones. It took them, on average, 21 minutes and they reported the results with high false-positive and false-negative ratios as indicated in the figure.

To answer $Q2$, the InsightNotes group needs to only retrieve the number of the behavior-related annotations from the answer, i.e., *ClassBird1.Behavior*. It took them few seconds for writing and executing the query. In contract, the other group took very long time and still produced erroneous results—Notice that $Q2$ is an aggregation query, and thus each output tuple may have many annotations collected from multiple base tuples.

The $Q3$ query is more challenging because InsightNotes does not provide mechanisms for sorting the data based on their attached summaries. Thus, the InsightNotes group needed to go over the 100 reported tuples, and manually sort them according to the *ClassBird1.Disease* field. For the other group, it was not even feasible to analyze 100s of annotations over each of the reported tuples to figure out the number of disease-related annotations, and then sort based on that.

1.2 Limitations and Proposed Extensions

The results from the our study show that InsightNotes opens a promising direction for better understanding of large-scale annotations and extracting useful knowledge from them. However, the results also show that InsightNotes has the critical limitation of treating the annotation summaries as *"propagate-only objects"*. This limitation hinders the applications from mixing operations over both the data content and annotation summaries even within a single query (Refer to $Q3$ in Figure 2). In this paper, we propose extending the InsightNotes system by elevating the annotation summaries to be first-class citizens, where end-users and applications can manipulate them in various ways, e.g., selecting, joining, or ordering the data tuples based on their attached annotation summaries. To build such full-fledged summary-based annotation management engine, we propose the following contributions:

- **Seamless Manipulation of Diverse Summary Types:** InsightNotes supports three types of summarization techniques, i.e., clustering, classification, and text summarization. And hence, the summary objects attached to the data tuples can have diverse types, structures, and properties (Refer to Figure 1). Therefore, we propose manipulation functions at different granularities, e.g., at the *tuple-level* to manipulate the entire set of attached summary objects, and at the *object-level* to manipulate the individual summary objects according to their types.

- **Summary-Based Query Processing:** We propose building an extended query engine, where end-users can process both the data and their attached annotation summaries seamlessly in a single query plan. For example, $Q3$ in Figure 2 involves a *summary-based ordering* operation. Another query may be interested in retrieving only the data tuples with zero provenance-related annotations, i.e., `ClassBird2.Provenance = 0`, which involves a *summary-based selection* operation. Therefore, we extend the InsightNotes's query engine by introducing new summary-based query operators, e.g., filter, selection, join, and sort, that operate on the summaries' content. We define their algebraic semantics and integrate them with the standard operators in a single query plan.

- **Efficient Access Methods and Retrieval Mechanisms:** Applying predicates and operators on top of the annotation summaries warrants the need for efficient retrieval mechanisms and indexing techniques to achieve scalable performance. For example, how could the system efficiently answer the two queries mentioned above, i.e., a selection query based on `ClassBird2.Provenance = 0`, and an ordering query based on `ClassBird1.Disease`. We propose summary-based indexing techniques that achieve efficient execution for the summary-based queries, while retaining the optimal summary-propagation performance.

- **Extended Summary-Based Query Optimizer:** The integration between the summary-based and the standard SQL operators within a single query engine opens several new opportunities for query optimization. For example, one query may now involve joins and selections based on both the data and the summaries, and thus the query optimization becomes even more challenging. Therefore, we introduce several new equivalence and transformation rules as well as an extended cost model that guide the query optimizer in generating efficient execution plans.

• **Realization and Evaluation:** We developed the proposed extensions within the InsightNotes prototype engine [22]. The experimental analysis demonstrates the value-added functionalities of directly manipulating and querying the annotation summaries, e.g., enabling a seamless expression of more complex annotation-based analytical queries, and the significant performance gain from the proposed optimizations.

The rest of the paper is organized as follows. In Section 2, we overview the InsightNotes system. In Section 3, we present the new summary-based functions and query operators. Sections 4 and 5 introduce the summary-based indexing scheme, and the extended query optimizer, respectively. The experimental evaluation is presented in Section 6, while the related work is presented in Section 7. Finally, the conclusion remarks are included in Section 8.

2. OVERVIEW ON InsightNotes SYSTEM

InsightNotes addresses several challenges related to managing the annotation summaries, which include: (1) Designing an extensible engine where domain experts and database admins can define how to summarize and mine their annotations, (2) Developing efficient and incremental mechanisms for the maintenance of annotation summaries to scale up with large number of annotations, (3) Extending the query engine and relational algebra to operate on and propagate the annotation summaries along with the queries' answers, and (4) Building zoom-in query processing mechanisms that enable end-users to zoom-in and retrieve the raw annotations of specific summaries of interest. In this section, we overview the basic functionalities of InsightNotes needed for this paper.

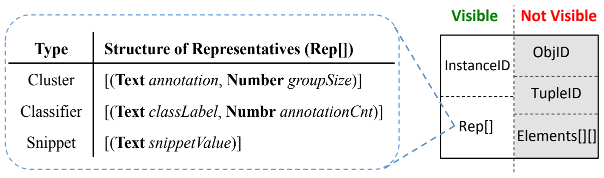
2.1 InsightNotes's Data Model

The system supports three widely-used families (types) of mining and summarization techniques, which are: *Text Summarization*, *Clustering*, and *Classification* techniques. The system is extensible such that the database admins can customize these techniques—and instantiate what is called *Summary Instances*—to fit their domains and produce the desired summaries. Each user relation R can be linked to as many summary instances as needed. For example, Figure 1 illustrates Table Birds having four summary instances linked to it (2 Classifiers, 1 Snippet, and 1 Cluster). Therefore, the raw annotations attached to each data tuple in this table (the R.H.S) will be summarized according to these four summary instances. This will result in creating the *Summary Objects*, which will be attached back to the corresponding data tuple (the L.H.S).

Assume a user's relation R having n data attributes and k summary instances linked to it. Then, each tuple $r \in R$ has the following conceptual schema:

$$r =< a_1, a_2, ..., a_n, \{s_1, s_2, ..., s_k\} >$$

where $a_1, a_2, ..., a_n$ are the data values of r, and $s_1, s_2, ..., s_k$ are the summary objects attached to r. Each summary object consists of a five-ary vector {ObjID, InstanceID, TupleID, Rep[], Elements[][]} as depicted in the following figure:



Type	Structure of Representatives (Rep[])
Cluster	[(**Text** *annotation*, **Number** *groupSize*)]
Classifier	[(**Text** *classLabel*, **Numbr** *annotationCnt*)]
Snippet	[(**Text** *snippetValue*)]

The *ObjID* is the objects's unique identifier, and the *InstanceID* and *TupleID* are references for the corresponding summary instance, and the data tuple, respectively. The *Rep[]* array stores the representatives produced from the summarization algorithm, while *Elements[][]* is a two-dimensional array storing for each representative, the references (Ids) to its contributing raw annotations. At query time, end-users will see only the *InstanceID* and *Rep[]* fields of each propagated summary object as illustrated in Figure 1.

For each summary object s_i, the structure of its representatives stored in Rep[] depends on s_i's type as depicted in the above figure. For example, in the case of the *Cluster* type, each cluster (group) will report an annotation as its representative as well as the number of annotations in that group. Hence, the Rep[] array consists of a list of representatives in the form of pairs [(*Text annotation, Number groupSize*)]. In the case of the *Classifier* type, each representative will have a class label along with the number of annotations assigned to this label. For the *Snippet* type, each large annotation will have a corresponding short snippet as its representative.

2.2 Summary-Aware Query Processing and Propagation

InsightNotes's query engine has several extensions that enable efficient and seamless propagation of the summary objects under complex transformations, e.g., projection, join, grouping and aggregations, and duplicate elimination. We proposed extensions to the semantics and algebra of each query operator to manipulate the summary objects on-the-fly without the need for accessing the raw annotations. The following example demonstrates a Select-Project-Join (SPJ) query involving summary propagation in InsightNotes. The formal semantics of all query operators can be found in [22].

Example 1: *Assume an SQL query* `"Select r.a, r.b, s.z From R r, S s Where r.a = s.x And r.b = 2"` *over the two tuples r and s presented in Figure 3. Tuple r has four summary objects attached to it, while tuple s has only two attached summary objects. We proved in [22] in Theorems 1 and 2 that to guarantee identical summary propagation under different—but equivalent—query plans, InsightNotes needs to project out the un-needed annotations before any merge operation over the summary objects. Therefore, the projection operator in Step 1 in Figure 3 projects out attributes $r.c$ and $r.d$ and eliminates the effect of their annotations from r's summary objects. For example, the* `annotationCnt` *field in the classifier objects is decremented, the wikipedia article in the snippet object is deleted, and the cluster objects are modified, e.g., some annotations are dropped from each cluster, and hence the* `groupSize` *field is decremented. Moreover, if a cluster's representative is dropped, then another representative is elected (See $A5$ representative replacing the dropped $A2$ representative). The same operation takes place over tuple s, where the effect of all annotations attached to both $s.x$ and $s.y$ is removed from s's summary objects. The only difference is that $s.x$ attribute will not be projected out because it is needed in the subsequent join operator.*

The next operator in the query plan is the selection operator over r (Step 2). Based on the query's predicate, r will pass the operator and all its summary objects will propagate without any change. Then, the produced tuples will join and their summary objects will be merged (Step 3). According to the merge procedure, r's summary objects `ClassBird1` *and* `TextSummary1` *will propagate without any change since they do have no counterpart objects over s. Whereas summary objects* `ClassBird2` *and* `SimCluster` *will be combined. This action takes into account the case where the same annotation may be attached to both tuples r and s, and hence the annotation's effect on the summary objects should not be double counted. For example, assuming that there are five common annotations on both r and s classified as* `Comment`*, then when the two objects are merged the sum of that classifier label will be 22 instead of 27 as illustrated in the figure. The merge of the clus-*

ter summary objects is slightly more complex. The main idea is that the overlapping groups from both sides, e.g., the groups represented by $A1$ and $B5$, will be combined together, whereas the non-overlapping groups, e.g., the groups represented by $A5$ and $B7$, will propagate separately as illustrated in the figure. Finally attribute $s.x$ will be projected out before producing the output.

3. SUMMARY-BASED FUNCTIONS & OPERATORS

3.1 Summary-Based Manipulation Functions

The first step in treating the annotation summaries as first-class citizens is to design a set of interfaces and manipulation functions on top of them. In the following, we demonstrate few of the developed functions, which we use throughout the paper. We also expect the end-users to leverage these basic functions to create more semantic-rich summary-based UDFs.

• **Summary Set Functions:** We introduce a special variable "\$" for each data tuple that represents the set of summary objects attached to this tuple, i.e., $r.\$$ represents the set of summary objects attached to r. Then, we define interface functions over the \$ variable, which include:

∘ **Int \$.getSize():** Returns the number of summary objects within the set. For example, referring to tuple r in Table `Birds` in Figure 1(c), $r.\$.getSize() = 4$.

∘ **SummaryObj \$.getSummaryObject(String** *InstName***):** The function takes a summary instance name as input, and returns the summary object corresponding to that name, otherwise it returns Null. For example, $r.\$.getSummaryObject(‘ClassBird1')$ and $r.\$.getSummaryObject(‘TextSummary1')$ return the Classifier and Snippet summary objects attached to tuple r.

∘ **SummaryObj \$.getSummaryObject(Int** i **):** This function takes a position within the summary set as input, and returns the summary object at that position. Since the objects in the set do not follow a pre-defined order, this function is more useful when used within UDFs, e.g., to iterate over the objects within a summary set and apply a certain functionality.

We then define a set of manipulation functions over each summary object O according to its summary type. Some functions are common to all types. For example, O**.getSummaryType()** and O**.getSummaryName()**, return the type of the summary object—as either "Classifier", "Snippet", or "Cluster"—, and the summary instance name, respectively. Another common function to all types is O**.getSize()**, which returns the number of representatives within object O, i.e., the size of $O.Rep[]$. For example, referring to Figure 1, the *ClassBird1* classifier object has 4 representatives, while *SimCluster* cluster object has 2 representatives. Other functions are specific to each summary type. For example:

• **Classifier Type Functions:** For a summary object O of type Classifier, the defined functions include:

∘ **String** O**.getLabelName(Int** i**):** Returns the class label at position i, i.e., Rep[i].classLabel. The order among the class labels is pre-defined based on the order specified when creating the classifier summary instance in the system.

∘ **Int** O**.getLabelValue(Int** i | **String** *label***):** This function takes either an index i or a class label *label* as input, and returns the corresponding value, i.e., Rep[i].annotationCnt (for input i), or Rep[j].annotationCnt, where Rep[j].classLabel = *label* (for input *label*).

• **Snippet Type Functions:** For a summary object O of type Snippet, the defined functions include:

∘ **String** O**.getSnippet(Int** i**):** Returns the snippet value at position i. The order among the snippets is arbitrary and does not follow a pre-defined order.

∘ **Boolean** O**.containsSingle(String** kw_1 **[, String** kw_2**, ...]):** Returns True if all of the given keywords $kw_1, kw_2, \ldots$ are contained within any one of O's snippets or the raw annotations. As we studied in [16], there is a tradeoff—w.r.t accuracy and performance—between searching the snippets vs. searching the raw annotations.

○ **Boolean O.containsUnion(String kw_1 [, String kw_2, ...]):** Returns True if all of the given keywords $kw_1, kw_2, ...$ are contained within the union of O's snippets or O's raw annotations. In this function, the keywords may span multiple annotations attached to the same tuple.

Internally, InsightNotes—which uses PostgreSQL as its underlying DBMS— implements the summary objects as composite data types. On top of these types, the manipulation functions presented above are defined.

3.2 Summary-Based Relational Operators

We now introduce several summary-based relational operators. Unlike the standard SQL operators, these operators operate on the summary objects attached to each tuple instead of its data content. The summary-based operators can be mixed with other standard relational operators in a single query pipeline for seamless processing. The new operators include:

• **Filter Operator ($\mathcal{F}_p(R)$):** The filter operator takes a set of summary-based predicates p, and returns each tuple $r \in R$ along with only its summary objects satisfying p. The operator is formally defined as:

$$\mathcal{F}_p(r) = \{r' =< a_1, a_2, ..., a_n, \{s_i, ...\} > \mid p(s_i) = True, \text{ where } 1 \leq \text{i} \leq \text{k} \}$$

For example, referring to Figure 1(c), the predicate `(getSummaryName() = 'SimCluster')` returns r along with only the the specified cluster summary object. In contrast, the predicates `(getSummaryType() = 'Classifier')` return r along with only the two classifier summary objects *ClassBird1* and *ClassBird2*.

• **Selection Operator ($\mathcal{S}_p(R)$):** The summary-based selection operator takes a set of summary-based predicates p, and returns the data tuples $r \in R$ having summary objects satisfying p. Otherwise, r is dropped. For qualifying tuples, all their summary objects will pass without change. The algebraic expression of the operator is as follows:

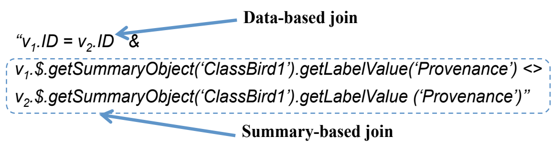
$$\mathcal{S}_p(R) = \{r \in R,\ r =< a_1, a_2, ..., a_n, \{s_1, s_2, ..., s_k\} > \mid p(r.\$) = True\}$$

The summary-based predicates may range from black-box UDFs that take $r.\$$ as a parameter and return a Boolean value, to explicit predicates based on the system-defined manipulation functions presented in Section 3.1. In the latter case, the system can reason about and optimize the execution of these predicates as will be presented in Section 4. For example, the predicate `(r.$.getSummaryObject('ClassBird2').getLabelValue('Provenance') = 0)` returns only R's tuples having no provenance-related annotations attached to them. In contrast, the predicate `(r.$.getSummaryObject('TextSummary1').containsSingle('Wikipedia', 'hormone'))` returns R's tuples that have at least one annotation containing both keywords. Such predicates can be efficiently evaluated using the the summary-based indexes presented in Section 4.

• **Join Operator ($\mathcal{J}_p(R, S)$):** The summary-based join operator joins two input tuples $r \in R$ and $s \in S$ iff the summary-based join predicates p evaluate to True over $r.\$$ and $s.\$$. The algebraic expression of the operator is as follows:

$$\mathcal{J}_p(R, S) = \{< r, s >, where\ r \in R\ \&\ s \in S \mid p(r.\$, s.\$) = True\}$$

For example, referring to Table *Birds* in Figure 1, assume we have two revisions of this table, V_1 (after Revision 1) and V_2 (after Revision 2). Then, reporting the data tuples whose number of provenance annotations has changed between the two revisions would involve the following expression:



"v_1.ID = v_2.ID &
v_1.$.getSummaryObject('ClassBird1').getLabelValue('Provenance') <>
v_2.$.getSummaryObject('ClassBird1').getLabelValue ('Provenance')"

The expression combines both data- and summary-based join operators. As will be discussed in Section 5 and based on the available indexes and statistics, the query optimizer may decide to join the tuples based on the data values and then applies a summary-based selection operator, i.e., ($\mathcal{S}(R \bowtie S)$). Alternatively, it may join the tuples based on the summary objects and then applies a standard selection operator ($\rho(\mathcal{J}(R, S))$).

• **Sort Operator ($\mathcal{O}_{f[,direction]}(R)$):** The summary-based sort operator orders the data tuples in R according to the summary-based function $f(r.\$)$. Function f must return values of a data type having a *full-ordering* property, e.g., number, string, and Boolean. Using the $\mathcal{O}$ sort operator, the $Q3$ query in the case study (Figure 2) can now be fully automated and answered in few seconds.

It is worth highlighting that these summary-based operators are new physical operators introduced to the InsightNotes engine. They are not implemented as UDFs within PostgreSQL DBMSs for the following fundamental reasons: (1) If the summary-based operators are implemented as UDFs, then their execution will be carried out and encapsulated within the standard SQL operators. As a result, none of the summary-based optimizations proposed in Section 5 would have been possible. (2) The annotation summaries are not like any other user-defined data types created through PostgreSQL extensibility. They are special tuple-based metadata information that requires extending the semantics of the core query operators [22]. That is why the core operators of InsightNotes in [22] do not manipulate the summaries through UDFs, and consequently, the newly proposed operators cannot be implemented as UDFs. And (3) The design choice of implementing the summary-based operators as new physical operators does not limit the extensibility of InsightNotes because the operators are defined at the summary-type level, i.e., Classifier, Snippet, and Cluster types. And thus, they apply to any driven instance under those types.

4. SUMMARY-BASED INDEX SCHEME

To enable efficient execution of the summary-based relational operators, we need to build a summary-based indexing scheme over the summary objects. In this paper, we will focus only on the Classifier-Type indexing scheme. The InsightNotes system will not automatically index all summary instances defined in the database. Instead, this process is triggered by DB admins using the following command:

```
Alter Table <tableName>
  [Add [Indexable] | Drop] <InstanceName>;
```

This extended SQL command is used in InsightNotes to link a Summary Instance SI to a given user's relation R (Refer to Section 2.1). The newly added optional clause `Indexable` will inform the system to build an index on SI's summary objects created over R's tuples.

Before we investigate possible indexing scheme, we briefly explain how the summary objects are currently stored in InsightNotes to optimize their propagation at query time. Referring to Figure 4(a), given a user's relation R, each tuple in R may have one or more summary objects attached to it according to number of summary instances linked to R. To optimize the propagation of the annotation summaries at query time, R's summary objects are stored in a de-normalized form in a corresponding catalog table *R_SummaryStorage*, as illustrated in Figure 4(b). Each tuple in R has a corresponding unique tuple in *R_SummaryStorage* linked together through unique tuple identifiers (OIDs). This scheme has two main advantages: (1) Since the summary objects are stored in tables separate from the data tables, there is no I/O or CPU overheads added to users' relations when queried in isolation, i.e., when the data is queried without annotation propagation, and (2) Since the summary objects are stored in a de-normalized form, there is no additional I/O or CPU overheads at query time to re-construct them from their primitive components. Thus, their propagations becomes more efficient as studied in [22].

4.1 Classifier-Type Indexing Scheme

Target Query: *The index will speedup summary-based selection operators in the form of* `"classLabel <Op> constant"`, *where* `classLabel` *is a classifier label within a classifier summary object, and Op is a comparison operator including* $\{=, >, <, \leq, \geq\}$. *The output are the data tuples whose classifier summary objects satisfy the given predicates. The index will also speedup summary-based join and sorting operators involving the indexed classifier column.*

Example 2: *Referring to Figure 4(a), assume we want to retrieve the data tuples having more than 5 associated questions. The SQL query will be:*

```
Select * From R r
   Where r.$.getSummaryObject('ClassBird2').
   getLabelValue('Question') > 5;
```

Baseline Indexing Scheme: A straightforward indexing strategy over the Classifier-type summary objects is to normalize their representation by replicating their components, i.e., the class labels and their counts, and storing them in a separate table (See Figure 4(c)). And then, we can build a standard B-Tree index on each of the columns, i.e., the `ClassLabel` and `Cnt` columns. Moreover, since most predicates over the Classifier-type objects will reference both columns, we may create a third system-maintained (derived) column that concatenates these two columns, and then index its values using the B-Tree index as illustrated in Figure 4(c).

The advantage of this scheme is that it uses the standard indexes without modifications. However, it has two major drawbacks. First, the storage overhead of the summary objects is doubled; one replicate is for efficient propagation, and another replica is for indexing. And second, starting from the index to reach the actual data tuples in relation R, we will need several join operations among multiple tables, which certainly degrades the query performance. The proposed Summary-BTree indexing scheme will overcome these limitations.

4.1.1 Summary-BTree Index Structure

The proposed *Summary-BTree* index is a variant of the standard B-Tree that can be directly built over the de-normalized representation of the Classifier-type summary objects. The structure of the index is depicted in Figure 4(d). Assume the index is built on top of the summary instance *ClassBird1* defined on Relation R. The creation of the index involves three steps:

○ **Itemization:** The Rep[] array within the object will be *itemized* by converting the array elements *(String classLabel, Integer AnnotationCnt)* to a sequence of text values in the form of `"classLable:ExtendedAnnotationCnt"` as illustrated in Figure 4(c) Step 1. The *ExtendedAnnotationCnt* will have an initial 3-character format to preserve the order among the integer values even after converting them into strings[1]. In Figure 4(d) Step 1, we illustrate the itemization of the *ClassBird1* summary object attached to tuple $r1$.

○ **Indexing:** The text values generated from the Itemization step will be inserted into the Summary-BTree index. The index follows the same structure and operations of the standard B-Tree. And hence, the B-Tree's maintenance algorithms, i.e., insertion and deletion, are all leveraged in the Summary-BTree index. The indexed values will appear in the leaf nodes of the index sorted alphabetically as depicted in the figure. The only exception compared to the standard B-Tree will be in the heap pointers stored in the leaf nodes, which are called *backward pointers* and described next.

○ **Backward Referencing:** We make use of the fact that the storage of the annotation summaries is entirely transparent from (and not directly query-able by) the end-users. Hence, we have the opportunity to optimize the internal structure of the proposed tables and indexes for efficient performance. A key trick in the Summary-BTree index is that the leaf nodes will point back to their annotated data tuples in Relation R instead of pointing back to the *R_SummaryStorage* table. For example, the index entries `"Disease:002"` and `"Disease:008"` will point back to tuple $R.r2$ and $R.r1$, respectively. These backward pointers will be created and maintained under the different operations as described in sequel [2].

The advantages of the Summary-BTree index are two fold: (1) It builds on the existing storage scheme of InsightNotes without the need to replicate or normalize the summary objects, and hence the optimized propagation performance is not affected. And (2) As the experimental evaluation will confirm (Section 6), the backward-referencing mechanism achieves up to 11x speedup in query performance compared to the baseline indexing scheme.

4.1.2 Summary-BTree Index Operations

To enable the backward-referencing mechanism, we developed an internal function, called *diskTupleLoc()*, within the database engine, which takes a tuple's identifier (OID) and returns its heap location. This function will be used inside the index's maintenance algorithms to create the correct backward pointers. Notice that this mechanism does not break the transparency concept in database systems since it is entirely encapsulated within the index structure and not exposed to the outside world (neither end-users nor database developers). The index is maintained under the following operations:

○ **Adding Annotation−Insertion:** Adding a new annotation on an un-annotated tuple in R results in inserting a new tuple in *R_SummaryStorage*. The system will then retrieve the heap location of the data tuple, itemize the indexed classifier summary object, and insert them into the Summary-BTree index as illustrated in Figure 4(d).

○ **Adding Annotation−Update:** Adding a new annotation on an already-annotated tuple in R will result in updating the corresponding summary objects in *R_SummaryStorage*. For example, if a new annotation highlighting a disease is added to $R.r1$, then the *ClassBird1*'s summary object will be updated by incrementing the count

[1]If the number of annotations assigned to a single classifier's label exceeds 999, then InsightNotes automatically increments the number of allocated characters and re-builds the index. However, it is a very rare operation.

[2]The SummaryStorage tables are still directly accessible using SQL queries, but for administrative tasks only. Such administrative queries use table-scan plans instead of index-scan plans.

Figure 4: Summary-Btree Index For Indexing The *Classifier* Type Summary Objects.

of the *Disease* class label to be 9. To update the index, the system will trigger a deletion and then re-insertion only for the modified class label—The other class labels within the object will remain untouched. For example, a deletion of key `"Disease:008"` and insertion of key `"Disease:009"` will take place.

◦ **Deleting Annotation or Tuple:** The deletion of an annotation will result in updating the corresponding summary objects in *R_SummaryStorage*. Therefore, the same procedure described above will be applied. Similarly, the deletion of a data tuple from R will result in deleting the corresponding tuple in *R_SummaryStorage*, and all its index entries will be deleted.

◦ **Summary-BTree Querying:** To answer an equality query over the index, e.g., `"classLabel = constant"`, a probing key will be formed by concatenating the two operands, i.e., `"classLabel:Extended_constant"`, where `Extended_constant` is the 3-character format of the constant value. In the case of a range query, e.g., `"constant1 > classLabel > constant2"`, two probing keys will be formed; a *starting key* as `"classLabel:Extended_constant1"`, and a *stopping key* as `"classLabel:Extended_constant2"`. All the keys in between will lead to the qualifying data tuples. If either of the starting or stopping keys is missing, then it will be replaced by `"classLabel:000"`, or `"classLabel:999"`, respectively.

4.1.3 *Summary-BTree Theoretical Bounds*

The Summary-BTree inherits the efficient logarithmic performance from the B-Tree index since they have similar structure. The following Theorem states the theoretical bounds of the index.

Theorem: *Assuming that the number of data tuples in the user's relation R is M, the number of Classifier-type summary objects is N, the number of class labels per summary object is k, and the disk page size in records is B, then the following theoretical bounds hold for a Summary-BTree index:*

◦ *Adding Annotation—Insertion is O($kLog_BkN + Log_BM$)*

◦ *Adding Annotation—Update is O($2Log_BkN + Log_BM$)*

◦ *Deleting data tuple is O($kLog_BkN + Log_BM$)*

◦ *Equality search is O(Log_BkN)* □

Proof: Assuming N summary objects and each object has k class labels, then the number of indexed keys is O(kN). Therefore, any single search, insertion or deletion will be bounded by O(Log_BkN). When adding a new annotation that triggers a new insertion in the SummaryStorage table, the k class labels will be inserted into the index which will cost O($kLog_BkN$). In contrast, if the added annotation will trigger an update of an existing class label, then only that label is deleted and then re-inserted, which will cost O($2Log_BkN$). Finally, when inserting into or deleting from the index tree, the system needs to retrieve the heap location of the data tuple. This operation uses a B-Tree index on the OID column in R with the cost of O(Log_BM).

5. SUMMARY-BASED QUERY OPTIMIZATION

When a query involves both the summary-based and the standard SQL operators, then the traditional transformation and equivalence rules alone will be of a very limited use. This is because the semantics of the new operators are unknown to current optimizers. For example, the current optimizer may not be able to use the standard *selection-pushdown* rule to push a selection operator below a join operator because there is a summary-based operator in-between. Another example is illustrated in Figure 5(a), where the query plan involves a summary-based sort $\mathcal{O}$ and selection $\mathcal{S}$ operators on top of a traditional join operator $\bowtie$. In this case the current optimizers cannot apply any of the known transformation rules to create equivalent query plans. In this section, we introduce several important equivalence rules involving the summary-based operators, and extend the query optimizer to leverage them and create a larger pool of possible query plans.

5.1 Extended Equivalence Rules

• **Rules for Summary-Based Selection ($\mathcal{S}_p(R)$):** Few important rules involving the $\mathcal{S}$ operator include:

$$\mathcal{S}_p(\sigma_c(R)) = \sigma_c(\mathcal{S}_p(R)) \quad (1)$$

$$\mathcal{S}_p(R \bowtie_c S) = \mathcal{S}_p(R) \bowtie_c S, \text{ iff } p \text{ is on instances in } R \text{ not in } S. \quad (2)$$

Proof: Rule 1 is correct since neither the σ operator changes the summaries' content nor the $\mathcal{S}$ operator changes the data's content. And thus, the commutativity property between the two operators apply. This rule enables the system to switch the order of predicates and use the available indexes—either on the data or the summaries—as needed. Rule 2 enables pushing the summary-based selection operator before the join operator. Rule 2 is correct since predicates p are on instances linked only to one of the two relations, say R. Therefore, when the $\bowtie$ operator merges the summary objects attached to the joined tuples, the summary objects related to p are guaranteed not to change since they have no counterparts on S. And hence, the rule applies.

• **Rules for Summary-Based Sort ($\mathcal{O}_{f[,direction]}(R)$):** We focus on an important case where an existing Summary-BTree index can provide R's tuples in an *interesting order* to the query, and hence the sort operator can be eliminated. The following rules state that the order of R's tuples is preserved under certain transformations. We use notation $\overline{R}^L$ to indicate that R has an *interesting order* w.r.t a classifier instance L.

$$\sigma_c(\overline{R}^L) = \overline{\sigma_c(R)}^L \quad (3)$$

$$\mathcal{S}_p(\overline{R}^L) = \overline{\mathcal{S}_p(R)}^L \quad (4)$$

$$\overline{R}^L \bowtie S = \overline{R \bowtie S}^L, \text{ iff } \bowtie \text{ preserves } R\text{'s order, and L is not on } S. \quad (5)$$

$$\mathcal{J}(\overline{R}^L, S) = \overline{\mathcal{J}(R,S)}^L, \text{ iff } \mathcal{J} \text{ preserves } R\text{'s order, and L is not defined on } S. \quad (6)$$

Proof: Rules 3 and 4 indicate that the selection operators (σ and $\mathcal{S}$) do not change the interesting order of R and preserve it in the output. This is guaranteed since these operators do not change the content of their summaries. For the join operators (Rules 5 and 6), the order w.r.t L is preserved only if two conditions are met: (1) The join algorithm preserves R's order, e.g., R is the outer relation of the join, and (2) Relation S does not have the summary instance L defined on it. If the 2^{nd} condition is not met, then the join operators ($\bowtie$ or $\mathcal{J}$) would merge the summary objects of L, and thus the order may not be preserved. Otherwise, Rules 5 and 6 also applies.

Example 4: *Assume a query Q that joins Relation R depicted in Figure 4 with another relation $S(c1, c2)$ based on data attributes $R.c_1 = S.c_1$. Then, Q selects only the tuples with more than five disease annotations, i.e.,* `ClassBird1.disease > 5`*, and produces the output sorted by the count of these disease annotations. An initial query plan based on the sequence presented above is illustrated in the following figure (Figure 5(a)). Then, consider the following two cases:*
<u>*Case I*</u>*: Relation S has the* ClassBird1 *summary instance defined on it. In this case, the summary-based selection operator cannot be pushed below the join operator, and the system will use the initial plan in Figure 5(a).*
<u>*Case II*</u>*: Relation S does not have the* ClassBird1 *summary instance defined on it. In this case, the system will use Rule 2 to push the summary-based selection operator before the join. And assuming that* ClassBird1 *summary instance on R is indexed, then the index can be used to retrieve the tuples with more than five disease annotations (in a sorted order). Then, based on Rule 5, the join operator preserves the order of the tuples, and hence the summary-based sort operator can be removed as illustrated in Figure 5(b).*

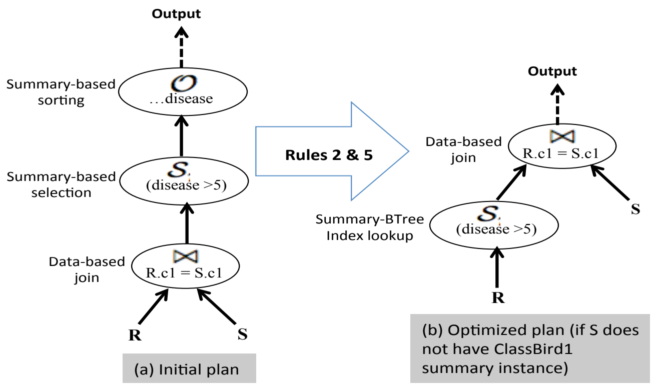

Figure 5: Rule-Based Equivalent Plans in InsightNotes.

• **Rules for Summary-Based Filter ($\mathcal{F}_p(R)$):** Few important rules involving the $\mathcal{F}$ operator include:

$$\mathcal{F}_p(R \bowtie_c S) = \mathcal{F}_p(R) \bowtie_c S, \text{ iff } p \text{ is on instances in } R \text{ not in } S. \quad (7)$$

$$\mathcal{F}_p(R \bowtie_c S) = \mathcal{F}_p(R) \bowtie_c \mathcal{F}_p(S), \text{ iff } p \text{ is structural predicate.} \quad (8)$$

Proof: Rules 7 and 8 address pushing the filter operator before the join. Both rules aim for eliminating unnecessary summary objects—and hence their processing cost in the query pipeline—as early as possible. Rule 7 can be proved in similar way to Rule 2, i.e., the $\bowtie$ operator is guaranteed not to alter the summary objects related to predicate p since they are attached to only relation R. Similarly, the $\mathcal{F}$ operator does not change the data's content, and hence the join predicates c are not affected. Therefore Rule 7 applies.

Rule 8 indicates that if the predicate is *structural*—A *structural* predicate is defined as a predicate on the *InstanceID* or the *SummaryType* of the summary object—then p can be pushed to both sides before the join operation. For example, referring to Figure 4, if a query is interested only in the summary objects of instance *ClassBird1*, then all other summaries of instances *ClassBird2* and *TextSummary1* can be dropped as early as possible. Rule 8 can be proved in the same way as Rule 7.

• **Rules for Summary-Based Join ($\mathcal{J}_p(R, S)$):** Few important rules involving the $\mathcal{J}$ operator include:

$$\sigma_c(\mathcal{J}_p(R,S)) = \mathcal{J}_p(\sigma_c(R), S), \text{ iff } c \text{ is on } R\text{'s attributes.} \quad (9)$$

$$\mathcal{S}_{p1}(\mathcal{J}_{p2}(R,S)) = \mathcal{J}_{p2}(\mathcal{S}_{p1}(R), S), \text{ iff } p1 \text{ is on instances in } R \text{ not in } S. \quad (10)$$

$$T \bowtie_c \mathcal{J}_p(R,S) = \mathcal{J}_p((T \bowtie_c R), S), \text{ iff } p \text{ is on instances not in } T \text{ and } c \text{ does not involve } S\text{'s attributes.} \quad (11)$$

Proof: Rules 9 and 10 address pushing the selection operators (σ or $\mathcal{S}$) before the summary-based join operator whenever possible. It is always a valid transformation in the case of the σ operator as long as the predicates c are on one of the two relations (Rule 9). This is because the σ and the $\mathcal{J}$ operate on disjoint pieces of the tuple, i.e., the data values, and the summaries, respectively. Rule 10 is correct since the summary objects related to $p1$ are only attached to relation R. And thus, the $\mathcal{J}$ is guaranteed not to alter these objects after the join. Rule 11 states the conditions for switching the order between summary- and data-based join operators. The order can be switched iff the summary-based join predicates p involve instances not defined on T. And thus, joining early with T ($T \bowtie_c R$) is guaranteed not to affect the evaluation of p.

Figure 6: Example of Classifier-Type Maintained Statistics.

5.2 Cost Model and Cardinality Estimation

Statistics Collection: The equivalence rules presented in Section 5.1 enable the query optimizer to generate a larger pool of equivalent query plans. The next step is to estimate the cost of the new summary-based operators in order to select the cheapest plan. Towards this goal, InsightNotes maintains several statistics over the summary objects attached to a given relation R. These statistics are similar to those maintained by traditional DBMSs except that they capture the internal semantics of the summary objects.

Demonstrating over an example, assume relation R has three summary instances linked to it as illustrated in Figure 6. Then, for each summary instance (one column in Figure 6), InsightNotes maintains the average object size (`AvgObjectSize`). In the case of Classifier-type objects, e.g., *ClassBird1* and *ClassBird2*, the size is fixed for all objects within one instance. In contrast, for the Snippet-type and Cluster-type objects, the size may differ from one object to another. Moreover, the system maintains several statistics for each classifier label within the Classifier-type objects. For example, for *ClassBird1*, four data structures are maintained—one for each class label. Each data structure holds some statistics on the *count* field associated with that label, which include `{Min, Max, NumDistinct, Equi-Width Histogram}` as depicted in Figure 6. These statistics are maintained whenever a summary object is updated.

Cardinality and Cost Estimation: To avoid re-inventing the wheel, the new summary-based operators leverage the same heuristics that the standard SQL operators use to estimate their cardinalities and costs. For example, the filter operator $\mathcal{F}$ uses the same heuristics as the standard projection operator π, e.g., based on the *AvgObjectSize* statistics, the $\mathcal{F}$ operator estimates the size of the new tuples and the number of needed disk blocks. Similarly, the summary-based selection operator $\mathcal{S}$ uses the same heuristics as the standard selection operator σ, e.g., referring to the $\mathcal{S}$ operator in Example 4, the system uses the maintained statistics (`{Min, Max, NumDistinct, Equi-Width Histogram}`) over the *ClassBird1.Disease* label to estimate the number of output tuples having more than 5 disease-related annotations. Moreover, if a Summary-BTree index is used to answer this predicate, then the number of performed I/Os can be estimated based on the index's theoretical bounds.

The summary-based join operator $\mathcal{J}$ also follows the same heuristics as the standard join operator $\bowtie$, e.g., the size of joining two relations R and S based on an equality join on `ClassBird2.Provenance` can be estimated by multiplying the size of both relations, and then dividing by the largest value between the `NumDistinct` statistics on `ClassBird2.Provenance` from both sides. Currently, InsightNotes supports only two implementation choices for the $\mathcal{J}$ operator, which are either a block nested-loop join, or an index-based join.

6. EXPERIMENTS

The proposed extensions are implemented within the InsightNotes prototype engine [22], which is based on the open-source PostgreSQL DBMS. The experiments are conducted using an AMD Opteron Quadputer compute server with two 16-core AMD CPUs, 128GB memory, and 2 TBs SATA hard drive.

Application Datasets: We use annotated database that stores information related to 10s of thousands of birds worldwide. The largest annotated table in the database is the *Birds* table that stores the birds' basic information. The table consists of 45,000 tuples, each consisting of 12 attributes, e.g., scientific name, Ids across different systems, description, genus, family, and habit. The table size in the database is approximately 450MBs. The collected number of annotations is approximately 9x10^6 annotations describing a wide range of bird related information, e.g., color, body shape or weight, certain behavior or sound, eating habits, geographic location, or observed diseases. The size of each annotation varies between 150 and 8,000 characters. The total size of the raw annotations table (the 9x10^6 annotations) is around 5GBs.

Summarization Techniques: InsightNotes has several integrated data mining techniques for annotation summarization, e.g., the Naive Bayes [10] technique for annotation classification, the CluStream technique [2] for incremental clustering of annotations, and the LSA (Latent Semantic Analysis) technique [18] for text summarization and snippet creation. For the purpose of our experiments, we link the *Birds* table with two summary instances: (1) A Classifier summary instance *ClassBird1* that classifies each annotation to one of the labels: {*'Disease', 'Anatomy', 'Behavior', 'Other'*}, and (2) A Snippet summary instance *TextSummary1* that summarizes each annotation larger than 1,000 characters and creates a snippet that has a maximum of 400 characters. We then create a Summary-BTree index over *ClassBird1*.

Index Creation Overhead: The first set of experiments study the overheads associated with the creation of the summary-based index (Figures 7, 8, and 9). In the experiments, we vary the number of annotations (over the x-axis) between 450x10^3 (corresponding to 10 annotations per tuple on average), to 9x10^6 (corresponding to 200 annotations per tuple on average). Figure 7 illustrates the storage overhead of both the *Baseline* and *Summary-BTree* schemes discussed in Section 4.1. In the former scheme, the summary objects are replicated and stored in a normalized form, and then a standard B-Tree index is created over them. In contrast, in the latter scheme, a Summary-BTree index is created over the de-normalized representation of the summary objects. As the results show, the index size in both cases is almost the same. However, the proposed *Summary-BTree* scheme saves up to 65% of the storage overhead as it requires no replication of the data. The results also show that the storage overhead is almost fixed under the different sizes of the raw annotations. The reason is that once each data tuple has an attached classifier summary object, then the number and size of the summary objects becomes fixed and will not change. The increase in the number of annotations only changes the integer value assigned to the class labels, which does not affect the size.

In Figures 8 and 9, we measure the time overhead of creating the indexes in *bulk* and *incremental* modes, respectively. In the *bulk* mode (Figure 8), the raw annotations and the summary objects will be first created, and then the indexes will be built. This is the recommended mode for initial uploading of large datasets into the database. We measured, over the y-axis, the relative time of creating the index to the time of uploading the raw annotations and creating the summary objects. The indexing time under the *Summary-BTree* scheme involves the time for itemization, insertion

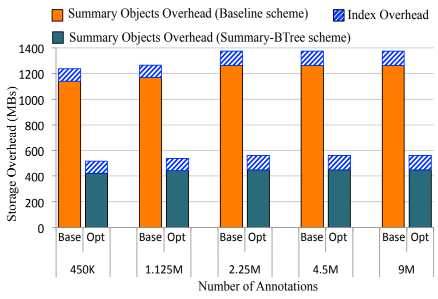

Figure 7: Storage Overhead.

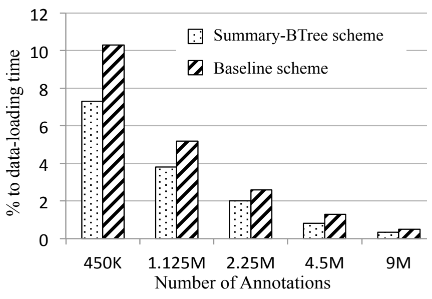

Figure 8: Bulk Index Creation.

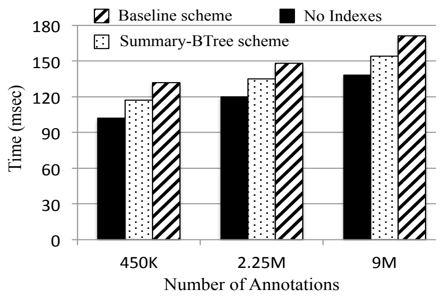

Figure 9: Incremental Indexing.

of indexed keys, and computing the backward references. For the *Baseline* scheme, the indexing time includes the de-normalization and storage in other tables, and the insertion of the indexed keys. The figure illustrates that the creation of the Summary-BTree index is more efficient than the baseline index by up to 35%.

The performance of the incremental indexing is studied in Figure 9. We considered the cases of inserting annotations with: (1) No indexes, (2) A Summary-BTree index, and (3) A Baseline B-Tree index. For each data point in the figure, we insert 100 annotations, measure the insertion time of each annotation under the three cases, and then report the average over the 100 insertions. As the figure shows, the indexing overhead using the Summary-BTree index is approximately 10% to 15% of the insertion time, while the baseline indexing scheme has around 20% to 37% overhead due to the de-normalization step.

Query Performance: The next set of experiments study the effect of utilizing the Summary-BTree index to speedup queries involving summary-based predicates (Figures 10, 11, 12, and 13). The results in Figure 10 illustrate the performance gain from the Summary-BTree index using a Select-Project (SP) query, where the selection predicate is in the form of: `"r.$.getSummaryObject('ClassBird1').getLabelValue('Disease') = constant"`. The query's response time is presented in the y-axis (in Log scale) under three cases: (1) using no indexes, (2) using the *Baseline* standard B-Tree index, and (3) using the Summary-BTree index. We experimented with different query selectivities, i.e., 0.1%, 1%, and 5%, and the differences were minor in each case. Therefore, in Figure 10 we report the results of only the 1% selectivity (around 450 data tuples). The figure illustrates that the Summary-BTree index has approximately 3x speedup over the baseline index. This is because the latter index involves more levels of indirection, and hence requires more join operations to reach the desired data tuples. As expected both indexes achieve around two orders of magnitude speedup compared to the *NoIndex* case.

The experiment in Figure 11 studies the performance of a Select-Project (SP) query involving two conjunctive predicates: (1) A range predicate selecting the tuples having a number of anatomy-related annotations within a given range, i.e., `"r.$.getSummaryObject('ClassBird1').getLabelValue('Anatomy') in [x,y]"`, and (2) A keyword search predicate over the text summarization instance, i.e., `"r.$.getSummaryObject('TextSummary1').containsUnion(kw1, ...)"`. When the index scan over *ClassBird1* is disabled (the *NoIndex* case), InsightNotes uses a table scan followed by a summary-based selection operator $\mathcal{S}$ to apply both predicates. In contrast, when the index scan is enabled, InsightNotes uses the index to evaluate the range predicate and on top of that a $\mathcal{S}$ operator to apply the keyword search predicate. The results illustrate that the *Summary-BTree* index is around 2x faster than the baseline index.

It is worth noting that in the previous experiments, the *Baseline* indexing scheme is used only to evaluate the selection predicates involved in the query. Yet, the for the summary propagation purpose to end-users, InsightNotes still reads the summary objects from its de-normalized storage, i.e., *R_SummaryStorage* (Refer to Figure 4). And hence, both indexes do not pay the cost of building the summary objects from their primitive components. To confirm that depending only on the *Baseline* scheme (the normalized storage of summary objects) can significantly slowdown the summary propagation, we performed the experiment in Figure 12. In the experiment, we used the same query as in Figure 11 and compared between the two indexing schemes. The only difference is that the *Baseline* scheme in this experiment will not only evaluate the predicates, but also form the summary objects for propagation. In this case, the *Baseline* scheme showed around 7x slower performance compared to the Summary-BTree indexing scheme.

In Figure 13, we study the effectiveness of augmenting the Summary-BTree index with backward pointers that point directly to the annotated data tuples instead of the conventional pointers that point to the indexed objects. We use the same SP query used in Figures 10. In the experiments, we consider four cases. The first case is that the index uses the backward pointers, and the annotation summaries are propagated along with the query's result (labeled `Backward-Propagation`). The second case is that the index uses the backward pointers, and the annotation summaries are not propagated along with the query's result (labeled `Backward-NoPropagation`). The other two cases are the same of the above except that the index uses the conventional pointers instead of the backward pointers, i.e., the Summary-BTree index pointers will point to the *ClassBird1* summary objects. The results in Figure 13 show that propagating the annotation summaries has almost the same cost under both the backward and conventional pointers. The reason is that the join operation between the data table and its SummaryStorage table has a 1-1 cardinality, and hence the performance is very similar regardless of which table is used as the outer table in the join. In contrast, if the summary propagation is not required, then the backward pointers will save unnecessary join with the SummaryStorage table, which achieves up to 4x speedup in query execution.

Effectiveness of Query Optimization and Transformation Rules: In Figures 14 and 15, we study the effect of some of the new transformation rules and query optimizations proposed in Section 5. The first experiment (Figure 14) measures the performance of the query demonstrated in Example 4 in Section 5. Relations R and S in the rules correspond to the *Birds* and *Synonyms* tables, respectively. The *Synonyms* table consists of approximately 225,000 tuples and linked to the *Birds* table in a many-to-one relationship.

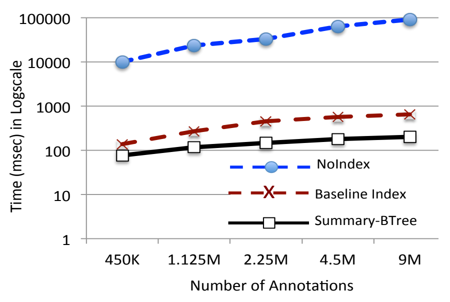

Figure 10: Index vs. No Index (SP Query)

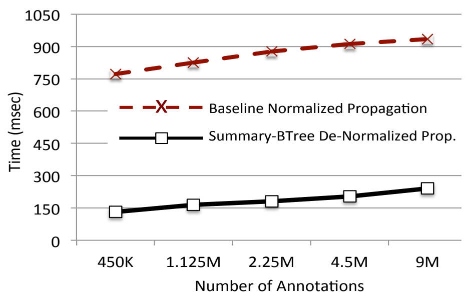

Figure 12: De-Normalized Propagation.

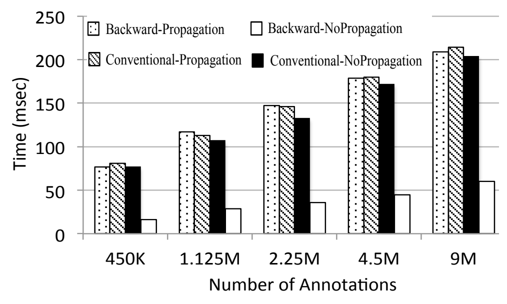

Figure 13: Effectiveness of Backward Ptrs.

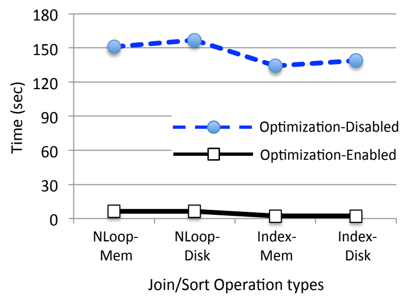

Figure 14: Optimization Rules {2, 5}.

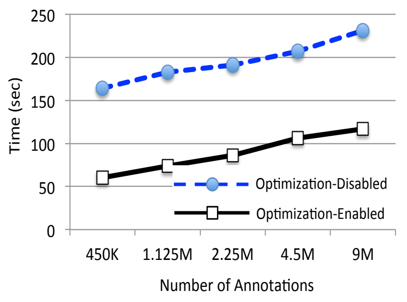

Figure 15: Optimization Rule {11}.

Only the *TextSummary1* instance is linked to the *Synonyms* table, and hence Optimization Rules 2 and 5 can be applied. The experiment compares the response time of the default query plan (Figure 5(a)) against that of the optimized query plan (Figure 5(b)). We set the dataset size to 9x10^6 annotations, and we consider two cases for each of the join and sort operators as illustrated in the x-axis. The join operator either uses an index-based algorithm with an index on the join column in S (labeled `Index`), or a block nested-loop join algorithm (labeled `NLoop`), and the sort operator either uses a memory-based (labeled `Mem`) or disk-based (labeled `Disk`) sort algorithms. The figure illustrates the effectiveness of the transformation and optimization rules in all of the four cases to speedup the query's response time by a factor of 15x.

In Figure 15, we study the effectiveness of Optimization Rule 11, where the order between data- and summary-based join operators can be switched. Relations R and S correspond to the same tables as in the previous experiment, and the summary-based join between them involves a summary-based keyword search on their combined *TextSummary1* summary objects—No summary-based index can be used in this case. Relation T is a replica to relation R, and hence they have a 1-1 relationship through an indexed column for the birds' unique identifiers. With no optimizations, the default plan performs the $\mathcal{J}(R, S)$ operation first using a block nested-loop join, and then performs the data-based join ($\bowtie$) with T. In contrast, the optimized plan switches the join order to make use of the available index on the birds' identifiers in T. Thus, the join operation $R \bowtie T$ is performed first using an index-based join, and then the results is summary-based joined ($\mathcal{J}$) with S. The performance results in Figure 15 indicate that the optimized plan achieves around 3.5x speedup compared to the default plan.

Usability Case Study: Similar to the motivating example presented in Section 1.1, we performed a usability case study to show direct impact of the newly added features on users' experience. We formed a team of 20 students divided into two groups, where one group uses the basic InsightNotes engine while the other group uses the extended system (called *InsightNotes+*). Each student will answer each of the three queries highlighted in Figure 16. In the figure, we report the average time taken by each group (including the time of writing the query), and the results' accuracy.

Query Semantics	# Qualifying data tuples	InsightNotes Group	InsightNotes+ Group
Q1: Report the data tuples sorted based on the number of attached disease-related annotations	100	Time: 5.2 min Accuracy: 100%	Time: 40 sec Accuracy: 100%
Q2: Join version 1 of the data (V1) with version (V2) and report the same objects, i.e., V1.ID = V2.ID, having different number of provenance-related annotations	5	Time: 8.1 min Accuracy: 100% ***(Reports 450 Tuples)***	Time: 54 sec Accuracy: 100%
Q3: Select the birds' records having more than 3 question-related annotations	10	--- ***(Reports 45K Tuples)***	Time: 52 sec Accuracy: 100%

Figure 16: Usability Case Study.

As the results show, both groups are able to answer $Q1$ and $Q2$ queries with 100% accuracy. However, the *InsightNotes* group took significantly longer time to produce the results—which may not be acceptable in many applications. The reason is that InsightNotes cannot fully answer any of these queries, and thus a manual effort is needed to post-process the answer produced from InsightNotes. For example, in $Q1$ the students need to manually sort the 100 data tuples based on the number of their disease-related annotations (summary-based sorting), while in $Q2$, they needed to go over the joined tuples (based on the ID data columns)—which are 450 tuples—and manually check the second join predicate (based on the number of provenance-related annotations) and report the 5 qualifying tuples. For $Q3$, since InsightNotes cannot apply a summary-based selection operation, all the data tuples (45,000) will be reported, and it is impractical to manually select the desired tuples from them. On the other hand, the *InsightNotes+* group is able to answer the three queries in few seconds.

7. RELATED WORK

Annotation management has been extensively studied in the context of relational DBMSs [4, 9, 14, 15, 21]. Several of these systems focus on extending the relational algebra and query semantics for propagating the annotations along with the queries' answers [4, 9, 14, 21]. The Mondrian system [14] has proposed extensions to treat the annotations as first-class citizens, where users can query and manipulate the annotations through newly defined operators. Other systems address the annotation propagation in the context of containment queries [21], logical views [7], or automated copying to newly inserted data [11, 17]. The systems proposed in [8, 13] support special types of annotations, e.g., treating annotations as data and annotating them [8], and capturing users' beliefs as annotations [13]. All of these systems share a common limitation, which is that they all manipulate the raw annotations. Therefore, they do not provide any support for summarizing, extracting useful knowledge, or applying analytics over the raw annotations. The InsightNotes system and its extensions proposed in this paper address such limitations, and enable end-users to query the annotation summaries in novel ways, which otherwise were not possible.

In the domains of e-commerce, social networks, and entertainment systems, e.g., [12, 19], the annotations are usually referred to as *tags*. These systems deploy advanced mining and summarization techniques for extracting the best insight possible from the annotations to enhance users' experience. They use such extracted knowledge to take actions, e.g., providing recommendations and targeted advertisements. However, unlike relational DBs, the retrieval mechanisms in these systems are typically straightforward and do not involve complex processing or transformations, i.e., no advanced query processing is required over the annotations summaries once created. Therefore, these techniques do not address the complex query processing and optimization challenges prevalent to scientific relational DBs that are addressed in this paper.

Scientific systems and workflows have also leveraged the concept of semantic and ontology-based annotations, e.g., [3, 6]. These systems use semantic annotations to either summarize complex workflows [3], or help in building and verifying workflows [6]. These systems are based on process-centric annotations, e.g., annotations capturing the semantics of each function in a workflow, the structure of their input and output arguments, etc. In contrast, InsightNotes manages data-centric annotations that are independent from how the data is processed. Nevertheless, the proposed summary-based query operators, access methods, and optimizations are all new and have not beed addressed in current systems.

8. CONCLUSION

The large volume, increasing complexity, and hidden semantics of the emerging annotation repositories in modern applications create unprecedented challenges to annotation management techniques. In this paper, we proposed extensions to the *InsightNotes* system for elevating the annotation summaries from being *"propagate-only"* objects to be *"first-class"* citizens. Hence, it becomes feasible for applications to express complex queries over both the data and their attached annotation summaries, which otherwise is not possible. The key contributions include: (1) Proposing manipulation functions and query operators to seamlessly operate on the summary objects at query time, (2) Developing specialized summary-based indexing scheme and access methods for efficient predicate evaluation and retrieval of the summary objects, and (3) Introducing an extended query optimizer that enables advanced optimizations for queries involving both the summary-based and the standard query operators. The extensions are implemented within the InsightNotes prototype engine, and the results have demonstrated the practicality and efficiency of the proposed extensions and techniques w.r.t both the system's performance, and users' experience.

As part of future work, we plan to enrich the system with more implementation choices for the summary-based operators, enable multi-level (hierarchical) summarization, and extend the querying mechanisms over the multi-level model.

ABSTRACT

Data cleaning and data integration have been the topic of intensive research for at least the past thirty years, resulting in a multitude of specialized methods and integrated tool suites. All of them require at least some and in most cases significant human input in their configuration, during processing, and for evaluation. For managers (and for developers and scientists) it would be therefore of great value to be able to estimate the *effort* of cleaning and integrating some given data sets and to know the pitfalls of such an integration project in advance. This helps deciding about an integration project using cost/benefit analysis, budgeting a team with funds and manpower, and monitoring its progress. Further, knowledge of how well a data source fits into a given data ecosystem improves source selection.

We present an extensible framework for the automatic effort estimation for mapping and cleaning activities in data integration projects with multiple sources. It comprises a set of measures and methods for estimating integration complexity and ultimately effort, taking into account heterogeneities of both schemas and instances and regarding both integration and cleaning operations. Experiments on two real-world scenarios show that our proposal is two to four times more accurate than a current approach in estimating the time duration of an integration process, and provides a meaningful breakdown of the integration problems as well as the required integration activities.

1. COMPLEXITY OF INTEGRATION AND CLEANING

Data integration and data cleaning remain among the most human-work-intensive tasks in data management. Both require a clear understanding of the semantics of schema and data – a notoriously difficult task for machines. Despite much research and development of supporting tools and algorithms, state-of-the-art integration projects involve significant human resource cost. In fact, Gartner reports that 10% of all IT cost goes into enterprise software for data integration and data quality[1,2], and it is well recognized that most of those expenses are for human labor. Thus, when embarking on a data integration and cleaning project, it is useful and important to estimate in advance the effort and cost of the project and to find out which particular difficulties cause these. Such estimations help deciding whether to pursue the project in the first place, planning and scheduling the project using estimates about the duration of integration steps, budgeting in terms of cost or manpower, and finally monitoring the progress of the project. Cost estimates can also help integration service providers, IT consultants, and IT tool vendors to generate better price quotes for integration customers. Further, automatically generated knowledge of how well and how easy a data source fits into a given data ecosystem improves source selection.

However, "*project estimation for [. . .] data integration projects is especially difficult, given the number of stakeholders involved across the organization as well as the unknowns of data complexity and quality.*" [14]. Any integration project has several steps and tasks, including requirements analysis, selection of data sources, determining the appropriate target database, data transformation specifications, testing, deployment, and maintenance. In this paper, we focus on exploring the database-related steps of *integration* and *cleaning* and automatically estimate their effort.

1.1 Challenges

There are simple approaches to estimate in isolation the complexity of individual mapping and cleaning tasks. For the mapping, evaluating its complexity can be done by counting the matchings, i.e., correspondences, among elements. For the cleaning problem, a natural solution is to measure its complexity by counting the number of constraints on the target schema. However, as several integration approaches have shown, the interactive nature of these two problems is particularly complex [5, 11, 13]. For example, a data exchange problem takes as input two relational schemas, a transformation between them (a mapping), a set of target constraints, and answers two questions: whether it is possible to compute a valid solution for a given setting and how. Interestingly, to have a solution, certain conditions must hold on the target constraints, and extending the setting to more complex languages or data models bring tighter restrictions on the class of tractable cases [6, 12].

In our work, the main challenge is to estimate complexity and effort in a setting that goes beyond these ad-hoc studies while satisfying four main requirements:

Generality: We require independence from the language used to express the data transformation. Furthermore, real cases often fail the existence of solution tests considered in formal frameworks,

[2] *http://www.gartner.com/newsroom/id/2292815*

10.5441/002/edbt.2015.07

e.g., weak acyclicity condition [11], but an automatic estimation is still desirable for them in practice.

Completeness: Only a subset of the constraints that hold on the data are specified over the schema. In fact, business rules are commonly enforced at the application level and are not reflected in the metadata of the schemas, but should nevertheless be considered.

Granularity: Details about the integration issues are crucial for consumption of the estimation. For a real understanding and proper planning, it is important to know which source and/or target attributes are cause of problems and how, e.g., phone attributes in source and target schema have different formats. Existing estimators do not reason over actual data structures and thus make no statements about the causes of integration effort.

Configurability and extensibility: The actual effort depends on subjective factors, such as the capabilities of available tools and the desired quality of the output. Therefore, intuitive, yet rich configuration settings for the estimation process are crucial for its applicability. Moreover, users must be able to extend the range of problems covered by the framework.

These challenges cannot be tackled with existing syntactical methods to test the existence of solutions, as they work only in specific settings (*Generality*), are restricted to declarative specifications over the schemas (*Completeness*), and do not provide details about the actual problems (*Granularity*). On the other hand, as systems that compute solutions require human interaction to finalize the process [8, 13], they cannot be used for estimation purpose and their availability is orthogonal to our problem (*Configurability*).

1.2 Approaching Effort Estimation

Figure 1 presents our view on the problem of estimating the effort of data integration. The starting point is an integration scenario with a target database and one or more source databases. The right-hand side of the figure shows the actual integration process performed by an integration specialist, where the goal is to move all instances of the source databases into the target database. Typically, a set of integration tools are used by the specialist. These tools have access to the source and target and support her in the tasks. The process takes a certain effort, which can be measured, for instance as amount of work in hours or days or in a monetary unit.

Our goal is to find that effort without actually performing the integration. Moreover, we want to find and present the problems that cause this effort. To this end, we developed a two-phase process as shown on the left-hand side of Figure 1.

The first phase, the *complexity assessment*, reveals concrete integration challenges for the scenario. To address *generality*, these problems are exclusively determined by the source and target schemas and instances; if and how an integration practitioner deals with them is not addressed at this point. Thus, this first phase is independent of external parameters, such as the level of expertise of the specialist or the available integration tools. However, it is aided by the results of schema matching and data profiling tools, which analyze the participating databases and produce metadata about them (to achieve *completeness*). The output of the complexity assessment is a set of clearly defined problems, such as number of violations for a constraint or number of different value representations. This detailed breakdown of the problems achieves *granularity* and is useful for several tasks, even if not interpreted as an input to calculate actual effort. Examples of application are *source selection* [9], i.e., given a set of integration candidates, find the source with the best 'fit'; and support for *data visualization* [7], i.e., highlight parts of the schemas that are hard to integrate.

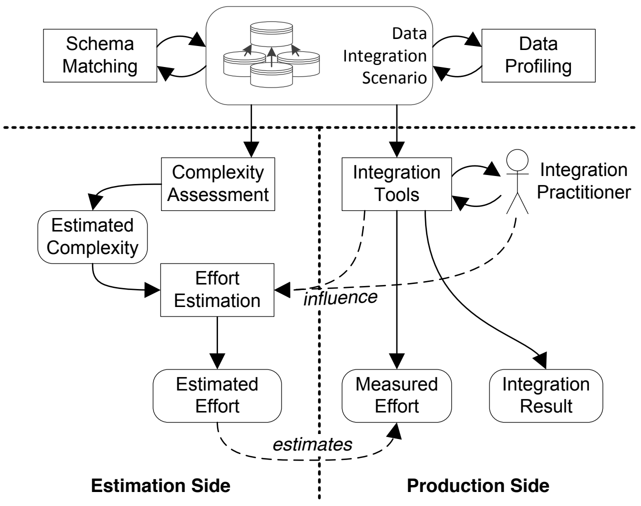

Figure 1: Overview of effort estimation and execution of data integration scenarios.

The second phase, *effort estimation*, builds upon the complexity assessment to estimate the actual effort for overcoming the previously revealed integration challenges in some useful unit, such as workdays or monetary cost. Thereby, this phase addresses *configurability* by taking external parameters into account, such as the experience of the integration practitioner and the features of the integration tools to be used.

1.3 Contributions and structure

Section 2 presents related work and shows that we are the first to systematically address a dimension of data integration and cleaning that has been passed over by the database community but is relevant to practitioners. In particular, we make the following contributions:

- Section 3 introduces the extensible Effort Estimation framework (EFES), which defines a two-dimensional modularization of the estimation problem.
- Section 4 describes an estimation module for structural conflicts between source and target data. This module incorporates a new formalism to compare schemas in terms of mappings and constraints.
- Section 5 reports an estimation module for value heterogeneities that captures formatting problems and anomalies in data that may be missed by structural conflicts.

These building blocks have been evaluated together in an experimental study on two real-world datasets and Section 6 reports on the results. Finally, we conclude our insights in Section 7.

2. RELATED WORK

When surveying computer science literature, a pattern becomes apparent: much technology claims (and experimentally shows) to reduce human effort. The veracity of this claim is evident – after all, any kind of automation of tedious tasks is usually helpful. While for scientific papers this reduction is enough of a claim, the absolute measures of effort and its reduction are rarely explained and measured.

General effort estimation. There are several approaches for effort estimation in different fields, however, none of them considers information coming from the datasets.

In the software domain, an established model to estimate the cost of developing applications is COCOMO [3, 4], which is based on parameters provided by the users such as the number of lines of existing code. Another approach decomposes an overall work task into a smaller set of tasks in a "work breakdown structure" [16]. The authors manually label business requirements with an effort class of simple, medium, or complex, and multiply each of them by the number of times the task must be executed.

In the ETL context, Harden [14] breaks down a project into various subtasks, including requirements, design, testing, data stewardship, production deployment, but also the actual development of the data transformations. For the latter he uses the number of source attributes and assigns for each attribute a weighted set of tasks (Table 1). In sum, he calculates slightly more than 8 hours of work for each source attribute.

Task	Hours per attribute
Requirements and Mapping	2.0
High Level Design	0.1
Technical Design	0.5
Data Modeling	1.0
Development and Unit Testing	1.0
System Test	0.5
User Acceptance Testing	0.25
Production Support	0.2
Tech Lead Support	0.5
Project Management Support	0.5
Product Owner Support	0.5
Subject Matter Expert	0.5
Data Steward Support	0.5

Table 1: Tasks and effort per attribute from [14].

One can find other lists of criteria to be taken into account when estimating the effort of an integration project[3]. These include factors we include in our complexity model, such as number of different sources and types, duplicates, schema constraints, and others we exclude for sake of space from our discussion, such as project management, deployment needs, and auditing. There are also mentions of factors that influence our effort model, such as familiarity with the source database, skill levels, and tool availability. However, merely providing a list of factors is only a first step, whereas we provide novel measures for the database-specific causes for complexity and effort. In fact, existing methods: (i) lack a direct numerical analysis of the schemas and datasets involved in the transformation and cleaning; (ii) do not regard the properties of the datasets at a fine grain and cannot capture the nature of the possible problems in the scenario, (iii) do not consider the interaction of the mapping and the cleaning problems.

Schema-matching for effort estimation. In our work, we exploit schema matching to bootstrap the process. This is along the lines of what authors of matchers suggested. For example, in [24] the authors have pointed out the multiple usages of schema matching tools beyond the concrete generation of correspondences for schema mappings. In particular, they mention "project planning" and "determining the level of effort (and corresponding cost) needed for an integration project". In a similar fashion, in the evaluation of the similarity flooding algorithm, Melnik et al. propose a novel measure "to estimate how much effort it costs the user to modify the proposed match result into the intended result" in terms of additions and deletions of matching attribute pairs [19].

Data-oriented effort estimation. In [25], the authors offer a "back of the envelope" calculation on the number of comparisons needed to be performed by human workers to detect duplicates in a dataset. According to them, the estimate depends on the way the potential duplicates are presented, in particular their order and their grouping. Their ideas fit well into our effort model and show that specific tooling indeed changes the needed effort, independently of the complexity of the problem itself. Complementary work on source selection has focused on the benefit of integrating a new source based on its marginal gain [9, 23].

Data-cleaning and data-transformation. Many systems (e.g., [8, 13]) address the problem of detecting violations over the data given a set of constraints, as we also do in one of our modules for complexity estimation. The challenge for these systems is mostly the automatic repair step, i.e., how to update the data to make it consistent wrt. the given constraints with a minimal number of changes. None of these systems provide tools to estimate the complexity of the repair nor the user effort before actually executing the methods to solve the integration problem. In fact, the challenge is that solving the problem involves the users, and estimating this effort (even in presence of these tools) is our main goal. Similar problems apply to data exchange and data transformation [1, 15].

In the field of model management, the use of metamodels has been investigated to represent in a more general language several alternative data models [2, 21]. Our cardinality-constrained schema graphs (Section 4) can be seen as a proposal for a metamodel with a novel static analysis of cardinalities to identify problems in the underlying schemas and the mapping between them.

3. THE EFFORT ESTIMATION FRAMEWORK

Real-world data integration scenarios host a large number of different challenges that must be overcome. Problems arise in common activities, such as the definition of a mapping between different schemas, the restructuring of the data, and the reconciliation of their value format. We first describe these problems and then introduce our solution.

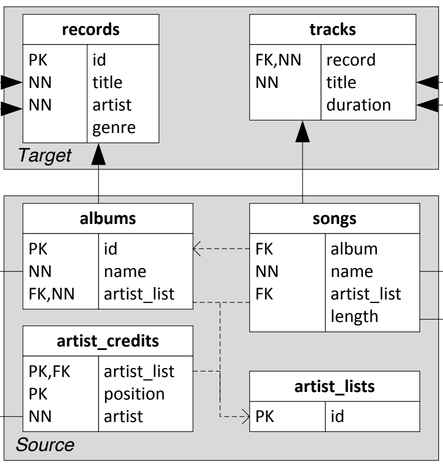
3.1 Data Integration Scenario

A *data integration scenario* comprises: (i) a set of source databases; (ii) a target database, into which the source databases shall be integrated; and (iii) correspondences to describe how these sources relate to the target. Each *source database* consists of a relational schema, an instance of this schema, and a set of constraints, which must be satisfied by that instance. Likewise, the *target database* can carry constraints and possibly already contains data as well that satisfies these constraints. Furthermore, each *correspondence* connects a source schema element with the target schema element, into which its contents should be integrated.

Oftentimes constraints are not enforced at the schema level but rather at the application level or simply in the mind of the integration expert. Even worse, for some sources (e.g., data dumps), a schema definition may be completely missing. To achieve *completeness*, techniques for schema reverse engineering and data profiling [20] can reconstruct missing schema descriptions and constraints from the data.

Example 3.1. *Figure 2 shows an integration scenario with music records data. Both source and target relational schemas (Figure 2a) define a set of constraints, such as primary keys (e.g.,* id *in*

[3]Such as *http://www.datamigrationpro.com/data-migration-articles/2012/2/9/data-migration-effort-estimation-practical-techniques-from-r.html* and *http://www.information-management.com/news/1093630-1.html*



(a) Schemas, constraints, and correspondences.

record	title	duration
1	"Sweet Home Alabama"	"4:43"
1	"I Need You"	"6:55"
1	"Don't Ask Me No Questions"	"3:26"
...		

(b) Example instances from the target table tracks.

album	name	artist_list	length
s3	"Hands Up"	a1	215900
s3	"Labor Day"	a1	238100
s3	"Anxiety"	a2	218200
...			

(c) Example instances from the source table songs.

Figure 2: An example data integration scenario.

records*), foreign keys (*record *in* tracks*, represented with dashed arrows), and not nullable values (*title *in* tracks*).*

Solid arrows between attributes and relations represent correspondences, i.e., two attributes that store the same atomic information or two relations that store the same kind of instances. The source relation albums *corresponds to the target relation* records *and its source attribute* name *corresponds to the* title *attribute in the target. That means, that the albums from the source shall be integrated as records into the target, while the source album names serve as titles for the integrated records.* ◇

We assume correspondences between the source and target schemas to be given, as they can be automatically discovered with schema matching tools [10]. Notice that correspondences are not an executable representation of a transformation, thus they do not induce a *precise* mapping between sources and the target. However, they contain enough information to reason over the complexity of data integration scenarios and detect their integration challenges, as in the following example.

Example 3.2. *The target schema requires exactly one artist value per record, whereas the source schema can associate an arbitrary number of artist credits to each album. This situation implies that integrating any source album with zero artist credits violates the not-null constraint on the target attribute* records.artist*. Moreover, two or more artist credits for a single source album cannot be naturally stored by the single target attribute. Integration practitioners have to solve these conflicts. Hence, this schema heterogeneity increases the necessary effort to achieve the integration.* ◇

Not all kinds of integration issues can be detected by analyzing the schemas, though. The data itself is equally important. While we assume that every instance is valid wrt. its schema, when data is integrated new problems can arise. For example, all sources might be free of duplicates, but there still might be target duplicates when they are combined [22]. These conflicts can also arise between source data and pre-existing target data.

Example 3.3. *Tables 2b and 2c report sample instances of the* tracks *table and the* songs *table, respectively. The duration of tracks in the target database is encoded as a string with the format m:ss, while the length of songs is measured in milliseconds in the source. The two formats are locally consistent, but the source values need a proper transformation when integrated into the target column, thereby demanding a certain amount of effort.* ◇

3.2 A General Framework

Facing different kinds of data integration and cleaning actions, there is the need of different specialized models to decode their complexity and estimate their effort properly. We tackle this problem with our general effort estimation framework EFES. It handles different kinds of integration challenges by accepting a dedicated *estimation module* to cope with each of them independently. Such modularity makes it easier to revise and refine individual modules and establishes the desired *extensibility* by plugging new ones. In this work, we present modules for the three general and, in our experience, most common classes of integration activities: writing an executable mapping, resolving structural conflicts, and eliminating value heterogeneities. While the latter two are explained in subsequent sections, we present the *mapping module* in this section to explain our framework design. For *generality*, the modules do not depend on a fixed language to express the transformations.

Figure 3 depicts the general architecture of EFES. The architecture implements our goal of delivering a set of integration problems and an effort estimate by explicitly dividing the estimation process into an objective *complexity assessment*, which is based on properties of schemas and data, followed by the context-dependent *effort estimation*. We now describe these two phases in more detail.

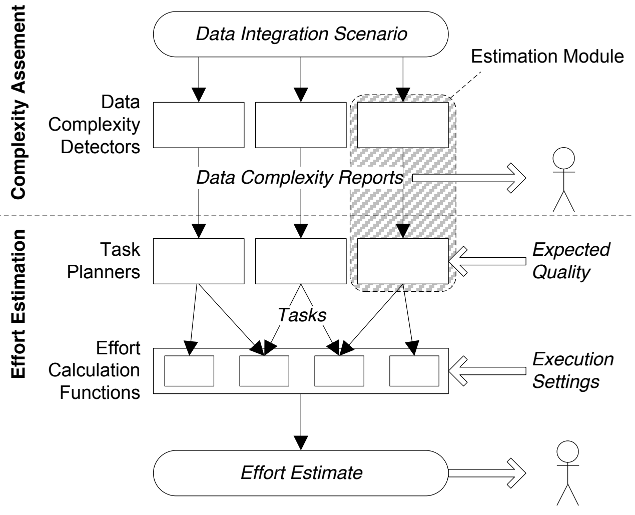


Figure 3: Architecture of EFES.

3.3 Complexity assessment

The goal of this first phase is to compute *data complexity reports* for the integration scenario. These reports serve as the basis for the subsequent effort estimation but also are used to inform the user about integration problems within the scenario. This is particularly useful for source selection [9] and data visualization [7].

Each estimation module provides a *data complexity detector* that extracts complexity indicators from the given scenario and writes them into its report. There is no formal definition for such a report; rather, it can be tailored to the specific, needed complexity indicators. For example, the mapping module builds on the following idea: For each table in the target schema and each source database that provides data for that table, some connection has to be established to fetch the source data and write it into the target table. The overall complexity of the mapping creation is composed of the individual complexities for establishing each of these connections. Furthermore, every connection can be described in terms of certain metrics, such as the number of source tables to be queried, the number of attributes that must be copied, and whether new IDs for a primary key need to be generated.

Example 3.4. *The data complexity report for the scenario in Figure 2 can be found in Table 2. To fetch the data for the* records *table, the three source tables* albums*,* artist_lists*, and* artist_credits *have to be combined, two attributes must be copied, and unique* id *values for the integrated tuples must be generated.* ◇

Target table	Source tables	Attributes	Primary key
records	3	2	yes
tracks	3	2	no

Table 2: Mapping complexity report of the scenario in Figure 2.

3.4 Effort estimation

Based on the data complexity, the effort estimation shall produce a single estimate of the human work to address the different complexities. However, going from an objective complexity measure to a subjective estimate of human work requires external information about the context. We distinguish one aspect that is specific to the data integration problem, (i) the *expected quality* of the integration result, and, as a more common aspect, (ii) the *execution settings* for the scenario.

(i) Expected quality: Data cleaning is the operation of updating an instance such that it becomes consistent wrt. any constraint defined on its schema [8, 13]. However, such results can be obtained by automatically removing problematic tuples, or by manually solving inconsistencies involving a domain expert. Each choice implies different effort.

Example 3.5. *Consider again Example 3.3 with the duration format mismatch. As* duration *is nullable, one simple way to solve the problem is to drop the values coming from the new source. A better, higher quality solution is to transform the values to a common format, but this operation requires a script and a validation by the user, i.e., more effort [15].* ◇

(ii) Execution settings: The execution settings represent the circumstances under which the data integration shall be conducted. Examples of common context information are the expertise of the integration practitioners and their familarity with the data [4]. In our setting, we also model the level of automation of the available integration tools, and how critical the errors are, e.g., integrating medical prescriptions requires more attention (and therefore effort) than integrating music tracks.

Example 3.6. *Consider again the problem with the cardinality of record artists. There are* schema mappings *tools [18] that are able to automatically create a synthetic value in the target, if a source album has zero artist credits, and to automatically create multiple occurrences of the same album with different artists, if multiple artists are credited for a single source album. Such tools would reduce the mapping effort.* ◇

For the effort estimation, each estimation module has to provide a *task planner* that consumes its data complexity report and outputs *tasks* to overcome the reported issues. Each of these tasks is of a certain type, is expected to deliver a certain result quality, and comprises an arbitrary set of parameters, such as on how many tuples it has to be executed. We defined two instances of expected quality, namely *low effort* (removal of tuples) and *high quality* (updates). This criterion is extensible to other repair actions, but it already allows to choose between alternative cleaning tasks as shown in Example 3.5.

Example 3.7. *A complexity report for the scenario from Figure 2 states that there are albums without any artist in the source data that lead to a violation of a not-null constraint in the target. The corresponding task model proposes the alternative actions* Reject violating tuple *(low effort) or* Add missing value *(high quality) to solve the problem.* ◇

Once the list of tasks has been determined, the effort for their execution is computed. For this purpose, the user specifies in advance for each task type an *effort-calculation function* that can incorporate task parameters. As an example, we report the effort-calculation functions for the execution settings of our experiments in Table 9. The framework uses these functions to estimate the effort for each of the tasks. Finally, the total of all these task estimates forms the overall effort estimate.

Example 3.8. *We exemplify the effort-calculation functions for the tasks derived from the report in Table 2. The* Create mapping *task might be done manually with SQL queries. Then an adequate function would be*

$$\textit{effort} = 3 mins \cdot \textit{tables} + 1 min \cdot \textit{attributes} + 3 mins \cdot \textit{PKs}$$

leading to an overall effort of 25 (18 + 4 + 3) minutes. However, if a tool can generate this mapping automatically based on the correspondences (e.g., [18]), then a constant value, such as $\textit{effort} = 2 mins$*, can reflect this circumstance, leading to an overall effort of four minutes.* ◇

The above described task-based approach offers several advantages over an immediate complexity-effort mapping [14], where a formula directly converts statistics over the schemas into an effort estimation value. Our model enables *configurability*, as it treats execution settings as a first-class component in the effort-calculation functions and these can be arbitrarily complex as needed. Furthermore, instead of just delivering a final effort value, our effort estimate is broken down according to its underlying tasks. This *granularity* helps users understand the required work and explains how the estimate has been created, thus giving the users the opportunity to properly plan the integration process.

4. STRUCTURAL CONFLICTS

Structural heterogeneities between source and target data structures are a common problem in integration scenarios. This section describes a module to detect these problems and estimate the effort arising out of them. It can be plugged into the framework architecture in Figure 3 with the following workflow: Its data complexity detector (*structure conflict detector*) analyzes how source and target data relate to each other, and counts the number of emerging structural conflicts. Based on those conflicts, the task planner (*structure repair planner*) then (i) derives a set of cleaning tasks to make the conflicting source data fit into the target schema, and (ii) estimates how often each such task has to be performed. These tasks can finally be fed into the effort calculation functions.

4.1 Structure Conflict Detector

In the first step of structural conflict handling, all source and target schemas of the given scenario are converted into *cardinality-constrained schema graphs* (short *CSG*), a novel modeling formalism that we specifically devised for our task. It offers a single, yet expressive constraint formalism with a set of inference operators that allow elegant comparisons of schemas. Additionally, it is more general than the relational model and can describe (integrated) database instances that do not conform to the relational model. For instance, an integrated tuple might provide multiple values for a single attribute, like in Example 3.2. The higher expressiveness of CSGs allows to reason about necessary cleaning tasks to make the integrated databases conform to the relational model. In the following, we formally define CSGs and explain how to convert relational databases into CSGs.

DEFINITION 1. *A CSG is a tuple $\Gamma = (N, P, \kappa)$, where N is a set of nodes and $P \subset N^2$ is a set of relationships. Furthermore, $\kappa\colon P \rightarrow 2^{\mathbb{N}}$ expresses schema constraints by prescribing cardinalities for relationships.*

DEFINITION 2. *A CSG instance is a tuple $\mathcal{I}(\Gamma) = (\mathcal{I}_N, \mathcal{I}_P)$, where $\mathcal{I}_N$ assigns a set of elements to each node in N and $\mathcal{I}_P$ assigns to each relationship links between those elements.*

To convert a relational schema, for each of its relations, a corresponding *table node* (rectangle) is created to represent the existence of tuples in that relation. Furthermore, for each attribute, an *attribute node* (round shape) is created and connected to its respective table node via a *relationship*. While these attribute nodes hold the *set of distinct* values of the original relational attribute, the relationships link tuples and their respective attribute values. With this proceeding, any relational database can be turned into a CSG without loss of information.

Example 4.1. *Figure 4 depicts two CSGs for the example scenario schemas in Figure 2a, one for the source and one for the target schema*[4]. *For instance, the example* tracks *tuple t = (1, "Sweet Home Alabama", "4:43") from Figure 2b is represented in the CSG instance as follows: The table node* tracks $\in N$ *holds an abstract element id_t, i.e., $id_t \in \mathcal{I}_N(\text{tracks})$, representing the tuple's identity. Likewise,* record $\in N$ *holds exactly once the value 1, i.e., $1 \in \mathcal{I}_N(\text{record})$, and the relationship $\rho_{\text{tracks}\rightarrow\text{record}}$ contains a* link *for these elements, i.e., $(id_t, 1) \in \mathcal{I}_P(\rho_{\text{tracks}\rightarrow\text{record}})$, thus stating that $t[\text{record}] = 1$. The other values for the* title *and* duration *attributes are represented accordingly. Furthermore, foreign key relationships are represented by special* equality relationships *(dashed line) that link all equal elements of two nodes, e.g., all common values of the* id *and* record *nodes in the target CSG of Figure 4.* ◇

[4]Some correspondences between the schemas are omitted for clarity, but are not generally discarded.

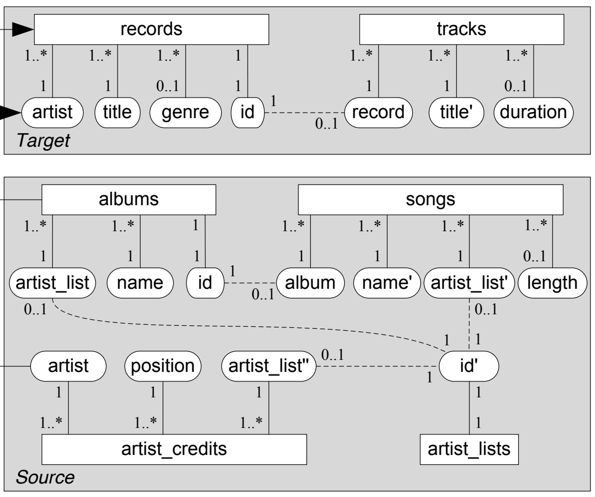

Figure 4: The integration scenario translated into cardinality-constrained schema graphs.

To express schema constraints in CSGs, all relationships are annotated with *prescribed cardinalities*, that restrict the number of elements and/or values of connected nodes that must relate to each other via the annotated relationship. For example, tracks.record is not nullable, which means, that each tracks tuple must provide exactly one record value. Translated to CSGs, this means that for each tuple t_i, the relationship $\rho_{\text{tracks}\rightarrow\text{record}}$ must contain exactly one link:

$$\forall t_i\colon\ |\{v \in \mathcal{I}_N(\text{record}) \mid (id_{t_i}, v) \in \mathcal{I}_P(\rho_{\text{tracks}\rightarrow\text{record}})\}| = 1 \quad .$$

Formally, this is expressed by $\kappa(\rho_{\text{tracks}\rightarrow\text{record}}) = \{1\}$, which is also graphically annotated in Figure 4. However, tracks.record is not subject to a unique-constraint. In consequence, every record value can be found in one or more tuples. Therefore, $\kappa(\rho_{\text{record}\rightarrow\text{tracks}}) = 1..* = \{1, 2, 3, \ldots\}$. By means of prescribed cardinalities, unique, not-null, and foreign key constraints can be expressed, as well as two conformity rules for relational schemas: each tuple can have at most one value per attribute, and each attribute value must be contained in a tuple.

As stated above, another important feature of CSGs is the ability to combine relationships into *complex relationships* and to analyze their properties. As one effect, prescribing cardinalities not only to atomic but also to complex relationships further allows to express n-ary versions of the above constraints and functional dependencies. We devised the following relationship construction operators:

'$\circ$': The *composition* concatenates two adjacent relationships. Formally, $\mathcal{I}_P(\rho_1 \circ \rho_2) \overset{def}{=} \mathcal{I}_P(\rho_1) \circ \mathcal{I}_P(\rho_2)$.

'$\cup$': The *union* of two relationships $\rho_1 \cup \rho_2$ contains all links of the two relationships, i.e., $\mathcal{I}_P(\rho_1 \cup \rho_2) \overset{def}{=} \mathcal{I}_P(\rho_1) \cup \mathcal{I}_P(\rho_2)$. This is particularly useful, when multiple source relationships need to be combined.

'$\bowtie$': The *join* operator connects links from relationships $\rho_{A\rightarrow C}$, $\rho_{B\rightarrow C}$ with equal codomain values, thereby inducing a relationship between $A \times B$ and C. Formally, $\mathcal{I}_P(\rho_{A\rightarrow C} \bowtie \rho_{B\rightarrow C}) \overset{def}{=} \{((a, b), c) : (a, c) \in \mathcal{I}_P(\rho_{A\rightarrow C}) \wedge (b, c) \in \mathcal{I}_P(\rho_{A\rightarrow B})\}$. The join can be combined with other operators to express n-ary uniqueness constraints.

'$\|$': The *collateral* of two relationships $\rho_{A\to B}\|\rho_{C\to D}$ induces a relationship between $A \times C$ and $B \times D$: $\mathcal{I}_P(\rho_{A\to B}\|\rho_{C\to D}) \overset{def}{=} \{((a,c),(b,d)) : (a,b) \in \mathcal{I}_P(\rho_{A\to B}) \wedge (c,d) \in \mathcal{I}_P(\rho_{C\to D})\}$. The collateral can be applied to express n-ary foreign keys.

Based on these definitions, efficient algorithms can be devised to infer the constraints of complex relationships.

LEMMA 1. *Let $\rho_1, \rho_2 \in P$ be two relationships in a graph Γ and ρ_1's end node is ρ_2's start node. Then the cardinality κ of $\rho_1 \circ \rho_2$ can be inferred as*

$$\begin{aligned} &\kappa(\rho_1 \circ \rho_2) \overset{def}{=} \kappa(\rho_1) \circ \kappa(\rho_2) \\ = \;& a_1..b_1 \circ a_2..b_2 \overset{def}{=} (\operatorname{sgn} a_1 \cdot a_2)..(b_1 \cdot b_2) \end{aligned}$$

where $\operatorname{sgn}(0) = 0$ *and* $\operatorname{sgn}(n) = 1$ *for* $n > 0$.

LEMMA 2. *Let $\rho_1, \rho_2 \in P$ be two relationships in a graph Γ. Then the cardinality of $\rho_1 \cup \rho_2$ can be inferred as*

$$\kappa(\rho_1 \cup \rho_2) \overset{def}{=} \begin{cases} \kappa(\rho_1) \cup \kappa(\rho_2) & \textit{if } \mathcal{I}_P(\rho_1) \textit{ and } \mathcal{I}_P(\rho_2) \textit{ have disjoint domains} \\ \kappa(\rho_1) + \kappa(\rho_2) & \textit{if } \mathcal{I}_P(\rho_1) \textit{ and } \mathcal{I}_P(\rho_2) \textit{ have equal domains but disjoint codomains} \\ \kappa(\rho_1) \hat{+} \kappa(\rho_2) & \textit{if } \mathcal{I}_P(\rho_1) \textit{ and } \mathcal{I}_P(\rho_2) \textit{ have equal domains and overlapping codomains} \end{cases}$$

where $\kappa_1 + \kappa_2 \overset{def}{=} \{a + b : a \in \kappa_1 \wedge b \in \kappa_2\}$ *and* $\kappa_1 \hat{+} \kappa_2 \overset{def}{=} \{c : a \in \kappa_1 \wedge b \in \kappa_2 \wedge \max\{a, b\} \leq c \leq (a + b)\}$.

Note, that Lemma 2 can also be applied to relationships with partially overlapping domains by splitting those into the overlapping and the disjoint parts.

LEMMA 3. *Let $\rho_1, \rho_2 \in P$ be two relationships in a graph Γ with a common end node and let $m = \min\{\max \kappa(\rho_1), \max \kappa(\rho_2)\}$. Then the cardinality of $\rho_1 \bowtie \rho_2$ can be inferred as*

$$\kappa(\rho_1 \bowtie \rho_2) \overset{def}{=} \begin{cases} \emptyset & \textit{if } m = 0 \vee m = \perp \\ 1..m & \textit{otherwise} \end{cases}$$

and its inverse cardinality as

$$\begin{aligned} &\kappa((\rho_1 \bowtie \rho_2)^{-1}) \\ &\overset{def}{=} (\min \kappa(\rho_1) \cdot \min \kappa(\rho_2))..(\max \kappa(\rho_1) \cdot \max \kappa(\rho_2)) \end{aligned}$$

LEMMA 4. *Let $\rho_1, \rho_2 \in P$ be two relationships in a graph Γ. Then the cardinality of $\rho_1 \| \rho_2$ can be inferred as*

$$\kappa(\rho_1 \| \rho_2) \overset{def}{=} 0..(\max \kappa(\rho_1) \cdot \max \kappa(\rho_2))$$

Given the means to combine relationships and infer their cardinality, it is now possible to compare the structure of source and target schemas. As data integration seeks to populate the target relationships with data from the sources, the structure conflict detector must determine how the atomic target relationships are represented in the source schemas. In general, target relationships can correspond to arbitrarily complex source relationships, in particular to compositions. The composition operator particularly allows to treat the matching of target relationships to source relationships as a graph search problem, as is exemplified with the atomic target relationship records $\to$ artist from Figure 4.

First, the relationship's start and end node are matched to nodes in the source schema via the correspondences, in this case to albums and artist. Then, a path is sought between those nodes. In the example, there are two possible paths, namely albums $\to$ artist_list $\to$ id$'$ $\to$ artist_list$''$ $\to$ artist_credits $\to$ artist, and albums $\to$ id $\to$ album $\to$ songs $\to$ artist_list$'$ $\to$ id$'$ $\to$ artist_list$''$ $\to$ artist_credits $\to$ artist. To resolve this ambiguity, it is assumed that the most *concise* detected source relationship is the best match for the atomic target relationship. A relationship is more concise than another relationship, if its (inferred) cardinality κ_1 is more specific than the other relationship's cardinality κ_2, i.e., $\kappa_1 \subset \kappa_2$. In the case of equal cardinalities, the shorter relationship is preferred, according to Occam's razor principle[5]. Here, both detected relationships have the same inferred cardinality $0..*$ according to Lemma 1, but the former is shorter and therefore selected as match.

Having matched a target relationship to a source relationship, comparing these two can finally reveal structural conflicts. The example target relationship records $\to$ artist has the annotated cardinality 1, but its corresponding source relationship is less concise, having an inferred cardinality of $0..*$. This lower conciseness causes a structural conflict: The target schema accepts only one artist value per record, while the source potentially offers an arbitrary amount of artists per album. To refine the statement about this violation, we can count the number of albums in the source data, that are associated to no or more than one artist, hence, determining the number of actually conflicting data elements. This *violation count* is applicable to any database constraint that can be expressed in CSG as listed above. Supporting more advanced constraints in CSGs, such as *conditional functional dependencies* [8], is left for future work.

The above described matching and checking process is performed for each target relationship. In the example scenario, there is only one more structural violation: artist $\to$ records has $0..*$ as inferred cardinality, so there may be artists with no albums. Afterwards, all collected structure violations, depicted in Table 3, are forwarded to the structure repair planner.

Constraint in target schema	Violation count in source data
$\kappa(\rho_{\text{records}\to\text{artist}}) = 1$	503
$\kappa(\rho_{\text{artist}\to\text{records}}) = 1..*$	102

Table 3: Complexity report of the structure conflict detector.

4.2 Structure Repair Planner

The structure repair planner proposes necessary cleaning tasks to cope with the structural violations in an integration scenario, that form the base for the following effort calculation. It ships with ten such cleaning tasks listed in Table 4; one per type of violation, e.g., of a not-null constraint, and expected result quality (low or high). The structure conflict detector can automatically select exactly those tasks that the integration practitioner has to perform in the data integration scenario to fix structural violations.

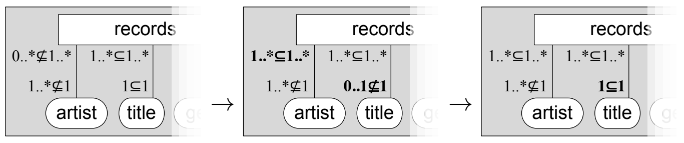
However, simply designating a task for each given violation is not sufficient, as data cleaning operations usually have side effects that can cause new violations. For instance, the structure conflict detector reveals that there are 102 artists in the source data that have no albums and can thus not be represented in the target schema.

[5]Among competing hypotheses, the one with the fewest assumptions should be selected.

	Result quality	
Constraint	Low effort	High quality
Not null violated	Reject tuple	Add missing value
Unique violated	Set values to null	Aggregate tuples
Multiple attribute values	Keep any value	Merge values
Value w/o enclosing tuple	Drop value	Create enclosing tuple
FK violated	Delete dangling value	Add referenced value

Table 4: Structural conflicts and their corresponding cleaning tasks.

The high-quality solution is to apply the task *Create tuples for detached values*, that creates record tuples to store these artists, so that they do not have to be discarded. These new tuples would violate the not-null constraint on the title attribute, though, so subsequent cleaning tasks are necessary. To account for such impacts, we simulate applied cleaning tasks on *virtual CSG instances* as exemplified in Figure 5. In addition to the prescribed cardinalities, the target CSG is annotated with *actual cardinalities*. In contrast to the prescribed cardinalities, those do not *prescribe* schema constraints but *describe* the state of the (conceptually) integrated source data – in terms of its relationships' cardinalities. Hence, the actual cardinalities are initialized with the inferred cardinalities from the source database. Figure 5a depicts this initial state. As long as there are actual cardinalities (on the left-hand side) that are not subsets of the prescribed ones, the CSG instance is invalid wrt. its constraints. Now, if the structure repair planner has chosen a cleaning task, e.g., adding new records tuples for artists without albums, its (side) effects are simulated by modifying the actual cardinalities, as shown in Figure 5b with bold print. So, amongst others the actual cardinality of artist $\rightarrow$ records is changed from $0..*$ to $1..*$, reflecting that all artists appear in a record after the task, and the cardinality of records $\rightarrow$ title is altered from 1 to 0..1, stating that some records would then have no title. The latter forms a new constraint violation. Now, a successive repair task can be applied on this altered CSG instance, e.g., the task *Add missing values*, which leads to the state of Figure 5c.



(a) Initial state. (b) State after *Add new tuples* for records. (c) State after *Add missing values* for title.

Figure 5: Extract of a virtual CSG instance as cleaning tasks are performed on it.

This procedure of picking a task and simulating its effects is repeated until the virtual CSG instance contains no more violations. Furthermore, the structure repair planner orders the repair tasks, so that tasks that cause new structural violations (or might break an already fixed violation) precede the task that fixes this violation. This is not computationally expensive, because we need to order only tasks that affect a common relationship, but doing so allows for the detection of "infinite cleaning loops", where the execution order of cleaning tasks forms a cycle. In most cases, these cycles are a consequence of contradicting repair tasks. EFES proposes only consistent repair strategies. Additionally, the knowledge of the necessary cleaning tasks in a data integration scenario, including their order, are a valuable aid that can positively impact the integration effort spent on coping with structural conflicts. Therefore, the ordered task list is provided to the user. Finally, the determined cleaning tasks are fed into the user-defined effort calculation functions, which automatically determine the effort for dealing with structural violations in the given scenario. Table 5 presents this effort for the example scenario.

Task	Repetitions	Effort
Add tuples (records)	102	5 mins
Add missing values (title)	102	204 mins
Merge values (title)	503	15 mins
Total		224 mins

Table 5: High-quality structure repair tasks and their estimated effort using the effort calculation functions from Table 9.

5. VALUE HETEROGENEITIES

Value heterogeneities are a frequent class of data integration problems with a common factor: corresponding attributes in the source and target schema use different representations for their values. For instance, in Example 3.3 the target table tracks stores song durations as strings, whereas the source table songs stores these durations in milliseconds as integers. An integration practitioner might therefore want to convert or discard the source values to avoid having different value representations in the tracks.duration attribute. Thus, value heterogeneities can increase the integration effort.

This section presents a module in EFES to estimate the effort caused by value heterogeneities. The data complexity is computed by the *value fit detector*, which analyzes the source and target data to detect different types of value heterogeneities between them. These heterogeneities are then reported to the *value transformation planner*, the task model that proposes data cleaning tasks in response to the heterogeneity issues. Finally, the effort for the proposed tasks can be calculated.

5.1 Value Fit Detector

The basic approach of the value fit detector is to aggregate source and target data into statistics and compare these statistics to detect heterogeneities. Statistics are eligible for this evaluation, because they allow efficient comparison for large amounts of data, while enabling extensibility (as new functions can be added) and completeness (as issues that are not captured by available metadata can be discovered). Furthermore, statistics help to detect the especially meaningful, general data properties that characterize the data as a whole. In particular, if the source data does not match the observed or specified characteristics of the target dataset, plainly integrating this source data would impair the overall quality of the integration result: integration practitioners might want to spend effort to make source data consistent with the target data characteristics.

The value fit detector implements this idea as follows: Given an integration scenario, it processes all pairs of source and target attributes that are connected by a correspondence. For each such pair, statistic values of both attributes are calculated, with the target attribute's datatype designating which exact statistic types to use. In particular, we consider the following statistics:

- The *fill status* counts the null values in an attribute and the values that cannot be cast to the target attribute's datatype.

- The *constancy* is the inverse of Shannon's information entropy and is useful to classify whether the values of an attribute come from a discrete domain [17].
- The *text pattern statistic* collects frequent patterns in a string attribute.
- *Character histogram* captures the relative occurrences of characters in a string attribute.
- The *string length statistic* determines the average string length and its standard deviation for a string attribute.
- Similarly, the *mean statistic* collects the mean value and standard deviation of a numeric attribute.
- The *histogram statistic* describes numeric attributes as histograms.
- *Value ranges* are used to determine the minimum and maximum value of a numeric attribute.
- For attributes with values from a discrete domain, the *top-k values statistic* identifies the most frequent values.

For Example 3.3, the string-typed duration target attribute designates the fill status, the text pattern statistic, the character histogram, the string length statistic, and the top-k values as interesting statistics to be collected.

In the next step, a decision model identifies, based on the gathered statistics values, the different types of value heterogeneities within the inspected attribute pair. Algorithm 1 outlines this decision model, which consists of a sequence of rules. The evaluation of each rule has its own, mostly simple, logic. The first rule ($substantiallyFewerSourceValues$), for instance, is evaluated by comparing the fill status statistics of the source and target attribute.

Algorithm 1: Detect value heterogeneities.

```
Data: source attribute statistics $\mathcal{S}_s$, target attribute statistics $\mathcal{S}_t$
Result: value heterogeneities $V$
1  if substantiallyFewerSourceValues($\mathcal{S}_s, \mathcal{S}_t$) then
2      add Too few source elements to $V$;
3  if hasIncompatibleValues($\mathcal{S}_s$) then
4      add Different value representations (critical) to $V$;
5  if domainRestricted($\mathcal{S}_s$) $\wedge$ $\neg$domainRestricted($\mathcal{S}_t$) then
6      add Too coarse-grained source values to $V$;
7  else if $\neg$domainRestricted($\mathcal{S}_s$) $\wedge$ domainRestricted($\mathcal{S}_t$) then
8      add Too fine-grained source values to $V$;
9  else if domainSpecificDifferences($\mathcal{S}_s, \mathcal{S}_t$) then
10     add Different value representations to $V$;
```

For the above example attribute pair, the fill-statuses are for both attributes near 100 %, there are no incompatible source values (integers can always be cast to strings), and neither of the attributes is domain-restricted. Still, possible domain-specific differences between them might be present. The evaluation of this last rule is more complex. For this purpose, a set of statistics, that are specific to the target attribute's datatype, are computed, e.g., the string format and string length statistic for the string-typed, not domain-restricted duration attribute. To compare these statistics among attributes, for each of them of type τ, an *importance score* $i\big(\mathcal{S}_t(\tau)\big)$ and a *fit value* $f\big(\mathcal{S}_s(\tau), \mathcal{S}_t(\tau)\big)$ are calculated. These calculations are specific to the actual statistics. Intentionally, the importance score describes how important the statistic type at hand is for the target attribute. For example, in the duration attribute, all values have the same text pattern *[number ":" number]*, so the string format statistic is presumably an important characteristic and should therefore have a high importance score. If it had many different text patterns in contrast, its importance would be close to 0. In addition, the fit value measures to what extent the source attribute statistics fit into the target attribute statistics. For instance, the length attribute provides only values with the differing pattern *[number]* leading to a low fit value. Eventually, the fit values for all applied statistic types are averaged using the importance scores as weights:

$$f \overset{def}{=} \sum_{\tau} \Big(i\big(\mathcal{S}_t(\tau)\big) \cdot f\big(\mathcal{S}_s(\tau), \mathcal{S}_t(\tau)\big) \Big)$$

This overall fit value tells to what extent the source attribute fulfills the most important characteristics of the target attribute. If it falls below a certain threshold, we assume domain-specific differences in between the compared attributes and Algorithm 1 issues an according value heterogeneity, e.g., *Different value representations* between the attributes length and duration. In experiments with importance scores and fit values between 0 and 1, we found 0.9 to be a good threshold to separate seamlessly integrating attribute pairs from those that had notably different characteristics.

The set of all value heterogeneities for all attribute pairs forms the complexity report of the value fit detector that can in the following be processed by the value transformation planner. Table 6 shows the complexity report for the example scenario. Note that the value heterogeneities can carry additional information that are derived from the attribute statistics as well and that can be useful to produce accurate estimates. These parameters are not further described in this paper.

Value heterogeneity	**Additional parameters**
Different value representation (length $\rightarrow$ duration)	274.523 source values, 260.923 distinct source values

Table 6: Complexity report of the value fit detector.

5.2 Value Transformation Planner

The value transformation planner proposes tasks to solve value heterogeneities as specified in Table 7. In contrast to the structure repair tasks from Section 4.2, those tasks do not have interdependencies. Therefore, the value transformation planner can simply propose an appropriate task for each given value heterogeneity based on the expected result quality of the data integration. For the four different types of value heterogeneities, there are only five different tasks, because for a low-effort integration result, value heterogeneities can in most cases be simply ignored. So, the *Different value representations* between the duration and length attributes might either be neglected (leading to no additional effort) or, for a high-quality integration result, the value fit detector issues the task *Convert values*. This task is then again fed into the effort calculation functions that compute the effort that is necessary for the task completion. Table 8 illustrates the resulting effort estimate.

6. EXPERIMENTS

To show the viability of the general effort estimation architecture and its different models, we conducted experiments with real-world data from two different domains. In the following, we first introduce the system and its configuration. We then describe the

Value heterogeneity	**Result quality** low effort	high quality
Too few elements	-	Add values
Different representations		
critical	Drop values	Convert values
uncritical	-	Convert values
Too specific	-	Generalize values
Too general	-	Refine values

Table 7: Value heterogeneities and corresponding cleaning tasks.

Task	**Parameters**	**Effort**
Convert values (length → duration)	274.523 values, 260.923 distinct values	15 mins
Total		15 mins

Table 8: Value transformation tasks and their estimated effort.

integration scenarios and how we created the ground truth effort by manually integrating them. Finally, we compare our system to a baseline approach from the literature and to the measured effort in creating the ground truth.

6.1 Setup

The EFES prototype is a Java-based implementation of the effort estimation architecture presented in the paper, along with the three modules discussed. It offers multiple configuration options via an XML file and a command-line interface. As input, the prototype takes correspondences between a source and a target dataset, all stored in PostgreSQL databases. The prototype and the datasets are available for download.[6]

Configuration and External Factors. In our experiments, the only available software for conducting the integration are (i) manually written SQL queries, and (ii) a basic admin tool like pgAdmin. We also assume the user has not seen the datasets before and that she is familiar with SQL. Based on these external factors, corresponding effort conversion functions are reported in Table 9. For example, the intuition behind the formula for adding values is that it takes a practitioner two minutes to investigate and provide a single missing value. In contrast, deleting tuples with missing values requires five minutes, because independently from the number of violating tuples, one can write an appropriate SQL query to perform this task. Furthermore, we fine-tuned these settings for our experiments as we explain in Section 6.2.

Integration Scenarios. We considered two real-world case studies. The first is the well-known Amalgam dataset from the bibliographic domain, which comprises four schemas with between 5 and 27 relations, each with 3 to 16 attributes. The second is a new case study we created with a set of three datasets with discographic data. In those datasets, there are three schemas with between 2 and 56 relations and between 2 and 19 attributes each. Links to the original datasets can be found on the web page mentioned above.

For each case study, we created four integration scenarios, each consisting of a source and target database and manually created correspondences, because we do not want the evaluation results to depend on the quality of a schema matcher at this point. Within each domain, we included a data integration scenario with identical source and target schema and three other, randomly selected

Unlink all but one tuple	5
Write mapping	$3 \cdot$ #FKs $+ 3 \cdot$ #PKs $+$ #atts $+ 3 \cdot$ #tables

Table 9: Effort calculation functions used for the experiments.

scenarios with different schemas.

Effort Estimates. In order to obtain effort estimations, we applied the following procedure to each data scenario twice, once striving for a low-effort integration result, once for a high-quality result. At first, we executed EFES on the scenario to obtain the data complexity reports and a set of initially proposed mapping and cleaning tasks. If a data complexity aspect was properly recognized but we preferred a different integration task, we have adapted the proposed tasks. For instance, in one scenario, our prototype proposed to provide missing *FreeDB IDs* for music CDs to obtain a high-quality result; this ID is calculated from the CD structure with a special algorithm. Since there was no way for us to obtain this value, we exchanged this proposal with *Reject tuples* to delete source CDs without such a disc ID instead.

Ground Truth Effort. Finally, we gathered the ground truth of necessary integration tasks manually and conducted them with SQL scripts and *pgAdmin*, thereby measuring the execution time of each task. We believe these two manually integrated scenarios with time annotations are a contribution per se, as they can be used also for benchmarking of mapping and cleaning systems for other data integration projects.

6.2 Experimental Results

The correspondences that were created for the case study datasets have been fed into EFES to compare its effort estimates to the actual effort. As a baseline, we used the standard approach based on attribute counting [14], as discussed in Section 2. To obtain fair calibrations of EFES and this baseline model, we employed cross validation: We used the effort measurements from the bibliographic domain to calibrate the parameters of EFES and the attribute counting approach for the estimation of the music domain scenarios, and vice versa. Thus, we have for both scenarios different training and test data and both models can be regarded as equally well-trained. To compare the two models against the measured effort, we applied the root-mean-square error (rmse):

$$\text{rmse} = \sqrt{\frac{\sum_{s \in S} \left(\frac{\text{measured}(s) - \text{estimated}(s)}{\text{measured}(s)}\right)^2}{\#\text{scenarios}}}$$

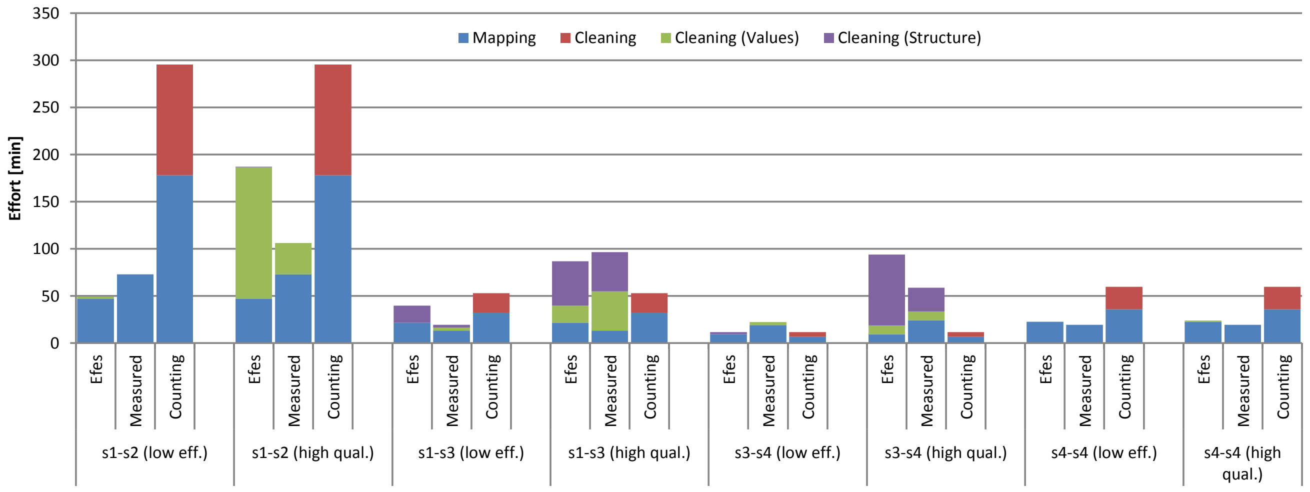

Figure 6: Effort estimates (EFES), actual effort (Measured), and baseline estimates (Counting) of the Bibliographic scenario.

where S is a set of integration scenarios.

We start our analysis with the Amalgam dataset with the results reported in Figure 6. EFES consistently outperforms the counting approach in all scenarios. This is explained by the fact that the baseline has no concept of heterogeneity between values in the datasets, but it is one of the main complexity drivers in these integration scenarios. In terms of the root-mean-square error, EFES achieves 0.47, while the baseline obtains 1.90 (lower values indicates better estimations), thus there is an improvement in the effort estimation by a factor of four. Moreover, EFES not only provides the total number of minutes, but also a detailed break down of where the effort is to be expected. This turned out to be particular useful to revise the effort estimate as described above, thus enriching the estimation process with further input. In fact, it makes a significant difference if an integration practitioner has to add hundreds of missing values or if tuples with missing values are dropped. The baseline approach also distinguishes between mapping and cleaning efforts, but it relates them neither to integration problems nor actual tasks. The *s4-s4* scenario demonstrates this: source and target database have the same schema and similar data, so there are no heterogeneities to deal with. While we can detect this, the counting approach estimates considerable cleaning effort.

When we move to the music datasets, the results in Figure 7 show a smaller difference between the two estimation approaches. In fact, EFES outperforms the baseline four times, in three cases baseline does a better job, and in one case the estimate is basically the same. The explanation is that in this domain, there are fewer problems at the data level and the effort is dominated by the mapping, which strongly depends on the schema. However, when we look at the root-mean-square error, EFES achieves 1.05, while the baseline obtains 1.64. Therefore, even in cases where EFES cannot exploit all of its modules, and when counting should perform at its best, our systematic estimation is better.

It is important to consider the generality of the presented comparison. The two case studies are based on real-world data sets with different complexity and quality. When putting the results over the eight scenarios together, EFES achieves a root-mean-square error of 0.84, while the baseline obtains 1.70. In terms of execution time, EFES relies on simple SQL queries only for the analysis of the data and completes within seconds for databases with thousands of tuples. This overhead can be neglected in the context of the dominating integration cost.

7. CONCLUSIONS

We have tackled the problem of estimating the complexity and the effort for data integration scenarios. As data integration is composed of many different activities, we proposed a novel system, EFES, that integrates different ad-hoc estimation modules in a unified fashion. We have introduced three modules that take care of estimating the complexity and effort of (i) mapping activities, (ii) cleaning of structural conflicts arising because of different structures and integrity constraints, and (iii) resolving heterogeneity in integrated data, such as different formats. Experimental results show that our system outperforms the standard baseline up to a factor of four in terms of precision of the estimated effort time in minutes. When compared to the effective time required by a human to achieve integration, EFES provides a close estimate for most of the cases.

We believe that our work is only a first step in this challenging problem. One possible general direction is to integrate EFES with approaches that measure the benefit of the integration, such as the marginal gain [9]. This integration would allow to plot cost-benefit graphs for the integration: the more effort, the better the quality of the result.

A rather technical challenge in our system is to drop the assumption that correspondences among schemas are given. In practice, the effort for creating quality correspondences cannot be completely neglected – although, in our experience it takes considerably less time than other integration activities – and automatically generated correspondences introduce uncertainty wrt. the produced estimates. The accuracy measure as proposed Melnik et al. [19] seems to be a good starting point to tackle this issue.

Acknowledgments. We would like to thank ElKindi Rezig for valuable discussions in the initial phase of this project.

ABSTRACT

This paper studies the problem of mining frequent co-occurrence patterns across multiple data streams, which has not been addressed by existing works. Co-occurrence pattern in this context refers to the case that the same group of objects appear consecutively in multiple streams over a short time span, signaling tight correlations between these objects. The need for mining such patterns in real-time arises in a variety of applications ranging from crime prevention to location-based services to event discovery in social media.

Since the data streams are usually fast, continuous, and unbounded, existing methods on mining frequent patterns requiring more than one pass over the data cannot be directly applied. Therefore, we propose DIMine and CooMine, two algorithms to discover frequent co-occurrence patterns across multiple data streams. DIMine is an Apriori-style algorithm based on an inverted index, while CooMine uses an in-memory data structure called the Seg-tree to compactly index the data that are already seen but have not expired yet. CooMine employs a one-pass algorithm that uses the filter-and-refine strategy to obtain the co-occurrence patterns from the Seg-tree as updates to the streams arrive. Extensive experiments on two real datasets demonstrate the superiority of the proposed approaches over a baseline method, and show their respective applicability in different senarios.

1. INTRODUCTION

We study the problem of mining frequency co-occurrence patterns across multiple data streams. Given a set of unbounded streams of objects s_i ($i = 1, 2, \ldots, n$), we call a set of objects $\mathcal{O} = (o_1, o_2, \ldots, o_k)$ a frequent co-occurrence pattern (FCP) if (1) they appear in at least θ streams within a period of time no longer than τ, and (2) their appearance within each of those streams happens within a time window of size no greater than ξ, where θ, τ, and ξ are user-specified thresholds.

[*]Corresponding author.

1.1 Motivation

FCPs usually indicate strong correlations between these objects, and their timely discovery has applications in a wide spectrum of contexts. The following are some typical examples.

- *Crime prevention.* An increasing number of cities are now having traffic surveillance cameras installed on major roads and intersections for traffic management and public safety. A picture is taken when a vehicle passes by, and a structured vehicle passing record (VPRs) is sent to the data center for processing. Thus, each camera effectively produces a continuous stream of VPRs. Finding FCPs across these streams can help uncover groups of vehicles that travel together within a short time span, which is often a good indicator for potential gang crimes.

- *Discovering emerging topics.* Each user of a microblogging platform (e.g., Twitter) can be considered to produce a stream of words by posting microblogs. The intensive co-occurrence of a set of keywords in many streams (microblogs) over a short period of time can often imply the emergence of a new topic.

- *Location-based services.* Check-in apps (e.g., Foursquare) allow mobile users to check-in to the places they are located. Finding FCPs across the streams in real-time, where each stream consists of the checkin locations of a user, would help discover groups of people that are currently hanging out together, so that location-based advertising can be better targeted (e.g., offering group buying deals).

- *E-Commerce.* The browsing trace of a particular user on a e-commerce website contains a stream of items she has visited. When a set of items appear in the traces of a lot of users over a short period, it could be a sign of strong correlation

10.5441/002/edbt.2015.08

between those items, and sales strategies can be adjusted accordingly in real-time (e.g., offering combo deals for those products).

In all of the examples above, a common theme is the need to discover the frequent co-occurrence of a set of items (vehicles, people, keywords, etc.) over a short time span in multiple streams.

1.2 Challenges

Mining FCPs in realtime present some unique challenges. First, the streams are unbounded and often contain a vast volume of data with high arrival rates, allowing only one pass over the data. For example, the peak of 143,199 tweets per second were recorded by Twitter on August 3, 2013, and on average, 58 million tweets are produced per day. As another example, in the City of Jinan, a provincial capital in eastern China with a population of 6 million, the traffic surveillance cameras (each generating a stream) produce 20 million VPRs per day on average. Second, mining FCPs is a cross-stream operation, making it highly complex when many streams are involved. For instance, there are around 3,000 traffic surveillance cameras installed in Jinan; not to mention the more than 600 million active registered users of Twitter.

Existing methods for mining frequent patterns cannot be directly applied to solve the FCP mining problem. Most of the algorithms for mining frequent patterns from databases require multiple passes over the data, rendering them inapplicable in the streaming data context. Methods proposed for data streams [4, 10, 18, 15], on the other hand, focus on mining patterns from a *single* stream where the frequent patterns are defined as those that occur more often than a given threshold in *that* stream. Contrastingly, the problem we tackle is concerned with the occurrences of patterns within *multiple* streams, where the number of streams in which a pattern appears is an important parameter.

Probably the most related work to ours is that by Guo et al. [8] which considers frequent patterns in multiple data streams. But according to the their definition, whether a pattern is considered frequent totally depends on the number of its occurrences within a single stream. The frequent patterns are discovered separately from each stream, and then analysis of those patterns is performed to find the interesting ones based on their presence across multiple streams. In contrast, in order for a pattern to be considered frequent in our problem, it has to appear in at least θ streams within a short period of time. It is not the number of times a patten appearing in any single stream that matters; it is the number of streams the pattern appears in. Moreover, the algorithms proposed by Guo et al. are approximate, whereas we focus on computing exact solutions.

One seemingly promising strategy to simplify this problem is to first combine all streams into one, and then mine the FCPs on the combined data stream with some time window constraints. However, the complexity of the problem remains the same as discovering FCPs from the combined data stream still requires the differentiation between the component streams (e.g., we count a pattern twice if it appears in two different component streams, but only once if it appears twice in the same component stream), as well as restriction on the time interval of the pattern occurring in these data streams.

1.3 Our proposal

To address the above challenges, we propose two algorithms for discovering FCPs across multiple streams. They both adopt a filter-and-refine strategy with two stages. The first stage produces a set of candidate co-occurrence patterns (CPs) from the data streams, and the second stage generates the FCPs from those candidate CPs. To limit the scope of search, we divide each data stream into overlapping segments, guaranteeing that any FCP can only appear in those segments. This allows us to solve the problem of finding FCPs by focusing only on the recent segments in each stream.

As we are dealing with unbounded streams, the search for new candidate CPs is an ongoing process. The key is to efficiently search for new candidate CPs when there are newly arrived objects in any of the streams. In the DIMine approach, we introduce an inverted index called DI-Index to index the existing segments, and it computes FCPs based on the DI-Index with an Apriori-style heuristic. Although straightforward to implement, it needs to be improved in terms of memory consumption and maintenance cost.

In the CooMine approach, we propose a compact in-memory data structure called Seg-Tree to maintain the existing segments, which are dynamically updated as streams proceed, including the deletion of segments when they are guaranteed not to contain any FCPs. When a new segment is generated resulting from newly arrived objects, we search the existing segments using the Seg-Tree to find the common CPs they all contain, which form the set of candidate CPs that must be examined further. With all candidate CPs obtained, an Apriori-style algorithm is then used to compute the FCPs.

1.4 Contributions and outline

The contributions of this paper can be summarized as follows.

- For the first time, we tackle the problem of mining frequent co-occurrence patterns across data streams, an operation that has extensive applications in a variety of contexts but cannot be readily solved using existing frequent pattern mining techniques.

- We propose the DIMine and CooMine approaches with several facilities specifically designed for discovering FCPs across unbounded streams. The CooMine method includes the segmentation of data streams to limit the scope of processing, the Seg-Tree structure that compactly indexes and stores the segments for further processing, the SLCP algorithm that searches the candidate CPs for each new incoming segment, and an Apriori-style algorithm for generating FCPs from candidate CPs.

- Extensive experiments are conducted on two real data sets (a traffic surveillance data set and a Twitter data set), which demonstrate the superiority of two proposed approaches over the baseline method. Indeed, the CooMine method has been deployed in the City of Jinan's Traffic Surveillance and Public Safety Control System, and it has helped the early detection of dozens of criminal activities including vehicle thefts and burglaries over a period of six months.

The remainder of the paper is organized as follows. Section 2 reviews the related work and discusses the distinctions between our proposal and existing methods. Section 3 introduces the preliminaries, and presents the DIMine method as a first attempt to solve the FCP mining problem. Section 4 presents the Seg-tree, which is a novel index structure to maintain the valid segments. The CooMine algorithm based on Seg-tree is described in detail in Section 5. Section 6 presents the experimental results, and Section 7 concludes this paper.

2. RELATED WORK

2.1 Mining frequent patterns from databases

Mining frequent patterns (FPs) from databases is one the classic topic in data mining and has been well studied [2]. Agrawal et al. [3] present the Apriori algorithm to discover the association rules in databases, followed by a great volume of studies (e.g., [19, 18]) that also adopt Apriori-like approaches. All of them require repeatedly scanning the databases to generate candidate frequent patterns. Han et al [9] propose the FP-Tree that can discover frequent patterns without candidate generation, but the method still requires two database scans. Since the data streams are unbounded, in general only one-pass over the data is allowed, rendering those methods inapplicable.

The methods proposed by Tanbeer et al. [20] are claimed to require only a single pass over the database. However, the premise is that all relevant information is captured and stored during this pass over the database, which is then processed in later stages. This is clearly infeasible for unbounded streams.

2.2 Mining frequent patterns from data streams

Mining frequent patterns in data streams has also received considerable attention. The works based on the landmark model (e.g., [15, 21]) aim at mining frequent patterns from the start of the stream to the current moment. Other studies [4, 13, 12, 17] utilize the sliding window technique to discover the recent frequent patterns from data streams. All of these approaches obtain only approximate results with an error bound.

Some methods are proposed to obtain the exact set of recent frequent patterns from data streams [4, 12]. Chang et al [4] propose a data mining method for finding recent frequent itemsets adaptively over an online data stream with diminishing effect for old transactions. Leung and Khan propose a novel tree structure (DSTree) to capture important data from the streams to mine exact frequent patterns [12].

Although these approaches can mine frequent patterns in data streams, they cannot be directly employed to solve the FCP mining problem. Most of them focus on mining frequent patterns in a single data stream, while our task is finding FCPs across multiple data streams.

The only exception to our knowledge is the H-Stream algorithm to discover frequent patterns from multiple data streams [8]. At a first glance, that problem is very similar to ours, but indeed they are quite different. As discussed in Section 1, that work aims to search the frequent patterns that take place in multiple data streams, but does not care about the time interval of the frequent patterns occurring in these data streams. In our problem, the time interval of any FCP across multiple data streams cannot be greater than the specified threshold. Second, this work provides an approximate method but our approach can obtain the exact results. Therefore, the H-Stream algorithm cannot be applied to solve our problem.

The aforementioned existing works about mining frequent patterns from data streams always assume the streams are composed of transactions, and they can directly discover frequent patterns within transactions. But in our problem, the streams just consist of continuous unbounded objects and we have to first determine which objects in one data stream probably can construct a FCP, making the problem more complex.

2.3 Mining spatio-temporal patterns

An extensive body of literature exists on mining interesting patterns from spatio-temporal data [7, 11, 14, 5]. Some [11, 5] study the discovery of valuable trajectories of moving objects, while Li et al. [14] focus on mining spatial association rules. Moreover, there also exist works [7, 16] that study the problem of mining temporally annotated sequences. However, none of them addresses the same problem as mining FCPs, and methods proposed therein cannot be directly applied to our problem.

3. PRELIMINARIES AND A FIRST ATTEMPT

In this section, we first introduce the terminology used in the following discussion and formally define the problem, and then present a first attempt to the FCP mining problem.

3.1 Preliminaries and problem definition

DEFINITION 1. *(**Data stream**) A data stream is a continuous ordered (by timestamps) sequence of objects.*

Data streams are unbounded, and thus it is infeasible to store the data stream locally in its entirety. For an object o_i in the data stream, its ID and timestamp are id_i and t_i respectively.

DEFINITION 2. *(**Co-occurrence pattern, or CP**) For a set of objects $\mathcal{O}=\{o_1, o_2, \cdots, o_k\}$ that appear in a data stream s_i, we say that $\mathcal{O}$ is a co-occurrence pattern CP_k (where k is the number of objects) if $t_{max}^{\mathcal{O}^{s_i}} - t_{min}^{\mathcal{O}^{s_i}} \leq \xi$, where $t_{max}^{\mathcal{O}^{s_i}} = \max\{t_1, \cdots, t_k\}$, $t_{min}^{\mathcal{O}^{s_i}} = \min\{t_1, \cdots, t_k\}$, and ξ is a user-specified threshold.*

DEFINITION 3. **(Frequent co-occurrence pattern, or FCP**) *A co-occurrence pattern CP_k that appears in a set of l streams $\{s_1, s_2, \ldots, s_l\}$ is deemed a frequent co-occurrence pattern, FCP_k, if it satisfies the following conditions: (1) $l \geq \theta$, where θ is a user specified threshold; and (2) $T_{\mathcal{O}}^{\max} - T_{\mathcal{O}}^{\min} \leq \tau$, where $T_{\mathcal{O}}^{\max} = \max\{t_{max}^{\mathcal{O}^{s_1}}, \cdots, t_{max}^{\mathcal{O}^{s_l}}\}$, $T_{\mathcal{O}}^{\min} = \min\{t_{min}^{\mathcal{O}^{s_1}}, \cdots, t_{min}^{\mathcal{O}^{s_l}}\}$, and τ is a user-specified threshold and $\tau \gg \xi$.*

To understand the differences between our problem and the frequent pattern mining problem defined in earlier literature, we also present below the definition of frequent pattern in data streams given in [6].

DEFINITION 4. *(**Frequent patterns, or GHP-FP [6]**) Let the* frequency *of an itemset I over a time period (τ) in the data stream s_i be the number of transactions (where transactions correspond to non-overlapping time windows) in which I occurs. The support of I is the frequency divided by the total number of transactions observed within the time interval t_w of s_i. The itemset I is deemed a frequent pattern if its support is no less than a user-specified threshold, δ.*

We use some examples to illustrate the differences between the above definitions. In Section 1, we have discussed the scenario of each surveillance camera producing a continuous stream of VPRs, and the stream can be divided into time windows, where each window can considered as corresponding to a transaction defined in Definition 4. Consider the following cases.

Case 1: A group of cars are captured by one camera within time span ξ. This group forms a CP even if it is not captured by any other cameras.

Case 2: Within the time interval τ, a group of cars are captured by the same camera together in k non-overlapping time windows and the total number of such windows within τ is f. If $k/f \geq \delta$, this group constitutes a GHP-FP. It is not necessarily a CP unless this group of cars appear within time span ξ ($\xi \ll \tau$) at least once.

Case 3: Within the time interval τ , a group of cars are captured by m different cameras and they pass each camera within the time span ξ. If $m \geq \theta$ (where θ is a threshold that corresponds to the support δ in Definition 4), then this groups is deemed a FCP. By definition, it is also a CP.

Problem Statement. Given a set of data streams of objects and the values of parameters θ, ξ and τ, the problem of mining frequent co-occurrence patterns is to identify, on the fly, the FCPs within the streams as streams evolve over time.

To facilitate the search for FCPs, we divide each stream into overlapping *segments*. Each segment is a sequence of objects ordered by their timestamps, and the time span of a segment is the time interval between its first and last objects.

DEFINITION 5. (**Segment**) *For a given data stream s, a segment $G(o_1 o_2 \cdots o_m)$ is a subsequence of s that satisfies both of the following conditions:*

(1) $|t_i - t_j| \leq \xi$, $\forall$ o_i, o_j in G; and

(2) The time span of G must be maximal with respect to ξ. That is, that does not exist a subsequence of s, G', such that G' is a segment and G is a strict subsequence of G'.

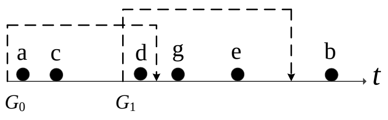

Figure 1: A segment. The temporal relationship between the objects is as follows: $t_d - t_a < \xi$, $t_g - t_a > \xi$, $t_g - t_d < \xi$, $t_g - t_c > \xi$, $t_e - t_d < \xi$, $t_b - t_d > \xi$.

Example 1. Figure 1 shows a stream of objects, where *a* is the first object of the segment G_0. Because $t_d - t_a < \xi$ and $t_g - t_a > \xi$, *d* is the last object of G_0. Note that the objects *c*, *d*, and *g* do not constitute a segment because $t_g - t_c > \xi$.

DEFINITION 6. (**Prefix of the segment**) *For a given segment G_i $(o_1 o_2 \cdots o_m)$, its prefix is a subsequence of G, $o_1 o_2 \cdots o_j$, where $1 \leq j \leq m$.*

The definition of segment dictates that any data stream can be uniquely partitioned. In addition, any CP must be covered by some segment(s). Therefore, the problem of mining FCPs accross multiple streams can be converted to finding the FCPs contained in the segments of the data streams.

3.2 A first attempt: the DIMine approach

Our first attemp to solve the problem of mining FCP is a simple method called DIMine. Following the discussion in Section 3.1, the basic approach is to divide the data streams into segments as the streams evolve, and then discover FCPs from those segments. To this end, we use an inverted index called DI-index to index all existing segments, and also maintain a list storing the information related to each segment including its starting and ending times as well as the ID of the data stream it belongs to. The DI-index can be implemented as a hash map, with each entry taking the form of $(o_i, \mathcal{G}_i)$, where o_i is an object and $\mathcal{G}_i$ stores the set of IDs of the segments containing o_i.

For an incoming segment G, DIMine finds the newly formed FCPs caused by G in the following steps using the anti-monotone Apriori heuristic based on the DI-Index.

(1) For each object o_i in G, it finds the entry $(o_i, \mathcal{G}_i)$ from the DI-Index and then sets $\mathcal{G}_i = \mathcal{G}_i \cup G$, It then verifies whether o_i is a FCP$_1$ (a FCP with only one object) by straightforward counting based on $\mathcal{G}_i$.

(2) It next iteratively generates the set of candidate FCPs with (k+1) objects from FCP$_k$ ($k \geq 1$) caused by G, and picks those that conform to the FCP definition. Assuming that P_{k+1} is a candidate FCP with the set of objects $\{o_1, \cdots, o_{k+1}\}$ and $\mathcal{G} = \mathcal{G}_1 \cap \cdots \cap \mathcal{G}_{k+1}$, if the segments in the set $\mathcal{G}$ involve no less than θ data streams within the time interval τ , then P_{k+1} is a FCP.

As the DI-Index is a hash map, the DIMine approach can find the segments containing a given object o with constant time. Also, the use of the Apriori heuristic helps prune the search space, making the algorithm more efficient.

In addition to finding the FCPs, we also need to worry about the maitenance of the DI-Index, as streams constantly evolve over time, and some objects may become obsolete. The DIMine approach needs to scan all entries of the DI-index frequently to remove the identifiers of the obsolete segments because the expired data will not only cause false positive results but also increase the memory consumption. This task incurs non-trivial cost. Assuming that in a stable state, the number of segments being indexed is n and the average number of objects in a segment is p, then it takes $O(n \cdot p)$ time to detect all expired segments. As will be shown in the experimental results in Section 6, this is actually much more expensive than finding the FCPs.

4. THE SEG-TREE

Addressing the problems with DI-Mine, we present the CooMine approach that has better maintenance efficiency with an index that is more compact when significant overlapping exists between adjecent segments. We call this index the Seg-Tree.

4.1 Motivation

There are two critical issues to be addressed in mining FCPs across multiple data streams. First, as a large volume of segments may be generated at a varying rate, it is important to effectively index them with in a space-efficient manner for further processing. Second, for a new incoming segment, not every existing segment can form FCPs with it; thus it is necessary to quickly narrow down the search space. As such, we need an effective index structure that meets the following requirements: (1) good support for mining FCPs; (2) efficient handling of the insertion of new segments and deletion of obsolete segments; and (3) being frugal with its memory usage.

4.2 Overview of the Seg-tree structure

To satisfy the above requirements, we propose the Seg-Tree, a main-memory-based structure, to manage the valid segments. A segment G is valid, if and only if $t_{now} - t_G^f \leq \xi$, where t_{now} is the current time and t_G^f is the timestamp of the first object of G.

The Seg-tree index structure has three components: the *Seg-tree* itself and two auxiliary structures,*Hlist* and *Tlist*. Figure 2 shows a Seg-tree that indexes the segments in Figure 3.

The Seg-tree is a trie-like structure (but with notable differences) with its nodes corresponding to the objects. (We hereinafter use nodes and objects interchangeably when there is no ambiguity.) Edges exist between objects that appear adjacent to each other in some segment. Segments can be continuously inserted based on their prefixes, and obsolete segments can be removed as time progresses. The nodes are doubly-linked between child and parent. The details of insertion and deletion will be discussed later in Sections 4.4 and 4.5.

The two auxiliary structures are used to quickly locate specific nodes in the Seg-tree. We maintain a separate linked list of references to the nodes corresponding to the same object, and the head of each list is stored in Hlist. In Figure 2, we show the Hlist containing the heads for some of the lists.

Tlist, on the other hand, stores references to all the tail nodes of the Seg-tree, where a tail node refers to the last object of a segment. Each node in the Tlist is a reference to a tail node in the Seg-tree.

Once a tail node expires, we can use Tlist to quickly locate the corresponding segment in the Seg-tree and remove it. Figure 2 shows the links of tail nodes k and o.

4.3 Node structure

For a segment G_j, its last object is represented in the Seg-tree by a tail node tn_j and other objects by *ordinary nodes*. An ordinary node has four attributes $\langle Id$, *object*, *distance*, *count*, *reference*$\rangle$), where Id is the identifier of the node, *object* is the reference to the object represented by this node, *distance* represents the distance (number of edges) from this node to tn_j, *count* records the number of segments containing this node, and $reference$ points to the next node corresponding to the same object in the Seg-tree. For the new segment G_j, for each node, $distance$ can be easily calculated, *object* is known, $count$ is set to 1, and *reference* is initialized to null.

The tail node tn_j has five attributes $\langle Id$, *object*, *distance*, *count*, *reference*, $\mathcal{L}\rangle$. Here, *Id*, *distance*, *count*, and *reference* have the same meaning as that for ordinary nodes. $\mathcal{L}$ is a set of tuples $\{G_j, l_j\}$, where G_j is the segment with tn_j being the tail node and l_j is the length of segment G_j. Because tn_j may be the tail nodes of multiple segments, for each segment G_j, we have to record its length l_j.

With the help of Tlist, the Seg-tree structure has the following property. For the segment G_i, since tn_i records the length (l_i) of G_i, backtracking l_i-1 steps from tn_i to the root of the Seg-tree can uniquely determine the segment G_i, which is linear with respect to the length of the segment.

4.4 Constructing the Seg-tree

The Seg-tree is initialized as a root node (*null*). A new segment G_j can be inserted into the Seg-Tree using the following steps.

- We search for the longest matching prefix (pre_j) of G_j in the Seg-tree, the details of which will be discussed later.
- If pre_j exists, the remaining objects in G_j are appended to pre_j. For a segment, its longest matching prefix probably exists in different branches of the Seg-tree. In case this happens, the first being found will be picked. Otherwise, G_j will be directly added to the root.
- If pre_j exists, we need to update attribute values of the nodes in pre_j after G_j being inserted into the Seg-tree; the attribute values of other nodes remain unchanged.
- We insert the tail node tn_j into Tlist, and append each node of G_j to the respective linked list for the corresponding object.

Example 2. In Figure 2, the Seg-tree manages the segments in data streams s_1 and s_2 (as shown in Figure 3). Now we describe the process of inserting the segments from s_1. At the beginning, the Seg-Tree contains the root only. When the segment G_0 (*b, c, d*) appears, it is added to the root. As to the segment G_1 (*c, d, f, k*), since its prefix (*c, d*) exists in the tree, the objects *f, k* can be appended to the existing prefix. The segment G_2 (*h*, *m*, *n*) has no matching prefix, so it is inserted at the root. The segments G_3 (n, c, p, o) and G_4 (h, b, k, r, s, t) also have existing matching prefixes n and h separately in the Seg-tree, so they can be appended to their existing prefixes.

The Seg-tree is similar to *trie* [1], but they have significant differences. In a trie, the children of any node must have the common prefix. But in the Seg-tree, if a segment has a matching prefix in any branch of the Seg-tree (not necessarily starting from the root), then this segment can be appended to the existing prefix that are shared by multiple segments. Because there may be extensive overlapping between adjacent segments, this sharing can be quite effective in saving memory. For the trie, on the other hand, most of the overlapping segments cannot be compacted because they start with different objects.

Algorithm 1 *Searching prefix* Algorithm

```

15:             break;
16:         end if
17:     end while
18:     if $pre_j.size < pre_i.size$ then
19:         $pre_j$ =$pre_i$;
20:     end if
21: end for
```

In the aforementioned procedure of building the Seg-tree, two issues need to be discussed further.

(1) *Searching matching prefixes.* Searching the matching prefixes in the Seg-tree for an incoming segment is critical for its insertion. We can utilize the Hlist to accelerate this process. To search the matching prefix (pre_j) of a segment G_j ($o_1 o_2 \cdots o_{l_j}$), we first determine the set ($\mathcal{H}$) of nodes matching o_1 based on the Hlist. Next, for each node n_r ($n_r \in \mathcal{H}$), we shall traverse its children to find the node matching o_2. If the child n_c matches o_2, then $\{n_r, n_c\}$ is the current matching prefix of G_j, and we only need to scan the children of n_c to expand pre_j, while other children of n_r can be safely discarded because it is impossible for n_r to have two children that correspond to the same object. In this iterative fashion, pre_j can be determined. The details of searching prefixes are shown in Algorithm 1.

THEOREM 1. *For a given segment G_j with length l_j, the time complexity of searching for the longest matching prefix of G_j from the Seg-tree is $O(l_j)$.*

PROOF. Suppose that there are f nodes corresponding to the object o_1 (the first object of G_j). For any node n_r matching o_1, we at most traverse l_k levels of the subtree rooted at n_r. Hence, the dominating time cost of searching the longest existing prefix of G_j is $f \cdot l_k \cdot t_p$, where t_p is the unit time of traversing one level of the subtree. Since the parameters f and t_p are constants, the time complexity of searching the prefix of G_j is $O(l_j)$. □

(2) *Updating the attribute values of the nodes being inserted.* When G_j is inserted into the Seg-tree, for any node $n_i \in pre_j$, its attribute values have to be updated. Assuming that ($distance_i$, $count_i$ and $reference_i$) and ($distance'_i$, $count'_i$ and $reference'_i$)

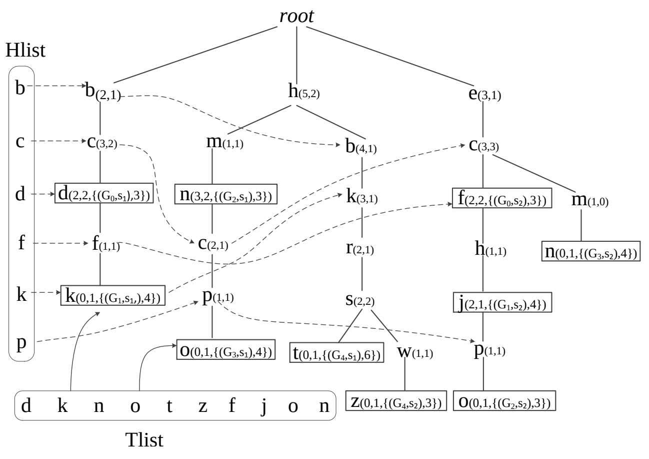

Figure 2: A sample Seg-tree. In this tree, the node in bold boxes are tail nodes and others are ordinary. The node annotation $h_{(5,2)}$ indicates that the distance between h and the farthest tail node t of G_4 is 5, and it appears in two segments. For the tail node $t_{(0,1,((G_4,s_1),6))}$, the tuple $((G_4, s_1)$,6)) represents that t is the tail node of the segment G_4 in s_1, and the length of G_4 is 6.

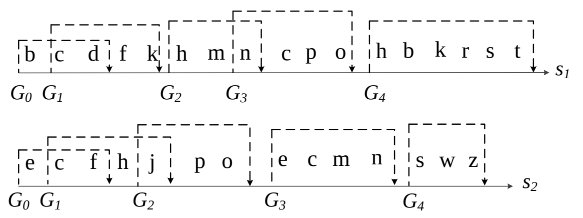

b c d f k h m n c p o h b k r s t
s_1
G_0 G_1 G_2 G_3 G_4
e c f h j p o e c m n s w z
s_2
G_0 G_1 G_2 G_3 G_4

Figure 3: The segments managed by the Seg-tree shown in Figure 2

are the original and updated attribute values of n_i, the attribute values can be updated as follows.

- $distance'_i$=$max\{distance_i, distance'_i\}$. If n_i belongs to multiple segments, $distance'_i$ records the distance between n_i and the farthest tail node of the segments containing n_i.
- $count'_i$=$count'_i + 1$, which means that the number of segments that n_i appears in increases by one.
- $reference'_i$ is still null. If a node n'_i corresponding to the same object as n_i is inserted later, then $reference'_i$ will point to n'_i.
- If the tail node tn_j also belongs to pre_j, then aside from doing the above updates, we also need to add the tuple $\{G_j, l_j\}$ into $\mathcal{L}'_j$, that is, $\mathcal{L}'_j = \mathcal{L}'_j \cup \{G_j, l_j\}$.

Example 3 In Figure 2, before inserting the segment G_1 from stream s_1, the $distance$ and $count$ values of c and d in the Seg-tree are $(1, 1)$ and $(0, 1)$ separately. When G_1 is inserted, since c and d belong to the matching prefix of G_1, the values will be updated to (3,2) and (2,2) respectively.

4.5 Removing obsolete segments from the Seg-tree

As streams proceed, some segments in the Seg-tree will become obsolete. These obsolete segments will waste memory and have negative influence on mining FCPs, and they thus should be removed from the Seg-Tree in time, taking into the cost of removal. On one hand, the existing segments become obsolete frequently, so it is unwise to continuously monitor all segments and delete a segment as soon as it becomes obsolete. On the other hand, if the expired segments are retained in memory for too long, its impact on the memory consumption as well the search efficiency will become an issue.

As a good trade-off between effects of obsolete segments and the deletion cost, a Lazy Deletion (LD) strategy is introduced. In this strategy, we do not delete all expired segments at once, but only remove those that are relevant to the new incoming segment that needs to be processed. The deletion can also be triggered by the used memory exceeding the specified threshold, at which time we will scan the Tlist to find and remove all obsolete segments. Here, the relevant obsolete segments for a new segment can be determined by Algorithm 3 to be presented in Section 5.

Deleting an obsolete segment G_e involves two specific tasks: (1) decreasing the attribute value *count* of nodes in G_e and removing the nodes with *count* being zero from the Seg-tree; and (2) inserting the disconnected subtrees into the Seg-tree. Deleting G_e can possibly cause one or more subtrees being disconnected from the Seg-Tree, and these subtrees need to be added back into the Seg-Tree. For a disconnected subtree, we define its *single prefix* as the path from the root to the first node with more than one child. We treat the single prefix as a segment and insert it into the Seg-tree using the insertion method. The other objects of the disconnected subtree are appended to the prefix. In this way, any disconnected subtree can be inserted back into the Seg-tree.

The deletion cost can be reduced with the help of the Tlist. In the Tlist, we order the tail nodes by their arrival time, and thus we only need to determine the latest obsolete tail node, and then we can infer that all the tail nodes preceding this node are all obsolete. Hence, the obsolete segments can be quickly determined.

4.6 Comparison of Seg-tree and FP-tree

We are inspired by the FP-tree [9] in designing the Seg-tree to support the mining of FCPs. Compared with FP-tree, the Seg-Tree has the following advantages for the problem addressed in this paper.

(1) To construct the FP-tree, the objects in the transactions need to be sorted according to their counts. But in the Seg-tree, the objects in the segments do not need to be sorted, saving on the sorting cost. To be more specific, the count of each object changes frequently as data streams evolve, and therefore the order of objects in existing transactions needs to be adjusted constantly as required by the FP-tree. The FP-tree thus has to be updated or rebuilt frequently, causing inhibitive maintenance cost. As such, the FP-tree is not suitable for mining FCPs across data streams in real-time.

(2) In our problem, there may exist extensive overlapping between nearby segments. If we employ the FP-tree to index them without sorting, no compaction can be achieved according to the insertion rules defined in [9]. When the Seg-tree is used, however, many overlapping segments can be compacted tightly because they have common matching prefixes in the Seg-tree.

(3) The FP-tree deals with static datasets and does not specifically consider the effect of frequent updates, while in our case, the Seg-Tree has to be constantly updated and thus efficient maintenance cost is vital. By adopting the LD strategy to delete the obsolete data at different time granularities, we strive to achieve a balance between memory consumption and deletion cost.

5. THE COOMINE APPROACH

We propose the CooMine approach that can utilize the Seg-tree for mining FCPs. We first give an overview of this approach, and then describe each component in more detail.

5.1 Overview of the CooMine approach

As discussed in Section 3, any FCP is covered by at least θ segments. We thus propose the CooMine approach to mine FCPs from the segments in each data stream. Since the streams are constantly changing with newly arrived objects, the task of mining FCPs is a continuous process, with actions triggered by the creation of each new segment as new objects arrive. For the new segment G_j, the *CooMine* approach consists of two components.

(1) *Searching for the largest common CPs*: If the new segment G_j can form new FCPs with existing segments, the FCPs must be covered by their common CPs. The largest common CP between any two segments refers to the largest set of common objects between them, so any common CP of two segments must be covered by their largest common CP. Therefore, we design an algorithm to find the largest common CPs between G_j and the existing segments to narrow down the search scope. Hereinafter, we use LCP to represent the longest common CP.

(2) *Mining FCPs from the LCPs*: Since the set of LCPs is finite and its size is usually small, mining FCPs boils down to the problem of finding the CPs that appear in at least θ data streams within time interval τ. This problem can be solved with an Apriori-style algorithm.

5.2 The SLCP algorithm for searching LCPs

A naive method to find the LCP is to compare the new segment with every existing segment. However, since only a few existing segments have common CPs with the new segment, comparisons with many segments are wasteful. Also, the cost will be huge when the Seg-tree is large.

To cut down the search cost, we design the *SLCP* algorithm to find the LCPs between the new segment G_j and existing segments. This algorithm first searches the *relevant segments* for each node of G_j, where the relevant segments are defined below in Definition 7. Next, it can deduce which common nodes with G_j each relevant segment has. The set of common nodes between each relevant segment and G_j is a LCP.

DEFINITION 7. (Relevant segment): *For any node n_i (except the root) in the Seg-tree, if the segment G_i contains n_i, then G_i is a relevant segment of n_i, and tn_i is a relevant tail node of n_i.*

Algorithm 2 describes the SLCP algorithm. First, for each node n_i of G_j, we find all nodes that have the same identifier with n_i based on Hlist (Line 4). Second, for any node n_j that corresponds to the same object as n_i, we determine its valid relevant segments (Line 5). Third, once the relevant segments of each node are determined, the LCPs are computed (Line 6-8).

In the SLCP algorithm, discovering the LCPs is a non-trivial problem. In the procedure of building the Seg-tree, any segment itself will be discarded after being inserted into the Seg-tree. Meanwhile, the ordinary nodes of the Seg-tree no longer record the information of their relevant segments for memory saving. In this case, for any ordinary node, we cannot directly determine the segments containing it. Therefore, we need to find an efficient way to determine the relevant segments for the specified nodes.

5.2.1 Searching relevant segments

We propose the *DistanceBound* method that can efficiently find relevant segments for the specified nodes. The *DistanceBound* method can prune the search scope by utilizing the distance between each node and its furthest relevant tail node as bound to accelerate searching relevant segments for the specified node. For the specified node

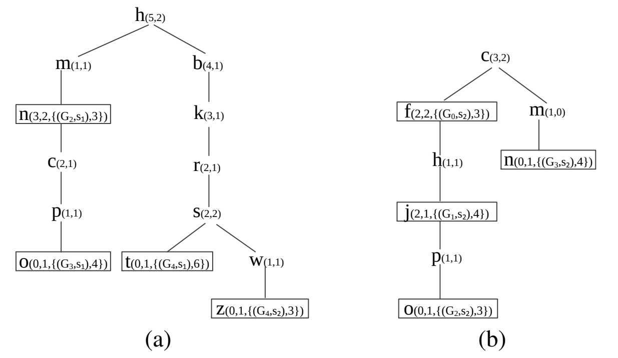

Figure 4: Two subtrees of the Seg-tree

n_j, this method visits n_j and guarantees that by visiting Dis_j levels of the tree rooted at n_j, it can find all relevant tail nodes for n_j according to Theorem 2. When this method visits any child n_c of n_j, only $min\{Dis_c, Dis_j - 1\}$ levels of the tree rooted at n_c need to be traversed. In this way, the search algorithm can quickly converge and the search space can be reduced.

Algorithm 3 describes the process of searching relevant segments for n_j, which consists of four steps:

Step 1: Build a queue *Q* and enqueue the pair $\langle n_j, stepcount\rangle$ into *Q*, where *stepcount*=Dis_j. (Lines 1-4)

Step 2: Get the first pair $\langle n_x, stepcount\rangle$ from *Q*. (Line 6)

Step 3: If n_x is a relevant tail node of n_j, insert n_x into the set $\mathcal{R}$. Otherwise, for each child n_c of n_x, set *stepcount* as $min\{Dis_c$, *stepcount*-1$\}$ and enqueue $\langle n_c, stepcount\rangle$ into *Q* if $stepcount \neq 0$. (Lines 7-15)

Step 4: If *Q* is not empty, go to step (2); otherwise, return the set $\mathcal{R}$ and the search ends. (Line 5)

In Step 3 , for the tail node n_x, if we assume that its corresponding segment is G_x with length l_x and the distance from n_j to n_x is D_{jx}, then G_x is a relevant segment of n_j if l_x is no less than D_{jx} and G_x is valid.

THEOREM 2. *For any node n_j in the Seg-tree, all relevant tail nodes of n_j can be found by visiting at most Dis_j levels of the tree rooted at n_j.*

PROOF. Suppose that there is a tail node tn_j that cannot be discovered even if after taking (Dis_j-1) steps in each branch of n_j. Since n_j and tn_j belong to the same segment, tn_j and n_j must be in the same branch. Because tn_j cannot be found by taking Dis_j steps from n_j in this branch, the distance from n_j to tn_i must be greater than Dis_j. However, Dis_j is the distance between n_i and the farthest relevant tail node. Contradiction. $\square$

The *DistanceBound* algorithm can effectively prune the search space based on the attribute $distance$ of nodes. Figure 4 shows two subtrees of the Seg-tree in Figure 2. In Figure 4(a), the node h has attribute Dis_h as 5; the *DistanceBound* algorithm thus probably needs to take 5 steps in its each branch to find the relevant tail nodes for h. However, when it visits the node m and finds that Dis_m is equal to 1, it then only needs to take one step in the branch of m to search the relevant tail node n. The nodes after n do not need to be scanned. As to the node c in Figure 4(b), since Dis_c is 3, we only need to traverse its left branch by 3 steps to search for the relevant tail node j, and nodes after j can be ignored.

5.2.2 Obtaining the LCPs

For each node n_i in G_i, all relevant segments of n_i can be determined by the *DistanceBound* algorithm. If we employ a hash table

Algorithm 2 Searching for LCPs (*SLCP*)

```
Require:
    The new segment $G_j$, the Seg-Tree;
Ensure: :
    The LCPs between $G_j$ and existing segments;
1: $\mathcal{H}_i$=null; // a set of nodes have the same identifier with $n_i$
2: The Map$< G_i, P_i >$ map=null; // $P_i$ is the LCP between $G_j$ and $G_i$
3: for $n_i$:$G_j$ do
4:     $H_i$=Hlist($n_i$);
5:     $\mathcal{R}_i$=DistanceBound ($H_i$); // $\mathcal{R}_i$ includes segments covering $n_i$
6:     for $G_i$:$\mathcal{R}_i$ do
7:         map.add($< G_i, n_i >$);
8:     end for
9: end for
10: Output map;
```

Algorithm 3 *DistanceBound* Algorithm

```
Require:
    $H_i$;
Ensure: :
    The relevant segments of $n_i$;
1: stepcount=0, $\mathcal{R}$=null, Queue=null;
2: for $n_k$:$H_i$ do
3:     stepcount=$Dis_k$ and generate the pair $\langle n_k$, stepcount$\rangle$;
4:     Queue.put($\langle n_k$, stepcount$\rangle$);
5:     while Queue$\neq$ empty do
6:         $n_f$=Queue.getfirst();
7:         if $n_f$ is a tail node and $G_f$ covers $n_k$ and $G_f$ is valid then
8:             $\mathcal{R}_k$.add($G_f$)
9:         end if
10:        for $n_c$:children of $n_f$ do
11:            stepcount=min$\{Dis_f, (stepcount - 1)\}$;
12:            if stepcount $\neq 0$ then
13:                Queue.put($\langle n_c$, stepcount$\rangle$);
14:            end if
15:        end for
16:    end while
17:    $\mathcal{R}$=$\mathcal{R} \cup \mathcal{R}_k$;
18: end for
19: return $\mathcal{R}$;
```

to store the relevant segments with the key being the ID of each relevant segment and the value being a list of nodes common to this segment and G_i, then the largest set of common nodes between each relevant segment and G_i can be immediately determined, and the largest set of common nodes is a LCP between G_i and the corresponding relevant segment.

5.3 Mining FCPs from the LCPs

5.3.1 Mining FCPs with the Apriori heuristic

For the new incoming segment G_j, if it can form new FCPs with existing segments, then these FCPs must be covered by their LCPs. Therefore, we can mine the FCPs from the these LCPs with the anti-monotone Apriori heuristic. The basic idea is to iteratively generate the set of FCPs with $(l + 1)$ objects based on the set of FCPs with l $(l \geq 1)$ objects. Theorem 3 guarantees the correctness of the CooMine algorithm.

Table 1: Summary of common CPs

LCPs	segments
$\{m, n, \}$	$\{G_2, s_1\}$
$\{n, p, o\}$	$\{G_3, s_1\}$
$\{p, o\}$	$\{G_2, s_2\}$
$\{m, n\}$	$\{G_3, s_2\}$
$\{n\}$	$\{G_4, s_2\}$

Algorithm 4 CooMine Algorithm

```
Require:
    The new segment $G_i$, The Seg-Tree;
Ensure: :
    The FCPs of length $k$ formed by $G_i$;
1: LCPtable = SLCP($G_i$, Seg-tree);
2: $l$=1;
3: while $l < k$ do
4:     if $l = 1$ then
5:         Obtaining FCPs of length $l$ based on the LCPtable;
6:     else
7:         Generating candidate FCPs with length $l$ based on the FCPs of length $l - 1$;
8:         Detecting each candidate FCP based on the LCPtable and discover the FCPs of length $l$;
9:     end if
10: end while
11: Output the FCPs of length $k$.
```

THEOREM 3. *If a set of objects $\mathcal{O}_n$ is a FCP, then any of its subset $\mathcal{O}_n^{'}$ must also be a FCP.*

Since LCPs are found from valid segments, the time span of all obtained LCPs must be no greater than the threshold τ. According to the Definitions 2 and 3, if a CP occurs in more than θ data streams within the time interval τ, then this CP must be a FCP. Hence, the CooMine algorithm only needs to consider the number of data streams that the LCPs appear in. Because all LCPs between T_k and existing segments have been found by the *SLCP* algorithm, the CooMine algorithm (Algorithm 4) only needs to mine all FCPs from the LCPs.

Example 4. Assuming that G_0 (*mnpo*) is a new segment in data stream s_3 and the parameters k and θ (cf. Definition 3) are 2 and 3 separately. Table 1 shows the LCPs between G_0 and existing segments in Figure 2. Based on Table 1, CooMine can find the FCPs of size 1 ($\{m\}$, $\{n\}$, $\{o\}$, $\{p\}$), and then deduce the FCPs of size 2 ($\{m, n\}$, $\{p, o\}$). Since only one LCP has three objects, we assert that there does not exist a FCP of size 3.

5.4 Advantages of our approach

CooMine has the following advantages.

(1) The use of the Seg-tree to index the valid segments can help save on memory consumption. The segments are inserted into the Seg-tree based on the prefix rule, and many common objects in multiple segments can be compacted to save memory. In addition, the ordinary nodes in the Seg-tree do not record the segments that they belong to and only the tail nodes maintain this information. Since ordinary nodes make up the largest part of the Seg-tree and each ordinary node always takes place in multiple segments, omitting the segments information from ordinary nodes can save much on memory consumption.

(2) The maintenance cost of the Seg-tree is low. A new segment can be inserted into the Seg-tree with a small cost because its

Table 2: The parameters used in the experiments

parameters	meaning
ξ	the time interval in Definition 2
k	the number of objects in one FCP
τ	the time interval in Definition 3
θ	the number of streams in Definition 3
D_s	the scale of data

matching prefix can be quickly determined; the obsolete segments can be immediately determined with the help of the Tlist, and the LD strategy can remove the obsolete data at different granularities to reduce the deletion cost.

(3) CooMine first searches the LCPs covering all FCPs between each new segment and existing ones; this step can effectively narrow down the search scope for mining FCPs.

6. EXPERIMENTS

We conduct experiments to evaluate the performance of DIMine and CooMine methods, and compare them with the MatrixMine algorithm that is introduced as a baseline method. The parameters involved in experiments are illustrated in Table 2.

Specifically, we first evaluate the index structures employed in three methods with respect to memory consumption and maintenance cost, and then compare the performance of the three methods for computing FCPs. Finally, we test the influence of varying parameters on the CooMine algorithm in the following aspects: the time of discovering FCPs, the sustainable workload, and the number of FCPs.

In our experiments, we implement three methods (CooMine, DIMine, and MatrixMine) using Java and the indexes of three methods all employ the standard Java Collection classes as the storage structure to record the segments information. To make the results more accurate, every evaluation is repeated ten times and the average values are recorded as the final results.

6.1 Experimental setup

The experiments are conducted on a Dell OPTIPLEX 990, a PC with a 3.1GHz Intel i5-2400 processor and 8GB RAM. Two real datasets are used. One dataset is a traffic records dataset (TR dataset) of Jinan city in China. The TR dataset contains all VPRs (vehicle passing records) of each monitoring camera in Jinan on May 1, 2013. For each monitoring camera, we simulate its passing records as a data stream, then the TR dataset can be viewed as multiple data streams. For the TR dataset, D_s represents the number of VPRs, and each vehicle (identified by its license plate) is an object.

The other dataset (the Twitter dataset) is provided by Twitter for academic research purposes[1]. In Twitter dataset, each word is considered an object and a tweet corresponds to a segment. In this case, all of the objects in a segment appear at once, as a tweet as a collection of words is posted as a whole. The tweets by the same user constitute one data stream. D_s represents the number of all segments (tweets).

6.2 The baseline method

Since none of the existing methods is applicable to the problem of finding FCPs in real-time either because they address a different problem or because their cost is apparently too expensive when applied to this problem, we introduce the MatrixMine algorithm as the baseline method, and compare it with our proposed methods w.r.t. memory consumption, maintenance cost, mining time, and total cost.

MatrixMine also divides the data stream into segments and then mines FCPs from the segments. The information of all segments are maintained in an independent list and we can obtain the information of each segment based on its identifier from this list. MatrixMine maintains a matrix M that keeps track of each pair of co-occurring objects. If we assuming that there are n distinct objects ($\{o_1, \cdots, o_n\}$) in a particular application, then M is a $n \times n$ matrix, where each element $c_{i,j}$ of M corresponds to the pair $p_{i,j}$ that consists of objects o_i and o_j ($1 \leq i, j \leq n$). Because the pair $p_{i,j}$ probably occurs in different segments, the corresponding element $c_{i,j}$ has to maintain a set $\mathcal{I}_{i,j}$ that contains multiple tuples and each tuple is represented as $\langle G_j, s_h \rangle$, where G_j is the identifier of the segment that $p_{i,j}$ belongs to, and s_h is the data stream containing G_j.

For any pair $p_{i,j}$ of the new segment G_j, MatrixMine can determine whether $p_{i,j}$ is a FCP based on $\mathcal{I}_{i,j}$ because it records the identifiers of all segments covering the pair $p_{i,j}$. Once the FCPs with two objects are obtained, MatrixMine can iteratively generate the FCPs with more objects employing the Apriori heuristic.

The maintenance of the matrix M includes the insertion of newly generated pairs and the deletion of obsolete pairs. When a new pair $p_{i,j}$ appears, it must be inserted into M right away. To reduce the deletion cost of the Matrix structure, we also adopt the Lazy Deletion strategy to remove the obsolete data from the matrix.

6.3 The performance of index structures

We compare the Seg-tree, the DI-Index, and the *Matrix* with respect to memory consumption and the maintenance cost, and the results are shown in Figure 5.

Memory consumption. Figure 5(a) shows the memory consumption of index structures on the TR dataset. Here, we test the memory consumption for processing the incoming data within one second with varying arrival rates when D_s is fixed, where D_s represents the volume of data that has been processed. The experimental results demonstrate that the memory consumed by Seg-tree is about 80% of that consumed by DI-Index and only 25% of that by *Matrix* because of the overlap between segments makes it possible to compact them tightly in the Seg-tree. *Matrix* consumes much more memory than Seg-tree and DI-Index, and the reason is the *Matrix* has to maintain a large volume of elements.

Figure 5(b) shows the result on the Twitter dataset, where the Seg-tree consumes slightly more memory than DI-Index. The reason is that most adjacent segments (tweets) do not overlap, and the Seg-tree cannot compact them as well as for TR. However, the Seg-tree still consumes much less memory than the *Matrix*.

Maintenance cost. Figure 5(c), 5(d) and 5(e) show the maintenance time of processing the data within one second with different arrival rates for the two datasets. In Figure 5(c), we evaluate the maintenance cost of the Seg-tree, DI-Index, and *Matrix* with the fixed values of the parameters ξ, τ, and D_s . The results demonstrate that the maintenance cost of the Seg-tree is much smaller than that of DI-Index and *Matrix*, while the *Matrix* has the largest maintenance cost. Specifically, the maintenance cost of the Seg-tree is approximately 50% of that consumed by DI-Index, while the maintenance cost of *Matrix* is almost 20 times as big as that of Seg-tree. In the Seg-tree, we can immediately determine the expired segments based on the Tlist and remove them, which can save much maintenance time. But in DI-Index and *Matrix*, we have to detect each element to remove the obsolete data, increasing the maintenance cost. Since the number of elements in *Matrix* is greater than that of elements in DI-Index, maintaining *Matrix* is more expensive than maintaining the DI-Index.

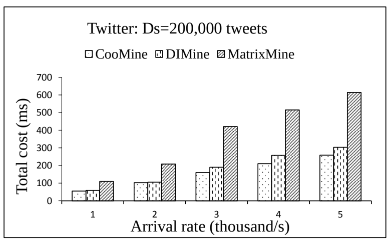
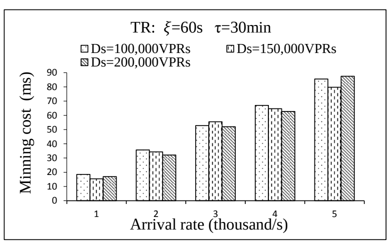
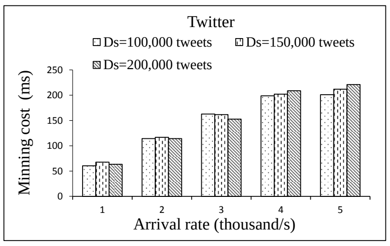
(c) Comparison of total cost (TR)



(d) Comparison of total cost (Twitter)



(e) Mining cost w.r.t D_s



(f) Mining cost w.r.t D_s

Figure 6: Performance of mining algorithms

Figure 5(d) shows that the parameter ξ has little influence on the maintenance time of the Seg-tree, but it affects the maintenance cost of DI-Index and *Matrix* more significantly. The reason is that the sizes of segments will become larger when ξ takes greater values, and the larger segments have very slight influence on the maintenance time of the Seg-tree because each segment can be inserted and removed in its entirety regardless of its length. However, the larger segments contain more objects, which can produce more elements for DI-Index and *Matrix*, and they thus need much more time to maintain the larger segments.

Fig. 5(e) shows the maintenance cost of the three index structures for the Twitter dataset. Similar to the case of the TR dataset, the Seg-tree has the less maintenance cost than DI-Index and *Matrix*.

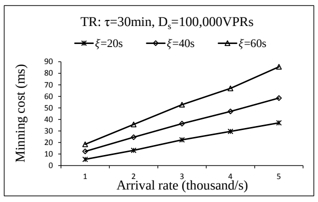
According to the aforementioned experimental results, we conclude that the Seg-tree and the DI-Index outperform the *Matrix* w.r.t. memory consumption and maintenance cost. In most cases, the performance of Seg-tree is better than that of the DI-Index structure except the memory consumption for processing the Twitter dataset.

Compression ratio. To help us better understand the memory consumption, assuming that the original data to be indexed is d_1 and the real data stored in the Seg-tree is d_2, the compression ratio of the Seg-Tree is defined as (d_1-d_2)/d_1. In Fig. 5(f), the compression ratio based on TR dataset is very high, which means the Seg-tree can compact the overlapping segments very well. As to the Twitter dataset, the compression ratio becomes very low as there are less overlapping between segments. Therefore, it would be helpful to look at the degree of overlapping between segments before deciding on the index structure for mining FCP.

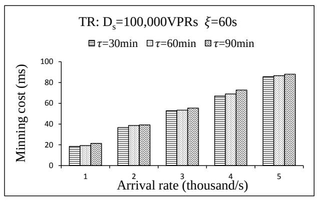
6.4 Performance comparison of the mining algorithms

Comparison of mining cost. First, we compare the mining performance of CooMine, DIMine, and MatrixMine algorithms on the two datasets in Fig. 6(a) and 6(b). For the TR dataset, the mining time of the three algorithms is almost identical. However, the mining cost of the CooMine algorithm is larger than that of the DIMine and MatrixMine methods on the Twitter dataset. This is again due to the lower degree of overlapping between segments, which renders some optimizations of the CooMine algorithm not applicable in reduing the mining cost.

Comparison of total cost. In this group of experiments, we evaluate the total cost of the three algorithms for processing the data within one second with varying arrival rates based on two datasets, and the results are shown in Fig. 6(c) and 6(d). For the set of data being processed, the total cost includes the time of inserting this set of data into the index structure and removing the relevant obsolete data from the index structure, as well as the time of mining FCPs from this set of data. The results show that CooMine performs best, and both CooMine and DIMine outperform the MatrixMine approach dramatically regardless of the dataset.



(a) Mining cost w.r.t ξ



(b) Mining cost w.r.t τ

Figure 7: FCPs w.r.t D_s

6.5 Evaluation of the CooMine algorithm

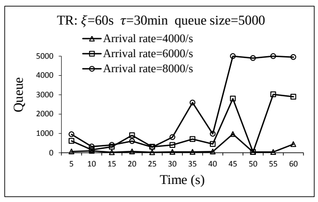
Since the CooMine algorithm is better than the other two methods with respect to the total cost, we only evaluate the influence of varying parameters on its performance.

Mining cost w.r.t. D_s. We test the influence of D_s on the performance of CooMine for mining FCPs on two datasets in Fig. 6(e) and 6(f). The results show that D_s has no evident effect on the mining cost because the CooMine algorithm only needs to search a small portion of the data to find FCPs.

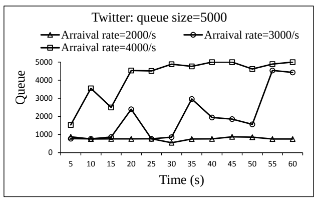
Mining cost w.r.t. ξ and τ. Fig. 7(a) shows that the mining time is also affected by the parameter ξ. The larger value of ξ will give rise to longer segments, and the segments with larger sizes will cause more LCPs between each new segment and existing ones, which can increase the mining time. Fig. 7(b) demonstrates that the parameter τ has little impact on the mining cost. This is because although the larger value of τ can cause more valid segments, the CooMine algorithm can still efficiently narrow down the search scope.

Maximum sustainable workload. To evaluate the maximum sustainable workload of the CooMine algorithm, we introduce a buffer queue with 5000 storage units to cache the incoming data, and the CooMine algorithm will fetch the data from this queue. In this case, the usage rate of the buffer queue reflects the processing capacity of the CooMine algorithm.

In Fig. 8(a), we evaluate the buffer queue usage at different time points based on the TR dataset. When the arrival rate reaches 8000 VPRs per second, the maximum usage of the buffer queue is 5000. Therefore, the maximum sustainable workload of the CooMine algorithm based on the TR dataset is 8000 VPRs per second. Fig.



(a) Maximum sustainable workload (TR)



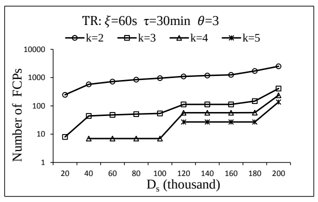
(b) Maximum sustainable workload (Twitter)

Figure 8: FCPs w.r.t D_s

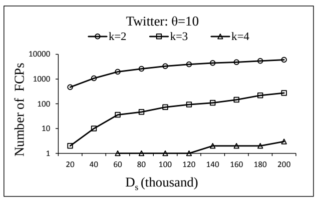
8(b) shows that the maximum sustainable workload based on the Twitter dataset is about 4000 tweets per second.

6.6 Effect of parameters on the number of FCPs

We now evaluate the influence of the parameters D_s and θ on the number of FCPs generated for the two datasets.



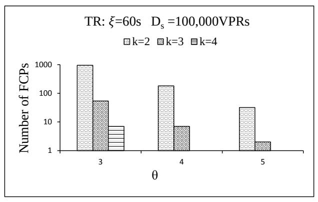
(a) Results on TR



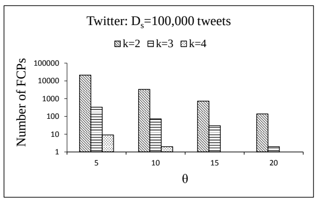
(b) Results on Twitter

Figure 9: The number of FCPs discovered w.r.t D_s

Fig. 9(a) and 9(b) show that the number of FCPs increases with more data being mined for the TR and Twitter datasets respectively. For a fixed volume of data, there exist more FCPs with smaller sizes (k).



(a) Results on TR



(b) Results on Twitter

Figure 10: The number of FCPs discovered w.r.t θ

We also test the effect of the parameter θ on the number of FCPs in Figure 10(a) and 10(b). When the value of θ becomes larger, the number of FCPs drops sharply, which coincides with our intuition that the higher the threshold, the less FCPs will appear.

Finally, we analyze the FCPs from the Twitter dataset with θ equal to 60 and illustrate some typical hot events that the FCPs imply in Table 3 and Table 4, demonstrating that mining FCP is indeed useful in such applications.

6.7 Discussion

We have compared the CooMine, DIMine, and MatrixMine approaches with respect to the memory consumption, the maintenance cost, the mining cost, and the total cost on two datasets. The results demonstrate that CooMine and DI-Mine approaches outperform the MatrixMine method significantly for mining FCPs. Between the CooMine and DI-Mine approaches, we find that the CooMine approach based on the Seg-tree is better suited to process

Table 3: Typical FCPs from the Twitter dataset

FCPs	The number of streams	Hot event
super bowl	1378	event1
green bay packers	213	
win steelers	226	
jack lalanne dies	139	event2
airport killed	111	event3

union state address	409	event4
obama sotu	456	
science fair	63	
health care	261	

Table 4: Hot events

Event	Meaning
event1	*Green Bay Packers and Pittsburgh Steelers played the Super Bowl on February 6, 2011.*
event2	*Jack lalanne, the American exerciser, and nutritional expert, died on January 23, 2011.*
event3	*The Domodedovo International Airport bombing on January 24, 2011.*
event4	*Barack Obama presented the 2011 State of the Union Address on January 25, 2011.*

data streams that have much overlap between segments, while the DIMine approach is more suitable for handling data streams without overlapping segments.

7. CONCLUSION

Mining frequent co-occurrence patterns (FCPs) across multiple data streams is essential to many real-world applications, but this problem has not been addressed by exiting works. In this paper, we design the DIMine and CooMine approaches to mine FCPs using only one pass over the data streams. In both approaches, we first divide each data stream into overlapping segments, and then mine the FCPs within those segments. The DIMine approach uses an inverted index (DI-Index) to maintain the valid segments in main memory and adopts an Apriori-style heuristic to iteratively discover FCPs based on this index. In the CooMine approach, we construct the Seg-tree, a memory-based index structure, to compactly index all valid segments. Based on the Seg-tree, the CooMine approach first finds the largest common CPs between each new segment and the existing ones to narrow down the search scope, and then discover the FCPs from the obtained common CPs. Finally, we introduce a baseline method and conduct extensive experiments to compare our proposed approaches with this baseline method. The experimental results demonstrate that our proposed approaches outperform the baseline method by a significant margin.

For future work, we would like to study how to extend the proposed approaches to a distributed environment to handle greater scales of data streams, when a single machine is no longer capable of managing the large volumes of data and computation.

ABSTRACT

Aggregate queries in integration contexts often do not have one "true" answer; there can be multiple correct answers for the same aggregate query. This is due to the existence of duplicate or overlapping data points, possibly with different values, across the data sources. Depending on the choice of data source combinations that are used to answer the query, different answers can be generated. Thus, representing the answer to the aggregate query as an *answer distribution* instead of a single scalar value, will allow the users to better understand the range of possible answers.

This work provides a suite of methods for extracting statistics that convey meaningful information about aggregate query answers in heterogeneous integration settings. We focus on the following challenges: 1. determining which statistics best represent an answer's distribution; and 2. efficiently computing the desired statistics.

Our solution includes the following answer statistics 1. a set of *point estimates* with confidence intervals; 2. a *high coverage interval* that unveils "hot areas" in a distribution; and 3. a *stability score* that measures the impact of source dynamics. We optimize the extraction of the above statistical information by minimizing the sampling load and applying fast approximate algorithms. We verify the effectiveness and efficiency of our methods with empirical studies using real-life and synthetic, scaled data sets.

1. INTRODUCTION

Aggregate queries are fundamental to relational databases. They group sets of data values and calculate informative statistics such as average, median, and sum. They are also important in heterogeneous integration systems [1, 2, 9] where the focus shifts from querying a single database to querying multiple, independently managed, domain heterogeneous databases. The characteristics of heterogeneous information systems make the generation of meaningful aggregate values for heterogeneous information systems significantly more challenging than aggregations in a typical

Figure 1: Climate data from BC weather stations.

relational database.

Answering aggregate queries in a heterogeneous information system often requires combining sets of data that are segmented across multiple sources. These sources may vary substantially with regard to their schemas and the instances they hold, i.e., semantically related content may be stored in different structures, at different levels of granularity, in different representations, and multiple formats.

There are three levels of heterogeneity in heterogeneous information systems [19]. The first is schema-level. This occurs when there are different schema elements representing the same concept, e.g., one schema may contain a "temp" attribute, while another contains a "temperature" attribute. The second is instance-level heterogeneity. This level requires performing entity resolution to tell if two objects are the same, e.g., that the data for "Vancouver Weather 2006/06/11" in one data source is the same as "Vancouver Weather 06/11/2006" in another. The third is value-level heterogeneity. Heterogeneity at this level deals with the fact that because the sources are independently created and maintained, a given data point can have multiple, inconsistent values across the sources. For example, one source may have the high temperature for Vancouver on 06/11/2006 as 17C, while another may list it as 19C. It is this value-level heterogeneity with which we are concerned throughout this paper. Particularly, we look at the problem of how to handle value-level heterogeneity in aggregations.

To illustrate the problem, consider JIIRP [17], a real-world disaster management project. In JIIRP, data from various sources are combined to simulate the impact of natural disasters. For example, JIIRP assesses weather phenomena and climate data to help plan emergency responses. Figure 1 shows local data sources containing climate data for cities located in British Columbia (BC, Canada). As shown in the figure, the sources differ in terms of their coverage of

10.5441/002/edbt.2015.09

the data instances and attributes. Additionally, data sources D_1, D_2, and D_3 hold different values for the same data point Vancouver on 06/11/2006.

Next, consider the following query, in which the data sources are queried to find the average temperature for months with an average temperature above 20 degrees Celsius:

```
Select Average(Temp), Month(Date), Province(Location)
From SemIS
GROUP BY Province(Location), Month(Date)
HAVING Average(Temp) > 20
```

Applying standard aggregation, however, is incorrect. In particular, standard aggregation would simply return the average of all the points. This is problematic for two reasons: (1) There are some values which are present in more than one source (e.g., Vancouver's temperature on 06/11/2006 is represented in all of sources D_1, D_2, and D_3; taking the simple average will cause Vancouver to be over-represented in the average.) (2) The different sources may have different values for the same conceptual answer (e.g., depending on which source is used, the temperature for Vancouver on 06/11/2006 is either 17, 19, or 22).

The correct aggregation requires using only one value per data point:

$$Average(t) = \frac{\sum_{c=1}^{|\mathcal{C}_{BC}|} \sum_{d=1}^{|\mathcal{D}_m|} t_{c,d}}{|\mathcal{C}_{BC}| * |\mathcal{D}_m|} \tag{1.1}$$

where t is temperature, c represents city, $|\mathcal{C}_{BC}|$ is the number of cities in BC, d represents day, $|\mathcal{D}_m|$ is the number of days in month m. The above aggregation requires 1470 data points (49 cities in BC * 30 days), each of which could have several duplicates across the sources. Depending on the choice of source and value combinations, there can be a whole range of *viable answers*.

For such queries, enumerating all the possible value combinations, and generating the entire set of viable answers as the answer to the aggregate, not only does not scale well (due to combinatorial explosion with regard to the number of data points and possible duplicates), but would still require the users to analyze the results and determine suitable answers.

This problem is not unique to weather data or the JIIRP scenario, for example, [19] examined inconsistency and redundancy at the value-level, in the stock and flight domains on the Deep Web. However, in [19] the authors assumed that there was a single "true" answer, which we do not.

In this paper, we assume meta-information that describes the mappings and bindings between data sources is available [25]. Similar to [19], we focus on value-level heterogeneity. Specifically, we propose a suite of methods for summarizing aggregate query answers in integration settings.

Our previous work [25] created a system where one could ask such aggregate queries. It defined what the possible viable answers were, but then it randomly chose a viable answer. This is inappropriate both since it does not explain the choice, and the aggregate answer would fluctuate upon reprocessing the query. Selecting a best guess answer or a top-K answer set is also inadequate; there is often no global mediator available to choose the value and source combination for the aggregation.

Our solution consists of first estimating the distribution of the viable answers. However, instead of enumerating all the viable answers and computing the full, accurate distribution, we combine a variety of statistical estimations into what we term the *viable answer distribution.* We then efficiently extract statistical summaries of the viable answer distribution to allow the user to better interpret and understand the viable answers. Thus, we contribute the following:

- We define aggregate answers in heterogeneous information systems as a distribution of viable answers computed from different data source and value combinations.

- We provide three summary statistics for the viable answer distribution, consisting of: 1. key point statistics with user defined confidence intervals; 2. high coverage intervals to convey distribution shape information and 3. a stability measure for the aggregation.

- We provide algorithms to efficiently extract the above statistics, including 1. estimating point statistics using sampling and ways to reduce sampling overhead while keeping the confident intervals tight; 2. a fast, greedy algorithm to extract hot areas; and 3. using a probabilistic model to calculate stability scores without simulating source removal. Overall, we can support online extraction of aggregation statistics.

- We describe our empirical study using real-life and synthetic data sets, further verifying our theoretical and algorithmic claims on effectiveness and efficiency.

The paper is organized as follows. We describe preliminary statistical methods applied in our solution in Section 2 and formalize the problem in Section 3. We present the technical details of the distribution estimate process and optimizations in Section 4, the empirical study in Section 5, and review related work in Section 6. We conclude in Section 7.

2. PRELIMINARIES

In this work we use lower case letters for scalars (e.g., a) and typeset the sets (e.g., $\mathcal{A}$); all other variables, including random variables, are denoted by capital letters (e.g., A).

2.1 Bootstrap sampling and bagging

Bootstrap sampling, or bootstrapping, is a resampling technique which combined with Bootstrap aggregating (bagging) [7], can be used to improve the quality of an estimate. The bootstrapping starts with an initial (small) sample set $\mathcal{S}_{alg}$ sampled according to some sampling algorithm alg. This set is then resampled according to alg to obtain a set of bootstrapped sample sets $\mathcal{S}_{boot} = \{\mathcal{B}^i_{boot}\}$ where $i = 1, 2, \ldots, |\mathcal{S}_{boot}|$. Next, an estimator is applied to each set to obtain an ensemble of bootstrapped estimates $\mathcal{E}_{boot} = \{E^i_{boot}\}$. Bagging then approximates a more accurate estimate with tighter confidence intervals by combining (e.g., averaging) this ensemble of estimates. For example, the median value of $\mathcal{E}_{boot}$ can be used as the estimate of the mean of the distribution. We use the above methods to estimate the density of the viable answer distribution.

2.2 Kernel density estimation

Kernel density estimation (KDE) estimates the probability density function (pdf) of a distribution using a sample set drawn from the distribution. We use kernel rather than histogram density estimation due to properties such as smoothness, independence of parameters like bin size, and because KDE often converges to the true density faster. It works as follows: Let the sample set be $\mathcal{S}_{alg} = \{x_i\}$, where $i = 1, 2, \ldots, |\mathcal{S}_{alg}|$. A sample point x_i's contribution to the pdf is measured using a kernel function $K(\frac{x-x_i}{h})$, where h is the bandwidth. After kernels are applied to all x_i's, the pdf is estimated by $f(x) = \frac{1}{|\mathcal{S}_{alg}|h} \sum_1^{|\mathcal{S}_{alg}|} K(\frac{x-x_i}{h})$.

Among the various possible kernel functions, typically Gaussian kernels $K(x) = \frac{1}{\sqrt{2\pi}} e^{-\frac{x^2}{2}}$, are used for convenience of theoretical analysis. Note that using a Gaussian kernel makes no assumption that the data adheres to a Gaussian distribution. The bandwidth parameter h controls the localness of a point's impact on the distribution. A large h results in a smooth density function, but is likely to underfit, whereas a small h fits better on the sample points but is likely to over-fit. Selecting an appropriate h value is challenging but there are automatic methods for choosing the value of h [6]. We use KDE to estimate the viable answer density distribution.

2.3 Distance measures for distributions

Several distance measures exist for comparing and quantifying the difference between two distributions p and q. For example, $d_{L_2}(p, q) = \sqrt{\int [p(x) - q(x)]^2 \, dx}$ is the L_2 norm. Also, $d_{Bh}(p, q) = \int \sqrt{p(x)\, q(x)} \, dx$ is the Bhattacharyya distance measure [4] that uses the integral of point-wise product of the two distributions.

In Section 4.4, we quantify the changes of the viable answer distribution under different data source settings. As we will see, the complexity of computing a distance measure largely depends on the mathematical properties of the measure. Our analysis shows that stability scores measured by d_{L_2} and d_{Bh}, as defined above, can be computed efficiently.

3. PROBLEM FORMALIZATION

Data sources in a heterogeneous information system may vary significantly in terms of coverage, quality, and accuracy. Regarding coverage, often a single data source provides information about a subset of the instances and a subset of the object attributes. Therefore, data values relevant to an aggregate query can be segmented across multiple sources in a heterogeneous information system. Furthermore, as in [19], the data sources can contain heterogeneity at three levels: schema-level, instance-level, and value-level. Heterogeneity at the schema-level and instance-levels means semantically related content can be stored using different schema elements and structures, and represented by different instances. At the value-level, depending on the source quality and accuracy, the sources can have inconsistent, or even conflicting data values for the same data points. In this work, similar to [19], we focus on value-level heterogeneity. We assume meta-information that describes the mappings and bindings between data sources is available [25].

Figure 1 demonstrated an example scenario with four data sources $D_1, \ldots, D_4$, and their corresponding data instances. As shown in the figure, the sources held different values for the same data point, e.g., Vancouver on 06/11/2006. As a consequence of the data value overlaps and inconsistencies, the answer to aggregate queries, such as "Sum(Temp)" for specific date ranges and locations, depends on the combination of data sources and instances that are selected. Therefore, the answer to the aggregation is a distribution of values, rather than a single scalar value. In order to show which values are under consideration as answers, we use the term "viable answer". While the work in this paper does not depend on the definition, for concreteness, we adopt the definition from [25]:

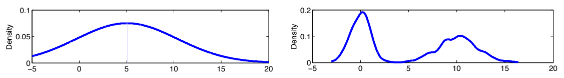

Figure 2: Two distributions with the same mean (5.0) and variance (5.0), but different shapes.

DEFINITION 1. *[Viable answer]*
Let $\mathcal{D}$ denote a set of data sources answering an aggregation, and let $v = agg(\mathcal{Z})$ be the aggregated value computed from some $\mathcal{Z} \subseteq \mathcal{D}$. Let $\mathcal{V} = \{v_i\}$ be the set of aggregated values from all possible source combinations. A viable answer to an aggregation is a value in the interval $W = [inf(\mathcal{V}), sup(\mathcal{V})]$ that adheres to type restrictions (e.g., integer) where inf and sup are infimum (greatest lower bound) and supremum (smallest upper bound), respectively. $\square$

Note that this definition allows any value in the defined interval, even if it does not correspond to the value produced by any source combination [25]. Furthermore, we assume prior knowledge regarding the coverage, quality and accuracy of the data sources is not available. Therefore, the data sources selected for inclusion have equal importance, but their contribution to the aggregate answer may not be of equal amount. As a reminder, in [25] we randomly chose a viable answer, which is inappropriate, both because it does not explain the choice and the aggregate answer would fluctuate upon reprocessing the query.

DEFINITION 2. *[Viable answer distribution] Let the random variable X be the answer to an aggregate query whose pdf is $f_X^{\mathcal{D}}(x) : W \to \mathbb{R}$. In this notation, the superscript $\mathcal{D}$ denotes the source set used to compute the viable answer set. We refer to $f_X^{\mathcal{D}}$ as the viable answer distribution.*
$\square$

Our objective, in this work, is to efficiently sample the set of viable answers, estimate a viable answer distribution, and report informative statistical summaries that allow the user to better understand the range of viable answers. Typically, the range of possible query answers are conveyed using point estimates such as mean and variance. However, such statistics are not informative when the shape of the density function is unknown; distributions with different shapes can have the same mean and variance but deliver very different information (depicted in Figure 2).

We propose to use the following three statistics as summaries of the viable answer distribution, and the answer to aggregate queries in heterogeneous information systems:

1. **Key point statistics:** Include mean, variance, and skewness of the viable answer distribution. These help users to identify appropriate scalar values for aggregate answers.
2. **High coverage intervals:** Tell where the majority of viable answers can be found. This is particularly useful when the distribution is multi-modal (i.e., the distribution has a pdf with two or more significant peaks.)

3. **A stability measure:** Tells how much the viable answer distribution would change when updates happen or some data sources become unavailable. It helps the heterogeneous information system to decide if a re-processing of an aggregate query is necessary.

The above three statistics communicate semantic information that enable the user to easily interpret and understand the distribution. Specifically, the mean, variance and skewness are standard measures most often desired in describing a distribution. High coverage intervals fill the gap that the point statistics are incapable of providing: "shape" information about a distribution, which is especially useful when the distribution is multi-modal. While the static behavior of the answer distribution is described by the first two statistics, the stability measure captures the update behavior of the distribution.

Furthermore, to focus our work, we assume that the queries that are being asked are aggregate queries. Specifically, we consider sum, average, median, variance, and standard deviation. While our methods may work on other aggregate functions, they were not our focus. We leave removing this restriction as future work.

4. EXTRACTING ANSWER STATISTICS

4.1 Overview

Algorithm 1 describes the overall procedure for extracting statistical summaries of the viable answer distribution. The extraction of all three statistics share the uniS sampling and bootstrap sampling steps. In the uniS sampling step (line 2) a set of viable answers are sampled by processing the aggregate query using values from different data sources. This is the most expensive step. The answer set is then bootstrap resampled (line 3). This enables the computation of point statistics such as mean, variance and skewness (line 4) with confidence intervals (line 5). The density estimation process (line 6) is used for finding high coverage intervals (line 7) and for stability analysis (line 8). We perform density estimation on sample sets rather than the entire data set to ensure that the statistics extraction scales well.

Figure 3 shows the application of Algorithm 1 to obtain answer statistics for the aggregation "Sum(Temp)" over the data sources in Figure 1. Ideally we would prefer to have the exact target viable answer distribution (shown in the top left corner of the figure), however it does not scale well to get this exact distribution. Instead we approximate using the inputs, consisting of the query, data sources, and the mappings between the sources. The algorithm works as follows: UniS sampling samples the data sources to obtain $\mathcal{S}_{uniS}$, a set of viable answer samples, where $|\mathcal{S}_{uniS}| = 400$. Next, this set is resampled to obtain a set of bootstrap sample sets $\mathcal{S}_{boot} = \{\mathcal{B}^i_{boot}\}$, where $|\mathcal{S}_{boot}| = 50$ and $|\mathcal{B}^i_{boot}| = 400$, which are then used to help obtain the 90% and 85% confidence intervals for mean and standard deviation (stddev). After the density function is estimated, Greedy algorithm CIO (Algorithm 2) is used to obtain 3 intervals covering 34% of the range of values, and approximately 90% of the estimated probability distribution. Finally, a stability score of 6.6442 is computed for the query. The outputs of the algorithm are shaded in grey.

In summary, the proposed methods efficiently provide the user with answer statistics that simplify the interpretation of the range of viable answers. This is in contrast to inefficient methods that not only do not scale well, but also require the user to examine and interpret the answers. Sections 4.2 – 4.4 , describe how the three statistics are extracted in detail.

4.2 Sampling and point statistics

We use the term *component* to indicate a data point that an aggregate requires, e.g., in the climate data example in the introduction, a component would be the temperature for Vancouver on 06/11/2006. The process of sampling a viable answer is: (1) find an assignment that determines the use of values from data sources and (2) compute the answer using the chosen assignments. We do not assume prior knowledge regarding the quality, reliability, accuracy, and coverage of the sources. In this context, to ensure correctness, the sampling procedure must select the data sources uniformly and independently to contribute to the aggregate.

We designed a sampling scheme called *uniS* that satisfies the above requirements. Let $\mathcal{D} = \{D_i\}$ where $i = 1, 2, \ldots, |\mathcal{D}|$ denote the data sources, $\mathcal{C}_i$ be the set of components on D_i, and $\mathcal{C}$ be the set of all components needed by the aggregate. UniS starts with an empty component set $\mathcal{T}_0$ and an initial partial aggregate p_0. Step i of uniS uniformly selects one data source D_k, and attempts to add as many components in $\mathcal{C}_k$ to the aggregate, i.e., it updates $\mathcal{T}_i = \mathcal{T}_{i-1} \cup \mathcal{C}_k$ and p_i with partial aggregate computed over component set $\mathcal{A}_i = \{c \mid c \in \mathcal{C}_k, c \notin \mathcal{T}_{i-1}\}$. This process is repeated until $\mathcal{T} = \mathcal{C}$ or all n data sources have been visited. It then computes a final aggregate from the partial

aggregate and uses it as a viable answer sample. [1]

Figure 4 shows an example scenario where uniS sampling is applied to the sources in Figure 1 for an avg() aggregate over $\mathcal{C} = \{c_1, \ldots, c_5\}$. It shows two different selection paths, $path(D_1, D_2, D_4)$ and $path(D_2, D_1, D_4)$. $\mathcal{T}_i$ is the set of covered components, p_i is the incrementally maintained partial aggregate. The arrows show the different selection paths for $\mathcal{T}_i$ and p_i. For $path(D_1, D_2, D_4)$, the algorithm begins at node D_1 and uses all the components in D_1. The remaining two components c_4 and c_5 are sampled from sources D_2 and D_4, respectively. Note that same component, e.g, c_1, can have different values on different data sources. Hence, using an alternative path, $path(D_2, D_1, D_4)$, yields a different viable answer; since D_2 is visited first, uniS takes both components, c_1 and c_4, from D_2.

D_4	$T_3=T_2\cup\{c_1, c_5\}$ $p_3=g(p_2,\{c_5\})$

Figure 4: UniS sampling for selection paths of $\{\mathbf{D_1}, \mathbf{D_2}, \mathbf{D_4}\}$ and $\{\mathbf{D_2}, \mathbf{D_1}, \mathbf{D_4}\}$, where $\mathbf{g} = \mathbf{sum}()$, and $\mathbf{p_i}$ is the incrementally maintained partial aggregate.

Drawing a sample from possibly distributed data sources involves processing an aggregate query with a randomly selected value assignment. Although partial-final aggregates helps to distribute the computational load of each aggregation, applying uniS to draw samples is still a costly operation. Thus, it is desirable to minimize $|\mathcal{S}_{uniS}|$. To this end, we apply bootstrap resampling on the sampled viable answers to improve the confidence for point statistics such as mean and variance. The three parameters: confidence level $1 - \alpha$, confidence interval length denoted by $len(CI)$, and the sampling size $|\mathcal{S}_{uniS}|$ are correlated to affect the computation of confidence intervals. Basically, the larger the samples in the initial set, the higher the accuracy of the point estimates and the confidence intervals. However, to reduce computational costs, we start with a fixed initial sample set and incrementally increase the size of this set (i.e., perform uniS sampling). With each increment, we perform bootstrap resampling and assess the value of $len(CI)$ with the specified α. The procedure ends when the values are satisfactory. Our implementation of bootstrapping uses the standard BC_a [13] method to obtain good quality confidence intervals using small amount of initial samples.

4.3 High coverage intervals and optimization

To better understand how viable answers are distributed, we estimate the viable answer distribution (Definition 2) using KDE (Section 2.2). Specifically, we perform density estimation for each bootstrap sample set and use the normalized point-wise mean of all the estimates as the viable answer distribution. Furthermore, we use two methods in addition to standard KDE. The adaptive method described in [6] automatically chooses the value of the bandwidth h depending on the sample set. Bagging (Section 2.1) makes use of the resampled set from bootstrapping. These methods help obtain a density estimation that is both smooth and stable, which is required to extract high coverage intervals and compute stability scores.

We now describe an algorithm for extracting statistics that convey shape information for $f_X^{\mathcal{D}}$, the pdf estimated by KDE.

DEFINITION 3. *[High coverage interval]*
Given an estimated viable answer distribution $f_X^{\mathcal{D}}$, and the viable answer range W, a high coverage interval *is a triple $(\mathcal{I}, L, C)$, where $\mathcal{I} = \{(I_i, C_i) : C_i = \int_{I_i} f_X^{\mathcal{D}}(x)dx$ and $I_i \subseteq W\}$; C_i is the coverage of I_i. $L = \frac{\sum_i |I_i|}{|W|}$ is the fraction*

[1]As an example for partial-final aggregate, for final aggregate avg(), the partial aggregate is sum().

of the intervals' total length to the viable answer range, and $C = \sum_i C_i$ is the total coverage. □

Definition 4. *[Coverage interval optimization (CIO)] Given a density function $f_X^{\mathcal{D}}$ for a distribution defined on a finite range, a coverage threshold $0 \le \theta \le 1$, and a constant t representing the number of modes, the CIO problem finds k intervals $I_1, I_2, \ldots, I_k$ where $k \le t$, to minimize $\sum_{i=1}^{k} |I_i|$ subject to $\sum_{i=1}^{k} \int_{I_i} f_X^{\mathcal{D}}(x)dx \ge \theta$.* □

We further note the following: First, the criterion of minimizing the total interval makes intuitive sense, e.g., the reported high coverage intervals, whether in the weather, the flight, or the stock exchange domain, should be as small as possible. For example, in the flight domain, it is preferable to have shorter rather than larger intervals for the departure time of a certain flight. Second, the coverage threshold θ, conveys the percentage of information covered by the data sources. The desired level can be defined by the user. Third, for single mode distributions (e.g., a Gaussian), the optimal solution is the classical $100\% * \theta$ confidence interval around the mode. The coverage intervals are more useful and deliver important information for multi-modal distributions.

Furthermore, note that k is not a given variable; the CIO problem finds k intervals to minimize the total length of the intervals returned, such that their coverage is above a threshold. Larger coverage is obtained by selecting higher modes. Motivated by this, we propose Algorithm 2 for the extraction of high coverage intervals. The inputs to the algorithm are the pdf $f_X^{\mathcal{D}}$, the desired coverage θ, and t modes of $f_X^{\mathcal{D}}$. [2] The algorithm works by greedily picking up new intervals around the modes (lines 5–7) or extending previously picked intervals (lines 9–11) for the highest $t-1$ modes. For the last mode, the interval is set to cover the average amount of the additional coverage needed (lines 17,18). The algorithm returns the obtained high coverage intervals if the desired coverage is met or it has finished searching all the t modes. Our formal analysis of the greedy algorithm relies on the following theorem.

Theorem 4.1 (CIO mode containment property). *If the probability density function $f_X^{\mathcal{D}}$ of a distribution (1) has t modes and (2) is second-order differentiable everywhere on its range, and the optimal solution for CIO has $k \le t$ intervals, then the largest k modes are contained by the k intervals in the optimal solution.*

Proof If an optimal solution for CIO has k intervals, but the i-th largest mode $(x_i, f_X^{\mathcal{D}}(x_i)), i \le k$ is not in the optimal solution, then there must exist an interval I_j for which any point $x \in I_j$ satisfies $f_X^{\mathcal{D}}(x) < f_X^{\mathcal{D}}(x_i)$; therefore we can construct a new interval around x_i and improve the previous result. □

If the conditions in Theorem 4.1 are satisfied, then the algorithm returns an optimal CIO solution. Otherwise, the greedy algorithm returns an approximation. There are two scenarios for an approximation: (1) the returned intervals may not reach the desired coverage, and (2) optimally choosing the next interval to extend coverage requires picking the I_j that has the minimal $|f_X^{\mathcal{D}\prime}(x_t^{+/-})|$ (i.e., the largest incremental on coverage).

[2]Because $f_X^{\mathcal{D}}$ is one-dimensional, the modes are easily computed numerically. We omit details on mode seeking.

Algorithm 2: Greedy algorithm CIO

```
input  : Estimated density function $f_X^{\mathcal{D}}$ over range $W$
input  : Desired coverage $\theta$
input  : A set $\mathcal{M} = \{(x_i, m_i)\}$ containing $t$ modes of $f_X^{\mathcal{D}}$
output : High coverage intervals $(\mathcal{I}, L, C)$
1  begin
2      $C \leftarrow 0.0$; $i \leftarrow 1$; array $s$; $\Omega \leftarrow \emptyset$;

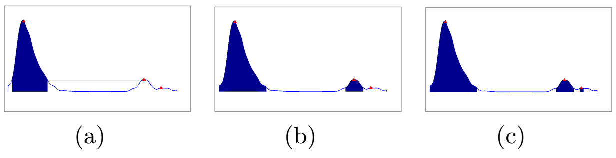
7          $s[i] \leftarrow (x_i^-, x_i^+)$; $\Omega \leftarrow \Omega \cup s[i]$; $C \leftarrow \int_\Omega f_X^{\mathcal{D}}(x)dx$;
           $j \leftarrow 1$;
8          while $C \le \theta$ do
9              $x_j^- \leftarrow$ largest $x$ s.t. $x < x_j$, $f_X^{\mathcal{D}}(x) = m_{i+1}$;
10             $x_j^+ \leftarrow$ smallest $x$ s.t. $x > x_j$, $f_X^{\mathcal{D}}(x) = m_{i+1}$;
11             $s[j] \leftarrow (x_j^-, x_j^+)$; $\Omega \leftarrow \Omega \cup s[j]$;
               $C \leftarrow \int_\Omega f_X^{\mathcal{D}}(x)dx$;
12             $j \leftarrow j+1$;
13         end
14         $i \leftarrow i+1$;
15     end
16     if $C \le \theta$ then
17         Find $(x_t^-, x_t^+)$ s.t. $x_t^- < x_t < x_t^+$ ,
           $\int_{x_t^-}^{x_t^+} f_X^{\mathcal{D}}(x)dx = \frac{1}{t}(\theta - C)$;
18         $s[t] \leftarrow (x_t^-, x_t^+)$; $\Omega \leftarrow \Omega \cup s[t]$; $C \leftarrow \int_\Omega f_X^{\mathcal{D}}(x)dx$;
19     end
20     Let $\omega_1..\omega_k$ be disjoint intervals s.t. $\bigcup_1^k \omega_i = \Omega$;
21     foreach $\omega_i$ do
22         $C_i = \int_{\omega_i} f_X^{\mathcal{D}}(x)dx$;
23     end
24     $\mathcal{I} \leftarrow \{(\omega_i, C_i)\}$; $L \leftarrow \sum_1^k |\omega_i|/|W|$;
25     return $(\mathcal{I}, L, C)$;
26 end
```

Obtaining an optimal solution in the above cases requires knowing the first derivative of the density function everywhere, which will bring a substantial cost to the computational overhead. Therefore, we decided to use an approximate answer. Another reason for not pursuing the full optimal solution is that the density function itself is an estimation, and thus has a built-in error. Our empirical study suggests that the greedy algorithm gives a good approximation, and more importantly for query processing, it is fast and scalable.

While the above CIO setting is useful in many situations, the dual of CIO is desired when we are constrained to a pre-determined interval length and asked to return the best possible coverage.

Definition 5. *[Dual of CIO] The dual problem of CIO optimizes the selection of intervals to maximize the coverage. The optimization maximizes $\sum_{i=1}^{k} \int_{I_i} f_X^{\mathcal{D}}(x)dx$ subject to $\sum_{i=1}^{k} |I_i| = \gamma$, where γ is a user-specified parameter.* □

The greedy algorithm can be easily modified for the dual of CIO by modifying the termination criteria to check if the



(a) (b) (c)

Figure 5: Finding high coverage intervals (Algorithm 2).

total length of the current set of intervals exceeds length γ and return the size of the covered region.

Figure 5 shows how the high coverage intervals are found for a pdf with 3 modes: the greedy algorithm starts from the highest mode and extends the coverage to lower modes until the coverage of the currently discovered intervals meets the coverage requirement. Eventually 3 intervals are reported.

The returned intervals deliver important information about the aggregation answers. For a fixed coverage θ (e.g., 0.9) and a single mode distribution, if the returned interval length is small, it means that different combinations of sources result in similar aggregation answers. It often indicates that the user can be quite confident of the returned answer. However, we still need to be careful to correctly interpret the result. A small interval length does not necessarily mean that all sources are holding the same value for the same component. It can be the case that the values of some components dominate others. For example, some components are significantly larger than others in a *sum* aggregation.

Additionally, high coverage intervals can be applied in uncertain and probabilistic databases [22]. Such databases represent an attribute as a set of value and probability pairs, $att = \{(A, Pr(A))\}$, where A represents the range of possible values and $Pr(A)$ the probability. High coverage intervals can be used to produce normalized probability measures $att = (I_i, \frac{C_i}{C})$, or simply $att = (I_i, C_i)$, for these databases.

4.4 The stability score for query answers

The point statistics and high coverage intervals provide static information on how viable answers are distributed. However, most heterogeneous information systems, such as PDMSs, are dynamic and data sources may freely leave. One natural question is how to keep aggregate answer statistics up-to-date given that the departure of data sources will affect the aggregate answer distribution. To answer this question, we define the *stability* of the aggregate query.

Stability measures the amount of change caused in the viable answer distribution when some of the sources are removed. It can be quantified as the distance measure between the viable answer distribution without and with some sources removed. Given a number of data sources to be removed r, we randomly remove a set $\mathcal{Q}$ of size r from $\mathcal{D}$ and denote the resulting viable answer distribution by $f_X^{\mathcal{D}\setminus\mathcal{Q}}$. We use the distance measures introduced in Section 2.3 to quantify the difference between the two distributions. Let $\mathcal{S}_{uniS} = \{x_i\}$, be the sampled viable set, with regard to all the sources $\mathcal{D}$, and uniS sampling.

Definition 6. *[Stability score of an aggregation] Let $\mathcal{G}$ be the set of all possible choices for removing r sources from $\mathcal{D}$, and $Pr(\mathcal{Q})$ be the probability of choosing (a particular) $\mathcal{Q}$ with size r. Given $\mathcal{S}_{uniS}$, we define the stability score of the aggregation as*

$$
\begin{aligned}
Stab_d(\mathcal{S}_{uniS}) &\doteq -\log\left(\mathbb{E}[d(f_X^{\mathcal{D}}, f_X^{\mathcal{D}\setminus\mathcal{Q}})]\right)\\
&= -\log\left(\sum_{\mathcal{Q}\in\mathcal{G}} Pr(\mathcal{Q})d(f_X^{\mathcal{D}}, f_X^{\mathcal{D}\setminus\mathcal{Q}})\right)
\end{aligned}
\tag{4.1}
$$

where $\mathbb{E}$ denotes expectation and d is a distance measure. □

Note that $f_X^{\mathcal{D}}$ is a constant distribution; however, random removal of r sources results in random distributions $f_X^{\mathcal{D}\setminus\mathcal{Q}}$, and subsequently random values for $d(f_X^{\mathcal{D}}, f_X^{\mathcal{D}\setminus\mathcal{Q}})$. We use the expectation of the difference between the two distributions, $\mathbb{E}[d(f_X^{\mathcal{D}}, f_X^{\mathcal{D}\setminus\mathcal{Q}})]$, as the stability measure for the answer distribution. We use the negative logarithmic over the expected distribution difference as the stability score so that a higher value indicates a higher stability score, i.e., that the viable answer distribution is expected to change less against data source changes.

Furthermore, note that we do not need to enumerate or choose $\mathcal{Q}$, and explicitly compute $f_X^{\mathcal{D}\setminus\mathcal{Q}}$; this is just for analysis. The computation of the L_2^2 stability score does not rely on it (Section 2.3).

When additional knowledge regarding the likelihood of the departure of sources is not available, we apply an equal chance assumption on data source removals, where $\Pr(\mathcal{Q}) = 1/\binom{|\mathcal{D}|}{r}$ is constant given r. Another assumption needed for stability analysis is that the number of data sources to be removed is small i.e., $r \ll |\mathcal{D}|$. This assumption is viable, because when the number is large, the system will re-evaluate all the queries regardless of the stability scores. A key benefit to the stability analysis is that it helps prioritize which queries need updating when sources are updated with new values.

Now we describe how to compute the stability score. Given $\mathcal{S}_{uniS} = \{x_i\}$, the sampled viable set, the answer distribution is estimated by $f_X^{\mathcal{D}}(x) = \frac{1}{|\mathcal{S}_{uniS}|h}\sum_{i=1}^{|\mathcal{S}_{uniS}|} K(\frac{x-x_i}{h})$ (Section 4.2). Let $\mathcal{R}_{\mathcal{Q}}$ be the set of sample points that belong to the removed sources $\mathcal{Q}$. To estimate the new distribution, we need to exclude the points in $\mathcal{R}_{\mathcal{Q}}$

$$
\begin{aligned}
f_X^{\mathcal{D}\setminus\mathcal{Q}}(x) &= \frac{1}{(n-|\mathcal{R}_{\mathcal{Q}}|)h}\sum_{x_i\notin\mathcal{R}_{\mathcal{Q}}} K(\frac{x-x_i}{h})\\
&= \frac{n}{n-|\mathcal{R}_{\mathcal{Q}}|} f_X^{\mathcal{D}}(x) - \frac{1}{(n-|\mathcal{R}_{\mathcal{Q}}|)h}\sum_{x_i\in\mathcal{R}_{\mathcal{Q}}} K(\frac{x-x_i}{h})
\end{aligned}
\tag{4.2}
$$

where $n = |\mathcal{S}_{uniS}|$. The first term with $f_X^{\mathcal{D}}(x)$ is constant given a query, but the second term changes with different choices of $\mathcal{R}_{\mathcal{Q}}$.

We show in Theorem 4.2 that under the equal chance assumption for source removals, stability score can be obtained analytically for the L_2 distance measure.

Theorem 4.2 (L_2 stability score). *Given $\mathcal{S}_{uniS}$, its L_2^2 stability score*

$$Stab_{L_2}(\mathcal{S}_{uniS}) = -\frac{1}{2}\log\left(\frac{1}{2nh\sqrt{\pi}} * \frac{c_r}{1-c_r}(1-\frac{2}{n(n-1)}\Psi)\right) \tag{4.3}$$

where $n = |\mathcal{S}_{uniS}|$, h is the bandwidth parameter of the Gaussian kernel, the change ratio is estimated by $c_r = 1 -$

$(1 - \frac{y}{|\mathcal{D}|})^r$, *with y defined as the average number of sources needed for an answer, and the mutual impact factor is* $\Psi = \sum_{i,j} e^{-(x_i - x_j)^2/4h^2}$.

The proof to Theorem 4.2 is in Appendix A. This greatly reduces the computational overhead for the stability score. It eliminates the need of simulating source removal in order to compute a stability score.

We treat the change of viable answers due to data source removals as a random variable. The L_2 stability score is an estimator of the expectation of this random variable. We can also assess its 2nd moment, which gives the variance. To do this, we use the Bhattacharyya distance d_{Bh}, as the distribution difference measure and compute the stability score for the square of the viable answer distribution $\left(f_X^{\mathcal{D}}\right)^2$. Corollary 4.1 shows that this score can also be computed without source removal simulation.

Corollary 4.1. *Given $\mathcal{S}_{uniS}$, with n, h, and Ψ as defined in Theorem 4.2, the Bh (Bhattacharyya distance) stability score over the square of the viable answer distribution, is*

$$Stab_{Bh}(\mathcal{S}_{uniS}) = -\log\left(\frac{1}{2nh\sqrt{\pi}} + \frac{1}{n^2 h\sqrt{\pi}}\Psi\right) \quad (4.4)$$

Proving the corollary requires the same technique for Theorem 4.2 (in Appendix A). Since the expectation of the density $f_X^{\mathcal{D}\setminus\mathcal{Q}}$ is just $f_X^{\mathcal{D}}$, simple calculation by changing the order of expectation and summation, the result follows.

The stability score measures the likelihood of changes to query answers along with data source availability and updates. It can be used to prioritize the re-evaluation and update of queries, especially in a scenario where multiple continuous queries are managed. Note that the system needs to maintain neither the sampled viable answers nor the density estimation. A priority queue of the stability scores for the continuous queries is sufficient for maintenance.

5. EMPIRICAL STUDY

Dataset: We empirically tested the extraction of aggregate statistics using synthetic and real-life datasets. The synthetic tests allowed us to scale various parameters to verify the observations and predictions made in the analysis. For the real-life data, we experimented with Canadian climate data [8]. This archive contains official weather observations from stations located across Canada. The stations report hourly, daily, and monthly data measurements for attributes including, but not limited to: mean temperature, maximum temperature, total rainfall, total snow, direction of maximum gust, and total precipitation. Not all of the data is quality controlled. Furthermore, the sources may have missing values for some attributes, which typically implies the data had not been observed. In addition to the web interface, the data can be downloaded in XML or CSV format. We used the monthly climate data for the year 2006, from 1672 stations measuring climate data for 104 districts. Tables 1 and 2 summarize our data sets.

Aggregate Query: The query we use in all experiments sums temperature climate data over 500 components from the different data sets in Table 1 ($|\mathcal{C}| = 500$).

Settings: The algorithms were implemented in Matlab version 7.6.0 and the experiments were run on a PC with 2.5GHz Intel Core 2 duo CPU.

Data	Notes	Parameters

5.1 Sampling and bootstrap improvements

Table 3 shows the improvements that are obtained by using the bootstrap method compared to direct inference. In particular, we report improvements in deriving tight confidence intervals for point statistics, and on savings of the required sample size. These experiments were conducted on dataset D2.

In Table 3, the confidence interval length from direct inference denoted by $len(CI_{di})$, is used as the baseline for each individual sampling. We report the maximal and average improvements using an improvement ratio defined as $i_r = \frac{len(CI_{di})}{len(CI_{boot})}$, where $len(CI_{boot})$ is the confidence interval length from bootstrapping. Smaller confidence intervals represent more reliable estimates; thus, greater values of i_r show bootstrapping achieves better performance. We can see that by using bootstrap sampling (with BC_a) with sample sizes of 200 and 400, the average improvement ratio is approximately 2, which shows confidence intervals returned by bootstrapping are half of that guaranteed by direct inference method. They are 3 to 4 times tighter when the sample size is small (200).

Table 3 also shows the savings on the required sample size in order to reach the confidence interval achieved by using the bootstrap method. Similar to the improvement ratio for Table 3, the tighter confidence intervals are translated to the savings on the required size of samples if the same confidence interval length that bootstrapping reports needs to be achieved with direct inference. Hence the saving ratio is defined as $s_r = \frac{|\mathcal{S}_{di}|}{|\mathcal{S}_{uniS}|}$ where $|\mathcal{S}_{di}|$ is the sample size that direct inference needs, and $|\mathcal{S}_{uniS}|$ is the initial sample size that bootstrapping uses. We can see from Table 3 that the average savings on the sample size is about a factor of 4. The results indicate that the confidence interval reported with bootstrap sampling is much tighter than using direct inference especially when the theoretical upper-bound of variance is large.

5.2 High coverage intervals

We present the results of high coverage intervals detected for 4 *sum* aggregations S_1 to S_4 where S_1, and S_2 sum climate data in C and S_3 and S_4 sum values generated in D_3. Figure 7 shows that the viable answer distributions for the 4 aggregates are multi-modal, and when components in

$\lvert S_{uniS}\rvert$	$1-\alpha$	max i_r	avg i_r	max s_r	avg s_r
200	0.8	4.248	2.556	18.1	7.36
200	0.9	3.309	2.119	10.96	4.84
400	0.8	2.896	2.001	8.39	4.28
400	0.9	2.293	1.655	5.26	2.82

Table 3: Bootstrapping improves confidence intervals and the savings on required sample size.

Fig	Greedy	Optimal	Cover	Greedy/Optimal
a	0.2272	0.2272	85.72%	1.0
b	0.2475	0.2475	85.44%	1.0
c	0.3764	0.2724	73.82%	1.38
d	0.5552	0.5150	92.12%	1.08

Table 4: Approximation ratio of the CIO algorithm

the aggregation are differently distributed, the viable answer distribution has different modes (7 modes in Figure 7.c compared to 8 in Figure 7.d).

By returning intervals in "dense" areas, the intervals cover a small percentage of the range of data (under 25% for S_1, S_2 with 2 modes, 37% for S_3 with 7 modes) to cover the majority of the distribution. The mean of all 4 is in the central flat area; expanding confidence intervals centering at the distribution's mean will result in very large confidence intervals.

Table 4 compares the performance of the greedy algorithm with an optimal method that slices the range of the density function uniformly into 4096 pieces and sums the top t slices that cover the desired probability measure. The greedy approximation is better if the "Greedy/Optimal" value is closer to 1.0 (it is always ≥ 1.0). Note that although the optimal method is more likely to return "tighter' intervals , it does not guarantee the continuity of the returned intervals; thus we used the greedy method in our solution.

5.3 Stability

We designed a simulation process to test the effectiveness and sensitivity of the L_2 stability score. We used the same aggregations as Section 5.2. The simulation worked as follows: we deleted one data source from the 100 sources and drew samples from viable answers that are computable from the remaining 99 sources (e.g., for climate data set, it is 1 out of 104 reporting districts). We recorded the means of the viable answers computed from 99 data sources (103 sources for climate data set). The *deviation maps* in Figure 8 correspond to the four distributions in Figure 7. They show the changes on the sample means when different data sources are disabled. For each circular graph, the center is the mean $\mu^{\mathcal{D}}$ of the viable distribution when no data source is removed; the points represent the means $\mu^{\mathcal{D}\setminus\mathcal{Q}}$ of the viable answer distribution when different data sources are removed. The distance between the data points and the center is defined as $d = \frac{|\mu^{\mathcal{D}\setminus\mathcal{Q}} - \mu^{\mathcal{D}}|}{\mu^{\mathcal{D}}}$.

Comparing the four deviation maps in Figure 8, we can see that answer distributions that have a higher stability score are more "stable", as demonstrated by the fact that the viable distribution means are more densely populated around the center. Note that the L_2 stability does not directly assess the change of distribution means. For example, Figure 2 suggests that two distributions with large differences may have the same mean. We observed this as a consistent trend in our empirical study. While we can confirm that queries with higher L_2 stability scores are more stable, we are not yet able to answer questions like "Will the mean of viable answers shift for more than 10% for a query with score 6.3?" Our suggested use of the stability score is for prioritizing updating of queries by re-evaluating queries with lower stability scores. We plan to focus our future work on deeper evaluation of similarity scores and stability scores when more than one source is removed.

5.4 Processing overhead of operations

Figure 6 reports the execution times of three of the main operations consisting of bootstrap re-sampling, KDE, and greedy CIO algorithm. The time for computing stability scores is negligible and has been discarded (200 iterations required less than a millisecond). Networking overhead times have also been ignored.

As indicated by Figure 6, KDE dominates the processing overhead of the operations. In the experiments, we use 50 bootstrap sample sets with different sizes. The bootstrapping time increases with the sample size but takes less than $3/50 = 60ms$ per run. KDE takes about 5 seconds on 50 sample sets of size 800. The greedy CIO algorithm running time is constant as the sample size increases, since a density function with constant number of 4096 points, is used. We estimate the time needed for computing one viable answer to be $200ms$, which is optimistic since sampling over a distributed hierarchy usually takes up to several seconds when the networking overhead is considered. Therefore, sampling the viable answers dominates the overall time needed for sampling and extracting statistics (e.g., 80 seconds in sampling and 5 seconds to extract statistics). This suggests that our technique is fast and further optimizations should focus on more efficient aggregate computation.

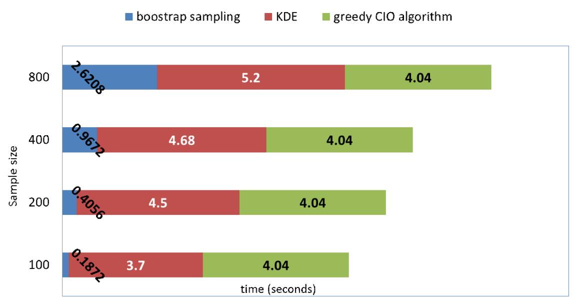

Figure 6: Time breakdown of operations.

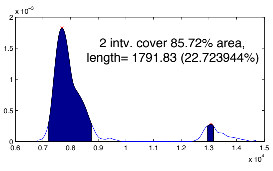
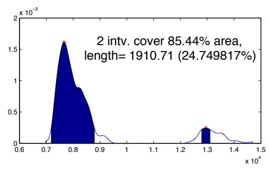
6. RELATED WORK

Data integration is concerned with increasing the coverage of data, and with representing it concisely and accurately [5, 11]. The first objective is typically realized by adding more sources. However, it is argued in [12] that "the more the better" is not always true for integration; obtaining, cleaning, and integrating data can be costly. Furthermore, adding low-quality sources can deteriorate integration quality. Instead, [12] proposes to balance integration cost and gain by selecting a subset of the sources wisely. Our sampling algorithm can be extended with similar ideas.

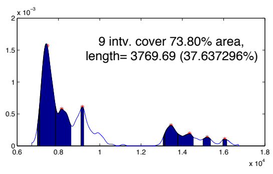
To realize the second objective, concise and accurate data representation, heterogeneity across data sources must be



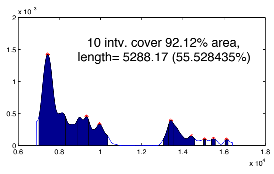
(a) S_1 (Climate Data C)



(b) S_2 (Climate Data C)

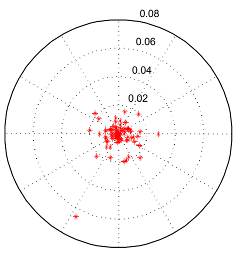


(c) S_3 (Mixture of 3 distributions - dataset D3)

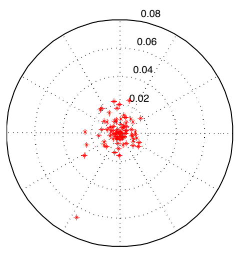


(d) S_4 (Mixture of 3 distributions - dataset D3)

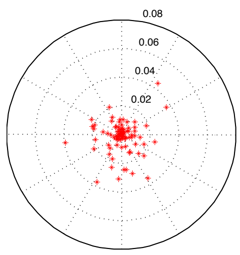
Figure 7: Multi-modal distributions and high coverage intervals



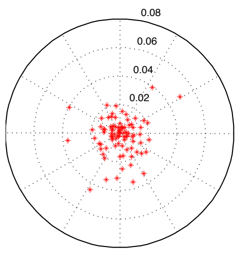
(a) S_1 L_2 score=6.5882



(b) S_2 L_2 score=6.4139



(c) S_3 L_2 score=6.4217



(d) S_4 L_2 score=6.3204

Figure 8: Deviations of empirical means when a single data source is disabled. Numbers indicate the relative distance ($0.02 = 2\%$) from the center. Higher stability scores correspond to figures that have denser distributions around the center.

resolved. As previously mentioned, [19] divides heterogeneity in heterogeneous information systems in three levels: schema (determining which schema elements correspond to each other), instance (determining which data instances correspond to each other), and value (given conflicting values for corresponding instances, choose which one to use). Our work focuses on the third objective. Data fusion [5, 11], also works on the third objective. It assumes a single true value for each component in a data set, and attempts to resolve value conflicts among the sources. In [18] information conflicts are resolved by estimating the reliability of sources and truth values in a joint inference on data with heterogeneous types. In our work, however, do not assume a single true value for components; instead we report a range of possible answers and aim to increase the users understanding and confidence in the reported results. In [19] the truthfulness of data on the Deep web, in particular, the flight and stock domain, is studied. In both domains, large amounts of redundancy and inconsistency at the data value level are observed. Furthermore, state of the art data fusion methods are also compared to resolve conflicts and estimate true values. Semantic ambiguity, out-of-date data, and pure errors are identified as reasons for inconsistent values across the sources. Semantic ambiguity, one the major reasons for value inconsistency, results from different semantics applied by the sources for the attributes they store. For example, one source may compute a statistic of the data over a year-long period, another may compute the same statistic over a half-year period. Both computations are correct with regard to the semantics applied; hence multiple true values are possible [19].

Substantial previous work on combining conflicting data values from multiple sources comes from wireless sensor network research [10, 15, 20, 21]. In a sensor network, sensor motes form an ad-hoc network and collaborate to transmit their sensor probe readings to a centralized repository that is usually beyond the range of a single mote. This is performed by transmitting data in a hierarchical aggregate network rooted at the central repository. Although the hierarchical aggregate network in our case has a lot in common with sensor networks, the operations are essentially different. The aggregate queries we process usually request a (small) part of data maintained in the distributed data sources; in the sensor network case, sensor motes have to upload all their data to the central repository. This results in different optimizations. We face the source combinatorial explosion and use sampling to make estimations, while a sensor network optimizes routing, transmission cost and seeks load balancing among battery powered sensor motes. In [23], the authors described a protocol to adaptively request data from remote sensors over time so as to control the error of approximate answers, while our work focuses on the snapshots of answer distributions when an aggregation is processed. The stability score helps maintain continuous queries but is not a direct approximation measure for a query.

In [14] a method to efficiently compute probability distribution functions in probabilistic databases, is proposed. While using such techniques could eliminate the need for sampling in many cases, in our scenario one of the goals is to reduce the need for data to be gathered from the distributed sources. Since we do not assume that we control the individual sources, we cannot ensure that they have the capabilities proposed in [14].

Research in databases with uncertainty, like our work, covers contexts that do not have one true answer. Various models exist, including uncertain databases [22], possibilistic [24] and probabilistic [16] databases, inconsistent databases [3]. Similarly, in data exchange, aggregate semantics with possible worlds [2] is discussed — there are many possible values that must be considered to find “the answer”.

Among the various models, the uncertain database [22] is closest to our setting: it also uses the relational model and the value of an attribute is a discrete distribution with positive probability on a finite set of values. This is similar to our setting, where the values from different data sources are transformed into values in a distribution. In [22] the authors discussed processing aggregate queries on uncertain databases where aggregates uses expectations of values in computation. Their work avoids the combinatorial explosion simply by disallowing exhaustive aggregates and does not give information about the viable answer distribution. In our semantic integration setting, computing the expectation of all component values is impractical as it requires collecting all single values from all data sources. Also, in our stability model, removal of one source will result in invalidating all components' values on that source. Therefore, these techniques cannot be applied to processing aggregates and providing distribution information.

7. CONCLUSION AND FUTURE WORK

This paper proposed our solution for estimating the distribution statistics for viable answers to aggregate queries in integration settings. Our technique extracts essential distribution statistics, returns intervals where aggregate answers have a high chance to be covered, and provides numerical stability scores for aggregate queries. We optimized the computation of the desired statistics using sampling and bootstrapping to minimize the sampling overhead and improved the confidence interval for point estimates of mean and variance. The greedy algorithm computes high coverage intervals quickly and provides good approximations. Our analysis enables the computation of stability scores without simulating source removal. All the optimizations allow the answer distribution estimation techniques described in this paper to be used with a query processing engine.

The stability analysis is the beginning of our investigation on monitoring query answers against changes in the data sources. We will try to establish links between the actual changes on aggregate answers and the stability score values as future work. In addition, the current uniS sampling algorithm assumes equal importance for the sources and samples them uniformly and independently. However, the sources may have different levels of quality and coverage. Future work should consider some notion of provenance. Furthermore, uniS is greedy. While this means that the sampling is not uniform on all viable answers, its speed may be an advantage. In addition, uniS can be fully parallelized as samples are obtained independently. Future work should examine how the algorithm scales when parallelized.

Another future direction, is to make inferences regarding the data and the sources based on the non-normality of the estimated viable answer distribution. In particular, the viable answer distribution can be used to diagnose possible errors in the data. Multi-modal distributions can indicate possible mapping problems in data integration. For example, the second high coverage interval in Figure 7 (a) is caused by combining supposedly cleaned data sets that incorrectly had values in both Fahrenheit and Celsius. Our work can be extended to help automatically detect such errors. Furthermore, using data stratification we can identify homogeneous data sources that apply similar semantics in their computations.

APPENDIX

A. PROOF OF THEOREM 4.2

Proving Theorem 4.2 requires first some background discussion on the product of two Gaussians (Section A.1) and then computing the integral of the square of the density estimation function (Section A.2)

A.1 The product of two Gaussians

Let $f_1(x) \sim \mathcal{N}(\mu_1, \sigma^2)$ and $f_2(x) \sim \mathcal{N}(\mu_2, \sigma^2)$:

$$\begin{aligned} f_1(x)f_2(x) &= \left(\frac{1}{\sqrt{2\pi\sigma^2}}\right)^2 e^{-\frac{(x-\mu_1)^2+(x-\mu_2)^2}{2\sigma^2}} \\ &= \frac{1}{2\sqrt{\pi\sigma^2}}\mathcal{N}(\frac{\mu_1+\mu_2}{2}, \frac{\sigma^2}{2})e^{-\frac{(\mu_1-\mu_2)^2}{4\sigma^2}} \quad \text{(A.1)} \end{aligned}$$

As a special case, let $f(x) = \frac{1}{\sqrt{2\pi\sigma^2}}e^{-\frac{(x-\mu)^2}{2\sigma^2}} \sim \mathcal{N}(\mu, \sigma^2)$:

$$\begin{aligned} f^2(x) &= \frac{1}{\sqrt{2\pi\sigma^2}}\left[\frac{1}{\sqrt{2\pi\sigma^2}}e^{-\frac{(x-\mu)^2}{\sigma^2}}\right] \\ &= \frac{1}{2\sqrt{\pi\sigma^2}}\mathcal{N}(\mu, \frac{\sigma^2}{2}) \quad \text{(A.2)} \end{aligned}$$

A.2 The integral of the square of the density function:

With the preparation in Appendix A.1, we can compute the summation of the square of the density estimation function. Recall in KDE using Gaussian kernel, the density function is estimated as $f(x) = \frac{1}{nh}\sum_1^n K(\frac{x-x_i}{h})$, where n is the size of the sample set. We now expand the integral on the square of the density, let $\alpha = \int f^2(x)dx$:

$$\begin{aligned} \alpha &= \int \frac{1}{(nh)^2}\left[\sum_{i=1}^n K(\frac{x-x_i}{h})\right]^2 dx \quad \text{(A.3)} \\ &= \frac{1}{(nh)^2}\int \sum_{i=1}^n K^2(\frac{x-x_i}{h})dx \quad \text{(A.4)} \\ &+ \frac{2}{(nh)^2}\int \sum_{i,j} K(\frac{x-x_i}{h})K(\frac{x-x_j}{h})dx \quad \text{(A.5)} \end{aligned}$$

The kernel function is Gaussian $K(\frac{x-x_i}{h}) = \frac{1}{\sqrt{2\pi}}e^{-\frac{(x-x_i)^2}{2h^2}}$, so $\frac{1}{h}K(\frac{x-x_i}{h}) \sim \mathcal{N}(x_i, h^2)$.

Switching the integral and summation in Equation (A.4), it is is simplified to

$$\frac{1}{2nh\sqrt{\pi}}$$

Similarly, Equation (A.5) is simplified to

$$\frac{1}{n^2h\sqrt{\pi}}\sum_{i,j} e^{-\frac{(x_i-x_j)^2}{4h^2}}$$

We can see that the integral (α) is a function over all the data points.

Now recall the stability analysis using the square d_{L_2} distance. Let $f_X^{\mathcal{D}}(x)$, $f_X^{\mathcal{D}\setminus\mathcal{Q}}(x)$ be the original and augmented density. We want to compute $\mathbb{E}\left[\int\left(f_X^{\mathcal{D}\setminus\mathcal{Q}}(x) - f_X^{\mathcal{D}}(x)\right)^2 dx\right]$. Since $\mathbb{E}[f_X^{\mathcal{D}\setminus\mathcal{Q}}(x)] = f_X^{\mathcal{D}}(x)$, this is the integral of the point-wise variance of the augmented function. It thus equals

$$d_{L_2^2} = \mathbb{E}\left[\int\left(f_X^{\mathcal{D}\setminus\mathcal{Q}}(x)\right)^2 dx\right] - \int\left(f_X^{\mathcal{D}}(x)\right)^2 dx$$

Using the above results on Gaussian square, and letting

$$\Psi = \sum_1^n e^{-(x_i-x_j)^2/4h^2} \quad \text{(A.6)}$$

$$f_X^{\mathcal{D}\setminus\mathcal{Q}} = \frac{1}{h(n-\mathcal{R}_\mathcal{Q})}\sum_1^{n-\mathcal{R}_\mathcal{Q}} e^{-(x_i-x_j)^2/4h^2} \quad \text{(A.7)}$$

$$\mathbb{E}[\mathcal{R}_\mathcal{Q}] = c_r * n \;\; for\, some\, constant\, c_r \quad \text{(A.8)}$$

we have

$$d_{L_2^2} = \frac{1}{2nh\sqrt{\pi}} * \frac{c_r}{1-c_r}(1 - \frac{2}{n(n-1)}\Psi) \quad \text{(A.9)}$$

and thus the stability score formula in Theorem 4.2 follows.

We can see that the distance is related to the viable answer distribution, $f_X^{\mathcal{D}}$, and the average fraction of affected answers when some sources are removed. Also it is easy to verify that when all the data points coincide, the distance is 0, i.e., most stable (the corresponding stability score is ∞).

Now we assess how many answers are likely to be affected when r sources are removed from a total of $|\mathcal{D}|$ data sources. This number relates to the number of data sources required for an answer. Suppose on average we need y (also called the weight) out of $|\mathcal{D}|$ data sources for a viable answer; then an estimate for the fraction that got affected is $c_r = \frac{\binom{|\mathcal{D}|}{y} - \binom{|\mathcal{D}|-r}{y}}{\binom{|\mathcal{D}|}{y}}$. We acknowledge that not all y combinations are answers to the query but this is still a good estimate when information regarding the coverage of the sources is not available. Moreover, the weight itself includes some of this information. The larger the average source coverage for components, the smaller the value of y.

Another way is to estimate the expected number of samples that become invalid when r sources are randomly removed This can be done by simulation with the sample set or using $c_r = 1 - (1 - \frac{y}{|\mathcal{D}|})^r$ which assumes that data sources uniformly contribute to aggregate answers. This completes the proof of Theorem 4.2.

In the proof we use the property of Gaussian distributions which limits the choice of kernel in KDE to Gaussian kernels. We note here that from the perspective of convergence, when the sample sizes increases, using any kernel will converge to the true distribution; thus the expectation of the changes computed here should also converge. Therefore if using any other kernels would make any difference, the divergence is from KDE, but it does not impact the stability analysis.

Discovering Recurring Patterns in Time Series

ABSTRACT

Partial periodic patterns are an important class of regularities that exist in a time series. A key property of these patterns is that they can start, stop, and restart anywhere within a series. We classify partial periodic patterns into two types: (i) regular patterns − patterns exhibiting periodic behavior throughout a series with some exceptions and (ii) recurring patterns − patterns exhibiting periodic behavior only for particular time intervals within a series. Past studies on partial periodic search have been primarily focused on finding regular patterns. One cannot ignore the knowledge pertaining to recurring patterns. This is because they provide useful information pertaining to seasonal or temporal associations between events. Finding recurring patterns is a non-trivial task because of two main reasons. (i) Each recurring pattern is associated with temporal information pertaining to its durations of periodic appearances in a series. Obtaining this information is challenging because the information can vary within and across patterns. (ii) Finding all recurring patterns is a computationally expensive process since they do not satisfy the anti-monotonic property. In this paper, we propose recurring pattern model by addressing the above issues. We also propose Recurring Pattern growth algorithm along with an efficient pruning technique to discover these patterns. Experimental results show that recurring patterns can be useful and that our algorithm is efficient.

1. INTRODUCTION

A time series is a collection of events obtained from sequential measurements over time. Periodic pattern mining involves finding all patterns that exhibit either complete or partial cyclic repetitions in a time series. Past studies on partial periodic search have been focused on finding *regular patterns*, i.e., patterns exhibiting either complete or partial cyclic repetitions throughout a series [1, 2, 3, 4, 5, 6, 7, 8, 9]. An example regular pattern of $\{Bat, Ball\}$ states that customers have been purchasing items 'Bat' and '$Ball$' almost every day throughout the year. A useful related type of partial periodic pattern is *recurring patterns*, i.e., patterns exhibiting cyclic repetitions only for particular time intervals within a series. An example recurring pattern of $\{Jackets, Gloves\}$ states that customers have often purchased '$Jackets$' and '$Gloves$' from 10-October-2012 to 26-February-2013 and from 2-November-2013 to 2-March-2014. The purpose of this paper is to discover recurring patterns by addressing mining challenges.

Recurring patterns are ubiquitous in very large datasets. In many real-world applications, they can provide useful information pertaining to seasonal or temporal associations between items. In retail, a user may be interested in determining seasonal purchases for efficient inventory management. Similarly, a social network data analyst may be interested in obtaining temporal information pertaining to bursts of hashtags, such as #earthquakes, #radiation and #floods. Also, an expert in the health-care sector may be interested in finding seasonal diseases in a geographical location. To improve web site design and administration, an administrator may be interested in obtaining temporal information of heavily visited web pages. In the stock market, the set of high stocks indices that rise periodically for a particular time interval may be of special interest to companies and individuals. In a computer network, an administrator may be interested in finding high severity events (e.g. cascading failure) against regular routine events (e.g. data backup).

Unfortunately, finding recurring patterns is a non-trivial task because of the following reasons.

1. Each recurring pattern is associated with temporal information pertaining to its durations of periodic appearances within the data. Obtaining this information is challenging because the information can vary within and across patterns.

2. Most current periodic pattern mining approaches take into account a time series as a symbolic sequence; therefore, they do not take into account the actual temporal

10.5441/002/edbt.2015.10

information of events.

3. Recurring patterns do not satisfy the *anti-monotonic property.* That is, all non-empty subsets of a recurring pattern may not be recurring patterns. This increases the search space, which in turn increases the computational cost of finding these patterns. Therefore, developing efficient pruning techniques to reduce the search space is challenging.

4. Since regular patterns exhibit periodic behavior throughout a series with some exceptions, regular pattern mining algorithms do not obtain temporal information pertaining to the durations of periodic appearances of a pattern within the series. As a result, these algorithms cannot be extended for finding recurring patterns.

5. In real-life, recurring patterns involving rare items can be interesting to users. For example, the knowledge pertaining to rare events, such as cascading failures, are more important than regular events for a network administrator. However, finding such patterns is difficult since rare items appear infrequently in the data. Classifying items into frequent or rare is subjective and depends on the user and/or application requirements.

In this paper, we propose a model that addresses all the above-mentioned issues while finding recurring patterns. In particular, our model takes into account time series as a time-based sequence and models it as a transactional database with transactions ordered in respect to a particular timestamp (without loss of generality). Our model consists of three novel measures, *periodic-support*, *periodic-interval* and *recurrence*, to determine the dynamic periodic behavior of recurring patterns. *Periodic-support* determines the number of consecutive cyclic repetitions of a pattern in a subset of data. *Periodic-interval* determines the time interval (or window) pertaining to the periodic appearances of a pattern within a series. *Recurrence* determines the number of interesting *periodic intervals* of a pattern. Finally, we propose a pattern-growth algorithm along with an efficient pruning technique to discover recurring patterns effectively. We call our algorithm recurring pattern-growth (RP-growth). Experimental results show that RP-growth is efficient and recurring patterns can provide useful information in many real-life applications.

The rest of the paper is organized as follows. Section 2 describes related work on mining periodic patterns. Section 3 introduces our model of recurring patterns. Section 4 presents RP-growth. Sections 5 reports on the experimental results. Finally, Section 6 concludes the paper with future research directions.

2. RELATED WORK

Since the introduction of partial periodic patterns [5], the problem of finding these patterns has received a great deal of attention [6, 8, 10, 11, 12]. The model used in all these studies, however, remains the same. That is, it takes into account a time series as a symbolic sequence and finds all patterns using the following two steps:

1. Partition the symbolic sequence into distinct subsets (or period-segments) of a fixed length (or *period*).

2. Discover all partial periodic patterns that satisfy the user-defined *minimum support* (*minSup*), which controls the minimum number of period-segments that a pattern must cover though the sequence.

A major limitation of the above studies is that they do not take into account the actual temporal information of the events within a sequence. To address this issue, Ma and Hellerstein [7] modeled a time series as a time-based sequence and proposed a model to discover a class of partial periodic patterns known as **p-patterns**. In this model, a pattern is considered partial periodic if its number of periodic appearances throughout the sequence satisfies the user-defined *minSup*. It should be noted that the concept of *minSup* is not the same in both frequent pattern mining and partial periodic pattern mining. In frequent pattern mining, *minSup* controls the minimum number of appearances of a pattern throughout the data. However, in partial periodic pattern mining, *minSup* controls the minimum number of periodic appearances (or cyclic repetitions) of a pattern throughout the data. Thus, the partial periodic patterns discovered in all the above studies [6, 8, 10, 11, 12, 7] represent *regular patterns.* Our study, on the other hand, was focused on discovering recurring patterns in a time-based sequence. Moreover, Ma and Hellerstein's model cannot be extended for finding recurring patterns. The reasons are as follows:

1. Their model fails to obtain the temporal information pertaining to the durations of periodic appearances of a pattern within the data.

2. Finding p-patterns with a single *minSup* leads to the dilemma known as the "rare item problem" [13]. If *minSup* is set too high, those patterns that involve rare items will not be found. To find patterns involving both frequent and rare items, *minSup* has to be set very low. However, this can lead to combinatorial explosion producing too many patterns. In particular, many uninteresting aperiodic patterns can be discovered as partial periodic patterns. For example, if we set a low *minSup*, say *minSup* = 5%, then we will be discovering an uninteresting aperiodic pattern that has only 5% of its periodically appearances throughout the data as a partial periodic pattern.

Recently, researchers have been investigating the **complete cyclic behavior** of the frequent patterns in a transactional database to discover a class of user-interest-based patterns known as periodic-frequent patterns [9, 14, 15, 16]. Informally, a frequent pattern satisfying *minSup* is said to be **periodic-frequent** if and only if all its inter-arrival times throughout the database satisfy the user-defined *period* threshold value. Thus, these studies were focused on finding regular patterns in a transactional database. For our study, we investigated the partial cyclic behavior of the patterns to discover recurring patterns; thus, generalizing the current model of periodic-frequent patterns. More importantly, none of the approaches presented in [9, 14, 15, 16] model time series data as a transactional database. Instead, they are based on the implicit assumption that there are transactional databases with a sequentially ordered set of transactions. This paper fills the gap by describing the procedure to model time series data as a transactional database without loss of generality.

Yang et al. [17] investigated the change in periodic behavior of patterns due to the intervention of random noise and introduced a class of user-interest-based patterns known as *asynchronous periodic patterns*. Although asynchronous-periodic pattern mining is closely related to our work, it cannot be extended for finding recurring patterns. The reason is asynchronous periodic pattern mining models a time series as a symbolic sequence; therefore, it does not take in account the actual temporal information of the events within a sequence.

The problem of finding sequential patterns [18] and frequent episodes [19, 20] has received a great deal of attention. However, it should be noted that *periodicity* is not considered in these studies. Ozden et al. [2] investigated the problem of finding cyclic association rules. However, that study is quite restrictive in finding the patterns that are present at every cycle.

Finding partial periodic patterns [4], motifs [21], and recurring patterns [22] has also been studied in time series; however, the focus was on finding numerical curve patterns rather than symbolic patterns.

Overall, the proposed model of finding recurring patterns is novel and is distinct from current models. In the next section, we introduce our model of recurring patterns.

3. PROPOSED MODEL

In this section, we first describe time series as defined in [7]. Next, we represent these series as a transactional database and introduce measures to find recurring patterns.

Definition 1. *Let I be a set of items (or event types).* ***An event*** *is a pair (i, ts), where $i \in I$ is an item and $ts \in R$ is the timestamp of the event. Let $X \subseteq I$ be a* ***pattern***. ***An event sequence*** *S is an ordered collection of events, i.e., $\{(i_1, ts_1), (i_2, ts_2), \cdots, (i_N, ts_N)\}$, where $i_j \in I$ is an item at the j-th event. The term ts_j represents the occurrence timestamp of the event, and $ts_h \leq ts_j$ for $1 \leq h \leq j \leq N$ [7].*

Definition 2. *A* ***point sequence*** *is an ordered collection of occurrence times. Given an event sequence $S = \{(i_1, ts_1), (i_2, ts_2), \cdots, (i_N, ts_N)\}$, there is an implied point sequence, $\widehat{S} = \{ts_1, ts_2, \cdots, ts_N\}$. An event sequence can be viewed as a mixture of multiple point sequences of each item. Let TSD denote the time series data (or a set of events) being mined.*

Example 1. *Figure 1 shows a TSD with a set of items $I = \{a, b, c, d, e, f, g\}$. In this figure, an item of each event is labeled above its occurrence timestamp. It should be noted that no item appears at the timestamps of 8 and 13. The item 'a' appears at the timestamps of 1, 2, 3, 4, 7, 11, 12 and 14. Therefore, the event sequence of 'a' is represented as $S^a = \{(a, 1), (a, 2), (a, 3), (a, 4), (a, 7), (a, 11), (a, 12), (a, 14)\}$. The point sequence of 'a' is represented as $\widehat{S^a} = \{1, 2, 3, 4, 7, 11, 12, 14\}$. Similarly, the point sequences of 'b' and 'ab' are represented as $\widehat{S^b} = \widehat{S^{ab}} = \{1, 3, 4, 7, 11, 12, 14\}$.*

The point sequence plays an important role in assessing the periodic behavior of the patterns in a time series. We now describe the temporally ordered transactional database which preserves the point sequence of items in the TSD.

A **transaction**, $tr = (ts, Y)$, is a tuple, where ts represents the timestamp and Y is a pattern. A **transactional**

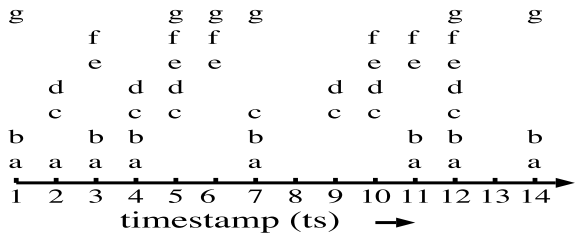

Figure 1: Running example: time-based sequence consisting of items from 'a' to 'g'

database TDB over I is a set of transactions, $TDB = \{tr_1, \cdots, tr_m\}$, $m = |TDB|$, where $|TDB|$ is the size of the TDB in total number of transactions. For a transaction $tr = (ts, Y)$, such that $X \subseteq Y$, it is said that X occurs in tr and such a timestamp is denoted as ts^X. Let $TS^X = \{ts_k^X, \cdots, ts_l^X\}$, where $1 \leq k \leq l \leq m$, denote an **ordered set of timestamps** at which X has occurred in the TDB. The TS^X in the TDB is the same as the point sequence of X in the TSD. Therefore, we do not miss any information pertaining to the temporal appearances of a pattern in the data.

Example 2. *Table 1 shows the transactional database constructed by grouping the items appearing together at a particular timestamp in Figure 1. Each transaction in this database is uniquely identifiable with a timestamp. All transactions have been ordered with respect to their timestamps. It can be observed that the constructed database does not contain the transactions with timestamps 8 and 13. The reason is that no item appears at these timestamps in Figure 1. In this database, the pattern 'ab' appears at the timestamps of* 1, 3, 4, 7, 11, 12, *and* 14. *Therefore, $TS^{ab} = \{1, 3, 4, 7, 11, 12, 14\}$.*

Table 1: Transactional database constructed from time-based sequence shown in Figure 1. The term 'ts' is an acronym for timestamp

ts	Items
1	*a, b, g*
2	*a, c, d*
3	*a, b, e, f*
4	*a, b, c, d*
5	*c, d, e, f,g*
6	*e, f, g*
7	*a, b, c, g*
9	*c, d*
10	*c, d, e ,f*
11	*a, b, e, f*
12	*a, b, c, d, e, f, g*
14	*a, b, g*

Definition 3. ***(Support of pattern X)*** *The number of transactions containing X in the TDB is defined as the support of X and denoted as $Sup(X)$. That is, $Sup(X) = |TS^X|$.*

Example 3. *The support of 'ab' in Table 1 is the size of TS^{ab}. Therefore, $Sup(ab) = |\{1, 3, 4, 7, 11, 12, 14\}| = 7$.*

Definition 4. ***(Periodic appearance of pattern X)*** *Let $ts_j^X, ts_k^X \in TS^X$, $1 \leq j < k \leq m$, denote any two consecutive timestamps in TS^X. The time difference between ts_k^X and ts_j^X is referred to as* ***an inter-arrival time*** *of X, and denoted as iat^X. That is, $iat^X = ts_k^X - ts_j^X$. Let $IAT^X = \{iat_1^X, iat_2^X, \cdots, iat_k^X\}$, $k = Sup(X) - 1$, be the* *set of all inter-arrival times of X in TDB. An inter-arrival time of pattern X is said to be* ***periodic*** *(or interesting) if it is no more than the user-defined period threshold value. That is, a $iat_i^X \in IAT^X$ is said to be* ***periodic*** *if $iat_i^X \leq per$, where 'per' represents the period.*

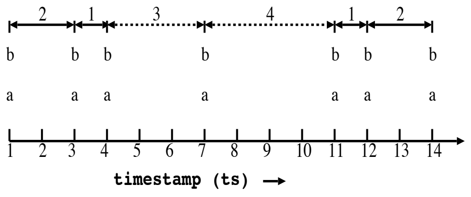

Figure 2: Inter-arrival times of '*ab*', IAT^{ab}

Example 4. *The pattern 'ab' has initially appeared at the timestamps of 1 and 3. The difference between these two timestamps gives an inter-arrival time of 'ab.' That is, $iat_1^{ab} = 2$ $(= 3 - 1)$. Similarly, other inter-arrival times of 'ab' are $iat_2^{ab} = 1$, $iat_3^{ab} = 3$, $iat_4^{ab} = 4$, $iat_5^{ab} = 1$ and $iat_6^{ab} = 2$. Therefore, the resultant $IAT^{ab} = \{2, 1, 3, 4, 1, 2\}$. If the user-defined $per = 2$, then iat_1^{ab}, iat_2^{ab}, iat_5^{ab} and iat_6^{ab} are considered the periodic occurrences of 'ab' in the data. On the other hand, iat_3^{ab} and iat_4^{ab} are considered the aperiodic occurrences of 'ab' as $iat_3^{ab} \not\leq per$ and $iat_4^{ab} \not\leq per$. Figure 2 shows the set of all inter-arrival times for pattern 'ab', i.e., IAT^{ab}. The thick lines represent the inter-arrival times that satisfy the period, while the dotted lines represent the inter-arrival times that fail to satisfy the period.*

Most current partial periodic pattern mining approaches use *minSup* to assess the periodic interestingness of a pattern [5]. This measure cannot be used for finding recurring patterns because it controls the minimum number of cyclic repetitions a pattern must have in all the data. Therefore, we introduce the following measures to determine the partial periodic behavior of recurring patterns.

Definition 5. ***(Periodic-interval of pattern X)*** *Let $TS_j^X = \{ts_p^X, \cdots, ts_q^X\} \subseteq TS^X$, $p \leq q$, be a set of timestamps such that $\forall ts_k^X \in TS_j^X$, $p \leq k < q$, $ts_{k+1}^X - ts_k^X \leq per$. The TS_j^X is a* ***maximal set*** *if there exists no superset in which an inter-arrival time between the two consecutive timestamps is no more than the period. The range of timestamps in TS_j^X represents a periodic-interval of X and is denoted as pi_j^X. That is, $pi_j^X = [ts_p^X, ts_q^X]$.*

Example 5. *The maximal sets of timestamps in which 'ab' has appeared within the user-defined $per = 2$ are: $TS_1^{ab} = \{1, 3, 4\}$, $TS_2^{ab} = \{7\}$, and $TS_3^{ab} = \{11, 12, 14\}$. Therefore, the corresponding periodic-intervals for 'ab' are $pi_1^{ab} = [1, 4]$, $pi_2^{ab} = [7, 7]$, and $pi_3^{ab} = [11, 14]$.*

The *periodic-interval*, as defined above, obtains information pertaining to the duration (or window) of periodic appearances of a pattern in a database. Most importantly, it can effectively determine the periodic durations that can vary within and across patterns. In very large databases, a pattern may have too many periodic-intervals. An efficient technique to reduce this number is to select only those periodic-intervals in which the number of cyclic repetitions of the corresponding pattern satisfies the user-defined threshold value. Thus, we introduce the following two definitions.

Definition 6. ***(Periodic-support of pattern X)*** *The size of TS_j^X is defined as the* periodic-support *of X, and denoted as ps_j^X. That is, $ps_j^X = |TS_j^X|$.*

Example 6. *The periodic-support of 'ab' in pi_1^{ab} is the size of $|TS_1^{ab}|$. Therefore, $ps_1^{ab} = |TS_1^{ab}| = 3$. Similarly, the periodic-supports of 'ab' in pi_2^{ab} and pi_3^{ab} are 1 and 3, respectively.*

In the real-world applications, some items appear very frequently in the data, while others rarely appear. We have observed that some rare items also exhibit periodic behavior in a portion of the data. The *periodic-support*, as defined above, facilitates the user to discover the knowledge pertaining to those frequent and rare items that have exhibited sufficient number of cyclic repetitions in a portion of database. Each *periodic-interval* of a pattern will have only one *periodic-support* and vice-versa. In other words, there is one-to-one relationship between the *periodic-intervals* and *periodic-supports* of a pattern.

Definition 7. ***(Interesting periodic-interval of pattern X)*** *Let $PI^X = \{pi_1^X, \cdots, pi_k^X\}$ and $PS^X = \{ps_1^X, \cdots, ps_k^X\}$, $1 \leq k$, be the complete set of periodic-intervals and periodic-supports of pattern X in the TDB, respectively. A $pi_k^X \in PI^X$ is said to be an interesting periodic-interval if its corresponding $ps_k^X \in PS^X$ has $ps_k^X \geq minPS$. The $minPS$ represents the user-defined minimum periodic-support.*

Example 7. *If the user-defined $minPS = 3$, then pi_1^{ab} and pi_3^{ab} are considered the interesting periodic-intervals of 'ab'. This is because $ps_1^{ab} \geq minPS$ and $ps_3^{ab} \geq minPS$. The pi_2^{ab} is considered an uninteresting periodic-interval of 'ab' as $ps_2^{ab} \not\geq minPS$.*

Since very large databases are generally composed over a very long time frame, it has been observed that some users may specify a constraint on the minimum number of interesting periodic-intervals. Thus, we introduce the following definitions.

Definition 8. ***(Recurrence of pattern X)*** *The* recurrence count *of a pattern represents its number of interesting periodic-intervals in a database. Let $IPI^X \subseteq PI^X$ be the set of periodic-intervals of X such that for every $pi_k^X \in IPI^X$, its corresponding $ps_k^X \geq minPS$. The* recurrence *of pattern X is denoted as $Rec(X) = |IPI^X|$.*

Example 8. *Continuing with the previous example, $IPI^{ab} = \{[1, 4], [11, 14]\}$. The recurrence of 'ab' is the size of IPI^{ab}. That is, $Rec(ab) = |IPI^{ab}| = 2$.*

Definition 9. ***(Recurring pattern X)*** *Pattern X is a* recurring pattern *if $Rec(X) \geq minRec$, where $minRec$ is the user-specified* minimum recurrence count. *Recurring pattern X is expressed as follows:*

$$X \quad [Sup(X), Rec(X), \{\{pi_k^X : ps_k^X\} | \forall pi_k^X \in IPI^X\}]. \quad (1)$$

Example 9. *If the user-defined $minRec = 2$, then 'ab' is a recurring pattern and is expressed as follows:*

$$ab \quad [support = 7, recurrence = 2, \{\{[1, 4] : 3\}, \{[11, 14] : 3\}\}].$$

The above pattern informs that 'ab' has occurred in 7 *transactions and its periodic occurrence behavior of once in every two transactions consecutively for at least three times has been observed at two distinct subsets of a database whose timestamps are in the range [1, 4] and [11, 14]. Table 2 shows the complete set of recurring patterns discovered from Table 1.*

Table 2: Recurring patterns in Table 1. Terms '*Sup*,' '*Rec*' and '*IPI*' respectively denote *support*, *recurrence*, and interesting periodic-intervals along with their periodic-supports

Pattern	*Sup*	*Rec*	*IPI*
a	8	2	{{[1,4]:4}, {[11,14]:3}}
b	7	2	{{[1,4]:3}, {[11,14]:3}}
d	6	2	{{[2,5]:3}, {[9,12]:3}}
e	6	2	{{[3,6]:3}, {[10,12]:3}}
f	6	2	{{[3,6]:3}, {[10,12]:3}}
ab	7	2	{{[1,4]:3}, {[11,14]:3}}
cd	6	2	{{[2,5]:3}, {[9,12]:3}}
ef	6	2	{{[3,6]:3}, {[10,12]:3}}

DEFINITION 10. ***(Problem Definition:)*** *Given a time-based sequence (i.e., a TSD), the problem of finding recurring patterns involve discovering all those patterns that satisfy the user-defined per, minPS and minRec constraints.*

The measures, *support*, *period* and *periodic-support*, can also be expressed in percentage of $|TDB|$. However, we use the former definitions for ease of explanation. Table 3 lists the nomenclature of different terms used in our model.

Table 3: Nomenclature of various terms used in our model

Terminology	Notation
The timestamp of a transaction containing X	ts_i^X
The set of all timestamps containing X	TS^X
The *support* of X	$Sup(X)$
An inter-arrival time of X	iat_i^X
The set of all inter-arrival times of X	IAT^X
The user-defined *period*	per
A *periodic-support* of X	ps_i^X
The set of all *periodic-supports* of X	PS^X
A *periodic-interval* of X	pi_i^X
The set of all *periodic-intervals* of X	PI^X
The set of interesting periodic-intervals of X	IPI^X
The *recurrence* of X	$Rec(X)$

The construction of a transactional database from a time series involves grouping the items appearing together at a particular timestamp and storing them in a linked hash table. As this process is simple and straight forward, we do not discuss it in this paper. Instead, we focus on finding the recurring patterns from the constructed database.

4. PROPOSED ALGORITHM

In this section, we first introduce our pruning technique to reduce the computational cost of finding recurring patterns. Next, we present our algorithm to mine the complete set of recurring patterns from the constructed database.

4.1 Basic Idea: Candidate patterns

The space of items in a database gives rise to a subset lattice. An itemset lattice is a conceptualization of search space while finding user-interest-based patterns. The **anti-monotonic property** has been widely used to reduce the search space [23]. Unfortunately, recurring patterns do not satisfy this property. This increases the search space, which in turn increases the computational cost of mining recurring patterns.

EXAMPLE 10. *Consider the patterns 'c' and 'cd' in Table 1. Given the user-defined* $per = 2$, $minPS = 3$ *and* $minRec = 2$, *the interesting periodic-intervals of 'c' and 'cd' are* $\{[2,12]\}$ *and* $\{[2,5],[9,12]\}$, *respectively. Therefore, the* $Rec(c) = |\{[2,12]\}| = 1$ *and* $Rec(cd) = |\{[2,5],[9,12]\}| = 2$. *As the* $Rec(c) \ngeq minRec$, *'c' is not a recurring pattern. However, its superset 'cd' is a recurring pattern because* $Rec(cd) \geq minRec$. *Thus, the recurring patterns do not satisfy the anti-monotonic property. The same can be observed in Table 2.*

We introduce the following pruning technique to reduce the computational cost of finding recurring patterns.

"Let $E_{rec}(X) = \sum_{i=1}^{|PS^X|} \left\lfloor \frac{ps_i^X}{minPS} \right\rfloor$. If $E_{rec}(X) < minRec$, then neither X nor its supersets will be recurring patterns"

The $E_{rec}(X)$ denotes the upper bound of *recurrence* that a superset of X can have in the database. Thus, we call $E_{rec}(X)$ the **estimated maximum recurrence of a superset of** X. The correctness of our pruning technique is straight forward to prove from Properties 1 and 2, and illustrated in Example 11.

PROPERTY 1. *For the pattern* X, $E_{rec}(X) \geq Rec(X)$.

PROPERTY 2. *If* $X \subset Y$, *then* $TS^X \supseteq TS^Y$ *and* $E_{rec}(X) \geq E_{rec}(Y)$.

EXAMPLE 11. *In Table 1, the item 'g' occurs in timestamps of* $1, 5, 6, 7, 12$ *and* 14. *Therefore,* $TS^g = \{1,5,6,7,$-$12,14\}$ *and* $S(g) = 6$. *If* $per = 2$, $minPS = 3$ *and* $minRec = 2$, *then* $TS_1^g = \{1\}$, $TS_2^g = \{5,6,7\}$, $TS_3^g = \{12,14\}$, $ps_1^g = |TS_1^g| = 1$, $ps_2^g = |TS_2^g| = 3$ *and* $ps_3^g = |TS_3^g| = 2$. *For this item,* $E_{rec}(g) = 1 \left(= \sum_{i=1}^{3} \left\lfloor \frac{ps_i^g}{3} \right\rfloor = \left\lfloor \frac{1}{3} \right\rfloor + \left\lfloor \frac{3}{3} \right\rfloor + \left\lfloor \frac{2}{3} \right\rfloor \right)$. *That is, any superset of 'g' can at most have recurrence value equal to 1, which is less than the user-defined minRec. Henceforth, pruning 'g' will not result in missing of any recurring pattern.*

Based on our proposed pruning technique, we introduce the following definition.

DEFINITION 11. ***(Candidate pattern*** X***.)*** *Pattern* X *is a candidate pattern if* $E_{rec}(X) \geq minRec$.

A candidate pattern containing only one item is called a **candidate item**. The candidate patterns satisfy the *anti-monotonic property* (Property 2). Therefore, we use candidate k-patterns to discover recurring $(k+1)$-patterns.

4.2 RP-growth: Structure, Construction and Mining

Traditional Frequent Pattern-growth algorithm [24] cannot be used for finding recurring patterns. This is because the structure of FP-tree captures only the frequency and disregards the periodic behavior of the patterns in a database. To address this issue, RP-growth introduces an alternative tree structure known as an Recurring Pattern-tree (RP-tree).

Our RP-growth algorithm involves the following two steps: (i) construction of an RP-tree and (ii) recursive mining of the RP-tree to discover the complete set of recurring patterns. Before we describe the above two steps, we introduce the structure of an RP-tree.

4.2.1 *Structure of RP-tree*

The structure of an RP-tree includes a prefix-tree and a candidate item list, called the RP-list. The RP-list consists of each distinct *item* (i) with *support* (s), *estimated maximum recurrence* (E_{rec}), and a pointer pointing to the first node in the prefix-tree carrying the item.

The prefix-tree in an RP-tree resembles the prefix-tree in FP-tree. However, to obtain both frequency and *periodic* behavior of the patterns, the nodes in an RP-tree explicitly maintain the occurrence information for each transaction by keeping an occurrence timestamp list, called a **ts-list**. To achieve memory efficiency, only the last node of every transaction maintains the ts-list. Hence, two types of nodes are maintained in a RP-tree: **ordinary node** and **tail-node**. The former is a type of node similar to that used in an FP-tree, whereas the latter represents the last item of any sorted transaction. Therefore, the structure of a *tail*-node is $i[ts_p, ts_q, ..., ts_r]$, $1 \leq p \leq q \leq r \leq m$, where i is the node's item name and ts_i, $i \in [1, m]$, is the timestamp of a transaction containing the items from *root* up to the node i. The conceptual structure of an RP-tree is shown in Figure 3. Like an FP-tree, each node in an RP-tree maintains parent, children, and node traversal pointers. Please note that no node in an RP-tree maintains the support count as in an FP-tree. To facilitate a high degree of compactness, items in the prefix-tree are arranged in support-descending order.

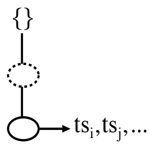

Figure 3: Conceptual structure of prefix-tree in RP-tree. Dotted ellipse represents ordinary node, while other ellipse represents tail-node of sorted transactions with timestamps $ts_i, ts_j \in R$

One can assume that the structure of the prefix-tree in an RP-tree may not be memory efficient since it explicitly maintains timestamps of each transaction. However, it has been argued that such a tree can achieve memory efficiency by keeping transaction information only at the *tail*-nodes and avoiding the support count field at each node [9]. Furthermore, an RP-tree avoids the *complicated combinatorial explosion problem of candidate generation* as in Apriori-like algorithms [23]. Keeping the information pertaining to transactional-identifiers in a tree can also be found in efficient frequent pattern mining [25].

Algorithm 1 RP-List(TDB: Transactional database, I: Set of items, *per*: period, $minPS$: minimum periodic-support, $minRec$: minimum recurrence)

```
1: Let $id_l$ be a temporary array that records the *timestamp* of the last appearance of each item in the $TDB$. Let $ps$ be another temporary array that records the periodic-support of an item in a subset of a database. Let $t = \{ts_{cur}, X\}$ denote the current transaction with $ts_{cur}$ and $X$ representing the timestamp of the current transaction and pattern, respectively.
2: for each transaction $t \in TDB$ do
3:   if an item $i$ occurs for the first time then
4:     Add $i$ to the RP-list.
5:     Set $s^i = 1$, $e^i_{rec} = 0$, $id^i_l = ts_{cur}$ and $ps^i = 1$.
6:   else
7:     if $(ts_{cur} - id^i_l) \leq per$ then
8:       Set $s^i++$, $ps^i++$ and $id^i_l = ts_{cur}$.
9:     else
10:      $e^i_{rec} += \left\lfloor \frac{ps^i}{minPS} \right\rfloor$.
11:      Set $s^i++$, $ps^i = 1$ and $id^i_l = ts_{cur}$. {Beginning of a new subset of a database.}
12:    end if
13:  end if
14: end for
15: To reflect the correct estimated recurrence value for each item in the RP-list, perform $e^i_{rec} += \left\lfloor \frac{ps^i}{minPS} \right\rfloor$.
```

Algorithm 2 RP-Tree(TDB, RF-list)

```
1: Create the root of an RP-tree, $T$, and label it "*null*".
2: for each transaction $t \in TDB$ do
3:   Set the timestamp of the corresponding transaction as $t_{cur}$.
4:   Select and sort the candidate items in $t$ according to the order of $CI$. Let the sorted candidate item list in $t$ be $[p|P]$, where $p$ is the first item and $P$ is the remaining list.
5:   Call $insert\_tree([p|P], t_{cur}, T)$.
6: end for
7: call RP-growth ($Tree$, $null$);
```

4.2.2 *Construction of RP-tree*

Since recurring patterns do not satisfy the *anti-monotonic property*, candidate 1-patterns (or items) will play an important role in effective mining of these patterns. The set of candidate items CI in a database for the user-defined *per*, $minPS$, and $minRec$ can be discovered by populating the RP-list with a scan on the database. Figure 4 shows the construction of an RP-list using Algorithm 1. Due to page limitation, we only present the key steps in the construction of the RP-list. Please note that the *per*, $minPS$, and $minRec$ values have been set to 2, 3 and 2, respectively.

The scan on the first transaction, "$1 : a, b, g$", with $ts_{cur} = 1$ initializes items 'a', 'b', and 'g' in the RP-list and sets their s, e_{rec}, id_l, and ps values to $1, 0, 1$, and 1, respectively (lines 1 to 5 in Algorithm 1). Figure 4(a) shows the RP-list generated after scanning the first transaction. The scan on the second transaction "$2 : a, c, d$" with $ts_{cur} = 2$ initializes the items 'c' and 'd' in the RP-list by setting their s, e_{rec}, id_l,

Algorithm 3 insert_tree($[p|P]$, t_{cur}, T)

```
1: while $P$ is non-empty do
2:   if $T$ has a child $N$ such that $p.itemName \neq N.itemName$ then
3:     Create a new node $N$. Let its parent link be linked to $T$. Let its node-link be linked to nodes with the same itemName via the node-link structure. Remove $p$ from $P$.
4:   end if
5: end while
6: Add $t_{cur}$ to the leaf node.
```

Algorithm 4 RP-growth($Tree$, α)

```
1: for each $a_i$ in the header of Tree do
2:   Generate pattern $\beta = a_i \cup \alpha$. Collect all of the $a_i's$ ts-lists into a temporary array, $TS^{\beta}$, and calculate $E^{\beta}_{rec}$.
3:   if $E^{\beta}_{rec} \geq minRec$ then
4:     Construct $\beta$'s conditional pattern base then $\beta$'s conditional RP-tree $Tree_{\beta}$. Call getRecurrence($\beta$, $TS^{\beta}$).
5:     if $Tree_{\beta} \neq \emptyset$ then
6:       call RP-growth($Tree_{\beta}$, $\beta$);
7:     end if
8:   end if
9:   Remove $a_i$ from the $Tree$ and push the $a_i$'s ts-list to its parent nodes.
10: end for
```

and *ps* values to 1, 0, 2, and 1, respectively. In addition, the s, e_{rec}, id_l, and *ps* values of an already existing item 'a' are updated to 2, 0, 2, and 2, respectively (lines 7 to 9 in Algorithm 1). Figure 4(b) shows the RP-list generated after scanning the second transaction. Figure 4(c) shows the RP-list constructed after scanning the seventh transaction. It can be observed that the 'e_{rec}' of 'a' and 'b' have been updated from 0 to 1. This is because their $\left\lfloor \frac{ps}{minPS} \right\rfloor = 1$ (line 10 in Algorithm 1). The *ps* value of 'a' and 'b' is set to 1 because they appeared periodically once again in the database (line 11 in Algorithm 1). Figure 4(d) shows the RP-list constructed after scanning every transaction in the database. The estimated recurrence (e_{rec}) value for all the items in the RP-list is once again computed to reflect the correctness (line 15 in Algorithm 1). Figure 4(e) shows the updated e_{rec} value for all items in the RP-list. Using our pruning technique, 'g' is removed from the RP-list as its $e_{cur} < minRec$. The remaining items are sorted in descending order of their support values (line 16 in Algorithm 1). Figure 4(f) shows the sorted list of candidate items in the RP-list.

After finding candidate items, we conduct another scan on the database and construct the prefix-tree of the RP-tree, as in Algorithms 2 and 3. These procedures are the same as those for constructing an FP-tree [24]. However, the major difference is that no node in an RF-tree maintains the *support* count, as in an FP-tree. The first transaction $\{1 : a, b, g\}$ is scanned and a branch is constructed in the RP-tree with only the candidate items 'b' and 'a.' The *tail* node 'b : 1' carries the *timestamp* of the transaction. The RP-tree generated after scanning the first transaction is shown in Figure 5(a). A similar process is repeated for the remaining transactions and the tree is updated accordingly. Figure 5(b) shows the RP-tree constructed after scanning the entire database. For simplicity, we do not show the node traversal pointers in trees; however, they are maintained like an FP-tree does.

Figure 5: Construction of RP-tree: (a) after scanning first transaction and (b) after scanning entire transactional database

The RP-tree maintains the complete information of all recurring patterns in a database. The correctness is based on Property 3 and shown in Lemmas 1 and 2. For each transaction $t \in theTDB$, $CI(t)$ is the set of all candidate items in t, i.e., $CI(t) = item(t) \cap CI$, and is called the candidate item projection of t.

PROPERTY 3. *An RP-tree maintains a complete set of candidate item projections for each transaction in a database only once.*

LEMMA 1. *Given a TDB and user-defined per, (minPS), and minRec values, the complete set of all recurring item projections of all transactions in the TDB can be derived from the RP-tree.*

PROOF. Based on Property 3, each transaction $t \in TDB$ is mapped to only one path in the tree, and any path from the *root* up to a *tail* node maintains the complete projection for exactly n transactions (where n is the total number of entries in the *ts*-list of the *tail* node). □

Lemma 2. *The size of the RP-tree (without the root node) on a TDB for user-defined per, minPS, and minRec is bounded by* $\sum_{t \in TDB} |CI(t)|$.

Proof. According to the RP-tree construction process and Lemma 1, each transaction t contributes at most one path of size $|CI(t)|$ to an RP-tree. Therefore, the total size contribution of all transactions can be $\sum_{t \in TDB} |CI(t)|$ at best. However, since there are usually many common prefix patterns among the transactions, the size of an RP-tree is normally much smaller than $\sum_{t \in TDB} |CI(t)|$. □

Algorithm 5 getRecurrence(X: pattern, TS^X:ts-list of pattern X)

```
1: Let $id_l$ be a variable that records the timestamp of the last transaction containing $X$. Let $subDB$ be a list of pairs of the form $(startTS, endTS)$, where $startTS$ and $endTS$ respectively represent the starting and ending timestamps of periodic appearances of a pattern in a subset of data. It is used to record the periodic-intervals of a pattern. Let $currentPS$ be a variable to measure the periodic-support of $X$ in a periodic-interval.
2: for each timestamp $ts_{cur} \in TS^X$ do
3:   if ($ts_{cur}$ is $X$'s first occurrence) then
4:     $currentPS = 1$, $startTS = ts_{cur}$;
5:   else
6:     if ($ts_{cur} - id_l \leq per$) then
7:       $currentPS++$;
8:     else
9:       if ($currentPS \geq minPS$) then
10:        $subDB.insert(startTS, id_l)$;
11:      end if
12:      $currentPS = 1$, $startTS = ts_{cur}$;
13:    end if
14:  end if
15:  $id_l = ts_{cur}$;
16: end for
17: // To reflect correct recurrence of $X$.
18: if ($currentPS \geq minPS$) then
19:   $subDB.insert(startTS, id_l)$;
20: end if
21: return (($subDB.size() \geq minRec$)?true:false);
```

4.2.3 Mining Recurring Patterns

Although an RP-tree and FP-tree arrange items in support-descending order, we cannot directly apply FP-growth mining on an RP-tree. The reasons are as follows: (*i*) an RP-tree does not maintain the support count at each node, and it handles the *ts*-lists at the *tail* nodes and (*ii*) recurring patterns do not satisfy the *anti-monotonic property.* We devised another pattern growth-based bottom-up mining technique to mine the patterns. The basic operations in mining an RP-tree includes: (*i*) counting length-1 candidate items, (*ii*) constructing the prefix tree from each candidate pattern, and (*iii*) constructing the conditional tree from each prefix-tree. The RP-list provides the length-1 candidate items. Before we discuss the prefix-tree construction process, we explore the following important property and lemma of an RP-tree.

Property 4. *A tail node in an RP-tree maintains the occurrence information for all the nodes in the path (from the tail node to the root) at least in the transactions in its ts-list.*

Lemma 3. *Let* $Z = \{a_1, a_2, \cdots, a_n\}$ *be a path in an RP-tree where node* a_n *is the tail node carrying the ts-list of the path. If the ts-list is pushed-up to node* a_{n-1}*, then* a_{n-1} *maintains the occurrence information of the path* $Z' = \{a_1, a_2, \cdots, a_{n-1}\}$ *for the same set of transactions in the ts-list without any loss.*

Proof. Based on Property 4, a_n maintains the occurrence information of path Z' at least in the transactions in its *ts*-list. Therefore, the same *ts*-list at node a_{n-1} maintains the same transaction information for Z' without any loss. □

The procedure to discover recurring patterns from RP-tree is shown in Algorithm 4. The working of this algorithm is as follows. We proceed to construct the prefix tree for each candidate item in the RP-list, starting from the bottom-most item, say i. To construct the prefix-tree for i, the prefix sub-paths of nodes i are accumulated in a tree-structure, PT_i. Since i is the bottom-most item in the RP-list, each node labeled i in the RP-tree must be a tail node. While constructing PT_i, based on Property 4, we map the *ts*-list of every node of i to all items in the respective path explicitly in the temporary array (one for each item). This temporary array facilitates the calculation of *support* and e_{rec} of each item in PT_i (line 2 in Algorithm 4). If an item j in PT_i has *support* $\geq$ *minSup* and $e_{rec} \geq$ *minRec*, then we construct its conditional tree and mine it recursively to discover the recurring patterns (lines 3 to 8 in Algorithm 4). Moreover, to enable the construction of the prefix-tree for the next item in the RP-list, based on Lemma 3, the *ts*-lists are pushed-up to the respective parent nodes in the original RP-tree and in PT_i as well. All nodes of i in the original RP-tree and i's entry in the RP-list are deleted thereafter (line 9 in Algorithm 4).

Using Properties 1 and 2, the conditional tree CT_i for PT_i is constructed by removing all those items from PT_i that have $e_{rec} <$ *minRec.* If the deleted node is a *tail* node, its *ts*-list is pushed-up to its parent node. The contents of the temporary array for the bottom item j in the RP-list of CT_i represent TS^{ij} (i.e., the set of all timestamps where items i and j have appeared together in the database). Therefore, using Algorithm 5, the *recurrence* of "ij" is computed and it is determined whether "ij" is a recurring pattern. The same process of creating a prefix-tree and its corresponding conditional tree is repeated for further extensions of "ij". The whole process of mining for each item is repeated until *RP-list* $\neq \emptyset$.

Consider item 'f', which is the last item in the RP-list in Figure 4(e). The prefix-tree for 'f', PT_f, is constructed from the RP-tree, as shown in Figure 6(a). There are five items, 'a, b, c, d', and 'e' in PT_f. Only item 'e' satisfies the condition $E_{rec}(e) \geq minRec$. Therefore, the conditional tree CT_f from PT_f is constructed with only one item 'e', as shown in 6(b). The *ts*-list of 'e' in CT_f' generates TS^{ef}. The "*recurrence*" of 'ef' is measured using Algorithm 5. Since $Rec(ef) \geq minRec$, 'ef' will be generated as a recurring pattern. A similar process is repeated for the other items in the RP-list. Next, 'f' is pruned from the original RP-tree

Table 4: **User-defined *per*, *minPS* and *minRec* values in different databases**

	per			*minPS*			*minRec*		
	1	2	3	1	2	3	1	2	3
T10I4D100k	360	720	1440	0.1%	0.2%	0.3%	1	2	3
Shop-14	360 (=6 hr.)	720 (=12 hrs.)	1440 (=24 hrs.)	0.1%	0.2%	0.3%	1	2	3
Twitter	360 (=6 hr.)	720 (=12 hrs.)	1440 (=24 hrs.)	2%	5%	10%	1	2	3

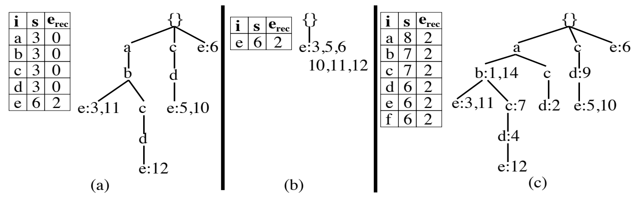

Figure 6: Finding RP-patterns for suffix item '*f*' in RP-tree: (a) prefix-tree for item '*f*' (i.e., PT_f), (b) conditional tree for item '*f*' (i.e., CT_f), and (c) RP-tree after pruning item '*f*'

and its *ts*-lists are pushed to its parent nodes, as shown in 6(c). All the above processes are once again repeated until the RP-list $\neq \emptyset$.

The above bottom-up mining technique on a support descending RP-tree is efficient, because it shrinks the search space dramatically as the mining process progresses.

5. EXPERIMENTAL RESULTS

In this section, we first evaluate the performance of RP-growth. Next, we discuss the usefulness of recurring patterns by comparing them against p-patterns and periodic-frequent patterns. It should be noted that our recurring patterns are the generalization of periodic-frequent patterns, as the latter patterns exhibit complete (rather than partial) cyclic repetitions in the entire database. There are only two Apriori-like algorithms, periodic-first and association-first, to discover p-patterns. We use the periodic-first algorithm to discover p-patterns since it is relatively faster than the association-first algorithm. We use the Periodic-Frequent pattern-growth++ algorithm (PF-growth++) [15] to discover periodic-frequent patterns. We do not compare the performance of RP-growth against the periodic-first and PF-growth++ algorithms. The reason is that the other algorithms discover regular patterns; therefore, they use different measures to assess the periodic interestingness of a pattern.

5.1 Experimental setup

The algorithms, RP-growth, periodic-first and PF-growth++, were written in GNU C++ and run with Ubuntu 14.4 on a 2.66 GHz machine with 8 GB of memory. To the best of our knowledge, there are no publicly available time-based sequences. Therefore, we conducted experiments using the following databases.

- **T10I4D100K database.** This database is a synthetic transactional database generated using the procedure given by [23]. This database contains 100,000 transactions and 941 distinct items.
- **Shop-14 database.** A Czech company provided click-stream data of seven online stores in the ECML/PKDD 2005 Discovery challenge. We considered the click stream data of product categories visited by the users in "Shop 14" (www.shop4.cz), and created a transactional database with each transaction representing the set of web pages visited by the people at a particular *minute interval.* The transactional database contains 59,240 transactions (i.e., 41 days of page visits) and 138 distinct items (or product categories).
- **Twitter database.** We created this database by considering the top 1000 English hashtags appearing in 44 million tweets/retweets from 1-May-2013 to 31-August-2013 (i.e., 123 days). The measure, *term frequency-inverse document frequency*, is used to rank the hashtags. The timestamp of each transaction represents a minute starting from 00:00 hours of 1-May-2013 to 24:00 hours of 31-August-2013. The resultant transactional database has 177,120 transactions with 1000 distinct items (or hashtags). More details on the data collection process and the usefulness of this data in finding interesting events has been presented in [26].

To mine p-patterns and recurring patterns, we transformed all the above databases into time-based sequences using the timestamps of each transaction. As this transformation process is a rather simple and straight-forward approach, we do not discuss it for brevity.

Table 4 lists the different *per*, *minPS* and *minRec* values used in above the databases. The periodic interval (i.e., *per* value) in both Shop-14 and Twitter databases varied from six hours to one day. Similarly, the *minRec* in these databases varied from 1 to 3. In this paper, we do not present the results for *minRec* values greater than 3 because very few recurring patterns were getting generated at *minRec* > 3. The *minPS* values in T10I4D100K and Shop-14 databases varied from 0.1% to 0.3%. The reason for choosing low *minPS* values is to discover the patterns involving both frequent and rare items. In the Twitter database, we set *minPS* at 2%, 5% and 10%. The reason for choosing a relatively high *minPS* values as compared with the other two databases is that very low *minPS* values are resulting in a combinatorial explosion producing too many patterns.

5.2 Generation of recurring patterns

Table 5 lists the numbers of recurring patterns discovered in T10I4D100K, Shop-14 and Twitter databases at different *per*, *minPS* and *minRec* values. The partial results of Table 5 are shown in Figure 7. The following observations can drawn from this figure:

- At a fixed *per* and *minRec*, the increase in *minPS* can decrease the number of recurring patterns. The reason is that many patterns failed to appear periodically for longer time periods.

Table 5: Number of recurring patterns generated at different *per*, *minPS* and *minRec* threshold values

Dataset	*minPS*	Number of recurring patterns								
		minRec = 1			*minRec* = 2			*minRec* = 3		
		per=360	*per*=720	*per*=1440	*per*=360	*per*=720	*per*=1440	*per*=360	*per*=720	*per*=1440

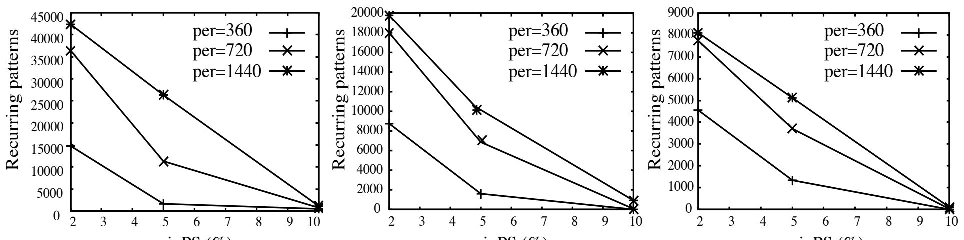
Twitter	2%	14736	36354	42319	8718	17982	19746	4551	7749	8103
	5%	1655	11268	26341	595	6847	7010	337	3713	5123
	10%	511	714	1190	11	34	912	6	17	98



(a) minRec=1 (b) minRec=2 (c) minRec=3

Figure 7: Recurring patterns discovered in Twitter data

- At a fixed *minPS* and *per*, the increase in *minRec* can decrease the number of recurring patterns. This is because many patterns failed to satisfy the increased *minRec* values.
- At a fixed *minPS*, the increase in *per* can have different impact on the generation of recurring patterns for the values $minRec = 1$ and $minRec > 1$. At $minRec = 1$, increase in *per* can increase the number of recurring patterns. The reason is that the inter-arrival times of the patterns that were considered as aperiodic at low *per* values were considered as periodic with the increase in the *per* value. For $minRec > 1$, increase in *per* can either increase or decrease the number of recurring patterns. The reason for decrease is due to the merging of interesting periodic-intervals discovered at low *per* values.

Table 6 lists some of the recurring patterns discovered from the Twitter database at $per = 360$, $minPS = 2\%$ and $minRec = 1$. Figures 8 (a) and (b) show the frequencies of the terms present in patterns {yyc, uttarakhand} and {nuclear, hibaku} on a daily basis. It can be observed that "uttarakhand" is a relatively rare term as compared with other terms, and our model has effectively discovered the knowledge pertaining to this term. Another interesting observation from Table 5 is that even at low *minPS* values, our model has generated only a limited number of recurring patterns in each database. This clearly shows that our model can discover the knowledge pertaining to rare terms without producing too many uninteresting patterns. In other words, our model is tolerant of the "rare item problem".

5.3 Performance of RP-growth

Table 7 lists the runtime required using RP-growth to discover recurring patterns in T10I4D100K, Shop-14, and

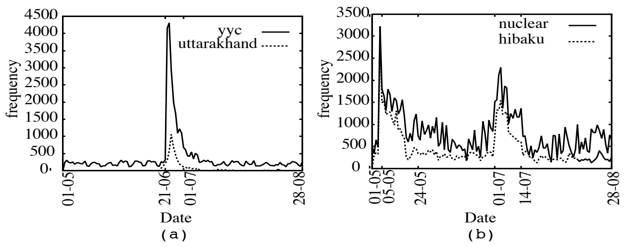


Figure 8: Frequency of hashtags at different days in database. Date is of form 'dd-mm'. Year of this date is 2013

Twitter databases. The runtime involves the time taken to transform the time-based sequence into a transactional database and mining of recurring patterns. Figure 9 shows the runtime required by RP-growth while mining the recurring patterns in Twitter database. The changes in the *per*, *minPS* and *minRec* threshold values shows a similar effect on runtime consumption as in the generation of recurring patterns. The proposed algorithm discovered the complete set of recurring patterns at a reasonable runtime even at low *minPS* thresholds.

5.4 Comparison of p-patterns, recurring patterns and periodic-frequent patterns

We compared p-patterns, recurring patterns and periodic-frequent patterns at different *per* and *minPS* values. For brevity, we present the results discovered when *period* is set to 1 day, i.e., $per = 1440$. The *minSup* and *minPS* values are set to 0.1% and 2% respectively for Shop-14 and Twitter databases. The p-pattern mining requires another parameter known as window length (w). We set $w = 1$ for our experiment.

Table 6: Some of the interesting recurring patterns discovered in Twitter database

S.No	Pattern	Periodic duration	Cause for the events
1	{yyc, uttarakhand}	[2013-06-21 01:08, 2013-07-01 04:27]	On June 20, Uttarakhand, a state in India and Alberta, a province in Canada have witnessed heavy floods.
2	{nuclear, hibaku} (In Japanese, hibaku means radiation.)	[2013-05-06 22:33, 2013-05-24 22:13], [2013-07-01 06:17, 2013-07-14 06:21]	(*i*) A Japanese minister has visited Chernobyl, Ukraine to learn from the recovery from the severe nuclear accident. (*ii*) People were tweeting about detection of Plutonium at a point 12 KM from Fukoshima nuclear reactor.
3	{pakvotes, nayapakistan}	[2013-05-09 16:15, 2013-05-15 14:11]	The general elections were held in Pakisthan. on May 11, 2013.
4	{oklahoma, tornado, prayforoklahoma}	[2013-05-21 11:52, 2013-05-24 21:38]	Oklahoma was struck with a tornado on May 20, 2013.

Table 7: Runtime of RP-growth at different *per*, *minPS* and *minRec* threshold values

Table 8 lists the numbers of periodic-frequent patterns, recurring patterns and p-patterns discovered in the Shop-14 and Twitter databases. The column labeled '*II*' in this table refers to the length of the longest pattern discovered in each of these databases. The following observations can be drawn from this table.

First, the total numbers of periodic-frequent patterns discovered in both databases were relatively less than the number of recurring patterns and p-patterns. The reason is that the strict constraint that a frequent pattern has to exhibit complete cyclic repetitions throughout the data has failed to identify many interesting partial periodically appearing patterns. Moreover, this strict constraint also resulted in finding the very short periodic-frequent patterns (see columns labeled '*II*' in Table 8). This is because longer patterns generally fail to exhibit complete cyclic repetitions throughout the data. Setting a high *period* threshold value can enable a user to discover long periodic-frequent patterns. However, this high *period* can result in discovering sporadically appearing patterns as periodic-frequent patterns. Thus, it is necessary to relax this strict constraint without changing the *period* threshold value. As our model enables a user to relax this strict constraint, recurring patterns have been found more interesting than the periodic-frequent patterns for a given *per* threshold.

Second, the total number of p-patterns discovered in both databases were much higher than the recurring patterns and periodic-frequent patterns. The reason is that the usage of a low *minSup* has facilitated Ma and Hellerstein's model [7] to discover not only all our recurring patterns as p-patterns, but also resulted in a combinatorial explosion of frequently appearing items producing too many p-patterns. Most importantly, many of the p-patterns discovered at low *minSup* were uninteresting to the users. The reason is that frequent

Table 8: Number of patterns discovered in Shop-14 and Twitter databases. Terms '*I*' and '*II*' represent *total number of patterns* and *maximum length of pattern* found in each database, respectively.

	Shop-14		Twitter	
	I	*II*	*I*	*II*
PF patterns	22	3	466	2
Recurring patterns	4,977	9	42,319	7
p-patterns	156,7001	12	442,076	16

items were combining with one another in all possible ways and generating p-patterns by satisfying a low *minSup* value. On the contrary, our model has reduced the combinatorial explosion of frequent items by assessing their interestingness with respect to their number of consecutive periodic appearances in a portion of data.

6. CONCLUSIONS AND FUTURE WORK

We introduced a new class of partial periodic patterns known as *recurring patterns* and discussed the usefulness of these patterns in various real-world applications. We also proposed a model for discovering such patterns. The patterns discovered with the proposed model do not satisfy the anti-monotonic property. Therefore, we proposed a novel pruning technique to reduce the computational cost of finding these patterns. We also proposed a pattern-growth algorithm to discover the recurring patterns effectively. Experimental results suggest that the model is tolerant to the "rare item problem" and that the algorithm is efficient. The usefulness of the recurring patterns was discussed by comparing them against the periodic-frequent and p-patterns.

In our current study, we did not considered noisy data and the phase-shifts of the items within the data. For fu-

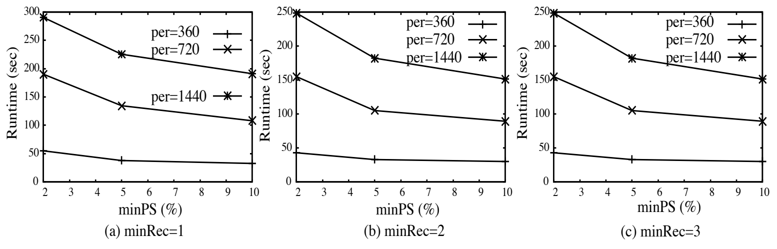

Figure 9: Runtime of RP-growth

ture work, we will develop methods for handling these two scenarios. Another interesting future work will be extending our model to improve the performance of an association rule-based recommender system.

ABSTRACT

We investigate the problem of learning graph queries by exploiting user examples. The input consists of a graph database in which the user has labeled a few nodes as *positive* or *negative examples*, depending on whether or not she would like the nodes as part of the query result. Our goal is to handle such examples to find a query whose output is what the user expects. This kind of scenario is pivotal in several application settings where unfamiliar users need to be assisted to specify their queries. In this paper, we focus on *path queries* defined by *regular expressions*, we identify fundamental difficulties of our problem setting, we formalize what it means to be *learnable*, and we prove that the class of queries under study enjoys this property. We additionally investigate an interactive scenario where we start with an empty set of examples and we identify the *informative nodes* i.e., those that contribute to the learning process. Then, we ask the user to label these nodes and iterate the learning process until she is satisfied with the learned query. Finally, we present an experimental study on both real and synthetic datasets devoted to gauging the effectiveness of our learning algorithm and the improvement of the interactive approach.

1. INTRODUCTION

Graph databases [41] are becoming pervasive in several application scenarios such as the Semantic Web [5], social [37] and biological [36] networks, and geographical databases [2], to name a few. A graph database is essentially a directed, edge-labeled graph. As an example, consider in Figure 1 a graph representing a geographical database having as nodes the neighborhoods of a city area (N_1 to N_6), along with cinemas (C_1 and C_2), and restaurants (R_1 and R_2) in such neighborhoods. The edges represent public transportation facilities from a neighborhood to another (using labels *tram* and *bus*), along with other kind of facilities (using labels *cinema* and *restaurant*). For instance, the graph indicates that one can travel by bus between the neighborhoods N_2 and N_3, that in the neighborhood N_4 exists a cinema C_1, and so on.

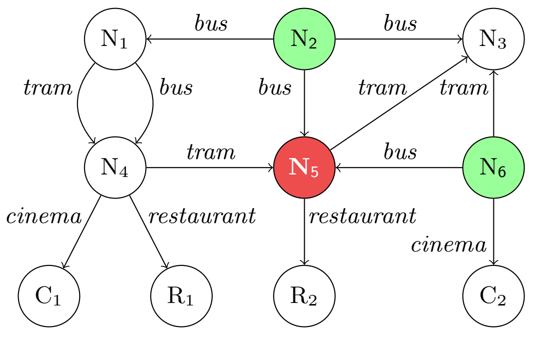

Figure 1: A geographical graph database.

Many mechanisms have been proposed to query a graph database, the majority of them being based on *regular expressions* [7, 41]. By continuing on our running example, imagine that a user wants to know from which neighborhoods in the city represented in Figure 1 she can reach cinemas via public transportation. These neighborhoods can be retrieved using a *path query* defined by the following *regular expression*:

$$q = (tram + bus)^* \cdot cinema$$

The query q selects the nodes N_1, N_2, N_4, and N_6 as they are entailed by the following *paths* in the graph:

$$N_1 \xrightarrow{tram} N_4 \xrightarrow{cinema} C_1,$$
$$N_2 \xrightarrow{bus} N_1 \xrightarrow{tram} N_4 \xrightarrow{cinema} C_1,$$
$$N_4 \xrightarrow{cinema} C_1,$$
$$N_6 \xrightarrow{cinema} C_2.$$

Although very expressive, graph query languages are difficult to understand by non-expert users who are unable to specify their queries with a formal syntax. The problem of *assisting non-expert users to specify their queries* has been recently raised by Jagadish et al. [24, 34]. More concretely, they have observed that "constructing a database query is often challenging for the user, commonly takes longer than the execution of the query itself, and does not use any insights from the database". While they have mentioned these problems in the context of relational databases, we argue that they become even more difficult to tackle for graph databases. Indeed, graph databases usually do not carry proper metadata as they lack schemas and/or do not ex-

10.5441/002/edbt.2015.11

hibit a clear distinction between instances and schemas. The absence of metadata along with the difficulty of visualizing possibly large graphs make unfeasible traditional query specification paradigms for non-expert users, such as query by example [43]. Our work follows the recent trend of specifying graph queries by example [33, 25]. Precisely, we focus on graph queries using regular expressions, which are fundamental building blocks of graph query languages [7, 41], while both [33, 25] consider simple graph patterns.

While the problem of executing path queries defined by regular expressions on graphs has been extensively studied recently [6, 32, 27], no research has been done on how to actually specify such queries. Our work focuses on the problem of assisting non-expert users to specify such path queries, by exploiting elementary user input.

By continuing on our running example, we assume that the user is not familiar with any formal syntax of query languages, while she still wants to specify the above query q on the graph database in Figure 1 by providing examples of the query result. In particular, she would positively or negatively label some graph nodes according to whether or not they would be selected by the targeted query. Thus, let us imagine that the user labels the nodes N_2 and N_6 as *positive examples* because she wants these nodes as part of the result. Indeed, one can reach cinemas from N_2 and N_6, respectively, through the following paths:

$$\mathrm{N}_2 \xrightarrow{bus} \mathrm{N}_1 \xrightarrow{tram} \mathrm{N}_4 \xrightarrow{cinema} \mathrm{C}_1,$$

$$\mathrm{N}_6 \xrightarrow{cinema} \mathrm{C}_2.$$

Similarly, the user labels the node N_5 as a *negative example* since she would not like it as part of the query result. Indeed, there is no path starting in N_5 through which the user can reach a cinema. We also observe that the query q above is *consistent* with the user's examples because q selects all positive examples and none of the negative ones. Unfortunately, there may exist an infinite number of queries consistent with the given examples. Therefore, we are interested to find either the "exact" query that the user has in mind or, alternatively, an equivalent query, which is close enough to the user's expectations.

Apart from assisting unfamiliar users to specify queries, our research has other crucial applications, such as mining *scientific workflows*. Regular expressions have already been used in the literature as a well-suited mechanism for inter-workflow coordination [21]. The path queries on graph databases that we study in this paper can be applied to assist scientists in identifying interrelated workflows that are of interest for them. For instance, assume that a biologist is interested in retrieving all interrelated workflows having a pattern that starts with protein purification, continues with an arbitrary number of protein separation steps, and ends with mass spectrometry. This corresponds to the following regular expression:

$$\mathit{ProteinPurification} \cdot \mathit{ProteinSeparation}^* \cdot \mathit{MassSpectrometry}.$$

Instead of specifying such a pattern in a formal language, the biologist may be willing to label some sequences of modules from a set of available workflows as positive or negative examples, as illustrated in Figure 2. Our algorithms can be thus applied to infer the workflow pattern that the biologist has in mind. Typically in graphs representing workflows the labels are attached to the nodes (e.g., as in Figure 2) instead of the edges. In this paper, we have opted for

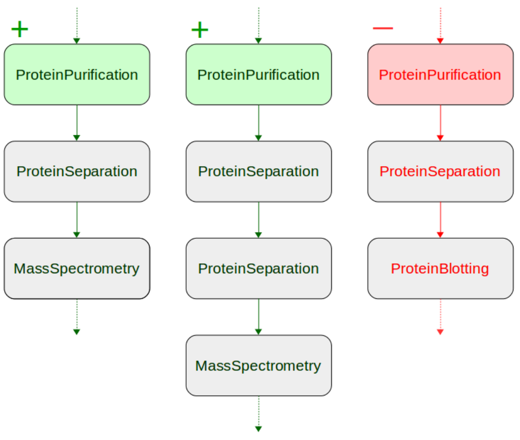

Figure 2: A set of scientific workflows examples.

edge-labeled graphs rather than node-labeled graphs, but our algorithms and learning techniques for the considered class of queries are applicable to the latter class of graphs in a seamless fashion. The problem of mining scientific workflows has been considered in recent work [8], which leverages data instances as representatives of the input and output of a workflow module. In our approach, we rely on simpler user feedback, namely Boolean labeling of sequences of modules across interrelated workflows.

Since our goal is to infer the user queries while minimizing the amount of user feedback, our research is also applicable to *crowdsourcing* scenarios [19], in which such minimization typically entails lower financial costs. Indeed, we can imagine that crowdworkers provide the set of positive and negative examples mentioned above for path query learning. Moreover, our work can be used in assisting non-expert users in other fairly complex tasks, such as specifying *schema mappings* [42] i.e., logical assertions between two path queries, one on a source schema and another on a target schema.

To the best of our knowledge, our work is the first to study the problem of learning path queries defined by regular expressions on graphs via user examples. More precisely, we make the following main contributions:

- We investigate a learning framework inspired by computational learning theory [26], in particular by grammatical inference [18] and we identify fundamental difficulties of such a framework. We consequently propose a definition of learnability adapted to our setting.
- We propose a learning algorithm and we precisely characterize the conditions that a graph must satisfy to guarantee that every user's goal query can be learned. Essentially, the main theoretical result of the paper states that for every query q there exists a polynomial set of examples that given as input to our learning algorithm guarantees the learnability of q. Additionally, our learning algorithm is guaranteed to run in polynomial time, whether or not the aforementioned set of examples is given as input.
- We investigate an interactive scenario, which bootstraps with an empty set of examples and builds it along the way. Indeed, the learning algorithm finely

interacts with the user by proposing nodes that can be labeled and repeats the interactions until the goal query is learned. More precisely, we analyze what it means for a node to be informative for the learning process, we show the intractability of deciding whether a node is informative or not, and we propose efficient strategies to present examples to the user.

- To evaluate our approach, we have run experiments on both real-world and synthetic datasets. Our study shows the effectiveness of the learning algorithm and the advantage of using an interactive strategy, which significantly reduces the number of examples needed to learn the goal query.

Finally, we would like to spend a few words on the class of queries that we investigate in this paper. As already mentioned, we focus on regular expressions, which are fundamental for graph query languages [7, 41] and lately used in the definition of SPARQL property paths[1]. Graph queries defined by regular expressions have been known as *regular path queries.* Intuitively, such queries retrieve pairs of nodes in the graph s.t. one can navigate between them with a path in the language of a given regular expression [7, 41]. Although the usual semantics of regular path queries is *binary* (i.e., selects pairs of nodes), in this paper we consider a generalization of this semantics that we call *monadic*, as it outputs only the originated nodes of the paths. The motivation behind using a monadic semantics is essentially threefold. First, it entails a larger space of potential solutions than a binary semantics. Indeed, with the latter semantics the end node of a path is fixed, which basically corresponds to have a smaller number of candidate paths that start at the originated node and that can be possibly labeled by the user. Second, in our learning framework, the amount of user effort should be kept as minimal as possible (which led to design an interactive scenario) and thus we let the user focus solely on the originated nodes of the paths rather than on pairs of nodes. Third, the development of the learning algorithm for monadic queries is extensible to binary queries and n-ary queries in a straightforward fashion, as shown in the paper.

Organization. In Section 2, we introduce some basic notions. In Section 3, we define our framework for learning from a set of examples, we present our learning algorithm, and we prove our learnability results. In Section 4, we propose an interactive algorithm and characterize the quantity of information of a node. In Section 5, we experimentally evaluate the performance of our algorithms. Finally, we conclude our paper and outline future directions in Section 6. Due to space restrictions, in this paper we omit the proofs of several results and we refer to the appendix of our technical report [11] for detailed proofs.

Related work

Learning queries from examples is a popular and interesting topic in databases. Very recently, algorithms for learning relational queries (e.g., quantifiers [1], joins [14, 15]) or XML queries (e.g., tree patterns [38]) have been proposed. Besides learning queries, researchers have investigated the learnability of relational schema mappings [40], as well as schemas [9] and transformations [30] for XML. A fairly close problem to learning is definability [4]. In this paragraph, we discuss the positioning of our own work w.r.t. these and other papers.

A wealth of research on using computational learning theory [26] has been recently conducted in databases [1, 9, 14, 30, 38, 40]. In this paper, we use *grammatical inference* [18] i.e., the branch of machine learning that aims at constructing a formal grammar by generalizing a set of examples. In particular, all the above papers on learning tree patterns [38], schemas [9, 16], and transformations [30] are based on it.

Our definition of learnability is inspired by the well-known framework of *language identification in the limit* [20], which requires a learning algorithm to be polynomial in the size of the input, *sound* (i.e., always return a concept consistent with the examples given by the user or a special *null* value if such concept does not exist) and *complete* (i.e., able to produce every concept with a sufficiently rich set of examples). In our case, we show that checking the consistency of a given set of examples is intractable, which implies that there is no algorithm able to answer *null* in polynomial time when the sample is inconsistent. This leads us to the conclusion that path queries are not learnable in the classical framework. Consequently, we slightly modify the framework and require the algorithm to learn the goal query in polynomial time if a polynomially-sized characteristic set of examples is provided. This learning framework has been recently employed for learning XML transformations [30] and is referred to as learning with *abstain* since the algorithm can abstain from answering when the characteristic set of examples is not provided.

The classical algorithm for learning a regular language from positive and negative word examples is RPNI [35], which basically works as follows: (i) construct a DFA (usually called prefix tree acceptor or PTA [18]) that selects all positive examples; (ii) generalize it by state merges while no negative example is covered. Unfortunately, RPNI cannot be directly adapted to our setting since the input positive and negative examples are not words in our case. Instead, we have a set of graph nodes starting from which we have to select (from a potentially infinite set) the paths that led the user to label them as examples. After selecting such paths, we generalize by state merges, similarly to RPNI.

A problem closely related to learning is *definability*, recently studied for graph databases [4]. Learning and definability have in common the fact that they look for a query consistent with a set of examples. The difference is that learning allows the query to select or not the nodes that are not explicitly labeled as positive examples while definability requires the query to select nothing else than the set of positive examples (i.e., all other nodes are implicitly negative). Nonetheless, some of the intractability proofs for definability can be adapted to our learning framework to show the intractability of consistency checking (cf. Section 3). To date, no polynomial algorithms have been yet proposed to construct path queries from a consistent set of examples.

2. GRAPH DATABASES AND QUERIES

In this section we define the concepts that we manipulate throughout the paper.

Alphabet and words. An *alphabet* Σ is a finite, ordered set of symbols. A *word* over Σ is a sequence $a_1 \dots a_n$ of symbols from Σ. By $|w|$ we denote the *length* of a word w. The *concatenation* of two words $w_1 = a_1 \dots a_n$ and $w_2 =$

[1]`http://www.w3.org/TR/sparql11-query/`

$b_1 \ldots b_m$, denoted $w_1 \cdot w_2$, is the word $a_1 \ldots a_n b_1 \ldots b_m$. By ε we denote the *empty word*. A *language* is a set of words. By Σ^* we denote the language of all words over Σ. We extend the order on Σ to the standard lexicographical order $\leqslant_{lex}$ on words over Σ and define a well-founded *canonical order* $\leqslant$ on words: $w \leqslant u$ iff $|w| < |u|$ or $|w| = |u|$ and $w \leqslant_{lex} u$.

Graph databases. A graph database is a finite, directed, edge-labeled graph [7, 41]. Formally, a *graph* (*database*) G over an alphabet Σ is a pair (V, E), where V is a set of *nodes* and $E \subseteq V \times \Sigma \times V$ is a set of *edges*. Each edge in G is a triple $(\nu_o, a, \nu_e) \in V \times \Sigma \times V$, where ν_o is the *origin* of the edge, ν_e is the *end* of the edge, and a is the *label* of the edge. We often abuse notation and write $\nu \in G$ and $(\nu_o, a, \nu_e) \in G$ instead of $\nu \in V$ and $(\nu_o, a, \nu_e) \in E$, respectively. For example, take in Figure 3 the graph G_0 containing 7 nodes and 15 edges over the alphabet $\{a, b, c\}$.

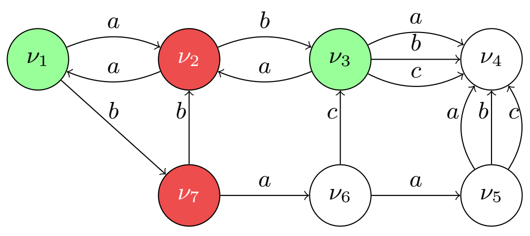

Figure 3: A graph database G_0.

Paths. A word $w = a_1 \ldots a_n$ *matches* a sequence of nodes $\nu_0 \nu_1 \ldots \nu_n$ if, for each $1 \leqslant i \leqslant n$, the triple (ν_{i-1}, a_i, ν_i) is an edge in G. For example, for the graph G_0 in Figure 3, the word aba matches the sequences of nodes $\nu_1\nu_2\nu_3\nu_4$ and $\nu_3\nu_2\nu_3\nu_4$, respectively, but does not match the sequence $\nu_1\nu_2\nu_7\nu_2$. Note that the empty word ε matches the sequence $\nu\nu$ for every $\nu \in G$. Given a node $\nu \in G$, by $paths_G(\nu)$ we denote the language of all words that match a sequence of nodes from G that starts by ν. In the sequel, we refer to such words as *paths*, and moreover, we say that a path w is *covered* by a node ν if $w \in paths_G(\nu)$. Paths are ordered using the canonical order $\leqslant$. For example, for the graph G_0 in Figure 3 we have $paths_{G_0}(\nu_5) = \{\varepsilon, a, b, c\}$. Note that $\varepsilon \in paths_G(\nu)$ for every $\nu \in G$. Moreover, note that $paths_G(\nu)$ is finite iff there is no cycle reachable from ν in G. For example, for the graph G_0 in Figure 3, $paths_{G_0}(\nu_1)$ is infinite. We naturally extend the notion of paths to a set of nodes i.e., given a set of nodes X from a graph G, by $paths_G(X) = \bigcup_{\nu \in X} paths_G(\nu)$.

Regular expressions and automata. A *regular language* is a language defined by a *regular expression* i.e., an expression of the following grammar:

$$q := \varepsilon \mid a \quad (a \in \Sigma) \mid q_1 + q_2 \mid q_1 \cdot q_2 \mid q^*,$$

where by "$\cdot$" we denote the *concatenation*, by "$+$" we denote the *disjunction*, and by "$*$" we denote the *Kleene star*. By $L(q)$ we denote the *language* of q, defined in the natural way [22]. For instance, the language of $(a \cdot b)^* \cdot c$ contains words like $c, abc, ababc$, etc. Regular languages can alternatively be represented by automata and we also refer to [22] for standard definitions of *nondeterministic finite word automaton* (*NFA*) and *deterministic finite word automaton* (*DFA*). In particular, we represent every regular language by its *canonical DFA* that is the unique smallest DFA that describe the language. For example, we present in Figure 4 the canonical DFA for $(a \cdot b)^* c$.

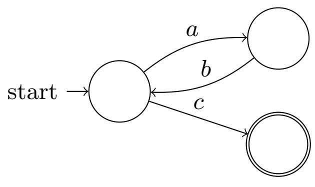

Figure 4: Canonical DFA for $(a \cdot b)^* c$.

Path queries. We focus on the class of path queries defined by regular expressions i.e., that select nodes having at least one *path* in the language of a given regular expression. Formally, given a graph G and a query q, we define the set of nodes *selected* by q on G:

$$q(G) = \{\nu \in G \mid L(q) \cap paths_G(\nu) \neq \varnothing\}.$$

For example, given the graph G_0 in Figure 3, the query a selects all nodes except ν_4, the query $(a \cdot b)^* \cdot c$ selects the nodes ν_1 and ν_3, and the query $b \cdot b \cdot c \cdot c$ selects no node. In the rest of the paper, we denote the set of all path queries by PQ and we refer to them simply as *queries*. We represent a query by its canonical DFA, hence the *size* of a query is the number of states in the canonical DFA of the corresponding regular language. For example, the size of the query $(a \cdot b)^* \cdot c$ is 3 (cf. Figure 4).

Equivalent queries. Two queries q and q' are *equivalent* if for every graph G they select exactly the same set of nodes i.e., $q(G) = q'(G)$. For example, the queries a and $a \cdot b^*$ are equivalent since each node having a path $ab \ldots b$ has also a path a. This example can be easily generalized and yields to defining the class of prefix-free queries. Formally, we say that a query q is *prefix-free* if for every word from $L(q)$, none of its prefixes belongs to $L(q)$. Given a query q, there exists a unique prefix-free query equivalent to q, which, moreover, can be constructed by simply removing all outgoing transitions of every final state in the canonical DFA of q. Our interest in prefix-free queries is that they can be seen as *minimal representatives* of *equivalence classes* of queries and as such they are desirable queries for learning. Indeed, every prefix-free query q is in fact equivalent to an infinite number of queries $q \cdot (q' + \varepsilon)$, where q' can be every PQ. In the remainder, we assume w.l.o.g. that all queries that we manipulate are prefix-free.

3. LEARNING FROM EXAMPLES

The input of a learning algorithm consists of a graph on which the user has annotated a few nodes as *positive* or *negative examples*, depending on whether or not she would like the nodes as part of the query result. Our goal is to exploit such examples to find a query that satisfies the user. In this paper, we explore two learning protocols: (i) the user provides a *sample* (i.e., a set of examples) that remains *fixed* during the learning process, and (ii) the learning algorithm *interactively* asks the user to label more examples until the learned query behaves exactly as the user wants.

First, we concentrate on the case of a fixed set of examples. We identify the challenges of such an approach, we show the unfeasability of the standard framework of *language identification in the limit* [20] and slightly modify it to propose a learning framework with *abstain* (Section 3.1). Next, we present a learning algorithm for the class of PQ (Section 3.2) and we identify the conditions that a graph and a sample must satisfy to allow polynomial learning of the user's goal query (Section 3.3). We study the case of query learning from user interactions in Section 4.

3.1 Learning framework

Given a graph $G = (V, E)$, an *example* is a pair (ν, α), where $\nu \in V$ and $\alpha \in \{+, -\}$. We say that an example of the form $(\nu, +)$ is a *positive example* while an example of the form $(\nu, -)$ is a *negative example*. A *sample* S is a set of examples i.e., a subset of $V \times \{+, -\}$. Given a sample S, we denote the set of positive examples $\{\nu \in V \mid (\nu, +) \in S\}$ by S_+ and the set of negative examples $\{\nu \in V \mid (\nu, -) \in S\}$ by S_-. A sample is *consistent* (with the class of PQ) if there exists a (PQ) query that selects all positive examples and none of the negative ones. Formally, given a graph G and a sample S, we say that S is *consistent* if there exists a query q s.t. $S_+ \subseteq q(G)$ and $S_- \cap q(G) = \emptyset$. In this case we say that q is *consistent with* S. For instance, take the graph G_0 in Figure 3 and the sample S s.t. $S_+ = \{\nu_1, \nu_3\}$ and $S_- = \{\nu_2, \nu_7\}$; S is consistent because there exist queries like $(a \cdot b)^* \cdot c$ or $c + (a \cdot b \cdot c)$ that are consistent with S.

Next, we want to formalize what means for a class of queries to be *learnable*, as it is usually done in the context of *grammatical inference* [18]. The standard learning framework is *language identification the limit* (*in polynomial time and data*) [20], which requires a learning algorithm to operate in time *polynomial* in the size of its input, to be *sound* (i.e., always return a query consistent with the examples given by the user or a special *null* value if no such query exists), and *complete* (i.e., able to produce every query with a sufficiently rich set of examples).

Since we aim at a polynomial time algorithm that returns a query consistent with a sample, we must first investigate the *consistency checking* problem i.e., deciding whether such a query exists. To this purpose, we first identify a necessary and sufficient condition for a sample to be consistent.

Lemma 3.1 *Given a graph G and a sample S, S is consistent iff for every $\nu \in S_+$ it holds that $paths_G(\nu) \nsubseteq paths_G(S_-)$.*

From this characterization we can derive that the fundamental problem of consistency checking is PSPACE-complete.

Lemma 3.2 *Given a graph G and a sample S, deciding whether S is consistent is PSPACE-complete.*

PROOF SKETCH. The membership to PSPACE follows from Lemma 3.1 and the known result that deciding the inclusion of NFAs is PSPACE-complete [39]. The PSPACE-hardness follows by reduction from the universality of the union problem for DFAs, known as being PSPACE-complete [28]. ▫

This implies that an algorithm able to always answer *null* in polynomial time when the sample is inconsistent does not exist, hence our class of queries is not learnable in the classical framework. One solution could be to study less expressive classes of queries. However, as shown by the following Lemma, consistency checking remains intractable even for a very restricted class of queries, referred as "SORE($\cdot$)" in [4].

Lemma 3.3 *Given a graph G and a sample S, deciding whether there exists a query of the form $a_1 \cdot \ldots \cdot a_n$ (pairwise distinct symbols) consistent with S is NP-complete.*

PROOF SKETCH. For the membership of the problem to NP, we point out that a non-deterministic Turing machine guesses a query q that is a concatenation of pairwise distinct symbols (hence of length bounded by $|\Sigma|$) and then checks whether q is consistent with S. The NP-hardness follows by reduction from 3SAT, well-known as being NP-complete. ▫

The proofs of Lemma 3.2 and 3.3 rely on techniques inspired by the definability problem for graph query languages [4]. We also point out that the same intractability results for consistency checking hold for binary semantics.

Another way to overcome the intractability of our class of queries is to relax the soundness condition and adopt a learning framework with *abstain*, similarly to what has been recently done for learning XML transformations [30]. More precisely, we allow the learning algorithm to answer a special value *null* whenever it cannot efficiently construct a consistent query. In practice, the *null* value is interpreted as "not enough examples have been provided". However, the learning algorithm should always return in polynomial time either a consistent query or *null*. As an additional clause, we require a learning algorithm to be *complete* i.e., when the input sample contains a *polynomially-sized characteristic sample* [18, 20], the algorithm must return the goal query. More formally, we have the following.

Definition 3.4 *A class of queries $\mathcal{Q}$ is* learnable with abstain in polynomial time and data *if there exists a polynomial learning algorithm learner that is:*

1. **Sound with abstain.** *For every graph G and sample S over G, the algorithm learner(G, S) returns either a query in $\mathcal{Q}$ that is consistent with S, or null if no such query exists or it cannot be constructed efficiently.*
2. **Complete.** *For every query $q \in \mathcal{Q}$, there exists a graph G and a polynomially-sized characteristic sample CS on G s.t. for every sample S extending CS consistently with q (i.e., $CS \subseteq S$ and q is consistent with S), the algorithm learner(G, S) returns q.*

Note that the polynomiality depends on the choice of a representation for queries and recall that we represent each PQ with its canonical DFA. Next, we present a polynomial learning algorithm fulfilling the two aforementioned conditions and we point out the construction of a polynomial characteristic sample to show the learnability of PQ.

3.2 Learning algorithm

In a nutshell, the idea behind our learning algorithm is the following: for each positive node, we seek the path that the user followed to label such a node, then we construct the disjunction of the paths obtained in the previous step, and we end by generalizing this disjunction while remaining consistent with both positive and negative examples.

More formally, the algorithm consists of two complementary steps that we describe next: *selecting the smallest consistent paths* and *generalizing* them.

Selecting the smallest consistent paths (SCPs). Since the labeled nodes in a graph may be the origin of multiple paths, classical algorithms for learning regular expressions from words, such as RPNI [35], are not directly applicable to our setting. Indeed, we have a set of nodes in the graph from which we have to first select (from a potentially infinite set) the paths responsible for their selection. Therefore, the first challenge of our algorithm is to select for each positive node a path that is not covered by any negative. We call such a path a *consistent path*. One can select consistent paths by simply enumerating (according to the canonical order $\leqslant$) the paths of each node labeled as positive and stopping when a consistent path for each node is found. We refer to the obtained set of paths as the set of *smallest consistent paths* (SCPs) because they are the smallest (w.r.t. $\leqslant$) consistent paths for each node. As an example, for the graph G_0 in Figure 3 and a sample s.t. $S_+ = \{\nu_1, \nu_3\}$ and $S_- = \{\nu_2, \nu_7\}$, we obtain the SCPs abc and c for ν_1 and ν_3, respectively. Notice that in this case the disjunction of the SCPs (i.e., the query $c + (a \cdot b \cdot c)$) is consistent with the input sample and one may think that a learning algorithm should return such a query. The shortcoming of such an approach is that the learned query would be always very simple in the sense that it uses only concatenation and disjunction. Since we want a learning algorithm that covers all the expressibility of PQ (in particular including the Kleene star), we need to extend the algorithm with a further step, namely the generalization. We detail such a step at the end of this section.

Another problem is that the user may provide an inconsistent sample, by labeling a positive node having no consistent path (cf. Lemma 3.1). To clarify when such a situation occurs, consider a simple graph such as the one in Figure 5 having one positive node (labeled with $+$) and two negative ones (labeled with $-$). We observe that the positive

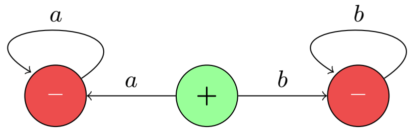

Figure 5: A graph with an inconsistent sample.

node has an infinite number of paths. However, all of them are covered by the two negative nodes, thus yielding an inconsistent sample. This example also shows that the simple procedure described above (i.e., enumerate the paths of the positive nodes and stop when finding consistent ones) fails because it leads to enumerating an infinite number on paths and never halting. On the other hand, we cannot perform consistency checking before selecting the SCPs since this fundamental problem is intractable (cf. Lemma 3.2 and 3.3). As a result, to avoid this possibly infinite enumeration, we choose to fix the maximal length of a SCP to a bound k. This bound engenders a new issue: for a fixed k it may not be possible to detect SCPs for all positive nodes. For instance, assume a graph that the user labels consistently with the query $(a \cdot b)^* \cdot c$, in particular she labels three positive nodes for which the SCPs are c, abc, and $ababc$. For a fixed $k = 3$, the SCP $ababc$ is not detected and the disjunction of the first two SCPs (i.e., $c + (a \cdot b \cdot c)$) is not a query consistent with the sample.

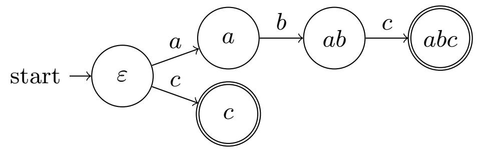
For all these reasons, we introduce a generalization phase in the algorithm, which permits to solve the two mentioned shortcomings i.e., (i) to learn a query that covers all the expressibility of PQ, and (ii) to select all positive examples even though not all of them have SCPs shorter than k.

Generalizing SCPs. We have seen how to select, whenever possible, a SCP of length bounded by k for each positive example. Next, we show how we can employ these SCPs to construct a more general query. The *learning algorithm* (Algorithm 1) takes as input a graph G and a sample S, and outputs a query q consistent with S whenever such query exists and can be built using SCPs of length bounded by k; otherwise, the algorithm outputs a special value *null*.

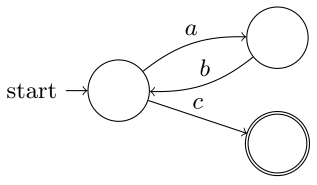
Algorithm 1 Learning algorithm – *learner*(G, S).

```
Input: graph $G$, sample $S$
Output: query $q$ consistent with $S$ or null
Parameter: fixed $k \in \mathbb{N}$ //maximal length of a SCP
1: for $\nu \in S_+ .\ \exists p \in \Sigma^{\leqslant k}.\ p \in paths_G(\nu) \setminus paths_G(S_-)$ do
2:     $P := P \cup \{\min_{\leqslant}(paths_G(\nu) \setminus paths_G(S_-))\}$
3: let $A$ be the prefix tree acceptor for $P$
4: while $\exists s, s' \in A.\ L(A_{s' \to s}) \cap paths_G(S_-) = \varnothing$ do
5:     $A := A_{s' \to s}$
6: if $\forall \nu \in S_+ .\ L(A) \cap paths_G(\nu) \neq \varnothing$ then
7:     return query $q$ represented by the DFA $A$
8: return null
```

We illustrate the algorithm on the graph G_0 in Figure 3 with a sample S s.t. $S_+ = \{\nu_1, \nu_3\}$ and $S_- = \{\nu_2, \nu_7\}$. For ease of exposition, we assume a fixed $k = 3$ (we explain how to obtain the value of k theoretically in Section 3.3 and empirically in Section 5). At first (lines 1-2), the algorithm constructs the set P of SCPs bounded by k for the positive nodes from which these paths in P can be constructed. Note that by $\Sigma^{\leqslant k}$ we denote the set of all paths of length at most k. For instance, on our example in Figure 3, we obtain $P = \{abc, c\}$. Then (line 3), we construct the *PTA* (*prefix tree acceptor*) [18] of P, which is basically a tree-like DFA accepting only the paths in P and having as states all their prefixes. Figure 6(a) illustrates the obtained PTA A for our example. Then (lines 4-5), we *generalize* A by merging two of its states if the obtained DFA selects no negative node. Note that by $A_{s' \to s}$ we denote the DFA obtained from A by modifying each occurrence of the state s' in s. Recall that on our example we have $P = \{abc, c\}$ and the PTA A in Figure 6(a). Next, we try to merge states of A: the states ε and a cannot be merged (because the obtained DFA would select the path bc that is covered by the negative ν_2), the states ε and c cannot be merged (because the path ε is covered by both negatives), while the states ε and ab can be merged without covering any negative example. On our example, we obtain the DFA in Figure 6(b), where no further states can be merged. Finally, the algorithm checks whether the query represented by A selects all the positive examples (not only those from whose SCPs we have constructed A), and if this is the case, it outputs the query (lines 6-7). In our case, the obtained $(a \cdot b)^* \cdot c$ selects all positive nodes hence is returned.



(a) Prefix tree acceptor.



(b) Result of generalization.

Figure 6: DFAs considered by *learner* for Figure 3.

3.3 Learnability results

Recall that in Section 3.1 we have formally defined what means for a class of queries to be learnable while in Section 3.2 we have proposed a learning algorithm for PQ. In this section, we prove that the proposed algorithm satisfies the conditions of Definition 3.4, thus showing the main theoretical result of the paper. We conclude the section with practical observations related to our learnability result.

By $\text{PQ}^{\leqslant n}$ we denote the PQ of size at most n.

Theorem 3.5 *The query class* $\text{PQ}^{\leqslant n}$ *is learnable with abstain in polynomial time and data, using the algorithm learner with the parameter k set to* $2 \times n + 1$.

PROOF. First, we point out that *learner* works in *polynomial time* in the size of the input. Indeed, the number of paths to explore for each positive node (lines 1-2) is polynomial since the length of paths is bounded by a fixed k. Then, both testing the consistency of queries considered during the generalization (lines 3-5) and testing whether the computed query selects all positive nodes (lines 6-7) reduce to deciding the emptiness of the intersection of two NFAs, known as being in PTIME [29]. Moreover, *learner* is *sound with abstain* since it returns either a query consistent with the input sample if it is possible to construct it using SCPs of length bounded by k, or *null* otherwise.

As for the *completeness* of *learner*, we show, for every $q \in \text{PQ}$, the construction of a graph G and of a characteristic sample CS on G with the properties from Definition 3.4 i.e., for every sample S that extends CS consistently with q (i.e., $CS \subseteq S$ and q is consistent with S), the algorithm $learner(G, S)$ returns q. The idea behind the construction is the following: we know that RPNI [35] is an algorithm that takes as input positive and negative word examples and outputs a DFA describing a consistent regular language, and moreover, the core of RPNI is based on DFA generalization via state merges similarly to *learner*; hence, for a query q, we want a graph and a sample on it s.t. when *learner* selects the SCPs, it should get exactly the words that RPNI needs for learning q if we see it as a regular language. Then, since RPNI is guaranteed to learn the goal regular language from these words, we infer that if *learner* selects and generalizes the SCPs corresponding to them, then *learner* is also guaranteed to learn the goal PQ.

We exemplify the construction on the query $q = (a \cdot b)^* \cdot c$. First, given q, we construct two sets of words P_+ and P_- that correspond to a characteristic sample used by RPNI to infer the regular language of q. In our case, we obtain $P_+ = \{c, abc\}$ and $P_- = \{\varepsilon, a, ab, ac, bc\}$. Then, the characteristic graph for learning the graph query q needs (i) for each $p \in P_+$, a node $\nu \in CS_+$ s.t. $p = \min_{\leqslant}(L(q) \cap paths_G(\nu))$, (ii) for each $p \in P_-$, a node $\nu \in CS_-$ s.t. $p \in paths_G(\nu)$, and (iii) for each p' that is smaller (w.r.t. the canonical order $\leqslant$) than a word $p \in P_+$ and is not prefixed by any word in $L(q)$, a node $\nu \in CS_-$ s.t. $p' \in paths_G(\nu)$. For our query $(a \cdot b)^* c$, (i) implies two positive nodes: a node ν s.t. $c \in paths_G(\nu)$ and another node ν' s.t. $abc \in paths_G(\nu')$ and $c \notin paths_G(\nu')$, while (ii) and (iii) imply a node ν'' s.t. $\nu'' \notin q(G)$ and $\{\varepsilon, a, ab, ac, bc\} \subseteq paths_G(\nu'')$ (cf. ii) and $\{\varepsilon, a, b, aa, ab, ac, ba, bb, bc, aaa, aab, aac, aba, abb\} \subseteq paths_G(\nu'')$ (cf. iii). In Figure 7 we illustrate such a graph and we highlight the two positive and one negative node examples.

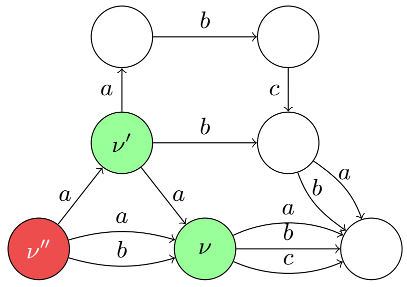


Figure 7: Graph from the proof of Theorem 3.5.

Recall that the size of a query is the number of states of its canonical DFA. According to the above construction, we need $|CS_+| = |P_+|$ and $|CS_-| = 1$. Since $|P_+|$ is polynomial in the size of the query [35], we infer that $|CS|$ is also polynomial in the size of the query. Moreover, to learn the regular language of a query of size n, the longest path in P_+ is of size $2 \times n + 1$ [35]. Hence, to be able to select this path with *learner* (assuming the presence of a characteristic sample), we need the parameter k of *learner* to be at least $2 \times n + 1$. Thus, for each possible size n of the goal query there exists a polynomial learning algorithm satisfying the conditions of Definition 3.4, which concludes the proof. □

We end this section with some practical observations related to our learnability result.

First, we point out that although Theorem 3.5 requires a certain theoretical value for k to guarantee learnability of queries of a certain size, our experiments indicate that small values of k (between 2 and 4) are enough to cover most practical cases. Then, even though the definition of learnability requires that one characteristic sample exists, in practice there may be many of such samples and there exists an infinite number of graphs on which we can build them. In fact, a graph that contains a subgraph with a characteristic sample is also characteristic.

Second, we also point out that a practical sample may be characteristic without having all negative paths on the same node as required by the aforementioned construction. For instance, the sample that we have used to illustrate the learning algorithm (i.e., the sample s.t. $S_+ = \{\nu_1, \nu_3\}$ and $S_- = \{\nu_2, \nu_7\}$ on the graph in Figure 3) is characteristic for $(a \cdot b)^* \cdot c$ and all above mentioned negatives paths are covered by two negative nodes.

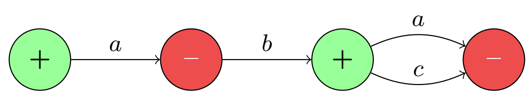

Figure 8: A graph and a sample for $(a \cdot b)^* \cdot c$.

Third, if a graph does not own a characteristic sample, the user's goal query on that graph cannot be exactly identified. In such a case, the learning algorithm returns a query equivalent to the goal query on the graph and hence *indistinguishable* by the user (i.e., they select exactly the same set of nodes). For instance, take the graph in Figure 8 and assume a user labeling the nodes w.r.t. the goal $(a \cdot b)^* \cdot c$. The learning algorithm returns the query a that selects exactly the same set of nodes on this graph.

Fourth, the presented learning techniques are directly applicable to different query semantics such as binary and n-ary queries. We give here only the intuition behind these applications and we point out that more details about the corresponding algorithms can be found in the appendix of our technical report [11]. To learn a binary query, the only change to Algorithm 1 is that each positive example implies a smaller number of candidate paths from which we have to choose a consistent one (since the destination node is also known). Then, for the n-ary case (i.e., when an example is a tuple of nodes labeled with $+$ or $-$), we have simply to apply the previous algorithm to learn a query for each position in the tuple and then to combine those.

4. LEARNING FROM INTERACTIONS

In this section, we investigate the problem of query learning from a different perspective. In Section 3 we have studied the setting of a fixed set of examples provided by the user and no interaction with her during the learning process. In this section, we consider an *interactive scenario* where the learning algorithm starts with an empty sample and continuously interacts with the user and asks her to label additional nodes until she is satisfied with the output of the learned query. To this purpose, we first propose the *interactive scenario* (Section 4.1). Then, we discuss different parameters for it, in particular what means for a node to be *informative* and what is a *practical strategy* of proposing nodes to the user (Section 4.2). We also point out that we have employed the aforementioned interactive scenario as the core of a system for interactive path query specification on graphs [12].

4.1 Interactive scenario

We consider the following *interactive scenario*. The user is presented with a node of the graph and indicates whether the node is selected or not by the query that she has in mind. We repeat this process until a sufficient knowledge of the goal query has been accumulated (i.e., there exists at most one query consistent with the user's labels). This scenario is inspired by the well-known framework of *learning with membership queries* [3] and we have recently formalized it as a general paradigm for learning queries on big data [13]. In Figure 9, we describe the current instantiation for path queries on graphs and we detail next its different steps.

(1) (2) We consider as input a graph database G. Initially, we assume an empty sample that we enrich via simple interactions with the user. The interactions continue until

Figure 9: Interactive scenario.

a *halt condition* is satisfied. A natural halt condition is to stop the interactions when there is exactly one consistent query with the current sample. In practice, we can imagine weaker conditions e.g., the user may stop the process earlier if she is satisfied by some candidate query proposed at some intermediary stage during the interactions.

(3) We propose nodes of the graph to the user according to a *strategy* Υ i.e., a function that takes as input a graph G and a sample S, and returns a node from G. Since our goal is to minimize the amount of effort needed to learn the user's goal query, a smart strategy should avoid proposing to the user nodes that do not bring any information to the learning process. The study of such strategies yields to defining the notion of *informative nodes* that we formalize in the next section.

(4) A node by itself does not carry enough information to allow the user to understand whether it is part of the query result or not. Therefore, we have to enhance the information of a node by zooming out on its *neighborhood* before actually showing it to the user. This step has the goal of producing a small, easy to visualize fragment of the initial graph, which permits the user to label the proposed node as a positive or a negative example. More concretely, in a practical scenario, all nodes situated at a distance k (as the parameter of Algorithm 1 explained in Section 3.2) should be sufficient for the user to decide whether she wants or not the proposed node. In any case, the user has neither to visualize all the graph that can be potentially large, nor to look by herself for interesting nodes because our interactive scenario proposes such nodes to the user.

(5) (6) The user visualizes the neighborhood of a given node ν and labels ν w.r.t. the goal query that she has in mind. Then, we propagate the given label in the rest of the graph and prune the nodes that become uninformative. Moreover, we run the learning algorithm *learner* (i.e., Algorithm 1 from Section 3.2), which outputs in polynomial time either a query consistent with all labels provided by the user, or *null* if such a query does not exist or cannot be constructed efficiently. When the halt condition is satisfied, we return the latest output of *learner* to the user. In particular, the halt condition may take into account such an

intermediary learned query q e.g., when the user is satisfied by the output of q on the instance and wants to stop the interactions.

In the next section, we precisely describe what means for a node to be informative for the learning process and what is a practical strategy of proposing nodes to the user.

4.2 Informative nodes and practical strategies

Before explaining the informative nodes, we first define the set of all queries consistent with a sample S over a graph G:

$$\mathcal{C}(G,S) = \{q \in \text{PQ} \mid S_+ \subseteq q(G) \wedge S_- \cap q(G) = \varnothing\}.$$

Assuming that the user labels the nodes consistently with some goal query q, the set $\mathcal{C}(G,S)$ always contains q. Initially, $S = \varnothing$ and $\mathcal{C}(G,S) = \text{PQ}$. Therefore, an ideal strategy of presenting nodes to the user is able to get us quickly from $S = \varnothing$ to a sample S s.t. $\mathcal{C}(G,S) = \{q\}$. In particular, a good strategy should not propose to the user the *certain nodes* i.e., nodes not yielding new information when labeled by the user. Formally, given a graph G, a sample S, and an unlabeled node $\nu \in G$, we say that ν is *certain* (w.r.t. S) if it belongs to one of the following sets:

$$\begin{aligned}
Cert_+(G,S) &= \{\nu \in G \mid \forall q \in \mathcal{C}(G,S).\ \nu \in q(G)\},\\
Cert_-(G,S) &= \{\nu \in G \mid \forall q \in \mathcal{C}(G,S).\ \nu \notin q(G)\}.
\end{aligned}$$

In other words, a node is certain with a label α if labeling it explicitly with α does not eliminate any query from $\mathcal{C}(G,S)$. For instance, take the graph in Figure 10 with a positive, a negative, and an unlabeled node, which belongs to $Cert_+$ because it is selected by the unique (prefix-free) query in $\mathcal{C}(G,S)$ (i.e., b). Additionally, we observe that labeling it otherwise (i.e., with a $-$) leads to an inconsistent sample. The notion of certain nodes is inspired by possible world semantics and certain answers [23], and already employed for XML querying for non-expert users [17] and for the inference of relational joins [14].

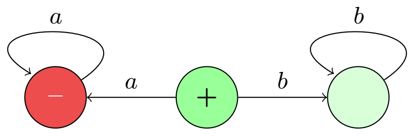

Figure 10: Two labeled nodes and a certain node.

Next, we give necessary and sufficient conditions for a node to be certain, for both positive and negative labels:

Lemma 4.1 *Given a sample S and a node ν from G:*

1. *$\nu \in Cert_+(G,S)$ iff there exists $\nu' \in S_+$ s.t. $paths_G(\nu') \subseteq paths_G(S_-) \cup paths_G(\nu)$,*
2. *$\nu \in Cert_-(G,S)$ iff $paths_G(\nu) \subseteq paths_G(S_-)$.*

Additionally, given a graph G, a sample S, and a node ν, we say that ν is *informative* (w.r.t. S) if ν has not been labeled by the user nor it is certain. Unfortunately, by using the characterization from Lemma 4.1, we derive the following.

Lemma 4.2 *Given a graph G and a sample S, deciding whether a node ν is informative is PSPACE-complete.*

An intelligent strategy should propose to the user only informative nodes. Since deciding the informativeness of a node is intractable (cf. Lemma 4.2), we need to explore *practical strategies* that efficiently compute the next node to label. Consequently, we propose two simple but effective strategies that we detail next and that we have evaluated experimentally. The basic idea behind them is to avoid the intractability of deciding informativeness of a node by looking only at a small number of paths of that node. More precisely, we say that a node is *k-informative* if it has at least one path of length at most k that is not covered by a negative example. If a node is k-informative, then it is also informative, otherwise we are not able to establish its informativeness w.r.t. the current k. Then, strategy kR consists of taking *randomly* a k-informative node while strategy kS consists of taking the k-informative node having the *smallest* number of non-covered k-paths, thus favoring the nodes for which computing the SCPs is easier. In the next section, we discuss the performance of these strategies as well as how we set the k in practice.

5. EXPERIMENTS

In this section, we present an experimental study devoted to gauge the performance of our learning algorithms. In Section 5.1, we introduce the used datasets: the *AliBaba biological graph* and randomly generated *synthetic graphs*. In Section 5.2 and Section 5.3, we present the results for the two settings under study: *static* and *interactive*, respectively. Our algorithms have been implemented in C and our experiments have been run on an Intel Core i7 with 4 × 2.9 GHz CPU and 8 GB RAM.

5.1 Datasets

Despite the increasing popularity of graph databases, benchmarks allowing to assess the performance of emerging graph database applications are still lacking or under construction [10]. In particular, there is no established benchmark devoted to graph queries defined by regular expressions. Due to this lack, we have adopted a real dataset recently used by [27] to evaluate the performance of optimization algorithms for regular path queries. This dataset, called *AliBaba* [36], represents a real graph from research on biology, extracted by text mining on PubMed. The dataset has a semantic part consisting of a network of protein-protein interactions and a textual part, reporting text co-occurrence for words. The first part was more appropriate to apply our learning algorithms than the second. Therefore, we have extracted the semantic part from the original graph, thus obtaining a subgraph of about 3k nodes and 8k edges. Similarly, from the set of real-life queries reported in [27], we have retained those that select at least one node on the graph to obtain at least one positive example for learning. Thus, we have used 6 biological queries (denoted by $bio_1, \ldots, bio_6$), which are structurally complex and have selectivities varying from 1 to a total of 711 nodes i.e., from 0.03% to 22% of the nodes of the graph. We summarize these queries in Table 1. By small letters a, b we denote symbols from the alphabet while by capital letters A, C, E, I we denote disjunctions of symbols from the alphabet i.e., expression of the form $a_1 + \ldots + a_n$. These disjunctions contain up to 10 symbols, with possibly overlapping ones among them.

Additionally, we have implemented a synthetic data generator, which yields graphs of varying size and similar to real-world graphs. The latest feature let us generate *scale-free* graphs with a *Zipfian* edge label distribution [27]. We report here the results for generated graphs of size 10k, 20k,

	Query	*Selectivity*
bio_1	$b \cdot A \cdot A^*$	0.03%
bio_2	$C \cdot C^* \cdot a \cdot A \cdot A^*$	0.2%
bio_3	$C \cdot E$	3%
bio_4	$I \cdot I \cdot I^*$	11%
bio_5	$A \cdot A \cdot A^* \cdot I \cdot I \cdot I^*$	12%
bio_6	$A \cdot A \cdot A^*$	22%

Table 1: Biological queries.

and 30k nodes, and with a number of edges three times larger. Moreover, we focus on synthetic queries that are similar in structure to the aforementioned real-life biological queries. In particular, the three queries that we report here (denoted by syn_1, syn_2, and syn_3) have the structure $A \cdot B^* \cdot C$, where A, B, and C are disjunctions of up to 10 symbols, with overlapping ones among them. The difference between these three queries is w.r.t. their selectivity: regardless the actual size of the graph, syn_1, syn_2, and syn_3 select 1%, 15%, and 40% of the graph nodes, respectively.

Before presenting the experimental results, we say a few words about how we set empirically the parameter k from *learner*. Since in our experiments we assume that the user labels the nodes of the graph consistently with some goal query, the input sample is always consistent. Hence, there exists a consistent path for each positive node and we dynamically discover the length of the SCPs. In particular, we start with $k = 2$; if for a given k, the query learned using SCPs shorter that k does not select all positive nodes, we increment k and iterate. For the interactive case, the aforementioned procedure becomes: start with $k = 2$; seek k-informative nodes (cf. Section 4.2) and increase k when the current k does not yield any k-informative node. In practice, in the majority of cases $k = 2$ is sufficient and it may reach values up to 4 in some isolated cases.

5.2 Static experiments

The setup of static experiments is as follows. Given a graph and a goal query, we take as positive examples some random nodes of the graph that are selected by the query and as negative examples some random nodes that are not selected by it. All these examples are given as input to *learner*, which returns a consistent query. We consider the learned query as a binary classifier and we measure the F1 score w.r.t. the goal query. Thus, for different percentages of labeled nodes in the graph, we measure the F1 score of the learned query along with the learning time. We present the summary of results in Figure 11 and 12, which show the F1 score and the learning time for the biological (a) and synthetic queries (b, c, d), respectively. Since the positive effect of the generalization in addition to the selection of SCPs is generally of 1% in F1 score, we do not highlight the two steps of the algorithm for the sake of figure readability.

We can observe that, not surprisingly, by increasing the percentage of labeled nodes of the graph, the F1 score also increases (Figure 11). Overall, the F1 score is 1 or sufficiently close to 1 for all queries, except a few cases that we discuss below. The worst behavior is clearly exhibited by query bio_5, when we can observe that the F1 score converges to 1 less faster than the others. For this query, we can also observe that the learning time is higher (Figure 12(a)). This is due to the fact that the graph is not characteristic for it (cf. Section 3.3), hence the selection of SCPs yields paths that are not relevant for the target query.

For what concerns the learning time, this remains reasonable (of the order of seconds) for all the queries and for both datasets. The most selective queries (bio_4, bio_5, bio_6) are more problematic since they entail a larger number of positive nodes in the step of selection of the SCPs. As a conclusion, notice that even when the F1 score is very high, these results on the static scenario are not fully beneficial since we need to label at least 7% of the graph nodes to have an F1 score equal to 1. As we later show with the interactive experiments, we can significantly reduce the number of labels needed to reach an F1 score equal to 1.

Finally, the synthetic experiments on various graph sizes and query selectivities confirm the aforementioned observations. In particular, when the queries are more selective (as syn_2 and syn_3), increasing the number of examples implies more visible changes in the learning time (cf. Figure 12). Additionally, we observe the goal queries with higher selectivity converge faster to a F1 score equal to 1 (cf. Figure 11). Intuitively, this is due to the fact that such cases imply a bigger number of positive examples from which the learning algorithm can benefit to generalize faster the goal query.

5.3 Interactive experiments

The setup of interactive experiments is as follows. Given a graph and a goal query, we start with an empty sample and we continuously select a node that we ask the user to label, until the learned query selects exactly the same set of nodes as the goal query or, in other words, until the goal query and the learned query are indistinguishable by the user (cf. Section 3.3). This corresponds to obtaining an F1 score of 1. In this setting, we measure the percentage of the labeled nodes of the graph and the learning time i.e., the time needed to compute the next node to label. In particular, the number of interactions corresponds to the total number of examples, the latter being the sum of the number of positive examples and the number of negative examples. The summary of interactive experiments is presented in Table 2.

We can observe that, differently from the static scenario, labeling around 1% of the nodes of the graph suffices to learn a query with F1 score equal to 1. Even for the most difficult one (bio_5), we get a rather significant improvement, as the percentage of interactions is drastically reduced to 7.7% of the nodes in the graph (while in the static case it was 87% of the nodes in the graph). Overall, these numbers prove that the interactive scenario considerably reduces the number of examples needed to infer a query of F1 score equal to 1. The synthetic experiments confirm this behavior for various graph sizes and query selectivities. While learning a query with F1 score equal to 1 corresponds to the strongest halt condition of our interactive scenario (cf. Figure 9), we believe that in practice the user may choose to stop the interactions earlier (and hence label less nodes) if she is satisfied by an intermediate query proposed by the learning algorithm. We consider such halt conditions in our system demo [12].

Moreover, these experiments also show that the two strategies (kS and kR, cf. Section 4.2) have a similar behavior, even though kS is slightly better (w.r.t. minimizing the number of interactions) for the most selective queries. Intuitively, this happens because such a strategy favors the nodes for which computing the SCPs has a smaller space of solutions (cf. Section 4.2). Finally, we can observe that the two strategies are also efficient, as they lead to a learning time of the order of seconds in all cases.

6. CONCLUSIONS AND FUTURE WORK

We have studied the problem of learning path queries defined by regular expressions from user examples. We have identified fundamental difficulties of the problem setting, formalized what means for a class of queries to be learnable, and shown that the above class enjoys learnability. Additionally, we have investigated an interactive scenario, analyzed what means for a node to be informative, and proposed practical strategies of presenting examples to the user. Finally, we have shown the effectiveness of the algorithms and the improvements of using an interactive approach through an experimental study on both real and synthetic datasets.

We envision several directions of our work, one of which being to sample a graph and finding informative nodes on representative samples, in the spirit of [31]. Moreover, motivated by the absence of benchmarks devoted to queries defined by regular expressions, we want to develop such a benchmark. This would permit to better analyze the performance of algorithms involving regular expressions on graphs, including the learning algorithms proposed in this paper.

ABSTRACT

Since most graphs evolve over time, it is useful to be able to query their history. We consider historical reachability queries that ask for the existence of a path in some time interval in the past, either in the whole duration of the interval (conjunctive queries), or in at least one time instant in the interval (disjunctive queries). We study both alternatives of storing the full transitive closure of the evolving graph and of performing an online traversal. Then, we propose an appropriate reachability index, termed TimeReach index, that exploits the fact that most real-world graphs contain large strongly connected components. Finally, we present an experimental evaluation of all approaches, for different graph sizes, historical query types and time granularities.

1. INTRODUCTION

In recent years, increasing amounts of graph structured data are being made available from a variety of sources, such as social, citation, computer and hyperlink networks. Almost all such real-world networks evolve over time, as nodes and edges are added or deleted. Analysis of their evolution finds a large spectrum of applications, ranging from social network marketing, to virus propagation and digital forensics.

In this paper, we assume that we are given an evolving set of graph snapshots corresponding to the state of the graph at different time instants. We address the problem of efficiently answering queries that involve such snapshots. In particular, we focus on a basic query type, namely reachability queries, that ask whether a node u was reachable from another node v during specific time intervals in the past. We call such queries *historical reachability queries*.

Although, there has been considerable interest in processing graph data, through a variety of graph queries including reachability, distance and pattern-based ones, querying the graph history is much less studied. The only other two approaches to building indexes for processing historical graph queries that we are aware of consider historical shortest-path queries [9, 2]. Specifically, the authors of [9] propose a method based on ordering nodes or edges pertinent to shortest path computation, while the dynamic index construction proposed in [2] does not support node or edge deletions.

All other work on historical queries focuses mainly on efficiently storing and retrieving the graph snapshots required for processing each query [14, 13, 21, 17]. In particular, in [14], a combination of graph deltas and selected materialized snapshots are explored, while in [13], the focus is on storing, sharing and processing deltas. In [21], temporally close snapshots are clustered, one representative per cluster is selected and used for an initial evaluation of the query. Finally, in [17], the placement and replication of snapshots in a distributed setting is studied. Instead, in this paper, we address the problem of building indexes for answering historical reachability queries.

Reachability queries on static graphs have been extensively studied. Research in this area follows two general directions through efficiently storing the transitive closure and speeding-up online traversal. With regards to transitive closure, various approaches have been proposed including the chain method [10, 5], methods exploring spanning trees, bit-vector compression [26] and interval [1, 28, 12], and hop [7, 22, 6] labeling. In the case of online traversal, often interval labeling [4, 25, 30] is used to prune the search space. There has also been some work on incrementally maintaining the reachability indexes in case of evolving graphs [1, 3, 23, 31], however, reachability still considers a single snapshot, i.e., the current version of the graph.

In this paper, we explore a compact representation of graph snapshots, called *version graph*, where each node and edge is annotated with the set of time intervals during which the corresponding node and edge existed in the evolving graph. We call such sets *lifespans* and seek for their minimum representation through using non-overlapping and non-continuous intervals. We also introduce a set of basic operations for efficiently manipulating lifespans of paths.

For processing historical reachability queries, we start by revisiting the basic transitive closure and online traversal approaches. For the transitive closure, we compute a minimum representation of reachability information for each pair of nodes. For the online traversal, we propose a novel interval-based traversal of the version graph along with a number of pruning steps. Furthermore, to avoid the cost and space overheads associated with precomputing the transitive closure and improving the processing cost of the online traversal, we propose a new approach, termed *TimeReach*.

TimeReach exploits the fact that most graphs consist of strongly connected components (SCCs) [20, 15]. Thus, instead of maintaining reachability information for pairs of nodes, we maintain *posting lists* with information about node membership in SCCs. We minimize the size of posting lists through an appropriate assignment of identifiers to SCCs. We show that the problem of the optimal assignment of identifiers to SCCs is equivalent to the maximum bipartite matching problem among SCCs in consequent graph snapshots. Along with postings, we maintain a condensed version graph which corresponds to the version graph of the SCCs evolution. To improve the performance of answering historical queries, we also introduce an interval-2hop approach based on pruned landmark labeling [2, 29] on the condensed version graph.

We have extensively evaluated our approach with three real social network datasets. Our experimental results show that TimeReach is space efficient, in particular for graphs consisting of large SCCs as is the case of social networks. Its incremental construction is fast; indexing a new snapshot graph takes just a few seconds. Finally, processing historical queries using TimeReach is orders of magnitude faster than the online traversal of the version graph.

The rest of this paper is structured as follows. In Section 2, we present related work, while in Section 3, we formally define historical reachability queries. In Section 4, we introduce the version graph and operations on lifespans and present the two baseline approaches, namely, the transitive closure and online traversal. In Section 5, we introduce the TimeReach Index approach, while in Section 6, we present experimental results. Section 7 concludes the paper.

2. RELATED WORK

Although, graph data management has been the focus of much current research, work in processing historical queries is rather limited. The main focus of research on evolving graphs has been on efficiently storing and retrieving graph snapshots. In this paper, our focus in on indexing for processing queries. To this end, we assume a compact representation of the sequence of graph snapshots in the form of a version graph. Alternatively, one can store just some subset of the graph snapshots in the sequence along with appropriate deltas, such that, any other snapshot can be reconstructed by applying the deltas on the selected snapshots [14, 13]. Various optimizations for reducing the storage and snapshot re-construction overheads have been proposed, such as a hierarchical index of deltas and a memory pool for the overlapping storage of snapshots [13]. Clustering temporally close snapshots and computing a representative for each cluster was also proposed [21], Deltas from representatives are stored for each cluster to achieve high compression. In the G* graph database, snapshots are efficiently stored by taking advantage of commonalities among them [16]. Different versions of each node are stored only once regardless of the number of snapshots it belongs to, and indexed by a compact in-memory index. For load balance and availability snapshot data are replicated among a number of workers.

Historical query processing in these approaches requires as a first and costly step reconstructing the relevant snapshots. Then, queries are processed through an online traversal on each of them. Query performance is addressed by trying to minimize the number of snapshots that need to be reconstructed by minimizing the number of deltas applied [14, 13], avoiding the reconstruction of all snapshots [21], or by parallel query execution and proper snapshot placement and distribution [17]. In this work, we address a different problem, that of indexing for historical reachability queries.

Historical shortest path distance queries were addressed in [9]. The authors propose a method based on ordering nodes or edges pertinent to shortest path computation. Finally, the recent work of [2] also proposes a dynamic indexing scheme for historical distance queries. However, the authors consider only insertions. This assumption simplifies the problem, since two nodes that are reachable remain reachable. The authors propose a dynamic 2hop index construction that is not applicable in the case of node or edge deletions.

Reachability queries on static graphs have been thoroughly investigated along two general directions: transitive closure compression and improving online search.

Transitive Closure Compression. Related research aims at compressing the transitive closure by storing for each node only a subset of the nodes it can reach. The first idea is to decompose the graph in k node-disjoint chains and for each node store only the first node it can reach in each chain [10, 5]. Another line of research extracts a spanning tree of the graph, and uses it to compress the transitive closure. Each node of the tree is labeled with an interval of integers such that if node u is an ancestor of v, the interval of u contains that of v. Reachability through tree edges can be easily determined by a label containment check. To incorporate reachability through non-tree edges each node inherits the intervals of its successors in the graph [1], or a partial transitive closure of non-tree edges is constructed [28]. Building upon the idea of interval labeling, a tree whose vertices are pair-wise disjoint paths extracted from the original graph is used in [12]. Another approach in compressing the transitive closure is 2-hop labeling [7, 22, 6]. Each node stores two sets of intermediate nodes: a set L_{out} of nodes it can reach and a set L_{in} of nodes that can reach it. Node u can reach node v only if $L_{out}(u) \cap L_{in}(v) \neq \emptyset$.

Speeding-up Online Traversal. These methods use interval labeling to aid online traversal by pruning the search space. In [4] and [25], a tree cover of the graph is constructed and then, for the queries that can not be answered by the tree labeling, an online search on the non-tree edges is performed using the labeling to guide the search. In [30], multiple intervals are used for the labeling. If the label containment check does not produce a negative answer, the graph is traversed online using the intervals for pruning the search.

Some of the works discuss the incremental maintenance of the index in the case of evolving graphs [1, 3, 23, 31]. However, the updated index contains reachability information only about the current version of the graph and cannot be used for answering historical queries.

The presented approaches are orthogonal to our approach in that they can be adapted so that they can be used to speed-up or avoid the online traversal of the condensed graph. We have demonstrated this by adapting, one of them, namely 2hop labeling.

3. PROBLEM DEFINITION

Most real world graphs evolve over time as new nodes or edges are added, or existing nodes or edges are deleted. We assume that time is discrete and use successive integers to denote successive time instants. There are two intuitive interpretations of time instants. One interpretation is that of actual time, for example time instant t may correspond to say October 20, 2014, 5:00am PDT. Another view is operational. In this case, time is advanced each time a graph operation, update or delete, occurs. Both interpretations of time instants are consistent with our representation.

Let $G = (V, E)$ be a directed graph where V is the set of nodes and E the set of edges. We use $G_t = (V_t, E_t)$ to denote the *graph snapshot* at time instant t, that is, the set of nodes and edges that exist at time instant t.

Definition 1 (evolving graph). *An evolving graph $\mathcal{G}_{[t_i,t_j]}$ in time interval $[t_i, t_j]$ is a sequence $\{G_{t_i}, G_{t_i+1}, \ldots, G_{t_j}\}$ of graph snapshots.*

An example is shown in Figure 1(a) which depicts an evolving graph $\mathcal{G}_{[t_0,t_3]}$ consisting of four graph snapshots $\{G_{t_0}, G_{t_1}, G_{t_2}, G_{t_3}\}$. For brevity, we denote time instant $t_i + 1$ as t_{i+1} and use t_i and i interchangeably, when the meaning is clear from context.

We use the term *time granularity* to refer to how often a new time instant and the corresponding graph snapshot are created. In the case of actual time, granularity may range for example from milliseconds to years, whereas, in the case of operational time, granularity may be at the level of one or more operations. A fine-grained time granularity necessitates maintaining a large amount of historical information, but supports precise historical queries.

Given a static directed graph $G = (V, E)$ and two nodes $u, v \in V$, a *reachability query* asks whether there exists a path from u to v in G. For evolving graphs, we introduce the following two types of historical reachability queries.

Definition 2 (historical reachability query). *Let $\mathcal{G}_{[t_i,t_j]} = \{G_{t_i}, G_{t_i+1}, \ldots G_{t_j}\}$, be an evolving graph, $I_Q = [t_k, t_l] \subseteq [t_i, t_j]$ a time interval and v, u a pair of nodes:*

(i) a conjunctive historical reachability query $u \overset{I_{Q\wedge}}{\rightsquigarrow} v$ returns true, if there exists a path from u to v in all graph snapshots G_{t_m}, $t_k \leq t_m \leq t_l$ of $\mathcal{G}_{[t_i,t_j]}$.

(ii) a disjunctive historical reachability query $u \overset{I_{Q\vee}}{\rightsquigarrow} v$ returns true, if there exists a path from u to v in at least one graph snapshot G_{t_m}, $t_k \leq t_m \leq t_l$, of $\mathcal{G}_{[t_i,t_j]}$.

Our goal is to derive methods for answering reachability queries efficiently. A straightforward solution would be to build a different index for each of the graph snapshots and then pose a reachability query at each one of them. However, this solution imposes large space overheads. In addition, it requires extra processing for combining the results of each query. Instead, we propose building indexes for intervals.

4. VERSION GRAPH

In this section, we present the version graph, a natural concrete representation of an evolving graph. First, let us define the notion of lifespan. For a node u (or, edge e), its lifespan denotes the set of time intervals during which u (resp. e) existed in an evolving graph. More formally, given an evolving graph $\mathcal{G}_I = \{G_{t_i}, G_{t_i+1}, \ldots, G_{t_j}\}$, the *lifespan*, $\mathcal{L}(u)$, (resp. $\mathcal{L}(e)$) of a node u (resp. edge e) is a set of intervals such that an interval $[t_i, t_j] \subseteq I$ belongs to $\mathcal{L}(u)$, (resp. $\mathcal{L}(e)$), if and only if, for all $t_i \leq t_m \leq t_j$, $u \in V_{t_m}$ (resp. $e \in E_{t_m}$).

We model lifespans as sets of time intervals to capture the general case of graph evolution, where nodes and edges may be deleted and then re-inserted at subsequent snapshots. Set of time intervals are also known as *temporal elements* [11]. If we do not allow deleted nodes or edges to be re-inserted, then lifespans are just intervals. Furthermore, if there are no deletions, all lifespans are intervals of the form $[t_i, t_{curr}]$, where t_i is the time instant the node or edge first appeared and t_{curr} is the time instant of the current snapshot. Therefore, in this case, lifespans can be represented simply by the time instant t_i. In the following, we use I to denote time intervals and $\mathcal{I}$ to denote sets of time intervals. To represent an evolving graph $\mathcal{G}_I$, we use a *version graph* VG_I. A version graph is a labeled directed graph that captures the evolution of the graph in a concise manner.

Definition 3 (version graph). *Given an evolving graph $\mathcal{G}_I = \{G_{t_i}, G_{t_i+1}, \ldots, G_{t_j}\}$, its version graph is an edge and node labeled, directed graph $VG_I = (V_I, E_I, \mathcal{L}_u, \mathcal{L}_e)$ where: $V_I = \bigcup_{t_m \in I} V_{t_m}$, $E_I = \bigcup_{t_m \in I} E_{t_m}$, $\mathcal{L}_u : V_I \to \mathcal{I}$ assigns to each node u in V_I its lifespan $\mathcal{L}_u(u)$ and $\mathcal{L}_e : E_I \to \mathcal{I}$ assigns to each edge e in E_I its lifespan $\mathcal{L}_e(e)$.*

An example is shown in Figure 1(b) which depicts the version graph for the evolving graph in Figure 1(a).

4.1 Lifespan Operations

Let us define a number of operations on lifespans, i.e., set of intervals. For two sets $\mathcal{I}$ and $\mathcal{I}'$ of time intervals, we say that $\mathcal{I}$ *covers* $\mathcal{I}'$, denoted $\mathcal{I} \sqsupseteq \mathcal{I}'$, if for each time instant t in an interval I' of $\mathcal{I}'$, there is an interval I in $\mathcal{I}$ such that t belongs to I. We also use $\mathcal{I} \sqsupseteq I$ for an interval I and $\mathcal{I} \sqsupseteq t$ for a time instant t. We say that two sets $\mathcal{I}$ and $\mathcal{I}'$ of time intervals are equivalent, $\mathcal{I} \approx \mathcal{I}'$, if $\mathcal{I} \sqsupseteq \mathcal{I}'$ and $\mathcal{I}' \sqsupseteq \mathcal{I}$.

We would like to maintain the smallest among equivalent sets of intervals. We call such sets *minimum* sets. Let us first define some simple properties for time intervals. Two time intervals $I = [t_i, t_j]$ and $I' = [t'_i, t'_j]$ are called *disjoint*, when $I \cap I' = \emptyset$ and *overlapping* otherwise. They are called *continuous* when $t'_i = t_j + 1$ and non-continuous otherwise. It is easy to see that the following proposition holds.

Proposition 1.

(i) A set of intervals is minimum, if and only if, it consists of disjoint and non-continuous intervals.

(ii) For each set of time intervals, there is a unique equivalent minimum interval set.

We next define two useful operations on interval sets, namely, *join* and *merge*. Given two sets of intervals, join returns the time instants common to both, while merge returns the time instants present in at least one of them.

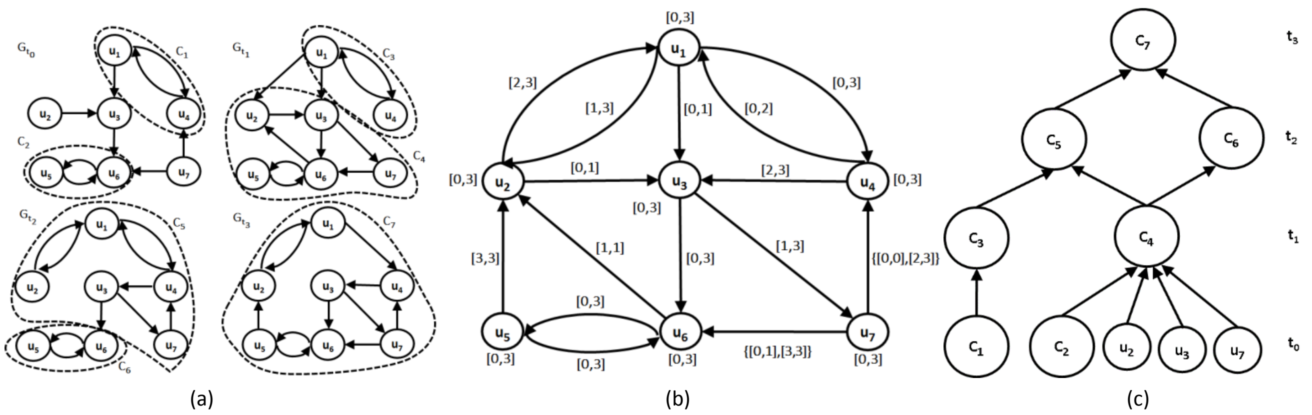

Figure 1: Example of (a) an evolving graph, (b) the corresponding version graph, (c) SCC evolution

Definition 4 (Join and Merge of Interval Sets). *Let $\mathcal{I} = \{I_1, \ldots\ I_k\}$ and $\mathcal{I}' = \{I'_1, \ldots\ I'_l\}$ be two sets of time intervals.*

(i) Join $\mathcal{I} \otimes \mathcal{I}'$ of $\mathcal{I}$ and $\mathcal{I}'$ is the minimum set equivalent to $\{I_1 \cap I'_1, \ldots\ I_1 \cap I'_l, \ldots, I_k \cap I'_1, \ldots\ I_k \cap I'_l\}$.

(ii) Merge $\mathcal{I} \oplus \mathcal{I}'$ of $\mathcal{I}$ and $\mathcal{I}'$ is the minimum set equivalent to $\mathcal{I} \cup \mathcal{I}'$.

Note that if $\mathcal{I}$ and $\mathcal{I}'$ are minimum, then the set $\{I_1 \cap I'_1, \ldots\ I_1 \cap I'_l \ldots, I_k \cap I'_1\ \}$ is a minimum set, whereas the set $\{I_1 \cup I'_1, \ldots\ I_1 \cup I'_l, \ldots, I_k \cup I'_1 \ldots\ I_k \cup I'_l\}$ may not be minimum.

The lifespan $\mathcal{L}(p)$ of a path p includes the time intervals during which all its edges coexist. Clearly, for a path $p = e_1 \ldots\ e_m$, it holds that $\mathcal{L}(p) = \mathcal{L}_e(e_1) \otimes \ldots \otimes \mathcal{L}_e(e_m)$, where $\mathcal{L}_e(e_i)$, $1 \leq i \leq m$, is the lifespan of e_i. For example, for path $p = ((u_4, u_3), (u_3, u_7), (u_7, u_6))$ in Figure 1(b), $\mathcal{L}(p) = \{[2,3]\} \otimes \{[1,3]\} \otimes \{[0,1], [3,3]\} = \{[3,3]\}$, while for path $p' = ((u_1, u_3), (u_3, u_7), (u_7, u_4))$, $\mathcal{L}(p') = \{[0,1]\} \otimes \{[1,3]\} \otimes \{[0,0], [2,3]\} = \emptyset$.

We can now define the lifespan, $\mathcal{L}(u,v)$, of the reachability between two nodes u and v. Let $P(u,v) = \{p_1, \ldots p_l\}$ be the set of all paths from u to v. $\mathcal{L}(u,v)$ depends on the lifespans of all possible paths in VG_I from u to v, in particular, $\mathcal{L}(u,v) = \mathcal{L}(p_1) \oplus \ldots \oplus \mathcal{L}(p_l)$. For example, for nodes u_4 and u_6 in Figure 1(b), $P(u_4, u_6) = \{p_1, p_2, p_3, p_4, p_5, p_6\}$ where $p_1 = u_4u_3u_6$, $p_2 = u_4u_3u_7u_6$, $p_3 = u_4u_1u_3u_6$, $p_4 = u_4u_1u_3u_7u_6$, $p_5 = u_4u_1u_2u_3u_6$, $p_6 = u_4u_1u_2u_3u_7u_6$ (note, that for notational brevity, paths were denoted by the participating nodes instead of edges). Then, $\mathcal{L}(u_4, u_6) = \{[2,3]\} \oplus \{[3,3]\} \oplus \{[0,1]\} \oplus \{[1,1]\} \oplus \{[1,1]\} \oplus \{[1,1]\} = \{[0,3]\}$.

Clearly, historical reachability queries can be represented in terms of lifespans. Specifically, given a version graph VG_I, a time interval $I_Q = [t_k, t_l] \subseteq [t_i, t_j]$ and two nodes v, u,

(i) a conjunctive historical reachability query $u \overset{I_{Q\wedge}}{\rightsquigarrow} v$ returns true, if and only if, $\{I_Q\} \otimes \mathcal{L}(u,v) \sqsupseteq I_Q$.

(ii) a disjunctive historical reachability query $u \overset{I_{Q\vee}}{\rightsquigarrow} v$ returns true, if and only if, $\{I_Q\} \otimes \mathcal{L}(u,v) \neq \emptyset$.

To represent lifespans, we use bit arrays. Assume without loss of generality, that the maximum time instant, that is, the number of graph snapshots, is T. Then, a lifespan, i.e., set of intervals, $\mathcal{I}$ is represented by a bit array B of size T, such that $B[i] = 1$ if $\mathcal{I} \sqsupseteq i$, and 0, otherwise. For example, take $\mathcal{I} = \{[2,4], [9,10], [13, curr]\}$ and $T = 16$. The bit array representation of $\mathcal{I}$ is 0011100001100111. This leads to an efficient implementation of both join $\otimes$ and merge $\oplus$. In particular, let $\mathcal{I}$ and $\mathcal{I}'$ be two set of intervals and B and B' be their bit arrays. Then, $\mathcal{I} \otimes \mathcal{I}'$ is computed as B logical-AND B' and $\mathcal{I} \oplus \mathcal{I}'$ as B logical-OR B'. An alternative representation would be to use ordered lists of intervals. Lifespan operations would then be performed using variations of merge sort resulting in $O(T)$ complexity. Lists impose in general large computational overheads in computing reachability.

4.2 Baseline Approaches

There are two baseline approaches to answering reachability queries on static graphs, namely pre-computation of the graph transitive closure and online traversal of the graph. In this section, we revisit these baseline approaches for historical reachability queries on a version graph.

4.2.1 Historical Transitive Closure

Instead of maintaining a different transitive closure for each graph snapshot of the evolving graph $\mathcal{G}_I$, we maintain a single transitive closure, CL_I for the version graph VG_I. The transitive closure includes for each pair of nodes u, v, their reachability lifespan, $\mathcal{L}(u,v)$. To construct the transitive closure, we use a variation of the Floyd-Warshall algorithm that takes into account lifespans, shown in Algorithm 1. If there is a path $p_{u,w}$ from node u to node w and a path $p_{w,v}$ from node w to node v then there exists a path $p_{u,v} = (p_{u,w}, p_{w,v})$ from u to v with $\mathcal{L}(p_{u,v}) = \mathcal{L}(p_{u,w}) \otimes \mathcal{L}(p_{w,v})$ and $\mathcal{L}(p_{u,v})$ is merged with the $\mathcal{L}(u,v)$ computed so far.

The time complexity for Algorithm 1 is $O(|V_I|^3 T)$ in the worst case and requires storage in the order of $|V_I|^2$. For answering a reachability query $u \overset{I_{Q\vee}}{\rightsquigarrow} v$ or $u \overset{I_{Q\wedge}}{\rightsquigarrow} v$, initially the entry $\mathcal{L}(u,v)$ in CL_I is located and then joined with the query interval I_Q, thus requiring constant time complexity.

4.2.2 Online Traversal of the Version Graph

A straightforward approach to process a reachability query for an interval I_Q would be to perform an online traversal on all graph snapshots G_t, $t \in I_Q$. When using the version graph representation, this corresponds to traversing

Algorithm 1 TransitiveClosure(VG_I)

Input: Version graph VG_I
Output: The transitive closure CL_I

```
1: for all $u$, $v \in V_I \times V_I$ do
2:   if $(u, v) \in E_I$ then
3:     $CL_I(u, v) = \mathcal{L}_e((u, v))$
4:   else
5:     $CL_I(u, v) = \emptyset$
6:   end if
7: end for
8: for $w = 1$ to $|V_I|$ do
9:   for all $u$, $v \in V_I \times V_I$ do
10:    $CL_I(u, v) = CL_I(u, v) \oplus (CL_I(u, w) \otimes CL_I(w, v))$
11:  end for
12: end for
```

Algorithm 2 Disjunctive-BFS(VG_I, u, v, $\{I_Q\}$)

Input: Version graph VG_I, nodes u, v, interval $I_Q \subseteq I$
Output: True if v is reachable from u in any time instant in I_Q and false otherwise

```
1: create a queue $N$, create a queue $INT$
2: enqueue $u$ onto $N$, enqueue $I_Q$ onto $INT$
3: while $N \neq \emptyset$ do
4:   $n \leftarrow N.dequeue()$
5:   $i \leftarrow INT.dequeue()$
6:   for all $w$ s.t. $(n, w)$ in $VG_I$ and $\{I_Q\} \otimes \mathcal{L}_e((n, w)) \neq \emptyset$ do
7:     if w == $v$ then
8:       Return(true)
9:     end if
10:    $\mathcal{I}' = \{I_Q\} \otimes \mathcal{L}_e(u, w)$
11:    if $\mathcal{IN}(w) \not\sqsupseteq \mathcal{I}'$ then
12:      $\mathcal{IN}(w) = \mathcal{IN}(w) \oplus \mathcal{I}'$
13:      enqueue $w$ onto $N$
14:      enqueue $\mathcal{I}'$ onto $INT$
15:    end if
16:  end for
17: end while
18: Return(false)
```

only edges e such that $\mathcal{L}_e(e) \sqsupseteq t$, once for each $t \in I_Q$. We call this approach, *instant based traversal*.

To avoid multiple traversals, i.e., one for each snapshot in I_Q, we consider an *interval based traversal* of the version graph. The BFS-based interval traversal for disjunctive historical queries is shown in Algorithm 2 and for conjunctive historical queries in Algorithm 3.

In particular, for conjunctive queries, since a node v may be reachable from u through different paths at different graph snapshots, we maintain an interval set $\mathcal{R}$ with the part of $\mathcal{L}(u, v) \otimes I_Q$ covered so far (line 9, Algorithm 3). The traversal ends when $\mathcal{R}$ covers the whole query time interval I_Q (line 10, Algorithm 3).

To speed-up traversal, we perform a number of pruning tests. The traversal stops when we reach a node whose lifespan is outside the query interval. In addition, the traversal stops at a neighbor w of a node n when $\{I_Q\} \otimes \mathcal{L}_e(n, w) \neq \emptyset$ since a node v cannot be reachable through an edge which is not alive in at least one t inside the query interval (line 6, Algorithms 2 and 3).

Still an edge may be traversed multiple times, if it participates in multiple paths from source to target. To reduce the number of such traversals, we provide additional pruning by recording for each node w, an interval set $\mathcal{IN}(w)$ with the parts of the query interval for which it has already been traversed. If the query reaches w again looking for interval I' $\subseteq I_Q$ and $\mathcal{IN}(w) \sqsupseteq I'$, the traversal is pruned (line 11 of Algorithm 2, line 15 of Algorithm 3).

For example, consider the version graph in Figure 1(b) and query $u_1 \overset{[0,3]\wedge}{\rightsquigarrow} u_5$. Paths $p_1 = u_1u_3u_6u_5$, $p_2 = u_1u_3u_7u_6u_5$, $p_3 = u_1u_2u_3u_6u_5$, $p_4 = u_1u_2u_3u_7u_6u_5$, $p_5 = u_1u_4u_3u_6u_5$ and $p_6 = u_1u_4u_3u_7u_6u_5$ with $\mathcal{L}(p_1) = \{[0, 1]\}$, $\mathcal{L}(p_2) = \{[1, 1]\}$, $\mathcal{L}(p_3) = \{[1, 1]\}$, $\mathcal{L}(p_4) = \{[1, 1]\}$, $\mathcal{L}(p_5) = \{[2, 3]\}$ and $\mathcal{L}(p_6)$ = $\{[3, 3]\}$ need to be traversed to conclude correctly that the result of the query is true. Hence, some edges, e.g., (u_3, u_6), (u_6, u_5) need to be traversed multiple times for different time intervals $I'_i \subseteq I_Q$. However, when the query reaches u_3 again through path p_3, it is pruned and it does not traverse the edge (u_3, u_6) since $\mathcal{IN}(u_3)$ is equal to {[0,1]} which covers the current query interval I' = {[1,1]}.

Since in the worst case for both instant and interval based traversal each edge may be traversed $|I_Q|$ times, the complexity for both traversals is $O((|V_I| + |E_I|)|I_Q|)$. However, in practice interval based traversal outperforms the instant based one since each edge traversal covers large parts of the query interval instead of a single time instant. Furthermore, pruning guarantees that an edge will not be traversed twice for the same interval.

5. THE TIMEREACH INDEX

Our approach exploits the fact that many real-world social graphs are characterized by large strongly connected components (SCC) [20, 15]. Thus, instead of maintaining reachability information for pairs of nodes, we maintain information about the SCCs that each node belongs to. If two nodes belong to the same component, then they are reachable. However, as the graph evolves over time, its strongly connected components change as well. An example is shown in Figure 1(c) that depicts the SCCs of the graph in Figure 1(b) as they evolve over time.

Given an evolving graph $\mathcal{G}_I = \{G_{t_i}, G_{t_i+1}, \ldots, G_{t_j}\}$, we invoke at each graph snapshot $G_{t_k} \in \mathcal{G}_I$ an algorithm, e.g., Tarjan's algorithm [24], to identify the corresponding set of SCCs. A unique id is assigned to each SCC at each snapshot.

For each node u, we maintain a list $P(u)$ that contains (C, t) pairs specifying the strongly connected component C to which node u belongs at time instant t. $P(u)$ is called *posting list* and each pair in the list a *posting*. The storage complexity is $\Omega(|V_I||I|)$, since each node participates in at most one SCC at each time instant. If we use Tarjan's algorithm [24], the time complexity for constructing the lists is $O((|V_I| + |E_I|)|I|)$, since each run of the Tarjan's algorithm has an $O(|V_I| + |E_I|)$ complexity.

For presentation clarity, we assume that single nodes form singleton SCCs whose ids are the ids of the corresponding nodes. However, for space efficiency, we do not maintain postings in this case.

We perform an additional optimization. Many nodes have strong connections, i.e. they remain in the same components even in the face of component splits and joins. We exploit this fact to reduce the storage space required for the postings by observing that the posting lists of these nodes consist of

Algorithm 3 Conjunctive-BFS(VG_I, u, v, $\{I_Q\}$)

Input: Version graph VG_I, nodes u, v, interval $I_Q \subseteq I$
Output: True if v is reachable from u in all time instants in I_Q and false otherwise

```
1: create a queue $N$, create a queue $INT$
2: enqueue $u$ onto $N$, enqueue $I_Q$ onto $INT$
3: while $N \neq \emptyset$ do
4:   $n \leftarrow N.dequeue()$
5:   $i \leftarrow INT.dequeue()$
6:   for all $w$ s.t. $(n, w)$ in $VG_I$ and $\{I_Q\} \otimes \mathcal{L}_e((n,w)) \neq \emptyset$ do
7:     $\mathcal{I}' = \{I_Q\} \otimes \mathcal{L}_e(n,w)$
8:     if $w == v$ then
9:       $R = R \oplus \mathcal{I}'$
10:      if $\mathcal{R} \sqsupseteq I_Q$ then
11:        Return(true)
12:      end if
13:      continue
14:    end if
15:    if $\mathcal{IN}(w) \not\sqsupseteq \mathcal{I}'$ then
16:      $\mathcal{IN}(w) = \mathcal{IN}(w) \oplus \mathcal{I}'$
17:      enqueue $w$ onto $N$
18:      enqueue $\mathcal{I}'$ onto $INT$
19:    end if
20:  end for
21: end while
22: Return(false)
```

the same elements. We avoid redundancy by storing such lists only once and replacing the posting lists of the relevant nodes with pointers to the common list. We call this approach *posting sharing.*

An example is shown in Figure 2(a), where, for instance, the first posting list indicates that nodes with ids 1 up to 50 belong to the strongly connected component with id C_1 at time t_0, C_6 at t_1 and C_9 at t_2.

In addition, for each graph snapshot G_{t_k}, we construct a SCC graph snapshot $G_{S_{t_k}} = (V_{S_{t_k}}, E_{S_{t_k}})$ such that there is a node U in $V_{S_{t_k}}$ for each SCC in G_{t_k}, and there is an edge (U, V) in $E_{S_{t_k}}$, if and only if, there is an edge (u,v) in G_{t_k} from a node u that belongs to the SCC that corresponds to U to a node v that belongs to the SCC that corresponds to V. For a time interval $I = [t_i, t_j]$, this results in an evolving SCC graph $\mathcal{G}_{S_I} = \{G_{S_{t_i}}, G_{S_{t_i+1}}, \ldots, G_{S_{t_j}}\}$. We construct the SCC graphs incrementally, as the SCCs are created. The size of each SCC graph depends on the size of the original snapshot graph and in the worst case is equal to it.

We call this approach simple *TimeReach* (TR). To answer a reachability query $u \overset{I_{Q\wedge}}{\rightsquigarrow} v$, (or, $u \overset{I_{Q\vee}}{\rightsquigarrow} v$), we check for each $t \in I_Q$ whether u and v belong to the same component. If this is not the case, we traverse the corresponding G_{S_t}.

Next, we present a more space efficient method of exploiting strongly connected components for historical queries.

5.1 Condensed TimeReach

While in the TR approach, we maintain information per time instant, we would like to aggregate such information to express SCC participations during time intervals. In this case, a posting (C, I'), $I' \subseteq I$, belongs to $P(u)$, if u participates in the SCC with id C at all time instants in I'. Our goal is to minimize the total number of such postings.

Problem 1 (Optimal SCC-id assignment). *Given a time interval I and a set of SCCs for each $t \in I$, find an assignment of ids to SCCs that results in the minimum number of postings.*

A new posting is created, each time a node participates in a different SCC. Thus, SCC ids should be re-assigned so that the number of such new postings is minimized. We use a weighted graph to formalize the optimal assignment of ids to SCCs.

In particular, we model SCC evolution over a time interval I using a weighted graph $G_C(V_C, E_C, \mathcal{W})$ where each node $U \in V_C$ corresponds to a SCC that existed at some time instant $t \in I$, and an edge $e = (U, V) \in E_C$, if and only if, SCC U existed at time t_k, SCC V existed at time $t_k + 1$ and there is at least one node that belongs to both U and V. $\mathcal{W}$ assigns to each edge $e = (U, V)$ a weight $\mathcal{W}(e)$ that corresponds to the number of nodes that belong to both U and V.

An example of a weighted graph is shown in Figure 2(b) that depicts the evolution of the graph whose posting lists are shown in Figure 2(a). For instance, component C_7 created at time instant t_1 consists of 100 nodes from component C_4 and 150 nodes from C_5.

Let $G_{C_{[t_k,t_k+1]}}(V_{C_{[t_k,t_k+1]}}, E_{C_{[t_k,t_k+1]}}, \mathcal{W})$ be the subgraph of $G_C(V_C, E_C, w)$, that consists of the nodes $U \in V_{C_{[t_k,t_k+1]}}$ that correspond to the SCCs that exist at time interval $[t_k, t_k+1]$. $G_{C_{[t_k,t_k+1]}}$ represents one step in the SCC evolution. Note that, from the definition of G_C, $G_{C_{[t_k,t_k+1]}}$ is a bipartite graph.

We make the following observation. At time instant $t_k + 1$, a new posting is created exactly for those nodes that participated in a different SCC at $t_k + 1$ than at t_k. The number of these new postings is equal to the sum of weights from node U to V in $G_{C_{[t_k,t_k+1]}}$ where U has a different id than V. Thus, to minimize the number of new postings, we have to maximize the weight of the edges between pairs of nodes that have the same id. This corresponds to finding a maximum bipartite matching of $G_{C_{[t_k,t_k+1]}}$.

Theorem 1. *The optimal SCC-id assignment problem can be reduced to the problem of finding the maximum weight bipartite matching (MWM) M_k of each $G_{C_{[t_k,t_k+1]}}$.*

Proof. As shown above, solving the MWM for each bipartite graph $G_{C_{[t_k,t_k+1]}}$ minimizes the number of new postings created at $t_k + 1$. We shall show that this step-wise assignment is optimal overall in G_C. For the purposes of contradiction, assume that the optimal assignment is a set N of edges, $N \subset E_C$ and that N is different from the set of edges attained through the maximum bipartite matchings, that is, $\sum_{e\in N} w(e) > \sum_k \sum_{e\in M_k} w(e)$. Hence, for some m, for $N_m = N \cap E_{C_{[t_m,t_m+1]}}$ it holds that $\sum_{e\in N_m} w(e) > \sum_{e\in M_m} w(e)$, which means that M_m is not a MWM, which is a contradiction. □

Figure 2(c) shows the weighted graph after the assignment of new ids through bipartite matching, while Figure 2(d) shows the new posting lists.

(d)

Figure 2: (a) Shared posting lists, (b) weighted graph modeling the evolution of SCCs, (c) weighted graph after the bipartite matching, and (d) the compressed shared posting lists

The maximum weight bipartite matching problem is well-studied (e.g., see [8] for a survey). The most widely used algorithm for solving this problem on a graph $G(V, E)$ is the Hungarian algorithm whose running time ranges from $O(|V|^3)$ to $O(|E||V| + |V|^2 loglog|V|)$ depending on the implementation. Another category of algorithms depends on the edge weights and the fastest one runs in $O(|E|\sqrt{|V|}logW)$ time, where W is the maximum edge weight. In addition, a number of fast approximation algorithms have been proposed. The simplest such algorithm is the greedy algorithm that sorts the edges by weight and repeatedly picks the edge with the largest weight. This algorithm can be implemented with $O(|E|)$ time complexity and produces a 1/2 worst case approximation.

The incremental algorithm for constructing the SCC postings is presented in Algorithm 4. It takes as input the current snapshot and the postings computed up to the previous snapshot, and constructs the current postings. It starts by computing the SCCs using Tarjan's algorithm with complexity $O(|V_t| + |E_t|)$ (line 2). Then, it constructs the graph $G_{C_{[t,t+1]}}$ with complexity $O(|E_{C_{[t-1,t]}}|)$ (line 5). Next, the MWM is computed and new ids are assigned to the new SCCs (lines 6 - 9). The complexity of this step depends on which algorithm is used for computing the MWM. We use the greedy algorithm with complexity $O(|E_{S_{[t-1,t]}}|)$. Finally, the SCC postings are created/updated for each node of the current snapshot, creating a new entry only for nodes that participate in a different SCC (with a different id) than the one in time instant $t - 1$ (lines 11 - 22). The complexity of these steps is $O(|V_t|)$ since each operation in the loop has constant time complexity. Thus, in total the running time of the algorithm is $O(|V_t| + |E_t|)$.

As in the simple TR approach, we also construct the evolving SCC graph, which in this case has a much smaller number of nodes due to the reduction of the number of strongly connected components achieved by the bipartite matching.

Finally, we construct the version graph $VG_{S_I} = (V_{S_I}, E_{S_I}, \mathcal{L}_u, \mathcal{L}_e)$ of the evolving SCC graph that we call *condensed version graph.* We construct the condensed version graph incrementally as follows. For each snapshot $G_{t_i} \in \mathcal{G}_I$, for each edge $(u, v) \in E_{t_i}$ we look up the postings $P(u)$, $P(v)$ for entries (U, I'), (V, I'') s.t. $t_i \in I'$ and $t_i \in I''$. If $U \neq V$ and edge $(U, V) \notin E_{S_I}$, the edge is added with lifespan $\{[t_i, t_i]\}$, otherwise the lifespan of the edge is extended to include t_i. We call the above approach *condensed TimeReach* (TRC).

5.2 Query Processing

Query processing of a (disjunctive or conjunctive) reachability query $u \overset{I_Q}{\leadsto} v$ is performed in two steps. In the first step, the appropriate postings of nodes u and v are retrieved. If the two nodes belong to the same strongly connected component during the whole query interval for conjunctive queries or once for disjunctive queries, the answer is true. Otherwise, let $\mathcal{I}'_Q$ be the set of intervals during which nodes u and v belong to different components. The query is re-written as a set of reachability sub-queries of the form $U_k \overset{I_{Q_i}}{\leadsto} V_m$, where u belongs to SCC U_k and v belongs to SCC V_m for some common time interval I_{Q_i}, $\mathcal{I}'_Q \sqsupseteq I_{Q_i}$, the set $\mathcal{I}_Q = \bigcup_i I_{Q_i}$ consists of disjoint intervals, and $\mathcal{I}_Q \approx \mathcal{I}'_Q$. The results of the sub-queries are combined to produce the answer for the query through an AND (OR) for conjunctive (disjunctive) queries.

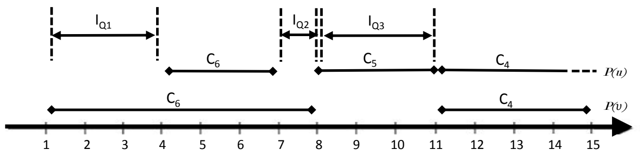

Figure 3: Example of splitting query $u \overset{[1,15]\wedge}{\leadsto} v$

For example, consider the query $u \overset{[1,15]\wedge}{\leadsto} v$ in Figure 3, where the posting lists for u and v are respectively, $P(u) = (C_6\ [4, 7],\ C_5\ [8, 11],\ C_4\ [11, curr]$ and $P(v) = (C_6\ [1, 8],\ C_4\ [11, 15])$. The query is split in three sub-queries: $u \overset{I_{Q1}\wedge}{\leadsto} C_6$, $u \overset{I_{Q2}\wedge}{\leadsto} C_6$, $v \overset{I_{Q3}\wedge}{\leadsto} C_5$.

In the worst case, the two nodes belong to a different SCCs at each time instant in I_Q, thus we need to traverse the condensed version graph for each t with a cost of $O(|I_Q|(|V_{S_I}| + |E_{S_I}|))$ Two factors that influence performance are the number of postings for each node and the size of the condensed version graph. The smaller the number of postings, the fewer sub-queries are required in the second step. The smaller the condensed version graph, the faster the traversals. Hence, the optimal assignment of SCC ids is crucial to query processing performance, since it keeps the posting lists short and the size of the condensed version graph small.

5.3 Interval 2Hop

Reachability on version graphs can be made more efficient by maintaining additional information. In this paper, we use an approach based on pruned landmark 2hop labeling [2, 29]. The idea is that for each node u of a given graph, we maintain two labels $L_{in}(u)$ and $L_{out}(u)$ which include nodes that can reach u and can be reached by u respectively. The labels are computed such that a node u reaches v, if an only if, $L_{in}(v) \cap L_{out}(u) \neq \emptyset$. Instead of traversing the graph, a reachability query can now be answered by using the labels.

For historical reachability queries, we also keep along with each node w in $L_{in}(v)$ the reachability lifespan $\mathcal{L}(w, v)$ and along with each node w in $L_{out}(u)$ the reachability lifespan

Algorithm 4 ConstructSccPostings(G_t, P_{t-1}, $G_{S_{[t-2,t-1]}}$)

Input: Snapshot G_t, SCC postings P_{t-1}
Output: SCC postings P_t

```
 1: $S_{SCC_t} = \emptyset$, $M = \emptyset$
 2: Run Tarjan's algorithm on $G_t$
 3: $S_{SCC_t}$ is the set of the detected SCCs where each
    $SCC_i \in S_{SCC_t}$ is assigned a unique id $C_i$
 4: if $t > 0$ then
 5:    Construct $G_{S_{[t-1,t]}}$ from $S_{SCC_t}$ and $G_{S_{[t-2,t-1]}}$
 6:    Compute maximum weight matching $M$
 7:    for all edges $e = (U, V) \in M$ do
 8:       $C_v = C_u$
 9:    end for
10: end if
11: for all nodes $u \in V_t$ do
12:    find $SCC_i \in S_{SCC_t}$ s.t. $u \in SCC_i$
13:    if $P_{t-1}(u) \neq \emptyset$ then
14:       if $P_{t-1}(u)[end].C \neq C_i$ then
15:          $P_{t-1}(u)[end].I = [t_s, t-1]$
16:          $P_{t-1}(u).add(C_i, [t, curr])$
17:       end if
18:    else
19:       $P_{t-1}(u).add(C_i, [t, curr])$
20:    end if
21: end for
22: $P_t = P_{t-1}$
```

$\mathcal{L}(u, w)$. In the presence of 2hop labels, to answer a query $u \overset{I_Q}{\leadsto}_{\wedge} v$ ($u \overset{I_Q}{\leadsto}_{\vee} v$), we compute the set $L_{in}(v) \cap L_{out}(u)$ and then for each w in $L_{in}(v) \cap L_{out}$, we join the lifespan of w in $L_{in}(v)$ with the lifespan of w in $L_{out}(u)$. To answer the query the joined lifespans $\mathcal{L}$ (w) of nodes w in $L_{in}(v) \cap L_{out}$ are joined with the query interval $\mathcal{L}$ to see whether they cover I_Q (or, have at least a time instant in common).

We compute the labels for the nodes of the condensed version graph, incrementally. For an interval $I = [t_i, t_j]$, we compute the labels for the SCC graph snapshots at each time t in I, starting from t_i. For each time t_k, $t_k > t_i$, we merge the labels computed for a node C at time t_k, with the labels computed for C at the previous time $t_k - 1$. For the construction of L_{in} and L_{out} for each SCC graph snapshot at time instant t_k, we process the nodes of the graph by using the $INOUT$ strategy that starts a BFS traversal from the nodes with the largest $(indegree(u){+}1) \times (outdegree(u){+}1)$ [29]. An example of the final 2hop labels of each SCC node in a version graph is given in Figure 4.

6. EXPERIMENTAL EVALUATION

To evaluate our approach, we used three real datasets: Facebook (FB) [27], Flickr (FL) [19] and YouTube (YT) [18]. The characteristics of each dataset are shown in Table 3. For example, FB consists of 871 daily snapshots of the New Orleans Facebook friendship graph, which correspond to 125 weekly or 29 monthly snapshots. We report the number of nodes, edges, and SCCs (singleton SCCs are not included) and the size of the largest SCC at the first and last snapshot.

All three datasets are treated as directed. Also, all datasets are insert-only, i.e. they do not contain information about node/edge deletions. Therefore, we synthetically generate random edge deletes. The input parameters and their de-

Figure 4: An example of interval 2hop labels

fault values are shown in Table 1.

We evaluate the size and the construction time of the Version Graph (VG), the Transitive Closure (TC), the simple TimeReach (TR), the condensed TimeReach (TRC) and the condensed TimeReach with 2hop labels (TRCH). We also evaluate the online processing of historical reachability queries using an instant-based (INS) or interval-based (INT) traversal of the version graph and using the various TimeReach indexes. Table 2 summarizes the various approaches.

We ran our experiments on a system with a quad-core Intel Core i7-3820 3.6 Ghz processor and 64 GB memory. We only used one core for all experiments.

Table 1: Input parameters

		# of nodes	**Snapshot granularity**	**Query interval (in days)**	**% of deletes**
FB	Default	61,096	day	7	10
	Range	117 - 61,096	day, week, month	7 - 35	0 - 30
YT	Default	1,138,499	day	7	10
	Range	1,004,777 - 1,138,499	day, week, month	7 - 35	0 - 30
FL	Default	2,302,925	day	7	10
	Range	1,487,058 - 2,302,925	day, week, month	7 - 35	0 - 30

6.1 Index Size

In the first set of experiments, we evaluate the various approaches in terms of their storage requirements. The size of the TR and TRC include the storage required for maintaining the posting lists and the SCC graphs, while the size of the TRCH includes in addition the storage required for the 2hop labels.

Table 2: Overview of difference approaches

VG	Version Graph
TC	Transitive Closure
TR	(Simple) TimeReach
TRC	Condensed TimeReach
TRCH	Condensed TimeReach with 2hop labels
INS	Instant-based traversal of the version graph
INT	Interval-based traversal of the version graph

Table 3: Dataset properties

	Snapshot Granularity	# nodes		# edges		# SCC		Max SCC (# nodes)	
		first	last	first	last	first	last	first	last
FB	(daily) 871	117	61,096	128	1,139,081	10	374	3	51,286
	(weekly) 125	1,429	61,096	2,365	1,139,081	138	374	18	51,286
	(monthly) 29	4,239	61,096	12,224	1,139,081	279	374	96	51,286
YT	(daily) 37	1,004,777	1,138,499	4,379,283	4,452,646	9,807	11,360	457,932	509,332
	(weekly) 6	1,025,536	1,138,499	4,379,283	4,452,646	9,807	11,360	465,668	509,332
	(monthly) 2	1,116,602	1,138,499	4,446,042	4,452,646	10,664	11,360	485,273	509,332
FL	(daily) 134	1,487,058	2,302,925	17,022,083	33,140,018	42,163	58,636	1,004,426	1,605,184
	(weekly) 20	1,507,700	2,302,925	17,393,321	33,140,018	42,163	58,636	1,010,498	1,605,184
	(monthly) 5	1,585,173	2,302,925	18,987,847	33,140,018	42,459	58,636	1,081,499	1,605,184

Graph Size (scalability). Figure 6 reports the size for varying number of nodes. As shown, TRC is much smaller than TR in all cases. For FB and FL, the largest SCC covers 83% and 70% of the graph respectively, while for YT, it covers just 45% (see Table 3). Thus, the TRC size for the FB dataset is 89% smaller, while for the YT and FL datasets, we achieve 40% and 57% of compression respectively. The larger the SCCs, the higher the compression achieved.

Since the size of the transitive closure (TC) grows rapidly, we compute TC for a smaller subset of the FB dataset varying the number of nodes from 1,000 to 6,000. As shown in Table 4, even for this small graph, the size of TC reaches 106 MB.

Percentage of Deletes. For each dataset, we vary the percentage of edge deletes from 0% to 30% of edge insertions. Table 5 presents the results for the FB dataset. We observe that the size of TR and TRC decreases; this can be explained by the fact that deletions affect the isolated nodes that become disconnected from the components and thus there are less edges between components and isolated nodes. The size of VG remains constant, since the size of the lifespan labels remains the same. Finally, the size of TRCH increases, because in case of deletes, additional nodes need to be included in the 2hop labels for ensuring the reachability test.

Table 4: Comparison with transitive closure

# nodes	Size (MB)			Constr. Time (sec)		
	TR	TRC	TC	TR	TRC	TC
1,000	0.013	0.012	2.91	0.01	4.76	167.49
2,000	0.026	0.009	11.56	0.23	5.02	1,457
3,000	0.039	0.012	26.27	0.35	5.89	5,788
4,000	0.052	0.018	47.12	0.41	6.33	16,580
5,000	0.063	0.026	73.97	0.59	6.79	39,112
6,000	0.074	0.032	106.82	0.72	7.13	81,123

Snapshot Granularity. Table 6 reports the storage required for maintaining daily, weekly and monthly snapshots of the three datasets. All sizes increase with the number of snapshots. For example, for FL, the increase of the number of snapshots by a factor of 30 (from 5 monthly to 134 daily) causes an increase of the size of TR by a factor of 3.44. The size of TR and TRC decreases with the snapshot granularity (number of snapshots) since less snapshots mean less postings and smaller SCC graphs. The size of VG

Table 5: Size per % of deletes (Facebook)

% of deletes	Size (MB)			
	VG	TR	TRC	TRCH
0	11	0.5	0.21	1,493
10	11	0.58	0.22	1,528
20	11	0.45	0.19	1,612
30	11	0.47	0.18	1,664

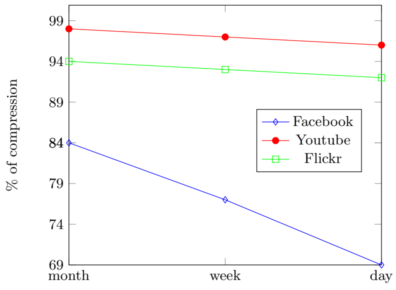

Figure 5: Compression ratio achieved by posting sharing

does not decrease significantly, because it requires memory to keep lifespan labels for all nodes and edges of the graph.

Posting Sharing. Finally, let us take a closer look at the posting sharing optimization by evaluating the reduction in the size of postings for various granularities as depicted in Figure 5. In general, we achieve compression ratios for the posting around 70% for FB, around 90% for FL and over 95% for YT. The compression ratio decreases with snapshot granularity due to the increase of the posting combinations. This is more evident for the FB dataset where the number of snapshots is higher.

6.2 Construction Time

In this set of experiments, we evaluate the time to construct the various indexes.

As seen in Figure 7, TRC is slower than TR, because of the additional time required for performing the bipartite matching. TRCH is even slower, since it also needs to construct the 2hop labels. We use the greedy algorithm for the bipartite matching and the INOUT strategy for computing the interval-2hop labels.

Constructing the TC for the whole graphs is prohibitive, since even for only 6,000 nodes, it takes over 22 hours, while

Table 6: Size (MB) per snapshot granularity

	Facebook			*YouTube*			*Flickr*		
	Days	Weeks	Months	Days	Weeks	Months	Days	Weeks	Months
VG	11	6	5	7.87	7.34	6.94	45.52	39.85	38.15
TR	0.58	0.47	0.42	44.28	21.28	14.98	141	73	41
TRC	0.22	0.08	0.07	3.21	1.92	1.46	2.89	2.27	1.88
TRCH	1,528	1,041	845	5,865	4,936	4,062	7,951	6,684	5,719

the TR construction takes just 0.72 seconds (Table 4).

Comparison of Different Bipartite Matching Algorithms. We also constructed the TRC using the Hungarian algorithm. For all datasets, the size of the resulting TRC is almost equal to the size of the TRC resulting from using the greedy algorithm (the difference is in the order of KB), thus confirming our expectation that greedy achieves a very close approximation of the optimal solution for social graphs. The Hungarian algorithm is much slower than greedy requiring an additional 1.5 hour for large datasets such as FL.

Comparison with 2hop for insert only. We adopted the pruned labeling algorithm proposed in [2] for distance queries to create an indexing scheme for historical reachability queries. Pruned labeling incrementally updates the index for each newly inserted edge, whereas in our approach we compute 2hop labels per snapshot. The pruned labeling algorithm does not support deletions, thus, we compare the two algorithms on the Facebook dataset without deletions. The pruned algorithm was found to be 5.4 times faster but it produced labels that were 12 times larger that the ones computed with our approach.

6.3 Query Processing

Let us now focus on query processing. In each experiment, we ran 500 historical reachability queries where the source and target nodes are chosen uniformly at random with the restriction that both nodes are present in the graph at the beginning and the end of the query interval. Queries involving nodes not present either at the beginning or the end of the query interval can be pruned fast by checking the lifespans of the nodes.

Online Traversal of the Version Graph. Let us first compare between an instant-based (INS) and an interval-based (INT) online traversal of the version graph for different time intervals (Figures 8 and 9). A general remark that holds independently of the method used to evaluate queries is that false conjunctive queries are faster than true conjunctive queries, since processing stops as soon as a time instant is found at which the two nodes are not reachable. Analogously, true disjunctive queries are faster than false disjunctive queries, since processing stops as soon as a time instant is found at which the two nodes are reachable.

Interval-based traversal is faster that instant-based traversal for almost all datasets and query types, since it can find the answer faster by searching for longer intervals. The only exception is FB and false conjunctive queries, where INS is slightly better. This happens because with INS, the search stops as soon as the first false answer is produced in any traversal. Hence, if this answer is found in the first few time instants of the query interval negative answers can be produced quickly for the smaller graph (i.e, the FB graph).

Online Traversal versus TimeReach. Let us now compare interval-based online traversal with query processing using the TR, TRC and TRCH approaches. The results for conjunctive queries are shown in Figure 10 and for disjunctive queries in Figure 11.

We see that all approaches are not significantly affected by the increase of the query interval due to fast posting lookups and short distances in the SCC graph for the TR and TRC, and the efficient implementation of edge lifespans for the version graph. We see that the TRC approach does not only produce a smaller structure than TR but it also attains faster query response for almost all datasets. TR is slower because for answering a query it needs to traverse the SCC graph per time instant when the query nodes do not belong to the same component. TRCH attains the fastest time when compared with all other approaches. The performance of TRCH is expected, since only two simple steps are needed: first to obtain the intersection $L_{in}(v) \cap L_{out}(u)$, and after that to check the lifespans $\mathcal{L}$ of the nodes in the intersection.

7. CONCLUSIONS

Most real-life graphs evolve over time. In this paper, we address the problem of efficiently answering historical reachability queries over such graphs. Such queries ask whether a node u was reachable from another node v during a time interval in the past. We have proposed an approach termed *TimeReach* that exploits the fact that most graphs consist of strongly connected components (SCCs). TimeReach maintains information about SCC membership for each node, and a graph which represents the links between the strongly connected components. We also maintain a condensed version graph which corresponds to the version graph of the SCCs evolution. Our extensive experiments with three real social network datasets show that TimeReach is storage-efficient and can be constructed incrementally with a small overhead. Historical queries are processed efficiently even when involving large time intervals.

There are many possible directions for future work. One such direction is exploiting TimeReach towards answering other types of historical queries, such as shortest path ones. Another direction concerns the distribution of TimeReach. Distribution may either be based on time or exploit the SCC evolution by placing together nodes that belong to the same SCCs.

ABSTRACT

Driven by many applications, in this paper we study the problem of computing the top-k shortest paths from one set of target nodes to another set of target nodes in a graph, namely the top-k shortest path join (KPJ) between two sets of target nodes. While KPJ is an extension of the problem of computing the top-k shortest paths (KSP) between two target nodes, the existing technique by converting KPJ to KSP has several deficiencies in conducting the computation. To resolve these, we propose to use the best-first paradigm to recursively divide search subspaces into smaller subspaces, and to compute the shortest path in each of the subspaces in a prioritized order based on their lower bounds. Consequently, we only compute shortest paths in subspaces whose lower bounds are larger than the length of the current k-th shortest path. To improve the efficiency, we further propose an iteratively bounding approach to tightening lower bounds of subspaces. Moreover, we propose two index structures which can be used to reduce the exploration area of a graph dramatically; these greatly speed up the computation. Extensive performance studies based on real road networks demonstrate the scalability of our approaches and that our approaches outperform the existing approach by several orders of magnitude. Furthermore, our approaches can be immediately used to compute KSP. Our experiment also demonstrates that our techniques outperform the state-of-the-art algorithm for KSP by several orders of magnitude.

1. INTRODUCTION

Data are often modeled as graphs in many real applications such as social networks, information networks, gene networks, protein-protein interaction networks, and road networks. With the proliferation of graph data, significant research efforts have been made towards analyzing large graph data. These include the problem of computing the top-k shortest paths between two target nodes in a graph, namely the k shortest path (KSP) query.

KSP is a fundamental graph problem with many applications. In general, KSP is used in the applications that besides lengths, other constraints against the paths could not be precisely defined [12, 25]. For example, computing KSP between two sensitive accounts in a large social network enables end-users to identify all accounts involved in the top-k shortest paths [14]. In gene networks, the lengths of top-k shortest paths may be used to define the importance of a target gene to a source gene [26]. Other applications of KSP include multiple object tracking in pattern recognition [3], hypothesis generation in computational linguistics, and trip planning against road networks. Thus, KSP has been extensively studied [8, 9, 14, 15, 18, 24, 28].

The problem of computing the top-k shortest paths between two "conceptual" target nodes (instead of between two physical nodes) in a graph, called *the top-k shortest path join* (KPJ), is recently investigated in [15]. A conceptual node is a set of physical nodes in the graph, which can be identified by categories, concepts, and keywords in the above applications. While a KSP query is a special case of a KPJ query where each of the two conceptual target nodes only contains one physical node, KPJ can support more general application scenarios than KSP since a target node is allowed to be a set of physical nodes. For example, in a social network, the KPJ query can be used to detect user accounts involved in the top-k shortest paths between two criminal gangs to identify other "most suspicious" user accounts; the KPJ query can also be used in route planning where the destination is any one from a group of nodes (e.g., "IKEA"). In this paper, we study KPJ.

Motivations and Challenges. KPJ query shares similarity with but is different from the well-studied KSP query. To process a KPJ query, [15] reduces it to a KSP query by introducing a virtual target node for each conceptual target node and connecting every physical node in the conceptual node to it. Then, [15] proposes to use the state-of-the-art algorithm for KSP developed in [15]. Since the technique for solving KSP in [15] is based on the deviation paradigm [9, 28], applying KSP to solve KPJ, as proposed in [15], has the following two deficiencies. 1) Firstly, the deviation based techniques for KSP need to compute $O(k \cdot n)$ "candidate paths". The candidate paths are computed by iteratively extending all "prefixes" of the obtained l-th ($l < k$) shortest path, where n is the number of nodes in a graph, and each candidate path is computed by running an expensive shortest path algorithm; this is time-consuming. 2) Secondly, edges that are added to connect to a virtual target node for processing KPJ by using the KSP techniques depend on queries. This makes the existing index structures [7, 10] for computing shortest paths inapplicable. Thus, the candidate paths are computed by traversing the graph exhaustively; this is very costly.

Our Approaches. For presentation simplicity, in this paper we present our techniques against the simplified case, where one conceptual target node consists of one physical node only - called *source* node s, and the other conceptual target node may consist of multiple physical nodes - called *destination* nodes; then we extend our techniques to the general case where source nodes may also be multiple. Let $\mathcal{P}$ denote the set of all *simple* paths (i.e., paths without loops) from s to any of the destination nodes as the entire search space. Clearly, the result of KPJ is the set of k paths in $\mathcal{P}$ with the shortest lengths.

We adopt the best-first paradigm to recursively divide $\mathcal{P}$ into smaller subspaces, and then compute shortest paths for the generated subspaces in a prioritized order based on their lower bounds, where lower bound of a subspace is the lower bound of the length of all paths in the subspace. The top-k shortest paths may be iteratively obtained over the subspaces whose lower bounds are smaller than the length of the current k-th shortest path, while other subspaces can be safely pruned without the time-consuming shortest path computation.

We further propose to iteratively "guess" and tighten the lower bound τ of a subspace. Initially, we assign the value of τ as the length of the (1st) shortest path. Then, we always choose the subspace with the smallest τ to test whether the shortest path in it has length larger than $\alpha \cdot \tau$ (for an $\alpha > 1$). If the shortest path in the subspace can be determined larger than $\alpha \cdot \tau$, then we enlarge τ into $\alpha \cdot \tau$ for the subspace; otherwise the shortest path in the subspace is computed. Moreover, we propose two online-built index structures, $\mathsf{SPT_P}$ and $\mathsf{SPT_I}$, to significantly reduce the exploration area of a graph in the lower bound testing as briefly described above.

Contributions. Our primary contributions are summarized as follows.

- We propose a framework based on the best-first paradigm for processing KPJ queries which significantly reduces the number of shortest path computations.
- We propose an iteratively bounding approach to guessing and tightening the lower bounds, as well as two online-built index structures to speed-up the lower bound testing.
- We conduct extensive performance studies and demonstrate the scalability of our approaches which outperform the baseline approach [15] by several orders of magnitude.
- Moreover, our approaches can be immediately used to process KSP queries, and our experiments also demonstrate that our techniques outperform the state-of-the-art algorithm for KSP query by several orders of magnitude.

Organization. The rest of this paper is organized as follows. A brief overview of related work is given below. We give the preliminaries and problem statement in Section 2. The existing KSP-based approach is given in Section 3, in which we also discuss its deficiencies. We present the best-first paradigm in Section 4, in which we also implement a best-first approach. Under this paradigm, in Section 5 we propose an iteratively bounding approach and two online-built indexes for efficiently processing KPJ queries. In Section 6, we extend our techniques to cover other applications including the case that the source node has multiple physical nodes. We conducted extensive experimental studies and report our findings in Section 7, and we conclude this paper in Section 8.

Related Work. Given two nodes s and t in a graph G, the problem of computing the top-k shortest paths from s to t is a long-studied problem, which can be classified into two categories, 1) top-k simple shortest paths, and 2) top-k general shortest paths.

1) Top-k Simple Shortest Path. The existing algorithms for computing top-k simple shortest paths are based on the deviation paradigm proposed by Yen [9, 28], which has a time complexity of $O(k \cdot n \cdot (m + n \log n))$, where m is the number of edges in G and $O(m + n \log n)$ is the time complexity of computing single source shortest paths. Techniques to improve its efficiency in practice have been studied in [8, 14, 15, 18, 24], which shall be discussed in Section 3. We discuss using these techniques to process KPJ queries in Section 3.

2) Top-k General Shortest Path. Finding top-k general shortest paths is studied in [2, 12, 19], where cycles in paths are allowed. Since not enforcing paths to be simple, the top-k general shortest path problem is generally easier than its counterpart. Eppstein's algorithm [12] has the best time complexity, $O(m+n \log n+k)$, which is achieved by precomputing a shortest path tree rooted at the destination node and building a sophisticated data structure. Recently, the authors in [1] propose a heuristic search algorithm that has the same time complexity as [12]. However, due to different problem natures, these techniques are inapplicable to finding top-k simple shortest paths.

Finding Top-k Objects by Keywords. Finding k objects closest to a query location and containing user-given keywords has been studied in [13, 20, 22, 23, 29]. Ranking spatial objects by the combination of distance and relevance score is also studied in [4, 5, 27]. Distance oracles for node-label queries in a labeled graph are studied in [6, 17]; that is, given a query which contains a node and a label, it returns approximately the closest node to the query node that contains the query label. Nevertheless, the above queries are inherently different from KPJ, and their techniques cannot be applied to process KPJ queries.

2. PRELIMINARY

In this paper, we focus on a *weighted* and *directed graph* $G = (V, E, \omega)$, where V and E represent the set of nodes and the set of edges of G, respectively, and ω is a function assigning a weight to each edge in E. In G, nodes belong to categories, and each category represents a conceptual node consisting of all nodes belonging to that category. The number of nodes and the number of edges of G are denoted by $n = |V|$ and $m = |E|$, respectively.

A *path* P in G is a sequence of nodes $(v_1, \ldots, v_l)$ such that $(v_i, v_{i+1}) \in E, \forall 1 \leq i < l$, and we say that P consists of edges $(v_i, v_{i+1}), \forall 1 \leq i < l$. Here, v_1 and v_l are called the *source* node and *destination* node of P, respectively. P is a *simple* path if and only if all nodes in P are distinct (i.e., $v_i \neq v_j, \forall i \neq j$). A *prefix* of P is a subpath of P starting from the source node of P. The *length* of a path is defined as the total weight of its constituent edges; that is $\omega(P) = \sum_{(v_i,v_{i+1}) \in P} \omega(v_i, v_{i+1})$. The shortest distance from v_1 to v_2 is the shortest length among all paths from v_1 to v_2, denoted $\delta(v_1, v_2)$.

Definition 2.1: Given a category T, a path P is said to be a ***path to category*** T if its destination node is in V_T, where V_T is the set of nodes belonging to category T. □

Problem Statement: Given a graph G, we study the *top-k shortest path join* (KPJ) query, which aims at finding the top-k shortest simple paths $P_1, \ldots, P_k$ from a source node s to a category T (i.e., to any node in V_T).

Formally, a KPJ query is given as $Q = \{s, T, k\}$, where s is a source node in G, T represents a destination category, and k specifies the number of paths to find. It is to find k simple paths $P_1, \ldots, P_k$ such that: 1) each P_i is a path from s to category T; 2) $\omega(P_i) \leq \omega(P_{i+1}), \forall 1 \leq i < k$; 3) $\omega(P_k) \leq \omega(P)$ for any other path P from s to category T.

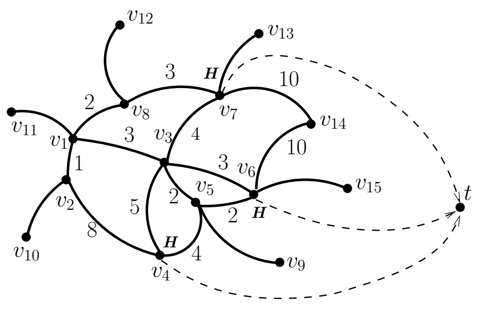

Figure 1: An example graph

Example 2.1: Fig. 1 illustrates a graph G, where $V = \{v_1, \ldots, v_{15}\}$ and nodes v_4, v_6, v_7 belong to category "H" (i.e., hotel). Here, edges are bidirectional, and weights are shown besides them with a default value 1. Consider a KPJ query $Q = \{v_1, \text{“}H\text{”}, 1\}$, which is to find the top-1 shortest path from v_1 to category "H". The top-1 path is $P_1 = (v_1, v_8, v_7)$ with $\omega(P_1) = 2 + 3 = 5$. □

For a KPJ query, V_T is the set of destination nodes. In the following, we assume that an inverted index [21] is offline built on the categories of nodes such that V_T can be efficiently retrieved online, and assume that a path is a simple path.

3. THE EXISTING KSP-BASED APPROACH

Reducing KPJ Query to KSP Query. The most related problem to KPJ is k shortest path (KSP) query defined below.

Definition 3.1:[28] Given a graph G, a KSP query $Q' = \{s, t, k\}$ is to find k simple paths $P_1, \ldots, P_k$ from s to t such that, 1) $\omega(P_i) \leq \omega(P_{i+1}), \forall 1 \leq i < k$, and 2) $\omega(P_k) \leq \omega(P)$ for any other path P from s to t. □

KSP query is a special case of KPJ query where V_T contains only one node. In other words, KSP query considers a single destination node while KPJ query considers multiple destination nodes. To process a KPJ query $Q = \{s, T, k\}$, [15] reduces it to a KSP query by adding a virtual destination node t to G and adding a directed edge from each node in V_T to t with a weight 0. Then, the result of Q on G is the same as the result of the KSP query $Q' = \{s, t, k\}$ on G_Q. Reconsider the KPJ query in Example 2.1, the modified graph G_Q is also shown in Fig. 1 with the virtual node t and the additional edges (dashed lines).

Deviation Algorithm (DA) for KSP Queries. The existing algorithms for KSP queries are based on the deviation paradigm [9, 28], denoted DA. It maintains a set C of candidate paths which include the next shortest path from s to t, and chooses k shortest paths from C one by one in a non-decreasing length order by incrementally updating C.

Pseudo-tree. The set of already chosen paths are encoded using a compact trie-like structure [21], called pseudo-tree. It is named because the same node may appear at several places in the tree; thus, we refer to nodes in a pseudo-tree as vertices to distinguish them from nodes in a graph. Let PT_i denote the pseudo-tree constructed for paths $P_1, \ldots, P_i$, and PT_0 consists of a single vertex s. PT_{i+1} is constructed by inserting P_{i+1} into PT_i by sharing the longest prefix; let d be the last vertex of the shared prefix, it is called the deviation vertex of P_{i+1} from PT_i. For example, Fig. 2 shows PT_1, PT_2, and PT_3, where PT_3 is constructed by inserting path (v_1, v_3, v_7, t) into PT_2, and v_3 is the deviation vertex.

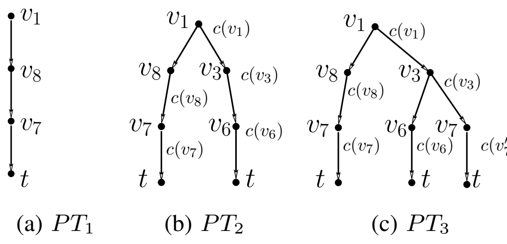

Figure 2: pseudo-trees

Candidate Path. Given a pseudo-tree PT_i, the DA algorithm maintains a set C_i of candidate paths, one corresponding to each vertex u in PT_i, denoted $c(u)$, which is *the shortest one among all paths from s to t that takes the path from s to u in PT_i as prefix and contains none of the outgoing edges of u in PT_i.* For example, in Fig. 2(c), $c(v_3)$ is the shortest one among all paths from s to t that take edge (v_1, v_3) as prefix and contain neither (v_3, v_6) nor (v_3, v_7); thus $c(v_3) = (v_1, v_3, v_5, v_6, t)$, and $C_3 = \{c(v_1), c(v_8), c(v_7), c(v_3), c(v_6), c(v_7')\}$.

Lemma 3.1: *[28]. Given a pseudo-tree PT_i and the corresponding C_i of candidate paths, the $(i+1)$-th shortest path from s to t is the path in C_i with shortest length.* □

Following from Lemma 3.1, the pseudocode of processing a KPJ query using DA is shown in Alg. 1, which is self-explanatory. The ingredient of Alg. 1 is to incrementally maintain PT_i and C_i after choosing each of the top-k paths.

```
Algorithm 1: DA($G_Q, Q' = \{s, t, k\}$)
1 Initialize $PT_0$ to contain a single vertex $s$;
2 Compute the shortest path $c(s)$ from $s$ to $t$, and $C_0 = \{c(s)\}$;
3 for each $i \leftarrow 1$ to $k$ do
4     $P_i \leftarrow$ the path in $C_{i-1}$ with the shortest length;
5     Construct $PT_i$ by inserting $P_i$ into $PT_{i-1}$, and let $d$ be the
      deviation vertex;
6     Construct $C_i$ by removing $P_i$ from $C_{i-1}$, computing the
      candidate paths corresponding to vertices in $P_i$ from $d$ to $t$, and
      inserting them into $C_{i-1}$;
7 return the $k$ paths $P_1, \ldots, P_k$;
```

Example 3.1: Fig. 2 demonstrates a running example for a KPJ query $Q = \{v_1, \text{“}H\text{''}, 3\}$ on the graph in Fig. 1. We first transform the graph G into G_Q, and reduce Q to a KSP query $Q' = \{v_1, t, 3\}$. The shortest path is $P_1 = (v_1, v_8, v_7, t)$ with length 5. After inserting P_1 into PT_0, the resulting PT_1 is shown in Fig. 2(a), where $C_1 = \{c(v_1), c(v_8), c(v_7)\}$. The 2nd shortest path is computed as $P_2 = c(v_1) = (v_1, v_3, v_6, t)$ which has the shortest length in C_1, and PT_2 is shown in Fig. 2(b). Then, candidate paths for v_1, v_3, v_6 are updated or computed, and $C_2 = \{c(v_8), c(v_7), c(v_1), c(v_3), c(v_6)\}$. The 3rd shortest path is $P_3 = c(v_3) = (v_1, v_3, v_7, t)$ with length 7. □

DA-SPT: Optimizations. The most time-consuming part of DA (Alg. 1) is Line 6, which needs to compute $O(k \cdot n)$ candidate paths in total. To efficiently compute a candidate path, several optimization techniques have been recently proposed [14, 24]. Pascoal [24] observes that, when computing $c(u)$ for u in a pseudo-tree PT, if the path formed by concatenating, 1) the path from s to u in PT, 2) an edge (u, v) in G_Q, and 3) the shortest path from v to t in G_Q, is simple, then it is $c(u)$. By preprocessing G_Q to generate a shortest path tree (SPT) storing shortest paths from all nodes to t, the path described above, if exists, can be found in constant time; otherwise, a shortest path algorithm is run to compute $c(u)$. Gao et al. [14, 15] improve Pascoal's approach by iteratively testing the above property during running Dijkstra's algorithm [11], and obtaining $c(u)$ once a simple path is found; this is known as the state-of-the-art approach, denoted DA-SPT, since a full SPT is built online.

Deficiencies of DA and DA-SPT. Both DA and DA-SPT are inefficient for processing KPJ queries due to the following three reasons. 1) Firstly, both need to compute $O(k \cdot n)$ candidate paths which are computed by iteratively extending all prefixes of the obtained l-th ($l < k$) shortest path; this is time-consuming. 2) Secondly, for processing a KPJ query using KSP techniques, the edges added to connect nodes in V_T to the virtual destination node depend on queries; this makes the existing index structures [7, 10] for efficiently computing shortest paths inapplicable. Thus, the candidate paths are computed by traversing the graph exhaustively, which is very costly. 3) Thirdly, although DA-SPT, compared to DA, can compute candidate paths more efficiently, it is time-consuming to construct the full SPT, which may be the dominating cost especially when the k shortest paths are short.

4. A BEST-FIRST APPROACH

In this section, to remedy the deficiencies of using the existing KSP techniques to process KPJ queries, we adopt a best-first paradigm which significantly reduces the number of shortest path computations thus enables fast query processing. In the following, we first discuss the paradigm, and then give an implementation of a best-first approach.

4.1 Best-First Paradigm

Given a KPJ query $Q = \{s, T, k\}$, let $\mathcal{P}_{s,T}(G)$ denote the set of all paths in G from s to category T (i.e., to any node in V_T). When the context is clear, $\mathcal{P}_{s,T}(G)$ is abbreviated to $\mathcal{P}$. Then, the query Q is to find the k paths in $\mathcal{P}$ with shortest lengths. Note that the size of $\mathcal{P}$ can be exponential to n.

Search Space and Subspace. The general idea is that we regard $\mathcal{P}$ as the entire search space $\mathcal{S}_0$. Then, the k paths in $\mathcal{P}$ with shortest lengths can be found by recursively dividing a subspace (initially $\mathcal{S}_0$) into smaller subspaces and computing the shortest path in each newly obtained subspace.

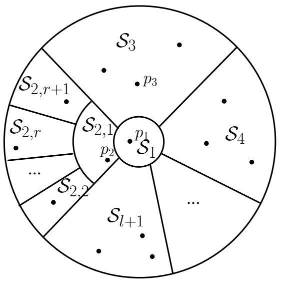

Figure 3: Overview of search space division

Before diving into the details, we first explain the main idea which is illustrated in Fig. 3. We conceptualize each path in $\mathcal{P}$ as a point, whose distance to the center (i.e., the origin) indicates the length of the path. Thus, the k paths with shortest lengths correspond to the k points closest to the center which can be computed as follows. First, we compute the closest point $P_1 = (v_1, \ldots, v_l)$ in the entire search space $\mathcal{S}_0 = \mathcal{P}$. Second, we divide $\mathcal{S}_0$ into $l+1$ subspaces, $\mathcal{S}_1, \mathcal{S}_2, \ldots, \mathcal{S}_l, \mathcal{S}_{l+1}$. Here, $\mathcal{S}_1$ consists of only P_1 and is excluded from further considerations. Each of the remaining subspaces, $\mathcal{S}_2, \ldots, \mathcal{S}_{l+1}$, represents the set of paths of $\mathcal{P}$ that share exactly the prefix of P_1 from v_1 to v_{i-1}; consequently, $\mathcal{S}_i \neq \mathcal{S}_j, \forall i \neq j$, and $\bigcup_{i=1}^{l+1} \mathcal{S}_i = \mathcal{S}_0$. Third, we compute the closest point in each of the l subspace, $\mathcal{S}_2, \ldots, \mathcal{S}_{l+1}$, and the one that is closest to the center among the l closest points represents the 2nd shortest path. Let it be $P_2 = (v'_1, \ldots, v'_r)$, and assume it is in $\mathcal{S}_2$. Fourth, we further divide $\mathcal{S}_2$ into $r+1$ subspaces, $\mathcal{S}_{2,1}, \mathcal{S}_{2,2}, \ldots, \mathcal{S}_{2,r}, \mathcal{S}_{2,r+1}$, and compute the closest point in each of them, where $\mathcal{S}_{2,1}$ consists of only P_2 and is excluded from further considerations. Thus, the point that is closest to the center among closest points in all subspaces $\mathcal{S}_3, \cdots, \mathcal{S}_{l+1}, \mathcal{S}_{2,2}, \ldots, \mathcal{S}_{2,r+1}$ represents the 3rd shortest path. We can repeat this process until k shortest paths are computed.

<u>Subspace Division.</u> We formally define a subspace below.

Definition 4.1: A ***subspace*** $\mathcal{S}$ is represented by a tuple $\langle P_{s,u}, X_u \rangle$, where $P_{s,u}$ is a path from s to u and X_u is a subset of the outgoing edges of u. It consists of all paths in $\mathcal{P}$ that *take* $P_{s,u}$ as prefix and *exclude* all edges of X_u. □

The entire search space $\mathcal{S}_0 (= \mathcal{P})$ is represented by $\langle P_{s,s} = (s), X_s = \emptyset \rangle$. Assume the shortest path in subspace $\langle P_{s,u}, X_u \rangle$ is P, then after choosing P as one of the k shortest paths, the subspace is divided into $l+1$ subspaces, where l is the number of nodes in the subpath of P from u to the destination node. The $l+1$ subspaces consist of a subspace containing only P, a subspace corresponding to node u (i.e., subspace $\langle P_{s,u}, X_u \cup \{(u,w)\} \rangle$), and one subspace corresponding to each node v in the subpath of P from u (exclusive) to the destination node (i.e., subspace $\langle P_{s,v}, \{(v,w')\} \rangle$), where $P_{s,v}$ is the prefix of P to v, and (u,w) and (v,w') are edges in P. It is important to note that the $l+1$ subspaces are disjoint, and their union is the original subspace $\langle P_{s,u}, X_u \rangle$ from which they are divided.

Example 4.1: Consider a KPJ query $Q = \{v_1, \text{“}H\text{”}, 2\}$ on the graph in Fig. 1. Initially, $\mathcal{S}_0 = \langle (v_1), \emptyset \rangle$ in which the shortest path is $P_1 = (v_1, v_8, v_7)$. Then, $\mathcal{S}_0$ is divided into four subspaces, $\mathcal{S}_1 = \{P\}$, $\mathcal{S}_2 = \langle (v_1), \{(v_1, v_8)\} \rangle$, $\mathcal{S}_3 = \langle (v_1, v_8), \{(v_8, v_7)\} \rangle$, and $\mathcal{S}_4 = \langle (v_1, v_8, v_7), \emptyset \rangle$, where $\mathcal{S}_1$ is the subspace containing only P_1. The 2nd shortest path is the one with shortest lengths among shortest paths in $\mathcal{S}_2, \mathcal{S}_3, \mathcal{S}_4$. □

Paradigm. It is easy to verify that there is a one-to-one correspondence between candidate paths defined in Section 3 and subspaces defined above. In the deviation paradigm, subspaces are implicitly maintained by storing candidate paths based on the fact that *each candidate path is the shortest path in a subspace*. Considering that shortest paths are expensive to compute, we remedy the deficiency of deviation paradigm by computing lower bounds of subspaces and pruning subspaces based on their lower bounds.

Definition 4.2: For a subspace $\mathcal{S} = \langle P_{s,u}, X_u \rangle$, we define the ***lower bound of a subspace***, denoted $\mathsf{lb}(\mathcal{S})$ (or $\mathsf{lb}(P_{s,u}, X_u)$), as the lower bound of lengths of all paths in $\mathcal{S}$, and denote the ***shortest path in a subspace*** by $\mathsf{sp}(\mathcal{S})$ (or $\mathsf{sp}(P_{s,u}, X_u)$). □

Based on lower bounds of subspaces, the best-first paradigm is shown in Alg. 2. Instead of directly computing the shortest path for each newly obtained subspace, we compute its lower bound first. All obtained subspaces and their lower bounds are maintained in a minimum priority queue $\mathcal{Q}$. Each entry of $\mathcal{Q}$ is a triple $\langle \mathcal{S}, \mathsf{lb}(\mathcal{S}), P \rangle$, where $\mathcal{S}$ and $\mathsf{lb}(\mathcal{S})$ are a subspace and its lower bound, respectively, and P is either $\emptyset$ or the shortest path in $\mathcal{S}$. Subspaces in $\mathcal{Q}$ are ranked by their lower bounds. Initially, $\mathcal{Q}$ contains a single entry representing the entire search space $\mathcal{S}_0$ (Line 1). Then, we iteratively remove the subspace with smallest lower bound from $\mathcal{Q}$, denoted $\langle \mathcal{S}, \mathsf{lb}(\mathcal{S}), P \rangle$ (Line 4): if $P \neq \emptyset$, then P is the

Algorithm 2: BestFirst$(G, Q = \{s, T, k\})$

```
1  Initialize a minimum priority queue $\mathcal{Q}$ to contain a single entry
   $\langle \mathcal{S}_0 = \langle (s), \emptyset \rangle, \mathsf{lb}(\mathcal{S}_0), \emptyset \rangle$;
2  $i \leftarrow 1$;
3  while $i \leq k$ do
4      $\langle \mathcal{S} = \langle P_{s,u}, X_u \rangle, \mathsf{lb}(\mathcal{S}), P \rangle \leftarrow$ remove the top entry from $\mathcal{Q}$;
5      if $P \neq \emptyset$ then
6          $P_i \leftarrow P$; $i \leftarrow i + 1$;
7          for each node $v$ in the subpath of $P$ from $u$ to the destination node do
8              Create a subspace $\mathcal{S}' = \langle P_{s,v}, X_v \rangle$;
9              $\mathsf{lb}(\mathcal{S}') \leftarrow \max\{\mathsf{CompLB}(P_{s,v}, X_v), \omega(P)\}$;
10             Put $\langle \mathcal{S}', \mathsf{lb}(\mathcal{S}'), \emptyset \rangle$ into $\mathcal{Q}$;
11     else
12         $\mathsf{sp}(\mathcal{S}) \leftarrow \mathsf{CompSP}(P_{s,u}, X_u)$;
13         if $\mathsf{sp}(\mathcal{S}) \neq \emptyset$ then Put $\langle \mathcal{S}, \omega(\mathsf{sp}(\mathcal{S})), \mathsf{sp}(\mathcal{S}) \rangle$ into $\mathcal{Q}$;
14 return the $k$ paths $P_1, \ldots, P_k$;
```

next shortest path to be output (Line 6), and we divide $\mathcal{S}$ by P and put those newly obtained subspaces into $\mathcal{Q}$ (Lines 7-10); otherwise, we compute the shortest path in $\mathcal{S}$ and put $\mathcal{S}$ into $\mathcal{Q}$ again with the computed shortest path (Lines 12-13). We will present an implementation of computing lower bound of a subspace and shortest path in a subspace in the next subsection.

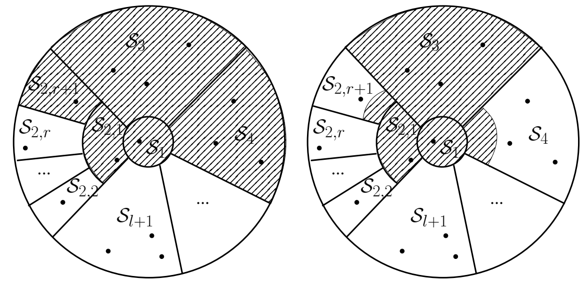
Lemma 4.1: *The set of shortest paths computed in Alg. 2 is a subset of that computed in Alg. 1; thus, the number of shortest path computations in Alg. 2 is not larger than that in Alg. 1. Assume that computing lower bound takes less time than computing shortest path for a subspace, then the time complexity of Alg. 2 is not larger than that of Alg. 1.* □

Proof Sketch: We prove the first part of Lemma 4.1 by proving that there is a one-to-one correspondence between subspaces inserted into $\mathcal{Q}$ in Alg. 2 and candidate paths computed in Alg. 1. This can be proved by induction. For $k = 1$, this is true, since there is only one subspace and one candidate path in Alg. 2 and Alg. 2, respectively. Now, we assume that this holds for general $k \geq 1$, then we prove that it also holds for $(k + 1)$. Since the k-th shortest path P_k corresponds to subspace $\mathcal{S}$ in Alg. 2, to obtain the $(k+1)$-th shortest path, we generate $O(n)$ new candidate paths from P_k in Alg. 1 and $O(n)$ new subspaces from $\mathcal{S}$ in Alg. 2; moreover, there is a one-to-one correspondence between these newly generated subspaces and newly generated candidate paths. Thus, there is a one-to-one correspondence between subspaces inserted into $\mathcal{Q}$ in Alg. 2 and candidate paths computed in Alg. 1. Considering that we compute shortest paths only for a subset of the subspaces inserted into $\mathcal{Q}$, the first part of the lemma holds.

Moreover, if we set all lower bounds computed at Line 9 of Alg. 2 to be 0, then the number of shortest path computations in Alg. 2 is the same as that in Alg. 1.

Second, in Alg. 2, any subspace is inserted into $\mathcal{Q}$ at most twice: once with computed lower bound (i.e., $P = \emptyset$), and once with computed shortest path. Thus, given that computing lower bound takes less time than computing shortest path for a subspace, the time complexity of Alg. 2 is not larger than that of Alg. 1. □

Following the proof of Lemma 4.1, we can also see that the maximum size of $\mathcal{Q}$ in Alg. 2 is $O(k \cdot n)$; moreover, given any algorithm computing a lower bound of a subspace, Alg. 2 correctly processes a KPJ query. Let P_k be the k-th shortest path for a KPJ query. Obviously, Alg. 2 does not compute shortest paths in subspaces whose lower bounds are larger than $\omega(P_k)$. Note that, in contrast, Alg. 1 needs to compute shortest paths in all subspaces in $\mathcal{Q}$. Conceptually, Fig. 4(a) shows by shadow the subspaces in which the shortest paths are computed: Alg. 2 computes only 5 shortest paths instead of $l + r + 2$ which is done by Alg. 1.



(a) Best First (b) Iteratively Bounding

Figure 4: Instances of shortest path computations

4.2 An Implementation of BestFirst

In the following, we present efficient techniques for computing a lower bound of a subspace (CompLB at Line 9 of Alg. 2) and for computing the shortest path in a subspace (CompSP at Line 12 of Alg. 2), denote the approach as BestFirst.

Algorithm 3: CompLB$(P_{s,u}, X_u)$

```
1  $lb \leftarrow +\infty$;
2  for each outgoing edge $(u, v)$ of $u$ do
3      if $v \notin P_{s,u}$ and $(u, v) \notin X_u$ then
4          Compute $\mathsf{lb}(v, V_T)$;
5          $lb \leftarrow \min\{lb, \omega(P_{s,u}) + \omega(u, v) + \mathsf{lb}(v, V_T)\}$;
6  return $lb$;
```

Computing Lower Bound of a Subspace. Given a subspace $\mathcal{S} = \langle P_{s,u}, X_u \rangle$, the set of paths in it corresponds to the set of paths from s to any node in V_T in a subgraph G' of G obtained as follows. We first remove all edges of X_u from G, and then for each node $v (\neq u)$ in $P_{s,u}$, we remove from G all outgoing edges of v except the one that is in $P_{s,u}$. Thus, for any two nodes u and v, the shortest distance from u to v in G' is lower bounded by that in G. Consequently, a naive lower bound of $\mathcal{S}$ is $\omega(P_{s,u}) + \mathsf{lb}(u, V_T)$, where $\mathsf{lb}(u, V_T)$ is the lower bound of shortest distance from u to any node in V_T, whose computation shall be discussed shortly. However, this is loose considering that many outgoing edges of u (i.e., X_u) are removed from G. Therefore, to estimate the lower bound of $\mathcal{S}$ (i.e., the shortest distance from s to any node in V_T in G') more accurately, we consider all valid outgoing edges (u, v) of u (i.e., $v \notin P_{s,u}$ and $(u, v) \notin X_u$), and choose the minimum estimation. The pseudocode is shown in Alg. 3 which is self-explanatory, and its correctness immediately follows from the above discussions.

Example 4.2: Continuing Example 4.1. After dividing $\mathcal{S}_0$ into $\mathcal{S}_1, \cdots, \mathcal{S}_4$, lower bounds of $\mathcal{S}_2, \mathcal{S}_3, \mathcal{S}_4$ are computed. Here, we illustrate how to compute $\mathsf{lb}(\mathcal{S}_2) = \mathsf{lb}((v_1), \{(v_1, v_8)\})$. v_1 has three valid outgoing edges, (v_1, v_2), (v_1, v_3), and (v_1, v_{11}), that can be considered for lower bound estimation. Thus, $\mathsf{lb}(\mathcal{S}_2)$ is computed as $\min\{\omega(v_1, v_2) + \mathsf{lb}(v_2, V_T), \omega(v_1, v_3) + \mathsf{lb}(v_3, V_T), \omega(v_1, v_{11}) + \mathsf{lb}(v_{11}, V_T)\}$. □

Computing $\mathsf{lb}(u, V_T)$. We propose a landmark-based approach [16] to estimating $\mathsf{lb}(u, V_T)$ in the following. Note that, the computation of $\mathsf{lb}(u, V_T)$ has not been studied in the literature.

A *landmark* is a subset of nodes, $L \subseteq V$. With L, the lower bound $\mathsf{lb}(u,v)$ of shortest distance from u to v is estimated as, $\mathsf{lb}(u,v) \doteq \max_{w\in L}\{\delta(w,v) - \delta(w,u)\}$, [1] where $\delta(w,v)$ and $\delta(w,u)$ are the shortest distance from w to v and to u, respectively, and are precomputed. This estimation is based on the fact that $\delta(w,u) + \delta(u,v) \geq \delta(w,v)$. Then, $\mathsf{lb}(u,V_T)$ can be estimated as,

$$\begin{aligned}\mathsf{lb}(u,V_T) &\doteq \min_{v\in V_T}\{\mathsf{lb}(u,v)\} \\ &= \min_{v\in V_T}\max_{w\in L}\{\delta(w,v) - \delta(w,u)\}\end{aligned} \quad (1)$$

However, the computation time is $O(|L|\cdot|V_T|)$ which is too costly especially when V_T is large. Therefore, motivated by the transformed graph G_Q in Section 3, we propose a new lower bound as follows,

$$\begin{aligned}\mathsf{lb}(u,V_T) &\doteq \max_{w\in L}\min_{v\in V_T}\{\delta(w,v) - \delta(w,u)\} \\ &= \max_{w\in L}\{\min\{\delta(w,v) \mid v\in V_T\} - \delta(w,u)\}\end{aligned} \quad (2)$$

The intuition is that, $\min\{\delta(w,v) \mid v \in V_T\}$ is the shortest distance from w to t in G_Q (i.e., $\delta(w,t)$); thus, Eq. (2) estimates $\mathsf{lb}(u,t)$. Consequently, $\mathsf{lb}(u,V_T)$ can be computed in $O(|L|)$ time by precomputing $\delta(w,t)$ for all $w \in L$ prior to any lower bound estimations. In what follows, we use Eq. (2) to compute $\mathsf{lb}(u,V_T)$.

Remarks & Time Complexity. Note that, the landmark index L is constructed offline in $O(|L|(m + n\log n))$ time where $O(m + n\log n)$ is the time complexity of a shortest path algorithm, while its space complexity is $O(|L|\cdot n)$. At the initialization phase of query processing, we compute $\delta(w,t)$ which is query dependent. The time complexity for computing $\delta(w,t)$ for all $w \in L$ is $O(|L|\cdot|V_T|)$; note that this is only computed once for each query.

Therefore, the time complexity of lower bound computation (i.e., Alg. 3) is $O(d(u)|L|)$ where $d(u)$ is the degree of u in G, since we traverse at most $d(u)$ edges at Line 2 while computing each $\mathsf{lb}(v,V_T)$ takes $O(|L|)$ time.

Computing Shortest Path in a Subspace. We use A* search [16] to compute $\mathsf{sp}(P_{s,u},X_u)$, denoted CompSP. In A* search, we consider only the valid edges (same as Line 3 of Alg. 3), and use Eq. (2) to estimate the shortest distance to destination. We omit the pseudocode.

Example 4.3: Continuing Example 4.2, after dividing $\mathcal{S}_0$, $\mathcal{Q}$ contains three subspaces, $\mathcal{S}_2, \mathcal{S}_3, \mathcal{S}_4$, together with their lower bounds. Assume the lower bounds are $\mathsf{lb}(\mathcal{S}_2) = 6$, $\mathsf{lb}(\mathcal{S}_3) = 11$, and $\mathsf{lb}(\mathcal{S}_4) = 12$. $\mathcal{S}_2$ has the smallest lower bound, and is removed from $\mathcal{Q}$. Then, $\mathsf{sp}(\mathcal{S}_2)$ is computed, which is the 2nd shortest path P_2, since its length is smaller than lower bounds of subspaces in $\mathcal{Q}$. Here, we compute the 2nd shortest path without computing shortest paths in subspaces $\mathcal{S}_3$ and $\mathcal{S}_4$. □

5. AN ITERATIVELY BOUNDING APPROACH

In this section, following the best-first paradigm in Section 4, we propose a new iteratively bounding approach to iteratively "guessing" and tightening lower bounds for subspaces in Section 5.1. Moreover, we propose two online-built indexes, in Section 5.2 and Section 5.3, respectively, based on which we can reduce the exploration area of a graph dramatically in tightening lower bounds.

5.1 Iteratively Bounding

In BestFirst, we prune subspaces whose lower bounds are larger than $\omega(P_k)$, where P_k is the k-th shortest path for a KPJ query. Therefore, BestFirst will run fast if we can prune more subspaces based on their lower bounds (i.e., by computing tighter/larger lower bounds for subspaces), considering that computing shortest path is time-consuming. However, in general, computing a tighter lower bound takes longer time, and in the extreme case computing the shortest path in a subspace provides the tightest lower bound. In Alg. 3, we present a light-weight lower bound estimation by considering only the immediate neighbors of u. Intuitively, we can compute a tighter lower bound by exploring multi-hop neighbors of u (e.g., neighbors of neighbors).

We propose to guess and tighten lower bounds of subspaces in a controlled manner by a threshold τ, which is achieved by a procedure TestLB. In a nutshell, given a subspace $\mathcal{S}$ and a threshold τ, TestLB tests whether the shortest path in $\mathcal{S}$ has a length larger than τ: if it is, then the lower bound is set as τ; otherwise, the shortest path $\mathsf{sp}(\mathcal{S})$ is obtained and returned. Details of TestLB will be discussed shortly. Ideally, we can set τ as $\omega(P_k)$, then all subspaces whose lower bounds are larger than $\omega(P_k)$ are pruned with the least amount of effort; however, P_k is unknown. Considering that TestLB takes longer time for a larger τ, we iteratively enlarge τ, and the k shortest paths of a KPJ query will be found once τ becomes no smaller than $\omega(P_k)$.

Algorithm 4: IterBound$(G, Q = \{s,T,k\})$
```
1  Compute the shortest path $P'$ from $s$ to any node in $V_T$ in $G$;
2  Initialize a minimum priority queue $\mathcal{Q}$ to contain a single entry
   $\langle \mathcal{S}_0 = \langle (s), \emptyset\rangle, \omega(P'), P'\rangle$;
3  $i \leftarrow 1$; $\tau \leftarrow \omega(P')$;
4  while $i \leq k$ do
5      $\langle \mathcal{S} = \langle P_{s,u}, X_u\rangle, \mathsf{lb}(\mathcal{S}), P\rangle \leftarrow$ remove the top entry from $\mathcal{Q}$;
6      if $P \neq \emptyset$ then
7          Same as Lines 6-10 of Alg. 3;   /* $P_i \leftarrow P$, $i \leftarrow i+1$,
           and divide $\mathcal{S}$ into subspaces */;
8      else
9          $\tau \leftarrow \alpha\cdot\max\{\mathsf{lb}(\mathcal{S}), \mathcal{Q}.top().key\}$; /* Enlarge $\tau$ */;
10         $P \leftarrow$ TestLB$(P_{s,u}, X_u, \tau)$;
11         if $P \neq \emptyset$ then Put $\langle \mathcal{S}, \omega(P), P\rangle$ into $\mathcal{Q}$;
12         else Put $\langle \mathcal{S}, \tau, \emptyset\rangle$ into $\mathcal{Q}$;
13 return the $k$ paths $P_1, \ldots, P_k$;
```

The algorithm IterBound is given in Alg. 4, which is similar to Alg. 2. We first compute the shortest path P' in G (Line 1), put subspace $\mathcal{S}_0 = \langle (s), \emptyset\rangle$ with path P' into $\mathcal{Q}$ (Line 2), and initialize τ as $\omega(P')$ (Line 3). Then, we iteratively remove the subspace $\mathcal{S}$ with smallest lower bound, together with path P, from $\mathcal{Q}$ (Line 5). If P is not empty, then it is the next shortest path P_i, and we perform the same subspace division as Lines 6-10 of Alg. 2. Otherwise, we enlarge τ (Line 9), test whether the shortest path of $\mathcal{S}$ has a distance larger than τ (Line 10), and put $\mathcal{S}$ back into $\mathcal{Q}$ together with either the computed shortest path P or a larger lower bound τ depending on what TestLB returns (Lines 11-12).

Note that τ controls the computation of a tighter lower bound which we want to make larger but a larger τ will make TestLB slow. In our approach, we use a parameter α to control the speed of increasing τ iteratively. Here, α can be any real number larger than 1, and we use $\alpha = 1.1$ as default. At Line 9, we enlarge τ as $\alpha\cdot\max\{\mathsf{lb}(\mathcal{S}), \mathcal{Q}.top().key\}$, where $\mathcal{Q}.top().key$ is the key value (i.e., lower bound) in the top entry of $\mathcal{Q}$ and is defined to be $+\infty$ if $\mathcal{Q} = \emptyset$. The intuition is that, $\omega(P_k)$ should be not much larger than $\omega(P_1)$, the initial τ (Line 3). Note that $\mathsf{lb}(\mathcal{S})$ is the previous τ we have tested for $\mathcal{S}$; thus, the lower bound τ we tested for a subspace increases by a factor of at least α. Therefore, we iteratively enlarge τ from $\omega(P_1)$ to approach $\omega(P_k)$, and obtain the k shortest paths for a KPJ query once τ becomes no smaller than $\omega(P_k)$.

[1]Note that this triangle inequality holds for the shortest distances based on any distance metrics not only Euclidean distance. Thus, our techniques work for general graphs.

Theorem 5.1: *Given* TestLB*,* IterBound *correctly computes k shortest paths for a* KPJ *query.* □

Proof Sketch: IterBound follows the best-first paradigm of Alg. 2, except that we iteratively compute lower bounds of subspaces. Moreover, it is easy to prove that the lower bound τ computed for the same subspace $\mathcal{S}$ at Line 9 is strictly increasing (assuming that $\alpha > 1$). Therefore, let P_i be the correct i-th shortest path, we can prove that τ will be no less than $\omega(P_i)$ when the algorithm terminates, and once τ becomes no less than $\omega(P_i)$, the path P_i will be computed and inserted into $\mathcal{Q}$, thus will be output. □

IterBound acts the same as BestFirst if we set τ as $+\infty$. Nevertheless, by iteratively enlarging τ with an initial value $\omega(P_1)$, IterBound runs much faster than BestFirst by pruning more subspaces. Conceptually, Fig. 4(b) shows the subspaces in which the shortest paths are computed by IterBound. Compared to Fig. 4(a), $\mathcal{S}_4$ and $\mathcal{S}_{2,r+1}$ are pruned based on their tighter lower bounds that are computed by TestLB. The shadow areas of $\mathcal{S}_4$ and $\mathcal{S}_{2,r+1}$ in Fig. 4(b) indicate the exploration areas of TestLB in testing lower bounds.

Testing Lower Bound. TestLB tests whether the shortest path in a subspace has length larger than a given threshold τ. This is achieved by considering multi-hop neighbors of u, denoted V'. Given τ, V' are those nodes v with $\delta_{\mathcal{S}}(s,v)+\mathsf{lb}(v,V_T) \leq \tau$, where $\delta_{\mathcal{S}}(s,v)$ is the shortest distance from s to v constrained in $\mathcal{S}$ (i.e., G' defined in Section 4.2). After obtaining V', if $\mathsf{V}' \cap V_T = \emptyset$ then $\omega(\mathsf{sp}(\mathcal{S})) > \tau$, otherwise, $\mathsf{sp}(\mathcal{S})$ is obtained by backtracking from $\mathsf{V}' \cap V_T$.

Algorithm 5: TestLB($P_{s,u}, X_u, \tau$)

```
1  Initialize a minimum-priority queue $\mathcal{Q}_V$ to contain $\langle u, 0\rangle$;
2  $d_s(u) \leftarrow \omega(P_{s,u})$, and $d_s(v) \leftarrow +\infty$ for all other nodes;
3  while $\mathcal{Q}_V \neq \emptyset$ do
4      $v \leftarrow$ remove the top node from $\mathcal{Q}_V$;
5      if $v \in V_T$ then return the path formed by concatenating $P_{s,u}$
       with the computed shortest path from $u$ to $v$;
6      else for each outgoing edge $(v,w)$ of $v$ do
7          if $w \notin P_{s,u}, (v,w) \notin X_u$ and $d_s(v) + \omega(v,w) < d_s(w)$
           then
8              $d_s(w) \leftarrow d_s(v) + \omega(v,w)$;
9              Compute $\mathsf{lb}(w, V_T)$;
10             if $d_s(w) + \mathsf{lb}(w,V_T) \leq \tau$ then
11                 Put $\langle w, d_s(w) + \mathsf{lb}(w,V_T)\rangle$ into $\mathcal{Q}_V$;
12 return $\emptyset$;
```

The pseudocode of TestLB is shown in Alg. 5, which is similar to A* search [16], where $d_s(v)$ stores the length of a path from s to v constrained in $\mathcal{S}$. We maintain the explored nodes together with their estimated distances (i.e., node v with $d_s(v) + \mathsf{lb}(v,V_T)$) in a minimum-priority queue $\mathcal{Q}_V$, which is initialized to contain u; nodes in $\mathcal{Q}_V$ are ranked by their estimated distances. Then, nodes are iteratively removed from $\mathcal{Q}_V$ (Line 4), and their neighbors are inserted into $\mathcal{Q}_V$ (Lines 6-11), until $\mathcal{Q}_V = \emptyset$ or we get a node from V_T; the latter case implies that $\mathsf{sp}(\mathcal{S})$ has been computed (Line 5). Here, V' is the set of nodes removed from $\mathcal{Q}_V$. Note that, following from [16], when a node v is removed from $\mathcal{Q}_V$, $d_s(v)$ stores the shortest distance from s to v constrained in $\mathcal{S}$ (i.e., $\delta_{\mathcal{S}}(s,v)$), and each node is removed from $\mathcal{Q}_V$ at most once.

The efficiency of TestLB is due to that, we only put into $\mathcal{Q}_V$ those nodes whose estimated distance are not larger than τ, as ensured by Line 10, which prunes a lot of nodes especially for a small τ.

Lemma 5.1: *Given a subspace $\mathcal{S}$ and τ,* TestLB *returns* $\mathsf{sp}(\mathcal{S})$ *if* $\omega(\mathsf{sp}(\mathcal{S})) \leq \tau$*, and returns $\emptyset$ otherwise.* □

Proof Sketch: First of all, we remark that if we remove Lines 9-10 from Alg. 5, then it is the same as the A* search algorithm [16] that computes the shortest path in $\mathcal{S}$. Thus, if $\omega(\mathsf{sp}(\mathcal{S})) \leq \tau$, then TestLB returns $\mathsf{sp}(\mathcal{S})$, since every node that is pruned at Line 10 will not be in $\mathsf{sp}(\mathcal{S})$ due to the nature of lower bound.

Secondly, we prove that if $\omega(\mathsf{sp}(\mathcal{S})) > \tau$, then TestLB returns $\emptyset$. The reason is that, for every node v obtained at Line 4 of Alg. 5, we have $d_s(v) \leq \tau$ due to the pruning at Line 10. Thus, Alg. 5 cannot find the path $\mathsf{sp}(\mathcal{S})$, and returns $\emptyset$. □

Time Complexity. The time complexity of Alg. 5 is $O(m'+n' \log n')$, where n' and m' are the number of visited nodes and edges in Alg. 5 (specifically, at Line 6), respectively. In the worst case, $n' = n$ and $m' = m$; thus the time complexity is $O(m + n \log n)$. However, in practice, n' and m' are usually small and much smaller than n and m, respectively.

Example 5.1: First, let's consider TestLB($(v_1, v_3), \{(v_3, v_6)\}, 6$). v_3 has three valid out-neighbors, v_4, v_5, v_7. v_4 and v_7 are pruned because $d_{v_1}(v_3) + \omega(v_3,v_4) > 6$ and $d_{v_1}(v_3) + \omega(v_3,v_7) > 6$. Assume $\mathsf{lb}(v_5, V_T) = 2$, then v_5 is also pruned since $d_{v_1}(v_3) + \omega(v_3,v_5)+\mathsf{lb}(v_5,V_T) = 7$. Thus, TestLB($(v_1,v_3), \{(v_3,v_6)\}, 6$) returns $\emptyset$. Now, let's consider $\tau = 7$. Among the three valid out-neighbors, v_4 is pruned because $d_{v_1}(v_3) + \omega(v_3,v_4) = 8$; v_5 and v_7 are put into $\mathcal{Q}_V$ with lower bounds 7. Then, v_5 is removed from $\mathcal{Q}_V$, and its out-neighbor, v_6, is put into $\mathcal{Q}_V$ with lower bound 7. After that, either v_6 or v_7 is removed from $\mathcal{Q}_V$, and the shortest path in $\langle (v_1, v_3), \{(v_3, v_6)\}\rangle$ is obtained. □

5.2 Partial Shortest Path Tree

Motivated by DA-SPT, in this subsection we propose to compute and store a partial SPT, denoted $\mathsf{SPT_P}$, which provides a more accurate estimation of $\mathsf{lb}(v,V_T)$. Recall that $\mathsf{lb}(v,V_T)$ is used in TestLB to prune nodes, thus a more accurate estimation of TestLB will result in faster computation time. In contrast to DA-SPT which online constructs a full SPT by incurring high overheads, we obtain $\mathsf{SPT_P}$ as a by-product of computing the shortest path in G (i.e., Line 1 of Alg. 4) without any extra cost.

Algorithm 6: PartialSPT(G, s, T)

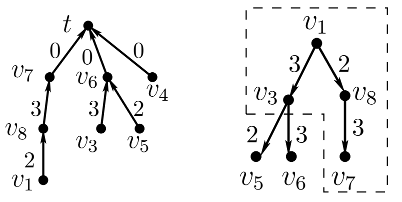
```
1  Initialize an empty minimum-priority queue $\mathcal{Q}_T$;
2  $\mathsf{SPT_P} \leftarrow$ a virtual root node $t$;        /* Build SPT_P */;
3  for each $w \in V_T$ do
4      Put $\langle w, \mathsf{lb}(s,w)\rangle$ into $\mathcal{Q}_T$, $d_t(w) \leftarrow 0, p(w) \leftarrow t$;
5  while $\mathcal{Q}_T \neq \emptyset$ do
6      $v \leftarrow$ remove the top node from $\mathcal{Q}_T$;
7      Add $v$ as a child of $p(v)$ to $\mathsf{SPT_P}$;  /* Build SPT_P */;
8      if $v = s$ then return the path from $s$ to $t$;
9      for each incoming edge $(w,v)$ of $v$ do
10         if $d_t(v) + \omega(w,v) < d_t(w)$ then
11             $d_t(w) \leftarrow d_t(v) + \omega(w,v), p(w) \leftarrow v$;
12             Put $\langle w, d_t(w) + \mathsf{lb}(s,w)\rangle$ into $\mathcal{Q}_T$;
```

The algorithm to construct $\mathsf{SPT_P}$ is given in Alg. 6, denoted PartialSPT, which is the A* search algorithm for computing the shortest path from s to any node in V_T in G by adding Lines 2,7. The algorithm runs in the reverse graph of G, since we want to compute shortest paths from different nodes to any node in V_T. $\mathcal{Q}_T$ is similar to $\mathcal{Q}_V$ in Alg. 5 and initially contains all nodes of V_T (Lines 3-4). Then, nodes are iteratively removed from $\mathcal{Q}_T$ (Line 6) and their incoming edges are explored (Lines 9-12). The shortest path from s to any node in V_T is obtained when s is removed from

$\mathcal{Q}_T$ (Line 8). For all nodes v removed from $\mathcal{Q}_T$, we add v as a child of $p(v)$ to $\mathsf{SPT_P}$. Intuitively, $\mathsf{SPT_P}$ contains all nodes removed from $\mathcal{Q}_T$ prior to s when computing the shortest path from s to any node in V_T.

Proposition 5.1: *For nodes $v \in \mathsf{SPT_P}$, the path from v to t in $\mathsf{SPT_P}$ is the shortest path from v to any node in V_T in G.* □

Computing $\mathsf{lb}(v, V_T)$ using $\mathsf{SPT_P}$. Both CompLB and TestLB, which are invoked by IterBound, require computing $\mathsf{lb}(v, V_T)$ for any $v \in V$. Eq. (2) computes $\mathsf{lb}(v, V_T)$ using a landmark-based approach. By utilizing $\mathsf{SPT_P}$, we can compute a more accurate $\mathsf{lb}(v, V_T)$ as follows. If v is in $\mathsf{SPT_P}$, then $\mathsf{lb}(v, V_T)$ is computed as the length of the path from v to t in $\mathsf{SPT_P}$, the correctness of which directly follows from Proposition 5.1; otherwise, it is computed by Eq. (2). Here, we give $\mathsf{SPT_P}$ a higher priority, because if $v \in \mathsf{SPT_P}$, then the lower bound computed using $\mathsf{SPT_P}$ is guaranteed to be not smaller than that by Eq. (2); for lower bound, the larger the better.



(a) $\mathsf{SPT_P}$ (b) $\mathsf{SPT_I}$

Figure 5: Partial and incremental SPT

Example 5.2: Fig. 5(a) shows the $\mathsf{SPT_P}$ constructed for $Q = \{v_1, \text{“}H\text{”}, 3\}$. For each node v in $\mathsf{SPT_P}$, its distance to t in $\mathsf{SPT_P}$ is the shortest distance from v to any node in V_T and can be used as an estimation of $\mathsf{lb}(v, V_T)$. For example, $\mathsf{lb}(v_3, V_T)$ is estimated as 3. □

IterBound-$\mathsf{SPT_P}$ Approach. We denote the approach that uses $\mathsf{SPT_P}$ to estimate $\mathsf{lb}(v, V_T)$ in Alg. 4 as IterBound-$\mathsf{SPT_P}$. The correctness of IterBound-$\mathsf{SPT_P}$ directly follows from that of IterBound and the above discussions.

5.3 Incremental Shortest Path Tree

$\mathsf{SPT_P}$ includes all nodes of V_T which can be large for a KPJ query, thus may take long time to construct. In this subsection, we propose an incremental SPT, denoted $\mathsf{SPT_I}$, by pruning nodes in V_T that are far-away from the source node s. Moreover, we incrementally enlarge $\mathsf{SPT_I}$, based on which we identify a new property for reducing the exploration area of a graph by TestLB.

Constructing $\mathsf{SPT_I}$. To prune from $\mathsf{SPT_I}$ those nodes in V_T that are far-away from s, in $\mathsf{SPT_I}$ we compute and store shortest paths from s to each node of a subset of V. Recall that, in $\mathsf{SPT_P}$, we store shortest paths from each node of a subset of V to V_T. Thus, the construction of $\mathsf{SPT_I}$ is run on G by starting from s, and consists of two phases. In the first phase, we construct an initial $\mathsf{SPT_I}$, which is a by-product of computing the shortest path from s to any node in V_T in a similar fashion to PartialSPT (i.e., Alg. 6) while running on G and starting from s; this is invoked at Line 1 of Alg. 4. In the second phase, we incrementally enlarge $\mathsf{SPT_I}$ by IncrementalSPT, which is invoked after Line 9 and before Line 10 of Alg. 4.

The pseudocode of IncrementalSPT is shown in Alg. 7, which is self-explanatory. The general idea is to include into $\mathsf{SPT_I}$ all nodes of V that are on paths from s to any node in V_T whose lengths are not larger than τ. Therefore, IncrementalSPT iteratively removes

Algorithm 7: IncrementalSPT(G, T, τ)

```
1 while $\mathcal{Q}_T.top().key \le \tau$ do
2     $v \leftarrow$ remove the top node from $\mathcal{Q}_T$;
3     Add $v$ as a child of $p(v)$ to $\mathsf{SPT_I}$;
4     if $v \in V_T$ then Add $v$ to $D$;
5     for each outgoing edge $(v, w)$ of $v$ do
6         if $d_s(v) + \omega(v, w) < d_s(w)$ then
7             $d_s(w) \leftarrow d_s(v) + \omega(v, w), p(w) \leftarrow v$;
8             Put $\langle w, d_s(w) + \mathsf{lb}(w, V_T)\rangle$ into $\mathcal{Q}_T$;
```

the top node v from $\mathcal{Q}_T$ (Line 2), and adds v into $\mathsf{SPT_I}$ (Line 3). Meanwhile, the subset of V_T that are in $\mathsf{SPT_I}$ is maintained into a set D (Line 4), which will be used later to improve the performance of testing lower bound for a subspace. In Fig. 5(b), the subtree in the rectangle shows the initial $\mathsf{SPT_I}$ constructed, and the entire tree is the resulting $\mathsf{SPT_I}$ for $\tau = 7$. Here, $D = \{v_6, v_7\}$. $\mathsf{SPT_I}$ has the following property.

Proposition 5.2: *The $\mathsf{SPT_I}$ constructed by Alg. 7 contains all nodes on paths from s to any node in V_T whose lengths are no larger than τ.* □

Algorithm 8: CompLB-$\mathsf{SPT_I}$ $(P_{t,u}, X_u)$

```
1 if $u \ne t$ then $N(u) \leftarrow$ {in-neighbors of $u$} else $N(u) \leftarrow D$;
2 $lb \leftarrow +\infty$;
3 for each $v \in N(u)$ do
4     if $v \notin P_{t,u}$ and $(v, u) \notin X_u$ then
5         if $v \notin \mathsf{SPT_I}$ then Compute $\mathsf{lb}(s, v)$ using Eq. (2);
6         else $\mathsf{lb}(s, v) \leftarrow$ the distance from $s$ to $v$ in $\mathsf{SPT_I}$;
7         $lb \leftarrow \min\{lb, \omega(P_{t,u}) + \omega(v, u) + \mathsf{lb}(s, v)\}$;
8 if $u = t$ and $lb = +\infty$ and $D \ne V_T$ then $lb \leftarrow 0$;
9 return $lb$;
```

Computing Initial Lower Bound for a Subspace using $\mathsf{SPT_I}$. We compute the lower bound of a subspace using $\mathsf{SPT_I}$ in a similar way to CompLB (Alg. 3), by considering the immediate neighbors of u. The algorithm is shown in Alg. 8, denoted CompLB-$\mathsf{SPT_I}$. Note that, here $P_{t,u}$ is a path from u to t in G and X_u is a subset of the incoming edges to u. CompLB-$\mathsf{SPT_I}$ differs from CompLB in the following two aspects. Firstly, $\mathsf{lb}(s, v)$ is estimated by utilizing $\mathsf{SPT_I}$ in the same way as that in Section 5.2. Secondly, when $u = t$, instead of considering all nodes of V_T, we consider only the subset that is in $\mathsf{SPT_I}$ (i.e. D). The reason is that, the entire V_T can be very large, while the small subset D is sufficient for our purpose of computing $\mathsf{lb}(P_{t,u}, X_u)$, which saves a lot of computations.

The correctness of CompLB-$\mathsf{SPT_I}$ when $u \ne t$ directly follows from that of CompLB. However, when $u = t$, there are two cases depending on whether there are any valid incoming edges to u. 1) If there is no valid incoming edge to u (i.e., every node of $N(u)$ is either in $P_{t,u}$ or in X_u, Lines 3-4), then lb will be $+\infty$. We reassign lb to 0 if $D \ne V_T$. 2) Otherwise, $lb \ne +\infty$, which is guaranteed to be a lower bound of the subspace $\langle P_{t,u}, X_u\rangle$.

Testing Lower Bound using $\mathsf{SPT_I}$. By utilizing $\mathsf{SPT_I}$, we propose a more efficient algorithm for testing lower bound, denoted TestLB-$\mathsf{SPT_I}$. We modify TestLB to develop TestLB-$\mathsf{SPT_I}$ in the same fashion as the development of CompLB-$\mathsf{SPT_I}$. Moreover, *we prune all nodes that are not in $\mathsf{SPT_I}$ from consideration* (i.e., from putting into $\mathcal{Q}_V$). Consequently, every $\mathsf{lb}(s, w)$ is computed as the distance from s to w in $\mathsf{SPT_I}$; that is, Eq. (2) is not evaluated. Therefore, TestLB-$\mathsf{SPT_I}$ is more efficient than TestLB. We prove the correctness of $\mathsf{TestLB\text{-}SPT_I}$ in the following lemma.

Lemma 5.2: *Given a subspace $\mathcal{S}$ and τ,* $\mathsf{TestLB\text{-}SPT_I}$ *returns $\emptyset$ if $\omega(\mathsf{sp}(\mathcal{S})) \geq \tau$, and returns* $\mathsf{sp}(\mathcal{S})$ *otherwise.* □

Proof Sketch: The lemma follows from Lemma 5.1 and Proposition 5.2. □

Example 5.3: We show running $\mathsf{TestLB\text{-}SPT_I}$ for subspace $\langle(v_7), \{(v_7, v_8)\}\rangle$ with $\tau = 6$, where $\mathsf{SPT_I}$ is shown in Fig. 5(b). Among v_7's in-neighbors, only v_3 is considered, since v_{13} and v_{14} are not in $\mathsf{SPT_I}$. For v_3, $\mathsf{lb}(v_1, v_3) = 3$ which is the distance in $\mathsf{SPT_I}$. Then, v_3 is also pruned since $\omega(v_3, v_7) + \mathsf{lb}(v_1, v_3) = 7$, and $\mathsf{TestLB\text{-}SPT_I}$ returns $\emptyset$. For $\tau = 7$, $\mathsf{SPT_I}$ remains the same. Then, v_3 is not pruned and the shortest path in $\langle(v_7), \{(v_7, v_8)\}\rangle$ is obtained, which is (v_1, v_3, v_7) with length 7. □

$\mathsf{IterBound\text{-}SPT_I}$ **Approach.** Based on $\mathsf{SPT_I}$ and the discussions above, we propose an approach following Alg. 4 for processing KPJ queries, denoted $\mathsf{IterBound\text{-}SPT_I}$. It runs on the reverse graph of G, and a subspace is represented by $\langle P_{t,u}, X_u\rangle$ where X_u is a subset of the incoming edges to u.

$\mathsf{IterBound\text{-}SPT_I}$ improves the efficiency by computing $\mathsf{SPT_I}$ and pruning all nodes not in $\mathsf{SPT_I}$ from consideration when conducting the iteratively bounding search. That is, we take as input only the small subgraph of G induced by nodes in $\mathsf{SPT_I}$. Note that, $\mathsf{SPT_I}$ enlarges for a larger τ, and the subgraph induced by nodes in $\mathsf{SPT_I}$ also enlarges; this guarantees that we can correctly process any KPJ query.

Time Complexity. The time complexity of the $\mathsf{IterBound\text{-}SPT_I}$ approach is $O(kn(m' + n' \log n'))$, where n' and m' are the number of nodes and edges, respectively, in the subgraph G' of G that is induced by nodes w with $d_s(w) + lb(w, V_T) <= \tau$ (see Line 10 of Alg. 5) for the largest τ obtained in $\mathsf{IterBound\text{-}SPT_I}$. Note that, n' and m' are usually small in real applications; thus, $\mathsf{IterBound\text{-}SPT_I}$ runs much faster than DA (see Alg. 1).

6. EXTENSIONS

In the following, we extend our techniques to other applications including the case that the source node also has multiple physical nodes and the case that landmarks are not available.

General KPJ. A general KPJ (GKPJ) query is an extension of KPJ query where the source node also has multiple physical nodes, denote as $Q = \{S, T, k\}$, where both S and T are categories. It is to compute the top-k shortest paths from any node in V_S to any node in V_T, where V_S is the set of nodes of V belonging to category S. We can convert a GKPJ query to a KPJ query by introducing a virtual source node s and connecting s to all nodes in V_S with weights 0. Then, Q is reduced to a KPJ query $Q' = \{s, T, k\}$ on the new graph, and all our proposed techniques can be used to process the query.

Computing without Landmark. Our techniques are presented based on landmarks which are used to estimate $\mathsf{lb}(u, V_T)$. Nevertheless, when landmarks are not available, all our techniques can still be directly applied by setting all $\mathsf{lb}(u, V_T)$ (i.e., computed by Eq. (2)) to be 0. Specifically, for $\mathsf{IterBound\text{-}SPT_I}$, the landmark is only used for constructing the $\mathsf{SPT_I}$ using A* search [16], as discussed in Section 5.3; thus, without landmark, we construct the $\mathsf{SPT_I}$ by setting $\mathsf{lb}(u, V_T)$ to be 0 (the A* search then becomes the Dijkstra's algorithm [11]), while other parts of $\mathsf{IterBound\text{-}SPT_I}$ remain the same.

Moreover, without landmark, our techniques still perform well; the reasons are as follows. The $\mathsf{IterBound\text{-}SPT_I}$ approach mainly consists of two parts: 1) incrementally constructing the partial shortest path tree $\mathsf{SPT_I}$, 2) computing lower bound or shortest path for a subspace. The dominating cost comes from the second part, while landmark is only used in the first part. Thus, by running $\mathsf{IterBound\text{-}SPT_I}$ without landmark will only increase the cost of the first part which is not a big factor in the total cost.

7. PERFORMANCE STUDIES

We conduct extensive performance studies to evaluate the efficiency of our approaches against the baseline approaches for processing KPJ queries. The following algorithms are implemented:

- DA [28] and DA-SPT [15]. They are in the deviation paradigm as discussed in Section 3, and are the baseline approaches for processing KPJ queries.
- BestFirst. It is the best-first approach as discussed in Section 4.
- IterBound, $\mathsf{IterBound_P}$, and $\mathsf{IterBound_I}$. They are the iteratively bounding approaches with or without SPT as discussed in Section 5. $\mathsf{IterBound_P}$ and $\mathsf{IterBound_I}$ are abbreviations of $\mathsf{IterBound\text{-}SPT_P}$ and $\mathsf{IterBound\text{-}SPT_I}$, respectively.
- $\mathsf{IterBound_I}$-NL. It is the $\mathsf{IterBound_I}$ approach however without landmark, as discussed in Section 6.

Note that, 1) in our testings, a KSP query is also considered as a KPJ query where the query category uniquely identifies the destination node; 2) the baseline approaches for processing KPJ queries are the state-of-the-art techniques for processing KSP queries.

All algorithms are implemented in C++ and compiled with GNU GCC by -O3 option. All tests are conducted on a PC with an Intel(R) Xeon(R) 2.66GHz CPU and 4GB memory running Linux. We evaluate the performance of the algorithms on real datasets as follows.

Dataset	#Nodes	#Edges
CAL	106,337	213,964
SJ	18,263	47,594
SF	174,956	443,604
COL	435,666	1,042,400
FLA	1,070,376	2,687,902
USA	6,262,104	15,119,284

Table 1: Summary of dataset

Datasets. We use six real road networks with real/synthetic points of interest (POIs), and each POI belongs to a category. They are: California road network (CAL), San Joaquin road network (SJ), San Francisco road network (SF), Colorado road network (COL), Florida road network (FLA), and Western USA road network (USA). The first three are downloaded from `www.cs.utah.edu/~lifeifei/SpatialDataset.htm`, and the last three are from DIMACS (`www.dis.uniroma1.it/~challenge9/download.shtml`). A summary is given in Table 1.

POIs. The CAL dataset is provided with real POIs, which have 62 different categories. For the other five road networks, we generate synthetic POIs randomly located on nodes. For each road network, we generate four sets of POIs, denoted T_1, T_2, T_3, T_4, corresponding to different number of physical destination nodes (i.e., $n \times 10^{-4}, 5n \times 10^{-4}, 10n \times 10^{-4}, 15n \times 10^{-4}$ POIs, respectively), where n is the number of nodes in a road network. For example, for

COL, $|T_1| = 43$, $|T_2| = 217$, $|T_3| = 435$, and $|T_4| = 653$. Note that, we generate the POIs in such a way that $T_1 \subset T_2 \subset T_3 \subset T_4$.

Graphs. We model each road network with POIs as a graph G. Here, an edge (u, v) in G represents a road segment, and has a non-negative weight $\omega(u, v)$ which can be any measure of the road segment, such as distance, travel time, travel cost, and etc. We take distance as weight in our experiments. Each node belongs to the categories of POIs that are located on it.[2]

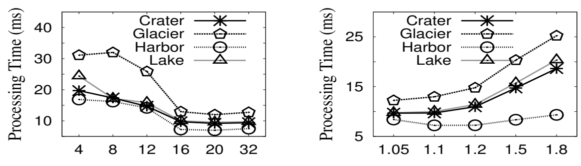
Queries. A query consists of a source node s, a destination node set V_T indicated by category T, and a value k indicating the number of paths to found. For each query, we first choose a category T, and then randomly generate source nodes. For the CAL dataset, we consider four representative categories, *"Glacier"*, *"Lake"*, *"Crater"*, and *"Harbor"*, which have 1, 8, 14, and 94 physical nodes, respectively. For the other datasets, we consider T_1, T_2, T_3, and T_4, and choose T_2 by default.

For a destination category T, the source nodes in a query are randomly generated as follows. We sort all nodes in increasing order regarding their shortest path lengths to category T, partition them into 5 groups, and generate 5 query sets, Q_1, Q_2, Q_3, Q_4, Q_5, each of which consists of 100 nodes randomly selected from the corresponding group. Thus, nodes in Q_i are closer to destination nodes than nodes in Q_j do, for $i < j$. We use Q_3 as the default query set.

k is chosen from 10, 20, 30, and 50, with 20 as the default.

7.1 Experimental Results

Eval-I: Parameters. We evaluate the influence of landmark size $|L|$ and parameter α on the performance of $\mathsf{IterBound_I}$.



(a) Varying $|L|$ (b) Varying α

Figure 6: Parameter testing on CAL ($Q_3, k = 20$)

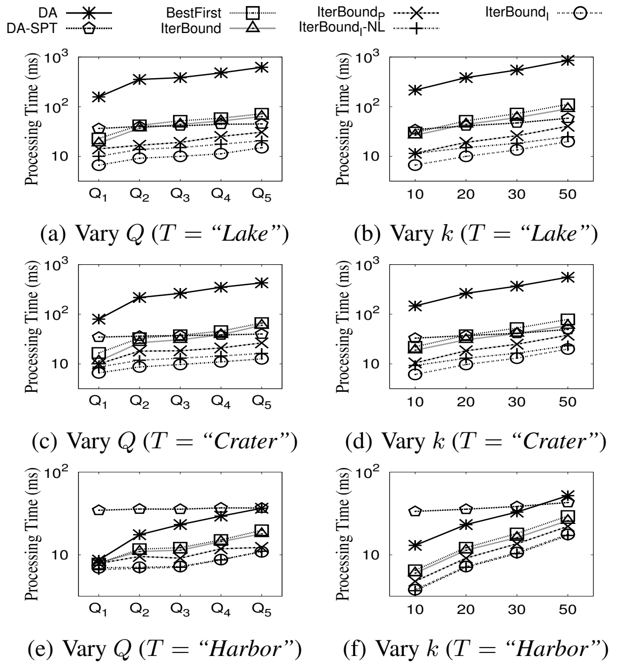
Choosing $|L|$. In our approaches, we use landmarks for estimating $\mathsf{lb}(v, V_T)$, the lower bound of shortest distance from v to any node in V_T. The landmarks are chosen following the most popular way in [16].[3] Fig. 6(a) shows the processing time of $\mathsf{IterBound_I}$ for different $|L|$ values. Clearly, when $|L|$ increases from 4 to 16, the processing time decreases, because more landmarks can provide more accurate estimation of $\mathsf{lb}(v, V_T)$. However, when $|L|$ increases from 16 to 32, the processing time increases a little due to longer computation time of $\mathsf{lb}(v, V_T)$. Therefore, we choose $|L| = 16$.

Choosing α. The running time of $\mathsf{IterBound_I}$ for different α values are illustrated in Fig. 6(b). Recall that α is used in our iterative bounding approaches for controlling the increasing ratio of τ (i.e., controlling the computation of a tighter lower bound, see Alg. 4). The running time increases when α increases from 1.1 to 1.8 due to building a larger $\mathsf{SPT_I}$. However, when α decreases from 1.1 to 1.05, the processing time also increases due to taking more iterations to reach the final τ. Therefore, we choose $\alpha = 1.1$.

Note that: 1) among our parameters, τ is determined by α; 2) better choices of $|L|$ and α will improve the performance of our algorithm marginally as shown in Fig. 6. It will be our future work to automatically find the best choice of $|L|$ and α.

[2]For simplicity, we assume that POIs are located on the nodes of G. When a POI is on an edge (u, v), we can add a new node w to G and connect w with u and v to replace (u, v). Note that, given a query with category T, we only need to consider the set of POIs belonging to category T.

[3]We firstly pick a random start node and select the farthest node from the start node as the first landmark, and then iteratively choose the node that is farthest away from the current set of landmarks as the next landmark.



(a) Vary Q (T = *"Lake"*) (b) Vary k (T = *"Lake"*)

(c) Vary Q (T = *"Crater"*) (d) Vary k (T = *"Crater"*)

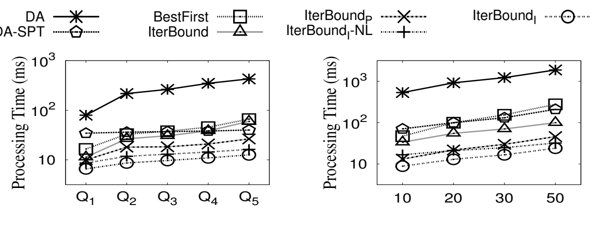
(e) Vary Q (T = *"Harbor"*) (f) Vary k (T = *"Harbor"*)

Figure 7: Against baseline approaches on CAL (Varying Q, k)

Eval-II: Against the Baseline Approaches. Here, we evaluate the performances of our approaches against the baseline approaches on CAL dataset.

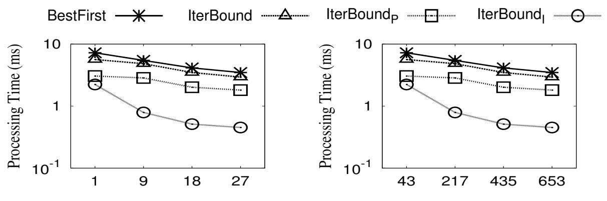
KPJ *Query.* The processing time of the seven approaches by varying query sets and k is demonstrated in Fig. 7, where the destination category is chosen from *"Lake"*, *"Crater"*, and *"Harbor"*. In general, all our approaches, BestFirst, IterBound, $\mathsf{IterBound_P}$, $\mathsf{IterBound_I}$, and $\mathsf{IterBound_I}$-NL, outperform the two baseline approaches, DA and DA-SPT. This is because our approaches use a best-first paradigm to reduce the number of shortest path computations. In Figures 7(a)-7(d), DA-SPT outperforms DA because DA-SPT online builds a full SPT to facilitate the shortest path computation. However, in Fig. 7(e)-7(f), DA-SPT performs worse due to the dominating cost of building the full SPT. When the lengths of shortest paths increase (i.e., varying Q from Q_1 to Q_5), the running time of all approaches increases except DA-SPT which is steady, due to the dominating cost of constructing the full SPT. Moreover, although without landmarks, $\mathsf{IterBound_I}$-NL outperforms all other approaches except $\mathsf{IterBound_I}$ across all testings. The trend of the processing time of these approaches by varying k is similar to that of varying query set. One exception is that, the processing time of DA-SPT also slightly increases due to computing more shortest paths for larger k.

KSP *Query.* We test the approaches for processing KSP queries by setting the destination category as *"Glacier"* which has only one



(a) Vary Q (T = *"Glacier"*) (b) Vary k (T = *"Glacier"*)

Figure 8: Testing KSP queries on CAL (Varying Q and k)



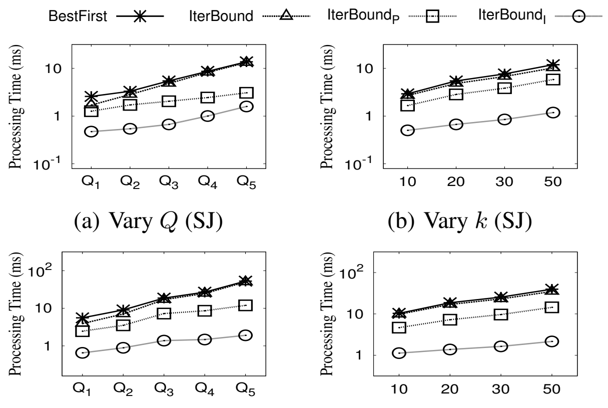
(a) SJ (b) COL

Figure 10: Vary #(destination nodes) ($Q = Q_3$, $k = 20$)

physical destination node; thus, the KPJ query is a KSP query. The results are shown in Fig. 8, which are similar to that for KPJ queries in Fig. 7.

Summary. There is no clear winner between DA and DA-SPT, and all our approaches perform better than these two baseline approaches. Despite using the same techniques, IterBound$_l$ outperforms IterBound$_l$-NL, which demonstrates the effectiveness of using landmarks for estimating lower bounds. Therefore, in the following testings, we omit DA, DA-SPT, and IterBound$_l$-NL, and evaluate the other approaches which use different techniques and all use landmark.

Eval-III: Evaluating Our Approaches. In this testing, we evaluate the efficiency of our different approaches, BestFirst, IterBound, IterBound$_P$, and IterBound$_l$, on SJ and COL.



(a) Vary Q (SJ) (b) Vary k (SJ)

(c) Vary Q (COL) (d) Vary k (COL)

Figure 9: Our approaches by varying Q and k ($T = T_2$)

Varying Q and k. The running time of the approaches on SJ and COL by varying Q and k is shown in Fig. 9. Similar to that in Fig. 7, the running time of these four approaches increases when either Q varies from Q_1 to Q_5 or k increases. IterBound slightly outperforms BestFirst due to less number of shortest path computations, however with more expensive lower bound computations. IterBound$_P$ performs better than IterBound because of the faster lower bound testing. IterBound$_l$ runs faster than IterBound$_P$ because IterBound$_l$ can further reduce the exploration area of a graph by SPT$_l$.

Varying Number of Destination Nodes ($|T|$). Fig. 10 shows the processing time of these four approaches on SJ and COL by varying the number of destination nodes (i.e., varying $|T|$). For all these four approaches, the processing time decreases, when the number of destination nodes increases (i.e., T varies from T_1 to T_4). This is because the shortest paths become shorter for more number of destination nodes as shown in Fig. 11 which will be discussed shortly. IterBound$_l$ outperforms IterBound$_P$ which then outperforms BestFirst and IterBound. The improvement of IterBound$_l$ over IterBound$_P$ becomes more significant when there are more destination nodes, since IterBound$_l$ can prune destination nodes and reduce the exploration area of a graph by SPT$_l$.

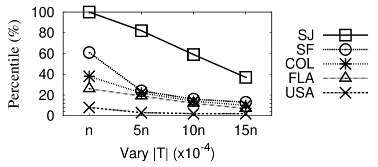


Figure 11: Shortest path length (Varying #(destination nodes))

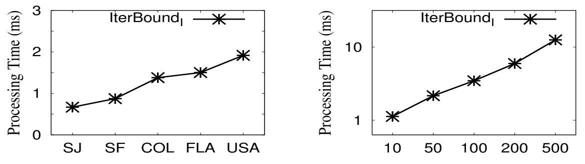
Fig. 11 illustrates the influence of the number of destination nodes on the shortest path lengths. Specifically, for each category T_i, we compute the longest length of shortest paths from nodes to T_i, and report its percentile position in the observations of all $n \cdot n$ shortest path lengths in the graph. For all datasets, the shortest path lengths decrease with more number of destination nodes; thus all approaches run faster as shown in Fig. 10. Note that, for a specific T_i, the number of destination nodes belonging to T_i are different, thus the shortest path lengths vary for different datasets; for example, for T_1, the number of destination nodes for SJ, SF, COL, FLA, USA are 1, 17, 43, 107, and 626, respectively.

Summary. IterBound$_l$ outperforms the other approaches, BestFirst, IterBound, and IterBound$_P$, across all different datasets, different number of destination nodes, different Q, and different k. Thus, in the following we only evaluate our IterBound$_l$ approach.

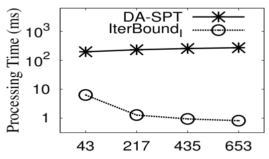


(a) Vary graph size ($k = 20$) (b) Vary k (COL)

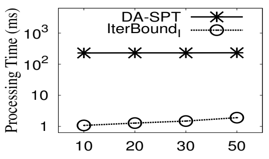
Figure 12: Scalability of IterBound$_l$ ($T = T_2$, $Q = Q_3$)

Eval-IV: Scalability Testing. The scalability testing results of IterBound$_l$ by varying graph size and k are shown in Fig. 12. Although the running time increases when either the graph size or k increases, IterBound$_l$ is scalable enough to process very large graphs. For example, when the graph size increases 40 times (i.e., from SJ to USA), the running time of IterBound$_l$ only increases slightly (e.g., by no more than 3 times).

Eval-V: GKPJ Testing. In this evaluation, we test the efficiency of IterBound$_l$ over DA-SPT, the state-of-the-art approach, for GKPJ



(a) Vary #(destination nodes) ($k = 20$)



(b) Vary k ($T = T_2$)

Figure 13: GKPJ query (COL)

queries $Q = \{S, T, k\}$. Here, the source category S has 4 physical nodes which are randomly chosen. Fig. 13 shows the running time by varying the number of destination nodes (i.e., $|T|$) or k. The trends of running time of DA-SPT and IterBound$_l$ are similar to the previous evaluations. The improvement of IterBound$_l$ over DA-SPT is more significant (e.g., by two orders of magnitude). This is because the lengths of k shortest paths become smaller with multiple source nodes.

8. CONCLUSION

In this paper, we studied the problem of top-k shortest path join (KPJ). We adopted the best-first paradigm to reduce the number of shortest path computations, compared to the existing deviation paradigm, by pruning subspaces based on their lower bounds. To improve the efficiency, we further proposed an iteratively bounding approach to tightening lower bounds of subspaces which is achieved by lower bound testing. Moreover, we proposed index structures to significantly reduce the exploration area of a graph in lower bound testing. We conducted extensive performance studies using real road networks, and demonstrated that our proposed approaches significantly outperform the baseline approaches for KPJ queries. Furthermore, our approaches can be immediately used to process KSP queries, and they also outperform the state-of-the-art algorithm for KSP queries by several orders of magnitude.

ABSTRACT

Shortest path computation is one of the most fundamental operations for managing and analyzing graphs. A number of methods have been proposed to answer shortest path distance queries on static graphs. Unfortunately, there is little work on answering distance queries on *dynamic* graphs, particularly graphs with edge failures. Today's real-world graphs, such as the social network graphs and web graphs, are evolving all the time and link failures occur due to various factors, such as people stopping following others on Twitter or web links becoming invalid. Therefore, it is of great importance to handle distance queries on these failure-prone graphs. This is not only a problem far more difficult than that of static graphs but also important for processing distance queries on evolving or unstable networks. In this paper, we focus on the problem of computing the shortest path distance on graphs subject to edge failures. We propose SIEF, a Supplemental Index for Edge Failures on a graph, which is based on distance labeling. Together with the original index created for the original graph, SIEF can support distance queries with edge failures efficiently. By exploiting properties of distance labeling on static graphs, we are able to compute very compact distance labeling for all singe-edge failure cases on dynamic graphs. We extensively evaluate our algorithms using six real-world graphs and confirm the effectiveness and efficiency of our approach.

1. INTRODUCTION

Recent years have witnessed the fast emergence of massive graph data in many application domains, such as the World Wide Web, linked data technology, online social networks, and Web of Things [21, 19, 22, 25]. In a graph, one of the most fundamental challenges centers on the efficient computation of the shortest path or distance between any given pair of vertices. For instance, distances or the numbers of links between web pages on a web graph can be considered a robust measure of web page relevancy, especially in relevance feedback analysis in web search [21]. In RDF graphs of linked data, the shortest path distance from one entity to another is important for ranking entity relationships and keyword querying [19, 14]. For online social networks, the shortest path distance can be used to measure the closeness centrality between users [22].

A large body of indexing techniques have been recently proposed to process exact shortest path distance queries on graphs [10, 23, 9, 8, 2, 26, 15]. Among them, a significant portion of indexes are based on *2-hop* distance labeling, which is originally proposed by Cohen et al. [12]. The 2-hop distance labeling techniques pre-compute a label for each vertex so that the shortest path distance between any two vertices can be computed by giving their labels only. These labeling indexes, such as [10, 8, 2, 15], have been proved to be efficient, i.e., being able to answer a distance query within microseconds.

Motivation. The above mentioned approaches generally make the assumption that graphs are static. However, in reality, many graphs are subject to edge failures. In this paper, we refer to graphs that are not subject to edge failures as *stable graphs*, i.e., static graphs. Similarly, we refer to graphs that are subject to edge failures as *unstable graphs*. For example, the emerging social Web of Things calls for graph data management with edge failures because smart things are normally moving and their connectivity could be intermittent, leading to frequent and unpredictable changes in the corresponding graph models [11, 25]. Another example is web graphs. It is not uncommon that some web links become invalid as the web evolves. All these are examples of unstable graphs, which are common in the real-world, calling for efficient graph computations by considering link failures. We believe that it is imperative to design novel algorithms that can compute shortest path indexes for fast response on distance queries avoiding any failed edge. Some real-world applications/scenarios that require the computa-

10.5441/002/edbt.2015.14

tion of shortest path distance avoiding a failed edge are described in the following.

Scenario 1. *The* **most vital arc** *problem [17, 6] aims to identify the edge on a given shortest path and the removal of this edge results in the longest replacement path. Here, a replacement path means a shortest path from a source vertex to a destination vertex in a graph that avoids a specified edge. To find the most vital arc in a graph, we need to compute the shortest path distances efficiently when we are given an arc (i.e., an edge) to avoid.*

Scenario 2. *In the* **sensitivity analysis** *and in many analytical applications of transportation networks, government agencies need to evaluate different road segments (i.e., to find how much a road segment is worth) through Vickrey pricing [16], such that maintenance budget can be allocated accordingly, or the amount of tolls can be adjusted reasonably [24]. For example, if tolls are not charged appropriately and avoiding an expensive toll point causes only a small detour, then it is more likely that most drivers would take the detour, rather than pay for the toll.*

Scenario 3. *In order to develop* **game-theoretic and price-based mechanisms** *to share bandwidth and other network resources, a natural economic question is [16]: how much is an edge in a network worth to a user who wants to send data between two nodes along a shortest path? Or in other words, what is the penalty of avoiding an edge in the given network?*

These application scenarios reveal an urge for handling shortest path computations in a graph with single-edge failures. Here, single-edge failure refers to graph failures with only one failed edge at a time [5]. Note that, other types of edge failure, such as dual-failure in [13], may allow multiple failed edges at a time. But they are considered much harder than single-failure [13]. To shed light on these challenging issues, we focus on single-edge failures in this paper.

Contributions. Since 2-hop labeling has shown its power to support instant responses to shortest path distance queries on stable graphs, our work aims at extending this technique to support unstable graphs. Existing shortest path indexing techniques based on 2-hop labeling can be used to precompute the whole shortest path index for a graph. The resulted indexes can normally answer distance queries fast using moderate storage space [2, 15]. However, applying indexing techniques designed for static/stable graphs directly to evolving/unstable graphs may lead to inefficiency. When considering every single-edge failure case and constructing a corresponding index for each case, the size of all these indexes will become too big to manage. For instance, a snapshot of the Gnutella peer-to-peer (P2P) file sharing network in August 2002 contains more than 6,000 vertices[1] and 20,000 edges. Using state-of-the-art method, Pruned Landmark Labeling (PLL) [2], the index size is slightly more than 5 MB. However, suppose we want to construct such index for each single-edge failure case, the total index size would be more than $5 \times 20,000 = 10^5$ MB.

To address the deficiency of existing shortest path indexing techniques, this paper proposes a generic framework named SIEF, a Supplemental Index for Edge Failures on a graph, to construct compact shortest path indexes efficiently for unstable graphs where single-edge failures may exist. As an initial attempt on this challenging issue, we focus on unweighted, undirected graphs. Similar to other distance labeling based indexing methods [2, 15], our method can be extended to weighted and/or directed graphs. We highlight our main contributions in the following.

- We present the concept of *well-ordering 2-hop distance labeling* and identify its important properties that can be utilized to design algorithms for shortest path indexes on graphs with edge failures.

- We analyze shortest path index constructions on graphs with edge failures theoretically. We develop the corresponding theorems as well as novel algorithms to enable constructions of compact indexes for all the single-edge failure cases of the entire graph. By applying our approach to the aforementioned Gnutella P2P dataset, the size of the generated SIEF index together with the original index created for the original graph is merely 14 MB, which is much more compact than 10^5 MB by directly using PLL method [2] to construct indexes for each single-edge failure case.

- We conduct extensive experiments on six real-world graphs to verify the efficiency and effectiveness of our method. The results show that our method can efficiently answer shortest path distance queries avoiding a failed edge with very compact labeling indexes.

The rest of this paper is organized as follows. In Section 2, we review the related work. In Section 3, we present some preliminaries on 2-hop distance labeling. We then present the framework and the details of our approach in Section 4. In Section 5, we report the results of an extensive experimental study using six graphs from real-world. Finally, we present some concluding remarks in Section 6.

2. RELATED WORK

In this section, we review the major techniques that are most closely related to our work.

Distance labeling has been an active research area in recent years. In [10], Cheng and Yu exploit the strongly connected components property and graph partitioning to precompute 2-hop distance cover. However, the graph partitioning process introduces high cost because it has to find vertex separators recursively. Hierarchical hub labeling (HHL) proposed by Abraham et al. [1] is based on the partial order of vertices. Smaller labeling results can be obtained by computing labeling for different partial order of vertices. In [18], Jin et al. propose a highway-centric labeling (HCL) that uses a spanning tree as a highway. Based on the highway, a 2-hop labeling is generated for fast distance computation.

Very recently, the pruned landmark labeling (PLL) [2] is proposed by Akiba et al. to pre-compute 2-hop distance labels for vertices by performing a breadth-first search from every vertex. The key idea is to prune vertices that have obtained correct distance information during breadth-first searches, which helps reduce the search space and sizes of labels. Further, query performance is also improved as the number of label entries per vertex is reduced. IS-Label (or ISL) is developed by Fu et al. in [15] to pre-compute 2-hop

[1] http://snap.stanford.edu/

distance label for large graphs in memory constrained environments. ISL is based on the idea of independent set of vertices in a large graph. By recursively removing an independent set of vertices from the original graph, and by augmenting edges that preserve distance information after the removal of vertices in the independent set, the remaining graph keeps the distance information for all remaining vertices in the graph. Apart from the 2-hop distance labeling technique, a multi-hop distance labeling approach [8] is also studied, which can reduce the overall size of labels at the cost of increased distance querying time.

Tree decomposition approach has been recently investigated [23, 4] for answering distance queries on graphs. Wei proposes TEDI [23], which first decomposes a graph into a tree and then constructs a tree decomposition for the graph. A tree decomposition of a graph is a tree with each vertex associated with a set of vertices in the graph, which is also called a *bag*. The shortest paths among vertices in the same bag are pre-computed and stored in bags. For any given source and target vertices, a bottom-up operation along the tree can be executed to find the shortest path. An improved TEDI index is proposed by Akiba et al. in [4] that exploits a core-fringe structure to improve index performance. However, due to the large size of some bags in the decomposed tree, the construction time for a large graph is costly and thus such indexing approaches cannot scale well.

Maintenance of 2-hop reachability labeling is also studied. For example, HOPI (2-HOP-cover-based Index) introduces some maintenance techniques for the constructed index. HOPI is developed by Schenkel et al. in [20] and is designed to speed up connection or reachability tests in XML documents based on the idea of 2-hop cover. HOPI is able to update indexes for insertions and deletions of nodes, edges or even XML documents. To the best of our knowledge, HOPI is the first work on maintenance of 2-hop labeling. Recently, maintenance of 2-hop labeling for large graphs has also been studied by Bramandia et al. in [7]. However, all these studies focus on reachability queries and are based on 2-hop labeling but not on 2-hop distance labeling.

Incremental maintenance of 2-hop distance labeling is also studied very recently by Akiba et al. in [3]. In that work, incremental updates (i.e., edge insertions) of 2-hop labeling indexes are investigated. To support fast incremental updates, outdated distance labels are kept, which will not affect the distance computation on the updated graphs in the incremental case. However, for the decremental case (i.e., edge deletions), this approach will not work, as outdated distance labels must be removed first and then some necessary labels of the 2-hop labeling index need to be recomputed. Hence, their update algorithms cannot be applied on edge deletions (i.e., edge failures), which will be discussed in this paper.

3. PRELIMINARIES

3.1 2-Hop Distance Labeling

The technique of 2-hop cover can be used to solve reachability problems (using reachability labels) and shortest path distance querying problems (using distance labels) on graphs [12]. Since our work focuses on the shortest path distance querying problems, we adopt distance labels with the 2-hop cover technique. We specifically refer to it as *2-hop distance labeling* or *2-hop distance cover*.

Assume a graph $G = (V, E)$, where V is a set of vertices and E is a set of edges. For each vertex $v \in V$, there is a pre-computed label $L(v)$, which is a set of vertex and distance pairs (u, δ_{uv}). Here u is a vertex and δ_{uv} is the shortest path distance between u and v. Given such a labeling for all vertices in G, denoted by L, for any pair of vertices s and t in G, we have

$$\begin{aligned} dist(s,t,L) =& min\{\delta_{vs} + \delta_{vt} | (v, \delta_{vs}) \in L(s) \\ & \text{and } (v, \delta_{vt}) \in L(t)\} \end{aligned} \quad (1)$$

If $L(s)$ and $L(t)$ do not share any vertices, we have $dist(s,t,L)$ $=\infty$. The distance between any given vertices s and t in G is denoted by $d_G(s,t)$. If we have $d_G(s,t) = dist(s,t,L)$ for all s and t in G, we call the labeling result L a 2-hop distance cover.

3.2 Well-Ordering 2-Hop Distance Labeling

For a connected graph G, there exists a sequence of vertices $\sigma =< v_0, v_1, v_2, \ldots, v_{n-1} >$. We denote the order of any vertex v_i as $\sigma[v_i]$ and we have $\sigma[v_i] = i$ for the above given vertex sequence. Based on this, we can define *Well-Ordering 2-Hop Distance Labeling* in the following.

Definition 1 (***Well-Ordering 2-Hop Distance Labeling***). Suppose that (1) each vertex v_i has a distance labeling $L(v_i)$, and the labeling result L of all vertices forms a 2-hop distance cover of G; (2) for any pair of vertices v_i and v_j, given that $\sigma[v_i] < \sigma[v_j]$, then v_j is not in $L(v_i)$ and v_i may be in $L(v_j)$. We call such a 2-hop distance cover a *well-ordering 2-hop distance labeling.* Alternatively we say that a 2-hop distance cover has well-ordering property.

Similar concepts of well-ordering 2-hop distance labeling also appear in recent research efforts such as HHL [1], PLL [2], and ISL [15]. This confirms that well-ordering 2-hop distance labeling is important in the related research area. More importantly, we will show in this paper that the well-ordering property is also a basic concept in the design of index construction algorithms for distance labeling computation on unstable graphs where edges may fail.

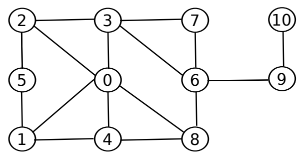

Figure 1: A graph example

In a graph containing multiple connected components, suppose its 2-hop labeling is L. For any pair of vertices u and v in different connected components, we can assert that $L(u)$ and $L(v)$ do not share any vertex according to the definition of 2-hop cover. Each connected component has its own vertex orders. For such a graph, we will have separate vertex orders for each connected component. We denote a connected component containing vertex u as $C(u)$. If u and v belong to the same connected component, we have $C(u) = C(v)$.

Figure 1 shows an example graph with 11 vertices and Table 1 shows a well-ordering 2-hop distance labeling result L for the graph (L can be constructed by PLL [2] using the same vertex ordering as that specified in the table). In the

Table 1: 2-Hop Distance Labeling L for Figure 1

Label	Entries
$L(0)$	(0,0)
$L(1)$	(0,1) (1,0)
$L(2)$	(0,1) (2,0)
$L(3)$	(0,1) (2,1) (3,0)
$L(4)$	(0,1) (1,1) (4,0)
$L(5)$	(0,2) (1,1) (2,1) (5,0)
$L(6)$	(0,2) (2,2) (3,1) (4,2) (6,0)
$L(7)$	(0,2) (2,2) (3,1) (6,1) (7,0)
$L(8)$	(0,1) (4,1) (6,1) (8,0)
$L(9)$	(0,3) (2,3) (3,2) (4,3) (6,1) (9,0)
$L(10)$	(0,4) (2,4) (3,3) (4,4) (6,2) (9,1) (10,0)

table, the order of vertices is $< 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10 >$. Take $L(5)$ as an example to further explain the idea of well-ordering 2-hop distance labeling. $L(5)$ is the label of vertex 5. By the well-ordering property, label entries in $L(5)$ can only contain vertices $0, 1, 2, 3, 4$ and 5. Since label entries containing vertices 3 and 4 are redundant in $L(5)$ (this will be explained in more details later in this section), label entries in $L(5)$ only contain vertices $0, 1, 2$ and 5.

3.3 Properties of Well-Ordering 2-Hop Distance Labeling

Technically speaking, if we index shortest paths for all pairs using a labeling method, we will obtain an index that occupies $O(n^2)$ disk space. This index can be considered as a special 2-hop distance labeling. Obviously, the space complexity of this is too high for large graphs. Constructing a minimal 2-hop distance labeling has been proven to be NP-hard [12]. Therefore, an alternative way to obtain labeling results with reduced sizes is by using heuristic methods [10, 8, 2, 15]. Well-ordering 2-hop distance labeling is one of the techniques that can help to design efficient algorithms for constructing shortest path distance labeling indexes and for index maintenance. We identify its useful properties in the following.

LEMMA 1. *Given a well-ordering 2-hop distance labeling L of a connected graph G, suppose $u \in G$ and $\sigma[u]$ is a minimum among all vertices in G, then for any vertex $v \in G$, we must have $(u, \delta_{uv}) \in L(v)$.*

PROOF. It is trivial to prove this when $v = u$ since $(u, 0) \in L(u)$. We prove the case when $v \neq u$ by contradiction. Suppose there exists a vertex $v \in G$, $(u, \delta_{uv}) \notin L(v)$. By the definition of L, since $\sigma[u]$ is minimum, $L(u)$ will contain only one label entry $(u, 0)$. Then it is obvious that $L(u)$ and $L(v)$ do not share any vertex, which leads to $dist(u, v, L) = \infty$. This implies that u and v belong to different connected components, which is false. Therefore, the lemma is proved. □

LEMMA 2. *Given a well-ordering 2-hop distance labeling L of a connected graph G, suppose $s, t, u \in G$ and $dist(s, t, L) = dist(s, u, L) + dist(u, t, L)$, then u must be an internal vertex of a certain shortest path between s and t.*

PROOF. Since $dist(s, t, L) = dist(s, u, L) + dist(u, t, L)$, there must exist some shortest path that starts from s, passes u, and ends at t. Hence the lemma is proved. □

Take vertices 5, 6 and 2 in Figure 1 as an example. From Table 1, we have $dist(5, 6, L)$=3 and $dist(5, 2, L)+dist(2, 6, L)$ =1+2=3. From Figure 1, we can see that vertex 2 is an internal vertex on some shortest path, denoted as p, between vertex 5 and vertex 6. In this case, we have $p =< 5, 2, 3, 6 >$.

LEMMA 3. *Given a well-ordering 2-hop distance labeling L of a connected graph G, suppose $s, t, u \in G$ and u has minimum vertex order $\sigma[u]$ among all shortest paths between s and t. Then we must have $(u, \delta_{us}) \in L(s)$ and $(u, \delta_{ut}) \in L(t)$ and $dist(s, t, L) = \delta_{us} + \delta_{ut}$.*

PROOF. We prove this by contradiction. Without loss of generality, suppose $(u, \delta_{us}) \notin L(s)$. In order to calculate $dist(s, u, L)$, there must exist some vertex v other than u, where $(v, \delta_{vs}) \in L(s)$, $(v, \delta_{vu}) \in L(u)$ and $dist(s, u, L) = \delta_{vs} + \delta_{vu}$. According to Lemma 2, v must be an internal vertex of some shortest path between s and u. Hence v must also be an internal vertex of some shortest path between s and t. Meanwhile, by definition, we must have $\sigma[v] < \sigma[u]$. This contradicts our assumption that u has the minimum vertex order among all shortest paths between s and t. Hence, we must have $(u, \delta_{us}) \in L(s)$. Furthermore, u is an internal vertex of some shortest path between s and t, thus $dist(s, t, L) = \delta_{us}+\delta_{ut}$. Hence the lemma is proved. □

Take vertices 1 and 6 in Figure 1 as an example. Paths $p_1 =< 1, 0, 8, 6 >$, $p_2 =< 1, 0, 3, 6 >$ and $p_3 =< 1, 4, 8, 6 >$ are all the shortest paths between vertices 1 and 6. Vertex 0 is the one with minimum order along all these paths. From Table 1 we can see that both vertices 1 and 6 contain a label entry $(0, \delta)$. We can also easily check that $dist(1, 6, L) = \delta_{0,1} + \delta_{0,6} = 1 + 2 = 3$.

LEMMA 4. *Given a well-ordering 2-hop distance labeling L of a connected graph G, suppose $\sigma[u] < \sigma[v]$. If there is a label entry $(u, \delta_{uv}) \in L(v)$, we must have for any label entry $(r, \delta_{rv}) \in L(v)$, (1) $\delta_{uv} \leq \delta_{rv} + dist(r, u, L)$; (2) if $\sigma[r] < \sigma[u]$ and $\delta_{uv} = \delta_{rv} + dist(r, u, L)$ then $(u, \delta_{uv}) \in L(v)$ is a redundant label entry.*

PROOF. We first prove the first claim that $\delta_{uv} \leq \delta_{rv} + dist(r, u, L)$. By definition and the triangle inequalities we must have $\delta_{uv} = d_G(u, v) = dist(u, v, L) \leq \delta_{rv}+dist(r, u, L)$.

We then prove the second claim. We need to prove that if $\delta_{uv} = \delta_{rv} + dist(r, u, L)$, then for any vertex t, when we calculate $dist(v, t, L)$, (u, δ_{uv}) in $L(v)$ is not required. For t, there are three cases: (1) $(u, \delta_{ut}) \notin L(t)$; (2) $(u, \delta_{ut}) \in L(t)$ but $\delta_{uv} + \delta_{ut} > dist(v, t, L)$; (3) $(u, \delta_{ut}) \in L(t)$ and $\delta_{uv} + \delta_{ut} = dist(v, t, L)$. For Case (1) and Case (2), it is trivial since (u, δ_{uv}) in $L(v)$ is not required to calculate $dist(v, t, L)$. For Case (3), according to Lemma 2, u is an internal vertex of some shortest paths between v and t. Similarly, since $\delta_{uv} = \delta_{rv} + dist(r, u, L)$, r is an internal vertex of some shortest paths between u and v, which means r is also an internal vertex of some shortest paths between v and t. In such case, we prove in the following that there must exist a vertex s other than u and we have $(s, \delta_{sv}) \in L(v)$, $(s, \delta_{st}) \in L(t)$ where $\delta_{st} + \delta_{sv} = dist(v, t, L)$.

Suppose s is the vertex with minimum vertex order among all shortest paths between v and t. According to Lemma 3, we must have $(s, \delta_{sv}) \in L(v)$, $(s, \delta_{st}) \in L(t)$ and $\delta_{st} + \delta_{sv} = dist(v, t, L)$. Since $\sigma[s] \leq \sigma[r] < \sigma[u]$, s is not the same vertex of u. Therefore, (u, δ_{uv}) in $L(v)$ is not required to calculate $dist(v, t, L)$. Hence, the second claim is also proved. □

Take label entries of vertex 5 in Table 1 as an example. We have $\sigma(3) < \sigma(5)$ and $\sigma(2) < \sigma(3)$. We also have $\delta_{3,5} = 2 = \delta_{2,5} + \delta_{2,3}$. Therefore $(3, 2)$ is a redundant label entry in $L(5)$, which can be removed from $L(5)$.

4. THE SIEF APPROACH

In this section, we first provide an overview of our SIEF approach. We then analyze the 2-hop distance labeling computation on graphs with single-edge failures and introduce a set of algorithms to achieve fast and compact index constructions.

4.1 SIEF Overview

After an edge fails on a graph, we observe that distances of a considerable proportion of shortest paths between any pair of vertices remain unchanged. Therefore, to construct a new index for each single-edge failure case, we only need to compute new labels for those vertices with changed shortest path distances due to the edge failure. Overall, our index construction approach can be divided into two main stages. In the first stage, *IDENTIFY*, we identify affected vertices after an edge fails. In the second stage, *RELABEL*, we relabel all affected vertices with necessary additional label entries for the single-edge failed graph. These new label entries form a new part of the index, which is called a *supplemental index*.

Before the detailed discussions of our algorithms, suppose that the failed edge is (u, v) in G, and the new graph is G', we introduce a concept for the supplemental index construction:

Definition 2 (***Affected vertices*** $AV_{(u,v)}$). For any vertices s and t, if $d_{G'}(s, t) \neq d_G(s, t)$, then $s \in AV_{(u,v)}$ and $t \in AV_{(u,v)}$.

To be specific, $AV_{(u,v)}$ contains all vertices whose distance to some other vertex must have been changed due to the failed edge (u, v). It is quite clear that supplemental indexes should be constructed to maintain all new distances for each single-edge failure case. In other words, supplemental indexes are constructed based on all the vertices in $AV_{(u,v)}$. Further, in order to be compact, the supplemental indexes should only answer distances that cannot be answered by the original index.

4.2 Identification of Affected Vertices

Before we can start to construct supplemental indexes, we need to identify all the affected vertices in $AV_{(u,v)}$ first. A naive method would be to compare distances for any possible pair of affected vertices in the original graph G and the new graph G' with a failed edge (u, v), but that would be very time consuming as it will need to test distances of $O(n^2)$ pairs of vertices. In the following, we will try to identify some important properties for vertices in $AV_{(u,v)}$ for us to identify $AV_{(u,v)}$ more efficiently and accurately.

LEMMA 5. *After removing the failed edge (u, v) from graph G, for any vertex s, t in G', we must have $d_{G'}(s, t) \geq dist(s, t, L)$.*

PROOF. In the old graph G, there are only two types of shortest paths: (1) shortest paths containing edge (u, v); and (2) shortest paths not containing edge (u, v). For the former, we have $d_{G'}(s, t) \geq d_G(s, t) = dist(s, t, L)$. For the latter, we have $d_{G'}(s, t) = d_G(s, t) = dist(s, t, L)$. Thus the lemma is proved. □

LEMMA 6. *After removing the failed edge (u, v) from graph G, for any vertex s, t in G', if $d_{G'}(s, t) > dist(s, t, L)$, and suppose a shortest path between s and t in G is $\pi_G(s, t)$, then we must have $uv \in \pi_G(s, t)$ or $vu \in \pi_G(s, t)$.*

PROOF. This can be proved by contradiction. Suppose we have $d_{G'}(s, t) > dist(s, t, L)$ but $uv \notin \pi_G(s, t)$ and $vu \notin \pi_G(s, t)$, which means edge (u, v) does not appear in $\pi_G(s, t)$. In such case, there must exist a path $P_{G'}(s, t)$ in G' where $\pi_G(s, t) = P_{G'}(s, t)$. This means $d_{G'}(s, t)$ must be at most the length of $P_{G'}(s, t)$, i.e., the length of $\pi_G(s, t)$. Thus, we must have $d_{G'}(s, t) = dist(s, t, L') \leq d_G(s, t)$. This contradicts our assumption $d_{G'}(s, t) > dist(s, t, L)$. □

According to Lemma 6 and the definition of affected vertices, if we have $d_{G'}(s, t) > dist(s, t, L) = d_G(s, t)$, we must have that $s, t \in AV_{(u,v)}$. This further means the shortest path(s) between s and t in the original graph G must contain the failed edge (u, v). Then, after edge (u, v) fails, take any one of these shortest paths (if multiple shortest paths exist; if not, we will have one and only one shortest path containing (u, v)) as an example, denoted as $\pi_G(s, t)$. Then it is easy to imagine that $\pi_G(s, t)$ will become two segments: one segment ends at u, denoted as Seg_u and the other segment ends at v, denoted as Seg_v. Without loss of generality, suppose s falls on the Seg_u and t falls on Seg_v. Since Seg_u and Seg_v must also be shortest paths from s to u and from t to v, respectively, this means we must have $d_G(s, u) = d'_G(s, u)$ and $d_G(t, v) = d'_G(t, v)$. But in the meantime, we must have $d_G(s, v) \neq d'_G(s, v)$ and $d_G(t, u) \neq d'_G(t, u)$ since otherwise we will have $d_{G'}(s, t) = d_G(s, t)$, which is impossible. Based on this observation, we can see that vertices in $AV_{(u,v)}$ form two disjoint sets: one set is $AV_{(u,v)}(u)$ and the other set is $AV_{(u,v)}(v)$, where for $\forall s \in AV_{(u,v)}(u)$ and $\forall t \in AV_{(u,v)}(v)$, we must have $d_{G'}(s, t) > d_G(s, t)$, $d_G(s, u) = d'_G(s, u)$ and $d_G(t, v) = d'_G(t, v)$. Since (u, v) is the failed edge, obviously, we must have $u \in AV_{(u,v)}(u)$ or $v \in AV_{(u,v)}(v)$. Further, it should be noted that, $\forall s, t \in AV_{(u,v)}(u)$, we must have $d_G(s, t) = d'_G(s, t)$. The same conclusion can be made on $\forall s, t \in AV_{(u,v)}(v)$.

Next, we are going to show that all vertices $s \in AV_{(u,v)}(u)$ form a tree rooted at u and similarly, all vertices $t \in AV_{(u,v)}(v)$ also form a tree rooted at v.

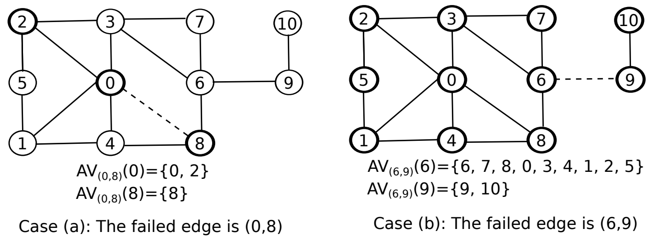
LEMMA 7. *After removing the failed edge (u, v), for any vertex w in G', suppose w is an affected vertex, i.e. $w \in AV_{(u,v)}(u)$ or $w \in AV_{(u,v)}(v)$. Without loss of generality, we assume $w \in AV_{(u,v)}(u)$. Then we must have $d_G(w, v) = d_G(w, u) + 1$.*

PROOF. Since $w \in AV_{(u,v)}(u)$, we must have that $d_G(w, v) \neq d'_G(w, v)$, which means that any shortest path between w and v in G, denoted as p_{wv} must contain the failed edge (u, v), which must also be a shortest path between w and v. Hence, there must exist a certain shortest path between w and v containing edge (u, v) in the original graph and we can denote it as $p_{wv} = p_{wu} + (u, v)$. Hence, we must have $d_G(w, v) = d_G(w, u) + 1$. □

LEMMA 8. *After removing the failed edge (u, v), suppose w in G' is an affected vertex, i.e. $w \in AV_{(u,v)}(u)$ or $w \in AV_{(u,v)}(v)$. Without loss of generality, we assume $w \in AV_{(u,v)}(u)$. Then there must exist a certain shortest path between w and v containing edge (u, v) in the original graph, where each internal vertex is an affected vertex in $AV_{(u,v)}(u)$.*

Algorithm 1 Identify affected vertices

```
Input: $G$, $(u, v)$, distance vectors $d_u, d_v, d'_u, d'_v$
Output: $AV_{(u,v)}(u)$, $AV_{(u,v)}(v)$
 1: Initialize flag $m[t] \leftarrow 0$ for any vertex $t$ in $G$
 2: $m[u] \leftarrow 1$
 3: $Q \leftarrow \emptyset$
 4: Enqueue $u$ into $Q$
 5: while $Q$ is not empty do
 6:     Dequeue $t$ from $Q$
 7:     for all neighbor vertex $r$ of $t$ do
 8:         if $m[r] = 0$ then
 9:             if $d_v[r] = d_u[r] + 1$ and $d'_v[r] \neq d_u[r] + 1$ then
10:                 $AV_{(u,v)}(u) \leftarrow AV_{(u,v)}(u) \cup \{r\}$
11:                 Enqueue $r$ into $Q$
12:             $m[r] \leftarrow 1$
13: Repeat the above steps by mapping $u \leftarrow v$ and $v \leftarrow u$
    to identify $AV_{(u,v)}(v)$
```



AV(0,8)(0)={0, 2}
AV(0,8)(8)={8}
Case (a): The failed edge is (0,8)
AV(6,9)(6)={6, 7, 8, 0, 3, 4, 1, 2, 5}
AV(6,9)(9)={9, 10}
Case (b): The failed edge is (6,9)

Figure 2: Affected vertices identification

PROOF. Since $w \in AV_{(u,v)}(u)$, then according to Lemma 7, we must have the fact that any shortest path between w and u, denoted as p_{wu}, plus edge (u, v) in the original graph must be a shortest path between w and v. Then, there must exist a certain shortest path between w and v containing edge (u, v) in the original graph and we can denote it as $p_{wv} = p_{wu} + (u, v)$.

It is clear that the internal vertices of p_{wv} must also be on some shortest path p_{wu}. And all shortest paths from these internal vertices to vertex v must contain edge (u, v), which means, their distances to vertex v must have changed in the new graph G'. Therefore, they must also be affected vertices in $AV_{(u,v)}(u)$ like w. □

Note that, according to Lemma 8, $AV_{(u,v)}(u)$ and $AV_{(u,v)}(v)$ can be considered as trees rooted at u and v, respectively. Moreover, we must have $AV_{(u,v)}(u) \bigcap AV_{(u,v)}(v) = \emptyset$. This is because otherwise, any vertex r in $AV_{(u,v)}(u) \bigcap AV_{(u,v)}(v)$ must have $d_G(r, v) = d_G(r, u)+1$ and $d_G(r, u) = d_G(r, v)+1$, which is impossible. Lemma 8 forms the basis of Algorithm 1. Note that, in Algorithm 1, we need to calculate distance vectors d_u, d_v, d'_u and d'_v for each single-edge failure case. Here, d_u stores distances from all vertices in G to vertex u while d'_u stores distances from all vertices in G' to vertex u. Distance vectors d_v and d'_v are similar. The calculations can be done efficiently using a BFS algorithm. To reduce the calculation cost, we will fix an end point of failed edges, i.e., we will firstly compute affected vertices for all edges attached to u then we move to other vertices for processing the rest single-edge failure cases.

Figure 2 shows two examples of identifying affected vertices. It uses the same graph in Figure 1. In this figure, the first example is Case (a), where the failed edge is $(0, 8)$. The second example is Case (b), where the failed edge is $(6, 9)$. In Case (a), starting from vertex 0, we identify the affected vertex set rooted at 0 as $AV_{(0,8)}(0) = \{0, 2\}$ since only vertices 0 and 2 have changed their distance to vertex 8. Meanwhile, starting from vertex 8, we identify the affected vertex set rooted at 8 as $AV_{(0,8)}(8) = \{8\}$ since only vertex 8 has changed its distance to vertex 0. Differently, in Case (b), as can be observed in the figure, the original graph will become two connected components rooted at vertices 6 and 9, respectively. In this case, it is obvious that we have $AV_{(6,9)}(6) = \{6, 7, 8, 0, 3, 4, 2, 5\}$ and $AV_{(6,9)}(9) = \{9, 10\}$.

4.3 Relabeling: Supplemental Index Construction

After identifying all affected vertices, we can start relabeling the affected vertices in order for fast computation of shortest path distances on the graph with single-edge failures. Only supplemental indexes will be created, i.e., only changed distance information will be captured in supplemental indexes. All the unchanged distance information will be still computed using the original indexes (such as the distance labeling in Table 1 for the example graph in Figure 1). We develop two relabeling algorithms for the supplemental index construction, namely the BFS AFF algorithm and the BFS ALL algorithm. Detailed descriptions of these two algorithms are presented in the following.

4.3.1 BFS AFF algorithm

The BFS AFF algorithm relabels affected vertices using the traditional BFS algorithm. The BFS AFF algorithm uses a *late label-pruning* strategy which can save memory usage during the relabeling process. The detail steps are shown in Algorithm 2. To help understand the main idea of the BFS AFF algorithm, Figure 3 also depicts an example of the supplemental index construction process using the BFS AFF algorithm.

The failed edge is (0,8) in this example and there are three steps in Figure 3. Each step relabels one affected vertex. At Step (1), BFS AFF algorithm performs BFS from vertex 0. The number beside each node is the distance from that node to the BFS root, vertex 0. In this step, vertex 8 is the only affected vertex in $AV_{(0,8)}(8)$ that has larger vertex order than vertex 0. Therefore, the BFS process starting from vertex 0 will stop at distance 2 and will not examine vertices 9 and 10. After the BFS process stops, we add a supplemental label entry to the supplemental label of vertex 8, resulting in $SL_{(0,8)}(8) = \{(0, 2)\}$. At Step (2), BFS process starts from vertex 2. Note that, the distance information has been discarded at this step. Similarly, vertex 8 is the only affected vertex in $AV_{(0,8)}(8)$ that has larger vertex order than vertex 2. Then the BFS process starting from vertex 2 will stop at distance 3. Then we may want to add another label entry $(2, 3)$ into $SL_{(0,8)}(8)$. But based on the original index shown in Table 1 and the current supplemental label $SL_{(0,8)}(8) = \{(0, 2)\}$, we find that $(2, 3)$ is a redundant label entry in $SL_{(0,8)}(8) = \{(0, 2)\}$ since the distance between vertex 2 and vertex 8 can be computed based on $SL_{(0,8)}(8) = \{(0, 2)\}$ and the original index in Table 1. We call this the late-pruning strategy. Finally, at Step (3), the BFS process will start from vertex 8. However, since no vertex in $AV_{(0,8)}(0)$ has smaller vertex order than vertex 8, no label entry will be added to the supplemental index at this step. The final supplemental index that is constructed

Algorithm 2 BFS AFF algorithm

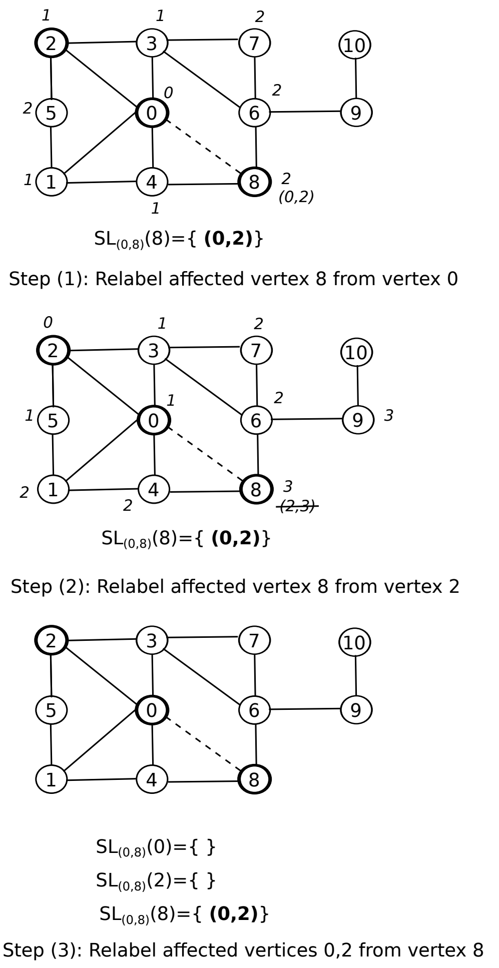
```
Input: $G$, $(u,v)$, $AV_{(u,v)}(u)$, $AV_{(u,v)}(v)$
Output: The supplemental index $SI_u$ and $SI_v$ for the edge
    failure case of $(u,v)$
 1: $G' \leftarrow G - \{(u,v)\}$
    //Construct $SI_u$ for vertices in $AV_{(u,v)}(u)$
 2: $SI_u \leftarrow \emptyset$
 3: for all $r \in AV_{(u,v)}(u)$ (in ascending vertex order) do
 4:     Initialize supplemental label for $r$: $SL \leftarrow \emptyset$
 5:     Start BFS algorithm to compute all the distances from
        $r$ to any vertices in $AV_{(u,v)}(v)$ that have larger vertex
        order than $\sigma(r)$
 6:     for all vertex t in $AV_{(u,v)}(v)$ that has $\sigma(t) > \sigma(r)$ do
 7:         if $(t, d_{G'}(t,r))$ is not a redundant label entry in $SL$
            then
 8:             $SL \leftarrow SL \cup (t, d_{G'}(t,r))$
 9:     $SI_u \leftarrow SI_u \cup (r, SL)$
    //Construct $SI_v$ for vertices in $AV_{(u,v)}(v)$
10: $SI_v \leftarrow \emptyset$
11: for all $r \in AV_{(u,v)}(v)$ (in ascending vertex order) do
12:     Initialize supplemental label for $r$: $SL \leftarrow \emptyset$
13:     Start BFS algorithm to compute all the distances from
        $r$ to any vertices in $AV_{(u,v)}(u)$ that have larger vertex
        order than $\sigma(r)$
14:     for all vertex t in $AV_{(u,v)}(u)$ that has $\sigma(t) > \sigma(r)$
        do
15:         if $(t, d_{G'}(t,r))$ is not a redundant label entry in $SL$
            then
16:             $SL \leftarrow SL \cup (t, d_{G'}(t,r))$
17:     $SI_v \leftarrow SI_v \cup (r, SL)$
```

for the failed edge $(0,8)$ on the graph shown in Figure 1 is shown at Step (3). We will show later in Section 4.4 that such supplemental index is adequate for distance query evaluation.

4.3.2 BFS ALL algorithm

The BFS ALL algorithm is very similar to the BFS AFF algorithm. The major diference is that the BFS ALL algorithm uses an *early label-pruning* strategy which consumes more memory during the relabeling process but gains acceleration of the relabeling process. The detail steps are shown in Algorithm 3. Figure 4 also depicts an example of the supplemental index construction process using the BFS ALL algorithm.

The failed edge is also (0,8) in this example and there are three steps in Figure 4. The main difference between BFS ALL an BFS AFF algorithms is that, in the BFS ALL algorithm, the distance information will be kept at each BFS step, using a set of temporary labels stored in TL. This distance information in TL can be used to prune label entries at the later BFS steps of the index construction process for all vertices in the graph and some vertices can be pruned during a BFS process. For example, at Step (2) in Figure 4, the number of vertices we need to visit (the vertices with bold label entries) is only seven, while at Step (2) in Figure 3, that number is 10 (by counting the vertices with distance information). Therefore, three vertices can be pruned at Step (2) in the BFS ALL algorithm. We call this the early-pruning strategy. It is obvious that the BFS ALL algorithm introduces more memory usage since BFS ALL has TL while BFS AFF does not. But the benefit of TL is that it



$SL_{(0,8)}(8)$={ **(0,2)**}
Step (1): Relabel affected vertex 8 from vertex 0
(0,2)
$SL_{(0,8)}(8)$={ **(0,2)**}
Step (2): Relabel affected vertex 8 from vertex 2
~~(2,3)~~
$SL_{(0,8)}(0)$={ }
$SL_{(0,8)}(2)$={ }
$SL_{(0,8)}(8)$={ **(0,2)**}
Step (3): Relabel affected vertices 0,2 from vertex 8

Figure 3: Supplemental index construction: BFS AFF on failed edge $(0,8)$

can prune vertices at an early stage, and as will be shown in Section 5, this can speed up the BFS process greatly. Nevertheless, the final supplemental index constructed by the BFS ALL algorithm is the same as that constructed by the BFS AFF algorithm as the construction of SI_u and SI_v in both algorithms is the same.

4.4 Distance Query Evaluation on SIEF

For each single-edge failure case, we classify all possible distance queries into different types. Suppose the graph is G, the original labeling index is L, the failed edge is (u,v), the affected vertices are in $AV_{(u,v)}(u)$ and $AV_{(u,v)}(v)$, and the supplemental index is $SI_{(u,v)}$ (here, $SI_{(u,v)} = SI_u \cup SI_v$). We also denote $G' = G - \{(u,v)\}$. Given any pair of vertices s,t, we would like to compute the distance between s,t on G', denoted as $d_{G'}(s,t)$. Then we have the following different cases:

- Case 1: $s \notin AV_{(u,v)}(u) \cup AV_{(u,v)}(v)$ and $t \notin AV_{(u,v)}(u) \cup AV_{(u,v)}(v)$
- Case 2: $s \notin AV_{(u,v)}(u) \cup AV_{(u,v)}(v)$ and $t \in AV_{(u,v)}(u) \cup AV_{(u,v)}(v)$, or similarly, $s \in AV_{(u,v)}(u) \cup AV_{(u,v)}(v)$ and $t \notin AV_{(u,v)}(u) \cup AV_{(u,v)}(v)$

Algorithm 3 BFS ALL algorithm

```
Input: $G$, $(u,v)$, $AV_{(u,v)}(u)$, $AV_{(u,v)}(v)$
Output: The supplemental index $SI_u$ and $SI_v$ for the edge
    failure case of $(u,v)$
 1: $G' \leftarrow G - \{(u,v)\}$
    //Construct $SI_u$ for vertices in $AV_{(u,v)}(u)$
 2: $SI_u \leftarrow \emptyset$
 3: Initialize temporary labels $TL \leftarrow \emptyset$
 4: for all $r \in AV_{(u,v)}(u)$ (in ascending vertex order) do
 5:     Initialize supplemental label for $r$: $SL \leftarrow \emptyset$
 6:     Start BFS algorithm to compute all the distances from
        $r$ to any vertices in $AV_{(u,v)}(v)$ that have larger vertex
        order than $\sigma(r)$ and record all temporary labels for all
        encountered vertices in $TL$; during the BFS process,
        if a new temporary label entry for a vertex $w$ is redundant
        in $TL$, all neighbor vertices of $w$ can be ignored
        by BFS
 7:     for all vertex t in $AV_{(u,v)}(v)$ that has $\sigma(t) > \sigma(r)$ and
        has been searched by the above BFS process do
 8:         if $(t, d_{G'}(t,r))$ is not a redundant label entry in $SL$
            then
 9:             $SL \leftarrow SL \cup (t, d_{G'}(t,r))$
10:     $SI_u \leftarrow SI_u \cup (r, SL)$
    //Construct $SI_v$ for vertices in $AV_{(u,v)}(v)$
11: $SI_v \leftarrow \emptyset$
12: Initialize temporary labels $TL \leftarrow \emptyset$
13: for all $r \in AV_{(u,v)}(v)$ (in ascending vertex order) do
14:     Start BFS algorithm to compute all the distances from
        $r$ to any vertices in $AV_{(u,v)}(u)$ that have larger vertex
        order than $\sigma(r)$ and record all temporary labels for
        all encountered vertices in $TL$; during the BFS process,
        if a new temporary label entry for a vertex $w$ is
        redundant in $TL$, then all neighbor vertices of $w$ will
        not be searched by BFS
15:     for all vertex t in $AV_{(u,v)}(u)$ that has $\sigma(t) > \sigma(r)$
        and has been searched by the above BFS process do
16:         if $(t, d_{G'}(t,r))$ is not a redundant label entry in $SL$
            then
17:             $SL \leftarrow SL \cup (t, d_{G'}(t,r))$
18:     $SI_v \leftarrow SI_v \cup (r, SL)$
```

- Case 3: $s \in AV_{(u,v)}(u)$ and $t \in AV_{(u,v)}(u)$, or similarly, $s \in AV_{(u,v)}(v)$ and $t \in AV_{(u,v)}(v)$
- Case 4: $s \in AV_{(u,v)}(u)$ and $t \in AV_{(u,v)}(v)$, or similarly, $s \in AV_{(u,v)}(v)$ and $t \in AV_{(u,v)}(u)$

Case 1 is trivial and we must have $d_{G'}(s,t) = d_G(s,t) = dist(s,t,L)$.

In Case 2 and in Case 3, according to Lemma 6 and the definition of affected vertices (see analysis in Section 4.2), we must also have $d_{G'}(s,t) = d_G(s,t) = dist(s,t,L)$.

In Case 4, suppose $s \in AV_{(u,v)}(u)$ and $t \in AV_{(u,v)}(v)$ (the other case can be analyzed in the same way). Obviously, distance between s and t changes to a larger value due to the failed edge. If s and t become disconnected to each other in G', both will not have labels in $SI_{(u,v)}$, then we have $d_{G'}(s,t) = \infty$. If s and t is still connected in G' and without loss of generality, suppose the vertex order is $\sigma(s) < \sigma(t)$, then at least vertex t contains supplemental label entries. This is because in both the BFS AFF algorithm and the BFS ALL algorithm, the affected vertex with

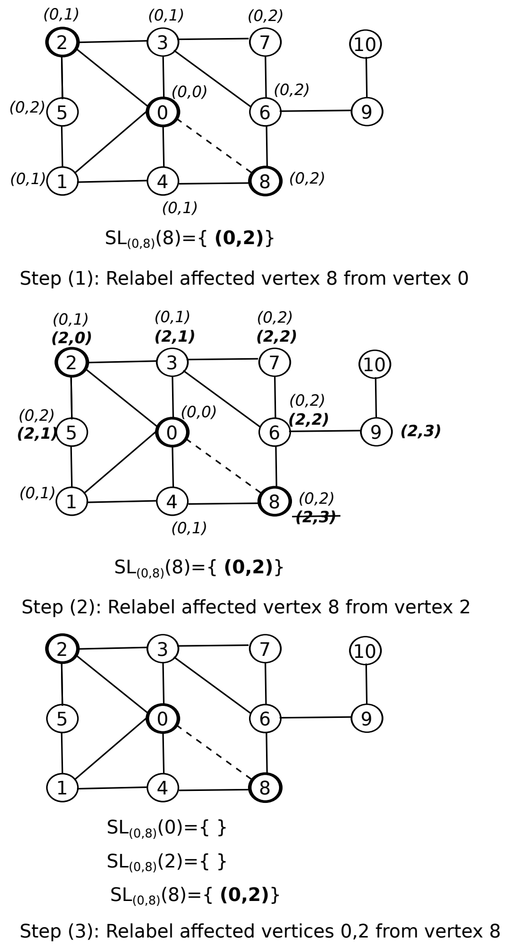


Figure 4: Supplemental index construction: BFS ALL on failed edge $(0, 8)$

minimum vertex order in $AV_{(u,v)}(u)$ (which is at most $\sigma(s)$) must produce one supplemental label entry for vertex t in $SI_{(u,v)}$ (see Lemma 3 for related details). For vertex s itself, if it does not produce any supplemental label entry for vertex t in $SI_{(u,v)}$, then it must be because the produced label entry is a redundant label. This means, in either case, the label entries of the supplemental label for vertex t in $SI_{(u,v)}$ must already contain adequate distance information for the computation of $d_{G'}(s,t)$. For example, to calculate $d_{G'}(2,8)$ in Figure 4, $SL_{(0,8)}(8) = \{(0,2)\}$ combining with $L(2) = \{(0,1)\ (2,0)\}$ in Table 1 is adequate and we can see that $d_{G'}(2,8) = 1 + 2 = 3$.

4.5 Some Remarks

Initial Index Construction. Pruned Landmark Labeling (PLL) technique presented in [2] is a state-of-the-art indexing technique for large static graphs. Indexes constructed by PLL [2] already have well-ordering property defined in Section 3. Therefore we use indexes constructed by PLL as the initial indexes for all original graphs in our experiments.

Time Complexity. Our algorithms can be directly applied on indexes constructed by PLL. Let w be the tree width [2] of G, n be the number of vertices and m be the number of edges in G. Also let (u,v) be the failed edge. If let $p = |AV_{(u,v)}(u) \cup$

$AV_{(u,v)}(v)|$ for each single-edge failure case (on average), the time complexity of the BFS AFF algorithm is $O(pn + pm)$ as it requires to perform p times BFS to compute SI_u and SI_v. Further, according to analysis of PLL in [2], the number of label entries per vertex is $O(w \log n)$. Then the time complexity of the BFS ALL algorithm is $O(nw \log n + p^2 w \log n)$, where $O(nw \log n)$ is the time upper bound to build temporary labels TL (note that p BFS rounds are enough to build the TL index that contains at most $nw \log n$ label entries) and $O(p^2 w \log n)$ is the time upper bound for redundancy tests.

5. EXPERIMENTS

We evaluated the performance of our proposed SIEF approach and this section reports the results. All experiments were performed under Linux (Ubuntu 10.04) on a server provided by eResearch SA[2]. The server was running on Dell R910 with 32 processing cores (four 8-core Intel Xeon E7-8837 CPUs at 2.67 GHz), 1024 GB main memory and 3 TB local scratch disk. All methods were implemented in C++ (the code of PLL [2] was obtained from the first author's code repository on GitHub[3]) using the same gcc compiler (version 4.4.6) with the optimizer option O3. It is worth mentioning that although we have a large amount of main memory on the server, the memory usage of our approach is in fact quite small and as observed during our experiments, the memory usage was within 12 GB for all datasets.

5.1 Datasets

Table 2 lists the six real-world datasets used in our experiments, which are briefly introduced as follows:

- `Gnutella` is a snapshot of the Gnutella peer-to-peer file sharing network collected in August 2002. Vertices represent hosts in the Gnutella network topology and edges represent connections between the hosts.
- The dataset `Facebook` consists of *circles* (or *friends lists*) from Facebook, which were collected from survey participants using a Facebook app called `Social Circles`.
- `Wiki-Vote` contains all Wikipedia voting data from the inception of Wikipedia till January 2008.
- `Oregon` is a graph of Autonomous Systems (AS) peering information inferred from Oregon route-views on May 26 2001.
- `Ca-HepTh` collaboration network of Arxiv High Energy Physics Theory category (there is an edge if authors coauthored at least one paper). The data covers papers in the period from January 1993 to April 2003 (124 months).
- `Ca-GrQc` collaboration network of Arxiv General Relativity category. Like `Ca-HepTh`, the data covers papers in the period from January 1993 to April 2003 (124 months).

More details on these datasets can be found at the Stanford Network Analysis Project website[4]. Similar to [3, 2], we treat all graphs as undirected, unweighted graphs.

[2]http://www.ersa.edu.au/

[3]https://github.com/iwiwi/pruned-landmark-labeling

[4]http://snap.stanford.edu/

It should be noted that, in Table 2, $|V|$ refers to the number of vertices and $|E|$ refers to the number of edges. In addition, IT denotes the indexing time or index construction time (in seconds) and LN denotes the average number of label entries of each vertex. We obtained these IT and LN results by using the Pruned Landmark Labeling (PLL) technique presented in [2]. As mentioned, we applied our index construction algorithms directly on the indexes constructed by PLL in our experiments.

Table 2: Real-world Datasets and Their Statistics

Dataset	|V|	|E|	IT (s)	LN
Gnutella	6,301	20,777	0.825	163.647
Facebook	4,039	88,234	0.173	25.887
Wiki-Vote	7,115	103,689	0.525	69.915

5.2 Performance Evaluation

We have conducted extensive experiments to validate our proposed approach. In the experiments, we compared the numbers of affected vertices (Section 5.2.3), the average label entry numbers with and without considering edge failures (Section 5.2.1). We performed queries with and without SIEF indexes (Section 5.2.4) and great efficiency improvement was observed if using SIEF indexes. We also studied the impact of our approach in terms of index size, identification time, and relabeling time for each dataset (Section 5.2.2 to 5.2.6). Note that, we construct SIEF indexes by computing supplemental indexes for all single-edge failure cases of a given graph.

5.2.1 *Supplemental Label Entry Numbers*

Figure 5 shows the difference between the original label entry number (OLEN) without support of single-edge failures and the supplemental label entry number (SLEN) with support of single-edge failures. SLEN and OLEN of `Wiki-Vote`[5] have the biggest gap, i.e., the ratio of SLEN to OLEN is observed around 80. SLEN and OLEN of `Facebook` have the second biggest gap and the ratio of SLEN to OLEN is around 40. For other datasets, the ratios of SLEN to OLEN are all under 10. This means, compared with the total number of label entries needed for the original graphs without considering edge failures, in the case of edge failures, the total extra number of label entries (in supplemental indexes) is less than 10 times of the number of the label entries in the original index. These results indicate that the SIEF indexes are very compact.

5.2.2 *Index Size*

Figure 6 shows the original index size for the graphs with no failed edges and the supplemental index size when considering edge failures. The sum of the original index size and the supplemental index size is the total index size for handling shortest path distances on graphs with all single-edge failure cases. From the figure, the `Gnutella` dataset shows comparatively smaller proportion of its supplemental index over its total index size while the `Facebook` dataset shows

[5]We use the first three letters in the names of each dataset (e.g., `Wik` for `Wiki-vote`) for better illustration in the figure.

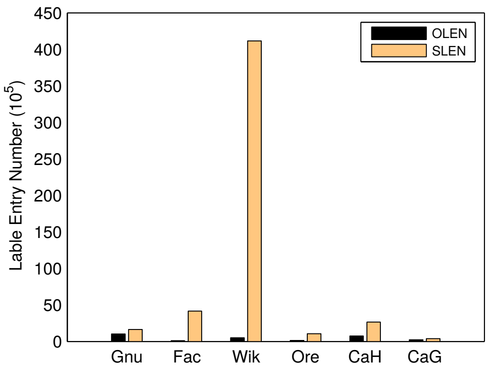

Figure 5: Comparisons between supplemental label entry numbers (SLENs) and original label entry numbers (OLENs)

largest proportion of its supplemental index over the related total index size. The `Wiki-Vote` dataset has the largest supplemental index size due to the fact that each single-failure case incurs a large number of affected vertices as well as a relatively large number of supplemental label entries (for more details, please see Table 3).

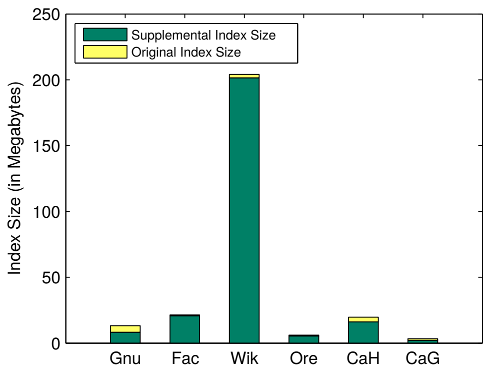

Figure 6: Index Size

5.2.3 *Affected Vertices*

Table 3 presents the relationship between affected vertices and average supplemental label entry number. *Avg* $|AU|/|V|$ represents the average percentage of affected vertices in a single-edge failure case, showing the impact of a single-edge failure on a graph. It is also the average proportion of affected vertices of the original graphs. *Avg* $|AU|$ represents the average number of affected vertices from the graph and *Avg SLEN* denotes the average number of supplemental label entries in a single-edge failure case.

From the table, we can see that the smallest percentage and the smallest average number of affected vertices are both observed in the `Ca-GrQc` dataset, with values of 1.486% and 77.884, respectively. We can also see from the table that the average supplemental label number decreases (or increases) together with the average number of the affected vertices. Also around 36% of vertices are affected in the `Wiki-Vote` dataset, which is the largest proportion. The largest average number of affected vertices is observed in the `Oregon` dataset, which is around 2,861 affected vertices for one failed edge. However, no clear linear relationship is found between the two. The largest gap occurs in the `Oregon` dataset, which indicates that the label pruning process on the affected vertices is quite powerful, leading to much fewer label entries per affected vertex. Meanwhile, the smallest gap happens in the `Gnutella` dataset and this indicates that label pruning is not very effective in this dataset.

Note that, although the proportion of affected vertices for a single-edge failure case could be large, as having been clarified in Figure 6, the final SIEF index for all single-edge failure cases is still of moderate sizes compared with the original index.

Table 3: Affected Vertices

Dataset	Avg $|AU|/|V|$	Avg $|AU|$	Avg SLEN
Gnutella	6.053%	381.386	78.445
Facebook	16.099%	650.241	47.042
Wiki-Vote	35.841%	2,550.090	396.971
Oregon	25.605%	2,861.070	45.323
Ca-HepTh	2.743%	270.881	51.095
Ca-GrQc	1.486%	77.884	13.064

5.2.4 *Query Time*

Table 4 shows the average BFS query time and the average SIEF query time. The former represents query time without using indexes proposed in this work, while the latter represents the query time when using SIEF indexes. From the table, we can see that the difference for `Oregon` dataset is the least, which still achieves at least 40 times faster when using SIEF indexes compared with the traditional BFS query approach. The largest gap occurs in the `Facebook` dataset, where the average BFS query time is around 500 times more than the SIEF query time. These results show that when using SIEF indexes, the query efficiency can be improved significantly and the query response times are normally no more than 5 μs. As mentioned in Section 4, we use supplemental indexes to support edge failures, the query process needs to examine the supplemental indexes first. When examining the supplemental indexes, SIEF checks whether the querying source and querying destination are both affected vertices given the edge failure constraint using binary search strategy. Based on the searching result, SIEF knows whether we can compute the shortest path distance based only on the supplemental indexes or based only on the original indexes. Nevertheless, the querying process is still much faster. The main reason is that the number of affected vertices for each single-edge failure case is typically small (more details are presented in Section 5.2.3) and hence the binary search process finishes quickly. This results in fast query responses in SIEF.

5.2.5 *Identification Time*

Table 5 shows the total time for identifying affected vertices for all single-edge failure cases. From the figure, we can see that, for the most datasets, the identification process can be done fairly fast and is normally finished within 80 seconds. The exception is `Wiki-Vote`, which requires a bit more than 600 seconds. The fast identification time is

Table 4: Average Query Time

Dataset	BFS Query Time	SIEF Query Time
Gnutella	140.329 μs	0.452 μs
Facebook	243.060 μs	0.522 μs
Wiki-Vote	284.867 μs	1.100 μs
Oregon	163.465 μs	4.985 μs
Ca-HepTh	325.196 μs	0.689 μs
Ca-GrQc	159.412 μs	0.479 μs

mainly because the affected vertices can be identified in a BFS manner and we only need to examine the distances between the affected vertices to one of the end vertices of a failed edge.

Table 5: Average Identification Time

Dataset	Identification Time
Gnutella	43.3708 s
Facebook	80.6844 s
Wiki-Vote	612.522 s
Oregon	35.6307 s
Ca-HepTh	36.2022 s
Ca-GrQc	4.32942 s

5.2.6 *Labeling Time*

Figure 7 shows the time for relabeling the affected vertices, which need extra distance label information to maintain correct distances to some other vertices due to a single-edge failure. Here, we used the estimated time for naive method (shown as "Estd Time for Naive Method" in the figure) as the baseline. The naive method refers to the method that we recompute a complete distance labeling index for each single-edge failure case. The process of labeling a new graph with a single-edge failure should be almost the same as the process of labeling the original graph. Therefore, the total labeling time of the naive method can be estimated by multiplying the total edge number in the original graph, i.e., the total number of single-edge failure cases, with the index time of the original graph (see Table 2).

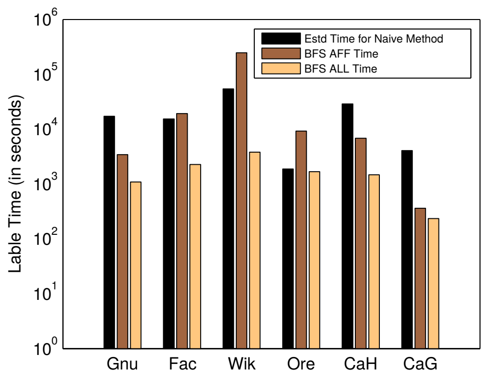

Figure 7: Labeling Time

Then, we compared the labeling times of the naive method and the two labeling methods proposed in our work: BFS AFF and BFS ALL. Recall that BFS AFF uses a late-label-pruning strategy and avoids labeling any unaffected vertices while BFS ALL uses an early-label-pruning strategy which needs labeling the unaffected vertices. From the figure, we can see that for some datasets, such as `Gnutella`, `Ca-HepTh` and `Ca-GrQc`, BFS AFF outperforms the naive method because the label-pruning process incurs some overhead when labeling unaffected vertices compared with the pure BFS process. However, BFS AFF is beaten by the naive method in terms of labeling time for other datasets, including `Facebook`, `Wiki-Vote` and `Oregon`, which contain a large number of vertices and/or a large number of edges. Hence, the late-label-pruning strategy in BFS AFF does not work well on all datasets. These results indicate that although label-pruning incurs some overhead on top of the BFS process, the label-pruning approach is quite effective in some datasets, especially datasets with more vertices and edges.

In contrast, BFS ALL performs the best on all datasets. For some datasets, such as `Facebook`, `Wiki-Vote` and `Ca-Hepth`, BFS ALL even performs orders of magnitude faster than both the naive method and the BFS AFF method. This confirms that the early-label-pruning strategy works very well on various datasets and the overhead on labeling unaffected vertices can be ignored due to the substantial label-pruning power it brings (for more details, please refer to Section 4.3).

6. CONCLUSION

This paper has studied the problem of computing the shortest path distance on graphs with single-edge failures based on 2-hop distance labeling techniques. The concept of well-ordering 2-hop distance labeling and its properties have been defined and analyzed. We have particularly focused on the constructions of compact distance labeling for all possible single-edge failure cases, a challenging problem that remains open, to the best of our knowledge. A generic framework, SIEF, has been designed for this purpose. Based on the most recent technique Pruned Landmark Labeling (PLL) [2] that handles only static graphs, we have implemented an extended version using the SIEF framework developed in this paper. Extensive experiments have also been performed on six real-world graphs to confirm its effectiveness and efficiency. SIEF is able to support compact index construction for all single-edge failure cases on graphs efficiently. Specifically, the SIEF index size is comparable to that of the indexes constructed for original static graphs, which is very compact. SIEF can answer distance queries with edge failure constraints several orders of magnitude faster than traditional Breadth-First-Search (BFS) algorithms.

In our future work, we will further investigate several aspects of answering distance queries on graphs with edge failures. The first one centers on how to support distance queries with more complex edge failure constraints, i.e., dual-failure on edges. The second aspect is to further speed up the index construction process in order to process larger graphs. Finally, it is also interesting to investigate the problem of answering distance queries on graphs with node failures, which is even more challenging than edge failures.

ABSTRACT

Cyber security is one of the most significant technical challenges in current times. Detecting adversarial activities, prevention of theft of intellectual properties and customer data is a high priority for corporations and government agencies around the world. Cyber defenders need to analyze massive-scale, high-resolution network flows to identify, categorize, and mitigate attacks involving networks spanning institutional and national boundaries. Many of the cyber attacks can be described as subgraph patterns, with prominent examples being insider infiltrations (path queries), denial of service (parallel paths) and malicious spreads (tree queries). This motivates us to explore subgraph matching on streaming graphs in a continuous setting.

The novelty of our work lies in using the subgraph distributional statistics collected from the streaming graph to determine the query processing strategy. We introduce a "Lazy Search" algorithm where the search strategy is decided on a vertex-to-vertex basis depending on the likelihood of a match in the vertex neighborhood. We also propose a metric named "Relative Selectivity" that is used to select between different query processing strategies. Our experiments performed on real online news, network traffic stream and a synthetic social network benchmark demonstrate 10-100x speedups over selectivity agnostic approaches.

1. INTRODUCTION

Social media streams and cyber data sources such as computer network traffic are prominent examples of high throughput, dynamic graphs. Application domains such as cyber security, emergency response, national security put a premium on discovering critical events as soon as they emerge in the data. Thus, processing streaming updates to a dynamic graph database for real-time situational awareness is an important research problem. These particular data sources are also distinguished by their natural representation as heterogeneous or multi-relational graphs. For example, a social media data stream contains a diverse set of entity types such as person, movie, images etc. and relations such as (*friendship, like etc.*). For cyber-security, a network traffic dataset can be modeled as a graph where vertices represent IP addresses and edges are typed by classes of network traffic [12]. Our work is focused on continuous querying of these dynamic, multi-relational graphs.

This downloads a script which establishes communication with the botnet command and control.

For social networks, we are often inundated with the stream of updates. Unless we choose to stay constantly connected to the social networks, it is highly desirable to report only the important patterns/events as they occur in the data; for example, we may choose to ask "tell me when two friends are meeting at a nearby location". The stakes are much higher in the cyber-security domain. As the volume and throughput of network traffic or event log datasets rise exponentially, the lack of ability to detect adversarial actions in real-time provides an asymmetric advantage to attackers. Internet backbone traffic collected by CAIDA [1]), which we use later as a dataset in our experiments typically accumulate 40 million packets every minute. In a study titled "Data Breach Investigations Report", US communications company Verizon analyzed 100,000 security incidents from the past decade and concluded that 90% of the incidents fell into ten attack patterns. A number of these attacks

[1]http://www.caida.org

10.5441/002/edbt.2015.15

can be naturally described as graph patterns. Figure 1 shows graph based patterns for a number of these attacks. Organizations such as internet service providers, content delivery networks etc. that receive network traffic from a wide area network are ideally poised to search for these attack patterns. Although there exists a significant number of graph databases and graph processing frameworks that scale to billion edge graphs, none of them support real-time subgraph pattern matching as a primary feature. Periodic export of network traffic flow or event alerts from log aggregation tools to a graph database, followed by post-attack querying on the static graph database is the most common workflow today. Despite cyber security being a multi-billion dollar market worldwide, the research on providing real-time querying capability on a **single, large streaming graph** is rather scarce.

Continuous querying of a dynamic graph raises a number of unique challenges. Indexing techniques that preprocess a graph and speed up queries are expensive to periodically recompute in a dynamic setting. Periodic execution of the query is an obvious solution under this condition, but the effectiveness of this approach will reduce as the interval between query executions shrinks. Also, periodic searching of the entire graph can be wasteful where the query match emerges slowly because we will find a partial match for the query every time we search and potentially redo the work numerous times. Very recent publications by Gao et al [7] and Mondal and Deshpande [15] presents algorithms for implementing continuous queries on graphs. This motivates us to study the problem of subgraph pattern matching in a streaming setting. We want to register a pattern as a graph query and continuously perform the query on the data graph as it evolves over time.

In addition to the cyber attack patterns in Figure 1, social queries are also drawn from LSBench, a benchmark for reasoning on streaming SPARQL data. A common theme that emerges is that all these query graphs are heterogenous in nature. They are composed of different edge types (in cyber security) as well as different node and edge types (in social media). None of the previous work on continuous pattern detection has addressed this issue of heterogeneity. Exploiting the heterogeneity in both the query graph and the data graph stream, and improving over heterogeneity agnostic continuous pattern detection approaches is the primary contribution of our research. The primary ideas behind our approach is described below. We believe the simplicity of our approach is its greatest strength, and it will allow easy adoption of our optimizations into the distributed system implementations developed by others in the field.

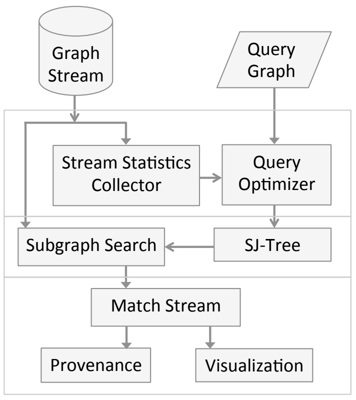

Figure 2: Framework for subgraph pattern matching on streaming graphs.

Figure 2 provides an overview of our approach. We approach the problem from an incremental processing perspective where search happens locally on every edge arrival. We do not search for the entire query graph around every new edge arriving in the stream. Given a query graph, the *query optimizer* decomposes it into smaller subgraphs as ordered by their *selectivity*. The selectivity information is obtained using the single-edge level and 2-edge path distribution obtained from the graph stream (section 5). We store the resulting decomposition into a data structure named SJ-Tree (Subgraph Join Tree) (section 3) that tracks matching subgraphs in the data graph. For a new edge in the graph, we always search for the *most selective* subgraph of the query graph. For other subgraphs of the query graph, a search is triggered if and only if a match for the previous subgraph in the selectivity order was obtained in the neighborhood of the new edge. This algorithm named "Lazy Search" is described in section 4. We introduce two metrics, *Expected and Relative Selectivity*, that captures the effectiveness of a given query decomposition (section 5). Further, we demonstrate how these metrics can be used to reason about the performance from different decompositions and select the best performing strategy.

1.1 Contributions

The most important takeaway from our work is that even as the subgraph isomorphism problem is NP-complete, it is possible to perform efficient continuous queries on dynamic graphs by exploiting the heterogeneity in the data and query graph. More specific contributions from the paper are listed below.

1. We present a dynamic graph search algorithm that demonstrates speedup of multiple orders of magnitude with respect to the state of the art.

2. We introduce two selectivity metrics for query graphs that are estimated using efficiently obtainable distributional statistics of single edge and 2-edge subgraphs from the graph stream.

3. We present an automatic query decomposition algorithm that selects the best performing strategy using the aforementioned graph stream statistics and *Relative Selectivity*.

Our observations are supported by experiments on datasets from three diverse domains (online news, computer network traffic and a social media stream).

2. BACKGROUND AND RELATED WORK

This section is aimed at providing an overview of the related field and provide the context for the studied problem. We begin with introducing the key concepts.

Multi-Relational Graphs We define a graph G as an ordered-pair $G = (V, E)$ where V is the set of vertices and the E is the set of edges that connect the vertices. In the following, we use $V(G)$ and $E(G)$ to indicate the set of vertices and edges associated with a graph G. A *labeled graph* is a six-tuple $G = (V, E, \Sigma_V, \Sigma_E, \lambda_V, \lambda_E)$, where Σ_V and Σ_E are sets of distinct labels for vertices and edges. λ_V and λ_E are vertex and edge labeling functions, i.e. $\lambda_V : V \rightarrow \Sigma_V$ and $\lambda_E : E \rightarrow \Sigma_E$.

Dynamic Graphs We define *dynamic graphs* as graphs that are changing over time through edge insertion or deletion. Every edge in a dynamic graph has a timestamp associated with it and therefore, for any subgraph g of a dynamic graph we can define a time interval $\tau(g)$ which is equal to the interval between the earliest and latest edge belonging to g. We focus on directed, labeled dynamic graphs with multi-edges in this work. The graph is maintained as a window in time. Given a time window t_W, edges are deleted as they become older than $t_{last} - t_W$, where t_{last} is the timestamp of the newest edge in the graph.

Subgraph Isomorphism Given the query graph G_q and a matching subgraph of the data graph (G_d) denoted as $G_d^{'}$, a matching between G_q and $G_d^{'}$ involves finding a bijective function $f : V(G_q) \rightarrow V(G_d^{'})$ such that for any two vertices $u_1, u_2 \in V(G_q)$, $(u_1, u_2) \in E(G_q) \Rightarrow (f(u_1), f(u_2)) \in E(G_d^{'})$.

2.1 Problem Statement

Every edge in a dynamic graph has a timestamp associated with it and therefore, for any subgraph g of a dynamic graph we can define a time duration $\tau(g)$ which is equal to the duration between the earliest and latest edge belonging to g. Given a dynamic multi-relational graph G_d, a query graph G_q and a time window t_W, we report whenever a subgraph g_d that is isomorphic to G_q appears in G_d such that $\tau(g_d) < t_W$. The isomorphic subgraphs are also referred to as *matches* in the subsequent discussions. Assume that G_d^k is the data graph at time step k. If $M(G_d^k)$ is the cumulative set of all matches discovered until time step k and E_{k+1} is the set of edges that arrive at time step $k+1$, we present an algorithm to compute a function $f\left(G_d, G_q, E_{k+1}\right)$ which returns the incremental set of matches that result from updating G_d with E_{k+1} and is equal to $M(G_d^{k+1}) - M(G_d^k)$.

2.2 Related Work

Graph querying techniques have been studied extensively in the field of pattern recognition over nearly four decades [4]. Two popular subgraph isomorphism algorithms were developed by Ullman [20] and Cordella et al. [5]. The VF2 algorithm [5] employs a filtering and verification strategy and outperforms the original algorithm by Ullman. Over the past decade, the database community has focused strongly on developing indexing and query optimization techniques to speed up the searching process. A common theme of such approaches is to index vertices based on k-hop neighborhood signatures derived from labels and other properties such as degrees and centrality [17, 18, 23]. Other major areas of work involve exploration of subgraph equivalence classes [8] and search techniques for alternative representations such as similarity search in a multi-dimensional vector space [13]. Apart from neighborhood based signatures, *graph sketches* is an important area that focuses on generating different synopses of a graph data set [22]. Development of efficient graph sketching algorithms and their applications into query estimation is expected to gain prominence in the near future.

Investigation of subgraph isomorphism for dynamic graphs did not receive much attention until recently. It introduces new algorithmic challenges because we can not afford to index a dynamic graph frequently enough for applications with real-time constraints. In fact this is a problem with searches on large static graphs as well [16]. There are two alternatives in that direction. We can search for a pattern repeatedly or we can adopt an incremental approach. The work by Fan et al. [6] presents incremental algorithms for graph pattern matching. However, their solution to subgraph isomorphism is based on the repeated search strategy. Chen et al. [2] proposed a feature structure called the *node-neighbor tree* to search multiple graph streams using a vector space approach. They relax the exact match requirement and require significant preprocessing on the graph stream. Our work is distinguished by its focus on temporal queries and handling of partial matches as they are tracked over time using a novel data structure. From a data-organization perspective, the SJ-Tree approach has similarities with the Closure-Tree [9]. However, the closure-tree approach assumes a database of independent graphs and the underlying data is not dynamic. There are strong parallels between our algorithm and the very recent work by Sun et al. [16], where they implement a query-decomposition based algorithm for searching a large static graph in a distributed environment. Here our work is distinguished by the focus on continuous queries that involves maintenance of partial matches as driven by the query decomposition structure, and optimizations for real-time query processing. Mondal and Deshpande [15] propose solutions to supporting continuous ego-centric queries in a dynamic graph, Our work focuses on subgraph isomorphism, while [15] is primarily focused on aggregate queries. We view this as complementary to our work, and it affirms our belief that continuous queries on graphs is an important problem area, and new algorithms and data structures are required for its development.

The query pattern matching approach recently proposed in [7] is most closely related to our work with some important distinctions. The authors build a vertex centric, query processing engine for dynamic graphs on top of Apache Giraph, a distributed computing framework inspired by the Pregel framework. Their query decomposition approach is based on identifying optimal sub-DAGs (directed acyclic graph) in the query graph. The DAGs' are then traversed to identify source and sink vertices to define message transition rules in the Giraph framework. Although they address significant challenges inherent of processing dynamic graphs, it is not suitable for all types of queries. Specifically, queries that have cyclic communications, such as infiltration attack query in Figure 1 cannot be decomposed in DAG to find exact matches. Also, in our work we exclusively focus on query graphs with labeled edges with specific constraints. This are not addressed in the framework proposed in [7]. Our work makes no assumptions about the query graph structure and will find exact matches even when there is no apparent sink vertices. Moreover, the focus in [7] is on distributed implementation, while we focus on selectivity based query decomposition - that can improve performance for heterogeneous graphs. We show via edge distribution and selectivity plots that real world heterogeneous graphs have a strong skew in subgraph selectivity. The novelty of our work lies in estimating the selectivity of subgraphs from the graph stream and using the selectivity to determine the subgraph search strategy.

In summary, we consider these works to pursue two related but distinct directions that needs to be implemented in a scalable system.

3. A QUERY DECOMPOSITION APPROACH

We introduce an approach that guides the search process to look for specific subgraphs of the query graph and follow *specific* transitions from small to larger matches. Following are the main intuitions that drive this approach.

1. Instead of looking for a match with the entire graph or just any edge of the query graph, partition the query graph into smaller subgraphs and search for them.

2. Track the matches with individual subgraphs and combine them to produce progressively larger matches.

3. Define a *join order* in which the individual matching subgraphs will be combined. Do not look for every possible way to combine the matching subgraphs.

Figure 3 shows an illustration of the idea. Although the current work is completely focused on temporal queries, the graph decomposition approach is suited for a broader class of applications and

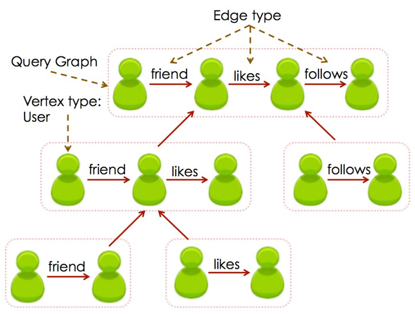

Figure 3: Illustration of the decomposition of a social query in SJ-Tree.

queries. The key aspect here is to search for substructures without incurring too much cost. Even if some subgraphs of the query graph are matched in the data, we will not attempt to assemble the matches together without following the join order.

The query decomposition approach can still suffer from having to maintain too many partial matches. If a subgraph of the query graph is highly *frequent*, we will end up tracking a large number of partial matches corresponding to that subgraph. Unless we have quantitative knowledge about how these partial matches transition into larger matches, we face the risk of tracking a large number of non-promising matching subgraphs. The “Lazy Search" approach outlined earlier in the introduction enhances this further. For any new edge, we search for a query subgraph if and only if it is the most selective subgraph in the query or if one of the either vertices in that edge participates in a match with the preceding (query) subgraph in the join order.

This section is dedicated towards introducing the data structures and algorithms for dynamic graph search. We begin with introducing the SJ-Tree structure (section 3.1) and then proceed to present the basic algorithms (Algorithm 1 and 2). The “Lazy Search"-enhanced version is introduced later in section 4. Automated generation of SJ-Tree is covered in section 5.

3.1 Subgraph Join Tree (SJ-Tree)

We introduce a tree structure called *Subgraph Join Tree (SJ-Tree)*. SJ-Tree defines the decomposition of the query graph into smaller subgraphs and is responsible for storing the partial matches to the query. Figure 3 shows the decomposition of an example query. Each of the rectangular boxes with dotted lines will be represented as a node in the SJ-Tree. The query subgraphs shown inside each “box" will be stored as a node property described below.

DEFINITION 3.1.1 A SJ-Tree T is defined as a binary tree comprised of the node set N_T. Each $n \in N_T$ corresponds to a subgraph of the query graph G_q. Let's assume V_{SG} is the set of corresponding subgraphs and $|V_{SG}| = |N_T|$. Additional properties of the SJ-Tree are defined below.

DEFINITION 3.1.2 A *Match* or a *Partial Match* is as a set of edge pairs. Each edge pair represents a mapping between an edge in a query graph and its corresponding edge in the data graph.

DEFINITION 3.1.3 Given two graphs $G_1 = (V_1, E_1)$ and $G_2 = (V_2, E_2)$, the join operation is defined as $G_3 = G_1 \bowtie G_2$, such that $G_3 = (V_3, E_3)$ where $V_3 = V_1 \cup V_2$ and $E_3 = E_1 \cup E_2$.

PROPERTY 1. The subgraph corresponding to the root of the SJ-Tree is isomorphic to the query graph. Thus, for $n_r = root\{T\}$, $V_{SG}\{n_r\} \equiv G_q$.

PROPERTY 2. The subgraph corresponding to any internal node of T is isomorphic to the output of the join operation between the subgraphs corresponding to its children. If n_l and n_r are the left and right child of n, then $V_{SG}\{n\} = V_{SG}\{n_l\} \bowtie V_{SG}\{n_r\}$.

Therefore, each leaf of the SJ-Tree represent subgraphs that we want to search for (perform subgraph isomorphism) on the streaming updates. Internal nodes in the SJ-Tree represents subgraphs that result from the joining of subgraphs returned by the subgraph isomorphism operations.

PROPERTY 3. Each node in the SJ-Tree maintains a set of *matches*. We define a function $matches(n)$ that for any node $n \in N_T$, returns a set of subgraphs of the data graph. If $M = matches(n)$, then $\forall G_m \in M$, $G_m \equiv V_{SG}\{n\}$.

PROPERTY 4. Each internal node n in the SJ-Tree maintains a subgraph, CUT-SUBGRAPH(n) that equals the *intersection* of the query subgraphs of its child nodes.

For any internal node $n \in N_T$ such that CUT-SUBGRAPH$(n) \neq \emptyset$, we also define a *projection operator* Π. Assume that G_1 and G_2 are isomorphic, $G_1 \equiv G_2$. Also define Φ_V and Φ_E as functions that define the bijective mapping between the vertices and edges of G_1 and G_2. Consider g_1, a subgraph of G_1: $g_1 \subseteq G_1$. Then $g_2 = \Pi(G_2, g_1)$ is a subgraph of G_2 such that $V(g_2) = \Phi_V(V(g_1))$ and $E(g_2) = \Phi_E(E(g_1))$.

Our decision to use a binary tree as opposed to an n-ary tree is influenced by the simplicity and lowering the combinatorial cost of joining matches from multiple children. With the properties of the SJ-Tree defined, we are now ready to describe the graph search algorithm.

3.2 Dynamic Graph Search Algorithm

Algorithm 1 DYNAMIC-GRAPH-SEARCH(G_d, T, edges)

```
1: $leaf\text{-}nodes$ =GET-LEAF-NODES($T$)
2: for all $e_s \in edges$ do
3:     UPDATE-GRAPH($G_d, e_s$)
4:     for all $n \in leaf\text{-}nodes$ do
5:         $g^q_{sub}$ =GET-QUERY-SUBGRAPH($T, n$)
6:         $matches$ =SUBGRAPH-ISO($G_d, g^q_{sub}, e_s$)
7:         if $matches \neq \emptyset$ then
8:             for all $m \in matches$ do
9:                 UPDATE-SJ-TREE($T, n, m$)
```

We begin with describing our dynamic graph search algorithm (Algorithm 1 and 2). The input to DYNAMIC-GRAPH-SEARCH is the dynamic graph so far G_d, the SJ-Tree (T) corresponding to the query graph and the set of incoming edges. Every incoming edge is first added to the graph (Algorithm 1, line 3). Next, we iterate over all the query subgraphs to search for matches containing the new edge (line 5-6). Any discovered match is added to the SJ-Tree (line 9).

Next, we describe the UPDATE-SJ-TREE function. Each node in the SJ-Tree maintains its sibling and parent node information (Algorithm 2, line 1-2). Also, each node in the SJ-Tree maintains a hash table (referred by the *match-tables* property in Algorithm 2, line 4). GET() and ADD() provides lookup and update operations on the hash tables. Each entry in the hash table refers to a *Match*. Whenever a new matching subgraph g is added to a node in the SJ-Tree, we compute a key using its projection ($\Pi(g)$) and insert the key and the matching subgraph into the corresponding hash table (line 12). When a new match is inserted into a leaf node we check to see if it can be combined (referred as JOIN()) with any matches that are contained in the collection maintained at its sibling node.

A successful combination of matching subgraphs between the leaf and its sibling node leads to the insertion of a larger match at the parent node. This process is repeated recursively (line 11) as long as larger matching subgraphs can be produced by moving up in the SJ-Tree. A complete match is found when two matches belonging to the children of the root node are combined successfully.

EXAMPLE Let us revisit Figure 3 for an example. Assuming we find a match with the query subgraph containing a single “friend" edge (e.g. $\{$(“George", “friend", “John")$\}$), we will probe the hash table in the leaf node with “likes" edges. If the hash table stored a subgraph such as $\{$(“John", “likes", “Santana")$\}$, the JOIN() will produce a 2-edge subgraph $\{$(“George", “friend", “John"), (“John", “likes", “Santana")$\}$. Next, it will be inserted into the parent node with 2-edges. The same process will be subsequently repeated, beginning with the probing of the hash table storing matches with subgraphs with a “follows" edge.

Algorithm 2 UPDATE-SJ-TREE($node, m$)

```
1: $sibling = sibling[node]$
2: $parent = parent[node]$
3: $k$ =GET-JOIN-KEY(CUT-SUBGRAPH[$parent$], $m$)
4: $H_s$ = match-tables[$sibling$]
5: $M_s^k$ = GET($H_s, k$)
6: for all $m_s \in M_s^k$ do
7:     $m_{sup}$ = JOIN($m_s, m$)
8:     if parent = root then
9:         PRINT('MATCH FOUND : ', $m_{sup}$)
10:    else
11:        UPDATE-SJ-TREE($parent, m_{sup}$)
12: ADD(match-tables[$node$], $k, m$)
```

4. LAZY SEARCH

Revisiting our example from Figure 3, it is reasonable to assume that the “friend" relation is highly frequent in the data. If we decomposed the query graph all the way to single edges then we will be tracking all edges that match “friend". Clearly, this is wasteful. One may suggest decomposing the query to larger subgraphs. However, it will also increase the average time incurred in performing subgraph isomorphism. Deciding the right granularity of decomposition requires significant knowledge about the dynamic graph. This motivates us to introduce a new algorithmic extension.

Assume the query graph G_q is partitioned into two subgraphs g_1 and G_q^1. We use the notation G_q^k to indicate what remains of G_q after the k-th iteration in the decomposition process. If the probability of finding a match for g_1 is less than the probability of finding a match for G_q^1, then it is always desirable to search for g_1 and look for G_q^1 only where an occurrence of g_1 is found. Therefore, we select g_1 to be the most selective edge or 2-edge subgraph in the query graph and always search for g_1 around every new edge in the graph. Once we detect subgraphs in G_d that match with g_1, we follow the same approach to search for G_q in their neighborhood. We partition G_q^1 further into two subgraphs: g_2 and G_q^2, where g_2 is another 1-edge or 2-edge subgraph.

DATA STRUCTURES With the SJ-Tree, the partitioning of G_q is done upfront at the query compile time with g_1, g_2 etc becoming the leaves of the tree. The main difference between Lazy Search and that of Algorithm 2 is that we will be searching for g_2 only around the edges in G_d where a match with g_1 is found. Therefore, for every vertex u in G_d, we need to keep track of the g_i-s such that u is present in the matching subgraph for g_i. We use a bitmap structure M_b to maintain this information. Each row in the bitmap refers to a vertex in G_d and the i-th column refers to g_i, or the i-th leaf in the SJ-Tree. If the search for subgraph g_i is enabled for vertex u in G_d, then $M_b[u][i] = 1$ and zero otherwise. Whenever a matching subgraph g' for g_i is discovered, we turn on the search for g_{i+1} for all vertices in $V(g')$. This is accomplished by setting $M_b[v][i+1] = 1$ where $v \in V(g')$.

ROBUSTNESS WITH SUBGRAPH ARRIVAL ORDER Consider a SJ-Tree with just two leaves representing query subgraphs g_1 and g_2, with g_1 representing the *more selective* left leaf. The above strategy is not robust to the arrival order of matches. Assume $g_1^{'}$ and $g_2^{'}$ are subgraphs of G_d that are isomorphic to g_1 and g_2 respectively. Together, $g_1^{'} \times g_2^{'}$ is isomorphic to the query graph G_q. Because we are searching for g_1 on every incoming edge, $g_1^{'}$ will be detected as soon as it appears in the data graph. However, we will detect $g_2^{'}$ only if appears in G_d after $g_1^{'}$. If $g_2^{'}$ appeared in G_d before $g_1^{'}$ we will not find it because we are not searching for g_2 all the time.

We introduce a small change to address this temporal ordering issue. Whenever we enable the search on a node in the data graph, we also perform a subgraph search around the node to find any match that has occurred earlier. Thus, when we find g_1 and enable the search for g_2 on every subsequent edge arrival, we also perform a search in G_d looking for g_1. This ensures that we will find g_2 even if it appeared before g_1.

Algorithm 3 summarizes the entire process. Lines 2-3 loop over all news edges arriving in the graph and update the graph. Next, given a new edge e_s, for each node in the SJ-Tree, we check to see if we should be searching for its corresponding subgraph around e_s (lines 4-8). The DISABLED() function queries the bitmap index and returns *true* if the corresponding search task is disabled. GET-QUERY-SUBGRAPH returns the query subgraph g_{sub}^q corresponding to node n in the SJ-Tree (line 9). Next, we search for g_{sub}^q using a subgraph-isomorphism routine that only searches for matches containing at least one of the end-point vertices of e_s (u and v, mentioned in line 5-6). For each matching subgraph found containing u or v, we enable the search for the query subgraph corresponding the sibling of n in the SJ-Tree. If n was not left-deep most node in the SJ-Tree, then we also query the left sibling to probe for potential join candidates (QUERY-SIBLING-JOIN(), line 16). Any resultant joins are pushed into the parent node and the entire process is recursively repeated at one level higher in the SJ-Tree.

5. SJ-TREE GENERATION

Here we address the topic of automatic generation of the SJ-Tree from a specified query graph. We begin with introducing key definitions, followed by the decomposition algorithm.

DEFINITION **Subgraph Selectivity** Given a large typed, directed graph G, the selectivity of a typed, directed subgraph g with k-edges (denoted as $S(g)$) is the ratio of the number of occurrences of g and the total number of all k-edge subgraphs in G. Instances of g may overlap with each other.

DEFINITION **Selectivity Distribution** The selectivity distribution of a set of subgraphs G_k is a vector containing the selectivity for every subgraph in G_k. The subgraphs are ordered by their frequencies in ascending order.

We present a greedy algorithm (Algorithm 4) for decomposing a query graph into its subgraphs and generating a SJ-Tree. Our choice for the greedy heuristic is motivated by extensive survey of the literature on optimal join order determination in relational databases [10, 14, 21]. A key conclusion of the survey states that *left-deep join plans* (or left deep binary trees in this case) is one

Algorithm 3 LAZY-SEARCH(G_d, T, edges)

```
1: $leaf\text{-}nodes$ =GET-LEAF-NODES($T$)
2: for all $e_s \in edges$ do
3:     UPDATE-GRAPH($G_d, e_s$)
4:     for all $n \in leaf\text{-}nodes$ do
5:         $u$ =src($e_s$)
6:         $v$ =dst($e_s$)
7:         if DISABLED(u, n) AND DISABLED(v, n) then
8:             continue
9:         $g^q_{sub}$ =GET-QUERY-SUBGRAPH($T, n$)
10:        $matches$ =SUBGRAPH-ISO($G_d, g^q_{sub}, e$)
11:        for all $m \in matches$ do
12:            if $n = 0$ then
13:                ENABLE-SEARCH-SIBLING($n, m$)
14:            else
15:                $M_j$ = QUERY-SIBLING-JOIN($n, m$)
16:                $p$ = PARENT($n$)
17:                for all $m_j \in M_j$ do
18:                    UPDATE($p, m_j$)
19:                    ENABLE-SEARCH-SIBLING($p, m$)
```

of the best performing heuristics. The above mentioned studies point to a large body of research using techniques such as dynamic programming and genetic algorithms to find the optimal join order. Nonetheless, finding the lowest cost join order or using a cost-driven join order determination remains an interesting problem in graph databases, and the approaches based on minimum spanning trees or approximate vertex cover can provide an initial path forward.

Inputs to Algorithm 4 are the query graph G_q and an ordered set of primitives M. Our goal is to decompose G_q into a collection of (possibly repeated) subgraphs chosen from M. Entries of M are sorted in ascending order of their subgraph selectivity. Given a query graph G_q, the algorithm begins with finding the subgraph with the lowest selectivity in M. This subgraph is next removed from the query graph and the nodes of the removed subgraph are pushed into a "frontier" set. We proceed by searching for the next selective subgraph that includes at least one node from the frontier set. We continue this process until the query graph is empty. SUBGRAPH-ISO performs a subgraph isomorphism operation to find an instance of g_M in G_q. Algorithm 4 uses two versions of SUBGRAPH-ISO. The first version uses three arguments, where the second argument is a vertex id v. This version of SUBGRAPH-ISO searches G_q for instances of g_M by only searching in the neighborhood of v. The other version accepting two arguments searches entire G_q for an instance of g_M. REMOVE-SUBGRAPH accepts two graphs as argument, where the second argument (g_{sub}) is a subgraph of the first graph (G_q). It removes all edges in G_q that belong to g_{sub}. A vertex is removed from G_q only when the edge removal results in a disconnected vertex.

5.1 Selectivity Estimation of Primitives

We propose computing the selectivity distribution of primitives by processing an initial set of edges from the graph stream. For experimentation purposes we assume that the selectivity order remains the same for the dynamic graph when we perform the query processing. This work does not focus on modeling the accuracy of this estimation. Modeling the impact on performance when the actual selectivity order deviates from the estimated selectivity order is an area of ongoing work.

Which subgraphs are good candidates as entries of M? Following are two desirable properties for entries in M: 1) the cost

Algorithm 4 BUILD-SJ-TREE(G_q, M)

```
1: $frontier = \emptyset$
2: while $|V(G_q)| > 0$ do
3:     $g_{sub} = \emptyset$
4:     for all $g_M \in M$ do
5:         if $frontier \neq \emptyset$ then
6:             for all $v \in frontier$ do
7:                 $g_{sub}$ =SUBGRAPH-ISO($G_q, v, g_M$)
8:                 break
9:         else
10:            $g_{sub}$ =SUBGRAPH-ISO($G_q, g_M$)
11:    if $g_{sub} \neq \emptyset$ then
12:        $frontier = frontier \cup V(g_{sub})$
13:        $G_q$ =REMOVE-SUBGRAPH($G_q, g_{sub}$)
```

for subgraph isomorphism should be low. 2) Selectivity estimation of these subgraphs should be efficient as we will need to periodically recompute the estimates from a graph stream. Based on these two criteria, we select single edge subgraphs and 2-edge paths as primitives in this study. Computing the selectivity distribution for single-edge subgraphs resolves to computing a histogram of various edge types. The selectivity distribution for 2-edge paths on a graph with V nodes, E vertices and k unique edge types can be done in $O(V(E + k^2))$ time. Algorithm 5 provides a simple algorithm to count all 2-edge paths. In our experiments, computing the path statistics for a network traffic dataset with 800K nodes and nearly 130 million edges takes about 50 seconds without any code optimization.

Algorithm 5 uses a Counter() data structure, which is a hashtable where given a key, the corresponding value indicates the number of times the key occurred in the data. A Counter() is updated via the UPDATE routine, which accepts the counter object, a key value and an integer to increment the corresponding key count. We iterate over all vertices in the input graph (G_d) (line 2). For an given vertex v, we count the number of occurrences of each unique edge type associated with it (accounting for edge directions). Line 8 iterates over all unique edge types associated with v. Next, given an edge type e_1 and its count n_1, we count the number of combinations possible with two edges of same type ($\binom{n}{2}$). Next, we compute the number of 2-edge paths that can be generated with e_1 and any other edge type e_2. We impose the LEXICALLY-GREATER constraint to ensure each edge is factored in only once in the 2-edge path distribution.

Note that we use a $Map()$ function instead of simply using the type associated with every edge. Most of our target applications have significant amount edge attributes in the graphs. As an example, in a network traffic graph we use the protocol information to determine the edge property. Thus, each network flow with the same protocol (e.g. HTTP, ICMP etc.) are mapped to the same edge type. Each flow is accompanied by multiple attributes such as source and destination ports, duration of communication etc.. Therefore, we can provide a hash function to map any user defined edge properties to an integer value. Thus, for queries with constraints on vertex and edge properties, a generic map function factors in both structural and semantic characteristics of the graph stream.

Counting the frequency for larger subgraphs is important. Given a query graph with M edges, ideally we would like to know the frequency of all subgraphs with size $1, 2, .., M - 1$. Collecting the frequency of larger subgraphs, specifically triangles have received a significant attention in the database and data mining community

[19]. Exhaustive enumeration of all the triangles can be expensive, specially in the presence of high degree vertices in the data. Approximate triangle counting via sampling for streaming and semi-streaming has been extensively studied in the recent years [11]. We foresee incorporation of such algorithms to support better query optimization capabilities for queries with triangles.

Algorithm 5 COUNT-2-EDGE-PATHS(G_d)

```
1: $P = Counter()$
2: for all $v \in V(G_d)$ do
3:     $C_v$ = $Counter()$
4:     for all $e \in Neighbors(G_d, v)$ do
5:         $e_t = Map(e)$
6:         $Update(C_v, e_t, 1)$
7:     $E_t = Keys(C_v)$
8:     for all $e_1 \in E_t$ do
9:         $n_1 = Count(C_v, e_1)$
10:        $key = (e_1, e_1)$
11:        $Update(P, key, n_1(n_1 - 1)/2)$
12:        for all $e_2 \in$LEXICALLY-GREATER$(E_t, e_1)$ do
13:            $n_2 = Count(C_v, e_2)$
14:            $key = (e_1, e_2)$
15:            $Update(P, key, n_1 n_2)$
```

5.2 Query Decomposition Strategies

Algorithm 4 shows that we can generate multiple SJ-Trees for the same G_q by selecting different primitive sets for M. We can initiate M with only 1-edge subgraphs, only 2-edge subgraphs or a mix of both. As an example, for a 4-edge query graph, the removal of the first 2-edge subgraph can leave us with 2 isolated edges in G_q. At that stage, we will create two leaf nodes in the SJ-Tree with 1-edge subgraphs. For brevity we refer to both the second and third choice as 2-edge decomposition in the remaining discussions. Clearly, these 1 or 2-edge based decomposition strategies has different performance implications. Searching for 1-edge subgraphs is extremely fast. However, we stand to pay the price with memory usage if these 1-edge subgraphs are highly frequent. On the contrary, we expect 2-edge subgraphs to be more discriminative. Thus, we will trade off lowering the memory usage by spending more time searching for larger, discriminative subgraphs on every incoming edge.

DEFINITION **Expected Selectivity** We introduce a metric called *Expected Selectivity*, denoted as $S(\hat{T_k})$. Given a SJ-Tree T_k, the Expected Selectivity is defined as the product of the selectivities of the leaf-level query subgraphs.

$leaves(T_k)$ returns the set of leaves in a SJ-Tree T_k. Given a node n, $V_{SG}(T, n)$ returns the subgraph corresponding to node n in SJ-Tree T. Finally, $S(g)$ is the selectivity of the subgraph g as defined earlier.

$$S(\hat{T_k}) = \prod_{n \in leaves(T_k)} S(V_{SG}(T_k, n)) \tag{1}$$

DEFINITION **Relative Selectivity** We introduce a metric called *Relative Selectivity*, denoted as $\xi(T_k, T_1)$. Given a 1-edge decomposition T_1 and another decomposition T_k, we define $\xi(T_k, T_1)$ as follows.

$$\xi(T_k, T_1) = \frac{S(\hat{T_k})}{S(\hat{T_1})} \tag{2}$$

We conclude the section with discussion on two desirable properties of a greedy SJ-Tree generation strategy.

THEOREM 1 Given the data graph G_d at any time t, assume that the query graph G_q is not guaranteed to be present in G_d. Then initiating the search for G_q by searching for g_{rare} where $g_{rare} \subset G_q$ and $\forall g \subset G_q ||E(g)| = |E(g_{rare})|, frequency(g) > frequency(g_{rare})$ is in optimal strategy.

PROOF The time complexity for searching for a $O(1)$ for a 1-edge subgraph and $O(\bar{d_v})$ for a 2-edge subgraph. Therefore, the runtime cost to search for g_{rare} is same as any other subgraph of G_q with the same number of edges. However, searching for g_{rare} will require minimum space because it has the minimum frequency amidst all subgraphs with same size. Therefore, searching for g_{rare} is an optimal strategy.

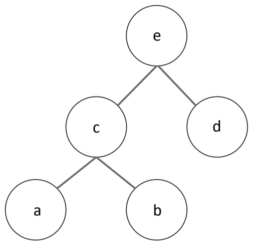

Figure 4: Example SJ-Tree used in proof of theorem 2.

THEOREM 2 Given a set of identical size subgraphs $\{g_k\}$ such that $\cup_k^n g_k = G_q$, a SJ-Tree with ordered leaves $g_k \prec g_{k+1} \prec g_{k+2}$ requires minimal space when $frequency(g_k \bowtie g_{k+1}) < frequency(g_{k+2})$.

PROOF By induction. Assume a SJ-Tree with three leaves as shown in Figure 4. Following the definitions of SJ-Tree, this is a left-deep binary tree with 3 leaves. Therefore, $frequency(c)$ denoted in shorthand as $f(c)$ $f(c)$ = $min(f(a), f(b))$. Substituting for the frequency of c, space requirement for this tree $S(T) = f(a) + f(b) + f(d) + min(f(a), f(b))$. Thus, the space requirement for this tree is minimum if $f(a) < f(b) < f(c)$.

Now we can consider any arbitrary tree where T_n refers to a tree with a left subtree T_{n_1} and a right child l_{n+2}. Above shows that T_1 constructed as above will have minimum space requirement, and so will T_2 if $f(a) < f(b) < f(c) < f(d)$.

OBSERVATION 3 Given g_k, a subgraph of query graph G_q, it is efficient to decompose g_k if there is a subgraph $g \subset g_k$, such that frequency(g) $> \left(\frac{frequency(g_k)}{d|V(g_k)|}\right)$, where $\bar{d}$ is the average vertex degree of the data graph and $|V(g_k)|$ is the number of vertices in g_k.

PROOF Given a graph g, the average cost for searching for another graph that is larger by a single edge is $\bar{d}$ multiplied by the number of vertices in g_k, and the proof follows.

Space Complexity The space complexity of the SJ-Tree can be measured in terms of the storage required by each leaf in the tree. The storage for any node in the tree is approximated by the product of the corresponding subgraph size (measured as the number of edges) and its frequency. Therefore, the space complexity of the SJ-Tree is $S(T) = \sum_k |E(g_k)| frequency(g_k)$. Given two subgraphs g_{small} and g_{big}, where g_{big} contains g_{small}, the frequency of g_{small} serves as an upper bound for g_{big}, assuming no overlapping edges. Therefore, we can assign each node in the tree to a group, where one node in each group serves to approximate the frequency of rest of the nodes in the group. Suppose $g_r(i)$ is the cardinality of the i-th group. Trivially, $\sum_i g_r(i) = N_T$, where N_T is the number of nodes in the SJ-Tree.

Therefore, given a query graph G_q and a SJ-Tree T expressing one possible query decomposition, we can estimate its space complexity as $S(T) = \sum_i g_r(i)|E(g_i)|frequency(g_i)$. There is clearly a tradeoff between the accuracy of this estimate and the computation required to obtain the necessary measurements. Approximating the space complexity in terms of single edge subgraphs is computationally easiest, although it would be a very loose bound when the frequency of a single edge subgraph is orders of magnitude higher than larger subgraphs containing that single edge subgraph. Realistically, we foresee the groups being composed of unique 1-edge, 2-edge subgraphs and triangles (if it exists in the SJ-Tree) and approximate all larger subgraph in the SJ-Tree assigned to these groups.

5.3 Comparison with selectivity agnostic approaches

Our pattern decomposition approach based on relative selectivity provides an optimal way to look for discriminate patterns compared to existing approaches. For e.g, consider the generic path query graph in 5(a). A DAG based decomposition approach [7] may look either for complete path query or decompose it randomly as shown in 5(b). As the source vertex(s1) in such a pattern may be lot more frequent than sink $v4$, our selectivity based approach will clearly identify the s2->s3->s4 pattern as being more selective and start processing search from there, clearly this is more optimal than searching for every pattern starting at s1->s2.

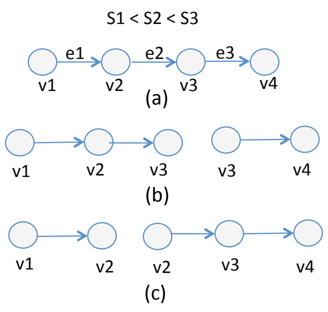

Figure 5: (a) Example path query. S_i indicates the selectivity of edge e_i. (b) A selectivity agnostic decomposition. (c) Decomposition using our selectivity based approach.

6. EXPERIMENTAL STUDIES

We perform experimental analysis on two real-world datasets (New York Times [1] (Internet Backbone Traffic data [1]) and a synthetic streaming RDF benchmark. In interest of space, we include result for CAIDA dataseti and RDF bencharк only, NYTimes performance being similar to CAIDA. The experiments are performed to answer questions in the following categories.

1. STUDYING SELECTIVITY DISTRIBUTION What does the selectivity distribution of 2-edge subgraphs look like in real world datasets? What is the duration of time for which the selectivity distribution or selectivity order of 2-edge subgraphs remains static?

2. COMPARISON BETWEEN SEARCH STRATEGIES In the previous sections, we introduced two different choices for query decomposition (1-edge vs 2-edge path based) and two different choices for query execution (lazy vs non-lazy). How do the strategies compare?

3. AUTOMATED STRATEGY SELECTION Given a dynamic graph and a query graph, can we choose an effective strategy using their statistics?

COMPARISON WITH OTHER APPROACHES Although other continuous subgraph query systems exist ([7, 15], their objectives are different. Both focus on distributed system implementations, and explore aggregate queries or approximate queries. Also, their support for the type of graph is different from ours. Our test datasets drawn from cyber security and social networks involve directed graphs with labeled vertices and edges. We believe that the research contributions complement each other; hence, we compare our implementation with a non-incremental approach that performs subgraph isomorphism for the query graph (using VF2) on every new edge in the dynamic graph. .

6.1 Experimental setup

The experiments were performed on a 32-core Linux system with 2.1 GHz AMD Opteron processors, and with 64 GB memory. The code was compiled with g++ 4.7.2 compiler with -O3 optimization.

Given a pair of data graph and query graph, we perform either of two tasks: 1) query decomposition and 2) query processing.

Query decomposition: Query decomposition involves loading the data graph, collecting 1-edge and 2-edge subgraph statistics and performing query decomposition using the selectivity distribution of the subgraphs. The SJ-Tree generated by the query decomposition algorithm is stored as an ASCII file on disk.

Query processing: The query processing step begins with loading the query graph in memory, followed by initialization of the SJ-Tree structure from the corresponding file generated in the query decomposition step. We initialize the data graph in memory with zero edges. Next, edges parsed from the raw data file are streamed into the data graph. The continuous query algorithm is invoked after each AddEdge() call to the data graph.

6.2 Data source description

Summaries of various datasets used in the experiments are provided in Table 1. We tested each dataset with a set of randomly generated queries. The following describes the individual datasets and test query generation.

Network Traffic The dataset is an internet backbone traffic dataset obtained from `www.caida.org`. CAIDA (Cooperative Association for Internet Data Analysis) is a collaborative program that provides a wide collection of network traffic data. We used the “CAIDA Internet Anonymized Traces 2013 Dataset" for experimentation. The dataset contains 22 million network traffic flow (subsequently referred to as *netflow*) records collected over a *one minute period*. We excluded the traffic to/from IP addresses matching patterns 10.x.x.x or 192.168.x.x. These address spaces refer to private subnets and a communication from a given IP address from these spaces can actually refer to multiple physical hosts in the real word. As an example, every internet service provider configures the routers or machines inside a home network with IPs selected from the private IP address range. Therefore, if we see a request from 192.168.1.1 to google.com, there is no way to determine the exact origin of this communication. From a graph perspective, allowing private IP address and the subsequent aggregation of communication will result in the creation of vertices with giant neighbor lists, which will surely impact the search performance. A detailed list of use cases describing subgraph queries for cyber traffic monitoring are described in [12].

Social Media Stream Our final test dataset is a synthetic RDF social media stream available from the Linked Stream Benchmark

Figure 6: Edge type distribution shown with the evolution of the dynamic graph.

Table 1: Summary of test datasets

Dataset	Type	Vertices	Edges
Internet Backbone Traffic	Network traffic	2,491,915	19,550,863
LSBench/CSPARQL Benchmark	RDF Stream	5,210,099	23,320,426
New York Times	Online News	64,639	157,019

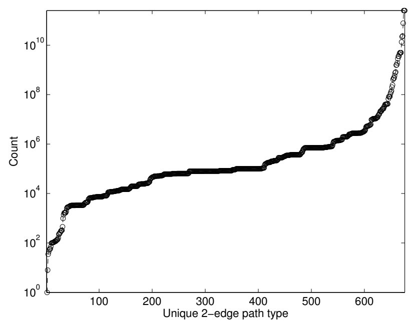
(LSBench) [1]. We generated the dataset using the sibgenerator utility with 1 million users specified as the input parameter. The generated graph has a static and a streaming component. The static component refers to the social network with user profiles and social network relationships. The streaming component includes 3 streams. The *GPS stream* includes user checkins at various locations. The *Post and Comments stream* includes posts and comments by the users, subscriptions by users to forums, and a stream of "likes" and "tags". Finally, the *photo stream* includes information about photos uploaded by users, and "tags" and "likes" as applied to photos.

6.3 Selectivity Distribution

Figure 6 shows the edge distribution plotted over time. X-axis shows the number of cumulative edges in the graph as it is growing. The plotted distribution is not cumulative. The edge distribution is collected after fixed intervals. The interval is 10 thousand, 100 thousand and 1 million respectively. There are 4, 7, and 45 edge types in these datasets. The first half of the RDF dataset contains data for a simulated social network. The second half contains simulated data about the activities in the network such as posts, and checkins at locations The shift in the edge distribution around the mid point reflects these different characteristics. The key observation is that the relative order of different types of edges stays similar even as the graph evolves.

There were 14, 62 and 676 unique 2-edge paths present in the New York Times, netflow and LSBench datasets. Figure 7 shows the 2-edge path distribution for the LSBench dataset. We found a small number of 2-edge subgraphs to dominate the distribution across all the datasets. Other datasets show a similarly skewed distribution, and was omitted for space. The skew is heaviest for the LSBench dataset, which is expected given the higher number of unique edge types and the larger size of the dataset.

The goal of this analysis was to observe the variability in the selectivity distribution over time. The selectivity distribution is expected to vary over time. However, it is the relative order of the unique single edge or 2-edge subgraphs that matters from the query decomposition perspective. For each of the test datasets, we took



(a) Synthetic social data stream in RDF

Figure 7: 2-edge path distribution in each test data set. Each point on X-axis represents a unique 2-edge path and Y-axis shows its corresponding count.

multiple snapshots of the selectivity order and found it to be stable, except with fluctuations for the very low frequency components (data points on the left end of the distributions in Fig. 7). Significant changes in the selectivity order can adversely impact the performance of the query. Estimating the duration over which the selectivity ordering stays stable for a given data stream, quantification of errors based on shift in the distribution, and adapting the query algorithm to handle such shifts is reserved for future work.

6.4 Query Performance Analysis

This section presents query performance results obtained through query sweeps on the network traffic and social network dataset. We restrict the analysis to these two datasets for their larger size. The analysis on New York Times dataset made available in the Appendix section in the interest of space. For each query, we collect performance from 4 different query execution strategies obtained by 1-edge or 2-edge decomposition of a query graph and the lazy vs. track everything approach adapted by the query algorithm. The following tags are used to describe the plots in the remainder of the paper: a) "*Single*": 1-edge decomposition, search tracks all matching subgraphs in SJ-tree, b) "*SingleLazy*": 1-edge based query decomposition, use "Lazy" approach to search, c) "*Path*": 2-edge decomposition, search tracks all matching subgraphs in SJ-Tree, and d) "*PathLazy*": 2-edge decomposition with "Lazy" search.

6.4.1 Network Traffic and LSBench

We present aggregated results for each query group for LSBench and CAIDA. Both of these datasets are orders of magnitude larger than New York Times and the scale allows us to magnify the differences between multiple strategies.

QUERY GENERATION We generate both path queries and binary tree queries for the netflow data. Figure 8 shows two decompositions of an example query. The vertex labels are fixed to type "ip" and the edge types are randomly chosen from a set of 7 protocols: ICMP, TCP, UDP, IPv6, AH, ESP and GRE. The binary tree queries were generated following the test generation methodology described in [16]. The LSBench dataset is tested with path queries and n-ary trees. A list of valid triples (vertex type, edge type , vertex type) is generated using the LSBench schema. A tree query is generated by randomly selecting an edge from the set of valid triples and then iteratively adding valid new edges from any of the nodes available. All our query graphs are unlabeled. Using netflow data as an example, we do not generate a query that has a label associated with any of the nodes. In practice, we expect users to employ labeled queries such as finding a tree pattern in the network traffic where the root of the tree has a IP address (i.e. label) from a certain subnet. For social data, we may look for paths with specified user ids (node labels) on the source and the destination nodes on the path. Here, our experiments are motivated to study the impact of subgraph distributional statistics on query processing.

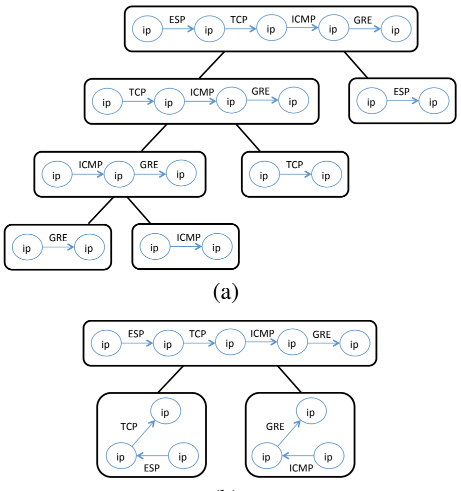


Figure 8: 1 and 2-edge based decompositions of a path query on netflow traffic data.

COMPARISON WITH OTHERS In our previous work [3] we had compared the performance of our implementation with the IncIsoMatch algorithm proposed by Fan et al. [6]. Our IncIsoMatch implementation was based on a variant of the well-known VF2 algorithm [5].

SUMMARIZATION OF RESULTS All queries of the same type (path or tree) and size (3-hop length or 5 nodes) are denoted as a group. We generated 100 queries for each group and then eliminated ones that contained 2-edge paths not seen in the sampled path distribution. This was done for two reasons; first, inclusion of an unseen 2-edge path combination makes the query artificially discriminative. Our goal is to observe query processing time as a function of varying selectivity, so including unusually discriminative queries bias our studies. Second, when asked to generate a path-based decomposition, our SJ-Tree generator resorts to generating a single-edge based decomposition when a query subgraph contains an unseen 2-edge path. This would bias our comparison between a path-based decomposition and single-edge based decomposition. Finally, for all the "valid" queries we further sampled them by the Expected Selectivity computed using 2-edge path distribution and reduced each group to a smaller set of queries that provide a near uniform sampling of the Expected Selectivity from the larger set. Finally, the reported runtime for a given strategy (e.g. "PathLazy") is obtained by averaging the runtimes from the reduced set of queries,

Figure 9a-d shows the query processing times collected for both datasets. The size of the query processing window was fixed at 8M triples, and the performance statistics were collected at at the middle and at the end of the graph stream. We profiled different components of the query processing such as the time spent in performing subgraph isomorphism and the time spent in updating the SJ-Tree. The latter is largely composed of the time spent in looking up the hash tables in various nodes of the SJ-Tree, performing joins between partial matches and inserting new entries. We found that the subgraph isomorphism operation (for 1 or 2-edge subgraphs) dominates the processing time. Considering both classes of queries with diameter 4 and 5, the subgraph isomorphism operation consumes more than 95% of the total query processing time.

A general observation is that the performance of non-incremental search by VF2 is found to be 10-100x slower. The Y-axis is plotted in log scale, and we can see how the run times of the "Path" and "Single" approaches rise exponentially as the query sizes are increased. Overall, we find the "SingleLazy" and "PathLazy" are the best performing search approaches. As the tree queries show, the growth rate in the query processing time is much slower for the "Lazy" variants. This conclusively demonstrates the effectiveness of restricting the search to where a match is emerging, and growing the match by starting from the most selective sub-query.

6.5 Analysis via Relative Selectivity

Figure 10 shows the distribution of relative selectivity for queries with 4 edges across all three datasets. We picked query graphs with 4 edges to find a common basis for comparing different type of queries (k-partite vs. path queries) across multiple datasets, and the discussion is equally applicable to larger or different query class combinations. The top subplot shows the relative selectivity of 10 k-partite queries from the New York Times data. For netflow and LSBench, we randomly sampled 25 queries from the randomly generated path query collection. As can be seen, the relative selectivity is very low for the netflow dataset. Following the definition of relative selectivity, its value is lowered when the path distribution based selectivity is low. In other words, there are some paths in the query which have very low probability of occurrence. Therefore, the "PathLazy" approach is superior for such queries. Empirical observation on larger path queries and other tree queries seem to suggest two prominent clusters of relative selectivity values. The first one typically ranges from 0.001 and above, and the second one contains values that are smaller by multiple orders of magnitude. This suggests a heuristic that "PathLazy" strategy could be employed for queries with relative selectivity below 0.001, and "SingleLazy" be employed for queries above 0.001.

7. CONCLUSION AND FUTURE WORK

We present a new subgraph isomorphism algorithm for dynamic graph search. We analyzed multiple real-world datasets and discovered that the distribution of 2-edge subgraphs are heavily skewed. We further demonstrated with a “Lazy" search algorithm that a query decomposition strategy exploiting this skew will be consistently efficient. Finally, we concluded with a Relative Selectivity based rule for selecting a search strategy.

The problem of continuous pattern detection is an emerging area, and there is an open field to explore. While our 2-edge subgraph based approach provides an initial foundation, deeper investigations are warranted for more accurate selectivity estimation. Subsequent research can leverage on the significant body of work on counting larger subgraphs such as triangles in streaming or semi-streaming scenarios to obtain quantitative estimates of space complexity of a given query decomposition. Adaptive query processing is an important follow-up problem as well. A long standing database query needs to be robust against shift in the data characteristics. While we propose a fast algorithm for periodic recomputation of the primitive distribution, we do not address the issues of modeling the inefficiency from operating under a different selectivity order and migrating existing partial matches from one SJ-Tree to another.

APPENDIX

A. ANALYSIS OF DYNAMIC GRAPH SEARCH ALGORITHM

At this point, it is probably obvious that different SJ-Tree structures can be generated from the same query graph (Figure 8). While multiple factors can lead to generation of different SJ-Trees, one primary factor is our choice for granularity of decomposition, the size and the structure of the subgraphs we decompose the query to. Henceforth, we often refer to these set of small subgraphs as *search primitives* or simply *primitives.* As a first step to understand the speed-memory tradeoff associated with different choices for primitives, we begin with the complexity analysis of the dynamic graph search described in Algorithm 1 and 2. A key operation in Algorithm 1 is the process of subgraph isomorphism around every new edge in the graph. Therefore, we exclusively focus on the complexity analysis in terms of 1-3 edge subgraphs as candidates for search primitives.

SINGLE EDGE SUBGRAPHS When the query graph (g^q_{sub} in Algorithm 1, line 5) contains a single edge, checking if an edge from the data graph (e_s) matches the query edge require comparing the types and potentially other attributes of the edges. Depending on the query constraint, we may need to look up the node label to perform a string comparison or evaluate a regular expression. The node labels or any other node-specific properties are stored in an array leading to constant time access to node labels. Therefore, a single-edge query can be matched in $O(1)$ time.

TRIADS Assume that the query graph is a triad with three vertices v_1, v_2 and v_3, and edges ordered as $e_1 = (v_1, v_2), e_2 = (v_2, v_3), e_3 = (v_3, v_1)$. For any edge e in the data graph, we can detect a match with e_1 in constant time. If e is matched, we search the neighborhood of the vertex that matches with v_2 to search for e_2. Denoting this vertex as $v_2^{'}$, the cost of this second level of search is $O(degree(v_2^{'}))$. In case of a 3-edge subgraph, each of the successful second level searches proceed to find a match for the third edge. Thus, the cost of a 2-edge subgraph is $O(degree(v_2^{'}))$ and a 3-edge subgraph is $O(degree(v_2^{'}) * degree(v_3^{'}))$. We can refine these estimates to obtain an average cost of the search as $O(\bar{d_2})$ for a 2-edge subgraph and $O(\bar{d_2}\bar{d_3})$ for a 3-edge subgraph, where $\bar{d_2}$ and $\bar{d_3}$ are the average degree of the vertices in the graph for the types of v_2 and v_3.

The next step is to estimate a cost for the SJ-Tree update operation (Algorithm 2). We begin with the hash-join operation (Algorithm 2, line 7). Assume the frequency of a graph g^i_q is n_i, where the frequency of a subgraph is defined as the count of its instances over an edge stream of length N. Therefore, over N edges, we can expect $O(n_1)$ matches for g^1_q and $O(n_2)$ matches for g^2_q. Therefore, H_2 (hash table associated with the SJ-Tree node representing g^2_q) will be probed for a match $O(n_1)$ times over N edges and H_1 (associated with the SJ-Tree node representing g^1_q) will be probed $O(n_2)$ times within the same period.

If we knew the frequency of G_q, henceforth referred as $f_S(G_q)$, then we can also estimate the number of new subgraphs that will be produced as the result of the hash-joins. Given that the frequency of the larger subgraph can not exceed that of the more selective component we can approximate $O(n(G^q)) \simeq min\left(O(n_1), O(n_2)\right)$. Therefore, the average work for every incoming edge in the graph can be expressed as,

$$\left(f_S(g^1_q) + f_S(g^2_q) + O(n_1) + O(n_2) + min\left(O(n_1), O(n_2)\right)\right)/N.$$

The Hash-Join combined with leaf level searches provides the simplest example of a SJ-Tree, a binary tree with height 1. In this section, we analyze the time complexity of the query processing as it happens in a multi-level SJ-Tree. Given any non-leaf node n, we can obtain the expression for average work by adapting the complexity expression shown above. Note that if a child of n, denoted by n_c, is not a leaf level node but an internal node, then the term corresponding to the search cost ($f_S(g)$) disappears. Additionally, we can replace the search cost with the cost corresponding to the average work incurred by the subtree rooted by n_c. Therefore, given a SJ-Tree (T_{sj}) the average work ($C(T_{sj})$) can be obtained by recursive computation from the root. $C(T_{sj}) = C(root(T_{SJ}))$

Scaling Unbound-Property Queries on Big RDF Data Warehouses using MapReduce[*]

ABSTRACT

Semantic Web technologies are increasingly at the heart of many integrated scientific and general purpose data warehouses. Flexible querying of such diverse data collections with (partially) unknown structures can be enabled using triple patterns with 'unbound' properties (edges with don't care labels). When evaluating such queries using relational joins, intermediate results contain redundancy due to repeated combination of bound-property mappings with those of the unbound properties. However, in distributed-processing contexts, the footprint of intermediate results directly impacts I/O and communication costs. Given the popularity of MapReduce-based platforms for periodic on-demand scaling using Cloud resources, we propose an algebraic optimization technique that interprets unbound-property queries on MapReduce, using a non-relational algebra based on a TripleGroup data model. The approach enables shorter execution workflows and reduced costs for processing RDF queries on MapReduce. This paper introduces new logical and physical operators, and query rewriting rules for interpreting unbound-property queries using the TripleGroup-based data model and algebra. A key optimization strategy is to concisely represent intermediate results as far along an execution workflow as possible, thus minimizing the effects of redundancy. The proposed work is integrated into Apache Pig. Experiments conducted on real-world and synthetic benchmark datasets demonstrate their benefit over popular relational-style MapReduce systems.

1. INTRODUCTION

The successful adoption of Semantic Web technologies to interlink diverse (related) datasets has led to large semantically-integrated scientific (Uniprot [8], Bio2RDF [9]) and general purpose (DBpedia [7], Billion Triple Challenge [1]) RDF data warehouses. The heterogeneous and evolving nature of such data collections makes it difficult for users to be familiar with different kinds of relationships that exist in the data. Consequently, exploration of datasets in data-integration [23] and data archival [36] scenarios require flexibility in querying, i.e., the ability to use structural variables or "don't cares" in queries. SPARQL [28], the standard query language to specify graph pattern queries on the Semantic Web, enables flexible querying of datasets by allowing `OPTIONAL` substructures or substructures with missing edge labels. The latter are called *unbound-property* triple patterns and can be used to query unknown relationships ("*Scientists in some way associated to the same city*"), relationships with partial knowledge ("*Gene Ontology terms related to a gene Rxr*"), or to retrieve all available information about a resource ("*What is known about the Hexokinase gene?*").

Consider an example SPARQL query $Q1$ on Bio2RDF, a Life Sciences RDF dataset. $Q1$ is useful to analyse the Parkinson's disease and involves two unbound-property triple patterns (1) and (5).

Query Q1	**Description**
`SELECT` ?s1, ?label1, ?s2, ?label2, ?o2	*Retrieve gene ontology (GO) terms*
`WHERE` {	*related to "rxr", a gene of interest*
?s1 ?p1 ?o1 . (1)	*in analyzing Parkinson's disease.*
`FILTER` regex(?o1, "rxr")	*Q1 contains two star subpatterns,*
?s1 label ?label1 . (2)	*SJ_1 (1-2) and SJ_2 (3-5).*
?s2 xGO ?o2 . (3)	*(1) matches triples whose object*
?s2 label ?label2 . (4)	*contains string "rxr" (any property).*
?s2 ?p2 ?s1 . (5)	*(5) specifies an unknown*
}	*relationship connecting the two*
	star subpatterns in the query.

Other than querying scenarios in integrated data warehouses, subqueries with unbound-property triple patterns are also generated while optimizing ontological queries by rewriting them as a union of conjunctive queries. Examples of unbound-property queries can be found in real [23] and synthetic Semantic Web benchmarks [11], as well as other studies [22, 36]. In fact, 84% of queries in [2] involve unbound-property triple patterns.

Given a triple relation T and subset relations T_{xGO} and T_{label} with property types xGO and $label$, respectively, the subquery SJ_2 can be evaluated using relational joins ($T_{xGO} \bowtie T_{label} \bowtie T$). Figure 1 (right) shows the subrelations of T participating in SJ_2 and a snapshot of the star-join result. An issue with intermediate results in such cases is redundancy. For example, the result for SJ_2 in Figure 1(top right) contains repeated occurrences for matches of the bound properties – xGO and $label$, with each match of the unbound-property triple pattern. The numbers of matches for the unbound-property triple pattern could be large if properties in the input dataset have high multiplicity ($gene9$ is associated with multiple $xRef$), further aggravating the issue of redundancy. High-multiplicity properties are common in real-world social networks as well as biological datasets such as Uniprot and Bio2RDF, e.g., some Uniprot properties have multiplicity as high as 13K.

For applications with periodic scale–up requirements, the growing trend is to employ cloud-processing platforms, e.g., Hadoop [10], Dryad [16], Hive [37], Pig [26], that are based on the MapReduce [12] computing model. However, any redundancy in interme-

Figure 1: A MapReduce workflow for an unbound-property graph pattern query $Q1$ with two star subqueries SJ_1 and SJ_2; Join result of unbound-property star subpattern SJ_2 contains redundant information related to bound properties (xGO, label)

diate results impacts query processing costs, particularly for MapReduce based distributed processing platforms that involve shipping of intermediate results across the network. The intermediate result footprint also impacts additional costs associated with sorting phases, materialization between the 2-steps of a MapReduce (MR) execution cycle, and total disk space requirements to store all intermediate states for fault-tolerance purposes. Hence, it is critical to minimize the footprint of intermediate results.

1.1 Related Work

Optimizing Relational Query Plans on MapReduce: There have been several efforts to shorten the length of MR workflows [6, 40, 15, 5, 27] to minimize the overall costs of MapReduce-based processing, sharing scans [24, 25, 39] and computations [24, 13] across MR workflows, cost-based and transformation-based MR workflow optimizer [20], and data skew problems [19]. Multi-way join algorithms [6, 40] cluster multiple joins into a single [6] or few [40] MR cycles, but have not been applied to join-intensive workloads. Amongst the MapReduce-based RDF processing systems, SHARD [32] uses initial MR cycles to cluster triples into star subgraphs, followed by separate MR cycles to process each clause in the SPARQL query. HadoopRDF [15] pre-processes triples using the vertical-partitioning (VP) [4] approach, and uses heuristics to greedily group non-conflicting joins in a query to minimize the required number of MR cycles. However, unbound-property queries would require processing a union of all VP property relations. The HadoopDB-based extension [14] uses a hybrid database-Hadoop architecture that exploits the partitioning scheme to push part of the execution into the database/RDF-3X. Hash partitioning on Subject can enable local evaluation of unbound-property star subpatterns. However, once the execution is handed over to Hadoop the redundancy in intermediate results impacts the disk I/O, sorting, and communication costs for the rest of the execution workflow. In order to minimize the data shuffle costs, MRShare [24] enables sharing of map output data across grouping operations on a common input relation. Some other works proposed a value-partitioning scheme [21] to manage reducer-unfriendly groups during the cube computation process, and a reducer-routing strategy [38] that groups intermediate keys to balance the data across reducers. The evaluation strategies proposed in this paper, i.e., lazy β-unnesting strategies, are in similar spirit.

Optimizing unbound-property queries: Earlier studies [35, 34] have shown that the vertical-partitioning (VP) [4] storage model may be inefficient for unbound-property queries. Such queries result in multiple joins and large unions of VP relations, which gets worse for data containing large number of property types. The multi-indexing schemes in systems such as RDF-3x [22] could benefit single-star unbound-property queries. However, such systems may not scale well for large RDF graphs, particularly for queries with low selectivity and unbound objects [15]. There have been efforts [36] to optimize simple unbound-property queries to RDF views over relational databases. Since naive translation of an unbound-property query into SQL results in unions of multiple subqueries, the proposed Group Common Term transformer [36] exploits common terms in complex disjunctive SQL queries and rewrites them into a smaller number of queries. Our work proposes a scalable solution for processing unbound-property queries on MapReduce-based parallel processing platforms.

Prior Work. A previous work explored the use of a non-relational data model and algebra, i.e., the *Nested TripleGroup Data Model and Algebra* (NTGA) [30, 17], for efficient RDF query processing on MapReduce. The NTGA allows an alternative interpretation of queries in terms of a "grouping" operation and a set of *triplegroups*, that enables shorter execution workflows when compared to relational query plans in systems such as Hive and Pig. For example, query $Q1$ requires 3 MR cycles altogether (two cycles for computing star-joins SJ_1, SJ_2, and a third cycle to join the stars) as shown in Figure 1, while the NTGA would compute both SJ_1 and SJ_2 in a single cycle using a "grouping" operation, followed by a second cycle to compute the join between the stars.

***Comparison with Redundancy due to Multi-valued Properties*.** Unlike the normalized representation of intermediate results of relational operations, the nested triplegroup data model can concisely represent intermediate results with multi-valued properties, e.g.,

{ ($gene9$, *xGO*, **{go1, go9}**) // A single triplegroup representing
($gene9$, *label*, retinoid...) // two n-tuples $t1$ and $t4$
($gene9$, *synonym*, RCoR-1)} // by nesting object component

Though the "nested object" model and *nesting-aware physical operators* [31, 29] reduce the I/O footprint of execution workflows, a join involving an unbound-property triple pattern would still produce 'n' triplegroups (assuming n triples with subject $gene9$). More importantly, all n triplegroups contain redundant bound-property component. In this paper, we generalize the concept of triplegroup nesting to allow *nesting of property-object components*, to implicitly represent intermediate results while evaluating unbound-property queries. However, such an implicit representation involves triples playing multiple roles, i.e., a triple may match the bound and the unbound component of a query, which needs to be incorporated into the "unnest" process, referred here after as β-`unnest`. Additionally, there are implications of when and what portion of a triplegroup is β-unnested during the different phases of an execution workflow, resulting in choices for evaluation strategies. Specifically, this paper makes the following contributions:

- We introduce new logical operators and query rewrite rules that allow the translation of unbound-property queries into NTGA-based logical plans. The correctness and sufficiency of query rewrite rules is also presented.
- We introduce new physical operators that offer different evaluation strategies - *eager vs. lazy β-unnesting* of intermediate results during query processing.
- Extensive evaluation using large RDF graphs, both Semantic Web synthetic benchmark and real-world biological datasets, demonstrates the efficiency of our approach over relational-style processing of unbound-property queries in Pig and Hive.

2. PRELIMINARIES

2.1 MapReduce and Data Processing

In the MapReduce programming model, data processing tasks are encoded as *map* and *reduce* functions, that are executed in parallel across a cluster of computing nodes. Relational operations such as a join between two relations, maps to a processing cycle consisting of two phases – the *Map* phase and the *Reduce* phase. In the *Map* phase, a set of slave nodes (*mappers*) execute the *map* function that tags each tuple based on the join key. Map output tuples are partitioned on the join key and *shuffled* across the network to another set of slave nodes (*reducers*). In the *Reduce* phase, each reducer receives a collection of tuples with the same join key, and computes the join. The output of the Reduce phase is written onto the *Hadoop Distributed File System* (HDFS) and read back in a subsequent cycle. Each MapReduce (MR) cycle involves costs associated with initial input data reads in the map phase (M_{Read}), the data shuffling costs between mappers and reducers that involve local disk writes at the mappers (M_{Write}), sort-merge costs (MR_{Sort}) as well as network transfer costs (MR_{TR}), and finally the cost of writing the reduce output to the HDFS (R_{Write}).

To evaluate graph pattern queries on MapReduce, one can exploit the fact that graph pattern queries often consist of multiple star-structured subqueries e.g., SJ_1 and SJ_2 rooted at variables *?s1* and *?s2* in query $Q1$, that can be evaluated using a multi-way join algorithm. For a graph pattern query with l star subpatterns, the typical MapReduce execution plan generated by relational-like platforms such as Hive and Pig consist of a sequence of MapReduce cycles $MR_1, MR_2, .., MR_n$ such that $1 \leq n \leq (l-1)$ cycles are used for executing the l star-joins, and $(n - l)$ MapReduce cycles for the remaining joins in the query. Our example query $Q1$ can be evaluated in 3 MR cycles as shown in Figure 1: MR_{SJ1} and MR_{SJ2} to compute star subpatterns SJ_1 and SJ_2 respectively, followed by a third cycle MR_{J1} to join the stars. Given such a MR workflow W, the overall processing cost of W is:

$$\text{Cost}(W) = \text{cost}(MR_1) + \text{cost}(MR_2) + ... + \text{cost}(MR_n)$$

where the I/O, sorting, and network transfer costs of each cycle compound across multiple cycles of a lengthy workflow. Furthermore, the portion of redundant data in the intermediate results directly impacts the HDFS writes (R_{Write}) for the current MR cycle, and the scan costs (M_{Read}) and shuffle costs (MR_{Sh}) of subsequent MR cycles. Hence, the redundancy has a ripple effect on the costs of reads, writes, sorting and the data transfer costs across a workflow with multiple MR cycles. Thus, lengthy workflows lead to performance inefficiency and an important optimization goal is to *minimize the length of an MR execution workflow* [6, 15, 40].

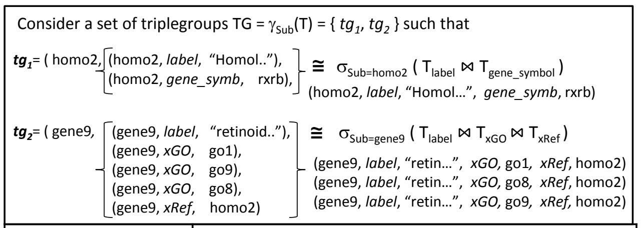
However, grouping of joins based on star structures does not necessarily result in the typical join order generated using traditional cost-based optimization. One challenge is that most cloud processing platforms are used in an on-demand model, where pre-computed statistics for cost-based optimization may not be available or take too long to compute, resulting in long lead times. More importantly, ordering joins in terms of their costs may generate some linear subplans requiring one input as the full triple relation, which in the absence of an index is a full scan. Such plans may incur larger overhead due to HDFS reads, which outweighs the savings achieved by pushing selective joins ahead.

Our previous work [30, 17] explored an algebraic optimization technique that rewrites graph pattern queries using operators that are more MapReduce-cognizant. It has been demonstrated that the underlying data model and algebra called the *Nested Triple-Group Data Model and Algebra* (NTGA), not only results in short execution workflows [30, 17], but also enable scan-sharing [18] across star subpatterns, while reducing the I/O footprint of intermediate results [31, 29]. In the next section, we overview the data model and algebraic operators in NTGA that enable nimble execution workflows while evaluating RDF graph pattern queries on MapReduce.

2.2 TripleGroup-based Processing of Graph Pattern Queries on MapReduce

The NTGA data model represents the RDF database as sets of related "group of triples" or *TripleGroups*. For example, triples in the database can be modeled as a set of *Subject TripleGroups*, each consisting of triples that share a common subject. For example, triplegroups tg_1 and tg_2 in Figure 2 represent subject triplegroups corresponding to triples sharing common subjects gene9 and homo2, respectively. Given such a data model, answering graph pattern queries translates to manipulation of triplegroups. Some of the most relevant triplegroup operators are summarized in Figure 2 and discussed below.

Algebraic Operators. Consider a query Q' with two star subpatterns St_1={$label$, $gene\_symb$} and St_2={$label$, xGO, $xRef$}. NTGA's grouping operator (γ) computes a set of subject triplegroups TG based on the subject column as shown in Figure 2. Given such a set of triplegroups TG, a match to a star subpattern is a selection operation (σ^{γ}) that extracts a subset of triplegroups that match the required join structure, i.e., a valid triplegroup must contain at least one triple corresponding to each of the property types



Consider a set of triplegroups TG = γ_{Sub}(T) = { tg_1, tg_2 } such that

tg_1 = (homo2, {(homo2, *label*, "Homol.."), (homo2, *gene_symb*, rxrb)}) $\cong$ $\sigma_{Sub=homo2}$ ($T_{label} \bowtie T_{gene\_symbol}$)
(homo2, *label*, "Homol...", *gene_symb*, rxrb)

tg_2 = (gene9, {(gene9, *label*, "retinoid.."), (gene9, *xGO*, go1), (gene9, *xGO*, go9), (gene9, *xGO*, go8), (gene9, *xRef*, homo2)}) $\cong$ $\sigma_{Sub=gene9}$ ($T_{label} \bowtie T_{xGO} \bowtie T_{xRef}$)
(gene9, *label*, "retin...", *xGO*, go1, *xRef*, homo2)
(gene9, *label*, "retin...", *xGO*, go8, *xRef*, homo2)
(gene9, *label*, "retin...", *xGO*, go9, *xRef*, homo2)

Notation	Semantics
TripleGroup Filter $\sigma^{\gamma}_{P_{bnd}}$(TG)	Enforces structural constraints in a star subpattern by matching the set of bound properties P_{bnd} and eliminating triplegroups in TG that violate the required join structure (structure-based validation) e.g., $\sigma^{\gamma}_{\{label,\ gene\_symb\}}$(TG) = $TG_{\{label,\ gene\_symb\}}$ ={ tg_1}
TripleGroup Join $\bowtie^{\gamma}$(tp1:TG_1, tp2: TG_2)	Joins triplegroups tg_1 εTG_1 and tg_2 εTG_2, based on the join conditions specified by triple patterns tp1 and tp2 respectively. e.g., $\bowtie^{\gamma}$(?s1 *label* ?label1 :$TG_{\{label,\ gene\_symb\}}$, ?s2 *xRef* ?s1 :$TG_{\{label,\ xGO,\ xRef\}}$) = { *ntg* } ntg = { (gene9, (*label*, "retinoid..."), (*xGO*, go1), (*xGO*, go8), (*xGO*, go9), (*xRef*, {homo2, (*label*, "Homolog...") (*gene_symb*, rxrb)}) }

Figure 2: Example NTGA Operators

in the star subpattern. Triplegroup tg_1 is a valid match for St_1 and is said to belong to the equivalence class $TG_{\{label,gene\_symb\}}$ that defines its join structure. Further, matching multiple star subpatterns translates to a disjunctive selection based on the set of properties in each star subpattern. For example, the two star subpatterns in Q' can be computed as follows:

$$\sigma^{\gamma}_{(\{label,gene\_symb\} \vee \{label,xGO,xRef\})}(TG)$$

Joins between star subpatterns can be computed using the join operator ($\bowtie^{\gamma}$) that is semantically equivalent to the relational join operator but is defined on triplegroups. The object-subject join between triplegroups tg_1 and tg_2 results in a nested triplegroup ntg whose root is the triplegroup tg_1 and child triplegroup is tg_2. Before proceeding, we review the notion of *content-equivalence* that enables lossless translation between relational algebra and NTGA plans.

Relational Algebra $\leftrightarrow$ NTGA Plans. Triplegroups are '*content-equivalent*' (represented as $\cong$) to the set of n-tuples computed using a set of relational-style joins. Let Stp be a star subpattern comprising of the set of bound properties $\{P_1, P_2, ..., P_k\}$, and T_{Stp} be the join result of vertically partitioned subset relations $T_{P_1}, T_{P_2}, ..., T_{P_k}$. Let $T_{Stp(s)}$ represent the subset of T_{Stp} with subject Sub = s.

$$T_{Stp(s)} = \sigma_{Sub=s}(T_{P_1} \bowtie T_{P_2} \bowtie ... \bowtie T_{P_k})$$

Each tuple in $T_{Stp(s)}$ is of 3k arity (each property in Stp is associated with 3 columns). Let π_{P_i} denote the projection of the (Sub, Prop, Obj) columns corresponding to the parent relation T_{P_i} with bound-property P_i. Let tg_s represent the set union of triples formed by the 3 columns, i.e.

$$tg_s = \pi_{P_1}(T_{Stp(s)}) \cup \pi_{P_2}(T_{Stp(s)}) \cup ... \cup \pi_{P_k}(T_{Stp(s)})$$

In summary, the tuples in $T_{Stp(s)}$ can be vertically partitioned into 'triples' whose union is equivalent to a subject triplegroup tg_s in the NTGA data model. For our example data in Figure 2,

$$tg_1 \cong \sigma_{Sub=homo2}(T_{label} \bowtie T_{gene\_symb})$$
$$tg_2 \cong \sigma_{Sub=gene9}(T_{label} \bowtie T_{xGO} \bowtie T_{xRef})$$

Benefits of NTGA Query Plans. For a query with 'n' star subpatterns, NTGA can compute ALL star subpatterns concurrently using a single 'grouping' operation, by first 'grouping' the triples into subject triplegroups and then applying a disjunctive selection based on the multiple star subpatterns. This is in contrast to the relational-style approach where each star subpattern is evaluated as a relational-style join. The grouping-based star-join computation naturally fits the *map-group-reduce* theme in MapReduce, and translates to just one MR cycle for computing all star-joins in the query (as opposed to 'n' MR cycles using relational-style plans). In addition to the reduction in the number of required MR cycles, NTGA also results in reduced size of intermediate results. Multiple related n-tuples resulting from relational-style joins involving a multi-valued property are implicitly represented as a single triplegroup in NTGA. For example, the 3 n-tuples corresponding to Stp_2 containing a multi-valued property *xGO* are implicitly represented using a single triplegroup tg_2 as shown in Figure 2. This is specifically important in minimizing the I/O footprint of long MapReduce execution workflows while processing RDF graph pattern queries.

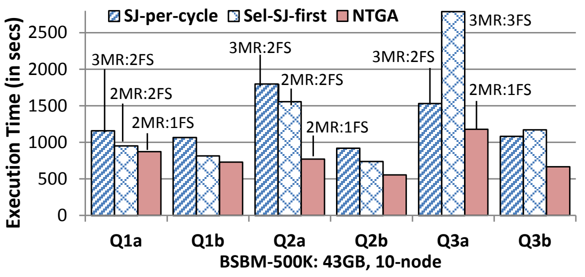


Figure 3: Evaluation of different groupings of star-joins (MR: No. of MapReduce cycles, FS: No. of Full Scans)

Consider a case study using 6 test queries (each with two star subpatterns) using the BSBM synthetic benchmark dataset (43GB) on a 10-node Hadoop cluster, as shown in Figure 3. The test queries have varying join structures with Object-Subject join (Q1a, Q1b, Q2a, Q2b) and Object-Object join (Q3a, Q3b) between star patterns. Queries Q1b, Q2b, Q3b are variations of Q1a, Q2a, Q3a respectively, where one of the two star-joins is highly selective due to an additional filter on the object column. Additional details about the evaluated queries are available on the project website [3]. We evaluated three different groupings of star subpatterns in a query, (i) a star-join per cycle approach (*SJ-per-cycle*), (ii) most selective grouping of joins first but preserving star structure as much as possible to minimize MR cycles (*Sel-SJ-first*), and (iii) concurrent evaluation of star-joins using the grouping-based approach in NTGA. *SJ-per-cycle* approach requires 3 MR cycles for all queries (2 of 3 cycles require full scan of triple relation). For Object-Subject joins, *Sel-SJ-first* approach can group joins into just 2 MR cycles (both cycles scan entire triple relation). For the Object-Object join (Q3a, Q3b), *Sel-SJ-first* still requires 3 MR cycles, but more importantly has very high HDFS reads due to full scan of triple relation in all 3 cycles. In contrast, the *NTGA* approach is able to minimize the number of MR cycles (2 cycles for all queries), as well as minimize the required number of full scans of the triple relation, thus outperforming the other two approaches for all test queries.

Earlier work on NTGA captures basic graph patterns. In this work, we build on the advantages of the TripleGroup data model and algebra for efficient evaluation of unbound-property graph pattern queries on MapReduce. Specifically, the semantics of the group-filter operator (σ^{γ}) requires all properties in the query structure to be bound. However, to capture more complex patterns, the algebra and the set of rewrite rules need to be extended. The following section introduces a number of extensions which allow us to relax the above constraint to provide an extended group-filter semantics for

Figure 4: Transformation: n-tuples to a triplegroup

evaluating unbound-property queries.

3. REWRITING UNBOUND-PROPERTY QUERIES USING NTGA

Consider an unbound-property star pattern $St_u = \{P_{bnd}, P_{unbnd}\}$ such that $P_{bnd} = \{P_1, P_2, ..., P_k\}$ represents the set of bound properties and P_{unbnd} represents an unbound property. Let T_{St_u} be the star-join result of relation $T(Sub, Prop, Obj)$ with vertically partitioned subset relations T_{P_1}, T_{P_2},...,T_{P_k}, and let $T_{St_u(s)}$ represent a subset of T_{St_u} with subject $Sub = s$.

$$T_{St_u(s)} = \sigma_{Sub=s}(T_{P_1} \bowtie T_{P_2} \bowtie ... \bowtie T_{P_k} \bowtie T)$$

The tuples in $T_{St_u(s)}$ have arity 3(k+1), where each property in St_u is associated with 3 columns in $T_{St_u(s)}$. Figure 4 represents the tuples in $T_{St_1(S1)}$ for a star-pattern St_1 with bound properties P_1, P_2 and an unbound property. To determine how St_u will be evaluated using NTGA, it will be useful to develop some correspondence between $T_{St_u(s)}$ and a subject triplegroup in NTGA. Note that a single triple may play multiple roles (occur multiple times) in the result of an unbound-property star pattern – one as a match for the bound property and the other as a match for the unbound property. For example, $(S1, P1, O1)$ in Figure 4 occurs once for the join with T_{P_1} and once for the join with T. In the NTGA data model, such multiple occurrences are implicitly represented once, which must be accounted for in the transformation process.

Continuing with the transformation process, let π_{P_i} and π_{P_u} denote the projection of the (Sub, Prop, Obj) columns corresponding to parent relation T_{P_i} with bound property P_i, and unbound property P_{unbnd} respectively. Let tg_s represent the set union of triples formed by the 3 columns, i.e.

$$tg_s = \pi_{P_1}(T_{St_u(s)}) \cup ... \cup \pi_{P_k}(T_{St_u(s)}) \cup \pi_{P_u}(T_{St_u(s)})$$

Figure 4 denotes the triples in tg_{S1} for our example star-pattern St_1, formed by the set union of the partitions π_{P_1}, π_{P_2}, and π_{P_u}. tg_s has the following properties:

(i) $\forall t_i, t_j \in tg_s$, the triples t_i, t_j agree on the subject column s.

(ii) $\exists$ non-empty subset of triples $tg_{P_i} \subseteq tg_s$ such that $tg_{P_i} = \pi_{P_i}(T_{St_u(s)})$, for each bound property $P_i \in P_{bnd}$.

(iii) $\exists$ a non-empty subset of triples $tg_{P_u} \subseteq tg_s$ such that $tg_{P_u} = \pi_{P_u}(T_{St_u(s)})$ and $tg_{P_u} \cap (tg_{P_1} \cup ... \cup tg_{P_k})$ may be non-empty.

Essentially, the tuples in T_{St_u} can be horizontally partitioned into sets of tuples with the same Subject column, and each element in the partition can be vertically partitioned into 'triples' whose union is equivalent to a subject triplegroup tg_s in the NTGA data model. The use of set union instead of bag union ensures that we have a triplegroup. Further, subsets of triples in tg_s represent matches to the bound and unbound-property triple patterns in St_u. This process basically describes a sequence of translation steps from the relational algebra to NTGA. In other words,

$$\begin{aligned} T_{St_u(s)} &= \sigma_{Sub=s}(T_{P_1}) \bowtie ... \bowtie \sigma_{Sub=s}(T_{P_k}) \bowtie \sigma_{Sub=s}(T_{P_u}) \\ &= tg_{P_1} \bowtie ... \bowtie tg_{P_k} \bowtie tg_{P_u} \end{aligned}$$

Conversely, for our example star-pattern St_1 in Figure 4, tuples in $T_{St_1(S1)}$ are implicitly represented in tg_{S1} and can be produced by $(tg_{P_1} \bowtie tg_{P_2} \bowtie tg_{P_u})$. A useful property is to distribute the join with the unbound-property triple pattern across a union of subset relations of T. In other words, if the triple relation T can be partitioned into two subset relations, i.e., $T = \{T_{P'_u} \cup T_{P''_u}\}$. Then by the distributivity of join over union, we have:

$$T_{P_{bnd}} \bowtie (T_{P'_u} \cup T_{P''_u}) \equiv (T_{P_{bnd}} \bowtie T_{P'_u}) \cup (T_{P_{bnd}} \bowtie T_{P''_u})$$

Evaluating St_u using NTGA requires applying group filter (σ^γ) to match the required query structures. Recall that σ^γ is defined in terms of a set of bound properties. One might consider evaluating an unbound-property star-pattern query using σ^γ with a disjunction of concrete pattern combinations. Each such combination will consist of the set of bound properties P_{bnd} with each property in the database. For example, if $P_{bnd} = \{P_1, P_2\}$ is the set of bound-properties in the star pattern and $P = \{P_1, P_2, ..., P_{10}\}$ represents the set of all properties in the database. Then, the σ^γ expression is:

$$\sigma^\gamma_{(\{P_1,P_2,P_1\} \vee \{P_1,P_2,P_2\} \vee ... \vee \{P_1,P_2,P_{10}\})}(TG)$$

This would filter out triplegroups that do not match any of the required pattern combinations. However, the approach of enumerating all possible pattern combinations may be inefficient depending on the number of properties in the database. Additionally, the subject triplegroup tg_s may contain additional triples relevant to other patterns, and hence may not exactly match a single pattern combination. Hence, there is a need to relax the σ^γ to restrict the matching of structural constraints to the bound properties of the unbound-property star pattern. This means that triplegroups that contain all the bound properties (may contain additional properties), should be produced as part of the result for σ^γ. Once this is done, we need to extract subsets of triples in tg_s that are exact matches for any of the required pattern combinations. This is achieved by extracting the subset of triples corresponding to P_{bnd} and generating their union with each triple in the unbound-property subset tg_{P_u}. In the following section, we provide the formal definitions for a specialized group-filter operator ($\sigma^{\beta\gamma}$) and the unnest operator (β-`unnest`) that extracts the perfect matches to the unbound-property star-pattern. From here on, we assume the convenience function $tg.props()$ ($st.props()$) to retrieve the set of properties in a triplegroup tg (star pattern st).

DEFINITION 1. *(β **Group-filter**) Given a set of subject triplegroups TG and a star pattern $St_u = \{P_{bnd}, P_{unbnd}\}$ contaning an unbound property, the β **group-filter** operator $\sigma^{\beta\gamma}$ returns the subset of triplegroups in TG that contain a non-empty subset of triples matching all bound properties P_{bnd}. Specifically,*

$$\sigma^{\beta\gamma}_{(P_{bnd}, P_{unbnd})}(TG) := \{\ tg_i \in TG \mid P_{bnd} \subseteq tg_i.props()\}$$

Essentially, $\sigma^{\beta\gamma}$ ensures that triplegroups contain a matching triple for each of the bound properties in P_{bnd}. Additionally, triplegroups

may also contain triples containing other property types. For example, given $P_{bnd} = \{label, xGO\}$, triplegroup ftg_1 forms a valid result for the $\sigma^{\beta\gamma}$ expression in Figure 5(a). However, ftg_2 does not contain a matching triple for the bound property xGO and hence gets filtered out.

Definition 2. *(β **unnest**) Given a set of triplegroups TG and an unbound-property star pattern $St_u = \{P_{bnd}, P_{unbnd}\}$, the **unnest** operator μ^β creates a set of triplegroups that are exact matches to St_u. Specifically,*

$$\mu^{\beta}_{(P_{bnd},P_{unbnd})}(TG) := \{\ tg_i = \{tg_{P_{bnd}} \cup t_i\} \mid tg_{P_{bnd}}, t_i \subseteq tg,\ tg_{P_{bnd}}.props() = P_{bnd},\ tg \in TG\ \}$$

In other words, the β-unnest operator extracts subsets of triples in a triplegroup tg that match the different pattern combinations corresponding to the unbound-property star-pattern. Figure 5(b) shows the 5 perfect triplegroups that are produced by β-unnesting the triplegroup ftg in Figure 5(a), each containing a subset of triples $tg_{P_{bnd}}$ matching the set of bound properties P_{bnd}, and a triple t_i that matches the unbound-property triple pattern.

Lemma 1. *Given a triple relation T and an unbound-property star pattern $St_u = \{P_{bnd}, P_{unbnd}\}$ such that the set of bound properties $P_{bnd} = \{P_1, P_2, ..., P_k\}$ and P_{unbnd} represents a single unbound property, the following equivalence holds:*

$$(T_{P_1} \bowtie ... \bowtie T_{P_k} \bowtie T) \cong \mu^{\beta}_{P_{bnd}}(\ \sigma^{\beta\gamma}_{(P_{bnd},P_{unbnd})}(\ \gamma_s(T)))$$

Proof: Let T_{St_u} and TG_{St_u} represent the set of tuples and triplegroups produced by evaluating an unbound-property star-pattern St_u using relational joins and NTGA respectively. We need to prove that all tuples in T_{St_u} are produced using NTGA. We prove by contradiction. Let us assume that there exists a tuple $tup_s \in T_{St_u}$ with subject s that cannot be produced using triples in tg_s. This can happen only if $\exists$ a triple $t_i \in tup_s$ such that $t_i \notin tg_s$. Firstly, since $t_i \in tup_s$, we know that the subject of t_i is s. If $t_i.\texttt{props}() \in P_{bnd}$, since t_i's subject is s, the $\sigma^{\beta\gamma}$ ensures that $t_i \in tg_s$. If $t_i.\texttt{props}() \notin P_{bnd}$, then $\sigma^{\beta\gamma}$ still retains t_i since its subject is s. Hence, $t_i \in tg_s$. The only other case is when a triple t_i plays multiples roles (matches both bound and unbound parts) which are implicitly represented in our data model. We rely on the correctness of the μ^β operator (illustrated earlier but proof omitted for brevity) to complete the proof.

Generalization to Multiple Unbound Properties. The β-unnest operator can be generalized to star-patterns containing multiple unbound-property triple patterns. Let P_α, P_β,...,P_m represent the m unbound properties in a star-pattern. Then the β-unnest operator results in a set of triplegroups $\{tg_{\alpha\beta...m}\}$ each containing the bound-property subset $tg_{P_{bnd}}$ and m triples, one each matching the unbound properties P_α, P_β,...,P_m.

$$\mu^{\beta}_{(P_{bnd},\{P_\alpha,P_\beta,..,P_m\})}(TG) := \{\ \{tg_{P_{bnd}} \cup t_\alpha \cup t_\beta \cup ... \cup t_m\}\ \}$$

such that $tg_{P_{bnd}} \subseteq tg$ is the bound-property subset, i.e., $tg_{P_{bnd}}.props()$ = P_{bnd}, and triples $t_\alpha, t_\beta, ...t_m \subseteq tg \in TG$.

4. TRANSLATION TO MAPREDUCE PLANS

The logical operators proposed in the previous section are integrated into RAPID+ [17] (an NTGA-based extension of Apache Pig). The query compilation process in RAPID+ begins with plans of logical operators, which are compiled to plans of physical operators, which could either be a single function or a function pair corresponding to the map and reduce phases of the logical operator. The MR plan is an assignment of physical operators to MR cycles.

The MR plan for an unbound-property query, executes the β-group-filtering using the `TG_UnbGrpFilter` ($\sigma^{\beta\gamma}$) operator in the reduce of the `TG_GroupBy`. This is followed by the β-`unnest` (μ^β) operator that produces a set of perfect triplegroups. Thus, both `TG_UnbGrpFilter` and `unnest` can be executed in the reduce of `TG_GroupBy` in a single MR cycle (MR_1). We call this as *eager* β-unnesting of triplegroups, represented in Figure 6(a). The joins between the triplegroups matching the different subpatterns can be computed using NTGA's `TG_Join` operator in the subsequent MR cycles. At the end of MR_1 for this strategy, we have intermediate results (perfect triplegroups for the star pattern subqueries) that contain redundancy with respect to the bound-properties. This increases the cost of $MR_1.R_{Write}$ and HDFS read ($MR_i.M_{Read}$) and shuffle costs ($MR_i.MR_{Shuffle}$) for subsequent cycles MR_i that process the output of MR_1. Therefore, optimization strategies to minimize the redundancy in intermediate results of the star-join computation phase would be useful to generate cost-effective MapReduce workflows.

4.1 Optimization using β-Unnesting Strategies

The intuition is to concisely represent the result of an unbound-property star-pattern as far along the MR workflow as possible. Unbound-property query structures such as $B4$ in Figure 8 do not involve further joins based on the bindings of the unbound-property triple pattern, and thus can remain in its (nested) implicit representation till the end of the MR workflow. Query structures such as our example query $Q1$ participate in joins based on the Object column of the unbound-property triple pattern. Hence, the star-join results for such star subpatterns need to be β-unnested before the join, since the map phase of `TG_Join` tags the triplegroups based on the join key and partitions them to different reducers. We propose evaluation strategies to delay the β-unnesting of triplegroups.

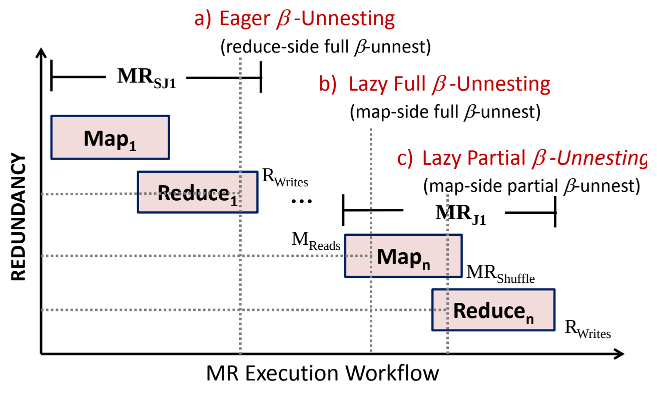

Figure 6: (a) eager β-unnest of a triplegroup during star-join, (b) lazy full and (c) lazy partial β-unnest in later join phase

Lazy Map-side β-Unnest: The β-unnesting of triplegroups can be delayed to a MR cycle that requires join on an unbound-property triple pattern, such as cycle MR_{J1} in Figure 6(b). Specifically, we push the β-`unnest` operator to the map phase of the corresponding `TG_Join` operator. We refer to the new physical operator as `TG_UnbJoin` (reduce phase remains same as `TG_Join`). By delaying the β-unnesting of triplegroups, we can minimize the redundancy in results of the star-join computation phase, and hence avoid unnecessary writes, reads, and shuffle costs for all subsequent intermediate MR phases. However, the β-`unnest` operator expands the map output of `TG_UnbJoin`, which impacts the shuffling costs. Assuming that `TG_UnbJoin` is assigned to the kth MR cycle MR_k in the workflow, then the redundancy in map output impacts $(MR_k.M_{Write} + MR_i.MR_{Sort} + MR_i.MR_{TR})$.

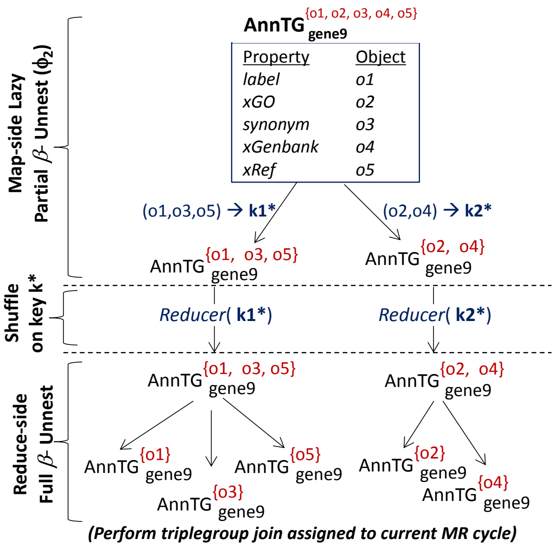

Figure 7: Lazy partial β-unnesting (ϕ_2)

Lazy Map-side Partial β-Unnest: We illustrate this strategy using Figure 7 . In order to support efficient look-up of (Property, Object) pairs in a triplegroup, we use an optimized internal representation scheme (extended multi-map) represented here as $AnnTG$, that concisely represents annotated triplegroups. Example annotated triplegroup $AnnTG^{\{o1,o2,o3,o4,o5\}}_{gene9}$ in Figure 7 represents the subject triplegroup ftg_1 (Figure 5(a)) which is a valid match for the unbound-property star subpattern SJ_2 in query $Q1$. Annotated TG $AnnTG^{\{o1,o2,o3,o4,o5\}}_{gene9}$ contains 2 bound-property triples (matching $label$ and xGO) and 5 triples matching the unbound-property triple pattern. A β-unnest operation produces 5 triplegroups (all containing the same bound-property component) that form a part of the map output for MR_k. The default partitioning scheme in Hadoop assigns the map output tuples to a reducer r based on the hash value of the join key, i.e., $hash(joinKey)\%r$. In the case that we have just 2 reducers, it is possible that triplegroups containing redundant bound-property component are partitioned and assigned to the same reducer based on the join keys (object of triples in the unbound-property component). For example, $AnnTG^{\{o1\}}_{gene9}$ and $AnnTG^{\{o3\}}_{gene9}$, may be assigned to the same Reducer, e.g., *Reducer1*. The redundancy in the map output of MR_k can be minimized if triplegroups that are eventually assigned to the same reducer are concisely represented during the shuffle phase, i.e., they are not β-unnested completely. By avoiding a part of the β-unnesting, we can reduce the size of map output, and hence reduce the shuffling costs. We propose a partial β-unnesting strategy that creates a set of triplegroups that each contain the bound-property component $tg_{P_{bnd}}$, and a subset of the unbound-property component $tg_{P_{unbnd}}$.

DEFINITION 3. *(**partial β-unnest**) Given a set of triplegroups TG, an unbound-property star-pattern St_u=$\{P_{bnd}, P_{unbnd}\}$, and a partition function ϕ_m that partitions the triples in $tg_{P_{unbnd}}$ into m partitions, the **partial-β-unnest** operator $\mu^{\beta'}$ produces a set of triplegroups such that:*

$$\mu^{\beta'}_{(P_{bnd},\phi_m)}(TG) := \{\ tg^i = \{tg_{P_{bnd}} \cup partition_i\}\ \}$$

where

- $\forall\ tg\ \in\ TG$, the bound-property subset $tg_{P_{bnd}}\ \subseteq\ tg$ such that $tg_{P_{bnd}}.props() = P_{bnd}$.
- A function ϕ_m assigns a triple $t_j \in tg_{P_u} \subseteq tg$ to $partition_i$, i.e., $\phi_m : t_j \rightarrow partition_i$, where $i \in \{1, 2, ..., m\}$.

The function ϕ partitions the triples in $tg_{P_{unbnd}}$ into m buckets based on the value of the join key. Essentially, $\mu^{\beta'}$ produces a maximum of m triplegroups for each triplegroup $tg \in TG$. For example, a partial β-unnest on $AnnTG^{\{o1,o2,o3,o4,o5\}}_{gene9}$ in Figure 7 using the partition function ϕ_2 produces 2 triplegroups - $AnnTG^{\{o1,o3,o5\}}_{gene9}$ and $AnnTG^{\{o2,o4\}}_{gene9}$ respectively. This implies that $\phi_2(o1) = \phi_2(o3) = \phi_2(o5) = k1^*$. Similarly, $AnnTG^{\{o2\}}_{gene9}$ and $AnnTG^{\{o4\}}_{gene9}$ are assigned to the same partition and hence remain implicitly represented as a single triplegroup. The redundant content in the map output is now a function of the partition range m. The partially β-unnested triplegroups are tagged and assigned to the reducers based on the partition key k^*. Triplegroup join with lazy partial β-unnest is implemented as a new physical operator, `TG_OptUnbJoin`. Figure 6(c) represents how the I/O footprint can be reduced by partial and delayed β-unnesting at map phase of MR_{J1}.

4.1.1 Algorithms For Physical Operators:

Algorithm 1 gives an overview of the job workflow for two key phases in the NTGA plan – Job_1, that computes 'matching' triplegroup equivalence classes that match all star subpatterns in the query, and Job_i, that computes the join between the triplegroup equivalence classes.

Job_1***: Compute 'matching' TG equivalence classes.*** The input to this job is a set of 3-tuples (triples) in the RDF database, and the output is a set of annotated triplegroups $AnnTG$ that match the star subpatterns in the query. In the map phase, each tuple is tagged based on the Subject component. In the reduce phase, all

```
Algorithm 1: MR job workflow for NTGA plan
  $Job_1$: Compute 'matching' triplegroup equivalence classes
    Map:
      $TG\_GroupBy$.Map(Tuples $T$);
    Reduce:
      $TG \leftarrow TG\_GroupBy$.Reduce($Sub$, List <Tuples>);
      $TG' \leftarrow TG\_UnbGrpFilter(TG, <EC, \{P_{bnd}, P_{unbnd}\}>)$;
  $Job_i$: Join between triplegroup equivalence classes
    Map:
      $TG\_OptUnbJoin$.Map($TG'$) //partial $\beta$-unnest
      or $TG\_UnbJoin$.Map($TG'$) //$\beta$-unnest
    Reduce:
      $TG'' \leftarrow TG\_OptUnbJoin$.Reduce($TG'$);
      or $TG'' \leftarrow TG\_UnbJoin$.Reduce($TG'$);
```

tuples corresponding to the same Subject component Sub are processed in the same reduce(), producing subject triplegroups. This is followed by a group-filtering phase to filter out triplegroups that violate the structural constraints in the query. Algorithm 2 shows the pseudocode for the β group-filtering operator, `TG_UnbGrpFilter`. The (Property, Object) pairs in a triplegroup (`tempMap` in line 1), are matched with all equivalence classes (star subpatterns) in the query (line 2). For each matching equivalence class EC, the bound properties P_{bnd} are extracted (line 4). The tuples in the group are considered relevant to the query only if they contain all bound properties (lines 5-9). If the matched equivalence class contains an unbound-property, the resultant $AnnTG$ contains all the (Property, Object) pairs for subject Sub (lines 6-7). If the matched equivalence class does not contain any unbound-property, only the relevant (Property, Object) pairs that match the bound properties are retrieved into the resultant triplegroup (line 8). Essentially, a group of tuples that does not contain the required set of bound properties for any of the star subpatterns in the query is filtered out.

```
Algorithm 2: TG_UnbGrpFilter
  $\beta$-GrpFilter ($tg$, $ECList$:<$EC$,{$P_{bnd}$, $P_{unbnd}$}>);
1 $tempMap \leftarrow$ extract triples in $tg$;
2 $matchedECList \leftarrow match(tempMap, ECList)$;
3 foreach $EC \in matchedECList$ do
4     $P_{bnd} \leftarrow$ extract bound properties in $EC$;
5     if $P_{bnd} \subseteq tempMap.keySet$ then
6         if $EC$ contains unbound property then
              //$\beta$ group filtering
7             $propMap \leftarrow tempMap$ ;
          else
              //Extract only bound properties in EC
8             $propMap \leftarrow$ extract $P_{bnd}$ entries from $tempMap$;
9         emit $\langle AnnTG(Sub, EC, propMap)\rangle$;
```

Job_i: ***Join between TG equivalence classes.*** The input to this phase is a set of annotated triplegroups, belonging to the two equivalence classes whose join is to be computed. The output is a set of annotated triplegroups, representing the joined result between the two equivalence classes. Based on the amount of redundancy in intermediate results due to the unbound-property star subpattern, a decision is made to either enable a partial or full β-unnest of the map output. Star subpatterns where the unbound-property is associated with a (partially) bound object, are not likely to cause redundancy, and hence a full β-unnest is enabled (`TG_UnbJoin` operator). For all other cases, the `TG_OptUnbJoin` operator is used.

Algorithm 3 shows the map-reduce functions for the operator `TG_OptUnbJoin` that integrates lazy partial-β-unnest operation. In the map phase, the annotated triplegroups that join on Subject are tagged using the Subject's partition key k* computed using ϕ_m (lines 1-3). For joins on Object, the AnnTG is partially β-unnested

```
Algorithm 3: TG_OptUnbJoin
   Map ($key$:null, $val$: AnnTG $atg$) ;
1  if join on $Sub$ then
2      $k$* $\leftarrow \phi_m(atg.Sub)$;
3      emit $\langle$ $k$*, $atg\rangle$ ;
   else if join on $Obj$ then
       //Partially $\beta$-unnest $atg$ using $\phi_m(Obj)$
4      $atgList \leftarrow$ partial-$\beta$-unnest ($atg$, $\phi_m$) ;
5      foreach $partialMap \in atgList$ do
6          $k$* $\leftarrow$ extract $k$* for $partialMap$ ;
7          emit $\langle$ $k$*, $partialMap\rangle$ ;

   Reduce ($key$:$k^*$, $val$:List of AnnTGs $TG'$) ;
8  $leftList \leftarrow \beta$-unnest leftEC AnnTGs from $TG'$;
9  $rightHash \leftarrow \beta$-unnest rightEC AnnTGs from $TG'$;
10 foreach $leftAnnTG \in leftList$ do
11     foreach $prop \in leftAnnTG.propMap$ do
           //Handle multi-valued property
12         $objList \leftarrow$ extract $prop$'s objects from $leftAnnTG$ ;
13         foreach $joinKey \in objList$ do
14             $rightAnnTG \leftarrow rightHash$.get($joinKey$) ;
15             emit $\langle$ joinTGs($leftAnnTG$, $rightAnnTG$)$\rangle$;
```

using the `partial-`β`-unnest` operation. The `partial-`β`-unnest` operator splits the (Property, Object) pairs in the triplegroup atg based on the Object's partition key resulting in a list of partially-unnested AnnTGs ($atgList$ in line 4). A map output tuple is generated for each partially-unnested AnnTG, tagged by its partition key k*(lines 5-7). The replication factor Rep is now a function of ϕ_m. In the reduce phase, all AnnTGs corresponding to the same group key k* but different join keys are processed in the same reduce(). In order to selectively join them based on the original join key, the AnnTGs corresponding to the right relation ($rightEC$) are β-unnested into perfect triplegroups and hashed based on the join key ($rightHash$ in line 9). The algorithm iterates through each AnnTG in the left relation ($leftEC$ in line 8), and probes the hashed relation ($rightHash$) based on the Object value (join key) for each property (lines 10-14). Multi-valued properties have multiple Object values and the probing is done for each value (lines 12-13). When a match is found, the two AnnTGs are joined (line 15) as per the definition of `TG_Join`. The partition factor used by ϕ depends on the size of input, potential redundancy factor, and average number of tuples that can be processed by a reducer.

5. EVALUATION

We evaluated the proposed algebraic optimization techniques on both real-world and synthetic datasets, and compared it with two popular relational-style MapReduce systems, Apache Pig and Hive. For NTGA, we evaluated two approaches for processing unbound-property graph pattern queries – *EagerUnnest* (Section 4), and the optimized *LazyUnnest* with map-side lazy β-unnesting. Experiments were conducted on NCSU's VCL [33], where each node in the cluster was a dual core Intel X86 machine with 2.33 GHz processor speed, 4G memory and running Red Hat Linux. 60 and 80-node Hadoop clusters (block size set to 256MB, 1GB heap-size for child jvms) were used with Pig release 0.11.1, Hive 0.10.0 and Hadoop 0.20.2. Only 20GB disk space was available per node, requiring large clusters to support large scale data, i.e., the 80-node Hadoop cluster made available ~1.6TB HDFS disk space. Results recorded were averaged over three trials.

Choice of Systems: Both Pig and Hive evaluate star-joins in a single MR cycle (one-star-join-per-cycle), resulting in same length workflows for all queries. Hive enables shared-scan of input relations within an MR cycle, thus minimizing the overall HDFS

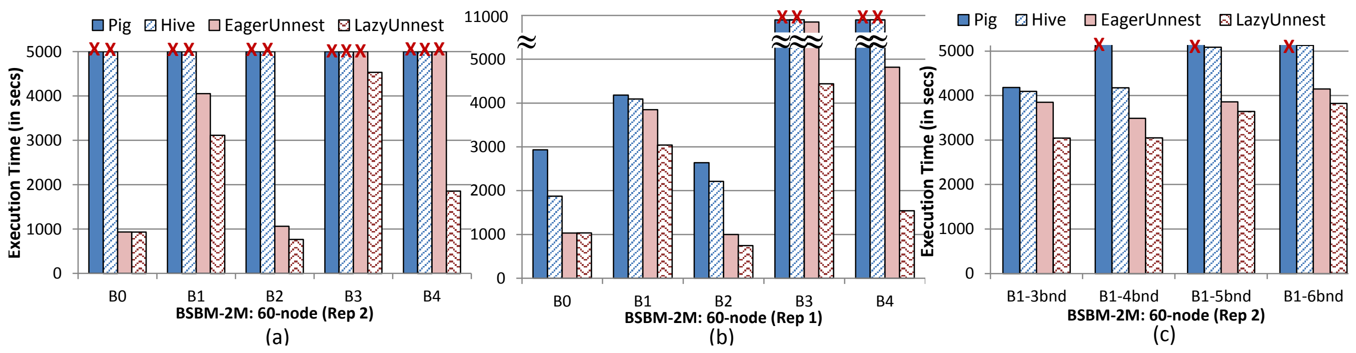

Figure 9: Performance with varying unbound-property star patterns with (a) replication factor 2 (b) replication factor 1 (c) Performance with varying size of bound-property component (BSBM-2M, 172GB, 60-node)

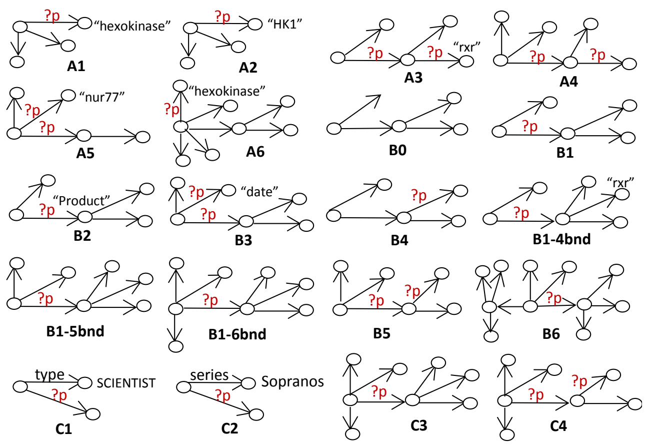

Figure 8: Testbed unbound-property RDF queries

reads. Pig can execute independent MR cycles concurrently, which is beneficial while evaluating multiple star subpatterns. NTGA approaches produce shorter workflows (all-star-joins in single MR cycle) when compared to Hive/Pig for queries with multiple star subpatterns. A triple relation is loaded as a 3-column table in Hive, where as Pig (and NTGA) process them as flat files. In Pig, the `SPLIT` operator is used to generate vertically-partitioning relations. HadoopRDF [15] does not currently support unbound-property queries and is not included for evaluation. Systems such as HadoopDB [14] scale well but rely on a heavy pre-processing phase that is more suitable for private clusters and less-evolving data. We focus on on-demand and pay-as-you-go workloads that involve quick exploration of datasets to get a sense of the data.

Testbed - Dataset and Queries: Real-world life sciences data from Bio2RDF [9] was used for evaluation. The queried biological data warehouse integrated 24 datasets, consisting of a total of ~4.7 billion triples (615GB in n-triple format). Two other real-world datasets, DBPedia Infobox (DbInfobox) [7] dataset of size 4.4GB (33.74M triples: 20.5M properties, 13.23M types) and the Billion Triple Challenge 2009 dataset (BTC-09) [1] of size 193GB (1.5B triples), were also used for evaluation. More than 45% of properties in both datasets are multi-valued with varying multiplicity. Two synthetic datasets generated by the BSBM [11] data generator tool – BSBM-1M (85GB dataset with 1 million Products, total ~370 million triples) and BSBM-2M (172GB dataset with 2 million Products, total ~700 million triples) were used for scalability study. The evaluation tested unbound-property queries with varying selectivity, varying join structures (single join to more complex structures with multiple star subpatterns) that are represented in Figure 8. Graph patterns in queries `A1`-`A6` have been extracted from Bio2RDF demo queries [2]. Additional details about the evaluated queries, along with the Pig / Hive scripts, are available on the project website [3].

Varying join structures (`B1`-`B6`): Scalability experiments were conducted to evaluate different join structures with varying number of unbound-property triple patterns, and varying arity of star subgraphs. Figures 9(a) and (b) show a performance comparison of Pig, Hive, and the NTGA approaches for two-star queries with no unbound properties (`B0`), one unbound-property triple pattern with join on unbound object (`B1`), one unbound property associated with a partially-bound object (`B2`), two unbound-property triple patterns in the same star with one partially-bound object (`B3`), and an unbound-property triple pattern (`B4`). Pig / Hive evaluate all three queries using 3 MR jobs (one per star-join), while NTGA evaluates them in 2 MR jobs. The queries involve a multi-valued property *prodFeature* that impacts redundancy.

In order to avoid data loss during node failure, fault-tolerant systems such as Hadoop rely on replication of data blocks on multiple nodes using a configurable parameter (dfs.replication). Initial set of experiments were conducted using a replication factor of 2 for the larger dataset BSBM-2M on a 60-node cluster (1.6TB disk space, 20GB per node). The results, shown in Figure 9(a), demonstrate how critical it is to concisely represent intermediate results and eliminate redundancy when possible. Missing bars marked with 'X' represent failed execution. Pig / Hive approaches failed during the last job (join between stars) for all 5 queries due to shortage of disk space. While *EagerUnnest* successfully executed for `B0`, `B1`, and `B2` by concisely representing subgraphs involving multi-valued properties, it failed for queries `B3` and `B4`. This is because the double unbound-property triple patterns in `B3` result in materialization of large intermediate results during the star-join computation phase, and we see the benefit of pushing the β-unnesting to a later phase (*LazyUnnest*) in executing this query. Similarly, for query `B4`, *LazyUnnest* successfully executes by materializing concise intermediate results, while other approaches fail.

In order to analyze the performance of the different approaches on the larger dataset, the same set of queries were repeated after reducing the HDFS replication factor to 1. Figure 9(b) shows the results comparing the performance of the approaches for BSBM-2M on the same 60-node cluster. In general, we see the benefit of the NTGA approaches for all queries. Query `B0` shows a baseline case with all bound properties where Hive and NTGA approaches outperform Pig due to scan-sharing. Further, NTGA approaches concisely represent results containing multi-valued property which leads to I/O savings. For query `B1` (join on unbound-property triple pattern), lazy partial β-unnesting reduces the shuffle

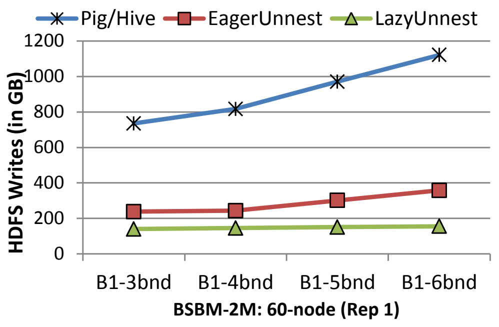

Figure 10: Total HDFS writes with varying size of bound-property component (BSBM-2M, 60-node)

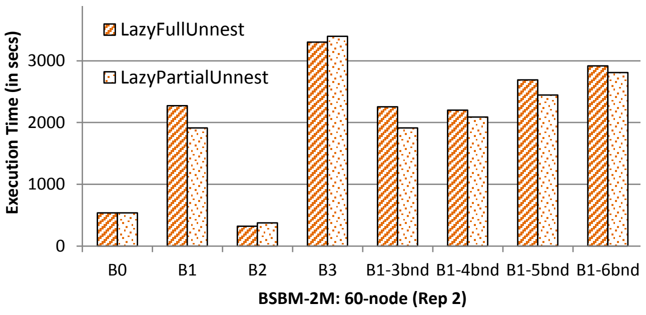

Figure 11: Lazy Full vs. Lazy Partial Unnesting: A comparative study of savings and overhead in MR cycle MR_{J1}

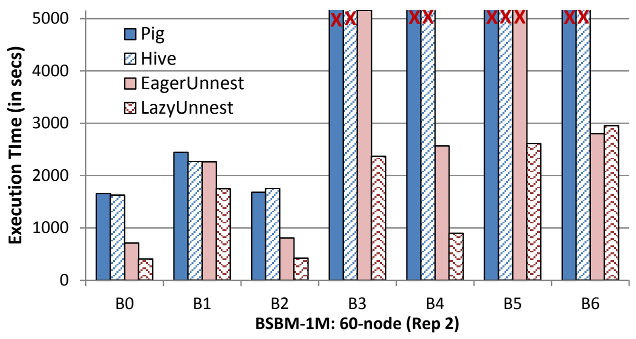

Figure 12: Performance comparison (BSBM-1M, 85GB)

costs and is 21% faster than eager β-unnesting (27% faster than Pig and 26% faster than Hive). For query B2, all approaches evaluate the filter on the partially-bound object associated with the unbound-property triple pattern in the initial map phase, and from there on, the execution is similar to the baseline query B0. As in the case of replication factor 2, Hive and Pig failed again for B3 and B4. The star subpattern with double unbound-property triple patterns (one with partially-bound object) in B3, is concisely represented in *LazyUnnest* with 80% less HDFS writes than *EagerUnnest*. In queries, such as B4, where the unbound-property triple pattern does not participate in join between stars, the lazy β-unnesting strategy keeps the result compact till the end, thus saving on intermediate disk reads / writes as well as final writes. Lazy β-unnesting using *LazyUnnest* results in 61% less HDFS writes than *EagerUnnest*, and overall has a 68% gain in performance times over the eager β-unnesting approach.

Choice of Lazy β-Unnesting Strategies: Testbed queries consist of varying structure of unbound-property triple patterns. For example, unbound-property triple patterns in queries B2 and B3 have partially-bound objects, i.e., the user does not know the exact property relationship but knows something about the object. In such cases, it is likely that the number of triples matching the unbound-property triple pattern are reduced and hence the associated star-join is more selective, i.e., results in less number of pattern combinations when compared to same triple pattern with an unbound object. Other queries such as B1 consist of unbound-property triple pattern with an unbound object. Though lazy β-unnesting is beneficial for all cases, we wanted to study benefits and overhead of lazy full and lazy partial β-unnest strategies. Figure 11 shows execution times for the last MR cycle (MR_{J1}) where the join involving the unbound-property triple pattern is computed. Since the size of input for MR_{J1} is same for both approaches, this analysis allows us to zoom into the map-side overhead for full and partial β-unnest, savings in shuffle costs, and analysis of reduce-side overhead in the case of partial-β-unnest. Our experiments show that a lazy full β-unnest may be sufficient for unbound-property queries with partially bound objects (queries B2 and B3). However, unbound-property queries with an unbound object ($B1$ series), benefit from partial-β-unnest. Other experiments were corroborative to these findings, and hence the *LazyUnnest* approach reported in this section evaluate lazy full-β-unnest for unbound-property queries with partially-bound-object patterns, and lazy partial-β-unnest for those with unbound-object patterns.

Varying number of bound-property edges: Unbound-property queries with bound-property triple patterns varying from 3 (B1-3bnd) to 6 (B1-6bnd) were evaluated. Figure 10 shows the total amount of HDFS writes for Pig, Hive and the NTGA approaches for the test queries evaluated on a 60-node cluster with BSBM-2M. In general, the increase in the number of bound-property components results in a gradual increase in the size of reduce output for Pig and Hive, while lazy β-unnesting keeps the result concise till the end of map phase of the last MR job (Job_2). The relational approaches produce 10 combinations of the bound component for the test queries since the relational arity of the subgraph that matches the unbound-property subpattern is 10. However, *LazyUnnest* compactly captures all the required combinations, resulting in approx. 80 to 86% less HDFS writes than Hive / Pig for queries B1-3bnd to B1-6bnd, respectively. Additionally, the reduce output for the NTGA approaches remain almost constant for such query patterns, which allows more flexible exploration of large datasets. Figure 9(c) shows a comparion of the execution times for all approaches. Note that Pig failed for all queries beyond three bound-property subpatterns. *LazyUnnest* (ϕ_{1K}) consistently outperformed the other approaches, running about 25% faster than Hive.

Varying size of RDF graphs: Figure 12 shows the evaluation of the BSBM queries using BSBM-1M (85GB) on the 60-node cluster (HDFS replication factor 2). NTGA approaches successfully executed for all datasets, with up to 80% less HDFS writes after the star-join computation phase for query B1 when compared to Hive. Once again it was observed that both Pig and Hive failed for queries B3 and B4 due to insufficient disk space. This is due to the high redundancy in star-join result that ripples into the next MR job, impacting the scan and I/O costs. For query B2, *LazyUnnest* outperforms all other approaches, executing about 75% faster than both Pig and Hive. *LazyUnnest* reduces the redundancy in intermediate results, and thus improves the execution time of the eager β-unnesting approach (*EagerUnnest*) by 54% (65%) for query B3 (B4). Hive / Pig failed to execute for more complex queries such as B5 and B6. These sets of experiments demonstrate the benefit of the proposed strategies in mitigating the effect of redundancy on MapReduce processing costs.

Real-world Unbound-property Queries (A1-A6): Figure 13

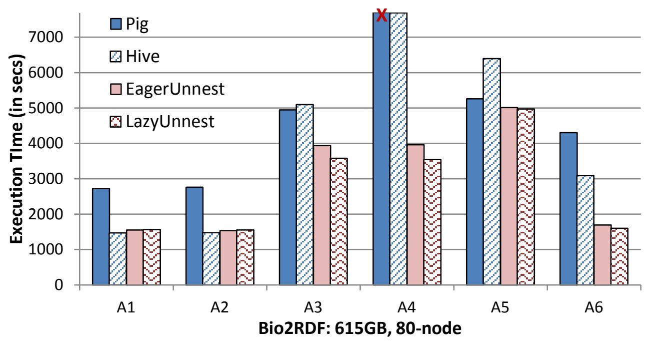

Figure 13: Evaluation of real-world unbound-property queries (Bio2RDF Life Sciences Dataset)

shows a performance comparison of Pig, Hive, and the two NTGA approaches for Bio2RDF queries `A1`-`A6` on a 80-node Hadoop cluster. Queries `A1` and `A2` have one star subpattern with one unbound-property triple pattern associated with partially-bound objects. For query `A1`, while Hive / Pig approaches produce all combinations of subtuples matching the bound property with triples matching the unbound property (∼63K tuples), *EagerUnnest* produces ∼7K triplegroups that concisely represent subtuples with multi-valued properties. *LazyUnnest* achieves more concise representation of all combinations corresponding to the unbound-property star pattern and produces only ∼3K triplegroups. The impact of the savings in HDFS writes due to elimination of redundancy in intermediate results, becomes more clear with the two-star queries (`A3`-`A6`).

Queries `A3` and `A4` contain an unbound-property in each of the two star subpatterns (one with partially-bound object). While Pig / Hive materialize 26GB of intermediate results in the star-join computation phase for query `A3`, the NTGA approaches write only about 1.3GB of data to the HDFS, contributing to the 32% performance gain over Hive while computing the star subpatterns. The *LazyUnnest* results in reduced HDFS writes in MR_1, and reduced scan costs and shuffling costs in MR_2, resulting in additional 18% performance gain over *EagerUnnest* in MR_2. For query `A4`, Pig initiates 4 MR jobs (initial map-only job to read entire input and compress it, 2nd and 3rd MR jobs to compute the two star patterns, and the 4th job to join the stars). However, Pig approach failed (marked as 'X') due to lack of HDFS space while executing the last job. Again, there is a huge savings in terms of HDFS writes, with *EagerUnnest* and *LazyUnnest* producing only 1.8GB and 0.6GB of intermediate results, respectively, after the initial star-join phase, as opposed to 152GB of writes in Hive. An important factor that results in large intermediate results with relational-style processing, is the redundancy due to the presence of large number of high multiplicity properties in biological datasets (representative of real-world datasets). For `A4`, *EagerUnnest* and *LazyUnnest* approaches are 48% and 53% faster than Hive, respectively.

Query `A5` contains a star pattern with two unbound-property triple patterns – one whose object matches a gene "nurr77", and the other with an unbound object, connecting the star to a single edge retrieving the *label* property type. Hive executes `A5` using 2 MR jobs, with both jobs requiring a full-table scan. NTGA approaches also execute using 2 MR jobs but with one full-table scan, resulting in overall savings of about 1400s (22% gain) over Hive. The single unbound-property triple pattern in query `A6` partially binds the object to "hexokinase". While Hive uses 3 MR jobs, including 2 for the star-join computation, Pig uses an extra map-only job to compress the input (total 4 jobs). NTGA's *LazyUnnest* approach shows a benefit of up to 48% over Hive.

DBPedia Queries (`C1`-`C4`): Additional experiments were conducted on varying sizes of real-world datasets, 4.3GB DBInfobox dataset (5-node cluster) and 193GB BTC-09 dataset (40-node cluster) as shown in Figure 14. Four different query structures were used. `C1` and `C2` are simple queries with single join that retrieve all information about Scientists (unselective) and Sopranos TV series (selective). In the case of DBInfobox dataset, since the data processed is quite small, the benefit of the NTGA approach is not seen for the first two queries. However, Pig does better than Hive since it processes two copies of the input relation, and hence initiates double the number of mappers and reducers. `C3` and `C4` represent real-world scenarios during exploration where the relationship between entities (star subpatterns) is unknown. NTGA approaches showed a performance gain of 20-22% and 50% over Hive and Pig respectively for query `C3`, and resulted in approx. 80% less HDFS writes than Hive. All four queries had redundancy factor greater than 0.6. In particular, `C4` which involved an unbound-property in each of the two star patterns showed a redundancy factor close to 0.89, and hence showed major improvement (50% gain over both Pig and Hive) with the lazy β-unnesting strategy.

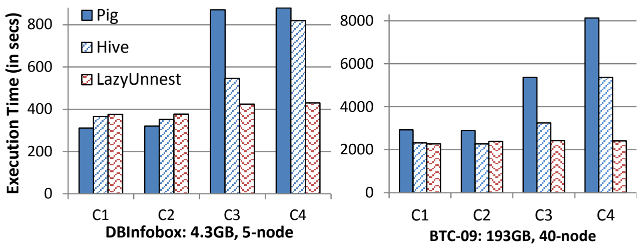

Figure 14: Evaluation of real-world unbound-property queries (DBInfobox and Billion Triple Challenge'09)

Unbound-property queries on the BTC-09 dataset resulted in very large HDFS reads which negatively impacted Pig the most, due to its multiple scans per star-join. The scan-sharing across star patterns in NTGA resulted in 50% less HDFS reads for the two star queries. NTGA approaches resulted in 54% (25%) gains over Pig (Hive) for query `C3` with 1 unbound-property. The result of the star-join phase for `C4` (2 unbound properties) has redundancy factor of 0.93 (0.75GB) and increases to 0.98 (14GB) in the final output for Pig/Hive. The lazy β-unnesting strategy results in 98% less HDFS writes, and have 70% (55%) performance gain over Pig (Hive) for `C4`. In general, real-world data contained multiple multi-valued properties with varying multiplicity, and highly benefited by the generalized nested representation of triplegroups and lazy β-unnesting strategies while processing unbound-property queries.

6. CONCLUSION

We propose a scalable solution for processing unbound-property graph pattern queries on MapReduce, by minimizing the redundancy in intermediate results that adds avoidable costs while processing long execution workflows. The proposed approach uses a nested triplegroup model to implicitly represent the intermediate results and lazily 'unnest' them only when necessary. A combination of the two result in significant savings in intermediate HDFS reads and writes, which form a major portion of query processing costs on MapReduce. Additional savings in intermediate map-reduce data shuffling costs can be achieved by delaying a portion of the 'unnest' to the reduce phase. Experiments show promising results for different query join structures with varying selectivities. Future directions include exploring more complex structures with multiple unbound-property patterns as well as unbound-property queries with aggregation constraints.

ABSTRACT

Social media and micro-blogging platforms have been successful for communication and information exchange enjoying vast number of user participation. Given their millions of users, it is natural that there is a lot of interest for marketing and advertising on these platforms as attested by the introduced advertising platforms on Twitter and Facebook.

In this paper, inspired by micro-blogging advertising platforms, we introduce two problems to aid ad and marketing campaigns. The first problem identifies topics (called *analogous* topics) that have approximately the same audience in a micro-blogging platform as a given query topic. The main idea is that by bidding on an analogous topic instead of the original query topic, we reach approximately the same audience while spending less of our budget. Then, we present algorithms to identify expert users on a given query topic and categorize these experts to finely understand their diversified expertise. This is imperative for word of mouth marketing where individuals have to be targeted precisely.

We evaluate our algorithms and solutions for both problems on a large dataset from Twitter attesting to their efficiency and accuracy compared with alternate approaches.

1. INTRODUCTION

Social media and micro-blogging have experienced exponential growth in user acquisition and participation over the last decade. Services such as Twitter, Facebook, and Pinterest allow millions of people to share billions of content and interact on a daily basis. Social platforms are targets of sophisticated advertising and marketing, mainly because of the large number of users, and the enormous amount of time users spend on them.

In micro-blogging platforms (e.g. Twitter), social connections get established by "following" an individual u. By establishing such a connection, you get to receive and view all posts (tweets) produced by u. The set of all posts that are visible by a user v is commonly referred to as the feed (timeline) of v. The act of following someone explicitly expresses interest in the information that person produces.

Social media and micro-blogging platforms are utilized by many as important marketing vehicles. By amassing a large number of followers, an individual or a company can broadcast messages targeted to these followers. Such messages vary depending on the type of the account (e.g., celebrity, professional, consulting, corporate) and what one wishes to achieve (e.g., brand/product awareness, sales leads, or general information dissemination). Typically, one produces information in the field of one's expertise – which is a topic or a set of topics that one knows well, professes, or is known for as an *expert* in the community. For example a celebrity (say a singer) will disseminate information of interest to fans, such as tour dates, personal events and announcements, as well as new songs and albums, whereas a company, say a technology startup, shares information related to its products, and the overall technology product space.

Recently, new advertising platforms have been introduced [10, 17]. In contrast to the keyword bidding model, as is popular in the case of search engine advertising, the micro-blogging platform takes a different approach. An advertiser selects a topic q, bids a specific dollar amount, and provides a post (known as a promoted post). The micro-blogging advertising platform identifies all the users that are *interested* in the topic q based on some internal algorithms and inserts the promoted post in the feed of these users (explicitly identifying it as a promoted post). The dollar amount is utilized by an auction that determines the winning bidder (for topic q). As an example, if we are interested in showing a promoted post to those users that are interested in *music*, we will bid an amount for the topic *music* and provide our promoted post. If we win, our promoted post will be inserted in the feed of those accounts interested in topic *music*. Commonly the amount we bid is per impression or per engagement (i.e., per person seeing or clicking on the promoted post).

In such a setting there are numerous opportunities for optimization. Of immediate interest would be reaching the same or approximately the same set of people with a lower cost. For example, by bidding on the topic *public relations* we can be successful only if we bid a price of x. What if we knew that if we bid on the topic *seo* (search engine optimization), we can reach the same people (and thus have the same impressions) for a price $y < x$? The first problem we outline in this paper is to produce a set of topics R *analogous* to a topic q (that we wish to bid on). These topics have the property that if we bid on one of them instead of q, our promoted post will be inserted in the feed of approximately (for a precise definition of approximate) the same people as those in the case of q. Now, by examining the associated cost of each topic, we can make a more informed decision by comparing the savings versus how many interested individuals our posts will reach for each of the analogous topics in R. We propose an algorithm called IAT to address this problem (Section 3).

Note that by advertising on a cheaper topic $t \in R$ instead of q, (1) (approximately) the same people see the ad and (2) expectedly same people engage with the ad. The cost we should spend in case of targeting t instead of q, therefore, would be lower (1) per impression (in cost per impression model) and (2) per engagement (in cost per engagement model). Hence by bidding on t, we reach same audience with a lower cost independent of the cost model in use.

Utilizing this technique provides a win-win situation for advertisers and the advertising platforms (e.g., Google, Twitter, etc.). Adopting the technique, advertisers who are interested in a topic will have more options (more topics with similar audience) to target. This prevents from the existence of a very popular topic that is too expensive to target alongside some cheaper topics that no one targets. In this situation, more advertisers afford to advertise. Hence the revenue of the advertising platform may significantly increase while advertisers also obtain more savings per advertisement.

A second popular marketing activity on micro-blogging platforms is to engage *experts* on specific topics into word of mouth marketing campaigns. By having experts on a topic become advocates of a product or a service, all of their followers become informed about the product or service. This is a typical form of word of mouth marketing. For example, if we are interested to market a new cloud computing product by word of mouth on a social media, we can engage cloud computing experts and persuade them to adopt, use, or talk about our product.

Finding the right advocates online is always challenging. Commonly, a user's account has a set of topics associated with it highlighting its expertise. Even if we have an a priori knowledge of the specific topics we wish our advocates to have expertise on, it may be impossible to find one that spans all these topics. Thus, a more iterative approach is desirable. Given that we can identify all experts on a single topic q, it would be very useful if we are capable of categorizing those experts based on other topics of their expertise. That would enable us to examine them in a more refined fashion and identify those that are closest to our topics of interest. For example, a set of experts in both *cloud computing* and *virtualization* may be more suitable for us than a set of experts in *cloud computing* and *data centers.* Being able to compute such expert groups algorithmically, given one specific topic of expertise q (cloud computing in our example), is imperative. We have typically no knowledge of what is the "right" number of groups and it is expected that some experts belong to many groups. We propose an algorithm (called CTE, Section 4) to group together all experts on any given topic in a varying number of groups (corresponding to high-level topics) based on the collective topics of expertise of all these users.

The problems discussed in this paper are inspired by social media and micro-blogging advertising platforms. Since the internal algorithms utilized by these platforms are unknown to public, we have proposed some models (e.g., expert identification, topic bidding model, etc. that are explained in the next sections) and utilized them in this paper as a proof of concept. We note that these models, our assumptions, and our methods are *not* based on or designed for any specific social media or micro-blogging platform.

As we have access to a large dataset from Twitter, we evaluate the algorithms on this dataset for various queries. Both IAT and CTE algorithms operate fast (a few minutes) in all experiments stressing the practicality of our developments. In addition, we deploy a qualitative study demonstrating the goodness of our findings and compare our CTE algorithm with some baseline techniques (Section 5). A literature review is provided in Section 6, followed by Section 7 concluding our discussion.

2. THE TARGETS

Different social media and micro-blogging platforms such as Twitter, Facebook, and Google+ have introduced the concept of *lists* (*circles* in case of Google+). A list is a user-defined set of accounts. Commonly, users create a list grouping their favourite accounts on a particular topic into that list which they annotate with a descriptive title. For example, in Twitter a user may create a list with the title of "politics" that include Twitter accounts @BarakObama, @AngelaMerkel, @HillaryClinton, @JohnKerry, and @DavidCameron. The utility of a list is to provide quick filtering (by list title) of posts from accounts belonging in the list. It is very typical to group together accounts that profess or depict expertise on a particular topic. A user can create multiple lists and an account can belong to any number of lists.

We utilize the infrastructure of the Peckalytics system [2] to associate with each account u, a set of topics T_u extracted from the titles of the lists containing that account. The process of extraction includes tokenization of the title, common word (stop word) and spam filtering, entity extraction, and related word grouping via Wikipedia and WordNet. The end result is, for each account u, a set of topics that best describes the topics associated (by other users) with u. We emphasize however, that *any* process of mapping an account to a set of topics that best describes the account can be utilized (e.g., machine learning methods). The techniques presented herein will work fine without any modification.

A user $u \in U$ is an *expert* on topic $t \in T$, iff $t \in T_u$. This means that (for our specific way of extracting topics) other users recognize u as an expert on topic t. We call topic t, a topic of expertise for u. The set of experts on topic t is denoted by E_t. A user $u \in U$ is *interested* in topic $t \in T$ iff the probability that u follows (reads) any content (a post, a shared video, a posted link, etc.) that is related to topic t is higher than a given threshold $\theta \in [0, 1]$. For a topic t, we refer to the set of all users who are interested in t as the *target set* of topic t denoted by S_t.

Micro-blogging platforms utilize several factors (content of posts, followers, etc.) to identify the interests of users and subsequently form target sets. However, such factors are largely proprietary. In this paper, we approximate the target set of a topic t by partitioning it into two categories: (1) users interested in t who are also expert on t (E_t) and (2) users interested in t who are not expert on t (I_t). In other words, users in E_t are producers of contents related to t, and users in I_t are consumers of contents related to t. Thus, $S_t = E_t \cup I_t$. For any topic t, the set of experts E_t is available to us; i.e., $E_t = \{u | t \in T_u\}$. However, the I_t sets are unknown to us (i.e., we do not know which users are interested in a given topic t). One may suggest to retrieve the interests for each user by taking the union of expertise topics of all accounts this user follows. This approach has some drawbacks. A given user (say u) may be an expert on several topics. When another user (say v) follows u, the user v may be interested in any of these topics but not necessarily in all of them. It is not straightforward to determine which topic is of interest to v, given the topics of u's expertise. In section 3.1, we present an approach to resolve this issue.

3. ANALOGOUS TOPICS

In an advertising scenario on a social media platform, by placing a bid for a particular topic q, assuming that the bid is granted, users in S_q will observe the promoted post on their feeds. Naturally, an interesting question is whether there is any other topic t that is cheaper than q (i.e., it is possible for a lower bid to be granted) with a target set S_t "close" to S_q. If possible, this would reduce advertising cost. This question is the key component of this Section. To formalize the question, we introduce some definitions.

Definition 1. *When a promoted post corresponding to a topic q is shown to a user belonging to $S_t \cap S_q$ (for some topic t), we say a* true impression *is achieved. If the promoted post is shown to a user in $S_t \backslash S_q$, we call that a* false impression. *Note that $X \backslash Y$ denotes the set difference between two arbitrary sets X and Y. As users in $S_t \backslash S_q$ are not interested in q, presenting a promoted post to them is not a desired outcome.*

Definition 2. *The* distance *between two arbitrary sets X and Y, denoted by $D(X,Y)$, is the size of the symmetric difference between them: $D(X,Y) = |(X\backslash Y) \cup (Y \backslash X)|$. Moreover, the* distance *between two topics q and t is the distance between their target sets S_q and S_t: i.e., $D(q,t) = D(S_q, S_t)$.*

We note that a low distance between topics q and t translates to a high true impression and a low false impression since $D(S_q, S_t) = |(S_t\backslash S_q) \cup (S_q \backslash S_t)| = |S_t \backslash S_q| + |S_q| - |S_t \cap S_q|$. Note that $|S_q|$ is a constant for a fixed query topic q.

Definition 3. *A topic t is* analogous *to topic q iff the distance between q and t is less than a given threshold $k \in \mathbb{N}$; i.e., $D(q,t) < k$. That is, t is* analogous *to topic q iff the true impression ($S_t \cap S_q$) is high while the false impression ($S_t \backslash S_q$) is low.*

The goal of this section is to identify a list of topics that are *analogous* to a query topic q. These topics are ranked subsequently based on a *weight function* (Equation 10) that involves both true and false impression values. If any of the *analogous* topics has a bidding cost lower than q, it is a potential alternative for bidding purposes.

Problem 1. *Let q be a given query topic. Identify all topics t that are* analogous *(Definition 3) to q.*

The solution to Problem 1 can be utilized by advertisers to instigate advertising campaigns by choosing the *analogous* topics instead of query topic q, target (approximately) the same set of audiences, and pay less.

Problem 1 could be solved if the target sets for all topics were known. Unfortunately, as explained in Section 2, finding the targets sets is not straightforward (since the I_t sets are unknown). To address this problem, in the rest of this section, we present an approach to identify analogous topics without calculating the exact target sets.

3.1 Properties of analogous topics

The target set of a topic t can be partitioned into two sets: the set of experts E_t and the set of interested users I_t. According to Section 2, the set E_t can be readily identified utilizing the lists. However, I_t is unknown. We aim to identify topics t such that I_t and I_q are "close" (for a suitable definition of close).

We reason about approaches to identify these desired topics. Through this reasoning, we gain some intuition about the properties of analogous topics. Based on the discussion, we conclude this section by introducing two properties of analogous topics that enables us to identify them without calculating the I_t sets.

Approach I: A well-known measure of similarity between two arbitrary sets X and Y is the correlation coefficient, denoted by $\rho(X,Y)$. The correlation between two sets can be calculated utilizing the Pearson product-moment correlation coefficient [15]: $\rho(X,Y) = \frac{cov(X,Y)}{\sigma_X \sigma_Y}$ that is equal to $\frac{n(\sum_{i=1}^n x_i y_i) - \sum_{i=1}^n x_i \sum_{i=1}^n y_i}{\sqrt{(n\sum_{i=1}^n x_i^2 - (\sum_{i=1}^n x_i)^2)(n \sum_{i=1}^n y_i^2 - (\sum_{i=1}^n y_i)^2)}}$ on a sample, where n is the number of elements, and x_i (y_i) is 1 if the i^{th} element belongs to X (Y) and 0 otherwise.

In Theorem 1, we show that there exists a direct translation between the correlation coefficient and the distance of two sets.

Theorem 1. *For any two arbitrary sets X and Y, if the correlation between them is greater than a threshold $\delta \in [-1,1]$, there exist a threshold $k \in \mathbb{N}$, negatively associated with δ ($k \sim -\delta$), such that the distance between X and Y is less than k:*

$$\forall X, Y, \forall \delta \in [-1,1], \\ \exists k \in \mathbb{N}, k \sim -\delta, \rho(X,Y) > \delta \Leftrightarrow D(X,Y) < k \quad (1)$$

Proof Proof Sketch. An increase in $\rho(X,Y)$ is equivalent to an increase in $\sum x_i y_i$ (number of similar items in both sets) that is equivalent to a decrease in $-\sum x_i y_i$ hence a decrease in $D(X,Y)$. Moreover, any increase in δ and subsequently $\rho(X,Y)$ translates to a decrease in $D(X,Y)$ and subsequently k. $\square$

Definition 4. *We define the* correlation *between two arbitrary topics t and t', denoted by $\rho(t,t')$, as the correlation between their target sets; i.e., $\rho(t,t') = \rho(S_t, S_{t'})$. Furthermore, we define the* expertise correlation *between two topics t and t', denoted by $\rho_E(t,t')$, as the correlation between their sets of experts; i.e., $\rho_E(t,t') = \rho(E_t, E_{t'})$.*

According to Theorem 1, for a given query topic q, all topics with a high correlation value with q can be reported as the analogous topics. Since the target sets are unknown, the correlation between two topics cannot be computed. However, we can compute the expertise correlation as follows (the Pearson product-moment correlation coefficient):

$$\rho_E(t,t') = \rho(E_t, E_q) = \frac{cov(E_t, E_q)}{\sigma_{E_t}\sigma_{E_q}}$$
$$= \frac{n(\sum_{i=1}^{n} t_i q_i) - r.s}{\sqrt{(n\sum_{i=1}^{n} t_i^2 - r^2)(n\sum_{i=1}^{n} q_i^2 - s^2)}} \qquad (2)$$

where n is the number of users, and r (s) is the number of expert users on topic t (q). Moreover, t_i (q_i) is 1 if the i^{th} user is expert on topic t (q) and 0 otherwise. The denominator is equal to $\sqrt{(nr - r^2)(ns - s^2)}$. The correlation coefficient can vary from -1 (negatively correlated) to +1 (positively correlated).

A basic approach to approximate the correlation between two topics might be to calculate the expertise correlation between them and to utilize it as a metric to assess the correlation between those topics; i.e., one may claim that $\rho(t,q) \sim \rho_E(t,q)$.

Note that a high expertise correlation between t and q suggests that the distance between E_t and E_q is small (Theorem 1). Thus, among experts, the true impression is large and the false impression is small. The primary idea of Approach I is that if the expertise correlation between t and q is high, one may conclude that the correlation between the whole target sets S_t and S_q is high; hence, according to Theorem 1, the distance between S_t and S_q would be small and t would be analogous to q (Definition 3). Unfortunately, this is not correct as clarified by the following example.

Example 1. *Consider two topics "oil" and "Persian classic dance". Note that as Persians actively argue about both topics (suppose independently in separate posts), many users may place them in lists corresponding to each topic. Therefore, many Persians belong to the expertise sets of both topics, creating a high expertise correlation between these topics. In this sense, we may end up concluding that the topic "oil" is analogous to the topic "Persian classic dance". On the other hand, however, the target sets of these two topics can be very different. A person who is interested in "oil" is not necessarily interested in "Persian classic dance". In other words, by targeting the interested users in one of these topics, we do not target the users interested in the other topic. Thus, a high correlation between sets of experts does not imply the same for the corresponding sets of interested users; therefore the target sets for these topics are not necessarily related and* $\rho(t,q) \not\sim \rho_E(t,q)$.

This problem may be resolved by not looking at topics "in isolation" but in conjunction with other topics. The two topics "oil" and "Persian classic dance" have high expertise correlation. However, let us consider other topics with high expertise correlation to "oil" or "Persian classic dance". The topic "oil" has high expertise correlation to topics in $\mathcal{S}_{oil} = \{energy, power, war, \cdots\}$ for example, whereas "Persian classic dance" has high expertise correlation to topics in $\mathcal{S}_{dance} = \{art, music, culture, \cdots\}$. The expertise correlation between topics in $\mathcal{S}_{oil}$ and $\mathcal{S}_{dance}$ is extremely low.

Example 1 suggests that a holistic view, that considers the expertise correlation of all topics in conjunction rather than individual topics in isolation, might help to determine

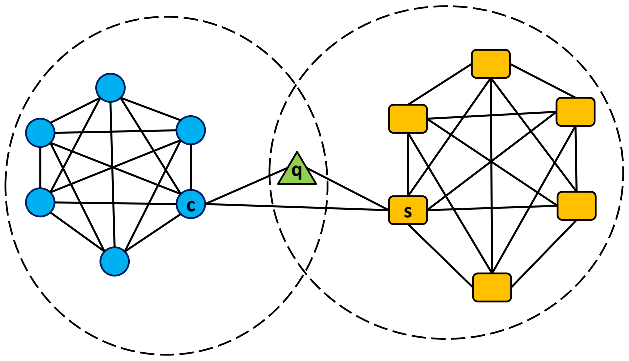

Figure 1: Partitioning a graph of topics. Any optimal clustering algorithm would generate two clusters as shown: node q may be assigned to each of the two clusters. Note that an optimal clustering will not generate a cluster $\{q, c, s\}$.

topics that are analogous to q. It is a natural tendency of users to be interested in high-level topic categories as well as topics under these categories. For example, if user u is interested in Wimbledon (the tennis tournament), it is natural to assume, that with a high probability, u is interested in the bigger category tennis as well as other tennis events such as French Open, US Open, Australian Open, etc. If u is interested in Oscars, it is safe to assume, with a high probability, u is also interested in other film events such as Golden Globe, BAFTA, Cannes film festival, Berlin film festival, etc. Based on this, we can conclude that for topics in the same category (e.g., Wimbledon and US Open which are both tennis events), the sets of interested users are close (i.e., if t_1 and t_2 are members of the same category of topics, the distance $D(I_{t_1}, I_{t_2})$ is small). This suggests that identifying the topics in the category that topic q belongs would aid in locating the analogous topics.

Approach II: One approach to incorporate this holistic view might be to calculate the expertise correlation between all topics and create a correlation graph where nodes represent topics and the weight of an edge between two arbitrary nodes t and t' is $\rho_E(t,t')$. Then partition (or classify) this graph and report all topics in the partition containing topic q, as the topics analogous to q. Unfortunately, this approach has its own shortcomings as shown in the following example.

Example 2. *Consider the graph shown in Figure 1. Each node in this graph represents a topic with node q being the query topic. All the nodes represented by a circle have a high expertise correlation with each other, and all nodes represented by a square have a high expertise correlation with each other. The expertise correlation is small between a circle and a square node. Node q has a high expertise correlation with nodes c and s, and there is a high expertise correlation between nodes c and s.*

If we are looking for topics analogous to q, ideally one should identify c and s. However, any clustering scheme that relies on a global objective function based on the expertise correlations will partition this graph into two clusters as shown in Figure 1 without returning $\{q, c, s\}$ *as a separate cluster. We note that for any algorithm that generates a given number of partitions k, one can generalize this example by creating sets of k different shapes, without changing the behavior observed.*

The problem encountered in Example 2 is a result of the fact that clustering algorithms rely on the optimization of a global objective function that does not take into account the original topic of interest q. Assigning q to a cluster takes place based on the optimality of a global function, and that can lead to poor performance in situations where the focus is solely on q.

Conclusion: These two examples suggest that one needs a hybrid approach considering both the direct expertise correlation between each topic and q, as well as the expertise correlation amongst the neighbors.

A topic t is analogous to topic q if and only if:

PROPERTY 1: The expertise correlation between q and t is greater than a threshold δ; i.e., $\rho_E(q,t) > \delta$.

PROPERTY 2: Topic t is in the same category of topics as topic q. In other words, the topics having high expertise correlation with topic t should have high expertise correlation with topic q and vice versa:

$$\forall t'; \rho_E(t,t') > \delta \Leftrightarrow \rho_E(q,t') > \delta$$

When property (1) is satisfied, the distance between E_t and E_q is small (Theorem 1). Moreover, property (2) suggests that the distance between I_t and I_q is small. Therefore, when both properties are satisfied, the distance between the target set of topic t ($S_t = E_t \cup I_t$) and the target set of topic q ($S_q = E_q \cup I_q$) is small; thus t is analogous to q.

In most real world scenarios, it is impossible to identify topics t that strictly satisfy both properties. Therefore, we introduce a technique in Section 3.2 that considers both properties, by defining a "trade-off" between them. In other words, our approach assigns weights to any topic t based on the direct expertise correlation between t and q (Property 1), and at the same time penalizes that weight (by associating a cost) if the topics having high expertise correlation with t have low expertise correlation with q, or the topics with low expertise correlation with t have high expertise correlation with q (Property 2).

3.2 Computing analogous topics

Recall that $U = \{u_1, u_2, \cdots, u_n\}$ denotes the set of users and $T = \{t_1, t_2, \cdots, t_m\}$ denotes the set of topics.

DEFINITION 5. *The* expert coverage probability *of topic $t \in T$, denoted by $\mathcal{P}(t)$, is the fraction of users in U that are expert on t. In particular, $\mathcal{P}(t) = \frac{|E_t|}{|U|}$. Moreover, the* expert coverage probability *of topic $t \in T$* given *topic q (the* conditional expert coverage probability, *denoted by $\mathcal{P}(t|q)$) is the fraction of users in $U' = E_q$ that are expert on t. In particular, $\mathcal{P}(t|q) = \frac{|E_t \cap E_q|}{|E_q|}$.*

As an example, suppose U consists of 1000 users, among them 10 users are expert on "drawing" and 50 users are expert on "music". This leads to $\mathcal{P}(drawing) = 10/1000 = 0.01$ and $\mathcal{P}(music) = 0.05$.

For any two topics t and q, the probabilities $\mathcal{P}(t|q)$ and $\mathcal{P}(t)$ may be significantly different. As an example, assume we observe that among experts on topic "Picasso", 60% are expert on "drawing" and 5% are expert on "music". Thus, $\mathcal{P}(drawing|Picasso) = 0.6 >> P(drawing)$ while $\mathcal{P}(music|Picasso) = \mathcal{P}(music) = 0.05$ (showing that music and Picasso are independent topics). We argue that these changes in the expert coverage probability of different topics given a fixed topic can be utilized as an equivalent measure to Property 1.

We utilize a two-state automaton to study whether any topic t is analogous to a given query topic q or not. This automaton has two states $\mathcal{N}$ and $\mathcal{A}$ corresponding, respectively, to the concepts of "Not-analogous" (t and q are not analogous) and "Analogous" (t and q are analogous). Given topic q, while considering topic t, the automaton can be in one of the states $\mathcal{N}$ or $\mathcal{A}$. The $\mathcal{N}$ state corresponds to low conditional expert coverage probability and the $\mathcal{A}$ state corresponds to high conditional expert coverage probability. These states determine how far $\mathcal{P}(t|q)$ is from the original $\mathcal{P}(t)$ assessing whether topic t satisfies Property 1 (Theorem 2). For any topic t, we aim to identify the state of the automaton with the maximum likelihood.

We deploy a binomial distribution as the basis to realize such measurement. The binomial distribution is a density function that determines the probability that r successes are achieved in a sequence of d independent experiments, when a success is yield with a fixed probability p. In the case of topics and experts, this expresses the probability that among d experts on q, r users are expert on a topic t where $p = \mathcal{P}(t)$. Adhering to the binomial distribution, the probability that the automaton is in state $\mathcal{N}$ for a topic $t \in T$ is:

$$\mathcal{P}(\mathcal{N}_t|q) = \frac{\binom{d}{r_t}\mathcal{P}(t)^{r_t}(1-\mathcal{P}(t))^{d-r_t}}{Z} \tag{3}$$

where $r_t = |E_t \cap E_q|$, $d = |E_q|$. Similarly the probability that the automaton is in state $\mathcal{A}$ is:

$$\mathcal{P}(\mathcal{A}_t|q) = \frac{\binom{d}{r_t}(\alpha \times \mathcal{P}(t))^{r_t}(1-\alpha \times \mathcal{P}(t))^{d-r_t}}{Z} \tag{4}$$

where $\alpha > 1$ (a constant), and $\alpha \times \mathcal{P}(t)$ is the expected expert coverage probability of t given q in case t is analogous to q. Here, $Z = \binom{d}{r_t}\mathcal{P}(t)^{r_t}(1-\mathcal{P}(t))^{d-r_t} + \binom{d}{r_t}(\alpha \times \mathcal{P}(t))^{r_t}(1-\alpha \times \mathcal{P}(t))^{d-r_t}$ is a normalizing constant. Since the denominator Z is similar in both equations and does not impact the calculations, hereafter, we ignore it and just consider the numerators in calculating and comparing $\mathcal{P}(\mathcal{A}_t|q)$ and $\mathcal{P}(\mathcal{N}_t|q)$.

THEOREM 2. *The value of $\frac{\mathcal{P}(\mathcal{A}_t|q)}{\mathcal{P}(\mathcal{N}_t|q)}$ increases (decreases) iff the distance $D(E_t, E_q)$ decreases (increases).*

PROOF. Let α be fixed. The value of $\frac{\mathcal{P}(\mathcal{A}_t|q)}{\mathcal{P}(\mathcal{N}_t|q)}$ increases (decreases) when $\alpha^{r_t}(\frac{1-\alpha\mathcal{P}(t)}{1-\mathcal{P}(t)})^{d-r_t}$ increases (decreases). The latter increases (decreases) when r_t increases (decreases) or $\mathcal{P}(t)$ decreases (increases). This is because $\alpha > 1$ and $0 < \frac{1-\alpha\mathcal{P}(t)}{1-\mathcal{P}(t)} < 1$. Moreover $\mathcal{P}(t)$ decreases (increases) when $|E_t|$ decreases (increases). In both cases $D(E_t, E_q)$ decreases (increases). $\square$

To incorporate Property 2, we create a *correlation graph*: a graph $G = (M, E)$ where any topic $t \in T - \{q\}$ corresponds to a node in G. Moreover, for any two nodes $m_i, m_j \in M$ representing topics t_i and t_j, the weight of the edge e connecting m_i and m_j is $w_e = w(m_i, m_j) = \rho_E(t_i, t_j)$.

DEFINITION 6. *Suppose the state of the automaton for any topic is determined. In particular, the automaton is in state s_i ($\mathcal{N}$ or $\mathcal{A}$) when considering topic t_i (t_i corresponds to node m_i in G). The edge $e = (m_i, m_j)$ is called* inconsistent *if ($w_e > 0$ and $s_i \neq s_j$) or ($w_e < 0$ and $s_i = s_j$).*

Definition 6 suggests that an edge $e = (m_i, m_j)$ is *inconsistent* if the automaton is in different states when the expertise correlation between topics t_i and t_j (corresponding to nodes m_i and m_j) is positive ($\rho_E(t_i, t_j) > 0$) or when the automaton is in the same state if $\rho_E(t_i, t_j) < 0$.

Problem 2 utilizes the automaton and the correlation graph to identify the most likely states for all topics maximizing $\prod_{t_i \in T-\{q\}} \mathcal{P}(s_i|q)$ (or equivalently $\sum_{t_i \in T-\{q\}} \log \mathcal{P}(s_i|q)$) where $s_i \in \{\mathcal{N}, \mathcal{A}\}$ is the state assigned to topic t_i. To satisfy Property 2, Problem 2 associates a cost with any inconsistent edge.

Problem 2. *Let $G = (M, E)$ be the correlation graph for topics in $T - \{q\}$. Identify the state of the automaton for each node $m_i \in M$ ($s_i \in \{\mathcal{N}, \mathcal{A}\}$) to*

$$maximize \sum_{m_i \in M} \log \mathcal{P}(s_i|q) - \sum_{e \in E} c_e \qquad (5)$$

Note that c_e is the cost of edge $e = (m_i, m_j)$ that is equal to $|w_e|$ if e is inconsistent or zero otherwise. By adding a constant factor $\sum_{\substack{e \in E \\ w_e < 0}} w_e$ to Equation 5, we get

$$(5) \equiv maximize \sum_{m_i \in M} \log \mathcal{P}(s_i|q) \; - \sum_{\substack{e=(m_i,m_j) \in E \\ s_i \neq s_j}} w_e \qquad (6)$$

Maximizing Equations 5 and 6 is equivalent to maximizing the probability that the correlation graph G is created by a two-state automaton where the probability that the automaton is in state $\mathcal{N}$ or $\mathcal{A}$ for each node in G is derived by Equations 3 and 4 (corresponding to Property 1) and for each edge e in G, the probability that the automaton maintains the same state over the two end-points of that edge depends on w_e (corresponding to Property 2).

Theorem 3. *Problem 2 is NP-hard.*

Proof. We reduce the max-cut problem to Problem 2. In max-cut problem, given a weighted graph G, the goal is to partition vertices of G into two subsets S_1 and S_2 such that the weight of edges between S_1 and S_2 is maximized. The max-cut problem is widely known to be NP-hard [12].

The reduction is as follows. Let us assume we want to identify the maximum cut for the graph G. We create a graph G' where there is a node u' in G' for any node u in G. For any edge $e = (u_i, u_j) \in G$, we add an edge $e' = (u'_i, u'_j)$ in G' (u'_i and u'_j are the nodes in G' corresponding to u_i and u_j in G) with a weight of $w_{e'} = -w_e$ where w_e is the weight of edge e in graph G. Moreover, for any two nodes v_i and v_j in G not connected to each other, we add an edge between their corresponding nodes v'_i and v'_j in G' with a weight of $w_{e'} = 0$. Finally, we set the probability that the automaton is in the $\mathcal{N}$ or $\mathcal{A}$ state for any node in G' to be equal. Identifying the maximum cut for graph G reduces to solving Problem 2 for graph G' by identifying the state of automaton for any node in G' that maximizes Equation 6 that is equivalent to maximizing $W = \sum_{e'=(u'_i,u'_j) \in E'; s_{u'_i} \neq s_{u'_j}} (-w_{e'})$.

After identifying the optimal states of the automaton for each topic, we define the set S_1 containing all nodes in G corresponding to nodes in G' that are assigned with a $\mathcal{N}$ state and S_2 containing all nodes in G corresponding to nodes in G' that are assigned with a $\mathcal{A}$ state. Thus, $W = \sum_{e \in E'} w_e$ where E' contains all edges in E with an endpoint in S_1 and the other endpoint in S_2. In this sense, maximizing W is equivalent to identifying the maximum cut. □

To identify analogous topics, a more general approach would be to model this process by a 3-state automaton. The automaton, for any topic, can be in any of the 3 states "Dissimilar", "Independent", or "Analogous". The conditional expert coverage probability of topic t on these states is, respectively, a_1, a_2 and a_3 where $a_1 < a_2 < a_3$. In particular, $a_2 = \mathcal{P}(t)$ is the expert coverage probability for topic t over U, a_1 is a lower conditional expert coverage probability showing that the topics t and q are dissimilar (perhaps negatively analogous), and a_3 is a higher conditional expert coverage probability showing that the topics t and q are analogous. In the present work, we simplify the model and merge the "Dissimilar" and "Independent" states to form a "Not-analogous" state $\mathcal{N}$. This generalization can be conducted easily following the developments in the section.

3.3 IAT: an algorithm to Identify Analogous Topics

According to Theorem 3, Problem 2 is NP-hard. It involves two parts: (1) maximizing the log-likelihood of expert coverage probabilities over all nodes; i.e., $\sum_{m_i \in M} \log \mathcal{P}(s_i|q)$, and (2) minimizing the cost of inconsistent edges; i.e., $\sum_{e \in E} c_e$. The value for the first part can be calculated for each node independently. Computing the second part, however, needs to be aware of the states of the neighboring nodes.

We propose a technique (called IAT) that adopts a heuristic approach to reduce the complexity of Problem 2. The main root of the complexity in Problem 2 is the existence of cycles in the graph. In an acyclic graph, we can order nodes of the graph and identify the best state assignment by optimizing both parts of Equation 5 node-to-node based on this ordering. However, when the graph contains a cycle, no ordering can be assumed between nodes in the cycle; the states of all these nodes depend on each other (due to the second part) and should be determined simultaneously. This leads to a complex structure to deal with. The basic idea of IAT is to obtain an acyclic subgraph (a spanning tree) of the original graph. We, then, identify the optimal states based on this tree. Our experiments show that by utilizing this technique, we can effectively locate the analogous topics.

This approach raises the question on how to choose the spanning tree. In Problem 2, before determining the state of a node, we consider the states of the neighboring nodes in order to reduce the cost of inconsistent edges. Among all edges connected to an arbitrary node u, some have the highest probability to be inconsistent. We refer to these as *inconsistency-prone* edges. The goal is to assign the states such that (1) the log-likelihood of expert coverage probabilities over all nodes is maximized and (2) the cost of inconsistency-prone edges is minimized. The idea is that since the inconsistency-prone edges are the most likely edges to induce costs, a state assignment that reduces the cost over these edges, reduces the cost over all edges.

To locate the inconsistency-prone edges, we define an *expected cost* value for each edge. The edges with high expected cost values are considered inconsistency-prone. Let $\hat{A}_u = \frac{\log \mathcal{P}(\mathcal{A}_u|t)}{\log \mathcal{P}(\mathcal{A}_u|t) + \log \mathcal{P}(\mathcal{N}_u|t)}$ determine the expected probability that u is associated with state $\mathcal{A}$ and $\hat{N}_u = 1 - \hat{A}_u$ be the expected probability that u is associated with state $\mathcal{N}$.

The *expected cost* of an edge $e = (u, v)$ denoted by $\hat{c}_e$ is:

$$\hat{c}_e = \begin{cases} |\hat{A}_u - \hat{A}_v| \times w_e & \text{if } w_e \geq 0, \\ (1 - |\hat{A}_u - \hat{A}_v|) \times |w_e| & \text{if } w_e < 0. \end{cases} \quad (7)$$

where the value $|\hat{A}_u - \hat{A}_v|$ (a value between 0 and 1) determines the difference in probability of being associated with state $\mathcal{A}$ for adjacent nodes u and v. High values of $|\hat{A}_u - \hat{A}_v|$ suggest that u and v are likely to be assigned with different states. Having the expected cost values, Problem 3 identifies the optimal acyclic subgraph.

PROBLEM 3. *Considering the expected cost of each edge in the graph $G = (M, E)$, identify an acyclic subgraph $T = (M, E^*)$ with maximum sum of the expected costs over all edges in E^*.*

Problem 3 is equivalent to the minimum spanning tree problem. We can create a new graph G' by negating the weights of all edges in G and identifying the minimum spanning tree in G'. This tree would be the optimal solution for Problem 3 that can be found utilizing any MST algorithm such as Kruskal [11] or Prim [4]. The run time complexity for these algorithms on a dense graph is $O(m^2)$ where m is the cardinality of M.

Assume tree T is the optimal solution for Problem 3. The IAT algorithm is a dynamic programming approach that calculates two values $LP(\mathcal{N}_u)$ and $LP(\mathcal{A}_u)$ for any node $u \in M$ starting from leaves, going upwards to the root. For each leaf u, $LP(\mathcal{N}_u) = \log \mathcal{P}(\mathcal{N}_u|q)$ and $LP(\mathcal{A}_u) = \log \mathcal{P}(\mathcal{A}_u|q)$ that are calculated based on Equations 3-4. For any inner node u, the values are calculated as follows:

$$LP(\mathcal{A}_u) = \log \mathcal{P}(\mathcal{A}_u|q) + \sum_{v \in C(u)} \max(LP(\mathcal{A}_v), LP(\mathcal{N}_v) - w(u,v)), \quad (8)$$

$$LP(\mathcal{N}_u) = \log \mathcal{P}(\mathcal{N}_u|q) + \sum_{v \in C(u)} \max(LP(\mathcal{A}_v) - w(u,v), LP(\mathcal{N}_v)), \quad (9)$$

where $C(u)$ is the set of u's children and $w(u, v)$ is the weight of edge (u, v).

When all values are calculated, IAT identifies the best state assignment to all nodes by locating the chain of states maximizing the value of $\max(LP(\mathcal{A}_r), LP(\mathcal{N}_r))$ where r is the root of the T.

The pseudo-code for IAT is presented as Algorithm 1. Note that p_u is the parent of u and $C(u)$ is the set of u's children in Tree T. The variable $APointer_u$ ($Npointer_u$) saves the optimal state assigned to u when its parent p_u is assigned with a state $\mathcal{A}$ ($\mathcal{N}$). The function "arg max(a, b)" returns $\mathcal{A}$ if $a > b$ and returns $\mathcal{N}$ otherwise. Finally, s_u holds the assigned state of node u. IAT reports all topics that are assigned with state $\mathcal{A}$ as the analogous topics. For each analogous topic t, we define a weight as

$$weight(t) = \log \mathcal{P}(\mathcal{A}_t|q) - \log \mathcal{P}(\mathcal{N}_t|q) \quad (10)$$

This weight determines the improvement we achieve when topic q is assigned with state $\mathcal{A}$ instead of $\mathcal{N}$. Thus, topics with higher weights correspond to more prominent relationships with topic q. Algorithm IAT ranks the analogous topics based on these weight values and returns Q, a ranked list of all nodes assigned with a $\mathcal{A}$ state.

Algorithm 1: The IAT algorithm

```
   input  : The correlation graph $G = (M, E)$, Topic $q$
   output: A ranked list of analogous topics $Q$
   // Identify the optimal spanning tree
1  Calculate the expected cost of edges according to Eq. 7
2  Identify the optimal spanning tree $T$ (e.g., by Prim)
   // Probability calculations
3  Traverse $T$ bottom-up (from leaves to the root):
4  foreach $u \in M$ do
5      $LP(\mathcal{A}_u) = \log \mathcal{P}(\mathcal{A}_u|q) + \sum_{v \in C(u)} \max(LP(\mathcal{A}_v), LP(\mathcal{N}_v) - w(u,v))$
6      $LP(\mathcal{N}_u) = \log \mathcal{P}(\mathcal{N}_u|q) + \sum_{v \in C(u)} \max(LP(\mathcal{A}_v) - w(u,v), LP(\mathcal{N}_v))$
7      $APointer_u = \arg\max(LP(\mathcal{A}_u), LP(\mathcal{N}_u) - w(u, p_u))$
8      $NPointer_u = \arg\max(LP(\mathcal{A}_u) - w(u, p_u), LP(\mathcal{N}_v))$
   // Identifying the state of the root
9  $s_r = \arg\max(LP(\mathcal{A}_r), LP(\mathcal{N}_r))$
   // Identifying the state for all nodes
10 Traverse $\mathcal{F}$ top-down (from roots to leaves):
11 foreach $u \in M$ do
12     $s_u = NPointer_u$;
13     if $s_{p_u}$ = "$\mathcal{A}$" then
14         $s_u = APointer_u$
   // Sort the analogous topics
15 $Q = \emptyset$
16 foreach $u \in M$ do

18         $Q = Q \cup \{u\}$
19 Sort $Q$ based on Eq. 10
```

THEOREM 4. *The IAT algorithm identifies the optimal state assignment on the tree. The run time complexity of IAT is $\theta(m^2)$ where m is the number of topics.*

PROOF PROOF SKETCH. IAT is a standard dynamic programming approach that solves Problem 2 step by step from leaves to the root. The value $LP(\mathcal{A}_u)$ is the optimal solution for Problem 2 on the subtree rooted at u when the state of u is $\mathcal{A}$. Similarly $LP(\mathcal{N}_u)$ is the optimal solution for Problem 2 on the same subtree when the state of u is $\mathcal{N}$. Therefore the value of $\max(LP(\mathcal{A}_r), LP(\mathcal{N}_r))$ is the optimal solution for the whole tree.

We can calculate the expected cost of each edge in constant time. Since there are m^2 edges, line 1 takes $\Theta(m^2)$. Prim's algorithm implemented with Fibonacci heap takes $\Theta(m^2)$ to identify the MST. The probability calculation phase takes $\Theta(m)$ since each edge in the MST can update LP of one node only once. The state identification phase also takes $\Theta(m)$ to calculate the optimal states for all nodes. Finally it takes $\Theta(m \log m)$ to sort the analogous topics. Thus, in total IAT takes $\Theta(m^2)$. □

4. CATEGORIZING THE FOLLOWERS

In Section 1 we explained it is very helpful to categorize all experts on a given topic q based on other topics of their expertise in order to engage them in word of mouth campaigns. For example, among all experts on *social media*, those who are expert on topics such as "consumer behavior", "distribution channel", "market-based pricing", "sales", etc. can be potentially categorized together (in a big category of "Marketing"); and those expert on topics such as "high ranking placement", "website visitors", "Google results", "search engine traffic", "white hat seo", etc. can form a big category of "Search Engine Optimization".

By categorizing the experts, we would be able to understand them in a more refined fashion and to locate the experts that are the "right" advocates to instigate a popularity propagation (based on word of mouth effects) in the network.

4.1 CTE: an algorithm to Categorize Topics and Experts

Let q be a topic, E_q be the set of experts on q, and T_u be the set of all topics user u is an expert on. We propose an algorithm (called CTE) to categorize users $u \in E_q$ based on the topics of their expertise. We introduce four desirable properties that CTE should have:
(1) Soft clustering: Users may be assigned to several categories. This is desirable as users usually have diverse topics of expertise hence they might belong to various categories.
(2) Unknown number of categories k: The optimal number of categories is unknown. The algorithm should identify the best number of categories instead of requiring it as an input.
(3) Coping with high dimensional data: The number of topics is large. On high dimensional datasets, any approach based on distance (e.g., the traditional clustering algorithms) is inaccurate since distances between all pairs converge.
(4) Considering the correlation between topics: Topics are correlated; any approach that is based on an assumption that dimensions (topics in this case) are independent is not applicable.

In Sections 5 and 6, we argue that traditional clustering algorithms fail to provide useful categorizations. Here, we present an approach (satisfying the properties above) that considers topics and users in two steps: first it categorizes the topics without taking into account the users (topic categorization phase); and then it assigns each user $u \in E_q$ based on T_u, to the topic categories (user assignment phase).

This separation of topics and users in categorization helps to segment topics into partitions that are representing high-level topic categories. When we utilize an approach that simultaneously categorizes users in E_q and topics in $\bigcup_{u \in E_q} T_u$ (e.g., the bi-clustering techniques), topics are categorized according to the correlations calculated utilizing the sets T_u of users u in E_q, instead of utilizing the sets T_u of all users in U. Incorporating the users in E_q (instead of *all* users) to capture correlations introduces *coverage bias*.

Coverage bias loosely means that users in E_q are not representative of the population. There are cases where the correlation between two topics t_1 and t_2 is low but the topics are highly correlated in the context of a query topic q (i.e., based on users in E_q). For example, consider topics "Queen's park" and "Government" in the context of topic "Ontario". These topics are not highly correlated in general. However, when the set we consider consists of experts on "Ontario", the two topics would be highly correlated, since Queen's park is the home for the Legislative Assembly of Ontario and is usually utilized as a metonym for the Government of Ontario. On the other hand, there are cases where two topics t_1 and t_2 are highly correlated but when considered in the context of experts on a query topic q, this correlation is small. Consider two topics "football" and "rugby" given the query topic "fifa" as an example. In general rugby and football are correlated due to the relation between rugby and the American football. However, given the topic "fifa", the term "football" would usually refer to the international "football" that has low correlation with "rugby".

4.1.1 *Topic categorization*

The CTE algorithm runs in two phases: (1) topic categorization, and (2) user assignment. Topic categorization starts by creating the correlation graph among topics as discussed in Section 3.2 (incorporating all users in U in weight calculations). Subsequently, we aim to segment topics (graph nodes) into categories such that topics with positive expertise correlation values are located in the same category and topics with negative expertise correlation values are located in different categories.

Problem 4. *Let* $G = (V, E)$ *be a* correlation graph *where topic* $t \in \bigcup_{u \in E_q} T_u$ *corresponds to a node in* V*. Also, the weight of the edge connecting any pair of nodes* $u_i, u_j \in V$ *(representing topics* t_i *and* t_j*) is* $w_{u_i u_j} = \rho_E(t_i, t_j)$*. Segment* G *into categories such that the sum of the weights of edges with positive weights that are cut and edges with negative weights that are uncut is minimized.*

Bansal et. al. have shown that Problem 4 is NP-hard even for a simple case where the weight of all edges are either -1 or $+1$ [1]. Demaine et. al. have shown that Problem 4 and the weighted multicut problem are equivalent; Problem 4 is APX-hard; and obtaining any approximation bound better than $\theta(\log n)$ is difficult ($n = |V|$). Utilizing the linear programming rounding and "region growing" techniques, they have proposed an algorithm to approximate Problem 4 with a tight bound of $\theta(\log n)$ [5].

This approach models the problem as a linear program. A zero-one variable x_{uv} is defined for any pair of vertices u and v. The equation $x_{uv} = 0$ suggests that u and v are in the same category; $x_{uv} = 1$ declares the opposite. Problem 4 translates to

$$\textit{minimize} \sum_{(u,v):\ w_{uv}<0} |w_{uv}|(1 - x_{uv}) + \sum_{(u,v):\ w_{uv}>0} |w_{uv}| x_{uv}$$

subject to the following constraints:
(1) $x_{uv} \in [0, 1]$, (2) $x_{uv} = x_{vu}$, and (3) $x_{uv} + x_{vw} \geq x_{uw}$.
A "region growing" technique is adopted, afterwards, to transform the fractional values of x_{uv} to integral values 0 or 1. The basic idea is to grow balls around graph nodes (with a fixed maximum radius). Each ball is reported as a category. Therefore, two nodes u and v with a high value x_{uv} would be assigned to two different balls and finally two different categories (equivalent to setting $x_{uv} = 1$).

The run time complexity of the algorithm proposed by Demaine et. al. is $\mathcal{O}(n^7)$. This approach is not practical for datasets containing a large number of topics. In our implementation of topics based on Twitter lists, we construct millions of topics for Twitter users. Any approach based on an $\mathcal{O}(n^7)$ algorithm is deemed not practical for our setting.

We propose a heuristic approach called MaxMerge to categorize the correlation graph when the graph is large. The CTE algorithm utilizes MaxMerge in the topic categorization phase. To start, MaxMerge constructs a category for each vertex in G. The algorithm proceeds iteratively. In each iteration, it calculates the value Δ_{AB} achieved by merging any pair of existing categories A and B. The value Δ_{AB} is the average of the weights of edges with one end-point in category A and one end-point in category B. According to Problem 4, the objective is to categorize G such that the edges with positive weights are in the same category and the edges with the negative weights are amongst different categories. The Δ_{AB} value expresses our progress towards the objective when the two categories are merged. At each iteration, categories A and B having the maximum positive value of Δ_{AB} will be merged; MaxMerge continues as long as this maximum positive value is greater than the average weight of all node pairs in the whole graph (stating that merging the two categories at hand should result in a value that is higher than the average weight of one big category that includes all topics). Pseudo code of MaxMerge is provided as Alg 2. The input is a graph $G = (V, E)$.

Algorithm 2: The MAXMERGE algorithm

```
1 Let $avr$ be the average of the weight of all edges in $E$
2 Consider each node as a category
3 foreach pair of categories $A$ and $B$ do
4     $SUM = \sum$ weight of all edges between A and B
      $\Delta_{AB} = SUM/(|A| * |B|)$
5 $Max = \max_{A,B} \Delta_{AB}$;   $A^*, B^* = \arg\max_{A,B} \Delta_{AB}$
6 if $Max > avr$ then
7     Merge $A^*$ and $B^*$ to one category and Goto step 3
8 return all categories
```

Theorem 5. *The run time complexity of Algorithm 2 is $\mathcal{O}(m^2 \log m)$ where $m = |V|$.*

Proof. Line 1 takes $\mathcal{O}(m^2)$ since there are m^2 edges between the topics. Line 2 takes $\mathcal{O}(m)$. At the beginning there are $\mathcal{O}(m^2)$ pairs of partitions and it takes $\mathcal{O}(1)$ to calculate Δ values for each pair. Thus it take $\mathcal{O}(m^2)$ to calculate these values at the first iteration. We can store these values in a priority queue. Based on the implementation it takes $\mathcal{O}(m^2)$ or $\mathcal{O}(m^2 \log m)$ to create this priority queue.

We do several iterations while $Max > avr$ to merge the partitions. The number of iterations is at most $m - 1$. In each iteration, it takes $\mathcal{O}(\log m)$ to find and delete the max value, $\mathcal{O}(m)$ to merge the two partitions, $\mathcal{O}(m)$ to update the values of Δ for the new merged partition, and $\mathcal{O}(m \log m)$ to update these values in the priority queue. Note that if we merge two partitions A and B into the new partition C, for any partition D: $SUM_{CD} = SUM_{AD} + SUM_{BD}$.

Therefore, overall the run time is $\mathcal{O}(m^2 \log m)$. □

4.1.2 Assigning the experts

Once the topic categories are identified, we assign users in E_q to these categories. CTE assigns a user $u \in E_q$ based on T_u (Algorithm 3): it assigns u to any category containing at least one topic in T_u. Note that adhering to this approach, a user u can be a member of several partitions expressing u's diversified expertise on various high-level topics.

5. EXPERIMENTS

We evaluate the proposed algorithms IAT and CTE on a dataset containing about 4.5 million lists (that is all lists available in Twitter when we collected the data). Each list l_i is associated with a topic t_i (hence 4.5 million topics)[1] For each user u in a list l_i, the corresponding topic t_i is considered as a topic of expertise for u (i.e., $t_i \in T_u$). There are 13.5 million distinct users in these lists.

Algorithm 3: Expert Assignments

```
1 Create an empty category $\tilde{C}$ for each topical category $C$
2 foreach user $u$ in $E_q$ do
3     foreach topic category $C$ do
4         if there exist topic $t \in C$ such that $t \in T_u$ then
5             $\tilde{C} = \tilde{C} \cup \{u\}$
6 Output all categories $\tilde{C}$
```

Table 1: The Impact of pruning on the number of topics.

Query topic	number of experts	number of topics	**size**: number of topics after the 1% pruning
social+media	375809	1360060	551
canada+politics	460	19080	1490
wine+Toronto	1337	27061	938
cloud+computing	56	2769	2769
fashion+trends	1112	36263	886

We execute the algorithms on a machine with a 16 core AMD *Opteron*^{TM} 850 Processor. This machine runs CentOS 5.5 (kernel version 2.6.18-194.11.1.e15) and contains 100GB of memory. All algorithms are single-threaded and are implemented in Java.

We observe similar trends when evaluating our algorithms with different query topics. Here, we report results for the following 5 queries: (1) canada+politics, (2) cloud+computing, (3) social+media, (4) toronto+wine, and (5) fashion+trends. For each query q (e.g., social+media), we retrieve all users whose topics of expertise match each input query (e.g., all users who are expert on social and also on media). These users form the set of experts E_q for the given query q.

5.1 Identifying the analogous topics

Identifying the analogous topics for the aforementioned queries involves two steps: (1) creating the correlation graph, and (2) assigning $\mathcal{A}$ or $\mathcal{N}$ states to topics (Algorithm IAT).

Figure 2(a) shows the distribution of topics and experts for query social+media. We count how many users in E_q (for a given query q) are expert in each topic in $\bigcup_{u \in E_q} T_u$. We see a similar trend for all other queries. This figure suggests that the curve displaying the number of experts on each topic has a heavy tail. Thus, pruning the topics with very small frequency can significantly help in improving performance. The run time of identifying analogous topics for the query social+media is measured utilizing different pruning percentages and reported in Figure 2(b). Here, pruning with a percentage of α means that the topics that appear in the expertise sets of less than α% of the experts are removed; i.e., a topic t is pruned iff $\frac{|\{u \in E_q | t \in T_u\}|}{|E_q|} < \frac{\alpha}{100}$.

We see that a pruning of only $1 - 2\%$ can significantly decrease the run time. On the other hand, pruning does not have a major impact on the accuracy of the results. The

[1]The precise process we follow to make this association can be found in [2].

20	cultur	govern	culinari	clouderati	entertain

topics that are reported as analogous are very similar for all these pruning percentages (e.g., no difference exists in the top 10 topics when we prune the topics with various percentages 0.1%-10%). We observe similar behavior for all other queries. For the rest of this section, we use a pruning of 1% of the topics to improve performance. Table 1 shows the number of topics that are not pruned in this step for the given five queries. According to Table 1, the pruning step with even a very small value of 1% significantly reduces the dimensionality of the problem. Hence, the problem can be solved more efficiently. The only exception here is the query for cloud+computing. We note that this query has 56 experts. A pruning of 1% removes any topic appearing in the expertise set of less than 0.56 users; thus, no topic is removed in this case (all topics appear in the expertise set of at least 1 user).

Table 2 reports the top-20 topics for each query as identified by IAT. The analogous topics are sorted based on Equation 10. In Table 2, we observe, for example, that topics such as "busi(ness)" (topics are presented stemmed), "entrepreneur", "journalist", "seo", "internet market(ing)", and "communic(ation)" are analogous to the query social+media.

The utility of this information is evident: instead of focusing on topics such as social+media for advertising campaigns (which due to their popularity could involve a high monetary premium), one can focus on peripheral topics, not as popular, but still be able to target an audience close to that of the original query.

Running IAT takes about 0.1 seconds on average for queries evaluated. Note that the majority of the run time to identify analogous topics is taken by the first step. The total run time is bound by the time required to calculate the correlation between the topics.

5.2 Categorizing experts and topics

The experts and topics categorization is done in two steps: (1) creating the correlation graph, and (2) executing CTE. As Figure 2(c) shows pruning significantly reduces the run time here as well for query social+media. We report the results when a pruning percentage of 1% is utilized. Similar behavior is observed for the other cases. We define the *size* of a query as the number of topics in $\bigcup_{u \in E_q} T_u$ after pruning takes place. Figure 2(d) reports the run time of CTE versus the size for different queries. On average, CTE takes less than 1 minute to run, making CTE practical for most real settings. As Theorem 5 suggests, the run time of CTE increases polynomially when the size increases.

We have evaluated the CTE algorithm for many queries and observed similar trends in results of all experiments. In what follows, due to space constraints, we present results using the query social+media. We stress however that these results are typical and consistent across a wide range of queries we experimented with. Thus, the specific query social+media is representative of the results obtained with algorithm CTE. Table 3 presents the categories identified by CTE for social+media. In each case, we insert an explanation for the set of topics in each category (in bold). It is evident that the contents of each category are highly related; i.e. from that point of view the results do make sense.

Evaluating the output of CTE qualitatively is challenging. To assess the utility of the results of CTE, we need to compare it with other applicable approaches and most importantly obtain confidence that the categories identified are indeed the correct ones. In the absence of ground truth to objectively compare the CTE approach with other applicable approaches (such as clustering), we resort to develop a base reference set that is manually constructed and compare our results against the base set. Running the CTE algorithm on multiple manually created base sets leads to highly consistent results.

To create these base sets, we choose several topics, categorize each topic into subsets pre-selected by us, and manually annotate each set with a descriptive name. Hereafter, we call these new datasets, the *manually annotated datasets*. These manually annotated datasets, present a "ground truth" in which we know (or expect) a preset number of categories to appear. The goal is to categorize topics and users in the manually annotated datasets utilizing different algorithms (without taking the manual annotations into account) and

Figure 2: Dataset distribution and run time analysis

Table 3: Topic categories for the query "social+media". Rows represent categories including a description followed by the topics in each category.

Tourism in North America (calgari, ottawa, vancouver, toronto, chicago, san fransisco, seattle; hotel, tourism, travel, beer, wine, restaurant, food, ...)
Australia (melbourn, sydney, australia, aussi)
UK (manchester, europe, uk, london)
Sports (tennis, golf, hockey, baseball, nfl, sport, football)
Health (mental heath, health well, pharmacy, healthcare, doctor, medic, psychology, ...)
Education (edu, edtech, learn, university, science, research, academy, ...)
Investments (invest, economia, economy, financ, realest, realtor, real estat)
South by South "SXSW" festivals (sxsw, west texas, austin, houston, dallas)
Law (legal, law, lawyer)
Twibes: groups of people with common interests (twibe socialnetwork, twibe journal, twibe blog, twibe writer, twibe travel, twibe photographi, twibe webdesign, twibe internetmarket, twibe brand, twibe socialmedia, twibe advertis, twibe entrepreneur, ...)

compare how close the results are to the manual annotations. We compare CTE with the baseline clustering algorithm k-means (denoted by kmeans in Figure 3) and 3 baseline co-clustering algorithms Euclidean distance (denoted by cocluster Euclidean), Information theoretic (denoted by cocluster IT), and minimum sum-squared residue co-clustering (denoted by cocluster MSR) [3,6,7]. The following categories form one sample manually annotated dataset:
(1) A category S_1 including topics {physics, math, chemistry}. We call this category, SCIENCE.
(2) A category S_2 including topics {democrats, republican, politics}. We call this category, POLITICS.
(3) A category S_3 including topics {soccer, football, fifa}. We call this category, SPORTS.
(4) A category S_4 including topics {google, tablet, android}. We call this category, TECHNOLOGY.
We create a dataset $\mathcal{D}$. The set of topics in $\mathcal{D}$ is $S =$ {physics, math, chemistry, democrats, republican, politics, soccer, football, fifa, google, tablet, android}. Users in $\mathcal{D}$ are all users who are expert in at least one topic in S ($U' = \{u \in U | T_u \cap S \neq \emptyset\}$ where U denotes the set of all users in the Twitter dataset). For each user $u \in U'$, $T_u \cap S$ is the set of all topics (among topics in $\mathcal{D}$) that u is an expert on. We compare the results of CTE and the baseline algorithms when deployed to categorize users and topics in $\mathcal{D}$.

The optimal categorization of $\mathcal{D}$ is achieved when (1) the topics in S are categorized into 4 categories S_1, S_2, S_3, and S_4 (in accordance with the way the data set was constructed); and (2) the users in U' are categorized into 4 categories of {users who are expert on a topic in S_1}, $\cdots$, {users who are expert on a topic in S_4}.

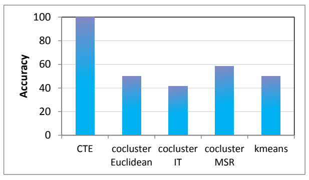
Although algorithm CTE does not need a number of categories as input, the baseline clustering techniques do require the number of clusters (categories). Thus, we provide them with the optimal number 4 providing them with an advantage. Algorithm CTE identifies the optimal number of categories without receiving it as an input.

To calculate the accuracy of an algorithm, we proceed as follows. Assume algorithm X outputs topic categories $C_1, C_2, \cdots, C_r$ and user categories $D_1, D_2, \cdots, D_s$. We utilize four annotations SCIENCE, POLITICS, SPORTS, and TECHNOLOGY to label each category produced by X. A category C_i (D_i) is labeled by the annotation having the maximum number of entities in that category. For example, consider a topic category $C_1 =$ {physics, soccer, math}. This category includes two topics in SCIENCE, one topic in SPORTS, and no topic in POLITICS or TECHNOLOGY. Thus, we label the category C_1 as SCIENCE. Moreover, assume $D_1 = \{u_1, u_2, u_3, u_4\}$, where $T_{u_1} =$ {soccer, math}, $T_{u_2} =$ {soccer}, $T_{u_3} =$ {math, democrats}, and $T_{u_4} =$ {chemistry, republican}. We can observe that 3 users in D_1 are experts on SCIENCE, 2 users on SPORTS, and 2 users on POLITICS. Therefore, we label the category D_1 as SCIENCE.

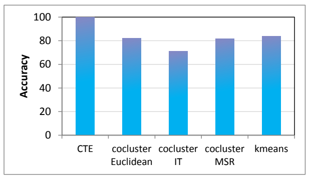
The topic categorization accuracy (user categorization accuracy) of an algorithm is the percentage of the topics (users) that are labeled correctly. Note that in the previous example, one topic is labeled inaccurately in C_1 (the topic soccer is labeled as SCIENCE) and one user is labeled inaccurately in D_1 (u_2 is labeled as SCIENCE without having any expertise on physics, math, or chemistry). Figure 3(a) reports the accuracy for topic categories and Figure 3(b) shows the accuracy for user categories for all algorithms. Figure 3 demonstrates the superiority of CTE when compared with baseline clustering algorithms.

6. RELATED WORKS

Twitter lists are recently used to address a few questions such as identifying users' topics of expertise [2,16] and separating elite users (e.g., celebrities) from ordinary users [18]. The problem of identifying a set of topics that can be utilized as a substitute for an expensive topic is studied for the case that target sets of topics are given and the cost for each topic is known [9]. In many real settings we don't have ac-



(a) Topic categories



(b) User categories

Figure 3: Comparison between the accuracy of different clustering algorithms

cess to this information. This paper focuses on the problem when the target sets and costs are unknown.

Automatons are utilized in several problems such as identifying bursts of activity in time-series data [13], spatial datasets [14], and subgraphs of social networks' graphs [8]. Perhaps the most similar work to our IAT algorithm is the DIBA algorithm [8] that is proposed to identify the bursty subgraphs of users in a social network when the information burst happens as a result of an external activity (such as an earthquake). We note that there are major differences between our IAT and DIBA algorithms: (1) DIBA is mainly designed for unweighted graphs; (2) DIBA does not consider negative edges. In fact, the optimization problem (Problem 2) in presence of negative edges is NP-hard (Theorem 3) while if all weights are non-negative, the problem would become equivalent to min-cut and can be solved in polynomial time [8]; (3) IAT addresses Problem 2 by locating the optimal cycle-free subgraph, while DIBA utilizes a heuristic approach that randomly orders graph nodes and attempts to find the best label for each node in this order; this approach does not identify the optimal subgraph and may ignore considering several important (costly) edges.

The traditional clustering algorithms can be categorized to partitioning methods (e.g., k-means), hierarchical methods (top-down, bottom-up), Density-based (e.g., DBSCAN), model-based (EM), link-based, bi-clustering, and graph partitioning (e.g., finding cliques or quasi-cliques in the graph, and correlation clustering). These algorithms also suffer from several disadvantages in the case of our problem. To the best of our knowledge none of these clustering algorithms provide all of the four desirable properties (introduced in Section 4.1); hence they are not applicable to categorize experts. For completeness, we compared our proposed algorithm with some of these algorithms in Section 5.

7. CONCLUSION AND FUTURE WORKS

In this paper we introduce two problems. The first problem is to identify topics (called analogous) that have (approximately) the same audience on a micro-blogging platforms as a query topic. The idea is that by bidding on an analogous topic instead of the original query topic, we will reach (approximately) the same audience while spending less budget on advertising. This is inspired by the social media advertising platforms. The second problem is to understand the diversified expertise of the experts on the given query topic and categorize these experts. We evaluate the techniques proposed for both problems on a large dataset from Twitter attesting their efficiency and accuracy.

An important direction for future work is to study the problems when the bids on each topic is known. This extension can assist advertisers to maximize their revenue while minimizing the advertising cost.

ABSTRACT

Recent advances in crowdsourcing technologies enable computationally challenging tasks (e.g., sentiment analysis and entity resolution) to be performed by Internet workers, driven mainly by monetary incentives. A fundamental question is: how should workers be selected, so that the tasks in hand can be accomplished successfully and economically? In this paper, we study the *Jury Selection Problem* (JSP): Given a monetary budget, and a set of decision-making tasks (e.g., "Is Bill Gates still the CEO of Microsoft now?"), return the set of workers (called *jury*), such that their answers yield the highest "Jury Quality" (or JQ). Existing JSP solutions make use of the *Majority Voting* (MV) strategy, which uses the answer chosen by the largest number of workers. We show that MV does not yield the best solution for JSP. We further prove that among all voting strategies (including deterministic and randomized strategies), *Bayesian Voting* (BV) can optimally solve JSP. We then examine how to solve JSP based on BV. This is technically challenging, since computing the JQ with BV is NP-hard. We solve this problem by proposing an approximate algorithm that is computationally efficient. Our approximate JQ computation algorithm is also highly accurate, and its error is proved to be bounded within 1%. We extend our solution by considering the task owner's "belief" (or *prior*) on the answers of the tasks. Experiments on synthetic and real datasets show that our new approach is consistently better than the best JSP solution known.

1. INTRODUCTION

Due to advances in crowdsourcing technologies, computationally challenging tasks (e.g., sentiment analysis, entity resolution, document translation, etc.) can now be easily performed by human workers on the Internet. As reported by the Amazon Mechanical Turk in August 2012, over 500,000 workers from 190 countries worked on human intelligence tasks (HITs). The large number of workers and HITs have motivated researchers to develop solutions to streamline the crowdsourcing process [6,7,14,25,27,31,43,44].

In general, crowdsourcing a set of tasks involves the following steps: (1) distributing tasks to workers; (2) collecting the workers' answers; (3) deciding final result; and (4) rewarding the workers.

An important question is: how should workers be chosen, so that the tasks in hand can be completed with high quality, while minimizing the monetary budget available? A related question, called the *Jury Selection Problem* (or JSP), has been recently proposed by Cao et al. [7]. Similar to the concept from law courts, a *jury*, or *jury set* denotes a subset of workers chosen from the available worker pool. Given a monetary budget and a task, the goal of JSP is to find the jury with the highest expected performance within the budget constraint. The kind of tasks studied in [7] is called the *decision-making task*: a question that requires an answer of either *yes* or *no* (e.g., "Is Bill Gates still the CEO of Microsoft now?") and has a definitive ground truth. Decision-making tasks [7,39,41,44] are commonly used in crowdsourcing systems because of their conceptual simplicity. The authors of [7] were the first to propose a system to address JSP for this kind of tasks.

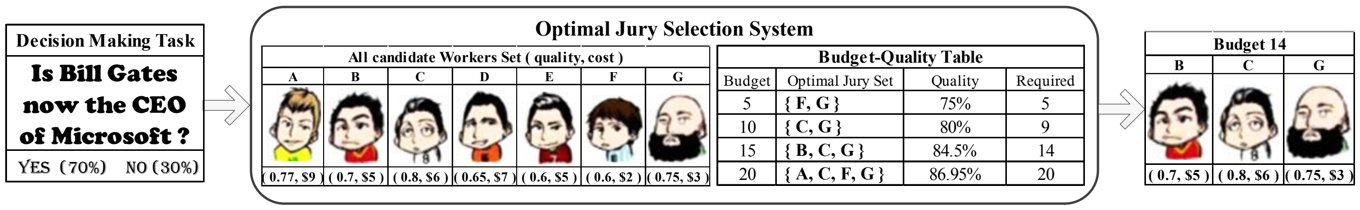
In this paper, we go beyond [7] and perform a comprehensive investigation of this problem. Particularly, we ask the following questions: (1) Is the solution in [7] optimal? (2) If not, what is an optimal solution for JSP? To understand these issues, let us first illustrate how [7] solves JSP.

Figure 1 shows a decision-making task, to be answered by some of the seven workers labeled from A to G where each worker is associated with a *quality* and a *cost*. The *quality* ranges from 0 to 1, indicating the probability that the worker correctly answers a question. This probability can be estimated by using her background information (e.g., her performance in other tasks) [7,25,37]. The *cost* is the amount of monetary reward the worker can get upon finishing a task. In this example, A has a quality of 0.77 and a cost of 9 units. For a jury, the *jury cost* is defined as the sum of workers' costs in the jury and the *jury quality* (or JQ) is defined as the probability that the result returned by aggregating the jury answers is correct. Given a budget of B units, a feasible jury is a jury whose *jury cost* does not exceed B. For example, if $B = \$20$, then $\{B, E, F\}$ is a feasible jury, since its *jury cost*, or $\$5 + \$5 + \$2 = \$12$, is not larger than \$20.

To solve JSP, a naive solution is to compute the JQ for every feasible jury, and return the one with the highest JQ. [7] studies how to compute JQ for a jury where the jury's returned result is decided by *Majority Voting* (MV). In short, MV returns the result as the one corresponding to the most workers. In the following, we consider each worker's answer as a "vote" for either "yes" or "no". Let us consider $\{B, E, F\}$ again, the probability that these workers gives a correct result according to MV is $0.7 \cdot 0.6 \cdot 0.6 + 0.7 \cdot 0.6 \cdot (1 - 0.6) + 0.7 \cdot (1 - 0.6) \cdot 0.6 + (1 - 0.7) \cdot 0.6 \cdot 0.6 = 69.6\%$. Moreover, since $\{A, C, G\}$ yields the highest JQ among all the feasible juries, it is considered to be the best solution by [7].

As illustrated above, MV is used to solve JSP in [7]. In addition to MV, researchers have proposed a variety of *voting strategies*,

10.5441/002/edbt.2015.18



Budget-Quality Table

Budget	Optimal Jury Set	Quality	Required
5	**{ F, G }**	75%	5
10	**{ C, G }**	80%	9
15	**{ B, C, G }**	84.5%	14
20	**{ A, C, F, G }**	86.95%	20

Figure 1: Optimal Jury Selection System.

such as Bayesian Voting (BV) [25], Randomized Majority Voting [20], and Random Ballot Voting [33]. Like MV, these voting strategies decide the final result of a decision-making task based on the workers' votes. For example, BV computes the posterior probability of answers according to Bayes' Theorem [3], based on the workers' votes, and returns the answer having the largest posterior probability.

In this paper, we investigate an interesting problem: is it possible to find the optimal voting strategy for JSP among all voting strategies? One simple answer to this question is to consider all voting strategies. However, as listed in Table 2, the number of existing strategies is very large. Moreover, multiple new strategies may emerge in the future. We address this question by first studying the criteria of a strategy that produce an optimal solution for JSP (i.e., given a jury, the JQ of the strategy is the highest among all the possible voting strategies). This is done by observing that voting strategies can be classified into two major categories: *deterministic* and *randomized*. A deterministic strategy aggregates workers' answers without any degree of randomness; MV is a typical example of this class. For a randomized strategy, each answer is returned with some probability. Using this classification, we present the criteria required for a voting strategy that leads to the optimal solution for JSP. We discover that BV satisfies the requirements of an optimal strategy. In other words, BV is the optimal voting strategy with respect to JQ, and will consistently produce better quality juries than the other strategies.

How to solve JSP with BV then? A straightforward solution is to enumerate all feasible juries, and find the one with the largest value of JQ. However, this approach suffers from two major problems:

1. Computing the JQ of a jury for BV requires enumerating an exponentially large number of workers' answers. In fact, we show that this problem is NP-hard;
2. The number of feasible juries is exponentially large.

To solve Problem 1, we develop a polynomial-time-based approximation algorithm, which enables a large number of candidate answers to be pruned, without a significant loss of accuracy. We further develop a theoretical error bound of this algorithm. Particularly, our approximate JQ computation algorithm is proved to yield an error of not more than 1%. To tackle Problem 2, we leverage a successful heuristic, the simulated annealing heuristic, by designing local neighborhood search functions. To evaluate our solutions, we have performed extensive evaluation on real and synthetic crowdsourced data. Our experimental results show that our algorithms effectively and efficiently solve JSP. The quality of our solution is also consistently better than that of [7].

We also study how to allow the provider of the tasks to place her confidence information (called *prior*) on the answers of the task. She may associate a "belief score" on the answers to the tasks, before the crowdsourcing process starts. For instance, in Figure 1, if she is more confident that Bill Gates is still the CEO of Microsoft, she can assign 70% to *yes*, and 30% to *no*. Intuitively, we prove that under BV, the effect of prior is just the same as regarding the task provider as another worker, having the same quality values as the prior.

Figure 1 illustrates our crowdsourcing system, which we called the "Optimal Jury Selection System". In this system, the task provider published a decision-making task. Then, based on the the workers' information (i.e., their individual quality and cost), a "budget-quality table" is generated. In this table, each row contains a budget, the computed optimal jury, its estimated jury quality and the required budget for the jury. Based on this table, the task provider can conveniently decide the best budget-quality combination. For example, she may deem that increasing the budget from 15 units to 20 units is not worthwhile, since the quality increases only by around 2.5%. In this example, the task provider selects the jury set $\{B, C, G\}$ that is the best under a budget of 15 units. This chosen jury set would cost her only 14 units.

Recall that [7] focuses on addressing JSP under MV on decision-making tasks and we address the optimality of JSP on decision-making tasks by considering all voting strategies, where each worker's quality is modeled as a single parameter. In reality, multiple choice tasks [25,34,42] are also commonly used in crowdsourcing and several works [1,34,36] model each worker as a confusion matrix rather than a single quality score. We also briefly discuss here the optimality of JSP for other task types and worker models, and how our solutions can be extended to these other variants.

The rest of this paper is arranged as follows. We describe the data model and the problem definition in Section 2. In Section 3, we examine the requirements of an optimal voting strategy for JSP, and show that BV satisfies these criteria. We present an efficient algorithm to compute JQ of a jury set in Section 4 and develop fast solutions to solve JSP in Section 5. In Section 6, we present our experimental results. We discuss how our solutions can be extended for other task types and worker models in Section 7. In Section 8, we review the related works and Section 9 concludes the paper.

2. DATA MODEL & PROBLEM DEFINITION

We now describe our data model in Section 2.1 and define the jury selection problem in Section 2.2.

2.1 Data Model

In this paper, we focus on the *decision-making tasks* where each task has two possible answers (either *yes* or *no*). We use 1 and 0 to denote *yes* and *no*, respectively. We assume that each task has a latent true answer (or ground truth) $\mathbf{t} \in \{0, 1\}$, which is unknown in advance. The task provider usually assigns a *prior* on the task, which describes her prior knowledge in the probability distribution of the task's true answer. We denote the prior by α where $\Pr(\mathbf{t} = 0) = \alpha$, and $\Pr(\mathbf{t} = 1) = 1-\alpha$. If the task provider has no prior knowledge for the task, then we assume $\alpha = 0.5$.

A *jury* (or *jury set*), denoted by J, is a collection of n workers drawn from a set of N candidate workers $W = \{j_1, j_2, \ldots, j_N\}$, i.e., $J \subseteq W$, $|J| = n$. Without loss of generality, let $J =$

$\{j_1, j_2, \ldots, j_n\}$. In order to infer the ground truth ($\mathbf{t}$), we leverage the collective intelligence of a jury, i.e, we ask each worker to give a vote for the task. We use V, a *voting*, to denote the set of votes (answers) given by a jury J, and so $V = \{v_1, v_2, \ldots, v_n\}$ where $v_i \in \{0, 1\}$ is the vote given by j_i. We assume the independence of each worker's vote, an assumption also used in [7,18,25,34].

We follow the worker model in previous works [7,25,44], where each worker j_i is associated with a quality $q_i \in [0, 1]$ and a cost c_i. The quality q_i indicates the probability that the worker conducts a correct vote, i.e., $q_i = \Pr(v_i = \mathbf{t})$, and the cost c_i represents the money (or incentive) required for j_i to give a vote. A few works [7,25,37] have recently addressed how to derive the quality and the cost of a worker by leveraging the backgrounds and answering history of individuals. Thus, similar to [7], we assume that they are known in advance.

We remark that the optimality of JSP and our solutions can be extended to address other task types and worker models used in [1,25,34,34,36,42]. We will briefly discuss these extensions in Section 7.

2.2 Problem Definition

Let B be the budget of a task provider, i.e., a maximum of B cost units can be given to a jury to collect their votes. Our goal is to solve the *Jury Selection Problem* (denoted by JSP) which selects a jury J under the budget constraint ($\sum_{j_i \in J} c_i \leq B$) such that the jury's collective intelligence is maximized.

The collective intelligence of a jury is closely related to the *Voting Strategy*, denoted by S, which estimates the true answer of the task based on the prior, the jury and their votes. We say the estimated true answer is the *result* of the voting strategy. A detailed discussion about the voting strategy is given in Section 3.1.

In order to quantify the jury's collective intelligence, we define the *Jury Quality* (or *JQ* in short) which essentially measures the probability that the result of the voting strategy is correct. The score of JQ is given by function $JQ(J, S, \alpha)$. We will give a precise definition for JQ in Section 3.2.

Let Θ denote the set of all voting strategies and $\mathcal{C}$ denote the set of all feasible juries (i.e., $\mathcal{C} = \{J \mid J \subseteq W \wedge \sum_{j_i \in J} c_i \leq B\}$). The aim of JSP is to select the optimal jury J^* such that

$$\textbf{given} \quad \alpha \text{ and } q_i, c_i \text{ (for } i = 1, 2, \ldots, N) \tag{1}$$

$$J^* = \arg\max_{J \in \mathcal{C}} \max_{S \in \Theta} JQ(J, S, \alpha) \tag{2}$$

Note that existing work [7] only focuses on majority voting strategy (MV) and solves $\arg\max_{J \in \mathcal{C}} JQ(J, MV, 0.5)$, which, as we shall prove later, is sub-optimal for JSP.

In the rest of the paper, we first discuss how to derive the optimal voting strategy S^* such that $JQ(J, S^*, \alpha) = \max_{S \in \Theta} JQ(J, S, \alpha)$ (Section 3). We then talk about the computation of $JQ(J, S^*, \alpha)$ (Section 4) and finally address of problem of finding J^* (Section 5).

Table 1 summarizes the symbols used in this paper.

3. OPTIMAL VOTING STRATEGY

In this section, we present a detailed description for the voting strategy in Section 3.1. We then formally define JQ in Section 3.2. Finally, we give an optimal voting strategy with respect to JQ in Section 3.3.

3.1 Voting Strategies

As mentioned, a *voting strategy* S gives an estimation of the true answer $\mathbf{t}$ based on the prior α, the jury J and their votes V. Thus, we model a voting strategy as a function $S(V, J, \alpha)$, whose result is an estimation of $\mathbf{t}$. Based on whether the result is given with degree of randomness, we can classify the voting strategies into two categories: *deterministic voting strategy* and *randomized voting strategy*.

Table 1: Table of Symbols

Symbol	Description
$\mathbf{t}$	the ground truth for a task, and $\mathbf{t} \in \{0, 1\}$
α	prior given by the task provider, and $\alpha = \Pr(\mathbf{t} = 0)$
W	a set of all candidate workers $W = \{j_1, j_2, \ldots, j_N\}$
J	a jury, $J \subseteq W$ and $\lvert J \rvert = n$, $J = \{j_1, j_2, \ldots, j_n\}$
V	a voting given by J, and $V = \{v_1, v_2, \ldots, v_n\}$
q_i	the quality of worker j_i and $q_i \in [0, 1]$
c_i	the cost of worker j_i
B	the budget provided by the task provider
Θ	a set containing all voting strategies
$\mathcal{C}$	the set of all possible juries within budget constraint

DEFINITION 1. *A deterministic voting strategy $S(V, J, \alpha)$ returns the result as 0 or 1 without any degree of randomness.*

DEFINITION 2. *A randomized voting strategy $S(V, J, \alpha)$ returns the result as 0 with probability p and 1 with probability $1 - p$.*

EXAMPLE 1. *The majority voting strategy (or MV) is a typical deterministic voting strategy, and it gives result as* 0 *if more than half of workers vote for* 0 *(i.e., $\sum_{i=1}^{n} (1 - v_i) \geq \frac{n+1}{2}$); otherwise, the result is* 1.

Its randomized counterpart is called randomized majority voting strategy (or RMV), which returns the result with probability proportional to the number of votes. That is, RMV returns 0 *with probability $p = \frac{1}{n} \sum_{i=1}^{n} (1 - v_i)$, and* 1 *with probability $1 - p$.*

Note that randomized strategies are often introduced to improve the error bound for worst-case analysis [23]. And thus, they are widely used when the worst-case performance is the main concern.

Table 2: Classification of Voting Strategies

Deterministic Voting Strategies	Randomized Voting Strategies
Majority Voting (MV) [7]	Randomized Majority Voting (RMV) [20]
Half Voting [28]	Random Ballot Voting [33]
Bayesian Voting [25]	Triadic Consensus [2]
Weighted MV [23]	Randomized Weighted MV [23]
...	...

Table 2 shows a few voting strategies, which are introduced in previous works, and their corresponding category.

3.2 Jury Quality

In order to measure the goodness of a voting strategy S for a jury J, we introduce a metric called *Jury Quality* (or *JQ* in short). We model JQ by a function $JQ(J, S, \alpha)$ which gives the quality score as the probability of drawing a correct result under the voting strategy, i.e.,

$$JQ(J, S, \alpha) = \Pr(S(\mathbf{V}, J, \alpha) = \mathbf{t}) \tag{3}$$

where $\mathbf{V} \in \{0, 1\}^n$ and $\mathbf{t} \in \{0, 1\}$ are two random variables corresponding to the unknown jury's voting, and the task's latent true answer. For notational convenience, we omit J and α in S when their values are understood and simply write $S(\mathbf{V})$ instead of $S(\mathbf{V}, J, \alpha)$.

Let $\mathbb{1}_{\{st\}}$ be the indicator function, which returns 1 if the statement st is true, and 0 otherwise. Let Ω be the domain of $\mathbf{V}$, i.e,

$\Omega = \{0,1\}^n$. $JQ(J, S, \alpha)$ can be rewritten as follows.

$$\begin{aligned} JQ(J,S,\alpha) &= 1 \cdot \Pr(S(\mathbf{V}) = \mathbf{t}) + 0 \cdot \Pr(S(\mathbf{V}) \neq \mathbf{t}) \\ &= \mathbb{E}[\mathbb{1}_{\{S(\mathbf{V})=\mathbf{t}\}}] \\ &= \sum_{t \in \{0,1\}} \sum_{V \in \Omega} \Pr(\mathbf{V} = V, \mathbf{t} = t) \cdot \mathbb{E}[\mathbb{1}_{\{S(V)=t\}}] \end{aligned}$$

We now give a precise definition for JQ as below.

DEFINITION 3 (JURY QUALITY). *Given a jury J and the prior α, the Jury Quality (or JQ) for a voting strategy S, denoted by $JQ(J, S, \alpha)$, is defined as*

$$\begin{aligned} &\alpha \cdot \sum\nolimits_{V \in \Omega} \Pr(\mathbf{V} = V \mid \mathbf{t} = 0) \cdot \mathbb{E}[\mathbb{1}_{\{S(V)=0\}}] \\ &+ (1-\alpha) \cdot \sum\nolimits_{V \in \Omega} \Pr(\mathbf{V} = V \mid \mathbf{t} = 1) \cdot \mathbb{E}[\mathbb{1}_{\{S(V)=1\}}]. \end{aligned} \tag{4}$$

For notational convenience, we write $\Pr(V|\mathbf{t} = 0)$ instead of $\Pr(\mathbf{V} = V|\mathbf{t} = 0)$, and $\Pr(V|\mathbf{t} = 1)$ instead of $\Pr(\mathbf{V} = V|\mathbf{t} = 1)$. Next, we give two marks in computing JQ.

1. Since workers give votes independently, we have

$$\begin{aligned} \Pr(V \mid \mathbf{t} = 0) &= \prod\nolimits_{i=1}^{n} q_i^{(1-v_i)} \cdot (1-q_i)^{v_i} \\ \Pr(V \mid \mathbf{t} = 1) &= \prod\nolimits_{i=1}^{n} q_i^{v_i} \cdot (1-q_i)^{(1-v_i)} \end{aligned}$$

2. $\mathbb{E}[\mathbb{1}_{\{S(V)=0\}}]$ and $\mathbb{E}[\mathbb{1}_{\{S(V)=1\}}]$ are either 0 or 1 if S is a deterministic voting strategy; or value of p and $1 - p$ if S is a randomized voting strategy (refer to Definition 2).

We next give an example to illustrate the computation of JQ.

EXAMPLE 2. *Suppose $\alpha = 0.5$ and there are 3 workers in J with workers' qualities as $0.9, 0.6, 0.6$ respectively. To compute JQ for MV, we enumerate all possible combinations of V $(\in \{0,1\}^3)$ and t $(\in \{0,1\})$, and show the results in Figure 2. The 3rd column in each table represents the probability that a specific combination (V and t) exists. The 4th column shows the result of MV for each V. The symbol $\surd$ indicates whether MV's result is correct or not (according to the value of t). And thus, $JQ(J, MV, \alpha)$ equals to the summation of probabilities where symbol $\surd$ occurs. Take $V = \{1,0,0\}$ and $t = 0$ as an example. First, $\Pr(\mathbf{V} = V, \mathbf{t} = 0) = 0.018$. Since $\sum_{i=1}^{3}(1 - v_i) = 2 \geq \frac{n+1}{2} = 2$, we have $MV(V) = 0 = t$. Thus, the probability 0.018 is added to $JQ(J, MV, \alpha)$. Similarly, for $V = \{1,0,0\}$ and $t = 1$, as $MV(V) = 0 \neq t$, then $\Pr(\mathbf{V} = V, \mathbf{t} = 1) = 0.072$ will not be added to $JQ(J, MV, \alpha)$. Considering all V's and t's, the final $JQ(J, MV, \alpha) = 79.2\%$.*

3.3 Optimal Voting Strategy

In the last two sections, we present a few voting strategies and define Jury Quality to quantify the goodness of a voting strategy. Thus an interesting question is: does an optimal voting strategy S^* with respect to JQ exist? That is, given any J and α, $JQ(J, S^*, \alpha) = \max_{S \in \Theta} JQ(J, S, \alpha)$. Note that if S^* exists, we can then solve JSP without enumerating all voting strategies in Θ (refer to Equation 2).

To answer this question, let us reconsider Definition 3. Let $h(V) = \mathbb{E}[\mathbb{1}_{\{S(V)=0\}}]$. We have (i) $h(V) \in [0,1]$; and (ii) $\mathbb{E}[\mathbb{1}_{\{S(V)=1\}}] = 1 - h(V)$. Also, let $P_0(V) = \Pr(\mathbf{V} = V, \mathbf{t} = 0)$, and $P_1(V) = \Pr(\mathbf{V} = V, \mathbf{t} = 1)$. Hence, $JQ(J, S, \alpha)$ can be rewritten as

$$\begin{aligned} &\sum\nolimits_{V \in \Omega} [\, P_0(V) \cdot h(V) + P_1(V) \cdot (1 - h(V)) \,] \\ = &\sum\nolimits_{V \in \Omega} [\, h(V) \cdot (P_0(V) - P_1(V)) + P_1(V) \,] \end{aligned}$$

No.	V	P(t = 0)*P(**V** = *V* | **t** = 0)	MV: [compare] (result) [√/×]	BV: [compare] (result) [√/×]

8	{ 1,1,1 }	0.5*0.9*0.6*0.6=0.162	[0 < 2] (1) [√]	[0.008 < 0.162] (1) [√]

(b) Enumeration of all $2^3 = 8$ possible votings in Ω ($\mathbf{t} = 1$)

Figure 2: Example of JQ computation for MV and BV ($\alpha = 0.5$, and the quality of workers are $0.9, 0.6$, and 0.6)

This gives us a hint to maximize $JQ(J, S, \alpha)$ and find the optimal voting strategy S^*. Let $h^*(V) = \mathbb{E}[\mathbb{1}_{\{S^*(V)=0\}}]$. It is observed that $P_1(V)$ is constant for a given V and $h(V) \in [0,1]$ for all S's (no matter it is a deterministic one or a randomized one). Thus, to optimize $JQ(J, S, \alpha)$, it is required that

1. if $P_0(V) - P_1(V) < 0$, $h^*(V) = 0$, and so, $S^*(V) = 1$;
2. if $P_0(V) - P_1(V) \geq 0$, $h^*(V) = 1$, and so, $S^*(V) = 0$.

We summarize this observation as below.

THEOREM 1. *Given α, J, and V, the optimal voting strategy, denoted by S^*, decides the result as follows:*

1. *$S^*(V) = 1$ if $\alpha \cdot \prod_{i=1}^{n} q_i^{(1-v_i)} \cdot (1-q_i)^{v_i} <$ $(1-\alpha) \cdot \prod_{i=1}^{n} q_i^{v_i} \cdot (1-q_i)^{(1-v_i)}$; or*
2. *$S^*(V) = 0$, otherwise.*

Note that S^* is a deterministic voting strategy, and it's essentially a voting strategy based on the Bayes' Theorem [11]. The reason is as follows. According to the Bayes' Theorem, based on the observed voting V, $\Pr(\mathbf{t} = 0|\mathbf{V} = V) = P_0(V)/\Pr(\mathbf{V} = V)$, and similarly $\Pr(\mathbf{t} = 1|\mathbf{V} = V) = P_1(V)/\Pr(\mathbf{V} = V)$. Therefore, $P_0(V) - P_1(V) < 0$ indicates $\Pr(\mathbf{t} = 0|\mathbf{V} = V) < \Pr(\mathbf{t} = 1|\mathbf{V} = V)$. And so, 1 has a higher probability to be the true answer than 0. Thus, the voting strategy based on the Bayes' Theorem returns 1 as the result, which is consistent with S^* in Theorem 1. Next, we give a formal definition for Bayesian Voting (BV) and summarize the above observation in Theorem 1.

DEFINITION 4. *The voting strategy based on the Bayes' Theorem, denoted by Bayesian Voting (or BV in short), returns the result as 1, if $\Pr(\mathbf{t} = 0) \cdot \Pr(\mathbf{V} = V|\mathbf{t} = 0) < \Pr(\mathbf{t} = 1) \cdot \Pr(\mathbf{V} = V|\mathbf{t} = 0)$; or 0, otherwise.*

COROLLARY 1. *BV is optimal w.r.t. JQ, i.e., $S^* = BV$.*

Note that the BV is also used in [1,18,25]. In the rest of the paper, we use S^* and BV interchangeably. We remark that the optimality of BV is based on two assumptions: (1) the prior and workers' qualities are known in advance; (2) JQ (Definition 3) is adopted to measure the goodness of a voting strategy.

EXAMPLE 3. *Let us reconsider Figure 2 and see how $JQ(J, BV, \alpha)$ is computed. The 5th column shows results given by BV. The two numbers in bracket correspond to $P_0(V)$ and $P_1(V)$, respectively. The value in parenthesis is the estimated true answer returned by BV. We again use a symbol $\surd$ to indicate the correct voting result. Take $V = \{1, 0, 0\}$ and $t = 0$ as an example. Since $\alpha \cdot (1 - q_1) \cdot q_2 \cdot q_3 = 0.018 < (1 - \alpha) \cdot q_1 \cdot (1 - q_2) \cdot (1 - q_3) = 0.072$, we have $BV(V) = 1 \neq t$, thus 0.018 is not added into $JQ(J, BV, \alpha)$. Otherwise, for $V = \{1, 0, 0\}$ and $t = 0$, similarly we derive that 0.072 is added in $JQ(J, BV, \alpha)$. Recall Example 2, when $V = \{1, 0, 0\}$, if we consider two cases of t, then 0.072 is added into $JQ(J, BV, \alpha)$; but here we have seen in Example 2 that 0.018 is added into $JQ(J, MV, \alpha)$. By considering all V and t, we have $JQ(J, BV, \alpha) = 90\% > JQ(J, MV, \alpha) = 79.2\%$.*

Intuitively, the reason why BV outperforms other voting strategies is that BV considers the prior and worker's qualities in deriving the result of a voting V, and only the one with larger posterior probability is returned. Thus, it is more likely to return a correct answer than other strategies. For example, assume $\alpha = 0.5$ and the voting $V = \{0, 1, 1\}$ is given by workers with individual quality 0.9, 0.6 and 0.6 respectively. As $0.5 \cdot 0.9 \cdot (1 - 0.6) \cdot (1 - 0.6) > 0.5 \cdot (1 - 0.9) \cdot 0.6 \cdot 0.6$, BV returns 0 as the result. However, MV does not leverage either the prior information or workers' qualities, and so, it returns 1, which is given by two lower quality workers.

Before we move on, we would like to discuss the effect of q_i for voting strategies. Intuitively, $q_i < 0.5$ indicates that worker j_i is more likely to give an incorrect answer than a correct one. Thus, we can either simply ignore this worker in the jury selection process, or modify her answer according to the specific voting strategy. For example, for MV, we can regard vote 0 as 1 and vote 1 as 0 if the vote is given by a worker whose quality is less than 0.5; for BV, according to its definition, it can reinterpret the vote given by a worker with quality $q_i < 0.5$ as an opposite vote given by a worker with quality $1 - q_i > 0.5$.[1] Moreover, in our experiments with real human workers, we observed that their qualities were generally well above 0.5. We thus assume that $q_i \geq 0.5$ in our subsequent discussions, without loss of generality.

4. COMPUTING JURY QUALITY FOR OPTIMAL STRATEGY

In the previous section, we have proved that BV is the optimal voting strategy with respect to JQ. And thus, in order to solve JSP, we only need to figure out J^* such that $JQ(J^*, BV, \alpha)$ is maximized. An immediate question is whether $JQ(J, BV, \alpha)$ can be computed efficiently. Unfortunately, we find that computing $JQ(J, BV, \alpha)$ is NP-hard (Section 4.1). To alleviate this, we propose an efficient approximation algorithm with theoretical bounds to compute JQ for BV in this section.

4.1 NP-hardness of computing $JQ(J, BV, \alpha)$

Note that [7] has previously proposed an efficient algorithm to compute $JQ(J, MV, 0.5)$ in $\mathcal{O}(n \log n)$. However, this polynomial algorithm cannot be adapted to compute JQ for BV. The main reason is that computing JQ for BV is an NP-hard problem.

THEOREM 2. *Given α and J, computing JQ for BV, or $JQ(J, BV, \alpha)$, is NP-hard.*

The proof is non-trivial and we present the detailed proof in the technical report [15] due to space limits. The idea of the proof is that the partition problem [32] (a well-known NP-complete problem) can be reduced to the problem of computing $JQ(J, BV, 0.5)$ for some J. Hence, the computation of $JQ(J, BV, 0.5)$ is not easier than the partition problem. Moreover, computing $JQ(J, BV, 0.5)$ is not in NP (it is not a decision problem), which makes the problem of computing $JQ(J, BV, \alpha)$ for $\alpha \in [0, 1]$ NP-hard.

To avoid this hardness result, we propose an approximation algorithm. We first discuss the computation of $JQ(J, BV, 0.5)$ in Section 4.2 and 4.3, and give its approximation error bound in Section 4.4. Finally, we briefly discuss how to adapt the algorithm to $\alpha \in [0, 1]$ in Section 4.5.

$R(V) = u(V) - w(V)$	$A_0(V)$	$A_1(\overline{V})$	$A_0(V) + A_1(\overline{V})$
$R(V) > 0$	$e^{u(V)}/2$	$e^{u(V)}/2$	$e^{u(V)}$
$R(V) = 0$	$e^{u(V)}/2$	0	$e^{u(V)}/2$
$R(V) < 0$	0	0	0

Figure 3: Expressing $A_0(V) + A_1(\overline{V})$ using $R(V)$ and $u(V)$

4.2 Analysis of Computing $JQ(J, BV, 0.5)$

Let us first give some basic analysis for computing $JQ(J, BV, 0.5)$ before we introduce our approximation algorithm. To facilitate our analysis, we first define a few symbols.

- $A_0(V) = 0.5 \cdot \Pr(V \mid \mathbf{t} = 0) \cdot \mathbb{1}_{\{BV(V)=0\}}$;
- $A_1(V) = 0.5 \cdot \Pr(V \mid \mathbf{t} = 1) \cdot \mathbb{1}_{\{BV(V)=1\}}$;
- $\overline{V} = \{\bar{v}_1, \bar{v}_2, \ldots, \bar{v}_n\}$, where $\bar{v}_i = 1 - v_i$ $(1 \leq i \leq n)$.

From Figure 2 we observe that $A_0(V) = A_1(\overline{V})$. For example, $A_0(\{0, 1, 0\}) = A_1(\{1, 0, 1\}) = 0.108$ and $A_0(\{1, 0, 1\}) = A_1(\{0, 1, 0\}) = 0$. The observation motivates us to consider $A_0(V)$ and $A_1(\overline{V})$ together, and we can prove that

$$\begin{aligned} JQ(J, BV, 0.5) &= \sum\nolimits_{V \in \Omega} [\, A_0(V) + A_1(V) \,] \\ &= \sum\nolimits_{V \in \Omega} [\, A_0(V) + A_1(\overline{V}) \,], \end{aligned} \tag{5}$$

as $V \to \overline{V}$ defines a one-to-one correspondence between Ω and Ω.

We further define $u(V)$ and $w(V)$ as follows.

$$u(V) = \ln \Pr(V | \mathbf{t} = 0) = \sum\nolimits_{i=1}^{n} [\, (1 - v_i) \ln q_i + v_i \ln(1 - q_i) \,],$$

$$w(V) = \ln \Pr(V | \mathbf{t} = 1) = \sum\nolimits_{i=1}^{n} [\, v_i \ln q_i + (1 - v_i) \ln(1 - q_i) \,],$$

Let $R(V) = u(V) - w(V)$ and $\sigma(q_i) = \ln \frac{q_i}{1-q_i}$ (as $q_i \geq 0.5$, $\sigma(q_i) \geq 0$), we have

$$R(V) = \sum_{i=1}^{n} [\, (1 - 2v_i) \cdot \sigma(q_i) \,], \;\; e^{u(V)} = \prod_{i=1}^{n} q_i^{(1-v_i)} \cdot (1 - q_i)^{v_i}. \tag{6}$$

As illustrated in Figure 3, we can express $A_0(V) + A_1(\overline{V})$ based on the sign of $R(V)$ and the value of $u(V)$. And therefore,

$$JQ(J, BV, 0.5) = \sum_{V \in \Omega} [\mathbb{1}_{\{R(V)>0\}} \cdot e^{u(V)} + \mathbb{1}_{\{R(V)=0\}} \cdot \tfrac{e^{u(V)}}{2}].$$

Motivated by the above formula[2], we can apply an iterative approach which expands J with one more worker at each iteration and thus compute $JQ(J, BV, 0.5)$ in n total iterations. In the k-th iteration, we consider $V^k \in \{0, 1\}^k$. We aim to construct a map structure with $(key, prob)$ pairs, where the domain of key is

[1]Details of the reinterpretation can be found in the technical report [15].

[2]Note that the reason why $A_0(V) \neq A_1(\overline{V})$ when $u(V) = w(V)$ is that as $0.5 \cdot e^{u(V)} = 0.5 \cdot e^{w(V)}$, based on Theorem 1, $BV(V) = BV(\overline{V}) = 0$, so $A_0(V) = 0.5 \cdot e^{u(V)}$ and $A_1(\overline{V}) = 0$.

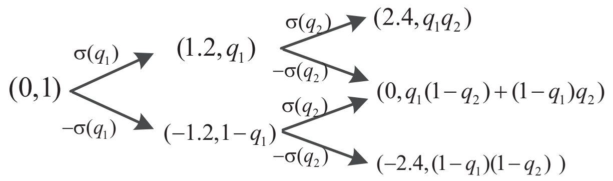

Figure 4: The iterative approach { pair $(key, prob)$ }

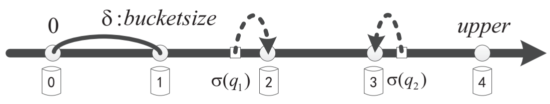

Figure 5: Principle of the bucket array.

$\{\ R(V^k)\ |\ V^k \in \{0,1\}^k\ \}$, and the corresponding value of the key, or $prob$ is

$$prob = \sum_{R(V^k)=key\ \wedge\ V^k\in\{0,1\}^k} e^{u(V^k)}\ . \tag{7}$$

Suppose in the k-th iteration, such a map structure is constructed. Then in the next iteration, we can generate a new map structure from the old map structure: for each $(key, prob)$ in the old map structure, based on the possible choices of v_{k+1} and by considering two formulas in Equation 6, we have

1. for $v_{k+1} = 0$, the new key $key + \sigma(q_{k+1})$ is generated and $prob \cdot q_{k+1}$ is added to the prob of the new key;

2. for $v_{k+1} = 1$, the new key $key - \sigma(q_{k+1})$ is generated and $prob \cdot (1 - q_{k+1})$ is added to the prob of the new key.

EXAMPLE 4. *We give an example to illustrate the above process in Figure 4, where $n = 2$ and $\sigma(q_1) = \sigma(q_2) = 1.2$. Starting from $(0, 1)$, for $v_1 = 0$ and $v_1 = 1$, it respectively creates $(\sigma(q_1) : q_1)$ and $(-\sigma(q_1) : (1 - q_1))$ in the first iteration. Then it leverages the stored $(key, prob)$ pair to generate new pairs in the second iteration by considering different v_2. Note that as $\sigma(q_1) = \sigma(q_2)$, if $(\sigma(q_1), q_1)$ takes $v_2 = 1$ and $(-\sigma(q_1), (1-q_1))$ takes $v_2 = 0$, then they go to the same $key = 0$, and their new prob, $q_1 \cdot (1 - q_2)$ and $(1 - q_1) \cdot q_2$ are added together.*

4.3 Bucket-Based Approximation Algorithm

By our intractability result for JQ we know that the domain of keys, or $\{R(V) \mid V \in \{0,1\}^n\}$ is exponential. In order to address this issue, we set a controllable parameter *numBuckets* and map $\sigma(q_i)$ to a bucket integer $b_i \in [\,0, numBuckets\,]$, where the interval between adjacent buckets, called bucketsize (denoted as δ) is the same. Suppose $numBuckets = d \cdot n$, i.e., a constant multiple of the number of jury members, then, for each iteration, the number of possible values in the key is bounded by $2dn^2 + 1$ (in the range $[-dn^2, dn^2]$) Considering all n iterations, the time complexity is bounded by $\mathcal{O}(dn^3)$, which is of polynomial order.

We detail this process in Algorithm 1. To start with, the function `GetBucketArray` assigns b_i to worker j_i based on $\sigma(q_i)$. The computation of b_i proceeds as follows. At first, we fix a range $[0, upper]$ where $upper = \max_{i\in[1,n]}\ \{\sigma(q_i)\}$. Then, we divide the range into $numBuckets$ of buckets with equal length, denoted by $\delta = \frac{upper}{numBuckets}$. Finally, each worker j_i's bucket number b_i is assigned to its closet bucket: $b_i = \left\lceil \frac{\sigma(q_i)}{\delta} - \frac{1}{2} \right\rceil$. Figure 5 illustrates an example where $numBuckets = 4$. Since $\sigma(q_1)$ is the closet to bucket number 2, so $b_1 = 2$, and similarly $b_2 = 3$.

Algorithm 1 `EstimateJQ`

```
Input:  $J = \{j_1, j_2 \cdots j_n\}$, $numBuckets$ , $n$
Output: $\widehat{JQ}$
 1: $b$ = GetBucketArray($J$, $numBuckets$, $n$);
 2: $b$ = Sort($b$); // sort in decreasing order, for pruning
 3: $J$ = Sort($J$); // sort based on worker quality, similar as above
 4: $aggregate$ = AggregateBucket($b$, $n$); // for pruning
 5: $\widehat{JQ} = 0$; // estimated JQ
 6: $SM[\,0\,] = 1$; //initialize a map structure
 7: for $i = 1$ to $n$ do
 8:     $M = map()$; //initialize an empty map structure
 9:     for $(key, prob) \in SM$ do
10:         $flag, value$ = Prune($key, prob, aggregate[i]$);
11:         if $flag$ = true then
12:             $\widehat{JQ} += value$;
13:             continue // for pruning
14:         if $key + b[i] \notin M$ then
15:             $M[\,key + b[i]\,] = 0$;
16:         $M[\,key + b[i]\,] += prob \cdot q_i$; // for $v_i = 0$
17:         if $key - b[i] \notin M$ then
18:             $M[\,key - b[i]\,] = 0$;
19:         $M[\,key - b[i]\,] += prob \cdot (1 - q_i)$; // for $v_i = 1$
20:     $SM = M$;
21: for $(key, prob) \in SM$ do
22:     if $key > 0$ then
23:         $\widehat{JQ} += prob$;
24:     if $key = 0$ then
25:         $\widehat{JQ} += 0.5 \cdot prob$;
26: return $\widehat{JQ}$;
```

Algorithm 2 `Pruning Techniques`

```
def AggregateBucket($b, n$):
    $aggregate = [\,0, 0 \cdots 0\,]$; // $n$ elements, all 0
    for $i = n$ to 1 do
        if $i = n$ then
            $aggregate[i] = b[i]$;
        else
            $aggregate[i] = aggregate[i+1] + b[i]$;
    return $aggregate$

def Prune($key, prob, number$):
    $flag$ = false;
    if $key > 0$ and $key - number > 0$ then
        $flag$ = true; $value = prob$;
    if $key < 0$ and $key + number < 0$ then
        $flag$ = true; $value = 0$;
    return $flag$, $value$;
```

After mapping each worker to a bucket b_i, we iterate over n workers (step 7-20). For a given worker j_i, based on each $(key, prob)$ pair in the stored map SM, we update key and $prob$, based on two possible values of v_i (steps 14-19)[3] in the new map M. SM will then be updated as the newly derived map M for next iteration (step 20). Finally, the $(key, value)$ pairs in SM are used in the evaluation of the Jury Quality (steps 21-25), based on the cases in Figure 3.

Pruning Techniques. We can further improve the running time of the approximation algorithm by applying some pruning techniques in Algorithm 2, in order to prune redundant computations. For example, assume $n = 5$, and the derived $b = [3, 7, 4, 3, 2]$. In the second iteration, consider the $key = 3 + 7 = 10$ ($v_1 = 0$ and

[3]Note that as we only care about the sign ($+$, 0 or $-$) of $R(V)$, and we approximate $\sigma(q_i)$ as $\delta \cdot b_i$, we can map $\sigma(q_i)$ to b_i and add/subtract the integer b_i.

$v_2 = 0$). No matter what the rest of the three votes are, the aggregated buckets cannot be negative (since $4+3+2 = 9 < 10$), so we can safely prune the search space for $key = 10$ (which takes $2^3 = 8$ computations). To further increase the efficiency, in Algorithm 2 we first sort the bucket array and J in decreasing order (step 2-3), guaranteeing that the highest bucket is considered first, and then compute the *aggregate* array via `AggregateBucket` (step 4), which makes the pruning phase (step 10-13) more efficient. The function `Prune` uses *aggregate* to decide whether to prune or not.

4.4 Approximation Error Bound

Let $\widehat{JQ}$ denote the estimated value returned by Algorithm 1, and JQ denote the real Jury Quality. We evaluate the *additive error* bound on $|JQ - \widehat{JQ}|$ and we can prove that:

$$\widehat{JQ} \le JQ \quad \text{and} \quad JQ - \widehat{JQ} < e^{\frac{n\delta}{4}} - 1, \tag{8}$$

where n is the jury size and $\delta = \frac{upper}{d \cdot n}$ is the bucketsize. Interested readers can refer to technical report [15] for the detailed proof.

We next show that the bound is very small ($< 1\%$ by setting $d \ge 200$) in real cases. First we notice that (i) $\sigma(q)$ is a strictly increasing function and (ii) $\sigma(0.99) < 5$. So let us assume $upper < 5$. We can safely make the assumption, since if not, there exists a worker of quality $q_i > 0.99$, and then $JQ \in (0.99, 1]$, as Lemma 1 will show. Thus we can just return $\widehat{JQ} = q_i > 0.99$, which makes $JQ - \widehat{JQ} < 1\%$. After dividing the interval $[0, upper]$ into $d \cdot n$ equal buckets, we have $\delta < \frac{5}{d \cdot n}$. Using this δ bound in Equation 8, we have $JQ - \widehat{JQ} < e^{\frac{5}{4 \cdot d}} - 1$. By setting $d \ge 200$, the bound is $JQ - \widehat{JQ} < 0.627\% < 1\%$.

4.5 Incorporation of Prior

In the previous section, we have assumed a prior $\alpha = 0.5$. Here, we drop this assumption and show how we can adapt our approaches to a generalized prior $\alpha \in [0, 1]$, given by the task provider. By Theorem 3, it turns out this is equivalent to computing $JQ(J', BV, 0.5)$, where J' is obtained by adding a worker (with quality α) to J:

THEOREM 3. *Given α and J, $JQ(J, BV, \alpha) = JQ(J', BV, 0.5)$, where $J' = J \cup \{j_{n+1}\}$ and $q_{n+1} = \alpha$.*

Due to lack of space, interested readers can refer to technical report [15] for the detailed proof.

Thus we can use Algorithm 1 for any prior α, by adding to the jury a pseudo-worker of quality α. Moreover, the approximation error bound proved in Section 4.4 also holds.

In summary, to compute $JQ(J, BV, \alpha)$, we have developed an approximation algorithm with time complexity $\mathcal{O}(d \cdot n^3)$, with an additive error bound within 1%, for $d \ge 200$.

5. JURY SELECTION PROBLEM (JSP)

Now we focus on addressing $J^* = \arg\max_{J \in \mathcal{C}} JQ(J, BV, \alpha)$, for $\mathcal{C}$, the set of all feasible juries (i.e., $\mathcal{C} = \{J \mid J \subseteq W \wedge \sum_{i=1}^{n} c_i \le B\}$).

Before formally addressing JSP, we turn our attention to two monotonicity properties of $JQ(J, BV, \alpha)$: with respect to varying the jury size ($|J|$), and with respect to a worker j_i's quality (q_i). These properties can help us solve JSP under certain cost constraints.

LEMMA 1 (MONOTONICITY ON JURY SIZE). *Given α and J , $JQ(J, BV, \alpha) \le JQ(J', BV, \alpha)$, where $J' = J \cup \{j_{n+1}\}$.*

LEMMA 2 (MONOTONICITY ON WORKER QUALITY). *Given α and J. Let $J' = J$ except that $q'_{i_0} \ge q_{i_0} \ge 0.5$ for some i_0, then $JQ(J', BV, \alpha) \ge JQ(J, BV, \alpha)$.*

PROOF. Due to space limits, interested reader can refer to technical report [15] about the proofs for Lemma 1 and 2. □

A direct consequence of Lemma 1 is that "the more workers, the better JQ for BV". So for the case that each worker will contribute voluntarily ($c_i = 0$ for $1 \le i \le N$) or the budget constraint satisfies on all subsets of the candidate workers W (i.e., $B \ge \sum_{i=1}^{N} c_i$), we can select all workers in W.

Lemma 2 shows that a worker with higher quality contributes not less in JQ compared with a lower quality worker. For the case that each worker has the same cost requirement c, i.e., $c_i = c_j = c$ for $i, j \in [1, N]$, we can select the top-k workers sorted by their quality in decreasing order, where $k = \min\left\{\left\lfloor \frac{B}{c} \right\rfloor, N\right\}$.

Although the above two properties can indicate us to solve JSP under certain conditions, the case for JSP with arbitrary individual cost is much more complicated as we have to consider not only the worker j_i's quality q_i, but also her cost c_i, and both may vary between different workers.

We can formally prove that JSP is NP-hard in Theorem 4. Note that JSP, in general, is NP-hard due to the fact that it cannot avoid computing $JQ(J, BV, \alpha)$ at each step, which is an NP-hard problem itself. Moreover, even if we assume the existence of a polynomial oracle for computing $JQ(J, BV, \alpha)$ (e.g., Algorithm 1), the problem still remains NP-hard, as we can reduce a n-th order Knapsack Problem [7] to it. Interested readers can refer to the technical report [15] for more details.

THEOREM 4. *Solving JSP is NP-hard.*

5.1 Heuristic Solution

To address the computational hardness issue, we use the *simulated annealing heuristic* [19], which is a stochastic local search method for discrete optimization problems. This method can escape local optima and is proved to be effective in solving a variety of computationally hard problems [5,10].

The simulated annealing heuristic mimics the cooling process of metals, which converge to a final, "frozen" state. A temperature parameter T is used and iteratively reduced until it is small enough. For a specific value of T, the heuristic performs several local neighbourhood searches. There is an objective value on each location, and let Δ denote the difference in objective value between the searched location and the original location. For each local search, the heuristic makes a decision whether to "move" to the new location or not based on T and Δ:

1. if the move will not decrease the objective value (i.e., $\Delta \ge 0$), then the move is accepted;
2. if the move will decrease the objective value (i.e., $\Delta < 0$), the move is accepted with probability $\exp(-\frac{\Delta}{T})$, i.e., by sampling from a Boltzmann distribution [21].

The reason for not immediately rejecting the move towards a worse location is that it tries to avoid getting stuck in local optima. Intuitively, when T is large, it is freer to move than at lower T. Moreover, a large Δ restricts the move as it increases the chances of finding a very bad case.

We can apply the simulated annealing heuristic to solve JSP in Algorithm 3 by assuming that each location is a jury set $J \subseteq W$ and its objective value is $JQ(J, BV, \alpha)$. What is important in simulated annealing is the design of local search. Before introducing

Algorithm 3 JSP

```
Input: $W = \{j_1, j_2, \dots, j_N\}$, $B$, $N$
Output: $\widehat{J}$
 1: $T = 1.0$; // initial temperature parameter
 2: $X = [\, x_1 = 0, x_2 = 0, \dots, x_N = 0 \,]$; // all initialized as 0

11:         $\widehat{J} = \widehat{J} \setminus \{j_a\} \cup \{j_b\}$;  $H = H \backslash \{a\} \cup \{b\}$;
12: return $X$, $M$, $\widehat{J}$, $H$
```

our design of local search, we first explain some variables to keep in Algorithm 3: H is used to store the indexes of selected workers, M is used to store their aggregated cost, and $X = [x_1, x_2, \dots, x_N]$ is used to keep the current state of each worker ($x_i = 1$ indicates that worker j_i is selected and 0 otherwise). Starting from an initial X, we iteratively decrease T (step 14) until T is small enough (step 6). In each iteration, we perform N local searches (steps 7-13), by randomly picking an index r out of the N worker indexes. Based on the randomly picked x_r, we either select the worker if adding the worker does not violate the budget B (steps 9-11), or execute Swap, which is described in Algorithm 4. The decision to swap is made based on different x_r values:

1. if $x_r = 0$, a randomly picked worker $k \in H$ is replaced with worker r if the replacement does not violate the budget constraint and the move is accepted based on Δ and T;

2. if $x_r = 1$, the algorithm performs similarly to the above case, and it replaces worker r with a randomly picked worker $k \in \{1, 2, \cdots, N\} \backslash H$ if the budget constraint still satisfies and the move is accepted as above.

While the heuristic does not have any bound on the returned jury ($\widehat{J}$) versus the optimal jury (J^*), we show in the experiments (Section 6) that it is close to the optimal by way of comparing the real and estimated JQ (i.e., $JQ(\widehat{J}, BV, \alpha)$ and $JQ(J^*, BV, \alpha)$).

6. EXPERIMENTAL EVALUATION

In this section we present the experimental evaluation of JQ and JSP, both on synthetic data and real data. For each dataset, we first evaluate the solution to JSP first, and then give detailed analysis on the computation of JQ. The algorithms were implemented in Python 2.7 and evaluated on a 16GB memory machine with Windows 7 64bit.

6.1 Synthetic Dataset

6.1.1 Setup

First, we describe our default settings for the experiments. Similar to the settings in [7], we generate each worker j_i's quality q_i and cost c_i via Gaussian distributions, i.e., $q_i \sim \mathcal{N}(\mu, \sigma^2)$ and $c_i \sim \mathcal{N}(\widehat{\mu}, \widehat{\sigma}^2)$. We also set parameters following [7], i.e., $\mu = 0.7$, $\sigma^2 = 0.05$, $\widehat{\mu} = 0.05$ and $\widehat{\sigma}^2 = 0.2$. By default, $B = 0.5$, $\alpha = 0.5$ and the number of candidate workers in W is $N = 50$. For JSP (Algorithm 3), we set $\epsilon = 10^{-8}$; for JQ computation (Algorithm 1), we set $numBuckets = 50$. To achieve statistical significance of our results, we repeat the results 1,000 times and report the average values.

6.1.2 System Comparison

We first perform the comparison of JSP with previous works, in an end-to-end system experiment. Cao et al. [7] is the only related algorithm we are aware of, which solves JSP under the MV strategy in an efficient manner. Formally, it addresses JSP as $\arg\max_{J \in \mathcal{C}} JQ(J, MV, 0.5)$. We denote their system as *MVJS* (Majority Voting Jury Selection System) and our system (Figure 1) as *OPTJS* (Optimal Jury Selection System). We compare the two systems by measuring the JQ on the returned jury sets.

The results are presented in Figure 6. We first evaluate the performance of the two systems by varying $\mu \in [0.5, 1]$ in Figure 6(a), which shows that *OPTJS* always outperforms *MVJS*, and *OPTJS* is more robust with low-quality workers. For example, when $\mu = 0.6$, the JQ of *OPTJS* leads that of *MVJS* for 5%. By fixing $\mu = 0.7$, Figure 6(b)-(d) respectively vary $B \in [0.1, 1]$, $N \in [10, 100]$, $\widehat{\sigma} \in [0.1, 1]$ and compare the performance of *MVJS* and *OPTJS*, which all show that *OPTJS* consistently performs better than *MVJS*. In Figure 6(b), *OPTJS* on average leads around 3% compared with *MVJS* for different B; in Figure 6(c), *OPTJS* is better than *MVJS*, especially when the number of workers is limited (say when $n = 10$, *OPTJS* leads *MVJS* for more than 6%); in Figure 6(d), compared with *MVJS*, *OPTJS* is more robust with the change of $\widehat{\sigma}$.

In summary, *OPTJS* always outperforms *MVJS* and, moreover, it is more robust with (1) lower-quality workers, (2) limited number of workers and (3) different cost variances.

6.1.3 Evaluating OPTJS

Next, we test the approximation error of Algorithm 3 by fixing $N = 11$ and varying $B \in [0.05, 0.5]$. Because of its NP-hardness, J^* is obtained by enumerating all feasible juries. We record the optimal $JQ(J^*, BV, 0.5)$ and the returned $JQ(\widehat{J}, BV, 0.5)$ in Figure 7(a). It shows that the two curves almost coincide with each other. As mentioned in Section 6.1.1, each point in the graph is averaged over repeated experiments. Thus, we also give statistics of the difference $JQ(J^*, BV, 0.5) - JQ(\widehat{J}, BV, 0.5)$ on all the 10,000 experiments considering different B (B changes in $[0.05, 0.5]$ with step size 0.05) in Table 3, which shows that more than 90% of them have a difference less than 0.01% and the maximum error is within 3%.

Our next experiment is to test the efficiency of Algorithm 3. We set $B = 0.5$ and vary $N \in [100, 500]$. The results are shown in Figure 7(b). We observe that the running time increases linearly with N, and it is less that 2.5 seconds even for high numbers of workers ($N = 500$). It is fairly acceptable in real situations as the JSP can be done offline.

Table 3: Counts in different error ranges

%	$[0, 0.01]$	$(0.01, 0.1]$	$(0.1, 1]$	$(1, 3]$	$(3, +\infty)$
Counts	9301	231	408	60	0

6.1.4 *JQ Computation*

We now turn our attention to the computation of JQ, which is an essential part of *OPTJS*. We denote here by n the jury size.

We first evaluate the optimality of BV with respect to JQ. Due to the fact the computing JQ in general is NP-hard, we set $n = 11$ and evaluate JQ for four different strategies: two deterministic ones (MV-Majority Voting, and BV-Bayesian Voting), and two randomized ones (RBV-Random Ballot Voting[4] and RMV-Randomized Majority Voting). We vary $\mu \in [0.5, 1]$ and illustrate the resulting JQ in Figure 8(a). It can be seen that the JQ for BV outperforms the others. Moreover, unsurprisingly, all strategies have their worst performance for $\mu = 0.5$ as the workers are purely random in that case. But when $\mu = 0.5$, BV also performs robust (with JQ 93.3%), the reason is that other strategies are sensitive to low-quality workers, while BV can wisely decides the result by leveraging the workers' qualities. Finally, the randomized version of MV, i.e., RMV, performs not better than MV for $\mu \geq 0.5$, as randomized strategies may improve the error bound in the worst case [23]. The JQ under RBV always keeps at 50% since it is purely random.

To further evaluate the performance of different strategies for different jury sizes, and for a fixed $\mu = 0.7$, we vary $n \in [1, 11]$ and plot the resulting qualities in Figure 8(b). The results show that as n increases, the JQ for the two randomized strategies stay the same and BV is the highest among all strategies. To be specific, when $n = 7$, the BV is about 10% better than MV. In summary, BV performs the best among all strategies.

Having compared the JQ between different strategies, we now focus on addressing the computation of JQ for BV, i.e., $JQ(J, BV, 0.5)$ in Figure 9. We first evaluate the effect of the quality variance σ^2 with varying mean μ in Figure 9(a). It can be seen that JQ has the highest value for a high variance when $\mu = 0.5$. It's because under a higher variance, worker qualities are more likely to deviate from the mean (0.5), and so, it's likely to have more high-quality workers.

Then we address the effectiveness of Algorithm 1 for approximating the real JQ. We first evaluate the approximation error in Figure 9(b) by varying $numBuckets \in [10, 200]$. As can be seen, the approximation error drops significantly with $numBuckets$, and is very close to 0 if we have enough buckets. In Figure 9(c) we plot the histogram of differences between the accurate JQ and the approximated JQ (or $JQ - \widehat{JQ}$) over all repeated experiments by setting $numBuckets = 50$. It is heavily skewed towards very low errors. In fact, the maximal error is within 0.01%.

Finally, we evaluate the computational savings of the pruning techniques of Algorithm 1 by varying the number of workers $n \in [100, 500]$ in Figure 9(d). The pruning technique is indeed effective, saving more than half the computational cost. Moreover, it scales very well with the number of workers. For example, when $n = 500$, the estimation of JQ runs within 2.5s without pruning technique, while finishing within 1s facilitated by the proposed pruning methods.

6.2 Real Dataset

6.2.1 *Dataset Collection*

We collected the real world data from the Amazon Mechanical Turk (AMT) platform. AMT provides APIs and allows users to batch multiple questions in Human Intelligence Tasks (HIT). Each worker is rewarded with a certain amount of money upon completing a HIT. The API also allows to set the number of assignments (denoted m) to a HIT, guaranteeing it can be answered m times by different workers. To generate the HITs, we use the public sentiment analysis dataset[5], which contains 5,152 tweets related to various companies. We randomly select 600 tweets from them, and generate a HIT for each tweet, which asks whether the sentiment of a tweet is positive or not (decision making task). The ground truth of this question is provided by the dataset. The true answers for *yes* and *no* is approximately equal, so we set the prior as $\alpha = 0.5$.

To perform experiments on AMT, we randomly batch 20 questions in a HIT and set $m = 20$ for each HIT, where each HIT is rewarded \$0.02. After all HITs are finished, we collect a dataset which contains 600 decision-making tasks, and each task is answered by 20 different workers. We give several statistics on the worker answering information. There are 128 workers in total, and each of them has answered on average $\frac{600 \times 20}{128} = 93.75$ questions. Only two workers have answered all questions and 67 workers have answered only 20 questions. We used these answers to compute every worker's quality, which is defined as the proportion of correctly answered questions by the worker in all her answered questions. The average quality for all workers is 0.71. There are 40 workers whose qualities are greater than 0.8, and about 10% whose quality is less than 0.6.

6.2.2 *JSP*

To evaluate JSP, for each question, we form the candidate workers set W by collecting all 20 workers who answered the question, i.e., having $N = |W| = 20$. We follow the settings in experiments on synthetic data except that worker qualities are computed using the real-world data. We then solve JSP for each question by varying $B \in [0.1, 1.0]$, $N \in [3, 20]$ and $\widehat{\sigma} \in [0, 1]$. We compute the average returned JQ by solving JSP for all 600 questions, which is recorded as a point in Figures 10(a)-(c), respectively. It can be seen that Figure 10(a)-(c) has a similar results pattern as Figure 6(b)-(d), i.e., experimental results on the synthetic datasets. Especially, *OPTJS* always outperforms *MVJS* in real-world scenarios.

6.2.3 *Is JQ is a good prediction?*

Finally, we try to evaluate whether JQ, defined in Definition 3, is a good way to predict the quality for BV in reality. Notice that, after workers give their votes, we can adopt BV to get the voting result, and then compare it with the true answer of the question. And thus, the goodness of BV in reality can be measured by the "accuracy", which counts the proportion of correctly answered questions according to BV.

We now test whether JQ is a good prediction of accuracy in reality. For each question, we vary the number of votes (denoted as z). For a given $z \in [0, 20]$, based on the question's answering sequence, we collect its first z votes, then
(i) for each question, knowing the first z workers who answered the question, we can compute the JQ by considering these workers' qualities. Then we take the average of JQ among all 600 questions;
(ii) by considering the first z workers' qualities who answered the question and their votes, BV can decide the result of the question. After that, the accuracy can be computed by comparing voting result and the true answer for each question.

[4]RBV randomly returns 0 or 1 with 50%.

(d) Is JQ a good prediction?

Figure 10: Real dataset evaluation

Now given a $z \in [3, 20]$, we compare the average JQ and accuracy in Figure 10(d), which shows that they are highly similar. Hence, it verifies that JQ for BV is really a good prediction of accuracy for BV in reality.

7. EXTENSIONS TO VARIOUS TASK TYPES AND WORKER MODELS

Previously we have talked about how to solve JSP under our data model. Note that we have made two assumptions: (1) it is a decision-making task with binary answer, and (2) each worker's quality is modeled as a constant. However, in reality, it is common for task provider to ask multiple-choice tasks. For example, sentiment analysis tasks [25] require workers to label the sentiment (*positive*, *neutral*, or *negative*) of each task. In addition, the worker's quality can be modeled by measuring the sensitivity and specificity of each possible answer [45], or the *confusion matrix* (CM) [18]. Specifically, a confusion matrix C is a matrix of size $\ell \times \ell$ where each element C_{jk} encodes the probability that the worker votes for k when the true answer is j.

Our proposed algorithms can be easily extended to support these variants. Due to the space limits, we only outline our basic ideas for these extensions, and interested readers are recommended to refer to our technical report [15] for more details.

We first clarify some notations for multiple-choice task. Note that for a task with ℓ possible choices, denoted as $\{0, 1, \ldots, \ell-1\}$, and there exists one unknown true answer [6] $\mathbf{t} \in \{0, 1, \ldots, \ell-1\}$. The domain of the voting from a jury J is $\mathbf{V} \in \Omega = \{0, 1, \ldots, \ell-1\}^n$. Moreover, the prior is now a vector $\vec{\alpha} = \{\alpha_0, \alpha_1, \ldots, \alpha_{\ell-1}\}$ s.t. $\sum_{j=0}^{\ell-1} \alpha_j = 1$.

Following the same solution framework, we first briefly show that BV is still the optimal voting strategy with respect to JQ under this general model, and then sketch how to extend the JQ computation. Finally the extensions for JSP is addressed.

Optimal Strategy Extension:

[6]For the case that each task can have multiple true answers, we can follow [30], which decomposes each task into ℓ decision-making tasks, and publish these ℓ tasks to workers.

To prove the optimality of BV for more general task here, we can follow the same flow as in Section 3.3. Similar to Equation 4, here $\mathbb{E}[\mathbb{1}_{\{S(\mathbf{V})=\mathbf{t}\}}]$ can be expressed as:

$$\sum\nolimits_{V\in\Omega} \sum\nolimits_{t=0}^{\ell-1} \Pr(\,\mathbf{t}=t\,)\cdot \Pr(\,V \mid \mathbf{t}=t\,)\cdot \mathbb{E}[\,\mathbb{1}_{\{S(V)=t\}}\,]. \quad (9)$$

For a given $V \in \Omega$, as

$$(\mathbb{E}[\,\mathbb{1}_{\{S(V)=0\}}\,], \mathbb{E}[\,\mathbb{1}_{\{S(V)=1\}}\,], \ldots, \mathbb{E}[\,\mathbb{1}_{\{S(V)=\ell-1\}}\,])$$

defines a discrete probability distribution, it is not hard to prove that the optimal strategy, or $S^*(V)$ is

$$S^*(V) = \underset{t'\in\{0,1,\ldots,\ell-1\}}{\arg\max}\ \alpha_{t'}\cdot \Pr(V \mid \mathbf{t}=t'), \qquad (10)$$

which corresponds to the Bayes' Theorem [3] that chooses the result as the label t^* with highest posterior probability, i.e., $t^* = \arg\max_{\,t'\in\{0,1,\ldots,\ell-1\}} \Pr(\mathbf{t}=t' \mid V)$. Thus $S^* = BV$.

Jury Quality Computation Extension:

Recall the definition of JQ in Equation 9, to facilitate our understanding, we express $\mathbb{E}[\mathbb{1}_{\{S(\mathbf{V})=\mathbf{t}\}}]$ in the following way

$$\sum\nolimits_{t'=0}^{\ell-1} \alpha_{t'}\cdot [\,\sum\nolimits_{V\in\Omega} \Pr(\,V \mid \mathbf{t}=t'\,)\cdot \mathbb{E}[\,\mathbb{1}_{\{BV(V)=t'\}}\,]\,] \quad (11)$$

This representation enables us to consider each possible true answer separately. For each $t' \in \{0,1,\ldots,\ell-1\}$, we compute

$$H(t') = \sum\nolimits_{V\in\Omega} \Pr(\,V \mid \mathbf{t}=t'\,)\cdot \mathbb{E}[\,\mathbb{1}_{\{BV(V)=t'\}}\,]$$

and then linearly combines the computed $H(t')$ with $\vec{\alpha}$ to get JQ. So the question falls to the computation of $H(t')$.

To compute $H(t')$, for a $V \in \Omega$, we have to keep track of
(1) whether $BV(V) = t'$ or not, and
(2) if $BV(V) = t'$, the value $\Pr(V \mid \mathbf{t} = t')$ should be added.
Similar to the analysis in Section 4.2, we apply an iterative approach, where in each iteration, we expand J with one more worker. We develop a map structure with $(key, prob)$ pairs to store the above two mentioned information. The key is an ℓ-tuple

$$\left(\ln\frac{\Pr(V \mid \mathbf{t}=t')\cdot\alpha_{t'}}{\Pr(V \mid \mathbf{t}=0)\cdot\alpha_0},\ \ldots\ ,\ \ln\frac{\Pr(V \mid \mathbf{t}=t')\cdot\alpha_{t'}}{\Pr(V \mid \mathbf{t}=\ell-1)\cdot\alpha_{\ell-1}} \right)$$

where the i-th element of the tuple is $\ln\frac{\Pr(V\ \mid\ \mathbf{t}=t')\cdot\alpha_{t'}}{\Pr(V\ \mid\ \mathbf{t}=i-1)\cdot\alpha_{i-1}}$. Intuitively, given a $V \in \Omega$, if $BV(V) = t'$, then $\Pr(V \mid \mathbf{t}=t')\cdot\alpha_{t'} \geq \Pr(V \mid \mathbf{t}=t)\cdot\alpha_t$ for any $t \in \{0,1,\ldots,\ell-1\}$, which means that the elements in the stored tuple are all ≥ 0. The value $prob$ corresponding to a key is the aggregated probability $\Pr(V \mid \mathbf{t}=t')$ for the same state. In the k-th iteration, the $V^k = \{0,1,\ldots,\ell-1\}^k$, for a key, we will generate ℓ new keys corresponding to different votes, and update their individual $prob$ for the next iteration. After n iterations, based on identifying the keys whose elements are all ≥ 0, we can get JQ by aggregating the corresponding $prob$s.

Since the values of elements in a tuple are unbounded, we can follow the similar idea in Section 4.3, that is to map each worker's vote to a bucket number. Note that each element in the tuple can be decomposed as the summation of individual worker's vote, thus the number of states in keys are bounded.

Jury Selection Problem Extension:

To address JSP, similarly we can prove that the monotonicity on jury size by extending Lemma 1, which means that "the more workers, the better JQ" still holds for more general case. As the worker is modeled as a confusion matrix (with size $\ell \times \ell$), the extension for Lemma 2 is non-trivial, and it stills remains an open question on what kind of confusion matrix will contribute more to the JQ. Previous works [18,34] have addressed how to rank workers (or to detect spammers in all workers) based on their associated confusion matrices, which may provide good heuristics for us.

For more general cost models where each worker requires arbitrary costs, the simulated annealing heuristic regards computing JQ as a black box, so it can be simply extended here.

8. RELATED WORKS

Crowdsourcing. Nowadays, crowdsourcing has evolved as a problem solving paradigm [6] to address computer-hard tasks. To incorporate the crowd into query processing, crowdsourced databases (e.g., CrowdDB [14], Deco [31], Qurk [27] and CDAS [25]) are built, compared with traditional database systems, they do not hold the closed-world assumption. As a novel paradigm, the power of crowdsourcing has also been leveraged in other applications. For example, in Optical Character Recognition [38], Entity Resolution [39,41], Tagging [43], Schema Matching [17,44], Web Table Understanding [12], Data Cleaning [40] and so on.

Voting Strategy. In order to aggregate the collective wisdom of a jury, given some specific voting of a task from the jury, voting strategies are widely used to return a result, which is an estimation of the ground truth for the task. For example, Majority Voting strategy [7] strictly returns the answer corresponding to higher votes, and Random Ballot Voting [33] randomly selects the returned result. Similarly other strategies [2,9,23–25,28,29] are also talked about in a great deal. Different from their works, here we give a systematic way to classify all the strategies into two categories, and try to observe the optimal strategy in all these strategies under the Jury Selection Problem. Note that different from our problem, people may evaluate strategies under different purposes. For example, [26] analyzes the optimal Bayesian manipulation strategies by assessing the expected loss in social welfare, and [11] applies Bayesian model to take a game-theoretic approach in characterizing the symmetric equilibrium of the game with juries.

Worker Model. To model a worker's quality in crowdsourcing, most existing works [7,25,28,44] define it as a constant parameter indicating the probability that the worker correctly answers a question, while other work [18] defines it as a confusion matrix, which tries to capture relations between labels in questions and is specific to choices in tasks. For the methods to derive worker's quality, a normal way is to leverage the answering history. If they are not sufficient, [25] hides golden questions (questions with known ground truth) and derive the quality based on the worker's answers for them, while other work [18] applies Expectation Maximization [8] algorithm to iteratively updates worker's quality until convergence. For micro-blog services especially in Twitter, the retweet actions are usually explored to derive the error rate for each worker [7]. In our work we define worker's quality by a constant parameter (commonly used by existing works) and assume that they are known in advance. Moreover, we also extend our method to address the confusion matrix mentioned in [18].

Online Processing. There are also some online processing systems [4,16,25] in crowdsourcing, which addresses how to assign tasks to workers and process the workers' answers. For example, [25] proposes quality-sensitive answering model and terminate assigning questions which has got confident answers; [4] proposes an entropy-like approach to define the uncertainty of each question and assigns questions with highest uncertainty; [16] proposes cost-sensitive model to address which questions are better answered by humans or machines. Different from them, we especially evaluate how to estimate the JQ before the workers are selected to answer the questions, and the quality estimation can provide statistics and guidance for the task publisher to wisely invest budget. Even though existing work [25,28] tried to estimate the quality, they assume that each worker is of the same quality.

Expert Team Formation. In social network, several works [13,22] studied the problem of expert team formation, that is, given the aggregated skill requirements for a task, how to find a team of experts with minimum cost (communication cost or individual financial requirement), such that the skill requirements are satisfied. Rather than the skill requirements in [13,22], we focus on the probability of drawing a correct answer, which requires to enumerate exponential number of possibilities and is indeed challenging. In fact we address the Jury Selection Problem, which is firstly proposed by [7]. But we find that the solution is sub-optimal in [7], which cannot leverage the known quality for workers. We formally address the optimal JSP problem in the paper. Some other works [9,35] also talk about how to wisely select sources for integration. The difference is that we assume the workers are given a multiple-label task and the worker model is known, while in their problem setting, the possible answers from different sources are not restricted, and the sources' exact real qualities are unknown in advance.

9. CONCLUSIONS

In this paper, we have studied Jury Selection Problem (JSP) for decision-making tasks, whose objective is to choose a subset of workers, such that the probability of having a correct answer (or Jury Quality, JQ) is maximized. We approach this problem from an optimality perspective. As JQ is related to voting strategy, we prove that an existing strategy, called Bayesian Voting Strategy (BV) is optimal under the JQ. Although computing JQ under BV is NP-hard, we give an efficient algorithm with theoretical guarantees. Moreover, we incorporate the task provider prior information, and we show how to extend JQ computation for different worker models and task types. Finally we evaluate JSP under BV, we prove several properties which can be used for efficient JSP computations under some constraints, and provide an approximate solution to JSP by simulated annealing heuristics.

ABSTRACT

In this paper, given a product database and a set of customer preferences, we address the problem of discovering a bounded set of r diverse products that attract the interests of different customers. This problem finds numerous applications in electronic marketplaces, e.g., for selecting the products that are placed in the home page of an online shop. Existing approaches to tackle this problem fall short because they ignore customer preferences, and instead rely solely on products' attributes. We model this problem as a diversity problem, where each product is represented by its reverse top-k result set, and seek r products that maximize their diversity value. Since the problem is NP-hard, we employ a greedy algorithm that takes as input the reverse top-k result sets of all candidate products. To further improve performance, we also design a more efficient approximate algorithm that does not require the computation of all reverse top-k sets. Our experimental evaluation demonstrates the performance of the proposed algorithms and quality of the selected diverse products.

1. INTRODUCTION

Top-k queries [17] help customers select a ranked set of k products that best match their preferences out of an overwhelmingly large collection of products. For a specific customer, her preferences are expressed by means of a top-k query, and highly ranked products in the top-k result are more attractive to the customer. Thus, from the perspective of product sellers, the visibility and the potential market of a product relates to the top-k queries for which the product is highly ranked. Towards this direction, reverse top-k queries [20] retrieve the set of user preferences for which a product appears in their top-k lists. Reverse top-k queries are very important for estimating the impact of the product on the market, as the cardinality of the result set defines an *influence score* [22] for the product, i.e., the number of customers that value a particular product.

In this paper, we study the problem of finding the r most diverse products based on the user preferences. The goal is to find a set of products that are attractive to a wide range of customers with different preferences. For instance, consider an electronic marketplace that wishes to advertise r products on its front page aiming to attract as many new customers as possible. Advertising diverse products that are attractive to different existing customers increases the probability that a new customer finds one of those products attractive. The strategy of advertising the r most influential products [22], i.e., the r products that attract the highest total number of customers, does not necessarily lead to a set of diverse products and may fail to attract many new customers, since such products may be attractive to customers with similar preferences.

User Preferences:

User	$w[1]$	$w[2]$	$w[3]$	**Top-k**
Bob	0.1	0.2	0.7	p_1
Tom	0.1	0.3	0.6	p_1
Jack	0.3	0.1	0.6	p_2
Max	0.8	0.1	0.1	p_3

Products:

Product	$p[1]$	$p[2]$	$p[3]$	**Reverse top-k**
p_1	1	2	6	Bob,Tom
p_2	2	1	6	Jack
p_3	6	5	2	Max

Table 1: Example of product database and user preferences.

Consider for example the set of user preferences and products depicted in Table 1, where maximum values in product attributes are preferable. Assume that the goal is to advertise two products for attracting new customers. Our proposed method selects the $r = 2$ most diverse products based on user preferences, which in our example is the set $\{p_1, p_3\}$. This set is more probable to attract more new customers because p_1 and p_3 satisfy more diverse preferences. For example, a customer with similar preferences to Jack is highly probable to be attracted also to p_1, even though it is not the best option for her on the market. This is because both p_1 and p_2 satisfy users that have high preference for the third dimension (expressed with a high weight $w[3]$). On the other hand, p_3 satisfies users that have totally diverse preferences compared to p_1 and p_2, namely users such as Max that prefer the first dimension.

In this paper, we introduce the problem of finding the r *most diverse* products based on user preferences. The user preferences are captured by the reverse top-k set of each product. We model this problem as a *dispersion* problem [15] using as distance function the dissimilarity of the reverse top-k sets. In this sense, the set of r objects with the maximum diversity is returned to the user. Consequently, the selected objects are appealing to many different customers with dissimilar user preferences. Different from our work, existing solutions for identifying diverse objects rely solely on product attributes and largely overlook user preferences [18]. On the other hand, approaches that identify r objects with high total number of customers [12, 22], often fail to discover truly diverse products that can be appealing to new customers with different preferences than those of the existing ones.

To summarize the contributions of this paper are:

- We study the novel problem of finding the r most diverse products based on user preferences. We model this problem as a *dispersion* problem and define an appropriate distance function that captures the dissimilarity of products based on their reverse top-k sets.
- As dispersion problems are known to be NP-hard [8], we use a greedy algorithm that retrieves r diverse products, after computing the reverse top-k sets of the products efficiently.
- To improve the performance of our algorithm, we propose an alternative algorithm that progressively computes an approximation of the reverse top-k sets of a limited set of candidate products and retrieves a set of r products of high diversity.
- We present maintenance techniques for updating the r most diverse products in the case of dynamic data in a cost-efficient way. In addition, we generalize our approach to support any set-based similarity function.
- We demonstrate the efficiency and achieved diversity of our algorithms using both synthetic and real-life data sets.

The rest of this paper is organized as follows: Section 2 reviews the related work. Section 3 provides the necessary preliminaries, while in Section 4 we formally define the r-Diversity problem. Thereafter, in Section 5, we present a greedy algorithm applied on the reverse top-k sets. In Section 6, we provide a more efficient algorithm that iteratively computes an approximation of the reverse top-k sets and refines the set of most diverse products. Section 7 addresses the case of dynamic data, while Section 8 generalizes our approach for set-based similarity functions. The experimental evaluation is presented in Section 9 and we conclude in Section 10.

2. RELATED WORK

Reverse top-k queries. Vlachou *et al.* first introduced the reverse top-k query in [20, 21]. Two versions of the reverse top-k query were presented, namely monochromatic and bichromatic. Based on the geometrical properties of the monochromatic reverse top-k query, an algorithm for the two dimensional case was proposed. For computing bichromatic reverse top-k queries, an algorithm (called *RTA*) was proposed that exploits the fact that similar queries share common results, in order to avoid evaluating the top-k queries for all user preferences. Thereafter, several papers have studied the problem of efficient reverse top-k computation. An efficient algorithm for the two-dimensional monochromatic reverse top-k that relies on a novel index was proposed in [4]. In [9], efficient evaluation of multiple top-k queries is studied, which in turn enables the computation of the reverse top-k set of a query point. The proposed method avoids evaluating the top-k queries one-by-one by grouping similar queries and evaluate them in a batch. This approach is suitable for processing many reverse top-k queries at once. An approach for processing a large number of continuous top-k queries has appeared in [27]. The proposed framework can be employed to process reverse top-k queries efficiently, however it requires to build an index over the k-th ranked objects of each query that results in high pre-processing cost. Recently, a novel branch-and-bound algorithm for reverse top-k queries has appeared in [23], where both the object data sets and the preferences set are indexed using an R-tree.

Product impact and visibility. Several papers have proposed methods that aim to quantify the impact of products in the market. DADA [11] aims to help manufactures position their products in the market, based on three types of dominance relationship analysis queries. Creating competitive products has been studied in [24]. Customer identification and product positioning has been recently studied in [2], where the attractiveness of a product is defined based on the concept of reverse skyline query. Nevertheless, in these approaches user preferences are expressed as data points that represent preferable products, whereas reverse top-k queries examine user preferences in terms of weighting vectors. Miah *et al.* [14] study a different problem, namely how to select the subset of attributes that increases the visibility of a new product. Product promotion is studied in [25, 26], where the aim is to find the most interesting regions for promotion of a product. Only a few papers have proposed methods for retrieving interesting products by using the reverse top-k queries. In [22], the influence of a product is defined as the size of its reverse top-k set. Then, an algorithm was presented to efficiently retrieve the m most influential products. Discovering k products with maximum number of customers has been studied in [12], where the number of customers is estimated as the size of the reverse top-k set. The problems studied in [12, 22] differ from the diversity problem studied in this paper. Both approaches focus on maximizing the number of existing customers and ignore the similarity of the retrieved reverse top-k sets. These approaches fail to take into account the fact that attracting new customers requires promoting products that are attractive to customers with diverse preferences. Koh *et al.* [10] consider as products packages consisting of multiple components. They study the problem of creating and selecting packages from an existing pool of components such that the number of potential customers is maximized. Similarly to the aforementioned approaches the number of potential customers is estimated using reverse top-k sets, yet they do not study the diversity of the result set.

Diversity in databases. Many approaches have been proposed for retrieving a set of diverse objects. Angel *et al.* [1] study the problem of retrieving k documents relevant to a query q, but are also diverse with each other. The diversity is computed based on document similarity metrics. Drosou *et al.* [7] study the problem of finding the k most

Symbol	Description
$\mathbb{R}^m$	m-dimensional dataspace
S	Set of data objects
D	Subset of S ($D \subseteq S$)
p,q	Data objects/products ($p, q \in S$)
W	Set of weighting vectors
$\mathbf{w}$	A weighting vector ($\mathbf{w} \in W$)
$f_{\mathbf{w}}$	Preference function associated with $\mathbf{w}$
k	Value of top-k
$TOP_k(\mathbf{w})$	Top-k data objects based on $\mathbf{w}$
$RTOP_k(p)$	Reverse top-k result set for object p
$\mathbf{c}_p$	Centroid of vectors in set $RTOP_k(p)$
$d(p, q)$	Cosine distance between centroids $\mathbf{c}_p, \mathbf{c}_q$
$d(\mathbf{u}, \mathbf{v})$	Cosine distance between vectors $\mathbf{u}, \mathbf{v}$
$div(D)$	Diversity value of a set of objects D
D^*	Optimal solution of the r-Diversity problem
$D_r(S)$	Approximate solution of the r-Diversity problem

Table 2: Overview of symbols.

diverse objects in a continuous data stream. DivDB, a system that provides query result diversification, was presented in [19]. Result diversification based on dissimilarity is studied also in [6]. Estimating the diversity of a set of points that fulfill a special property has been studied mainly for selecting representative skyline points. For instance the diversity of two skyline points can be defined as the distance between them [16] or by using their sets of dominated points [13, 18]. More specifically, in [16] the authors define the set of representative skyline to be a set of k objects that maximize the minimum Euclidean distance between any two of the k points. In [13], the representative skyline points are defined based on the distinct number of dominated points. Valkanas *et al.* [18] estimate the diversity of two skyline points by calculating the Jaccard distance of their respective sets of dominated points. The main difference to our work is that the definitions of diversity in the above approaches rely on the attribute values only and cannot exploit the existing user preferences.

3. PRELIMINARIES

Given a space $\mathbb{R}^m$, we assume that we have a set of data objects S where each object $p \in S$ can be represented as an m-dimensional point $p = \{p[1], \ldots, p[m]\}$ where $p[i] \in \mathbb{R}^+$. Each point p can be regarded as an object of a database and each dimension of the point as a specific numerical attribute. Without loss of generality, we assume that larger values are preferable.

Given a scoring function $f : S \to \mathbb{R}^+$,a *top-k* query returns the k objects of S with the best score. The scoring functions used more often, are linear functions of the form $f(p) = \sum_{i=1}^{m} w[i]p[i]$ where $w[i] \geq 0$. Such functions can be represented by an m-dimensional *weighting vector* $\mathbf{w} = \{w[1], \ldots, w[m]\}$. In such cases we denote the function that results from $\mathbf{w}$ as $f_{\mathbf{w}}$. When $\mathbf{w}$ represents the preferences of a user over the objects in S we call this vector *preference vector* or simply *preference.*

Definition 1. ***(Top-k query [20])*** *Given a data set $S \subseteq \mathbb{R}^m$ and a vector $\mathbf{w} \in \mathbb{R}^m$ the result set $TOP_k(\mathbf{w})$ of the top-k query is a set of points such that $TOP_k(\mathbf{w}) \subseteq S$, $|TOP_k(\mathbf{w})| = k$ and $\forall p_1, p_2 : p_1 \in TOP_k(\mathbf{w}), p_2 \in S - TOP_k(\mathbf{w})$ it holds that $f_{\mathbf{w}}(p_1) \geq f_{\mathbf{w}}(p_2)$*

If we have a set of preferences $W \subseteq \mathbb{R}^m$ over a set of products $S \subseteq \mathbb{R}^m$ then for a given product q, we say that the result set of a *reverse top-k* query is a set $RTOP_k(q)$ which consists of all the preference vectors $\mathbf{w}$ for which it holds that $q \in TOP_k(\mathbf{w})$.

Definition 2. ***(Reverse top-k query [20])*** *Given a set of points S, a point p, and a set of vectors W we say that a vector $\mathbf{w}$ belongs in the reverse top-k set $RTOP_k(p)$ of point p, if and only if $\exists q \in TOP_k(\mathbf{w})$ such that $f_{\mathbf{w}}(p) \geq f_{\mathbf{w}}(q)$.*

We can also define the *influence score* of a data object p as the cardinality of the set $RTOP_k(p)$. Table 2 provides an overview of the most basic symbols used in this paper.

4. PROBLEM STATEMENT

Let p and q denote two products (data objects) from a product database S. Also, given a set W of customer preferences (weighting vectors) and an integer k, let $RTOP_k(p) \subseteq W$ and $RTOP_k(q) \subseteq W$ denote the reverse top-k sets of p and q respectively. We also define a distance function $d : S \times S \to \mathbb{R}^+$ as:

$$d(p, q) = f_d(RTOP_k(p), RTOP_k(q))$$

that determines the dissimilarity of any two objects p and q based on their corresponding reverse top-k sets. Notice that this is a radically different approach from existing initiatives that define the distance of two objects based on the objects' attributes only.

The problem of selecting the r most diverse products from a given set S can be viewed as a *dispersion* problem [7, 8, 15, 18], where the aim is to find r objects such that an objective function of their distance d is optimized. The *dispersion sum problem* maximizes the sum of pairwise distances between the r selected products and it has been proved that it is NP-hard by reduction from the clique problem [8].

Problem 1. ***(r-Diversity Problem)***. *Given a set of data objects S and a distance function d measuring the dissimilarity between two objects, the r-Diversity problem is to identify a subset $D^* \subseteq S$ such that:*

$$D^* = \underset{\substack{D \subseteq S \\ |D| = r}}{\arg\max} \sum_{\substack{p,q \in D \\ p \neq q}} d(p, q)$$

The remaining challenge is to define an appropriate function f_d that captures the dissimilarity of the reverse top-k result sets. Hence, the function f_d takes as input two sets of weighting vectors and computes their dissimilarity. We employ a function that relies on the concept of a *centroid* of a set of vectors.

Definition 3. ***(centroid of RTOPk)***. *Given a set of data objects S, a set of weighting vectors W, and an object $p \in S$ such that $RTOP_k(p) \neq \emptyset$, we define as the* centroid *of p the vector:*

$$\mathbf{c}_p = \frac{1}{|RTOP_k(p)|} \sum_{\mathbf{w} \in RTOP_k(p)} \mathbf{w}$$

Since each $RTOP_k$ set corresponds to exactly one data point, the respective centroid corresponds to exactly one data point as well. Therefore each data point can be mapped to exactly one centroid vector and vice-versa.

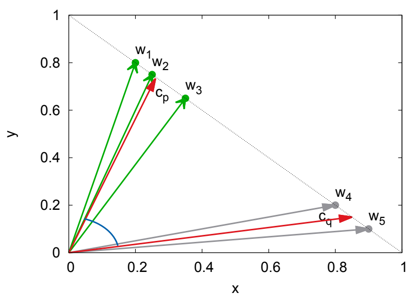

Figure 1: Example of dissimilarity function.

Definition 4. ***(Dissimilarity function*** f_d***).*** *Given a set of data objects* S*, a set of weighting vectors* W*, two objects* $p, q \in S$*, and their respective centroids* $\mathbf{c}_p$ *and* $\mathbf{c}_q$*, the distance of* p *and* q *is defined based on the cosine similarity of the centroids:*

$$f_d(RTOP_k(p), RTOP_k(q)) = 1 - cos(\mathbf{c}_p, \mathbf{c}_q)$$

The advantage of using the centroid $\mathbf{c}_p$ instead of the actual set of vectors $RTOP_k(p)$ is that the centroid is a compact and accurate representation of the set, which in turn allows efficient processing of the dissimilarity function, compared to other dissimilarity metrics that operate on sets of arbitrary size. As a result, we use $d(p, q) = 1 - cos(\mathbf{c}_p, \mathbf{c}_q)$ as distance function in this paper[1].

Example 1. *Figure 1 shows an example of the reverse top-k sets* $RTOP_k(p) = \{\mathbf{w}_1, \mathbf{w}_2, \mathbf{w}_3\}$ *and* $RTOP_k(q) = \{\mathbf{w}_4, \mathbf{w}_5\}$*, which belong to products p and q respectively. In the Euclidean space, a linear top-k query can be represented by a vector* $\mathbf{w}$ *[20, 21]. The magnitude of the query vector does not influence the query result, as long as the direction remains the same, therefore without loss of generality we assume that* $\sum_{i=1}^{m} w[i] = 1$*. In the 2-dimensional space, all weighting vectors belong to the line as depicted in Figure 1. Moreover, top-k queries defined by similar weighting vectors* $\mathbf{w}$ *are expected to produce similar result sets [20, 21]. Thus, the weighting vectors of the reverse top-k set of p are expected to lie nearby on the line. Furthermore, for a hypothetical weighting vector which lies on the line between* $\mathbf{w}_1$ *and* $\mathbf{w}_3$*, it is expected that p is highly ranked, and therefore it is highly probable that this vector would belong to the reverse top-k set of p.*

The centroid of the weighting vectors captures the above intuitions, and the angle between two centroids represents the dissimilarity of the weighting vectors. Obviously, different functions for set dissimilarity (hence also for measuring distance) are supported by our approach, including (for instance) the Jaccard similarity of the reverse top-k sets. Nevertheless, the Jaccard similarity fails to capture the locality of the weighting vectors.

Furthermore, we define the *diversity* $div(D)$ of a set of objects $D \subseteq S$. Notice that the set D^* with the highest diversity value $div(D^*)$ among all r-sets of points in S, is the optimal solution for Problem 1. The diversity value $div(D)$ is normalized in [0,1].

[1]In a slight abuse of notation, we also use $d(\mathbf{u}, \mathbf{v}) = 1 - cos(\mathbf{u}, \mathbf{v})$ to denote the cosine distance between any two vectors $\mathbf{u}$ and $\mathbf{w}$.

Definition 5. ***(Diversity value)*** *Given a set of points* S*, a subset* $D \subseteq S$ *of size* r*, and set of vectors* W*, we define as* diversity *of* D*:*

$$div(D) = \frac{2}{r(r-1)} \sum_{\substack{p,q \in D \\ p \neq q}} (1 - cos(\mathbf{c}_p, \mathbf{c}_q))$$

5. ALGORITHMS WITH CENTROID COMPUTATION

The process of discovering r diverse products $D_r(S)$ from a set of products S consists of two main steps: (1) identifying a set C of *candidate centroids* that correspond to candidate products for inclusion in the most diverse products (Section 5.1), and (2) selecting r of these candidates as the most diverse products (Section 5.2).

Each candidate centroid in $\mathbf{c}_p \in C$ corresponds to one product $p \in S$ and is the centroid vector of the $RTOP_k(p)$ set of p. More formally $C = \{\mathbf{c}_p | p \in S, RTOP_k(p) \neq \emptyset, \mathbf{c}_p \text{ is centroid of } RTOP_k(p)\}$. Obviously, products that are not preferable for any customer are ignored.

Algorithm 1 describes the afore-described method and returns a set of r diverse products. In line 1, the candidate centroids C are computed using any of the methods that will be described in Section 5.1. As the set of centroids C may be large depending on the data distribution, a sample R of fixed size s is created by picking centroids uniformly at random (line 2). Finally, in line 3, the second step entails solving the r-Diversity problem by applying a greedy algorithm, called Diverse Product Selection Algorithm (*DPSA*), on the sampled set of centroids R, as will be described in Section 5.2.

Algorithm 1 r-Diverse Products

```
Input: $S$: set of products
       $W$: set of weighting vectors
       $k$: value of top-$k$ and reverse top-$k$
       $s$ : size of initial sample
       $r$ : required number of diverse products
Output: $D_r(S)$: the set of $r$ most diverse products of $S$

1: $C \leftarrow$ CandidateCentroids($S$, $W$, $k$)
2: $R \leftarrow$random subset of $C$ with $|R| = s$
3: $D_r(S) \leftarrow DPSA(C, R, r)$
4: return $D_r(S)$
```

5.1 Retrieving the Candidate Centroids

Different alternatives exist in order to compute the set C of candidate centroids. In the following, we present three alternative methods for determining the set C. Notice that all methods produce an identical set C of centroids.

The most straightforward method is to perform a reverse top-k query for each product p in S and compute the centroid vector of each set $RTOP_k(p)$ using Definition 3. We denote this approach *Rtopk*. Its processing cost is basically determined by the computation of $|S|$ reverse top-k queries. Since any existing algorithm for reverse top-k processing can be employed for the underlying reverse top-k computation, this method is quite generic.

An improvement of the first method is derived based on the observation that some products have empty reverse top-k sets (i.e., they do not belong to the top-k result of any weighting vector). Hence, it is possible to avoid processing some reverse top-k sets. To achieve this, we exploit the progressive result generation of the algorithm in [22], which is able to retrieve objects in decreasing order of the sizes of their reverse top-k sets. We denote this method as *Itopk* based on the fact that the algorithm [22] has been proposed for retrieval of influential objects. As a result, we avoid processing a reverse top-k query for objects with empty reverse top-k sets, thus improving the performance of *Rtopk*.

The third method exploits the observation that it may be more efficient to process all top-k queries, instead of processing multiple reverse top-k queries. Thus, we perform a top-k query for each preference vector $w \in W$, which makes straightforward the computation of the reverse top-k sets of any data object, and hence also their respective centroids. In fact, the top-k sets do not need to be maintained until all top-k queries have been processed, but instead the centroids can be calculated progressively. For each retrieved object in the top-k result set, the centroid is updated by adding the new vector $\mathbf{w}$ to its previous centroid, while also the number of vectors per object is maintained. After finishing all top-k queries, for each centroid the coordinates are divided by the cardinality of the reverse top-k set. Since top-k queries for all vectors in W are processed, we call this method all top-k, i.e., *Atopk*. An advantage of *Atopk* is that the processing cost in terms of top-k evaluations is fixed, namely $|W|$ top-k queries, in contrast to *Rtopk* and *Itopk* where in the worst case the top-k evaluations can be up to $|W| \cdot |S|$. Thus, the efficiency of *Atopk* is influenced slightly by the cardinality of S, in contrast to *Rtopk* which computes the reverse top-k set even for products with empty reverse top-k sets.

5.2 Diverse Product Selection Algorithm

After having computed the centroid vectors of all non-empty reverse top-k sets, the next step is to find the r most diverse centroids and the products that they represent. As already mentioned, the r-Diversity problem is defined as a dispersion problem that is known to be NP-hard [8]. Thus, computing the optimal solution for the r-Diversity problem is not feasible even for relatively small data sets. Hence, we employ an algorithm that efficiently computes an approximate solution of high quality [5]. More specifically, we use a greedy algorithm, called Diverse Product Selection Algorithm (*DPSA*), that iteratively selects the next centroid that maximizes the value of the objective function. Its pseudocode is depicted in Algorithm 2.

Description. The algorithm takes as input the set of candidate centroids C, a random sample set R of the candidate centroids that is going to be used, and an integer r which is the desired number of most diverse products. It returns an approximate set $D_r(S)$ of the r most diverse products and their centroids. The sample R is typically much smaller in size than C, in order to reduce the cost of the first part of the algorithm, which is to find the two most distant vectors in R (line 2) and add them to the result set $D_r(S)$ (line 3). Then, the algorithm iteratively selects the next centroid $\mathbf{c}_q$ until r centroids have been retrieved (loop in line 4). Each time, the selected centroid is the one that maximizes the sum of distances from the already selected most diverse vectors $D_r(S)$. Notice that R is used only for the initialization of $D_r(S)$ (line 3), while the remaing centroids are selected from C.

Complexity. The selection of the two most diverse products (seeds) has a cost $O(|R|^2) = O(s^2)$. The remaining part of the algorithm has a cost of $O(r^2|C|)$ and therefore the total cost is equal to $O(s^2 + r^2|C|)$. If no sample is used ($s = |C|$) in the seed selection then the algorithm will have a cost of $O(|C|^2)$.

Algorithm 2 Diverse Product Selection Algorithm *DPSA*()

```
Input: $C$ : set of candidate centroids
       $R$ : sample of $C$
       $r$ : required number of diverse products
Output: $D_r(S)$: the set of $r$ most diverse products of $S$

1: $\mathbf{c}_{p1}, \mathbf{c}_{p2} \leftarrow \mathbf{c}_{p1}, \mathbf{c}_{p2} : \forall \mathbf{c}_{pi}, \mathbf{c}_{pj} \in R : d(\mathbf{c}_{p1}, \mathbf{c}_{p2}) \geq d(\mathbf{c}_{pi}, \mathbf{c}_{pj})$
2: $C \leftarrow C - \{p_1, p_2\}$
3: $D_r(S) \leftarrow \{p_1, p_2\}$
4: while $|D_r(S)| < r$ do
5:     $\mathbf{c}_q = \arg\max_{\mathbf{c}'_q \in C} \left(\sum_{p \in D_r(S)} d(\mathbf{c}'_q, \mathbf{c}_p)\right)$
6:     $D_r(S) \leftarrow D_r(S) \bigcup \{q\}$
7:     $C \leftarrow C - \{q\}$
8: end while
9: return $D_r(S)$
```

Implementation details. In each loop iteration of the *DPSA* algorithm (lines 4-8), the algorithm calculates the sum of distances between a centroid vector $\mathbf{c_q} \in C - D_r(S)$ and the centroid vectors in $D_r(S)$. As described above this procedure has a cost of $O(r^2|C|)$. In the case of the cosine distance we can reduce this cost to $O(r|C|)$ by exploiting the properties of the cosine function. As shown in Equation 1 the sum of distances of $\mathbf{c}_q$ to all centroids in $D_r(S)$ is equal to $|D_{r(S)}| - \frac{\mathbf{c}'_q}{|\mathbf{c}'_q|} \cdot \mathbf{c}_{D_r(S)}$. In that way it is only necessary to calculate the centroid of $D_r(S)$ before each loop iteration.

$$\begin{aligned}\sum_{p \in D_r(S)} d(\mathbf{c}'_q, \mathbf{c}_p) &= \sum_{p \in D_r(S)} 1 - cos(\mathbf{c}'_q, \mathbf{c}_p) \\ &= |D_r(S)| - \frac{\mathbf{c}'_q}{|\mathbf{c}'_q|} \cdot \sum_{p \in D_r(S)} \frac{\mathbf{c}_p}{|\mathbf{c}_p|} \qquad (1) \\ &= |D_r(S)| - \frac{\mathbf{c}'_q}{|\mathbf{c}'_q|} \cdot \mathbf{c}_{D_r(S)}\end{aligned}$$

6. SELECTIVE TOP-K ALGORITHM

The main drawback of the previous algorithm is that it requires the computation of all centroids, which has a significant processing cost regardless of the employed method for candidate centroid computation. In particular, depending on the cardinality of W and S, the computation of the centroids may be time-consuming. In order to alleviate this shortcoming, in this section, we propose a method that fuses the centroid computation with the selection of diverse objects. Our goal is to efficiently compute an approximation of the centroids (by evaluating only a handful of carefully selected top-k queries), which is sufficient to produce a set of r products with high diversity.

6.1 Centroid Approximation

Conceptually, the proposed algorithm uses a series of iterations, where each iteration consists of three parts: (1) select a weighting vector $\mathbf{w}_i$ in order to process the top-k query it defines, (2) compute an approximation of the centroid-set based on the results of all already processed top-k queries, and (3) select diverse products by invoking the *DPSA* algorithm (Section 5.2) with input the approximate centroid-set. In each iteration, a top-k query based on $\mathbf{w}_i$ is executed. Some objects $p \in TOP_k(\mathbf{w}_i)$ may not have been retrieved before and those are added to the centroid-set. For the remaining objects $p \in TOP_k(\mathbf{w}_i)$ the approximate centroid is updated, since $\mathbf{w}_i$ is added to their reverse top-k sets. In fact, the reverse top-k sets are not maintained, but the centroid of an object is computed progressively as in the case of *Atopk*. Thus, in each iteration the centroid-set is only an approximation of the candidate centroids C computed by Algorithm 1 because (a) C may contain more centroids as some objects may not have been retrieved yet and (b) the centroids of an object p are estimated based on a limited set of top-k queries only. However, in each iteration, the candidate-set is enriched with the results of the next top-k query. Additionally, a set of r diverse products $D_r(S)$ is computed based on the current set of centroids. Finally, the selection of the next weighting vector to be processed is based on maximizing the sum of distances to the set of centroids defined by $D_r(S)$.

The main idea of our algorithm is that the maximum cosine distance (i.e., maximum diversity) of two objects is bounded by the maximum cosine distance of any two weighting vectors. Let us assume that $\mathbf{w}_1$ and $\mathbf{w}_2$ are the two weighting vectors with the maximum cosine distance (the most diverse). Let us further assume that there exist two products p_1 and p_2 for which holds: $RTOP_k(p_1) = \{\mathbf{w}_1\}$ and $RTOP_k(p_2) = \{\mathbf{w}_2\}$. Then, it holds that for 2-Diversity problem the optimal solution is $\{p_1, p_2\}$ and their diversity equals to $1 - cos(\mathbf{w}_1, \mathbf{w}_2)$, since $\mathbf{c}_{p_i} = \mathbf{w}_i$. If more weighting vectors belong to $RTOP_k(p_1)$ then the diversity between $\{p_1, p_2\}$ decreases. Therefore, our algorithm starts by evaluating the top-k queries for the most diverse weighting vectors. In each step, the most diverse weighting vector to the current most diverse centroids is selected, as each centroid may summarize several weighting vectors.

6.2 Algorithmic Description

Algorithm 3 shows the pseudocode of the proposed algorithm that uses a limited set of top-k queries only. We call this algorithm *Selective Top-k Algorithm* and denote it with *Stopk*.

Description. The first major difference to Algorithm 1 is that the initial centroid computation is avoided. First, the algorithm computes a random sample W' (of size s) of W (line 1) and the two most dissimilar weighting vectors $\mathbf{w}_1$ and $\mathbf{w}_2$ of W' are selected (line 2). Notice that the sample W' is produced uniformly at random, thus it follows the distribution of W and is used only for the initialization of $\widehat{\mathcal{C}}$. Applying the initialization step on W would result in a cost of $O(|W|^2)$, while with the sample it is reduced to $O(|W'|^2)$. Next, the top-k queries for $\mathbf{w}_1$ and $\mathbf{w}_2$ are processed and from the resulting merged set of products a set $\widehat{\mathcal{C}}$ of centroids is computed (line 3). Notice that $\widehat{\mathcal{C}}$ is computed based solely on the products retrieved thus far by the two top-k queries. These centroids form the candidate set for finding the most diverse products. In the following step, the Algorithm 2 is invoked with input the candidate set, and the two most diverse products are retrieved and placed in $D_r(S)$ (line 4). Note that $\widehat{\mathcal{C}}$ is much smaller than C, thus *DPSA* algorithm is applied on $\widehat{\mathcal{C}}$ and no random sample is required.

Algorithm 3 Selective Top-k Algorithm

```
Input: S: set of products
       W: set of weighting vectors
       k: value of top-k and reverse top-k
       s : size of initial sample
       r : required number of diverse products
       steps : number of iterations (steps ≥ r)
Output: D_r(S): the set of r most diverse products of S

 1: $W' \leftarrow$random subset of $W$ with $|W'| = s$
 2: $\mathbf{w}_1, \mathbf{w}_2 \leftarrow \mathbf{w}_1, \mathbf{w}_2 : \forall \mathbf{w}_i, \mathbf{w}_j \in W' : d(\mathbf{w}_1, \mathbf{w}_2) \geq d(\mathbf{w}_i, \mathbf{w}_j)$
 3: $\widehat{\mathcal{C}} \leftarrow$ ComputeCentroids($\bigcup_{x=1,2} TOP_k(\mathbf{w}_x)$)
 4: $D_r(S) \leftarrow DPSA(\widehat{\mathcal{C}}, \widehat{\mathcal{C}}, 2)$
 5: $i = 2$
 6: while $i < steps$ do
 7:     $i{+}{+}$
 8:     $\mathbf{w}_i = \arg\max_{\mathbf{w} \in W} \left( \sum_{p \in D_r(S)} d(\mathbf{c}_p, \mathbf{w}) \right)$
 9:     $\widehat{\mathcal{C}} \leftarrow$ ComputeCentroids($\bigcup_{x=1 \ldots i} TOP_k(\mathbf{w}_x)$)
10:     $D_r(S) \leftarrow DPSA(\widehat{\mathcal{C}}, \widehat{\mathcal{C}}, min(i+1, r))$
11: end while
12: return $D_r(S)$
```

In each iteration, the most dissimilar weighting vector $\mathbf{w}_i$ to the centroid vectors $\mathbf{c}_p$ ($p \in D_r(S)$) is selected (line 8). For this $\mathbf{w}_i$, the respective top-k query is executed and the candidate list $\widehat{\mathcal{C}}$ is updated as before (line 9). Then, the *DPSA* algorithm is invoked again to produce a new set of diverse products (line 10). The same procedure is repeated for at least r steps. Notice that when the iteration counter i is smaller than r, the algorithm produces i diverse products, and only when i becomes greater than r does the algorithm return r diverse products.

In order to improve further the approximation of the centroids more iterations can be applied. The number of iterations (*steps*) is a system parameter that captures an interesting trade-off between the diversity of the result set and the processing time. Small values of *steps* increase the efficiency of the algorithm by reducing its processing time. In the experimental evaluation, we demonstrate that a small number of iterations is sufficient to produce results with diversity comparable to that of Algorithm 1, with significantly lower processing cost. Notice that in the extreme case that the number of iterations of *Stopk* is set equal to the cardinality of W and also no sampling is used ($s = |W|$), the set of diverse products and number of required top-k queries will be the identical with *Atopk*. Nevertheless, in this case, *Stopk* will have the computational overhead of applying multiple times the *DPSA* algorithm and finding the diverse weighting vectors.

EXAMPLE 2. *Table 3 shows an example of the execution of Stopk for $r = 2$. We assume that in the initialization step vectors $\mathbf{w}_1$ and $\mathbf{w}_2$ are selected. Furthermore (assuming $k = 3$), the top-3 results for the selected vectors are depicted. After the initialization step, the sets of approximate centroids $\widehat{\mathcal{C}}$ contains 5 centroids (namely $\mathbf{c}_{p_1}$, ..., $\mathbf{c}_{p_5}$),*

Initialization step:
$TOP_k(\mathbf{w}_1) = p_1, p_2, p_3$, $TOP_k(\mathbf{w}_2) = p_2, p_4, p_5$
$\mathbf{c}_{p_1} = \mathbf{w}_1$, $\mathbf{c}_{p_2} = \frac{1}{2}(\mathbf{w}_1 + \mathbf{w}_2)$,
$\mathbf{c}_{p_3} = \mathbf{w}_1$, $\mathbf{c}_{p_4} = \mathbf{w}_2$, $\mathbf{c}_{p_5} = \mathbf{w}_2$
First step:
$TOP_k(\mathbf{w}_3) = p_3, p_4, p_5$
$\mathbf{c}_{p_1} = \mathbf{w}_1$, $\mathbf{c}_{p_2} = \frac{1}{2}(\mathbf{w}_1 + \mathbf{w}_2)$, $\mathbf{c}_{p_3} = \frac{1}{2}(\mathbf{w}_1 + \mathbf{w}_3)$
$\mathbf{c}_{p_4} = \frac{1}{2}(\mathbf{w}_2 + \mathbf{w}_3)$, $\mathbf{c}_{p_5} = \frac{1}{2}(\mathbf{w}_2 + \mathbf{w}_3)$
Second step:
$TOP_k(\mathbf{w}_4) = p_1, p_2, p_6$
$\mathbf{c}_{p_1} = \frac{1}{2}(\mathbf{w}_1 + \mathbf{w}_4)$, $\mathbf{c}_{p_2} = \frac{1}{3}(\mathbf{w}_1 + \mathbf{w}_2 + \mathbf{w}_4)$,
$\mathbf{c}_{p_3} = \frac{1}{2}(\mathbf{w}_1 + \mathbf{w}_3)$, $\mathbf{c}_{p_4} = \frac{1}{2}(\mathbf{w}_2 + \mathbf{w}_3)$,
$\mathbf{c}_{p_5} = \frac{1}{2}(\mathbf{w}_2 + \mathbf{w}_3)$, $\mathbf{c}_{p_6} = \mathbf{w}_4$

Table 3: Example of *Stopk*.

which correspond to the data points that have been retrieved by at least one top-k query. Algorithm 2 is applied on $\widehat{C}$ and we assume that $\mathbf{c}_{p_1}$ and $\mathbf{c}_{p_4}$ as the two most diverse vectors. In the first iteration of Stopk, the most diverse (according to $\mathbf{c}_{p_1}$ and $\mathbf{c}_{p_4}$) weighting vector of W is selected. In this step, $\mathbf{w}_3$ is selected and the approximate centroids $\widehat{C}$ are updated based on $TOP_k(\mathbf{w}_3)$ as depicted in Table 3. Again, Algorithm 2 is applied on $\widehat{C}$ and $\mathbf{c}_{p_1}$ and $\mathbf{c}_{p_4}$ are identified as the two most diverse vectors. Stopk continues with a second iteration by evaluating $\mathbf{w}_4$. In this step, $\mathbf{c}_{p_6}$ is added to $\widehat{C}$ as it belongs to $TOP_k(\mathbf{w}_4)$. Again Algorithm 2 will be invoked and the most dissimilar weighting vector of W will be selected. The same procedure continues until steps iterations has been executed.

Complexity. To perform a cost analysis of the algorithm, we need to identify its basic cost factors. These factors include the initial computation of the two most dissimilar vectors ($O(s^2)$), the processing cost of *steps* top-k queries, the cost of determining the next most dissimilar weighting vector ($O(steps \cdot r \cdot |W|)$) (line 8), and the cost induced by invoking the *DPSA* algorithm *steps* times. The cost of processing *steps* top-k queries will always be much cheaper than Algorithm 1, which needs to process W top-k queries (in the case of *Atopk*) to perform the centroid computation. It should also be noted that the calls to the *DPSA* algorithm are much cheaper, because it operates on $\widehat{C}$ which is much smaller than C. Overall, the cost of the algorithm is $s^2 + steps \cdot r \cdot |W|$, since these are the dominant cost factors, and the complexity is linear with respect to W ($O(steps \cdot r \cdot |W|)$), when *steps* is small (r is typically small anyway).

7. MAINTENANCE

In this section, we present techniques for maintaining the diverse set of products in the case of dynamic data. In fact, the methodology of *Stopk* (Algorithm 3) can be applied to maintain the r-diverse products. We consider two cases: (1) new products are inserted in the product database, and (2) new preferences (in the form of weighting vectors) are added in the customer preference database. Both cases actually occur in online shops, when new products appear in the market and new customer preferences are extracted from social sites.

In order to support product insertions efficiently, we exploit the top-k queries that where computed during the computation of $\widehat{C}$. Let W^* be the set of weighting vectors for which the top-k queries have been computed. We maintain for each weighting vector $\mathbf{w} \in W^*$ the score of the k-th product. When a new product p_{new} is inserted in the database, we check for each query $\mathbf{w} \in W^*$ if p_{new} has a better score than the k-th product. If this does not occur for any $\mathbf{w} \in W^*$, we can safely ignore p_{new}, as it does not affect the determination of the diverse products. On the other hand, if p_{new} becomes top-k for some weighting vector $\mathbf{w}$, we compute the new centroids only for the affected products (i.e., p_{new} and the products p_i that used to be at the k-th rank, but were evicted by p_{new}) and update the set $\widehat{C}$. We then apply *DPSA* algorithm on $\widehat{C}$ and produce a new set of diverse products. Note that in the first case, we can ensure that the result set is the same as in the case where *Stopk* would be executed on the updated data set, but this does not hold for the second case. The similarity of the centroids before and after the update can be used in order to decide when the *Stopk* algorithm should be invoked to have a result set of higher quality.

In order to be able to handle new preferences effectively, during the computation of the diverse product we maintain the minimum (*min*) of all maximal sums of distances between a centroid and any selected weighting vector (i.e., the expression in line 8 of Algorithm 3). In the case of a new weighting vector $\mathbf{w}_{new}$, we follow the same principle as Algorithm 3 to decide whether the respective top-k query should be evaluated. If $\sum_{p \in D_r(S)} d(\mathbf{c}_p, \mathbf{w}_{new})$ is larger than *min*, then the top-k query for $\mathbf{w}_{new}$ is computed, the set of centroids $\widehat{C}$ updated and *DPSA* algorithm is executed on $\widehat{C}$ to produce a new set of diverse products. Intuitively, when vector $\mathbf{w}_{new}$ induces small changes to the set of centroids, we do not need to recompute the r-diverse products as $\mathbf{w}_{new}$ would not have been selected by *Stopk* in any case. Again, the retrieved diverse products are not the same as if *Stopk* would be executed on the updated weighting vector set, therefore a threshold on the similarity of the centroids before and after the update may trigger executing *Stopk* to get a set of higher quality.

8. SUPPORTING OTHER SET-BASED SIMILARITY FUNCTIONS

In general, our approach is applicable also for other functions that compute the similarity between sets of vectors. In such a case, our algorithms would not calculate centroids (which is simply a representation of a set of weighting vectors), but would instead directly operate on the reverse top-k sets of products. Following this line of thought, $\hat{C}$ would represent a set of approximate reverse top-k sets (instead of a set of centroids) and the computation of the most diverse sets becomes independent of the similarity or distance function.

In more technical terms, Algorithm 1 would not calculate centroids but would only maintain the reverse top-k sets, and Algorithm 3 would not compute centroids incrementally but would simply update the approximate reverse top-k sets of products based on the executed top-k queries. Then, Algorithm 2 can be directly applied to the reverse top-k sets.

For instance, one popular similarity function is the Jac-

card similarity, which is defined as the size of the intersection divided by the size of the union of two sets. Our approach readily supports the Jaccard similarity on reverse top-k sets, as outlined above. Notice that the advantage of the cosine similarity compared to Jaccard for the problem of finding diverse products is that it returns more fine-grained similarity values. For example, in the case of disjoint sets, the Jaccard similarity value equals to zero, and does not distinguish between the sets. Instead, the cosine similarity of the centroid vectors allows us to distinguish between them by returning a non-zero value. Moreover in the case of a set A that is a subset of another set B ($A \subseteq B$), the Jaccard similarity is equal to $\frac{|B|-|A|}{|B|}$ which can get arbitrarily close to the maximum value. In such cases, using the Jaccard similarity would not be helpful, as it could lead to selecting products which are possibly covered by others. The centroid vectors reduce this problem (they do not eliminate it) by choosing sets that are selected by distant user preferences.

9. EXPERIMENTAL EVALUATION

In this section, we present the results of the experimental evaluation. All algorithms were implemented in Java and the experiments run on 2x Intel Xeon X5650 Processors (2.66GHz). The algorithms are disk-based and the index structure used was an R-tree with a buffer size of 100 blocks and the block size is 4KB. The main parameters and values used through the experiments are presented in Table 4.

Data sets. For the data set S, we use both synthetic and real data. We examine four different synthetic data distributions, namely uniform (UN), correlated (CO), anticorrelated (AC) and clustered (CL). For the uniform data set, the data object values for all m dimensions are generated independently using a uniform distribution. The correlated and anticorrelated data sets are generated as described in [3]. The clustered data set was created as follows: first 5 cluster centroids were selected randomly. Then, each coordinate is generated on the m-dimensional space by following a normal distribution on each axis with variance $\sigma_S^2 = 0.345$, and a mean equal to the corresponding coordinate of the centroid. In addition, we use a real data set. HOUSE (Household) consists of 127930 6-dimensional tuples, representing the percentage of an American family's annual income spent on 6 types of expenditure: gas, electricity, water, heating, insurance, and property tax. For the data set W of the weighting vectors, we used a uniform (UN) distribution.

Algorithms. We implemented the three algorithms for centroid computation (*Rtopk*, *Itopk*, and *Atopk*) coupled with the *DPSA* algorithm as described in Section 5, and the selective top-k algorithm (*Stopk*) described in Section 6. We also implemented an exact algorithm (denoted *opt*) that finds the optimal solution, but obviously cannot scale well. For reverse top-k processing, *Rtopk* uses the state-of-the-art BBR* algorithm [23], while *Itopk* uses the BB algorithm [22]. In all algorithms the data set is indexed by an R-tree and for the top-k query processing we employ a state-of-the-art branch-and-bound algorithm [17].

Metrics. The metrics under which we evaluated the implemented algorithms were: (a) execution time required by each algorithm, (b) I/O accesses, (c) achieved diversity values. We also measured the number of processed top-k queries, but in the interest of space we do not report them since they follow exactly the I/O metric. We measure only the I/O induced on the data set S, since the I/O on W are caused by sequential access and accessing data sequentially is much faster than the random accesses of S.

We conduct an experimental study varying the parameters of dimensionality (3-6), cardinality (1K-500K) of S, cardinality (1K-500K) of W, value of k (5-50), value of r (3-30), sample size $|W'|$ ($0.001|W|$-$0.1|W|$), and number of *steps* (100-1000). Each experiment was repeated 10 times over different instances of the data sets with the same parameters and different seed to the random generator, in order to factor out the effect of randomization. Average values are reported in all cases.

Evaluation methodology. Our evaluation was divided in three parts. In the first part (9.1), we compare the algorithms *Atopk* and *Stopk* against the exact algorithm (*opt*) in order to evaluate the quality of approximation of diversity. In the second part (9.2), we evaluate the performance of *Stopk* against the algorithms that rely on centroid computation (*Rtopk*, *Itopk*, and *Atopk*). In the last part (9.3 and 9.4), we perform a thorough sensitivity analysis of *Atopk* (which proved to perform best among the algorithms with centroid computation) against *Stopk*. We should stress that the diversity of the result set of *Stopk* is calculated using the whole set of preferences W, and not only the vectors used for the identification of the most diverse products.

9.1 Quality of Diversity

The purpose of this series of experiments is to study the loss of diversity compared to optimal solution when using our algorithms *Atopk* and *Stopk*. Thus, we compare to the optimal diversity produced by an exact algorithm (*opt*), which examines all possible $\binom{|S|}{r}$ combinations of products exhaustively to find the optimal solution. Recall that *Rtopk* and *Itopk* produce exactly the same result set as *Atopk* and therefore have also the same diversity. The default setup for this series of experiments was: m=3, $|S| = 5K$, $|W| = 5K$, $k = 10$, $r = 5$, $s = 0.1 \cdot |W|$, $steps = 100$, S:UN, and W:UN.

Figure 2 depicts the diversity values for varying different parameters, namely $|S|$, $|W|$, r and k. The diversity achieved by the greedy algorithm (*Atopk*) is in most cases quite close to optimal, while *Stopk* results in similar diver-

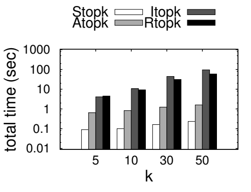
sity values. As we can observe, our approximate algorithms perform very well in comparison with the exact algorithm. In the worst case, when the size of the objects data set is only $|S|$=1000 objects (Figure 2(a)), the maximum difference in diversity is 19%. As the datasets grow in size, the diversity of the result set of the approximate algorithms approaches the optimal diversity. It is noteworthy that as the number of returned objects (r) increases, the diversity value drops. This behavior is expected as the more points we select the smaller their average distance will become.

We omit the figures comparing the performance of our algorithms to *opt*, since, as expected, our algorithms outperformed the exact approach by 1-4 orders of magnitude in terms of execution time.

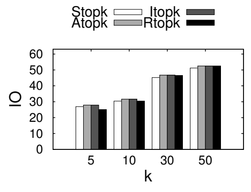
9.2 Scalability Analysis

In this series of experiments we compare the performance of the algorithms with centroid computation (described in Section 5) in terms of execution time and I/O. We also include the *Stopk* algorithm in the charts for completeness. The default setup for this series of experiments is m=3, $|S| = 10K$, $|W| = 10K$, $k = 10$, $r = 10$, S:UN, W:UN, $steps = 100$, $s = 0.01 \cdot |W|$.

Varying weight cardinality $|W|$. As Figure 3 illustrates, *Atopk* and *Stopk* outperform by orders of magnitude the *Rtopk* and *Itopk* algorithms in terms of execution time. This difference is not reflected in the measured I/O, because of the use of the buffer of the R-tree. When the number of issued top-k queries is considered, both *Rtopk* and *Itopk* process at least one order of magnitude more top-k queries than *Atopk* and *Stopk*. This processing cost is responsible for their slow runtime. We note that even though both *Rtopk* and *Itopk* are more efficient than *Atopk* when a single



(a) Time



(b) I/O

Figure 4: Performance when varying k.

reverse top-k query or a small number of influential points is needed, they are less efficient when they are run repeatedly multiple times. In this case, *Atopk* has a benefit and performs better. In particular, *Rtopk* has no memory of the completed executions for different queries, and therefore it computes repeatedly the top-k results of many preference vectors. On the other hand, *Itopk* performs fewer reverse top-k queries than *Rtopk*, but shares the same shortcoming for those reverse top-k queries that it processes. Therefore, it faces the same problem as the *Rtopk*, however in not such great extent. Similar conclusions are drawn when varying the data cardinality $|S|$. The performance of the algorithms is much less affected by the increase of data cardinality, as during the execution of the top-k queries very few data objects are accessed.

Varying k. Figure 4 illustrates the effect of varying parameter k. *Atopk* consistently outperforms *Rtopk* and *Itopk* in terms of time, while *Stopk* improves further the performance in terms of both time and I/O. *Atopk*, *Rtopk* and *Itopk* have the same performance in terms of I/O due to the R-tree buffer employed during query processing. Furthermore, for all algorithms, both time and I/O increase for increasing values of k.

Since *Atopk* consistently outperforms the two other algorithms (*Rtopk* and *Itopk*) that rely on centroid computation, we use only *Atopk* in the remaining experiments as representative of this family of algorithms.

9.3 Sensitivity Analysis

In this section, we provide a detailed sensitivity analysis by varying different parameters that influence the performance of our proposed algorithms. Due to space limitations, for some setups we omit the figures depicting the I/O since the time indicates the efficiency of the algorithms. The default setup for this series of experiments is m=3, $|S| = 100K$, $|W| = 100K$, $k = 30$, $r = 10$, S:UN, W:UN, $steps = 500$, $s = 0.01 \cdot |W|$.

Sensitivity analysis for varying $|S|$, $|W|$, Data Distribution and m. In Figure 5, we study the behavior of *Atopk* and *Stopk* for increasing cardinality of the data set S and the weighting vectors W, as well as for various data distributions (UN,CL,CO,AC) and dimensionality values m. First, we examine how the diversity values of *Atopk* and *Stopk* for the different parameters are influenced (Figures 5(a)–5(d)). We observe that *Stopk* benefits from the increased size of the data set and the preferences set. *Stopk* retrieves a set of r objects that have similar diversity compared to *Atopk*. In most cases the diversity achieved by *Stopk* is almost equal to the one achieved by *Atopk* and in some cases it is even slightly higher. This happens because *Stopk* locates the most diverse preferences and based

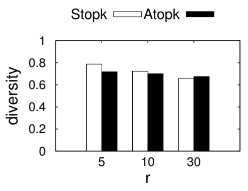
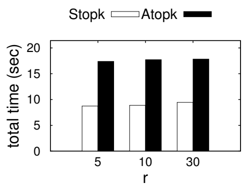
on them it identifies the most diverse products. *Atopk* on the other hand, bases the search for most diverse objects on the centroids of the $RTOP_k$ sets of the products. For increased dimensionality, as depicted in Figure 5(d), the diversity value of *Stopk* compared to *Atopk* is influenced more than for the other parameters. Recall that the diversity between the products was calculated for *Stopk* using all vectors in W and not only the ones used for the identification of the products.

Figures 5(e)–5(h) show the execution time of the algorithms with respect to various parameters. In Figure 5(e) we notice that none of the algorithms is influenced significantly by the data set cardinality, because top-k queries require retrieving only few data objects that are highly ranked independently of the data set cardinality. Figure 5(f) (which uses log-scale) shows that both algorithms are influenced in a similar way while varying the number of weighting vectors $|W|$, but *Stopk* is always more efficient than *Atopk*. In particular, the time increases with increasing number of weighting vectors $|W|$. In Figure 5(g), we depict the performance of both algorithms for different data distributions. In the case of anticorrelated data the execution time for *Atopk* is 4 times larger that in the case of a uniform distribution. On the other hand, the performance of *Stopk* is not affected by anticorrelated values significantly. Figure 5(h) shows that *Stopk* scales nicely for increased dimensionality, in contrast to *Atopk* whose cost increases by one order of magnitude when we go from 3 to 6 dimensions. This experiment provides strong evidence for the scalability of *Stopk* with increased number of dimensions.

Figures 5(i)–5(l) evaluate the performance of our algorithms in terms of I/O accesses. The conclusions for the I/O accesses are similar to those for the time, except for the case of increasing the data set cardinality $|S|$. In Figure 5(i), we notice that even though the time is not increased by varying $|S|$, the I/O accesses increase. Naturally, more I/O are needed for processing a top-k query of a larger data set, but this is not reflected on the time. Due to the buffering, the computational cost of processing multiple top-k queries is more significant than the time needed to retrieve the relevant index nodes. Nevertheless, in all cases *Stopk* outperforms *Atopk* in terms of I/O. For example Figure 5(l) shows that *Stopk* is two orders of magnitude cheaper than *Atopk* in I/O accesses as we increase the dimensions.



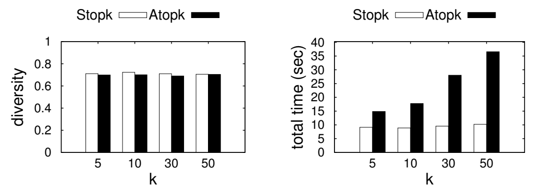
(a) Diversity



(b) Time

Figure 6: Varying r.

Varying r. Figure 6 examines the effect of varying the number r of retrieved products on our algorithms. First, we observe in Figure 6(a) a decreasing tendency of the diversity value as r increases for both algorithms, which is expected as also the diversity value of the optimal solution will decrease as the most diverse products are selected first. As far as the performance is considered, in Figure 6(b), the time of *Atopk* is not influenced by the increase of r, because *Atopk* computes all top-k queries independently of the size of the result set r and the computational cost of *DPSA* algorithm



(a) Diversity (b) Time

Figure 10: House Dataset: varying |W|

is not significant compared to the cost of the top-k queries. *Stopk* is also not significantly affected, since the values of r are relatively small, and the algorithm is executed *steps* times in any case. Still, *Stopk* remains always much faster than *Atopk*.

Varying k. In Figure 7, we gradually increase the parameter k of the reverse top-k queries from 5 to 50. In Figure 7(a), we notice that the diversity value is stable as k increases, which seems counter-intuitive at first. By increasing k the size of the reverse top-k set increases for some objects and more objects have a non-empty reverse top-k set. However, this does not influence the diversity value significantly, as the most diverse centroids may not change. Figure 7(b) depicts the time obtained for different values of k. Although we witness a small deterioration in the performance of both algorithms, *Stopk* consistently outperforms *Atopk*. Processing top-k queries is more time-consuming for higher values of k and the *DPSA* algorithm gets slower with increasing k because the number of candidates for finding the diverse objects increases. We should add however, that the effect of parameter k has much smaller impact on the performance of *Stopk* because *Stopk* performs a small number of top-k queries.

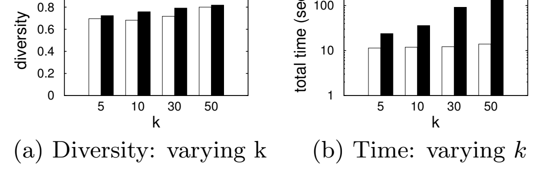
Varying steps. The *steps* parameter is an essential parameter for the *Stopk* algorithm as it balances the efficiency of the algorithm and the diversity the algorithm achieves. Recall that *Stopk* performs only *steps* top-k queries, which is only a small fraction of the $|W|$ top-k queries that *Atopk* performs. On the other hand, *Stopk* executes also *steps* times *DPSA* algorithm algorithm on a small set of approximate centroids, which is not necessary for *Atopk*. In Figure 8, we observe that the diversity achieved using very few vectors is quite close to the diversity achieved by *Atopk*. As we increase the *steps* parameter the achieved diversity increases marginally. However the execution time increases proportionally with the increase of the *steps* parameter. This experiment verifies that a small value of *steps* is sufficient to produce results of high diversity in a very efficient way.

Varying sample size $|W'|$. The size of sample of preferences from which we select the two initial centroids plays an important role in the performance of the *Stopk* algorithm. The complexity of the selection process is $O(|W'|^2)$ and therefore a large sample can have significant impact on the performance of the algorithm. However, as shown in Figure 9, the increased cost in performance is not accompanied by an increased gain in diversity. The reason behind this fact is that once the sample is large enough to offer a good representation of the whole set of preferences, further enlargement will not help significantly in finding better initial centroids.

9.4 Results on Real Data

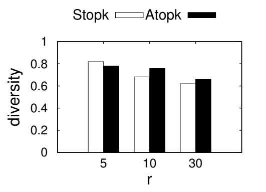
We have also performed an evaluation of our algorithm using a real data set. The conclusions drawn are overall in accordance with the conclusions made by the evaluation with synthetic data, thus verifying our findings. The default setup for this series of experiments is $|S| = 127930$, $|W| = 100K$, $k = 30$, $r = 10$, W:UN, $steps = 500$, $s = 0.01 \cdot |W|$. The size of the data set used and the high complexity of the exact algorithm (*opt*) did not allow the exact algorithm to terminate and therefore we did not include its performance results in this series of experiments.

Analysis for varying $|W|, k$, and r. Figures 10-12 depict performance of the two algorithms. For all values of the varying parameters *Stopk* achieves diversity values close to the ones of *Atopk*. For both algorithms we notice a drop in the diversity values when r is increases which is expected as analyzed in 9.1. With respect to processing time it is evident

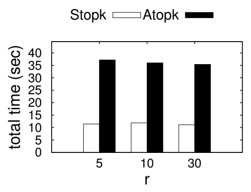


(a) Diversity: varying k (b) Time: varying k

Figure 11: House Dataset: varying *k*



(a) Diversity: varying r



(b) Time: varying r

Figure 12: House Dataset: varying r

that both parameters $|W|$ and k play a significant role in the performance of *Atopk*. This does not come as a surprise as the processing cost of *Atopk* is dominated by the processing cost of the top-k queries needed for the computation of the centroids of the $RTOP_k$ sets for each product. On the contrary *Stopk* is much less affected by those parameters as it performs a limited number of top-k queries. The increase of parameter r has little effect in both algorithms. The performance difference with respect to I/O is in all cases larger than two orders of magnitude. Only exception is for $k < 10$ where *Stopk* is one order of magnitude more efficient.

10. CONCLUSIONS

In this paper, we address the important problem of selecting the r most diverse products based on customers' preferences. The reverse top-k set of each product is represented by its centroid and the distance between centroids is then expressed using cosine distance. In order to find products that are attractive to customers with dissimilar preferences, we define the r-Diversity problem as a *dispersion* problem applied on the products' reverse top-k sets. As dispersion problems are known to be NP-hard, we propose two approximate algorithms that solve the problem. The first algorithm computes the reverse top-k sets and then applies a greedy algorithm that retrieves a set of products of high diversity. The second applies the greedy algorithm on an approximation of the reverse top-k sets by evaluating only some carefully selected top-k queries. In our experimental evaluation, we study the performance of the proposed algorithms and the diversity of the retrieved products in various experimental setups. In particular, we demonstrate that our algorithms both achieve diversity values close to optimal and are very efficient in practice.

ABSTRACT

Referential integrity is fundamental for data processing and data quality. The SQL standard proposes different semantics under which referential integrity can be enforced in practice. Under simple semantics, only total foreign key values must be matched by some referenced key values. Under partial semantics, total and partial foreign key values must be matched by some referenced key values. Support for simple semantics is extensive and widespread across different database management systems but, surprisingly, partial semantics does not enjoy any native support in any known systems. Previous research has left open the questions whether partial referential integrity is useful for any real-world applications and whether it can enjoy efficient support at the systems level. As our first contribution we show that efficient support for partial referential integrity can provide database users with intelligent query and update services. Indeed, we regard partial semantics as an effective imputation technique for missing data in query answers and update operations, which increases the quality of these services. As our second contribution we show how partial referential integrity can be enforced efficiently for real-world foreign keys. For that purpose we propose triggers and exploit different index structures. Our experiments with synthetic and benchmark data sets confirm that our index structures do not only boost the performance of the state-of-the-art recommendation for enforcing partial semantics in real-world foreign keys, but show trends that are similar to enforcing simple semantics.

1. INTRODUCTION

In his seminal paper [5] Codd introduced the principles of entity and referential integrity as two fundamental cornerstones of the relational model of data. While more than 100 classes of relational integrity constraints have been investigated [21], relational database management systems offer only native support for keys and foreign keys, which enforce entity and referential integrity, respectively. Indeed, keys and foreign keys provide principled mechanisms to process quality data efficiently. The SQL standard promotes the use of two different semantics for referential integrity. Under *simple* semantics, referencing tuples with null markers on some of their foreign key columns satisfy referential integrity by default. Under *partial* semantics, every referencing tuple requires a referenced tuple that matches all total values on the foreign key columns in the corresponding key columns. Partial semantics offers a higher degree of data quality as it subsumes simple semantics.

EXAMPLE 1. *For illustration consider an example from an Australian tourism company [8]. Tours in the* TOUR *table have a tour_id, for example a tour such as the "Gold Coast Grand Tour" has tour_id GCG. Tours have a fixed sequence of sites they visit. Sites are identified by a site_code (e.g., MV) but also have a unique site_name (e.g., Movie World). The primary key on* TOUR *is* {*tour_id, site_code*}. *Booking orders by visitors, who can join a tour from any allocated site, are stored in the* BOOKING *table. The foreign key*

$$[tour\_id, site\_code] \subseteq \text{TOUR}[tour\_id, site\_code]$$

is defined on BOOKING. *Consider the following database.*

TOUR

Tour_id	***Site_code***	***Site_name***
GCG	*OR*	*O'Reilly's*
BRT	*OR*	*O'Reilly's*
BRT	*MV*	*Movie World*
RF	*BB*	*Binna Burra*
RF	*OR*	*O'Reilly's*

BOOKING

Visitor_id	***Tour_id***	***Site_code***	***Date***
1006	*BRF*	`null`	*Sep* 19^{th}
1001	*BRT*	*OR*	*Nov* 21^{st}
1008	`null`	*BB*	*Sep* 5^{th}
1012	`null`	*BR*	*Nov* 2^{nd}
1011	*RF*	`null`	*Oct* 5^{th}

Simple referential integrity is satisfied: the only total foreign key value (BRT,OR) in the BOOKING *table is matched in the* TOUR *table. Partial referential integrity is violated: for the partial foreign key value (BRF,*`null`*) in the* BOOKING *table there is no tuple in the* TOUR *table with value "BRF" on tour_id, and similarly for (*`null`*, BR).*

While every database management system we know offers built-in support to enforce simple referential integrity,

*This research is supported by the Marsden fund council from Government funding, administered by the Royal Society of New Zealand.

10.5441/002/edbt.2015.20

it is surprising that none of them offers built-in support to enforce partial referential integrity [22]. Explanations for this gap between the SQL standard and its implementations have been brought forward by Härder and Reinhart, who analyzed in great detail the requirements of partial referential integrity on the operational level [9]. Two main questions remain open two decades after they have been posed in [9]:

1. Is partial referential integrity useful for any real-world application?
2. Can partial referential integrity be enforced efficiently?

Contribution. In the present paper we provide affirmative answers to both questions. Our first main contribution shows that partial referential integrity is useful for the two most significant real-world applications of database technology: updates and queries. More specifically, we propose intelligent update and query services that are based on efficiently enforcing partial semantics. Indeed, partial referential integrity can be exploited to impute missing data values. Our intelligent updates provide database users with sound choices to reduce the level of incompleteness in the database, which is an important measure for the quality of data [7]. In the example above, suppose that the last tuple is not already part of the BOOKING table but about to be inserted. Based on the assumption that the updated table shall satisfy partial referential integrity, our update service would provide the user with the option to replace the null marker by either "BB" or "OR". This service can be customized further depending on the authorization rights of the user, for example. Our intelligent query service provides database users with additional query answers that result from the imputation of missing data values in standard answers. In our example, the standard answer to the query that selects *tour_id* and *site_code* from tuples in the BOOKING table, may be augmented by the tuples (RF,BB), and (RF,OR) based on the partial semantics of the foreign key. We believe that intelligent updates and queries offer a strong affirmative answer to the first open question, that goes beyond the straightforward argument that partial referential integrity targets a higher level of data quality than simple referential integrity. Note that our applications cannot be supported by simple semantics. Indeed, they provide strong motivation to investigate the second open question, as the effectiveness of the applications largely depend on the efficiency of enforcing partial semantics for real-world foreign keys. Based on our experience, the literature [6] and public schemata, most real-world foreign keys have rarely more than four columns and the referenced key is commonly the primary key, or a candidate key where all columns are `NOT NULL`. Our second main contribution is a detailed analysis of partial referential integrity at the systems level, as proposed for future work in [9]. The main finding is that partial semantics for "real-world" foreign keys can be implemented in the form of triggers and enforced efficiently by a right combination of indices. In general, it is worthwhile investigating which subsets of the foreign key columns carry the most total values, and then define indices on those subsets. As updates include the maintenance of all affected indices, having too many indices means that the loss in time for their maintenance outweighs the gain in search time when enforcing referential integrity. Some organizations may have a good knowledge of the top-k indices they want to support, but we have made it part of our research to shed further light on what a reasonable number k could be. For this purpose, we applied our analysis to test data in which null marker occurrences are evenly distributed between all possible subsets of columns. That is, we have the least degree of information available about which indices to define. Our recommendation for an n-column foreign key is to exploit $n + 1$ indices on each of the referencing and referenced tables: one compound index on the n columns, and one index on each of the n individual columns. This combination of indices outperforms any other combination for all possible kinds of updates. The finding is confirmed by experiments on two benchmark and one real life database. We remark that the original proposal by Härder and Reinhart to utilize one index for each of the n key columns on the referenced table and one compound index on the foreign key columns of the referencing table performs well only for 2-column key relationships. Essentially, by doubling the number of indices over their proposal, we improve the speed for inserts by a factor of 7, and for deletions by a factor of 123, on the largest data set considered with a 5-column foreign key relationship. Note that this includes the maintenance of all indices involved. Further experiments explain this performance boost over the original proposal: Adding an index for each of the n foreign key columns on the referencing table overcomes the poor performance of the original proposal when deleting tuples from the referenced table that have no alternative match for referencing tuples. Furthermore, adding a single index for the compound key on the referenced table boosts the performance when inserting total tuples in the referencing table. The only trade-off we found is that the time for loading data on the referencing table is 1.5 times more, due to building twice as many indices. This one-time cost is feasible.

Organization. The remainder of this paper is organized as follows. We comment on some related work in Section 2. Details on the semantics of referential integrity constraints in SQL are given in Section 3. We describe our ideas of intelligent update and query services in Sections 4 and 5, based on partial semantics. In Section 6 we propose triggers as well as five different index structures for which we will analyze the performance of enforcing partial referential integrity on synthetic data sets in Section 7, and on TPC-C and TPC-H data sets in Section 8. We conclude in Section 9 where we also briefly comment on future work.

2. RELATED WORK

Work on referential integrity has largely addressed inclusion dependencies. A seminal paper on the theory of inclusion dependencies is [2], in which a finite axiomatization for the associated implication problem is presented and the non-k-ary-axiomatizability of both finite and unrestricted implication for functional and inclusion dependencies together is demonstrated. An axiomatization which is not k-ary for the finite implication of functional and inclusion dependencies is presented in [18]. Undecidability of (finite) implication for functional and inclusion dependencies taken together was shown independently by [4] and [19]. Another seminal paper is [12], which also observed the distinction between finite and unrestricted implication for functional and inclusion dependencies, generalized the chase to incorporate functional and inclusion dependencies, and used this to characterize containment between conjunctive queries. Databases have benefited from referential integrity constraints and inclusion dependencies in areas as diverse as database design [15], consistency enforcement [3], query optimization [12], data cleaning [1], data quality [20], and data profiling [24]. Inclusion dependencies have also been considered in XML [13] and RDF [14].

The different semantics of referential integrity, as proposed by the SQL standard [17], have not received much attention from neither academia nor practice. As observed in [22], there are no database management systems that offer built-in support for enforcing partial referential integrity while every database management system offers built-in support for enforcing simple referential integrity. In [9] Härder and Reinhart investigated the functional requirements for preserving simple and partial referential integrity. Indeed, they determined the number and kinds of searches necessary for referential integrity maintenance, without implementation considerations. Their main result was that a combined access path structure is the most appropriate for checking simple semantics, while partial semantics requires very expensive and complicated check procedures. Their "best advice is to avoid the use of `MATCH PARTIAL` at all". If required, they recommend the use of one index for each of the key columns on the referenced table and one compound index on the foreign key columns of the referencing table. They also investigate the performance of multi-dimensional access paths by considering grid file structures. Here, the access costs for partial match queries are remarkably more expensive than their suggested index option. The main reason is that grid files retrieve all matching tuples while partial referential integrity requires only one matching tuple. In conclusion, Härder and Reinhart say that their "presented results rely on the assumption that the search costs are indicative for the entire costs of referential integrity maintenance. This assumption has to be justified through further research especially at the system level. Another interesting question to be answered is whether or not `MATCH PARTIAL` is useful for a real world application". Here, we address both questions.

In a research-in-progress paper [16] we performed a static analysis of the costs for validating simple and partial semantics in a fixed database. Therefore, the analysis did not consider updates at all. It only applied to referential integrity constraints with two columns, and only considered compound indices which refer to all columns of a foreign key. The present paper presents a detailed analysis of the costs for enforcing simple and partial semantics in a dynamic database that is subject to updates; applies to foreign keys with up to five columns, considers multiple index structures on referenced and referencing tables, and proposes triggers and the new intelligent query and update services.

3. REFERENTIAL INTEGRITY IN SQL

Foreign keys form one of the most fundamental classes of integrity constraints, which implement Codd's proposal of referential integrity from his seminal paper [5]. Referential integrity maintains the relationship between two table schemata, which are the referencing schema or child schema, usually denoted by C_S, and the referenced schema or parent schema, usually denoted by P_S. A referential integrity constraint is commonly written as

$$[f_1, \ldots, f_n] \subseteq P_S[k_1, \ldots, k_n]$$

to denote the relationship between the sequence $[f_1, f_2, \ldots, f_n]$ of distinct column names on C_S, usually called the foreign key, and the sequence $[k_1, k_2, \ldots, k_n]$ of distinct column names, which form a candidate key on P_S. For $i = 1, \ldots, n$, the domains of the column names f_i and k_i must match. Intuitively, referential integrity requires that for each tuple c in a child table C there is a matching tuple p in the parent table P. The SQL standard recommends the use of the `MATCH` clause to specify different ways for handling occurrences of the null marker `null` in foreign key and key columns [17].

Under *simple* semantics, the foreign key constraint is satisfied if for every tuple c in the child table C, either $c(f_i) = \texttt{null}$ for some $1 \leq i \leq n$, or there is some tuple p in the parent table P such that $c(f_i) = p(k_i)$ for all $i = 1, \ldots, n$. More precisely,

$$\forall c \in C \left(\left(\bigwedge_{i=1}^{n} c(f_i) \neq \texttt{null} \right) \Rightarrow \exists p \in P \left(\bigwedge_{i=1}^{n} c(f_i) = p(k_i) \right) \right) .$$

Hence, simple referential integrity is never violated by tuples that are partially defined on the foreign key columns.

Under *partial* semantics, the foreign key constraint is satisfied if for every tuple c in the child table C there is some tuple p in the parent table P such that $c[f_1, \ldots, f_n]$ is subsumed by $p[k_1, \ldots, k_n]$. That is,

$$\forall c \in C \exists p \in P\, (c[f_1, \ldots, f_n] \sqsubseteq p[k_1, \ldots, k_n])$$

Here, a tuple c over the column sequence $[f_1, \ldots, f_n]$ is *subsumed* by a tuple p over the column sequence $[k_1, \ldots, k_n]$, if for every $i = 1, \ldots, n$, $c(f_i) = \texttt{null}$ or $c(f_i) = p(k_i)$.

The table from Example 1 satisfies the foreign key constraint [*tour_id*,*site_code*] ⊆TOUR [*tour_id*,*site_code*] on table BOOKING under simple semantics, but not under partial semantics. For instance, the BOOKING-tuple (BRF,`null`) over [*tour_id*,*site_code*] has no TOUR-tuple over [*tour_id*, *site_code*] by which it is subsumed.

Enforcing some referential integrity constraint means that each time the child or parent table is modified it must be verified that the constraint is satisfied by the modified database instance. Therefore, referential integrity is particularly important for transactional databases, or for updates of important data such as master data.

In general, six basic updates must be addressed to accommodate all possible modifications on parent tables P or child tables C. Tuple inserts into P and tuple deletions from C do not cause a violation of referential integrity. The other four update operations, however, ⟨*Insert a new tuple into C*⟩ and ⟨*Update C*⟩, ⟨*Update P*⟩ and ⟨*Delete a tuple from P*⟩ may lead to modified tables that violate referential integrity. If a tuple c from C references a tuple p from P, we call c a child of p, and p a parent of c.

⟨*Delete a tuple from P*⟩: A tuple p from P may be the only parent of some child c from C. That is, there is no other tuple p' in P which is a parent of c. Deleting such single parents from P will always violate referential integrity.

⟨*Update P*⟩: This update can be interpreted as ⟨*Delete a tuple from P*⟩ along with ⟨*Insert a new tuple into P*⟩. Therefore, it may only cause a referential integrity violation due to the Delete action.

⟨*Insert a new tuple into C*⟩: Referential integrity requires for every newly inserted child c in C the existence of a parent p in P. Otherwise, referential integrity is violated.

⟨*Update C*⟩: An update of a child in C can be interpreted as a delete from C followed by an insert into C. Only the insert into C can lead to a violation of referential integrity.

According to the SQL standard, inserts into C or updates on C are only allowed if they result in a new child table that satisfies the referential integrity constraints defined on C_S. However, different actions can be applied when a delete from P or an update on P results in the violation of some referential integrity constraint. Based on the SQL standard, "CASCADE", "SET NULL", "SET DEFAULT", "RESTRICT" and "NO ACTION" are available referential actions.

Under simple semantics, every child has at most one parent. Under partial semantics, any child may have several parents, given that the child has a null marker occurrence in some of its foreign key columns. If the state of a child is defined as the subset of the n foreign key columns on which it is `null`, then each given parent may have up to $2^n - 1$ children that have pairwise different states. If u denotes the number of null marker occurrences ($0 \leq u < n$), $\binom{n}{u}$ is the number of distinct states with u null marker occurrences [9].

Example 2. *Given a 3-attribute key with value $\langle 1,2,3\rangle$ on the key columns, the seven different states may result from children with the following values on their foreign key columns: $\langle 1,2,3\rangle$, $\langle null,2,3\rangle$, $\langle 1,null,3\rangle$, $\langle 1,2,null\rangle$, $\langle null, null,3\rangle$, $\langle null,2,null\rangle$ and $\langle 1,null,null\rangle$. Each of the non-total children may have some other parent. The parent with $\langle 4,2,3\rangle$, for example, has also children with the following values on their foreign key columns $\langle null,2,3\rangle$, $\langle null,2,null\rangle$ and $\langle null,null,3\rangle$.*

4. AN INTELLIGENT UPDATE SERVICE

We propose an intelligent update service that enables us to give an affirmative answer to Härder and Reinhart's question "whether or not `MATCH PARTIAL` is useful for a real world application?" [9].

Null markers offer great flexibility for data entry, but have serious consequences. Indeed, the level of information completeness is an important factor for data quality [7]. Partial data causes significant problems for enterprises: it routinely leads to misleading analytical results and biased decisions, and accounts for loss of revenue, credibility and customers [7]. We propose the use of `MATCH PARTIAL` for intelligent updates of data. For a given foreign key $[f_1,\ldots,f_n] \subseteq P_S[k_1,\ldots,k_n]$ on C_S we propose the following two strategies to reduce information incompleteness.

4.1 Intelligent Insertions

Suppose a new tuple c is inserted into the child table C and $c(f_i) =$ `null` on some foreign key column $f_1,\ldots,f_n$. Then the database management system (DBMS) determines all parents p of the parent table P where $c[f_1,\ldots,f_n] \sqsubseteq p[k_1,\ldots,k_n]$. For each of these parents p, the DBMS computes the tuple c_p that results from c by replacing each null marker occurrence $c(f_i) =$ `null` by the value $p(k_i)$, where $i = 1,\ldots,n$. Finally, the tuples c_p are presented as alternatives to c for insertion into C.

For instance, suppose again that the tuple $c =$ (1011, RF, `null`, Oct 5th) is not already part of the Booking table in Example 1, but about to be inserted into it. Our intelligent update service would determine all possible parents of c in Tour, which are $p =$ (RF, BB, Binna Burra) and $p' =$ (RF, OR, O'Reilly's), and present the tuples $c_p =$ (1011, RF, BB, Oct 5th) and $c_{p'} =$ (1011, RF, OR, Oct 5th) as alternatives to $c =$ (1011, RF, `null`, Oct 5th) for insertion into Booking.

4.2 Intelligent Deletions

Suppose an existing tuple p is deleted from P. For all children c of p in C where $c[f_1,\ldots,f_n] \sqsubseteq p[k_1,\ldots,k_n]$ and $c(f_i) =$ `null` on some $f_1,\ldots,f_n$, the DBMS determines all alternative parents of p in $P - \{p\}$, i.e. those tuples $p' \in P - \{p\}$ where $c[f_1,\ldots,f_n] \sqsubseteq p'[k_1,\ldots,k_n]$. It then computes the tuple $c_{p'}$ that results from c by replacing each null marker occurrence $c(f_i) =$ `null` by the value $p'(k_i)$, where $i = 1,\ldots,n$. Finally, for each child c of p the tuples $c_{p'}$ are presented as potential updates of c in C.

For instance, consider the tables from Example 1. Suppose the tuple $p =$ (RF, OR, O'Reilly's) is deleted from the Tour table. The only child of p in Booking is $c =$ (1011, RF, `null`, Oct 5th), and the only alternative parent of c in Tour is $p' =$ (RF, BB, Binna Burra). Consequently, the DBMS presents the tuple $c_{p'} =$ (1011, RF, BB, Oct 5th) as an update of the tuple c in Booking.

We propose two different approaches for implementing intelligent deletions. In Method 1, the existence of alternative parents is first checked in P. Then the potential updates are ranked according to the number of affected children in C and presented to the user for confirmation.

Algorithm 1 Intelligent Deletion: Method 1

```
Require: Deleted tuple: $p[k_1,\ldots,k_n]$, referential action
Ensure: Updated $C$ under Partial Semantics
 1: forall $c \in \mathbf{C}$ such that $\bigwedge_{i=1}^{n} c(f_i) \neq$ null and
    $\bigwedge_{i=1}^{n} c(f_i) = p(k_i)$ do Apply referential action
 2: for u:=1 to n-1 do
 3:     $S[u] \leftarrow \{S_{uj} |$ the $j^{th}$ state of $\langle k_1,\ldots,k_n\rangle$ with $u$
        nulls, for all j=1 to $\binom{n}{u}\}$
 4:     for all $S_{uj} \in S[u]$ do
 5:         $Q[S_{uj}] \leftarrow \{p' \in P - \{p\} | S_{uj} \sqsubseteq p'[k_1,\ldots,k_n]\}$
 6:         $l_{uj} \leftarrow$ number of $c$ in $C$ match $S_{uj}$
 7:         $l_{mj} \leftarrow$ number of $c$ in $C$ match $S_{mj}$ such that
            $m = u+1$ to $n-1$ and $S_{mj} \sqsubseteq S_{uj}$
 8:         $l'_{uj} \leftarrow l_{uj} + l_{mj}$
 9:         if $Q[S_{uj}] = \emptyset$ and $l_{uj} \neq 0$ then
10:             Apply referential action on $S_{uj}$ states in $C$
11:             $l'_{uj} \leftarrow 0$
12:     $L \leftarrow \{(l'_{uj}, Q[S_{uj}]\}$
13:     if $\exists\, l'_{uj} \neq 0 \in L$ then
14:         $S'_u \leftarrow S_{uj}$ with Max($l'_{uj}$)
15:         Output: Set $Q[S'_u]$ and $S'_u$ (foreign key)
16:         Input: If $p' \in Q[S'_u]$ is selected then Subsume all
            $c = S_{uj}$ and $c = S_{mj}$ by $p'$
17:         $l'_{uj} \leftarrow 0$ and $L \leftarrow \{(l'_{uj}, Q[S'_u]\}$
```

In Method 2, the intelligent system first finds all children of the given parent. For each of these children, the system then finds all alternatives. The choice of method depends on the requirements of the application.

4.3 Implementation

The system is available on `http://sqlkeys.info` and has been tested on the 3-column foreign key of the TPC-C benchmark database from the Transaction Processing Performance Council (`http://www.tpc.org`). Figure 1 shows how users can insert either their original record or a more informative record, whatever is perceived to be the better choice. Figures 2 and 3 show screenshots of the two deletion methods. Indeed, the choice of continuing with incomplete foreign keys

Algorithm 2 Intelligent Deletion: Method 2

```
Require: Deleted tuple: $p[k_1, \ldots, k_n]$, referential action
Ensure: Updated $C$ under Partial Semantics
 1: forall $c \in \mathbf{C}$ such that $\bigwedge_{i=1}^{n} c(f_i) \neq$ null and
    $\bigwedge_{i=1}^{n} c(f_i) = p(k_i)$ do Apply referential action
 2: for u:=1 to n-1 do
 3:     $S[u] \leftarrow \{S_{uj}|$ the $j^{th}$ state of $\langle k_1, \ldots, k_n \rangle$ with $u$
        nulls, for all j=1 to $\binom{n}{u}\}$
 4:     for all $S_{uj} \in S[u]$ do
 5:         $l_{uj} \leftarrow$ number of $c$ in $C$ match $S_{uj}$
 6:     $L \leftarrow \{(l_{uj}, Q[S_{uj}]\}$
 7:     if $\exists\, l_{uj} \neq 0 \in L$ then
 8:         $S'_u \leftarrow S_{uj}$ with Max$(l_{uj})$
 9:         $Q[S'_u] \leftarrow \{p' \in P - \{p\} | S'_u \sqsubseteq p'[k_1, \ldots, k_n]\}$
10:         if $Q[S'_u] = \emptyset$ then
11:             Apply referential action on $S'_u$ states in $C$
12:         else
13:             Output: Set $Q[S'_u]$ and $S'_u$ (foreign key)
14:             Input: If $p' \in Q[S'_u]$ is selected then Subsume
                all $c = S_{uj}$ and $c = S_{mj}$ by $p'$ where $m = u+1$
                to $n-1$ and $S_{mj} \sqsubseteq S_{uj}$
15:             $l_{uj} \leftarrow 0$ and $L \leftarrow \{(l_{uj}, Q[S'_u]\}$
```

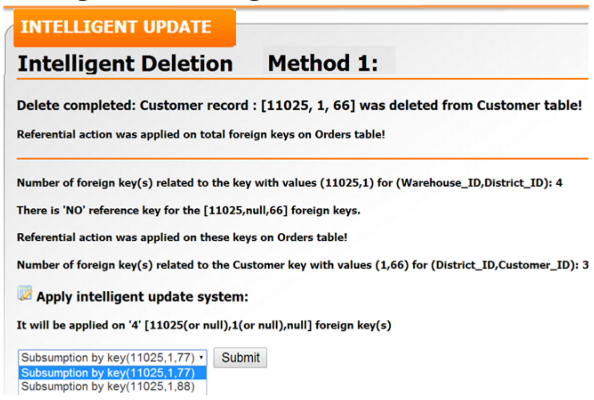
is available to users, however, referential action will be applied on the foreign keys which violate partial referential integrity.

Use cases. It is straightforward to envision novel use cases of the intelligent update service. For example, when updates are run manually, the user can be presented directly with available choices for the imputation of null markers. This can be customized further, for example, according to the preferred number of such choices or to the access rights the user enjoys. The decision should be based on the efficiency and quality requirements for data entry as well as the expertise of the user. When updates are run mechanically, it is particularly advisable to record the available choices for imputation in the form of a log. This log can be inspected later on for analytical purposes, or to assist with data cleaning. An interesting use case occurs whenever transactions are aborted due to null marker occurrences in child columns that are part of the primary key. Exploiting partial semantics to impute these occurrences by some matching consistent values may result in the successful completion of the transaction. In any case, the intelligent update service can help reduce information incompleteness in ways current services cannot.

Figure 2: Intelligent Deletion Method 1



INTELLIGENT UPDATE

Intelligent Deletion Method 1:

Delete completed: Customer record : [11025, 1, 66] was deleted from Customer table!

Referential action was applied on total foreign keys on Orders table!

Number of foreign key(s) related to the key with values (11025,1) for (Warehouse_ID,District_ID): 4

There is 'NO' reference key for the [11025,null,66] foreign keys.

Referential action was applied on these keys on Orders table!

Number of foreign key(s) related to the Customer key with values (1,66) for (District_ID,Customer_ID): 3

Apply intelligent update system:

It will be applied on '4' [11025(or null),1(or null),null] foreign key(s)

Subsumption by key(11025,1,77)
Subsumption by key(11025,1,77)

5. AN INTELLIGENT QUERY SERVICE

The occurrence of null markers in query answers restricts the insights that stakeholders can gain from data. It is therefore important that database systems raise user awareness of actual data values that null markers may represent. By example, we will now explain why partial referential integrity constitutes a prime mechanism to reduce information incompleteness in query answering. Consider the following query which returns the *tour_id* and *site_code* of all bookings:

```
SELECT Tour_id, Site_code
FROM BOOKING
```

On our database from Example 1, the standard answer to this query consists of the records that are written in normal font below:

Tour_id	Site_code
BRF	null
BRT	OR
null	BB
RF	**BB**

Tour_id	Site_code
null	BR
RF	null
RF	**BB**
RF	**OR**

Partial semantics suggests to add the records written in bold font, as these have corresponding parents in the TOUR table. As illustrated above, users benefit from highlighting non-standard answers and placing them directly below the records in the standard answer from which they originate.

Summary. Our intelligent query and update services exploit partial semantics to minimize information incompleteness. This results in higher quality data, better data-driven decision making, and more competitive organizations. Both services complement each other: Fewer choices for imputation mean fewer choices for intelligent updates, and more choices for imputation mean more non-standard query answers users can benefit from. So, whichever case we encounter at least one of the services is useful. It is beyond the scope of this paper to go deeper into the specific application of our proposed services. Instead, we see them as strong drivers to investigate the second open question, that is, whether partial semantics can be enforced efficiently.

6. OPERATIONAL REQUIREMENTS

This section examines the two main operational requirements for enforcing partial semantics. First, we propose implementation details in the form of triggers on child and parent schemas. Next we discuss five different index structures. Their impact on the performance of enforcing partial referential integrity will be analyzed in subsequent sections.

6.1 Triggers for Partial Referential Integrity

Foreign keys commonly enforce simple semantics in current database management system implementations. Our next goal is to define triggers that enforce partial referential integrity under updates. For that purpose we first propose a trigger on the referencing child schema C_S. This trigger will enforce partial referential integrity for ⟨*Insert*⟩ and ⟨*Update*⟩ modifications on any child table C. The referential action we uniformly consider in our experiments is ⟨*SET NULL*⟩.

We have designed a platform on `www.sqlkeys.info` which generates triggers for enforcing partial semantics on any arbitrary database with foreign keys up to size five. Below is the SQL code for a trigger that implements a referential integrity constraint on $n = 3$ columns:

```
Trigger on C_S:
BEFORE INSERT ON C_S FOR EACH ROW
Declare msg varchar(80);
If (new.f1 is not null and new.f2 is not null and
    new.f3 is not null) then
  if not exists (select * from P_S where (k1=new.f1
  and k2=new.f2 and k3=new.f3)) then
  set msg ='No reference is found, enter a valid value';
  signal sqlstate '02000' set message_text = msg;
  end if;
Elseif (new.f1 is not null and new.f2 is not null and
  new.f3 is null) then if not exists(select * from P_S
  where (k1=new.f1 and k2=new.f2) LIMIT 1) then
  set msg ='No reference is found, enter a valid value';
  signal sqlstate '02000' set message_text = msg;
  end if;
Elseif (new.f1 is not null and new.f3 is not null and
  new.f2 is null) then if not exists (select * from P_S
  where (k1=new.f1 and k3=new.f3) LIMIT 1) then
  set msg ='No reference is found, enter a valid value';
  signal sqlstate '02000' set message_text = msg;
  end if;
Elseif ... /* similar for all 2^n − 1 possible states */
End if;
End;
```

For ⟨*Delete*⟩ and ⟨*Update*⟩ modifications on the parent schema P_S another trigger is defined. The SQL code of the trigger in the case of $n = 3$ columns is as follows:

```
Trigger on P_S:
AFTER DELETE ON P_S FOR EACH ROW
Update C_S set f1 =null, f2 =null, f3 =null where
    (old.k1 = f1 and old.k2 = f2 and old.k3 = f3);
If   exists (select * from C_S where (f2 is null and f3
   is null and old.k1 = f1) limit 1) and not exists
  (select * from P_S where old.k1 = p.k1 limit 1)
then   update C_S set f1 =null, f2 =null, f3 =null
  where ((f2 is null or f3 is null) and old.k1 = f1);
end if;
If   exists(select * from C_S where (f1 is null and
  f3 is null and old.k2 = f2) limit 1) and not exists
  (select * from P_S where old.k2 = p.k2 limit 1)
then   update C_S set f1 =null, f2 =null, f3 =null
  where ((f1 is null or f3 is null) and old.k2 = f2);
end if;
If   exists (select * from C_S where (f1 is null and f2
  is null and old.k3 = f3) limit 1) and not exists
  (select * from P_S where old.k3 = p.k3 limit 1)
then   update C_S set f1 =null, f2 =null, f3 =null
  where ((f1 is null or f2 is null) and old.k3 = f3);
end if; /* similar for all 2^n − 1 possible states */
End;
```

6.2 Index Structures

One feature that significantly affects the system behavior is the index structure applied to the referenced and referencing tables. An appropriate index structure can optimize searches and improve the performance by several reads in one scan.

0) *No*: No index is defined. This option is a baseline for judging the performance of actual indices.

1) *Full*: One index is defined on $[k_1, \dots, k_n]$ over P_S, and one index on $[f_1, \dots, f_n]$ over C_S. Full enforces simple semantics [22]. Full might not improve partial referential integrity enforcement since a null marker in the foreign key may lead to a complete scan on all parent key values from the leftmost to the rightmost column [9].

2) *Singleton*: One index is defined for each k_i over P_S, and for each f_i over C_S, for $i = 1, \dots, n$, resulting in $2n$ indices. With individual access to each column this approach is expected to boost the performance of enforcing partially-defined foreign keys [9].

3) *Hybrid*: One index is defined for each k_i over P_S, and a single index on $[f_1, \dots, f_n]$ over C_S, resulting in $n+1$ indices. According to [9], Hybrid takes advantage of both Full and Singleton options, and the authors conjectured that Hybrid best supports partial semantic.

4) *Powerset*: One index is defined on each non-empty subset of P_S, and on each non-empty subset of C_S, resulting in $2^{n+1} - 2$ indices. Powerset shows the impact of having all possible indices available.

5) *Bounded*: One index is defined on $[k_1, \dots, k_n]$ and one index for each k_i over P_S, and one index is defined on $[f_1, \dots, f_n]$ and one index for each f_i over C_S, for $i = 1, \dots, n$, resulting in $2n + 2$ indices. This structure combines Full, Singleton, and Hybrid, and reduces Powerset to just the singletons (lower bound) and the full subset (upper bound) instead of all subsets. Bounded outperforms all other structures in our experiments.

Table 1: Execution Time (s) for Insertion with a 5-Column Foreign Key

Data Set Size	Partial Semantics												Simple Semantics	
	No Index		Full		Singleton		Hybrid		Powerset		Bounded			
	Ave	Max	Ave	Max	Ave	Max	Ave	Max	Ave	Max	Ave	Max	Ave	Max

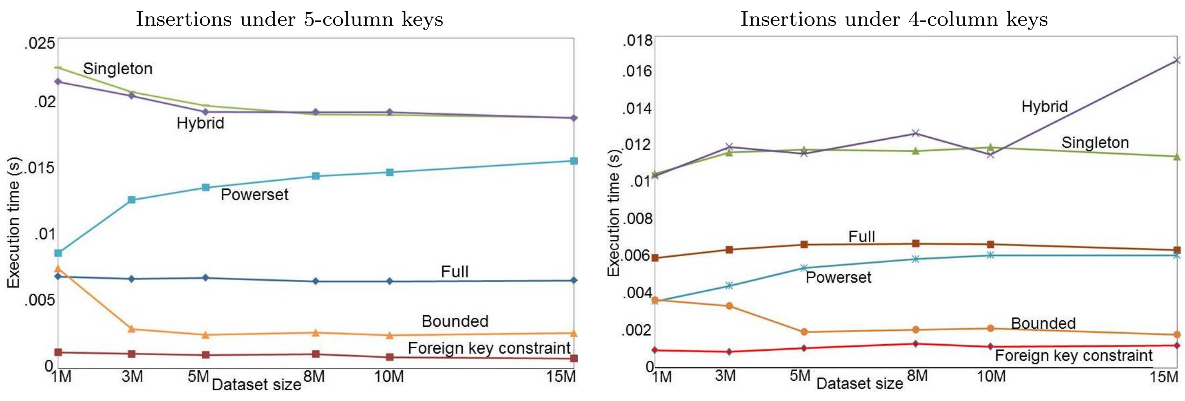
Figure 4: Performance Trends for Enforcing Partial Semantics under Insertions and Different Indices



7. EXPERIMENTS ON SYNTHETIC DATA

We report on some of our experiments to evaluate the performance of enforcing partial semantics. Experiments were run on a Dell Latitude E5530, Intel core i7, CPU 2.9GHz with 8GB RAM. The operating system was Windows 7 Professional, Service pack 1 on a 64-bit operating system. The DBMS we used was MySQL version 5.6.

7.1 Description

All experiments involved two table schemata P_S and C_S and the foreign key $[f_1, \ldots, f_n] \subseteq P_S[k_1, \ldots, k_n]$ on C_S. Here, n varied between 2 to 5 to focus on the constraints that mostly occur in practice. For $n = 1$ there is no difference between simple and partial semantics. Parent table P and child table C were populated with synthetic data sets of various sizes between 1M and 15M tuples in P and 1.5 times as many tuples in C, respectively. Columns of the candidate key $\{k_1, \ldots, k_n\}$ on P_S did not feature `null`, while null markers did occur in the foreign key columns $\{f_1, \ldots, f_n\}$ in C. This allows us to gain insights on the foreign keys that mostly occur in practice. Each non-empty subset S of $\{f_1, \ldots, f_n\}$ had the same number of tuples in C which featured null markers in all columns in S and no null markers in any column outside of S. This also meant that the order of columns in a compound index does not matter in the experiments. We also run experiments where 50% and 80% of the tuples in C featured null markers in the foreign key columns, but the performances were very similar in each case. The performance of enforcing $[f_1, \ldots, f_n] \subseteq P_S[k_1, \ldots, k_n]$ was measured as the average time to insert tuples in C and to delete tuples from P, respectively, exploiting the triggers and different index structures from Section 6. For each data set and each index structure, the average was taken over 5,000 deletes and 5,000 inserts, respectively. We also compared the performance against that of simple semantics, enforced by built-in foreign keys. Note that execution times include the time for the trigger and the maintenance of the index structure. All reported experiments used BTrees. Applying Hash indices to our experiments resulted in similar outcomes, showing worse performance with minor exceptions. For these reasons we do not further comment on Hash indices here.

7.2 Impact of Indices

The impact of the index structures from Section 6 on the performance of enforcing partial semantics is the central contribution of our work. Tables 1 and 2 show the times to perform insertions into C and deletions from P, respectively, on the different data sets and where $n = 5$. These times are illustrated in Figures 4 and 5, respectively, along with the results for the same tests where $n = 4$. As expected, the use of indices leads to tremendous time savings for insertions and deletions. Our experiments confirm Härder and Reinhart's calculations that *Hybrid* achieves a performance similar to that of *Singleton* under insertions, and to that of *Full* under deletions. That is, it combines the performance gains of *Singleton* over *Full* under insertions, and the gains of *Full* over *Singleton* under deletions [9]. However, *Powerset* performs better than *Hybrid* under both insertions and deletions, and *Bounded* is the clear winner for both operations. On the largest data set with the largest foreign key size, for example, *Bounded* performs insertions/deletions on average about 7/123 times faster than *Hybrid*. The difference is considerable: the average time for deletions is 7.03s for *Hybrid* while it is 57ms for *Bounded*. *Bounded* is 6/9 times faster than *Powerset* on the largest data set. The

Table 2: Execution Time (s) for Deletion with a 5-Column Foreign Key

Data Set Size	Partial Semantics												Simple Semantics	
	No Index		Full		Singleton		Hybrid		Powerset		Bounded

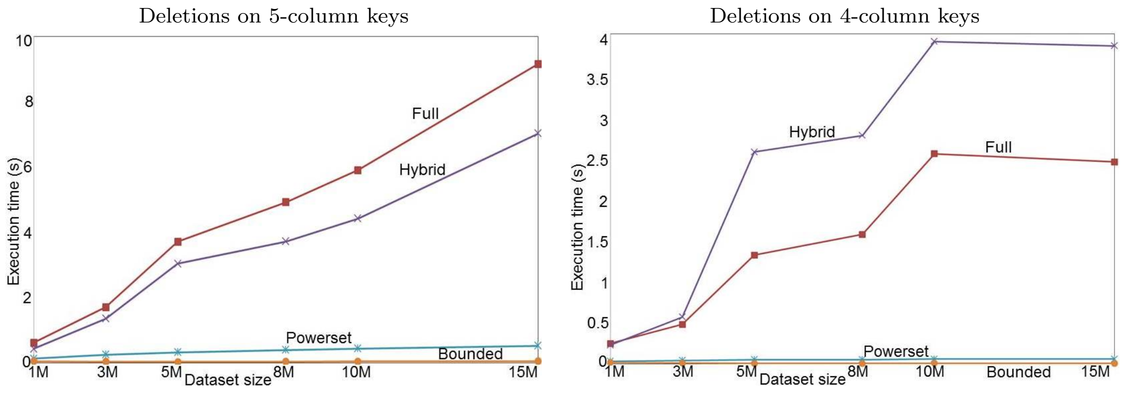
1M	19.61	41.77	0.62	13.58	3.5	25.4	0.44	8.70	0.140	0.577	0.057	0.266	0.0011	0.031

Figure 5: Performance Trends for Enforcing Partial Semantics under Deletions and Different Indices



performance gain of *Bounded* over *Powerset* shows that the additional time for maintaining further indices in *Powerset* and to choose the index from all the options in *Powerset* outweighs the time gains for the actual operations by *Powerset* in comparison to *Bounded.* Due to space restrictions we only present the results for 5-column foreign keys. For 3-column and 4-column foreign keys the index structures show similar behavior as the ones presented for 5-column foreign keys. Table 3 illustrates the results of applying *Bounded* and *Hybrid* on a synthetic data set of size 100M with a 5-column foreign key.

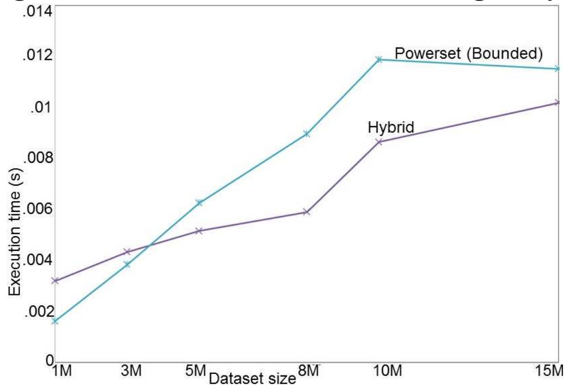
Table 3: Execution Time (s) for 100M Data Set under some Index Structures and 5-Column Foreign Key

	Insertion		Deletion	
	Mean	Max.	Mean	Max.
Hybrid	0.013	0.156	39.74	976.23
Bounded	0.0027	0.063	0.085	0.281
Simple S.	0.001	0.047	0.0021	0.062

Exception. *Hybrid* shows the best performance when $n = 2$ and the data set size is large. For example, on the largest data set it takes 2.8/10.2ms for insertions/deletions, while these times increase to 4.3/11.5ms on *Powerset*, see Figure 6. Note that *Powerset* and *Bounded* coincide when $n = 2$.

Simple semantics. Of course, it takes longer to enforce partial than simple semantics. However, the additional time becomes feasible under *Bounded.* For example, for insertions/deletions on the 15M data set with a 5-column foreign key, partial semantics is enforced by about 2.6/57ms, respectively. This takes 3.4/22 times longer than for simple

Figure 6: Deletions for 2-Column Foreign Keys



semantics, while it takes 22/2703 times longer than for simple semantics using *Hybrid.* Even on a data set with 100M tuples, inserts and deletions can be processed within 2.7ms and 84.8ms, respectively, using *Bounded.* This confirms the feasibility of enforcing partial semantics on even large foreign key sizes.

7.3 Index Building

While the time to load data and build the indices is just a *one-time* cost, we still include it in our analysis. Table 4 shows the time taken to load data and build the indices on all data sets. Not surprisingly, the more indices are defined the longer it takes to build them. Building *Powerset* is thus time-consuming: more than 3hrs and 53mins on the largest data set, while *Hybrid* takes just over 10mins. *Bounded*, with twice as many indices as *Hybrid*, takes about 14mins

Table 4: Times (s) for Loading Data and Building Indices for 5-Column Key

Data Size	No Index		Full		Singleton		Hybrid		Powerset		Bounded		Foreign key
	C	*P*	*C*	*P*	*C*	*P*	*C*	*P*	*C*	*P*	*C*	*P*

and 30s. The foreign key index is built in 9mins and 47s.

7.4 Impact of Update Size

We performed some experiments with transactions, that is, atomic sets of update operations. The reported experiments were conducted for the 5-column foreign key on the data set with 15M tuples. The first experiment featured an insert of 5,000 tuples into C, and the second experiment a deletion of 2,000 tuples from P. The results are illustrated in Table 5. The transaction with 5,000 inserts takes just under 7s with *Bounded*, and nearly 90s with *Hybrid*. For the transaction with 2,000 deletions it takes over 148mins with *Hybrid*, and just under 111s with *Bounded*.

Table 5: Execution Time (s) of Transactions under Index Structures on Data Set with 15M Tuples

	5000 Insertions	2000 Deletions
Full	28.533	13413.16
Singleton	90.137	59191.81
Hybrid	89.65	8922.6
Powerset	102.81	605.71
Bounded	6.973	110.37
Simple S.	0.811	32.92

7.5 Extended Tests and Analysis

Deletions. Tables 2 and 5 show the poor performance of *Hybrid* on delete actions, and that it is overcome by *Bounded*. We will now analyze how *Bounded* achieves this. For that purpose, we exploited MySQL's explain statement which shows the optimizer's plan in executing the statements of each test. Recall that *Hybrid* has only one compound index over all foreign key columns in C_S. When we *Delete* from P, this means that one scan through all tuples is required to apply the referential action to children that feature `null` on the left most column. However, the referential action is only needed when there is no alternative parent for these children. Establishing that referential action must be applied to children whose only parent has been deleted is therefore poorly supported by *Hybrid*. We validated this observation by applying a deeper analysis to the experiment with our data set of 10M tuples. For this purpose, we call a parent *unique* when it has only children for which it is the only parent. Therefore, referential actions apply to all children of a unique parent. Otherwise, the parent is called *non-unique*. Table 6 shows the average execution time for deleting unique and non-unique parents when *Hybrid* is applied.

Table 7 shows the average execution time for deleting non-unique and unique parents when *Bounded* is applied.

These results show that *Hybrid* performs particularly poor when deleting unique parents. The same analysis applies to transactions. In fact, only 3% of the deleted parents were unique. With *Hybrid* they occupied 145mins of the overall time of 148mins, but with *Bounded* they occupied only 0.5s of the overall time of 111s, refer to Table 13.

Table 6: *Hybrid* for Deletions, Average of Execution Times

Key size	Non-unique Parent	Unique Parent
5-Column keys	0.525s	40.47s
4-Column keys	2.37s	18.68s
3-Column keys	0.022s	17.59s

Table 7: *Bounded* for Deletions, Average of Execution Times

Key size	Non-Unique Parent	Unique Parent
5-Column keys	0.051s	0.005522s
4-Column keys	0.00976s	0.00305s
3-Column keys	0.00348s	0.00167s

This poor performance of *Hybrid* can be avoided by adding to *Hybrid* one index on each foreign key attribute f_i on C_s. The resulting structure consists of $2n + 1$ indices in total, and we refer to it by *Hybrid+nSingle*. Table 8 shows the average execution time for deleting non-unique and unique parents when *Hybrid+nSingle* is applied.

Table 8: *Hybrid+nSingle* for Deletions, Average of Execution Time

Key size	Non-Unique Parent	Unique Parent
5-Column keys	0.413s	0.0061s
4-Column keys	2.29s	0.003s
3-Column keys	0.0237s	0.00233s

Another index structure that we have also tested is *Hybrid+Compound*, which consists of *Hybrid* plus one index over the key columns of P_S. *Hybrid+Compound* has therefore a total of $n + 2$ indices. For deletions, the additional index improves the search for children which are not null in the leftmost columns. This is demonstrated by comparing the results for *Non-Unique Parents* in Tables 7 and 8.

Figure 7 illustrates how well *Hybrid+nSingle* and *Hybrid+Compound* perform deletions in comparison to the other indices. Clearly, the performance boost of *Bounded* over *Hybrid* for deletions is mainly due to adding *nSingle*.

Insertions. Figure 8 illustrates how well *Hybrid+nSingle* and *Hybrid+Compound* perform insertions in comparison to the other indices. Clearly, the performance boost of *Bounded* over *Hybrid* for insertions is mainly due to adding *Compound*.

A deeper analysis confirms our intuition that *Hybrid* performs particularly poorly when inserting tuples that have only total foreign key values. Figure 9 breaks down the per-

Figure 7: Performances under Deletions with 5-Column Foreign Keys

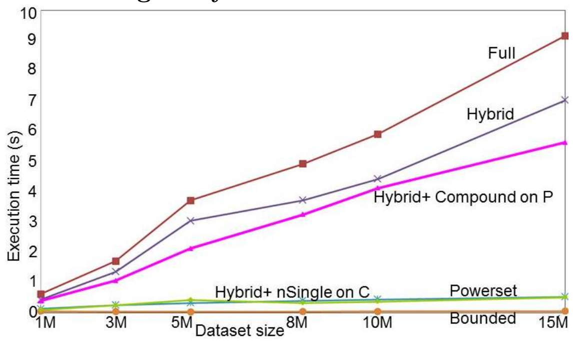

Figure 8: Performance under Insertions with 5-Column Foreign Keys

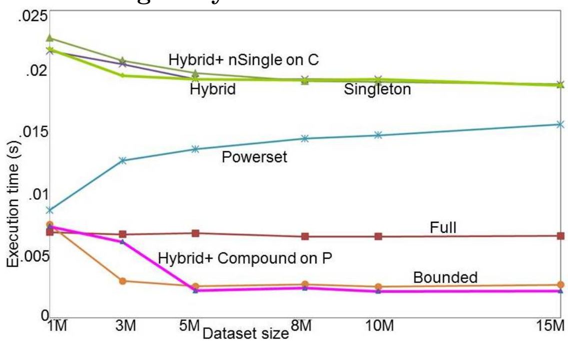
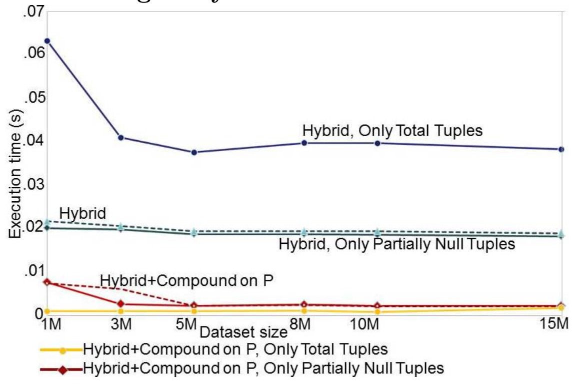


formance of *Hybrid* and *Hybrid+Compound* into insertions of tuples with only total foreign keys and those that are partially `null`.

Figure 9: Performance under Insertions with 5-Column Foreign Keys



Bounded is the only index structure that performs well under insertions and deletions, since it does not suffer from poor performance for insertions like *Hybrid+nSingle* and for deletions like *Hybrid+Compound*. In comparison to *Hybrid+nSingle* the better performances are achieved under negligible additional costs for building the indices, see Tables 11 and 12.

Transactions. Table 13 shows how the new index structures perform in transactions. *Hybrid+Compound* performs best for insertions but takes 149mins for deleting 2000 parents, while *Bounded* takes just 110s. *Hybrid+nSingle* is the runner-up to *Bounded* for deletions, but performs poorly for insertions.

8. BENCHMARK DATA

We extend our analysis of enforcing partial semantics to some benchmark and real-world data. For that purpose, we have run experiments on one two-column foreign key from the TPC-H database and two three-column foreign keys from the TPC-C database (`www.tpc.org`). In addition, we have tested one three-column foreign key from the Gene Ontology (GO) database (`www.geneontology.org/GO.database.shtml`). Table 9 shows the details of the foreign keys. Here, the data set size for test 1 on TPC-H was 1.43GB, and for test 2 it was 10GB; for TPC-C it was 0.39GB, and for the GO database it was 100MB. Applying the "Missing at Random" mechanism from [23], null markers were introduced randomly and spread evenly between the foreign key columns.

We have tested the TPC-H benchmark with two different data set sizes (0.8M and 8M tuples). Note that *Powerset* and *Bounded* coincide on 2-column foreign keys and thus on the experiments with TPC-H. The results of enforcing partial and simple semantics on these databases are shown in Table 10. The performances rank very similar to those on the synthetic data sets. Our results on TPC-H confirm the observed changes on the performance of *Hybrid* and *Powerset* on larger data sets with 2-column foreign keys, see Figure 6. The TPC-C data set with the 3-column foreign keys confirms our result with the synthetic data sets that

Table 9: Detail of the tested TPC databases

Database	Parent table	Child table	Foreign key
TPC-H	Partsupp Test 1: 0.8M records Test 2: 8M records	Lineitem 6M records 25% Null 60M records 60% Null	[*partkey*, *suppkey*] ⊆ Partsupp[*partkey*, *suppkey*]

Delete from Orders	2.92(s)	18.6	1.05(s)	15.58	3.78	3.52	1.285
GO Database: Insert into TT	15.6	6.16	1.31	1.16	2.37	1.3	1.12
Delete from T	54.2	2.11	17.35	12.6	2.4	1.87	1.06

Bounded outperforms *Hybrid* by a factor of 2 for insertions and by 5 for deletions. Similar results have been observed on the Gene Ontology database. The best times for enforcing partial semantics are never over 6ms while the times for enforcing simple semantics are never over 4ms.

9. CONCLUSION AND FUTURE WORK

Even two decades after its introduction to the SQL standard there are no database management systems with built-in support for partial referential integrity. Härder and Reinhart had argued on the operational level that partial semantics is too costly to implement [9]. They invited more research on its motivation and its costs at the systems level [9]. In this paper we addressed both questions. Firstly, we proposed intelligent update and query services that impute missing data values by exploiting partial semantics. In particular, we discussed how these services reduce information incompleteness in the database and suggest possible values by which null markers can be replaced in query answers. Secondly, we proposed two main operational requirements to enforce and speed up the enforcement of partial semantics, and conducted several performance tests in MySQL. Our tests were targeted at foreign keys that occur commonly in practice. These have very rarely more than five columns and reference candidate keys without null marker occurrences. Permitting occurrences of `null` in referenced candidate keys only affects our results marginally. Our first major finding confirms on the system level what Härder and Reinhart had calculated on the operational level: (1) The performance of the *Hybrid* index structure matches that of the *Singleton* index structure for insertions, and that of the *Full* index structure for deletions. (2) *Hybrid* is the best candidate to support `MATCH PARTIAL`, but only for 2-column foreign keys. We proposed here the new index structure *Bounded* for foreign keys with more than two columns. Our second major finding is that *Bounded* outperforms *Hybrid* for foreign keys with more than two columns. For example, for a 5-column foreign key on a data set with 15M tuples and a fair distribution of null markers, *Bounded* performed 7 times better for insertions and 123 times better for deletions. The better performance was confirmed on other synthetic data sets, for transactions, for two TPC-C data sets and a three-column foreign key on the Gene Ontology database. The only trade-off we found concerns the loading time of the data set and building of the indices, which essentially were 1.5 times more in comparison to *Hybrid*. Our third major finding is that the performance boost of *Bounded* for deletions results from adding one index to *Hybrid* on each foreign key column, and the performance boost of *Bounded* for insertions results from adding one index on the compound key to *Hybrid*. Overall, the enforcement of partial semantics with *Bounded* was never slower than 300ms for any atomic operation with a 5-column foreign key, while the enforcement of simple semantics was never slower then 62ms. Based on our results, we conclude that partial referential integrity can be enforced efficiently for real-life foreign keys, which opens up new applications such as intelligent queries and intelligent updates that lead to better quality data and better data-driven decision making. These applications do not apply to simple referential integrity. Our results demonstrate the benefits of partial semantics, and *Bounded* offers a principled approach to indexing foreign keys with partial semantics that can be added on top of existing databases in a non-intrusive fashion.

We hope our research will ignite future work on this topic. Certainly there are many interesting questions that a single paper cannot address, but which should be pursued in future work to unlock many potential benefits. Other indexing options can be studied, for example the combination of compound indices over key attributes and multidimensional access paths at the system level. An index option including $2n$ compound n-ary indices over the referenced key attributes $[k_i, \ldots, k_n, k_1, \ldots, k_{i-1}]$ and referencing key attributes $[f_i, \ldots, f_n, f_1, \ldots, f_{i-1}]$, for $i = 1, \ldots, n$, supports partial match index look-ups by the different prefixes of the compound indices. However, our initial analysis shows that *Bounded* outperforms this index option in deletions of 3, 4 and 5-column foreign keys by more than 3 times on data sets with 15M tuples. The loading times of the data sets and building of the indices in *Bounded* are always between 1.5 to 4 times cheaper. Exploiting $2n$ compound indices over key attributes is not enough to support all the possible partial match queries. For instance when $n = 5$, defining 2×5 compound indices in different orders only supports 21 of 31 match queries. Another interesting avenue deals with the trade-off between query and enforcement issues. While our results show that enforcement and maintenance of partial semantics are unlikely bottlenecks on databases of enterprise-level size (10GB in test 2 for TPC-H), future research should be aimed at guidelines for resolving conflicts between resources for query and update acceleration in schemata for big data. While our solution of implementing enforcement by database triggers and index primitives is appealing in several ways, future work may reveal potential performance gains that could be realized with an engine-level implementation. For instance, there may be custom index data structures that leverage partial and adaptive indexing methods, as well as a more streamlined trigger execution in order to improve enforcement costs. Furthermore, there are several techniques such as batching and shared execution across updates that apply within transactions, and could therefore optimize the enforcement of partial referential integrity in this context. Our proposed services of intelligent queries and updates each open up their own areas of future investigation. For updates it would be interesting to investigate how large numbers of choices for imputations can be represented or ranked, how logs of potential imputations can best be processed by data analysts, or how unsuccessful imputations can be reversed. For queries, it would be interesting to find re-writings of SQL queries that return not only standard but also non-standard answers that result from the application of partial semantics, and to investigate the overhead of such techniques. Information incompleteness is also inherent in other data models such as graphs, RDF, or XML. Finally, implication problems of inclusion dependencies under SQL semantics should be studied [10, 11].

ABSTRACT

Data market is an emerging type of cloud service that enables a data owner to sell their data sets in a public cloud. Buyers who are interested in a certain dataset can access the data in the market via a RESTful API. Accessing data in the data market may not be free. For example, it costs USD 12 per month to obtain 100 "transactions" from the WorldWide Historical Weather dataset in Windows Azure Data Marketplace, where a transaction is a unit of result size (e.g., a query result of 4400 records would consume 44 transactions as Windows Azure Data Marketplace confines one transaction to 100 records). Therefore, in this paper, we present PayLess, a system that helps data buyers to optimize their queries so that they can obtain the query results by paying less to the data sellers. Experiments over synthetic data and real data sets in Windows Azure Marketplace show that PayLess can cost-effectively handle SQL query processing over data markets.

1. INTRODUCTION

Data market [1, 16, 42] is an emerging type of cloud service that enables a data owner to host and sell their datasets in a public cloud. Buyers who are interested in a certain dataset can access the data in the market via a RESTful API. The REST based API has function-call like interface $\mathcal{X} \to \mathcal{Y}$, where $\mathcal{X}$ and $\mathcal{Y}$ are sets of attributes: given a range or a value for an attribute in $\mathcal{X}$, the data market returns values for the attributes in $\mathcal{Y}$ (if no values are specified for $\mathcal{X}$, the whole table is returned). For example, the Worldwide Historical Weather (WHW) dataset [13] in Windows Azure Marketplace [1] may take a country name and a date, and return a set of tuples, each details the temperature, precipitation, dew point, sea level pressure, windspeed, and wind gust recorded by each weather station in that country on that date.

Accessing data in the data market may not be free. For example, it costs USD 12 to grant access to every 100 "transactions" to the WHW data, where a transaction is a unit of result size (e.g., a query result of 4400 records costs 44 transactions in Windows Azure Marketplace, which confines one transaction to 100 records). There is an increasing trend of selling valuable datasets in data market [31]. Correspondingly, we envision that there is an increasing demand from end users (data buyers) to carry out analytics that involve those datasets. To this end, in this paper, we present PayLess, a system that helps users to optimize their queries so that they can obtain the query results by *paying less* to the data sellers.

Query optimization is never trivial. First, from a data buyer's (the company or the organization) perspective, it is hard to know in advance how many queries will be posed by their end users eventually. Otherwise, downloading the whole dataset would become a viable plan when the foreknowledge tells that the number of transactions incurred by user queries would eventually exceed the number of transactions required to download the complete data set. Second, query optimization would never work well without rich data statistics. Unfortunately, datasets in data market are rarely tagged with rich statistics (e.g., no value distribution), although basic information like the size (cardinality) of each table and the domain size of the attribute is usually available.

Tackling the above two challenges sounds not difficult, especially that we can build a *learning* optimizer like LEO [46] so that it begins with little statistic and introduces a feedback loop to correct the statistics when more queries are issued. The evil, however, lies in the detail of adopting the learning approach to data market query optimization.

First, learning-based optimizers like LEO [46] and POP [38] are originally designed for traditional databases that have full access to the data. In contrast, the access pattern of data market is restricted to only $\mathcal{X} \to \mathcal{Y}$ style. When a data source has limited access patterns, (a) operations might become complicated and (b) specialized access paths may shine. An example of (a) is that a query that asks `Country = 'Canada' OR Country = 'Germany'` has to decompose into two queries, one asks for `Country = 'Canada'` and another asks for `Country = 'Germany'`. An example of (b) is *bind joins* (other names include theta semi-join, dependent join) [27]. To explain, consider the real access patterns of Worldwide Historical Weather (WHW) dataset in Windows Azure Marketplace listed in Figure 1a.[1] The access patterns are specified using a notation of binding patterns extended from [27]. We write $R^{\alpha}(A_1, A_2, A_3)$ to denote a table R in the data market with three attributes A_1, A_2, and A_3 and *binding pattern* α. We write $\alpha = R(A_1^b, A_2^f)$ to denote a binding pattern that in any query accessing R, the value of attribute A_1 must be *bound* (given/specified). In contrast, the value of attribute A_2 is *free* to be specified or not specified in any query. If an attribute is not included in the binding pattern (e.g., A_3), it is solely served as an output attribute in a query result. In other words, if an access pattern of a table has only free attributes, then we can download the whole table by not specifying any value to any attribute.

Now, consider the following SQL query that asks the WHW

[1]The attribute names here are renamed for better exposition.

(c) Plan P_2

Figure 1: Query Processing in Data Market

dataset for the daily temperature of Seattle in June 2014:

```
SELECT Temperature          -------// Query Q1
FROM Station, Weather
WHERE City = 'Seattle' AND
      Country = 'United States' AND
      Date >= 20140601 AND Date <= 20140630 AND
      Station.StationID = Weather.StationID
```

Figure 1b shows an execution plan P_1 for this SQL. It first submits two RESTful GET calls C_1 and C_2, where C_1 gets the StationID of Seattle from Station table, and C_2 gets the weather records for all stations in the United States on June 2014 from Weather table. The final query result is obtained by carrying out a *local join* (i.e., regular join) operation at the end user (data buyer) side because joins cannot be done at the data market [1]. In plan P_1, a total of 238 transactions were incurred – one was spent on RESTful call C_1 and 237 were spent on RESTful call C_2 (there are 788 weather stations in the US and each station contributes 30 days records, resulting in $\lceil 788 \times 30/100 \rceil = 237$ transactions). Figure 1c shows an alternate execution plan P_2. It first gets the list of StationIDs of Seattle (call C_1). Then, it carries out a bind join ($\overrightarrow{\bowtie}$) operation that binds each StationID (e.g., 3817) to an individual RESTful call to Weather. Finally, the weather records for each station in Seattle are collectively retrieved and returned. In this case, plan P_2 incurs only two transactions: call C_1 costs one transaction and call C_3, which returns 30 days of weather records for the only one weather station in Seattle, costs also one transaction.

Second, although there are optimizers designed for queries over remote data sources with limited access patterns (e.g., [17, 24, 27, 33–36, 40, 45]), they focus on minimizing the number of calls to the remote data sources so as to reduce the overall execution time. As an example, assume that there are 15 weather stations in Seattle, those optimizers will pick plan P_1 because it incurs only two RESTful calls (C_1 and C_2). In data market, although P_2 needs to bind each Seattle's weather station id, resulting in $1 + 15 = 16$ RESTful calls and 16 transactions (each transaction returns 30 days of records for each weather station), it is still more economy than P_1, which requires 238 transactions. On the other hand, if we further assume that there are only 20 weather stations in the United States and 15 of them are in Seattle. Then, plan P_1 will cost only $1+\lceil 20\times 30/100 \rceil = 7$ transactions. In contrast, plan P_2 still costs 16 transactions. In this case, P_1 is better than P_2.

Summing up the above, we need a (i) learning-based optimizer that (ii) includes bind join as an access path with the goal of (iii) minimizing the amount of (intermediate) retrieved data measured in terms of data market pricing units. Traditional learning-based optimizers satisfy (i) and partially satisfy (iii)[2] but not (ii). Optimizers for queries over remote data sources satisfy only (ii). Therefore, the principal contributions of this paper are centered around the issues of building an optimizer for PayLess that satisfies all (i), (ii), and (iii) above. Those include:

- Defining the cost model and search space for data market query optimization.
- Devising effective techniques to reduce the amount of intermediate retrieved data (e.g., by adapting semantic query rewriting methods) and integrating those techniques into our optimizer.
- Implementing a prototype and evaluating its performance through extensive experiments over synthetic data and real data.

The remainder of this paper is organized as follows. Section 2 gives more background about the data market. Section 3 presents the architecture of PayLess. Section 4 describes the details of PayLess's optimizer. Section 5 reports the results of the evaluation. Section 6 discusses the related work and Section 7 concludes.

2. PRELIMINARIES

According to a recent survey [2], the three most established data marketplaces are Factual [8], Microsoft Windows Azure Data Marketplace [1], and DataMarket [4]. Factual [8] and DataMarket [4] are specialized data markets that sell datasets in a very specific domain (e.g., Factual sells mainly geographical data and DataMarket sells mainly economic indicators). Microsoft Windows Azure Data Marketplace offers data sets in all kinds and many popular data resellers in smaller size like Wolfram Alpha [11], ESRI [7], World Bank [12], data.gov [3], Xignite [14] also provide their data in the Windows Azure Data Marketplace [1]. After Infochimps [9], one of the early data market entrants, gradually leaves the data market business [5, 10], Microsoft Windows Azure Data Marketplace is becoming the de facto data market [2]. Therefore, in this paper, we base our setting on Windows Azure Data Marketplace.

2.1 Data Market

A data market hosts and sells multiple datasets. Each dataset's access/binding pattern is defined by the data owner on per table basis. For numeric attributes, the input can be bound with a single value or a range like $[150, 200)$. Datasets in data market are tagged with very basic statistics, normally the domain of each attribute and

[2]Traditional optimizers also aim to generate plans that minimize intermediate result size of each operation (e.g., push down selection).

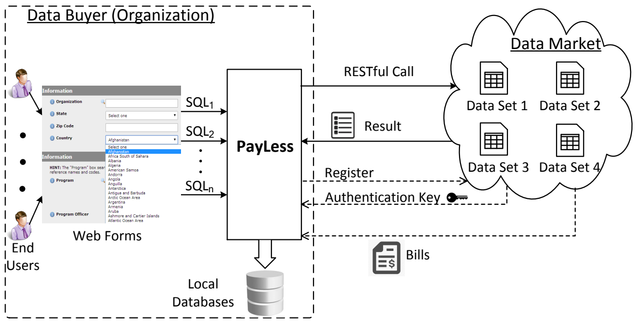

Figure 2: Setting of PayLess

the number of records (cardinality).[3] Datasets in a data market are *append-only* because they are released for analytic purposes. New data could be added periodically (e.g., every month). The price of accessing data is mainly based on the number of tuples retrieved. A *transaction* represents a page of t tuples (e.g., 100 tuples) and it is the smallest pricing unit. Let p be the price per transaction for a particular dataset. Then, the total price of a RESTful call is:

$$p \cdot \lceil \frac{\text{number of resulting records}}{\text{number of tuples per transaction } (t)} \rceil \quad (1)$$

For easy exposition, in the subsequent discussion, we assume $p =$ \$1 and a transaction page size is $t = 100$ tuples.

2.2 Queries over Data Market

Figure 2 shows the target setting of PayLess. An organization is interested in carrying out certain analytics that involve datasets hosted in a data market. The organization thus registers with the data market to obtain the authentication access keys of the datasets. The access keys are stored in PayLess, which constructs RESTful calls to the data market when necessary. PayLess encapsulates the details of interacting with the data market and exposes a SQL query interface for client query processing. A SQL query to PayLess can query against both tables in a local DBMS and tables in data market. The following is an example PayLess query that aims to retrieve the average temperature for each city in a country whose environmental pollution rank is lower than a threshold within a period:

```
SELECT City, AVG(Temperature)
FROM Pollution, Station, Weather, ZipMap
WHERE Station.Country = Weather.Country = ? AND
      Weather.Date >= ? AND Weather.Date <= ? AND
      Pollution.Rank <= ? AND
      Pollution.ZipCode = ZipMap.ZipCode AND
      ZipMap.City = Station.City AND
      Station.StationID = Weather.StationID
GROUP BY City
```

This query involves joining four tables: the Station and Weather tables from the aforementioned Worldwide Historical Weather (WHW) [13] dataset, another Data Market table, the Pollution table from the Environmental Hazard Ranking (EHR) [6] dataset, and a local table that maps Zip codes to a city name. The access patterns of these tables are shown in Figure 1a. We expect SQL queries to PayLess are parameterized queries embedded in certain application so that users (e.g., data scientists) issue the queries by specifying the parameter values via a web interface. We do not expect the organization restricts her users the number of queries to the data market because that is counter-productive.

[3]If not publicly available, the data sellers would release the basic statistic to data buyers upon email requests [1].

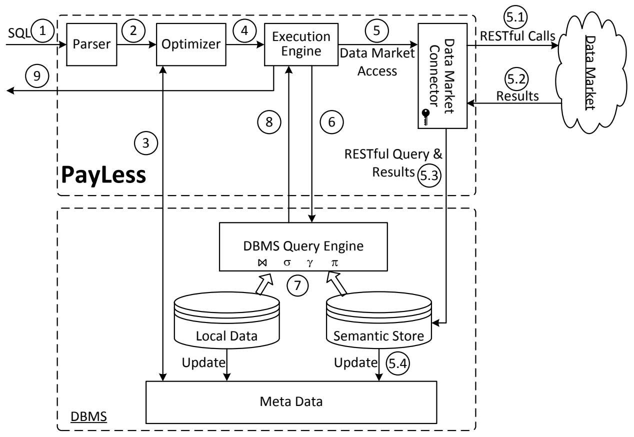

Figure 3: System Architecture

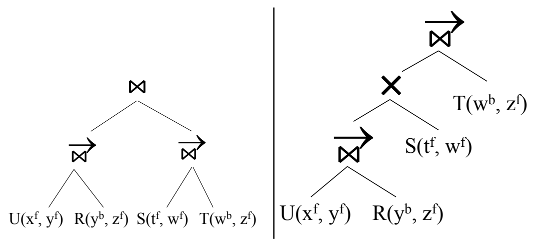
3. SYSTEM OVERVIEW

Figure 3 shows the architecture of PayLess. It is designed to be lightweight and offloads most query processing to a DBMS query engine. It accepts and parses a SQL query (with parameter values instantiated) ①. The parser differentiates local tables and tables from the data market using the information (e.g., the table name) obtained when registering with the data market (see Figure 2). Then, the optimizer of PayLess optimizes the query ② by consulting the statistics of local and data market data ③. The optimized query is then passed to an execution engine ④. A query, after optimization, may be able to skip some or the entire access to the data market. When it is necessary to access the data market, the execution engine will pass the access requests to the data market connector ⑤ and let the connector interact with the data market (5.1) (5.2). PayLess stores all the data market access requests and their returned data in a semantic store (5.3). Whenever new data is retrieved from the data market, PayLess will update its statistics (5.4). In our implementation, we implement our updatable statistics using ISOMER [44]. After this step, all data required by a query should be ready and stored in the DBMS and the execution engine of PayLess instructs the DBMS query engine ⑥ to process the query ⑦. In the end, the execution engine of PayLess retrieves the query result from the DBMS ⑧ and then returns it to the front end ⑨.

PayLess is supposed to be installed by each data buyer and serves all the end users from the same data buyer. As a data buyer would not be interested in all datasets available in the data market, the storage space (for the DBMS) is not a problem here. Cache management is out of PayLess's interest because we deliberately use cheap storage space to store all intermediate results (i.e., no eviction) in order to eschew retrieving redundant data from the data market. Besides, PayLess is indeed amenable for any updatable statistic. As our focus of this paper is to give a proof-of-concept first solution, we will test other updatable statistics (e.g., [25]) in place of ISOMER in the next version of PayLess.

4. QUERY OPTIMIZATION

PayLess's optimizer follows the typical bottom-up, cost-based, and dynamic programming approach [28]. That is, it first consid-



(a) Bushy tree (b) Left-deep tree

Figure 4: Bushy tree v.s. Left-deep tree

ers the best plan for single relations, then the best plan for joining two relations, and then for three relations, so on. On top of that, PayLess's optimizer considers bind joins $\overrightarrow{\bowtie}$as an access path in addition to the regular join $\bowtie$. The key feature of PayLess's optimizer is that it carries out *semantic query rewriting* to optimize its queries using the query results stored in the semantic store. Semantic query rewriting [23] is not new, but later we will explain why it is not included in limited access query optimizer (e.g., [17,27,45]) and why it is helpful to us here. We will also explain the limitations of current semantic query rewriting techniques in our setting and our solutions to unlock their potential and integrate them into our optimizer.

This section describes how to derive the optimal execution plan after parsing a SQL query. We first propose several techniques to reduce the plan search space and prove their correctness (see Section 4.1). After that, we illustrate the semantic query rewriting method used in PayLess (see Section 4.2). In the end, we end with some discussions about our query optimization approach (see Section 4.3).

4.1 Plan Space

When optimizing queries for limited access pattern data sources, *bushy trees* are included in the plan space to avoid plans with Cartesian products [27]. For example, consider a query that joins four relations U, R, S and T with access patterns: $U(x^f, y^f)$, $R(y^b, z^f)$, $S(t^f, w^f)$, $T(w^b, z^f)$. Since R has a bind attribute y, it must require values for attribute y to retrieve tuples. In the example, the only choice is thus to carry out a bind join $U \overrightarrow{\bowtie} R$. Similarly, since T has a bind attribute w, it must require values for attribute w to retrieve tuples. In the example, the only choice is thus to carry out a bind join $S \overrightarrow{\bowtie} T$. After that, the only way is to join them together by using a local join, resulting in a bushy tree like Figure 4a. So, if only left-deep plans are allowed, a "logical" cross product must be used to *logically connect* the relations like Figure 4b[4].

Including bushy trees would significantly enlarge the search space. In our problem setting, as our primary goal is to minimize the money-to-pay, we exclude bushy trees in our plan space because:

THEOREM 1. *Given any plan P, we can transform it to a left-deep plan P' such that $\phi(P) \geq \phi(P')$, where $\phi(\cdot)$ denotes the total price of a plan. In other words, the optimal plan must be one of the left-deep plans.*

PROOF. In what follows, we use the terms RESTful call, leaf node, and relation/table interchangeably.

First, we re-iterate a very important fact:

[4]The cross product is just logically connecting intermediate results U$\overrightarrow{\bowtie}$R and S$\overrightarrow{\bowtie}$T. Physically, (U$\overrightarrow{\bowtie}$R) joins (S$\overrightarrow{\bowtie}$T) is done by the DBMS, using any equi-join implementation like hash-join.

Fact *Only leaf nodes in P contribute to the price $\phi(P)$ because they represent RESTful calls to the data market. Therefore, $\phi(P)$ equals to the sum of prices of leaf nodes in P.*

Without loss of generality, we name the leaf nodes (RESTful calls) in P from left-to-right as: $C_1, C_2, \cdots, C_n$.

We write $P^{(k)}$ to denote that, for all leaf nodes of P, if named from left-to-right, the first k leaf nodes form a left-deep subtree. So, given a plan P with n leaf nodes, if we write $P^{(n)}$, we mean P is a complete left-deep tree. As an example, for the bushy tree P in Figure 4a. $P^{(1)}$ and $P^{(2)}$ hold. As another example, let P be the plan in Figure 4b, then we see that $P^{(1)}$, $P^{(2)}$, $P^{(3)}$ and $P^{(4)}$ all hold.

Now, we proceed to prove $\phi(P) = \phi(P^{(1)}) \geq \phi(P^{(2)}) \geq \cdots \geq \phi(P^{(n)})$. In the following, we first prove $\phi(P^{(1)}) = \phi(P)$ and then prove that for a given $1 \leq k \leq n-1$, we have $\phi(P^{(k+1)}) \leq \phi(P^{(k)})$.

<u>Base case: $k = 1$</u> $P^{(1)}$ simply means we just look at the left-most leaf nodes of P without moving any nodes, so the cost of the whole plan P is unchanged: $\phi(P^{(1)}) = \phi(P)$.

<u>General case: $\phi(P^{(k+1)}) \leq \phi(P^{(k)})$</u>

When C_{k+1} is C_k's uncle: Figure 5a illustrates this case. In this case, the left-most $k+1$ leaf nodes form a left-deep subtree. So, P^{k+1} holds. Note that we did not move any leaf node yet, so the plan cost would not change: $\phi(P^{(k+1)}) = \phi(P^{(k)})$.

When C_{k+1} is not C_k's uncle: Figure 5b illustrates this case. In this case, the uncle node of C_k, say U, must be a non-leaf node and its subtree contains C_{k+1}. Let T_F be the left-deep subtree rooted at F, the father of C_k. Further, we let G be the grandfather of C_k. Finally, we let T_{UL}, T_{UR} be the left and right subtrees rooted at U, respectively.

We now explain that making $P^{(k+1)}$ holds by joining T_F with C_{k+1} through a new node G' would not increase the overall plan cost. Figure 5c illustrates the resulting plan P' with $P'^{(k+1)}$ holds.

First, we see that the price of subtree T_F is the same among P and P'.

Second, the price of C_{k+1} is the same in both P and P' because C_{k+1} takes the same join result from T_F no matter G or G' is a bind join or a regular (local) join.

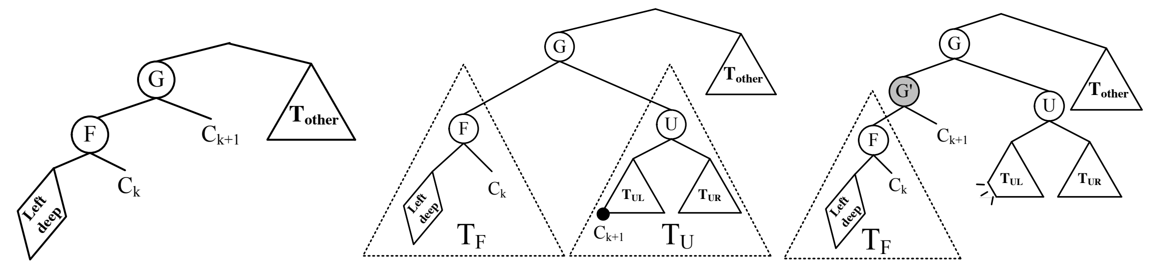
Now, we consider the price for each node (other than C_{k+1}) in T_{UL} and T_{UR} in P and P'. Let C_u be such a node. First, if C_u does not require any binding from C_{k+1}, then the price of C_u in P' is unchanged. Second, if C_u requires binding values from C_{k+1}, then the price of C_u depends on the number of distinct binding values from C_{k+1}. Note that in P', C_{k+1} has been joined with the others earlier than P, that causes the number of binding values to C_u possibly decreases. So, the price for C_u would not increase.

Finally, we look at the subtree T_{other}. As the result of the left operand of T_{other} remains the same, the price of T_{other} is unchanged.

As the price of any C_i in P would not increase, we have $\phi(P^{(k+1)}) \leq \phi(P^{(k)})$. $\square$

Traditional optimizers include only left-deep plans as a heuristic to improve the efficiency of the plan search. In PayLess, with Theorem 1, enumerating only left-deep plans is not a heuristic but with a guarantee that the optimal plan is not lost. Furthermore, in PayLess, including Cartesian product is not a problem because that would not contribute any extra data market transaction.

In addition to enumerating left-deep plans only (Theorem 1), PayLess's optimizer further trims the search space by first joining all relations that incur zero price to the data market. Those relations can either be local relations or relations whose required tuples can be found in the semantic store. In the following, we show that such



(a) When C_{k+1} is C_k's uncle (b) Before transformation P (c) After transformation P'

Figure 5: Illustration figures for Theorem 1

zero-price-relations-join-first idea retains the optimal plan in the plan space:

THEOREM 2. *Let $P = \langle C_1, C_2, \ldots, C_n \rangle$ be a left-deep plan with a leaf node (RESTful call) C_i whose price $\phi(C_i) = 0$. Then, the plan $P' = \langle C_i, C_1, \ldots, C_n \rangle$ has $\phi(P') \leq \phi(P)$.*

PROOF. We divide the other calls into two groups: (1) RESTful calls that executed before C_i, i.e. C_1 to C_{i-1}, and (2) RESTful calls that executed after C_i, i.e. C_{i+1} to C_n.

If we move C_i to the left-deepest node of P:

- $\phi(C_i)$ is unchanged and remains 0.
- $\phi(C_j)$ for $j > i$ is unchanged because the join results before executing C_j and the possible binding values for C_j are the same.
- $\phi(C_j)$ for $j < i$ cannot increase. If C_j does not use any binding attributes, then moving C_i before C_j would not increase $\phi(C_j)$. If C_j uses binding values from a bind join, then moving C_i before C_j would not increase (but may decrease) the number of bind join values for C_j, and that would not increase $\phi(C_j)$.

□

PayLess's optimizer applies Theorem 2 repeatedly and moves all zero price calls to the leftmost subtree of P. That way, the search space of PayLess's optimizer is further reduced.

Lastly, PayLess's optimizer would prune some candidate subplans during plan enumeration:

THEOREM 3. *When searching for the best plan for a set $\mathcal{C}$ of relations $C_1, C_2, \ldots, C_n$, if $\mathcal{C}$ can be partitioned into disjoint subsets $\mathcal{C}_1 \ldots \mathcal{C}_j$, where relations in $\mathcal{C}_i$ cannot join with relations in $\mathcal{C}_j$ (unless using Cartesian product $\times$). Then the best plan for $\mathcal{C}$ is $Best(\mathcal{C}_1) \times Best(\mathcal{C}_2) \times \ldots Best(\mathcal{C}_j)$, where $Best(\mathcal{C}_i)$ denotes the best plan for the set of relations in $\mathcal{C}_i$.*

PROOF. The proof is trivial because the relations in $\mathcal{C}_i$ cannot join with relations in $\mathcal{C}_j$, the price of calling $\mathcal{C}_j$ would not be influenced by $\mathcal{C}_i$. So, the best plan for $\mathcal{C}$ becomes simply connecting the best subplans of $\mathcal{C}_1 \ldots \mathcal{C}_j$ using Cartesian product. □

Consider a chain query that joins four relations: $\mathcal{C} = \{U(v,w), R(w,x), S(x,y), T(y,z)\}$. Assuming that the best plans determined for the pairs of relations are:

	$\{U,R\}$	$\{U,T\}$	$\{U,S\}$	$\{R,S\}$	$\{R,T\}$	$\{S,T\}$
Best Plan	$U \overrightarrow{\bowtie} R$	$U \times T$	$U \times S$	$R \overrightarrow{\bowtie} S$	$R \times T$	$S \overrightarrow{\bowtie} T$

So, when determining the best plan for 3-way join, the candidate plans that would be generated are:

	$\{U,R,S\}$	$\{U,R,T\}$	$\{U,S,T\}$	$\{R,S,T\}$
Candidate Plans	$(U \overrightarrow{\bowtie} R) \bowtie S$	$(U \overrightarrow{\bowtie} R) \bowtie T$	...	...
	$(U \overrightarrow{\bowtie} R) \overrightarrow{\bowtie} S$	$(U \times T) \bowtie R$	...	...
	$(U \times S) \overrightarrow{\bowtie} R$	$(U \times T) \overrightarrow{\bowtie} R$	...	...
	...	$(R \times T) \bowtie U$	...	...
	...	$(R \times T) \overrightarrow{\bowtie} U$	...	...

Observe that the set $\{U,R,T\}$ can be partitioned into two disjoint subsets: $\mathcal{C}_1 = \{U,R\}$ and $\mathcal{C}_2 = \{T\}$. So, we can apply Theorem 3 to determine the best plan for the set $\{U,R,T\}$ as $Best(U,R) \times T$, i.e., $(U \overrightarrow{\bowtie} R) \times T$. In other words, Theorem 3 eliminates many candidates (e.g., $(R \times T) \overrightarrow{\bowtie} U$) and eliminates their associated costing steps and semantic rewriting steps.

Let the total number of candidate plans in all levels of the dynamic programming approach be the size of the search space. For a chain query with n relations whose attributes are all free. The use of the above theorems can reduce the search space from $\approx 6^n - 5^n$ down to $\approx 2^{n'} + \frac{2}{3} \cdot n'^3$ with the optimal plan retained, where m is the number of zero price relations and $n' = n - m$. Specifically, the original plan space with dynamic programming is:

$$n + \sum_{k=2}^{n} \left(\binom{n}{k} \cdot \left(\sum_{i=1}^{k-1} \binom{k}{i} \cdot 4^{min\{i,k-i\}} \right) \right) \approx 6^n - 5^n$$

where k represents the level in dynamic programming (e.g., when $k = 2$, we consider joining two relations). At level k, there are $\binom{n}{k}$ size-k subsets to be examined. For each size k subset, we can form a plan by: (i) choosing a size i subset for the left subtree (and the complementary size $k - i$ subset for the right subtree), and (ii) deciding the binding attributes for the join (at root). For (ii), each call on the right subtree can bind with attributes from at most 2 calls from the left subtree; thus, there are 2·2=4 binding choices per call, and at most 4^{k-i} choices per plan. We can tighten this number to $4^{min\{i,k-i\}}$ when i is small and the left subtree can provide at most 4^i binding choices.

The plan space of PayLess's optimizer is:

$$4n' + \sum_{k=2}^{n'} \left(4 \cdot k \cdot (n' - k + 1) + \left(\binom{n'}{k} - (n' - k + 1) \right) \right)$$

$$\approx 2^{n'} + \frac{2}{3} \cdot n'^3$$

where m is the number of zero price relations and $n' = n - m$. Specifically by Theorem 2, we first build a plan with all local m relations. Then, in dynamic programming, we consider growing the plan by using the remaining $n' = n - m$ relations. At level k, there are $\binom{n'}{k}$ size-k subsets. We can divide them into (i) discon-

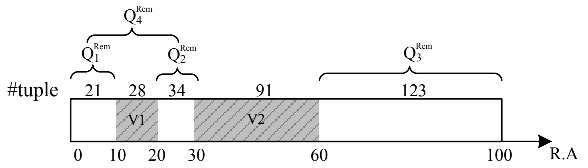


Figure 6: Generation of remainder queries

nected subsets (in which some relations must be joined by Cartesian product), and (ii) connected subsets. For the chain query, there are $n' - k + 1$ connected subsets and $\binom{n'}{k} - (n' - k + 1)$ disconnected subsets. For each disconnected subset, we can compute its best plan directly by Theorem 3. For each connected subset, we can obtain it by Theorem 1, i.e., combining a size-$(k-1)$ subset with a new call. There are k choices for the call and at most 2·2=4 binding choices for that call.

4.2 Semantic Query Rewriting

In PayLess, we store all RESTful queries issued to the data market and their corresponding results in the semantic store. The objective of doing so is to carry out *semantic query rewriting*, i.e., answer the queries using those stored results so as to reduce the amount of data retrieved from the data market. Semantic query rewriting falls into the category of rewriting queries using views [29, 48]. Given a query Q, a set $\mathcal{V}$ of RESTful queries and their corresponding stored results, the key step in semantic query rewriting is to compute the set $\mathcal{R}em(Q, \mathcal{V})$ of *remainder queries* [23]. The set $\mathcal{R}em(Q, \mathcal{V})$ essentially contains the set of RESTful queries that has to be sent to the data market in order to retrieve the tuples required by Q but not covered by $\mathcal{V}$.

Before we delve deeper, we first explain why optimizers for queries over remote data sources like [17, 27, 45] do not use semantic query rewriting. Consider our example query $Q1$ (page 1), which inquires about the daily temperature of Seattle in June 2014, has been issued, and its 30 resulting tuples (one tuple for each day in June) are stored in the semantic store. Assume that there is another query $Q2$ being issued, with $Q2$ shares the same query template like $Q1$ but the date ranges from May 2014 to July 2014 (3 months). Using semantic query rewriting, $Q2$ will generate two remainder queries: one asks for weather records in May (31 records; 1 transaction), another asks weather records in July (31 records; 1 transaction). The final result is then obtained by union the above with the stored results of $Q1$. The plan of using semantic query rewriting incurs a total of two calls to the external data source. In contrast, only one call to the external data source is required if $Q2$ is sent to the external data source without semantic query rewrite. So, in the context of minimizing the number of calls to external data sources, semantic query rewriting obviously is not a fruitful technique because it decomposes a call to several sub-calls.

Now, we show that how could we adapt semantic query rewriting to PayLess's optimizer to yield competitive plans for data market query processing. To illustrate, consider the example in Figure 6. The example assumes that the results of two queries V_1 and V_2 have been stored in the semantic store. Both V_1 and V_2 are range queries on an integer attribute A whose domain is $[0, 100]$. V_1 and V_2 respectively cover the ranges $[10, 20)$ and $[30, 60)$ on attribute A and have retrieved 28 and 91 tuples from table R. In what follows, we write a query Q in the form as

$$Q :-\ R_1(A[s, e], B = \beta, C), R_2(C, ..)$$

which means it joins R_1 and R_2 using C as the join attribute, and tuples in table R_1 have values in numeric attribute A fall between s and e and have values in categorical attribute B equal β.

Now, with V_1 and V_2, we assume the following query Q is posed:

$$Q :-\ R(A[0, 100])$$

Using the vanilla semantic query rewriting techniques, it will generate an invalid remainder query $Q^{Rem}_{invalid}$:

$$Q^{Rem}_{invalid} :-\ R(A[0, 10) \vee [20, 30) \vee [60, 100])$$

In data market, $Q^{Rem}_{invalid}$ is invalid because it involves disjunction, which is not supported by the access pattern of data market. Therefore, our first step to adapt semantic query rewriting techniques is to decompose remainder queries that violate the data source access patterns into a set of valid remainder (sub)queries. For the example above, PayLess will generate a set $\mathcal{R}em_1$ of remainder queries:

$Q_1^{Rem} :-\ R(A[0, 10))$ //21 tuples; 1 transaction
$Q_2^{Rem} :-\ R(A[20, 30))$ //34 tuples; 1 transaction
$Q_3^{Rem} :-\ R(A[60, 100])$ //123 tuples; 2 transactions

So, altogether, $\mathcal{R}em_1$ will cost a total 4 transactions.

Note that such straightforward decomposition may not yield the best plan. For example, the following is another possible set of remainder queries $\mathcal{R}em_2$:

$Q_4^{Rem} :-\ R(A[0, 30))$ //21+28+34= 83 tuples; 1 transaction
$Q_3^{Rem} :-\ R(A[60, 100])$//123 tuples; 2 transactions

The remainder query Q_4^{Rem}, although overlaps with stored query V_1, will still cost $\lceil (21 + 28 + 34)/100 \rceil = 1$ transaction. So, altogether, $\mathcal{R}em_2$ will cost a total 3 transactions only.

The example above illustrates a new and unique issue specific to the generation of remainder queries in data market. Specifically, we see that there are alternate ways to generate valid remainder queries and it is possible that a lower overall price can be achieved even when *a remainder query overlaps with a stored query*.

PayLess obviously does not want to miss the above opportunity when optimizing the queries. So, we have devised a remainder query generation method that leverages the above opportunity to reduce the overall price to access the data market.

We illustrate our idea using a more general example in Figure 7a. In the example, the query Q is a 2d-query that inquires table R:

$$Q :-\ R(A_1[30, 80], A_2[0, 50])$$

In the example, we assume there are ten RESTful queries $V_1, \ldots, V_{10}$ stored in the semantic store. Figure 7b shows the intersection of Q and the complement of $\mathcal{V}$, i.e., the data supposed to be retrieved from the data market. Denoting that space as $\overline{\mathcal{V}}$, there are alternate sets of remainder queries that can retrieve all the missing data. For example, consider the following set of remainder queries $\mathcal{R}em_3$:

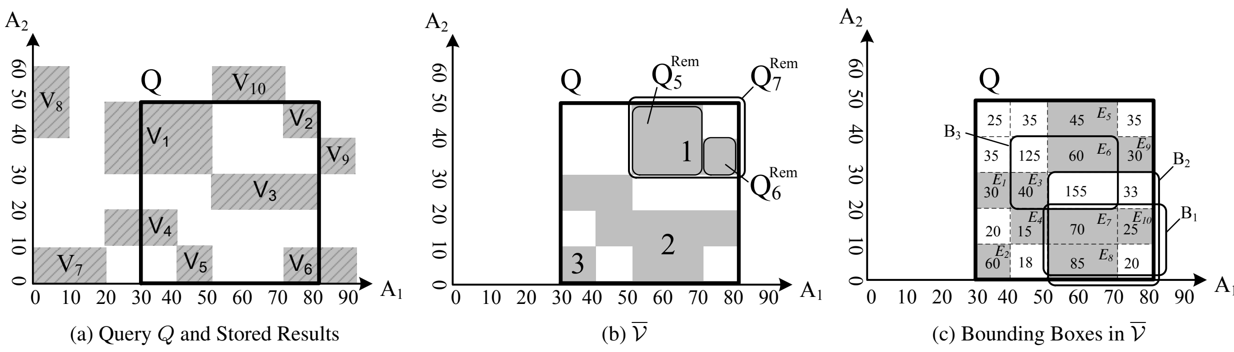
$Q_5^{Rem} :-\ R(A_1[50, 70), A_2[30, 50])$
$Q_6^{Rem} :-\ R(A_1[70, 80], A_2[30, 40])$

$\mathcal{R}em_3$ covers the missing data in region 1. Alternately, the following set of remainder queries $\mathcal{R}em_4$ can also cover data in region 1:

$Q_7^{Rem} :-\ R(A_1[50, 80), A_2[30, 50])$

From the above, we see that our goal boils down to finding a set of bounding boxes that cover all the data regions in $\overline{\mathcal{V}}$ using the least number of data market transactions.

To achieve a good solution, we use a two-step approach. The first step aims to generate a set of promising bounding box $\mathcal{B}$ candidates that cover different data regions in $\overline{\mathcal{V}}$. The bounding box candidates



(a) Query Q and Stored Results (b) $\overline{\mathcal{V}}$ (c) Bounding Boxes in $\overline{\mathcal{V}}$

Figure 7: Generation of remainder queries for data market

may possibly overlap with each other. The second step aims to extract from $\mathcal{B}$ the best set of bounding boxes that cover all the data regions in $\overline{\mathcal{V}}$ in minimum price.

We now elaborate the first step. Specifically, we begin with a decomposition of $\overline{\mathcal{V}}$ into a union $\mathcal{E}$ of disjoint *elementary boxes*. Figure 7c shows an example. On each dimension i, we collect a *separator* set S_i from the corners of each elementary box. For example, elementary box E_8 contributes values 50 and 70 to S_1 and contributes values 0 and 10 to S_2. Accounting for all elementary boxes, then we have $S_1 = \{30, 40, 50, 70, 80\}$ and $S_2 = \{0, 10, 20, 30, 40, 50\}$. Then, we exhaustively construct a set $\mathcal{B}$ of *bounding boxes*, where the extent of a bounding box $B \in \mathcal{B}$ on dimension i is picked from any two values in S_i. For example, the bounding box B_1 in Figure 7c has extent $[50, 80]$ on dimension A_1 and extent $[0, 20]$ on dimension A_2 when it picks values 50 and 80 from S_1 and values 0 and 20 from S_2. Each resulting bounding box represents a remainder query that covers certain data to be retrieved from the data market.

Algorithm 1 presents the pseudo-code of generating the bounding boxes, with powerful pruning rules to prune unpromising bounding boxes. First, it estimates the number of tuples falling into each elementary box in $\mathcal{E}$ from ISOMER (Lines 2–3). Figure 7c shows an illustration with those estimates. (We will discuss the case of insufficient/inaccurate statistics in the Section 4.3). Next, it enumerates a set of bounding boxes from the separator sets $S_1, S_2, ...S_d$, where d is the dimensionality of the query. It applies two pruning rules to discard unpromising bounding boxes.

The first pruning rule (Line 6) prunes a bounding box B if it is not tight. In other words, only *minimum bounding boxes* could stay. Consider the bounding boxes B_1 and B_2 in Figure 7c. They both contain the same set of elementary boxes E_7, E_8, E_{10} but B_2 contains B_1. Therefore, B_2 is not a minimum bounding box and is pruned. This makes sense because B_2 has to download an extra $155 + 33$ redundant tuples comparing with B_1.

The second pruning rule (Line 8) prunes a bounding box if its price is not smaller than the price sum of its individual elementary boxes. Consider bounding box B_3 Figure 7c. It requires $\lceil(125 + 60 + 40 + 155)/100\rceil = 4$ transactions. However, if E_3 and E_6 are individually retrieved, they collectively cost only $\lceil 40/100\rceil + \lceil 60/100\rceil = 2$ transactions. So, in this case, B_3 is not helpful and is pruned as well.

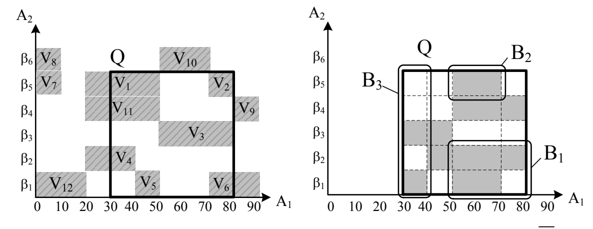
Algorithm 1 would enumerate $\binom{|S_i|}{2}^d$ bounding boxes for a d-dimensional query in the worst case. However, because of the high effectiveness of the pruning rules, the number of (minimum) bounding boxes considered is indeed much fewer than the worst case in practice.

The second step of our idea is to find the best subset of minimum bounding boxes (generated from Algorithm 1) that cover all the elementary boxes (all missing data) in minimum price. This is a weighted set cover problem [22]. Specifically, the weighted set cover problem states that, given (1) a set of elements $\mathcal{E} = \{E_1, E_2, ...\}$ and (2) a family $\mathcal{B}$ of subsets of $\mathcal{E}$, in which each subset in $\mathcal{B}$ is associated with a $cost_i$, find a collection of subsets, namely the cover, $Cover \subseteq \mathcal{B}$, whose union of the elements in $Cover$ is $\mathcal{E}$ and the sum of cost of elements in $Cover$ is the minimum. In our context, we have (1) $\mathcal{E}$ as all elementary boxes and (2) $\mathcal{B}$ as the set of candidate minimum bounding boxes returned by Algorithm 1, $cost_i$ is referred as a bounding box 's estimated transactions. To solve this $\mathcal{NP}$-hard problem, we use the greedy algorithm in [22] that runs in $O(|\mathcal{B}| \cdot |\mathcal{E}|)$ time with $(1 + \ln(|\mathcal{B}|))$ approximation ratio.

The generation of bounding boxes for queries with *categorical attributes* is illustrated as follows. Figure 8a shows an example similar to the previous one but with attribute A_2 now becomes a categorical attribute with the following domain: $\{\beta_1, \beta_2, \beta_3, \beta_4, \beta_5, \beta_6\}$. We remark that there are no stored queries that can span across multiple categorical values because of the limitation of the access interface.

Algorithm 1 Generating Candidate Remainder Queries

```
    Input (elementary boxes $\mathcal{E}$, separator sets $\{S_1, S_2, ..., S_n\}$)
    Output (A collection of minimum bounding boxes $\mathcal{B}$)
 1: initialize $\mathcal{B}$
 2: for each elementary box $E_i$ in $\mathcal{E}$ do
 3:     $E_i$.price ← estimate the price of $E_i$
 4: enumerate every possible bounding box $B$ using the separator
    sets $S_1, S_2, \ldots, S_n$.
 5: for each bounding box $B$ do
 6:     if $B$ is a minimum bounding box then        ▷ pruning rule 1
 7:         estimate the price of $B$
 8:         if $B$.price < $\sum_{E_i \in B} E_i$.price then    ▷ pruning rule 2
 9:             insert $B$ into $\mathcal{B}$
10: return $\mathcal{B}$
```



(a) Query Q and Stored Results (b) Bounding Boxes in $\overline{\mathcal{V}}$

Figure 8: Generation of remainder queries with a categorical attribute A_2

Figure 8b shows the corresponding space $\overline{\mathcal{V}}$. Since A_2 is a categorical attribute, the bounding box B_1, which represents the following remainder query, is invalid:

$$:-\ \ R(A_1[50,80), A_2 = \beta_1 \vee A_2 = \beta_2)$$

Therefore, we will only generate bounding boxes that span either one value or the whole domain of a categorical attribute. For example, bounding boxes B_2, which represents the following remainder query, is valid and would be generated:

$$:-\ \ R(A_1[50,70), A_2 = \beta_5)$$

Similarly, bounding boxes B_3, which represents the following remainder query, is also valid and would be generated:

$$:-\ \ R(A_1[30,40))$$

The generation of bounding boxes for queries with *bind joins* is illustrated as follows. Consider a relation U with binding pattern $U(A_1^f, A_2^f)$ and a relation S with binding pattern $S(A_2^b, A_3^f)$, where all attributes are integer attributes. Further, consider a query V that joins U and S:

$$V :-\ \ U(A_1[2,3], A_2), S(A_2, A_3[10,15])$$

V needs a bind join because A_2 is a bind attribute. So, assume that there are four tuples t_1, t_2, t_3, and t_4 in U having values within the range $[2,3]$ in attribute A_1 and their corresponding values in attribute A_2 are 2, 5, 9, and 10, respectively. Then, the bind join is carried out with S by binding the values 2, 5, 9, and 10 to S's attribute A_2. Note that when retrieving tuples from S whose attribute A_2 has a value, say, 2, those tuples have to satisfy the other condition $A_3[10,15]$ as well. Figure 9a illustrates the above process.

Now, assume the query results of V are stored in the semantic store and let us consider a query Q that shares the same query template as V but with a different query range:

$$Q :-\ \ U(A_1[2,5], A_2), S(A_2, A_3[8,18])$$

Note that in this case, assuming that we can estimate that two tuples t_x and t_y will be retrieved from U for $A_1 = 4$, one tuple t_z will be retrieved from U for $A_1 = 5$ (we don't need to estimate the cardinality for $A_1 = 2$ and $A_1 = 3$ because we know the exact cardinality from V), exact values of t_x, t_y, t_z's attribute A_2 are still unknown (denoted as ? in Figure 9b). In this case, it will generate $\overline{\mathcal{V}}$ like Figure 9c. Consequently, when enumerating the set of candidate bounding boxes, we can generate a bounding box for each individual elementary box (e.g., B_1), for a range of known values (e.g., B_2), or for the whole domain (e.g., B_3). In contrast, we cannot generate a bounding box like B_4 because the exact value for A_2 of t_z is actually unknown.

Algorithm 2 shows the pseudo code of PayLess optimization. It is self-explanatory and mainly summarizes what we have discussed above, so we do not give it a walkthrough here.

4.3 Discussion

We end this section with a number of discussions about our query optimization approach. First, as in traditional cost-based query optimization, our approach relies on metadata like histograms. In the beginning when no rich statistics such as value distributions are available, PayLess's optimizer would carry out the cardinality estimation using the basic textbook methods (e.g., using the domain size and uniform distribution assumption).

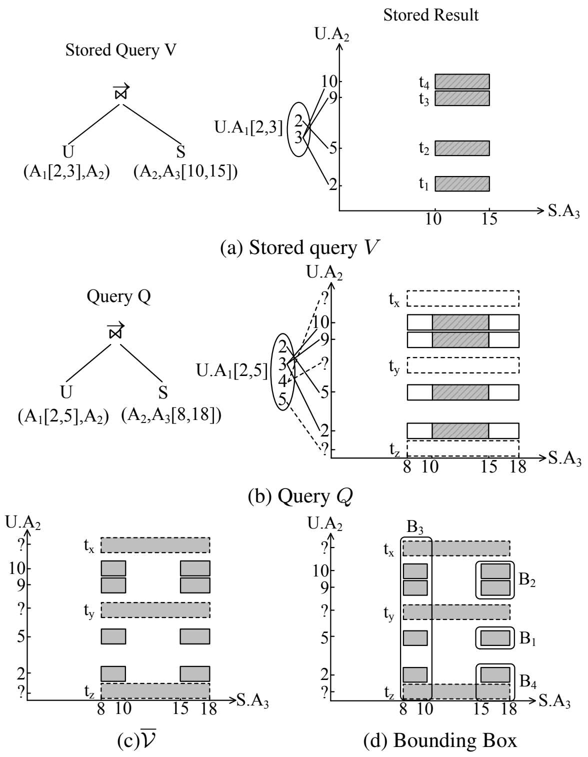


Figure 9: Example for 2D-Bind

Algorithm 2 PayLess Query Optimization

```
    Input ( a query $Q$, a set $\mathcal{V}$ of RESTful queries and their stored
    results, the metadata $\mathcal{M}$ for cost estimation )
    Output ( the optimal plan $P^*$ : $Best(Q)$ for the query $Q$ )
 1: $\mathcal{R}_{local} \leftarrow \{C_i \in Q : \phi(C_i) = 0\}$; $\mathcal{R}' \leftarrow \{C_i \in Q\} - \mathcal{R}_{local}$
 2: $P_{local} \leftarrow$ the best subplan for $\mathcal{R}_{local}$; found by offloading to a
    DBMS's optimizer
 3: for each $C_i \in Q$ do                                  ▷ size-1 subplans
 4:     $Best(C_i) \leftarrow$ SemanticRewrite($C_i, \mathcal{V}, \mathcal{M}$)
 5: execute Line 1 again to update $\mathcal{R}_{local}$ and $\mathcal{R}'$
 6: for each $k$ from 2 to $|\mathcal{R}'|$ do                           ▷ Theorem 2
 7:     for each size-$k$ subset $\mathcal{R}^k$ of $\mathcal{R}'$ do
 8:         if $\mathcal{R}_{local} \cup \mathcal{R}^k$ form $\ell$ disjoint subsets then          ▷
    Theorem 3
 9:             $Best(\mathcal{R}^k) \leftarrow Best(\mathcal{R}_1^k) \times Best(\mathcal{R}_2^k) \times \cdots \times$
    $Best(\mathcal{R}_\ell^k)$
10:         else for each call $C_i \in \mathcal{R}^k$                     ▷ Theorem 1
11:             rewrite $C_i$ as $\overrightarrow{C_i}$ by using binding from $P_{local} \bowtie$
    $Best(\mathcal{R}^k - C_i)$
12:             $P_{bind} \leftarrow$ SemanticRewrite($\overrightarrow{C_i}, \mathcal{V}, \mathcal{M}$)
13:             $P_{temp} \leftarrow Best(\mathcal{R}^k - C_i) \bowtie Best(C_i)$
14:             if $\phi(P_{bind}) \leq \phi(Best(C_i))$ then
15:                 $P_{temp} \leftarrow Best(\mathcal{R}^k - C_i) \overrightarrow{\bowtie} P_{bind}$
16:             update $Best(\mathcal{R}^k) \leftarrow P_{temp}$ if $\phi(Best(\mathcal{R}^k)) \geq$
    $\phi(P_{temp})$
```

Second, answering a query using the stored query results may include obsolete tuples if datasets permit *in-place* data update. However, so far the datasets we found in Windows Azure Marketplace are append-only. In case in-place data update exists, we will introduce several *consistency levels* into PayLess. That would allow organizations that install PayLess to choose between consistency levels like *(i) weak consistency*, *(ii) X-week consistency*, or *(iii) full consistency*. Weak consistency means all RESTful queries and their results are stored in the semantic store (with obsolete results get updated if new results are retrieved). Under weak consistency, semantic query rewriting is always enabled. Queries may however return partially obsolete results when there are in-place updates in the data market's datasets because it reuses some obsolete stored results. Strong consistency means semantic query writing is simply disabled and PayLess always go to the data market to obtain the latest results. X-week consistency is in the middle, it enables semantic query rewriting using query results retrieved from the past X weeks. The three options are trade-off between price-to-pay and the freshness of the result.

5. EVALUATION

PayLess aims to help organizations to pay less when their end users have to query against the data market. Without PayLess, one option is to employ query optimizers for data sources with limited access pattern because those optimizers at least consider binding patterns and bind joins in their architecture. Another option is to download all required tables from the data market upfront and carry out local processing afterwards. Notice this "Download All" option is not always bad. First, it is optimal if the queries have to scan the whole dataset. In this case, once the whole dataset is downloaded, all queries can work on the downloaded data locally. Second, if the number of transactions incurred by user queries would eventually exceed the number of transactions required to download the complete data set, then downloading the whole dataset upfront would be a more economical option. However, we re-iterate that it is always tough to predict how many user queries would eventually be issued in practice. Consider that the users walk away from the dataset forever after issuing just a few queries (maybe due to no interesting information is found), then downloading the whole dataset would become a very costly option.

In this section, we evaluate the effectiveness of PayLess using both real data and synthetic data. Specifically, we extract query templates from a meteorological application that involves queries to the Worldwide Historical Weather (WHW) [13] and Environmental Hazard Rank (EHR) [6] datasets in Windows Azure Marketplace. Table 1 lists the query templates and Figure 1a lists the sizes of the tables. We generate *valid* query instances from those templates by randomly assigning values to the parameters. A query instance is valid if it returns non-empty results (e.g., we would not instantiate Q_4 with a country equals 'USA' but a zip code in Germany). We also use the TPC-H workload in the experiments. We generate 1G of TPC-H data and 1G of TPC-H skew data [19] with $zipf = 1$. All parametric attributes in TPC-H queries are set as free attributes in the experiments. We set the relations `Nation` and `Region` local. By default, we set 100 tuples as one transaction (i.e., $t = 100$).

Overall effectiveness. We first study the overall effectiveness of PayLess under different workloads and datasets. For comparison, we include the results of using [27] to optimize the queries (denoted as "Minimizing Calls" in the figure). We also include the results of disabling semantic query rewriting (SQR) in PayLess (denoted as "PayLess w/o SQR" in the figure). We respectively generated q query instances per template. The query instances are issued in a random order and the results are reported as an average over 30 repeated experiments. In this experiment, we set $q = 10$ and $q = 200$ for TPC-H workload and real workload, respectively.

Figure 10a illustrates the total (cumulative) number of data market transactions used to answer the real queries. Except the "Download All" option, when more queries are issued, the total (cumulative) number of data market transactions increases. Comparing with those data buyers who recklessly download the whole dataset upfront, PayLess can now help them to answer the queries using about two orders of transactions fewer. The number of transactions used by PayLess grows slowly because many queries are rewritten using the stored results in the semantic cache. PayLess can answer the queries using about an order of transactions fewer than queries optimized using [27]. That is because semantic query rewriting (SQR) is not applicable to their setting but is a powerful helper here in our data market setting. When we disable SQR, PayLess still outperforms [27]. That is because PayLess can find optimal plans in a reduced search space using progressively refined statistics. In contrast, [27] has to find plans in a larger search space (including bushy trees) using heuristics.

Figures 10b and c show the results of using TPC-H workload. TPC-H queries scan a large portion of data. Therefore, without rewriting the queries using the stored data, each query optimized by [27] and PayLess (if SQR is disabled) would retrieve a large portion of the data from the data market, and those data are largely overlapping with each other. That explains why they are worse than "Download All", because the latter only downloads the whole dataset once. When PayLess is in full power with semantic query rewriting, we see that the subsequent queries can largely reuse the stored results, thereby saving a lot more transactions than "Download All" until about 80 queries have been issued. When about 80 queries have been issued, all the data required by TPC-H queries (indeed the whole TPC-H dataset) are stored by PayLess, therefore PayLess would not repeatedly retrieve the data from the data market anymore. From the above experimental results, we regard PayLess to be practically better than "Download All" in all means because nobody could have known the number of queries to be issued and the distribution of the data in practice. A data buyer can freely query against any dataset in the data market and walk away from that dataset anytime — she does not need to worry whether it is worth or not to download the whole dataset in the beginning, or switch to download the whole dataset when she finds out that she has to ask more queries after she has burned a certain amount of money.

Influence of number of tuples per transaction. We next study whether the effectiveness of PayLess would be influenced by the number of tuples per transaction, which could be a different value in different data markets. Since [27] is consistently outperformed by PayLess in all our experiments, so we remove it, together with PayLess with semantic query rewriting disabled, from our discussion.

Figure 11 shows the effectiveness of PayLess when we vary the number of tuples per transaction t. Note that when t is smaller, more transactions are required to retrieve the same number of tuples from the data market. Therefore, the number of transactions used by both PayLess and "Download All" must increase. Nevertheless, we see that the effectiveness of PayLess is not influenced by that data market parameter. PayLess still outperforms "Download All" under real data in all cases. In addition, it still outperforms "Download All" on TPC-H and TPC-H skew data until the whole dataset is retrieved.

Influence of number of query instances per query template. We next study whether the effectiveness of PayLess would be influenced by q, the number of query instances per query template. Figure 12 shows that the effectiveness of PayLess is not influenced by that parameter. We see that PayLess still consistently outperforms "Download All" on real data in all cases. In addition, it still outper-

forms “Download All" on TPC-H and TPC-H skew data until the whole dataset is retrieved.

Influence of data size. We also study whether the effectiveness of PayLess would be influenced when the size of the data is varied. As we cannot control the size of the real data, we control only the size of the synthetic data.

Note that when the data size increases, “Download all” needs more transactions to download the whole dataset. But PayLess also needs to retrieve more tuples for each query. Figure 13 shows that PayLess still outperforms “Download All" on TPC-H and TPC-H skew data until the whole dataset is retrieved.

Effectiveness of search space reduction techniques. We have also carried out an experiment to evaluate the effectiveness of our techniques devoted to reducing the search space size. Figure 14 shows the average number of candidate (sub)plans for all query instances under our default setting. We report the case when (i) SQR is disabled (Disable SQR), (ii) both SQR and search space pruning (Theorems 1 to 3) are disabled (Disable All), and (iii) nothing is disabled (PayLess). We can see that our techniques significantly reduce the search space by orders of magnitude. This is actually what enables us to look for optimal plans. We notice that enabling SQR indeed reduces the search plan because SQR would cause some relations become local, which can then trigger Theorem 2. This also explains why the average number of candidate (sub)plans PayLess has to considered decreases when we increase the number of query instances generated for each template. That is because if we increase the number of query instances generated for each template, that would retrieve more data from the data market, which in turn increases the chance of using Theorem 2 to reduce the search space.

Effectiveness of bounding box pruning. Our last experiment is to evaluate the effectiveness of the bounding box pruning rules in Algorithm 1. Figure 15 shows the average number of bounding boxes generated for all query instances under our default setting. We see that the two pruning rules can reduce about an order bounding boxes generated.

Efficiency. In all experiments, the execution time of a query is, as usual, dominated by the RESTful calls to the data seller. Nevertheless, a query can still finish within seconds. The query optimization and the query execution part done by PayLess on the data buyer side all finish within milliseconds. We omit the detailed numbers here for space reasons.

6. RELATED WORK

To the best of our knowledge, this paper is the first to tackle the issue of optimizing queries that access the data market. So far, projects related to the data market are mainly developed for *query market*. In their setting, the query market can support SQL. A data buyer sends a SQL query that accesses a dataset in the query market. The query market computes the results of the query and returns the answer to the buyer. The research focus is how to set the price of arbitrary SQL queries (e.g. [15,16,30,31,37,39,47]). The setting of query market is different from our data market setting. Specifically, existing data market like Windows Azure Marketplace [1] and Xignite [14] are still charging data buyers according to the size of retrieved data.

In terms of problem setting, PayLess is indeed more similar to projects that support queries over remote data sources with limited access patterns (e.g., [17,20,24,27,33–36,40,45]). Nevertheless, as mentioned, all these projects have a very different focus with us — they are designed to minimize the number of calls to external data and/or the execution time. In contrast, PayLess focuses on minimizing the amount of intermediate retrieved data measured in terms of data market transactions. Besides, the optimization of distributed queries with semi-join/magic sets [18,43] are similar to PayLess; however, they do not consider limited access patterns.

In terms of implementation, PayLess has borrowed the idea of learning optimizer from LEO [46] and has used feedback driven histogram ISOMER [44]. However, PayLess has to develop its own architecture, construct its own plan search space, and devise its own semantic query rewriting technique (e.g., [21,23,32,41]) to fit the data market. In computational geometry, the problem of partitioning an orthogonal polygon into rectangles (PiR) [26] is similar to our remainder query generation problem, but they are not the same. Using Figure 7b as an example, the PiR problem would NOT consider Q_7^{Rem}, which contains some empty regions. In contrast, in our context, Q_7^{Rem} could be a good choice according to our cost function.

7. CONCLUSION

This paper presents PayLess, a system that helps data buyers to freely query against any dataset in the data market and walk away from that dataset anytime. The data buyers do not need to worry whether it is worth or not to download the whole dataset in the beginning. They can simply issue their queries to PayLess and PayLess optimizes their queries with the objective of minimizing their money-to-pay-to-data-sellers. Currently, our use-case does not cover many end users using PayLess simultaneously. When it does, we will incorporate multi-query optimization in PayLess if users are willing to defer theirs to become a batch.

ABSTRACT

Information extraction systems extract structured data from natural language text, to support richer querying and analysis of the data than would be possible over the unstructured text. Unfortunately, information extraction is a computationally expensive task, so exhaustively processing all documents of a large collection might be prohibitive. Such exhaustive processing is generally unnecessary, though, because many times only a small set of documents in a collection is useful for a given information extraction task. Therefore, by identifying these useful documents, and not processing the rest, we could substantially improve the efficiency and scalability of an extraction task. Existing approaches for identifying such documents often miss useful documents and also lead to the processing of useless documents unnecessarily, which in turn negatively impacts the quality and efficiency of the extraction process. To address these limitations of the state-of-the-art techniques, we propose a principled, learning-based approach for ranking documents according to their potential usefulness for an extraction task. Our low-overhead, online learning-to-rank methods exploit the information collected during extraction, as we process new documents and the fine-grained characteristics of the useful documents are revealed. Then, these methods decide when the ranking model should be updated, hence significantly improving the document ranking quality over time. Our experiments show that our approach achieves higher accuracy than the state-of-the-art alternatives. Importantly, our approach is lightweight and efficient, and hence is a substantial step towards scalable information extraction.

1. INTRODUCTION

Information extraction systems are complex software tools that discover structured information in natural language text. For instance, an information extraction system trained to extract tuples for an *Occurs-in*(*NaturalDisaster*, *Location*) relation may extract the tuple <tsunami, Hawaii> from the sentence: "*A tsunami swept the coast of Hawaii.*" Having information in structured form enables more sophisticated querying and data mining than what is possible over the natural language text. Unfortunately, information extraction is a time-consuming task. A state-of-the-art information extraction system to extract *Occurs-in* tuples may take more than two months to process a collection containing about 1 million documents. Since document collections routinely contain several millions of documents, improving the efficiency and scalability of the extraction process is critical, even over highly parallel computation environments.

Interestingly, extracting a relation of interest with a properly trained information extraction system rarely requires processing all documents of a collection: Many times only a small set of documents produces tuples for a given relation, because relations tend to be topic-specific, in that they are associated mainly with documents about certain topics. For example, only 1.69% out of the 1.03 million documents in collections 1-5 from the TREC conference[1] produce *Occurs-in* tuples when processed with a state-of-the-art information extraction system and, not surprisingly, most of these documents are on environment-related topics. If we could identify the small fraction of documents that lead to the extraction of tuples, we would extract all tuples while decreasing the extraction time by over 90% without any need to change the information extraction system.

To identify the documents that produce tuples for an extraction task, which we refer to as the *useful* documents, existing techniques (e.g., QXtract [2], PRDualRank [14], and FactCrawl [7]) are based on the observation that such documents tend to share words and phrases that are specific to the extraction task at hand. For example, documents containing mentions of earthquakes—hence useful for the *Occurs-in* relation—many times include words like "richter" or "hypocenter." These words and phrases can then be used as keyword queries, to retrieve from the collection the (hopefully useful) documents that the extraction system will then process. To discover these words and phrases, a critical step in the process, these techniques analyze a sample of documents from the collection of interest. The size of this document sample is necessarily small to keep the overhead of the querying approach at reasonable levels.

Unfortunately, small document samples are unlikely to reflect the typically large variations in language and content

[1]http://trec.nist.gov/data.html

10.5441/002/edbt.2015.22

that useful documents for an extraction task may exhibit. For example, a document sample for *Occurs-in* may not include any documents on (relatively rare) volcano eruptions, and hence these techniques may fail to derive queries such as [lava] or ["sulfuric acid"] that would retrieve relevant, volcano-related documents. As a result, the queries from existing techniques may suffer from low recall during extraction. Furthermore, precision is also compromised: standard keyword search identifies documents whose topic is relevant to the queries, without considering their relevance to the information extraction task at hand.

To alleviate the precision-related issue above, FactCrawl [7] moves a step beyond keyword search: after retrieving documents with sample-derived keyword queries, FactCrawl reranks the documents according to a simple function of the number and "quality"—based on their F-measure [27]—of the queries that retrieved them, thus helping prioritize the extraction effort. However, FactCrawl exhibits two key weaknesses: (i) for document retrieval and ranking, FactCrawl relies on queries derived, once and for all, from a document sample, and hence suffers from the sample-related problems discussed above; (ii) for document ranking, FactCrawl relies on a coarse, query-based document scoring approach that is not adaptive (i.e., the scoring function does not change as we observe new documents). Therefore, this approach does not benefit from the information that is captured as the extraction process progresses.

In this paper, we advocate an adaptive document ranking approach that addresses the above limitations of the state-of-the-art techniques. Specifically, we propose a principled, efficient learning-to-rank approach that prioritizes documents for an information extraction task by combining: (i) online learning [30], to train and adapt the ranking models incrementally, hence avoiding computationally expensive retrains of the models from scratch; and (ii) in-training feature selection [17], to identify a compact, discriminative set of words and phrases from the documents to train ranking models effectively and efficiently. Importantly, our approach revises the document ranking decisions periodically, as the ongoing extraction process reveals (fine-grained) characteristics of the useful documents for the extraction task at hand. Our approach thus manages to capture, progressively and in an adaptive manner, the heterogeneity of language and content typically exhibited by the useful documents, which in turn leads to information extraction executions that are substantially more efficient—and effective—than those with state-of-the-art approaches, as we will see. In summary, we present an end-to-end document ranking approach for effective and efficient information extraction in an adaptive, online, and principled manner. Our main contributions are:

- Two low-overhead ranking algorithms for information extraction based on learning-to-rank strategies. These algorithms perform online learning and in-training feature selection (Section 3.1).
- Two techniques to detect when adapting the ranking model for information extraction is likely to have a significantly positive impact on the ranking quality (Section 3.2).
- An experimental evaluation of our approach using multiple extraction tasks implemented with a variety of extraction approaches (Sections 4 and 5). Our approach has low overhead and manages to achieve higher accuracy than the state-of-the-art approaches, and hence is a substantial step towards scalable information extraction.

2. BACKGROUND AND RELATED WORK

Information extraction systems extract structured information from natural language text. For instance, an extraction system properly trained to extract tuples of an *Occurs-in*(*NaturalDisaster*, *Location*) relation might extract the tuple <tsunami, Hawaii> from the sentence: "*A tsunami swept the coast of Hawaii.*" These systems often rely on computationally expensive processing steps and, consequently, processing all documents exhaustively becomes prohibitively time consuming for large document collections [2]. Ideally, we should instead focus the extraction effort on the *useful* documents, namely, the documents that produce tuples when processed with the information extraction system at hand.

As a crucial task, information extraction optimization approaches (e.g., Holistic-MAP [31]) choose a document selection strategy to identify documents that are likely to be useful. State-of-the-art approaches for such document selection (e.g., QXtract [2], PRDualRank [14], and FactCrawl [7]) are based on the observation that useful documents for a specific relation[2] tend to share distinctive words and phrases. Discovering these words and phrases is challenging because: (i) many extraction systems rely on off-the-shelf, black-box components (e.g., named entity recognizers), from which we cannot extract relevant words and phrases directly; and (ii) machine learning techniques for information extraction do not generally produce easily interpretable models, which complicates the identification of relevant words and phrases. QXtract learns these words and phrases through document classification: after retrieving a small document sample, QXtract automatically labels each document as useful or not by running the extraction system of interest over these documents. QXtract can thus learn that words like "richter" or "hypocenter" are characteristic of some of the useful documents for *Occurs-in*. Then, QXtract uses these learned words and phrases as keyword queries to retrieve (other) potentially useful documents (see Figure 1). More recent approaches (e.g., FactCrawl [7] and PRDualRank [14]) adopt similar retrieval-based document selection strategies.

QXtract issues queries to the standard keyword search interface of document collections in order to retrieve potentially useful documents for extraction. Such keyword search interface, unfortunately, is not tailored for information extraction: the documents that are returned for a keyword query are ranked according to how well they match the query and not on how useful they are for the underlying information extraction task [7]. For example, the query [tornado] for the *Occurs-in* relation returns only 145 useful documents among the top-300 matches from our validation split of the New York Times annotated corpus[3] (see Section 4) using Lucene[4], a state-of-the-art search engine library.

FactCrawl [7] moves a step beyond keyword search and reranks the retrieved documents to prioritize the extraction effort (see Figure 1). Specifically, FactCrawl scores documents proportionally to the number and quality of the queries that retrieve them. FactCrawl determines the quality of each learned query—and of the query generation method that

[2]Our approach is not applicable over open information extraction scenarios (e.g., [4]) where most documents often contribute tuples to the open-ended extraction task.
[3]http://catalog.ldc.upenn.edu/LDC2008T19
[4]http://lucene.apache.org/

was used to generate the query—in an initial step, once and for all, by retrieving a small number of documents with the query and running them through the extraction system in question. With this initial step, FactCrawl derives: (i) for each query q, the F-measure $F_\beta(q)$, where β is a parameter that weights precision over recall; and (ii) for each query generation method m, the average $F_\beta^{avg}(m)$ of the F_β value of all queries generated with method m. During the extraction process, after retrieving documents with a set Q_d of queries learned via a query generation method m, FactCrawl re-ranks the documents according to a scoring function $S(d) = \sum_{q \in Q_d} F_\beta(q) \cdot F_\beta^{avg}(m)$. FactCrawl's document re-ranking process improves the efficiency of the extraction, since the documents more likely to be useful are processed earlier. However, FactCrawl exhibits two key weaknesses: (i) for document retrieval and ranking, just as QXtract (see discussion above), FactCrawl relies on queries derived, once and for all, from a small initial document sample, and hence may miss words and phrases relevant to the information extraction task at hand; and (ii) for document ranking, FactCrawl relies on a coarse, query-based document scoring approach that is not adaptive, and hence does not benefit from the wealth of information that is captured as the extraction process progresses.

Adaptive models have been used for information extraction in a variety of ways. Early influential systems for large-scale information extraction, such as DIPRE [10] and Snowball [1], have relied on bootstrapping to adapt to newly discovered information. Starting with a small number of "seed" tuples for the extraction task of interest, these systems learn and iteratively improve extraction patterns and, simultaneously, build queries from the tuples that they discover using these patterns. However, these systems are not suitable for our problem for two main reasons. First, techniques based on bootstrapping often exhibit far-from-perfect recall, since it is difficult to reach all tuples in a collection by using previously extracted tuples as queries [2, 19]. Second, extraction systems are many times "black box" systems, which impedes the alteration of their extraction decisions. Other approaches (e.g., [12]) have relied on label propagation: starting with labeled and unlabeled examples, these approaches propagate the given labels to the unlabeled examples based on some example similarity computation. Such label propagation approaches are not beneficial for our extraction scenario, where the extraction system has already been trained and we can obtain new labels (i.e., useful or not) for previously unseen documents automatically by running the extraction system over them.

3. ONLINE ADAPTIVE RANKING

We now propose an end-to-end document ranking approach for scalable information extraction (see Figure 2) that addresses the limitations of the state of the art. Our approach prioritizes documents for an information extraction task—with a corresponding already-trained information extraction system—based on principled, efficient learning-to-rank approaches that exploit the full contents of the documents (Section 3.1). Additionally, our approach revises the ranking decisions periodically as the extraction process progresses and reveals (fine-grained) characteristics of the useful documents for the extraction task at hand (Section 3.2). Our approach thus manages to capture, progressively and in an adaptive manner, the heterogeneity of language and

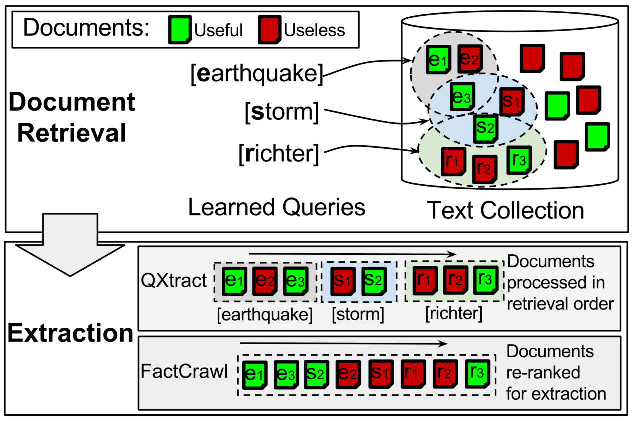

Figure 1: QXtract and FactCrawl.

content typically exhibited by the useful documents, which leads to extraction processes substantially more efficient—and effective—than those with state-of-the-art approaches, as we will show experimentally in Sections 4 and 5.

3.1 Ranking Generation

To prioritize the information extraction effort, by focusing on the potentially useful documents for the extraction system at hand, we follow a learning-to-rank approach (see Ranking Generation step in Figure 2). Similarly to state-of-the-art query-generation and ranking efforts (see Section 2), we obtain a small document sample and automatically "label" it with the information extraction system, without human intervention. We use the documents in this sample, with their words as well as the attribute values of tuples extracted from them as features, to train an initial document ranking model. After the initial document ranking is produced, we start processing documents, in order, with the information extraction system (see Tuple Extraction step in Figure 2).[5] Unfortunately, the initial ranking model is generally far from perfect, because it is learned from a necessarily small document sample. So our approach periodically updates and refines the ranking model (see Update Detection step in Figure 2), as new documents are processed and the characteristics of the useful documents are revealed, as we will discuss in detail in Section 3.2.

Unfortunately, state-of-the-art approaches for learning to rank [23] are problematic for our document ranking setting for two main reasons. First, such approaches tend to be computationally expensive [29], so updating and revising the ranking model continuously over time, as new documents are processed, would result in an unacceptably high overhead in the extraction process. Second, such approaches tend to require a relatively small feature space [3]. In contrast, in our ranking setting the feature space, including the document words and attributes of extracted tuples, is vast; furthermore, the feature space continues to grow as new documents are processed. Therefore, we need to develop unconventional learning-to-rank techniques for our ranking prob-

[5]The pool of documents to process is either the full document collection, for collections of moderate size over which we have full access, or, alternatively, the documents retrieved with queries learned from the document sample. In Sections 4 and 5, we discuss this issue further and experimentally study these two scenarios.

lem, to address the above two limitations of state-of-the-art approaches in an effective and efficient manner and without compromising the quality of the ranking models that we produce.

To address the efficiency limitation of learning-to-rank approaches, and to update the document ranking model efficiently, we rely on *online learning* [8]. Using online learning, we can train the ranking model incrementally, one document at a time. Therefore, we can continuously adapt the ranking model as we process new documents, without having to retrain it from scratch. To adapt online learning to our problem, the main challenge is to define an update rule for the model—to be triggered when we observe new documents along the extraction process—that is simple enough to be efficient but, at the same time, sophisticated enough to produce high-quality models. From among the most robust online learning approaches [8], the updates based on Pegasos gradient steps [30] are particularly well suited for our approach because of their efficiency and accuracy. Specifically, Pegasos gradient steps provide update rules that guarantee that learning techniques based on Support Vector Machines (SVM), the basis for some of the best-performing learning-to-rank approaches, learn high-quality models efficiently.

To address the feature-set limitation of learning-to-rank approaches, and to handle large (and expanding) feature sets, we rely on *in-training feature selection* [17]. In a nutshell, with in-training feature selection the learning-to-rank algorithm can efficiently identify the most discriminative features, out of a large and possibly expanding feature set, during the training of the document ranking model and without an explicit feature selection step. To do so, we rely on a sparse representation of the vectors that represent the feature weights, to discard all features with zero value. Therefore, our objective is to penalize models that rely on a large number of features with non-zero weight. Interestingly, we can rely on *regularization* [6] to control the feature weight distribution in our learned models: regularization penalizes models that have undesirable properties such as having many features with non-zero weights, so we can use it for in-training feature selection and also to avoid overfitting. In our approach, we rely on a linear combination of two regularization methods, usually called elastic-net regularization [35], which integrates: (i) the ℓ_1-norm regularization [32], which tends to learn models where only a small subset of the features have non-zero weights; and (ii) the ℓ_2-norm regularization, which produces high-quality models by avoiding overfitting. This combination is necessary because the ℓ_1-norm regularization does not perform well when the number of documents is smaller than the feature space [35], which is the case during early phases of the extraction process.

We now propose two learning-to-rank strategies, BAgg-IE and RSVM-IE, that overcome the limitations of state-of-the-art learning-to-rank approaches by integrating online learning and in-training feature selection, as discussed above.

BAgg-IE: Our first strategy incorporates online learning and in-training feature selection into a binary classification scheme where documents are ranked according to their assigned label and prediction confidence. Since binary classifiers optimize the accuracy of label assignment instead of the instance order, they are not optimized for ranking tasks [18]. For this reason, BAgg-IE adopts a more robust approach that exploits multiple binary classifiers based on bootstrapping aggregation, or bagging [9]. With this approach, the label assignments and confidence predictions derive from the aggregation of the answers of a committee of classifiers, rather than from an individual classifier. The intuition behind BAgg-IE is that each classifier is able to evaluate distinct aspects of the documents, thus collectively mitigating the limitations of each individual classifier. We adapt SVM-based binary classifiers [20] to support online learning and in-training feature selection. For online learning, our algorithm is based on Pegasos, in which each text document is a training instance and, hence, we update the model one document at a time. For in-training feature selection, each classifier in BAgg-IE combines the SVM binary classification problem with the regularization components of the elastic-net regularization framework that we discussed earlier, thus yielding the following learning problem to solve:

$$\arg\min_{\mathbf{w},b} \lambda_{All}\left(\frac{\lambda_{L2}}{2}\|\mathbf{w}\|_2 + (1-\lambda_{L2})\|\mathbf{w}\|_1\right) + \sum_{(\mathbf{d},y)\in\mathcal{S}} \ell(y\langle\mathbf{w},\mathbf{d}\rangle + b)$$

where b is the bias factor, ℓ is the hinge loss function, $\ell(t) = max(0, 1-t)$, and $\|\mathbf{w}\|_1$ and $\|\mathbf{w}\|_2$ are the ℓ_1 and ℓ_2-norms of the weight vector (i.e., the regularization components), respectively. Moreover, λ_{All} is the parameter that weights the regularization component over the loss function, and λ_{L2}, $0 \leq \lambda_{L2} \leq 1$, is the parameter that weights the ℓ_2-norm regularization over the ℓ_1-norm regularization.

The committee in BAgg-IE consists of three classifiers[6], trained over disjoint splits of the documents, which leads to different feature spaces for each, and with balanced labels (i.e., same number of useful and useless documents). Finally, to obtain the score of a text document we sum over the normalized scores of each classifier $s(\mathbf{d}) = \frac{1}{1+e^{-(\mathbf{w}^\top\mathbf{d}+b)}}$, which accounts for the differences in the feature weights of each classifier. In this equation, $\mathbf{w}$ and b are the weight vector and bias factor, respectively, of the classifier.

In summary, BAgg-IE addresses the ranking problem as an optimized classification problem. In contrast, our second technique, RSVM-IE, which we describe next, adopts a principled learning-to-rank approach natively.

RSVM-IE: Our second learning-to-rank strategy is based on RankSVM [21], a popular and effective pairwise learning-to-rank approach. Just as we did for BAgg-IE, we need to modify RankSVM's original optimization problem so that it incorporates in-training feature selection and, in turn, suits our ranking problem. In a nutshell, RankSVM scores the

[6]Additional classifiers would slightly improve performance at the expense of substantial overhead.

documents via a linear combination of the document features: the score of a document d is $s(d) = \sum_i w_i \cdot d_i$, where w_i is the weight of feature i and d_i is the value of feature i in document d. The objective of RankSVM is then to find the set of weights $\mathbf{w} = \{w_1, ..., w_n\}$ that is optimized to determine, in a pair of documents, if a document is more relevant than the other document. To achieve this, RankSVM learns the feature weights by comparing the features of useful and useless documents in pairs: each pair includes a useful and a useless document, and the label indicates whether the useful document is the first document in the pair.

By integrating the in-training feature selection discussed above into the original RankSVM formulation, we obtain the following optimization problem to solve for RSVM-IE:

$$\arg\min_{\mathbf{w}} \lambda_{All}(\frac{\lambda_{L2}}{2}\|\mathbf{w}\|_2+(1-\lambda_{L2})\|\mathbf{w}\|_1)+\sum_{(i,j)\epsilon\mathcal{P}} \ell(\mathbf{w}^\top(\mathbf{d}_i-\mathbf{d}_j))$$

where all variables are defined as for BAgg-IE, and $\mathbf{d}_i$ and $\mathbf{d}_j$ represent a useful and a useless document, respectively. For online learning, and in contrast to BAgg-IE, which uses the individual documents in the Pegasos scheme, the training examples are the pairs of useful and useless documents that the extraction process observes, which is known as *Stochastic Pairwise Descent* [29].

Unlike BAgg-IE, RSVM-IE is designed from the ground up to address a ranking task, so we expect it to outperform BAgg-IE. Moreover, we expect the overhead of RSVM-IE to be substantially lower than that of BAgg-IE, since BAgg-IE maintains multiple learned models (i.e., the classifiers in the committee). This overhead becomes noticeable when the models are frequently updated. Next, we explain our approach to decide when an update of the ranking models is desirable during the extraction process, thus reducing the overall document re-ranking overhead.

3.2 Update Detection

As we mentioned in Section 3.1, our adaptive extraction approach revises the ranking decisions periodically, to account for the new observations gathered along the extraction process. To determine when to update the ranking model (and, correspondingly, the document ranking), we introduce the *Update Detection* step (see Figure 2). To make this decision, we analyze whether the features of recently processed documents differ substantially from those in the ranking model. If this is the case, then we trigger a new ranking generation step (Section 3.1), which uses the recently processed documents as additional training examples. The new training examples often reveal novel features, or lead to adjusting the weight of known features, which in turn helps to more effectively prioritize the yet-unprocessed documents.

One possible approach for update detection is through feature shifting detection techniques [16]. Feature shifting predicts whether the distribution of features in a (test) dataset differs from the distribution of the features in the training data. Unfortunately, most feature shifting techniques are problematic: First, they rely on computationally expensive algorithms (e.g., kernel-based one-class SVM classifier [16]), thus incurring substantial overhead when applied repeatedly. Second, these techniques only detect changes in existing features, so they do not handle well the evolving feature space in our problem. Thus, the features that do not appear in the ranking would not be considered in the comparison, unless we re-train the kernel-based classifier from scratch, which would be prohibitively expensive.

As efficient alternatives, we introduce two update detection approaches, namely, Top-K and Mod-C. Top-K evaluates a reduced set of highly relevant features, determined independently from the ranking model, whereas Mod-C directly manipulates the low-level characteristics of the ranking model to detect changes in the feature space.

Top-K: Our first approach exploits the fact that the predicted usefulness of the documents in the current ranking varies the most when the highly influential features in the ranking model change. For instance, if the word "lava" becomes more frequent along the processed useful documents in our *Occurs-in* example, this feature will become (temporarily) more relevant than others. In that case, the predicted usefulness of documents that include such word should increase accordingly to be prioritized over other documents. Based on this observation, Top-K compares the K most influential features in the current ranking against the K most influential features according to the recently processed documents, and triggers an update when the difference between these two sets exceeds a given threshold τ, determined experimentally, as we explain in Section 4. Overall, Top-K consists of two key steps: (i) *feature selection*, which selects the K most influential features; and (ii) *feature comparison*, which measures the distance between two sets of features. To perform feature selection, we choose the K features with highest weight in an SVM-based linear classifier trained—and subsequently updated—on the same features (i.e., words and tuple attributes) as the ranking algorithm. To perform feature comparison, we compute a generalized version of the Spearman's Footrule[7] [22], which considers the relative position of the features and their weights. According to this measure, the difference between feature weights will be higher when heavily weighted features change positions.

As discussed, Top-K maintains its own set of relevant features according to an SVM-based binary classifier. The advantage of this approach is that it makes Top-K independent of the ranking technique. However, the relevant features in this classifier may differ from those in the ranking model [18]. In our *Occurs-in* example, for instance, a trained RankSVM model weighted the word "northern" as a top-20 feature, whereas a linear SVM model trained on the same documents weighted "northern" almost neutrally. Such discrepancies in the feature relevance may cause updates that have little impact on the document ranking or, alternatively, may lead to missing necessary updates because important features are not being evaluated. We now introduce Mod-C, which works directly with the ranking models, to capture feature relevance directly.

Mod-C: The techniques in Section 3.1 learn ranking models that consist of a vector of numeric weights, where each weight represents the captured relevance of one feature. We can then use a vector similarity metric, such as cosine similarity [24], to measure the difference between the relevance of features in two similar ranking models. Our second technique, Mod-C, exploits this observation and compares the current ranking model to an "updated" ranking model that also includes some of the recently processed documents. This

[7]The generalized version of the Spearman's Footrule that we use is given by $\sum_i w_i \cdot \left|\sum_{j:j\leq i} w_j - \sum_{j:\sigma(j)\leq\sigma(i)} w_j\right|$, where $\sigma(i)$ is the rank of feature i and w_i is its weight.

updated ranking model includes only a fraction ρ of the recently processed documents, since including all of these documents would incur substantial overhead. To compare the ranking models, Mod-C depends on a metric suitable for the ranking model (e.g., cosine similarity for RSVM-IE) and a threshold α, determined experimentally as we explain in Section 4, that needs to be exceeded to trigger an update. In our cosine similarity example, α would indicate the maximum allowed angle between ranking models, hence triggering an update when this angle is exceeded. Mod-C is thus able to handle the real relevance of features, crucial to precisely decide when an update in the ranking model will improve the current document ranking.

In summary, we propose two update detection techniques that decide efficiently when it is beneficial to revise the ranking decisions to adaptively improve the extraction process.

4. EXPERIMENTAL SETTINGS

We now describe the experimental settings for the evaluation of our adaptive ranking approach:

Datasets: We used the *NYT Annotated Corpus* [28], with 1.8 million New York Times articles from 1987 to 2007. We split this corpus into a training set (97,258 documents), a development set (671,457 documents), and a test set (1,086,944 documents). We evaluated different combinations of techniques and parameters on the development set. We ran the final experiments on the test set. Additionally, we used collections 1-5 from the TREC conference[8] to generate the queries for the query-based sample generation that we explain later in this section.

Document Access: As mentioned in Section 3.1, we consider two document-access scenarios: In the *full-access* scenario, we rank all documents in a (moderately sized) document collection. In contrast, in the (more realistic) *search interface access* scenario, we retrieve the documents to rank through keyword queries. We evaluate our ranking approach over both scenarios. For the search interface access scenario we learn the queries following QXtract (Section 2) to retrieve an initial pool of documents. Also, we provide a search interface over our collection using the Lucene indexer, to retrieve additional documents as the extraction process progresses: after each ranking update, we use the top-100 features of the updated ranking model as individual text queries to retrieve additional (potentially) useful documents.

Relations: Table 1 shows the broad range of relations from different domains that we extract for our experiments, with the number of useful documents for each relation in the test set. Our relations include *sparse* relations, for which a relatively small fraction of documents (i.e., less than 2% of the documents) are useful, as well as *dense* relations.

Information Extraction Techniques: We selected the extraction approach for each relation to include a variety of extraction approaches (e.g., both machine learning and rule-based approaches, as well as techniques with varying speed). Specifically, we considered different entity and relation extractors for each relation, and selected the best performing combination. However, for diversity, whenever we had ties in performance, we selected the (arguably) less common contender (e.g., a pattern-based approach to extract organizations and Maximum Entropy Markov Model [25], or MEMM, for natural disasters):

[8]http://trec.nist.gov/data.html

Relation	Useful Documents
Person–Organization Affiliation (PO)	185,237 (16.95%)
Disease–Outbreak (DO)	847 (0.08%)
Person–Career (PC)	458,294 (42.16%)
Natural Disaster–Location (ND)	18,370 (1.69%)
Man Made Disaster–Location (MD)	15,837 (1.46%)
Person–Charge (PH)	19,237 (1.77%)
Election–Winner (EW)	5,384 (0.50%)

Table 1: Relations for our experiments.

- For the Person–Organization Affiliation relation we used Hidden Markov Models [13] and automatically generated patterns [34] as named entity recognizers for Person and Organization, respectively. We used SVM [15] to extract the relation.
- For the Disease–Outbreak relation we used dictionaries and manually crafted regular expressions as named entity recognizers for Disease and Temporal Expression, respectively. We used the distance between entities to predict if they are related.
- For the remaining relations, we used Stanford NER[9] to find Person and Location entities, a MEMM [25] to find Natural Disasters, and Conditional Random Fields [26] to find the remaining entities. Then, we used the Subsequence Kernel [11] to identify relations between these entities.

Development Toolkits: We used the following off-the-shelf libraries: (i) Lingpipe[10], for rule-based named entity extraction; (ii) OpenNLP[11], for word and sentence segmentation; (iii) E-txt2db[12] and Stanford NER, to train and execute named entity extractors based on machine learning; and (iv) REEL[13] [5], to train relation extraction models.

Sampling Strategies: We compared two techniques to collect the initial document sample for our ranking techniques (Section 3.1):

- *Simple Random Sampling (SRS):* SRS picks 2,000 documents at random from the collection (only for the *full-access* scenario).
- *Cyclic Query Sampling (CQS):* CQS iterates repeatedly over a list of queries and collects the unseen documents from the next K documents that each query retrieves until it collects 2,000 documents. We learned 5 lists of queries using sets of 10,000 random documents (5,000 useful and 5,000 useless) from the TREC collection by applying the SVM-based method in QXtract [2].

Ranking Generation Techniques: We evaluated our ranking generation techniques from Section 3.1. To obtain the best parameters for these techniques, we performed several experiments over our development set, varying λ_{All} and λ_{L2}. The parameter values that we determined experimentally are as follows: for *BAgg-IE*, $\lambda_{All} = 0.5$ and $\lambda_{L2} = 0.99$; while for *RSVM-IE*, $\lambda_{All} = 0.1$ and $\lambda_{L2} = 0.99$. Setting $\lambda_{L2} = 0.99$ results in an ℓ_1-norm weight of $1 - \lambda_{L2} = 0.01$. This weight in turn results in models with 10 times fewer features—which are hence 10 times faster—than models that only use the ℓ_2-norm. Higher ℓ_1-norm weights would lead to

[9]http://nlp.stanford.edu/software/CRF-NER.shtml

[12]http://web.ist.utl.pt/ist155840/etxt2db/
[13]http://reel.cs.columbia.edu/

lower-quality ranking models, as discussed in Section 3.

We also evaluated the following (strong) baselines:

- *FactCrawl (FC):* FC corresponds to our implementation of FactCrawl [7], as described in Section 2.
- *Adaptive FactCrawl (A-FC):* We produced a new version of FC that re-ranks the documents. Specifically, to make FC more competitive with our adaptive ranking strategies, A-FC recomputes the quality of the queries, and re-ranks the documents with these new values after each document is processed. In addition, A-FC learns new queries and retrieves more documents before every re-ranking step.

(We evaluated other approaches, such as QXtract [2] and PRDualRank [14], but do not discuss them further because FactCrawl dominated the alternatives that we considered.)

Update Detection Techniques: We evaluated our update detection techniques from Section 3.2:

- *Top-K:* We set $K = 200$, which experimentally led to high coverage of the relevant features and small overhead in feature comparison. We set $\tau = \varepsilon \cdot K$, where ε indicates how much each feature can change without impacting the ranking. We experimented with several values of τ and finally picked $\tau = 0.5$ ($\varepsilon = 0.0025$).
- *Mod-C:* We evaluated several combinations of ρ and α: the best value for ρ is 0.1, while the best angle values for α are 5° and 30° for RSVM-IE and BAgg-IE, respectively.

We also compared against the following baselines:

- *Wind-F:* We implemented a naïve approach for update detection that updates the ranking model after processing a fixed number of documents. We experimented with several values and observed no substantial differences. We report our results for updating 50 times along the extraction process, which leads to updates after 13,429 and 21,739 documents for the validation and test sets, respectively.
- *Feat-S:* We implemented an efficient version of feature shifting [16] using an online one-class SVM based on Pegasos [30]. We used a Gaussian kernel with $\gamma = 0.01$ and $k = 6$, as suggested in [16]. Finally, we triggered an update when the geometrical difference $F = 1 - S$ exceeded a threshold $\tau = 0.55$. Since the features of the documents after each update tend to fluctuate, we only run Feat-S after processing 700 new documents or more.

Executions and Infrastructure: We ran all experiments over a cluster with 60 machines with a uniform configuration: Intel Core i5-3570 CPU @ 3.40 GHz processors, with 8 GB of RAM, and OS Debian GNU/Linux 7 (wheezy). We used multiple independent processes to test our approach with different configurations. We executed each experiment five times with different samples (i.e., five different random samples and five different sets of initial sample queries), to account for the effect of randomness in the results, and report the average of these executions.

Evaluation Metrics: We use the following metrics:

- *Average recall* is the recall of the extraction process (i.e., the fraction of useful documents in the collection that have been processed) at different points during the extraction (e.g., after processing $x\%$ of the documents) and averaged over all executions of the same configuration.
- *Average precision* is the mean of the precision values at every position of the ranking [33], averaged over all the executions of the same configuration.
- *Area Under the ROC (AUC)* is the area under the curve of the true positive rate as a function of the false positive rate, averaged over all the executions of the same configuration.

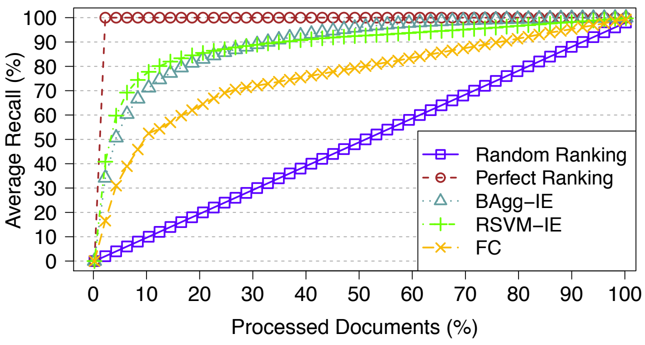

Figure 3: Average recall for Person–Charge for different base ranking generation techniques.

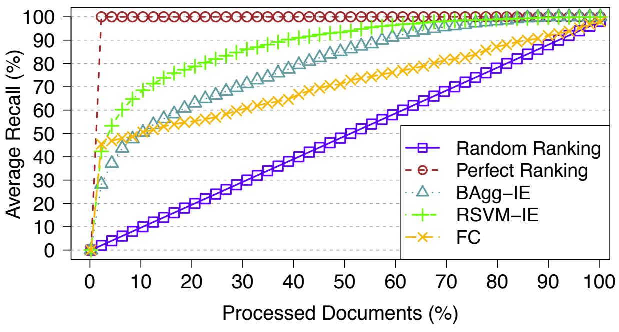

Figure 4: Average recall for Disease–Outbreak for different base ranking generation techniques.

- *CPU time* measures the CPU time consumed for extracting and ranking the documents.

5. EXPERIMENTAL RESULTS

We now present the results of the experimental evaluation of our adaptive ranking approach. We tuned the configuration of all components of our approach (i.e., the sampling strategy, the learning-to-rank approach, and the update detection approach) by exhaustively considering all possible combinations over the development set and selecting the best such combination. In the discussion below, for clarity, we consider the configuration choices for each component separately. Later, for the final evaluation of our approach over the test set and against the state-of-the-art ranking strategies, we use the best configuration according to the development set experiments.

Impact of Learning-To-Rank Approach: To understand the impact of using our learning-to-rank approach, we first evaluate our techniques of Section 3.1, *without the adaptation step*, against FC over the development set. Figure 3 shows the average recall for the Person–Charge relation for the full-access scenario. (For reference, we also show the performance of a random ordering of the documents, as well as of a perfect ordering where all useful documents are ahead of the useless ones.) Both RSVM-IE and BAgg-IE consistently outperform FC. Interestingly, RSVM-

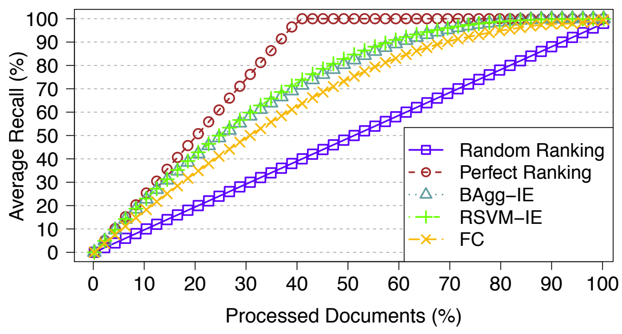

Figure 5: Average recall for Person–Career for different base ranking generation techniques.

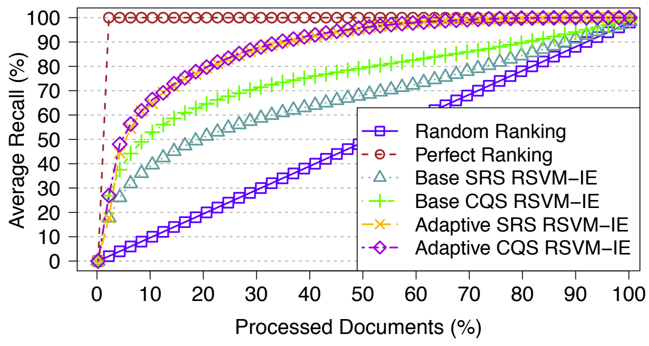

Figure 6: Average recall for Man Made Disaster–Location with different sampling techniques for the base and adaptive versions of RSVM-IE.

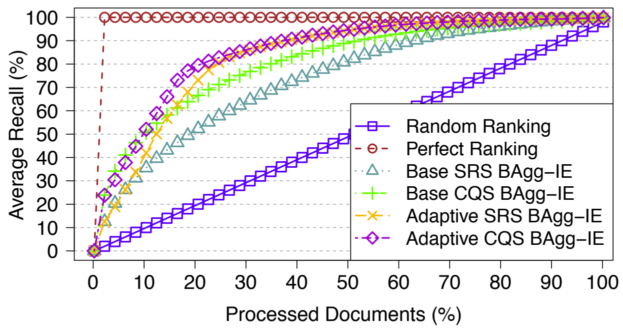

Figure 7: Average recall for Man Made Disaster–Location with different sampling techniques for the base and adaptive versions of BAgg-IE.

IE performs better in early phases of the extraction, while BAgg-IE performs better in the later phases, which agrees with our intuition from Section 3.1: RSVM-IE is at its core a ranking optimization technique, while BAgg-IE is based on classifiers. BAgg-IE separates useful from useless documents, thus obtaining high-accuracy in the middle of the extraction process, which in turn leads to high recall later on. We observed similar results for most of the relations (e.g., Figures 4 and 5 show the results for Disease–Outbreak and Person–Career respectively). However, RSVM-IE performs better than BAgg-IE for sparse relations, so RSVM-IE is preferable for such relations even in later phases of the extraction process (see Figure 4). Overall, even without an adaptation step, our techniques outperform the state-of-the-art ranking technique FC.

Impact of Sampling Strategies: To understand the impact of different sampling techniques to learn the initial ranking model, we compared RSVM-IE and BAgg-IE using the SRS and CQS sampling techniques (Section 4). Figure 6 shows the average recall for the Man Made Disaster–Location relation in the full-access scenario for RSVM-IE, both without the adaptation step (denoted with keyword "Base" in the plot) as well as with adaptation (denoted with keyword "Adaptive"). (The results for BAgg-IE were analogous; see Figure 7.) Using CQS, a sophisticated sampling technique, has a generally positive impact relative to using the (simpler) SRS strategy. The only exceptions were the dense relations, namely, Person–Organization and Person–Career, for which a simple random sample typically includes a wide variety of useful documents, thus leading to high-quality models.

Impact of Adaptation: We claimed throughout this paper that refining the document ranking along the extraction process significantly improves its efficiency. To support this claim, Figure 6 shows the average recall of RSVM-IE for the Man Made Disaster–Location relation for the full-access scenario. (The results for BAgg-IE are analogous, although the difference between the sampling techniques is higher than for RSVM-IE; see Figure 7.) These results show that by adapting the ranking model learned by RSVM-IE and, correspondingly, the document ranking, we significantly improve the efficiency of the extraction process. For example, Figure 6 shows that the adaptive versions of RSVM-IE can reach 70% of the useful documents after processing only 10% of the collection, whereas the base (non-adaptive) versions only reached 40% and 50% of the useful documents, for SRS and CQS, respectively. This same behavior was replicated by almost all relations. Additionally, as shown in Figure 6, the sampling technique does not have a significant impact anymore when we incorporate the adaptation step. Nevertheless, we observed that the results of average precision and AUC (see Table 2) are generally better for CQS than for SRS, since CQS leads to processing more useful documents at early stages of the extraction process.

Finally, we evaluated the number of new features incorporated into the ranking model during the adaptation step. In early stages of the extraction process, an average of 200 (or about 25% of the total number of features in the previous models) are incorporated; a similar number of features is removed in each adaptation step. However, in later stages, this behavior changes as the models become more stable. Specifically, the number of incorporated and removed features drops to 10 after each adaptation step. These results show that while the initial adaptation steps significantly impact the ranking model, the later ones are insignificant. Therefore, it is important to properly schedule the adaptation step to avoid insignificant updates to the ranking model.

Impact of Update Detection: To evaluate the update detection techniques that we introduced in Section 3.2, we fix the document sampling to SRS, and evaluate the tech-

Feat-S	5.72±0.29 ms
Top-K	1.89±0.71 ms
Mod-C	0.32±0.10 ms

Table 3: Average CPU time to perform update detection after processing each document.

niques according to their impact on the extraction process, distribution of updates, and overhead. Figure 8 shows the results of RSVM-IE for the Election–Winner relation for the full-access scenario. (The behavior for the other relations is analogous.) The Feat-S technique performed poorly in comparison to others, because Feat-S stops performing updates when the features observed in the data stabilize with respect to its kernel-based definition of shifting. For this reason, Feat-S misses late updates that prioritize other still poorly ranked useful documents. In addition, we observe that both Top-K and Mod-C produce consistently better results than Wind-F, especially at early stages of the extraction process, thus leading to high recall early in the extraction process. Overall, we show that both Top-K and Mod-C are robust alternatives for update detection in terms of ranking quality.

We also studied the distribution of updates across the extraction process, to understand the behavior of Top-K and Mod-C. Figure 9 shows the number of updates that each technique performs at different stages of the extraction process. Top-K and Mod-C tend to update much more frequently in early stages, where almost all documents carry new evidence of usefulness, than in later stages. For instance, most of the updates are performed while processing the first 10% of the collection. This behavior leads to ranking models that stabilize soon, since they are able to overcome the usual lack of training data in the initial document samples. Interestingly, despite the density of updates early in the process, the overall number of updates of Top-K and Mod-C remains smaller than that of Wind-F, since our techniques avoid unnecessary updates in late phases of the extraction process.

Additionally, we observed the percentage of features that are added to and eliminated from the models: the adaptation steps triggered by Top-K and Mod-C incorporate a consistent percentage of new features (i.e., about 10% per adaptation step) throughout the extraction process. This behavior significantly differs from that of Wind-F, which incorporates a large fraction of new features in early phases of the extraction process but only a small fraction of features later on: Top-K and Mod-C only perform an update when it will have a significantly positive impact on the model.

Finally, to evaluate the impact on efficiency of the update detection techniques, we calculated the overhead per document in terms of average CPU time, which we summarize in Table 3. As expected, Wind-F incurs negligible overhead (roughly 0.01 ms per document), since it only keeps a counter of the processed documents, whereas Feat-S incurs the highest overhead (5.72 ms per document). Our two techniques, Top-K (1.89 ms per document) and Mod-C (0.32 ms per document), exhibit a substantial difference in terms of efficiency, since the overhead of Top-K is dominated by the use of the binary classifier, as we discussed in Section 3.2. In conclusion, and considering also the quality results, Mod-C consistently outperforms the other techniques.

Scalability of our Approach: To understand how our

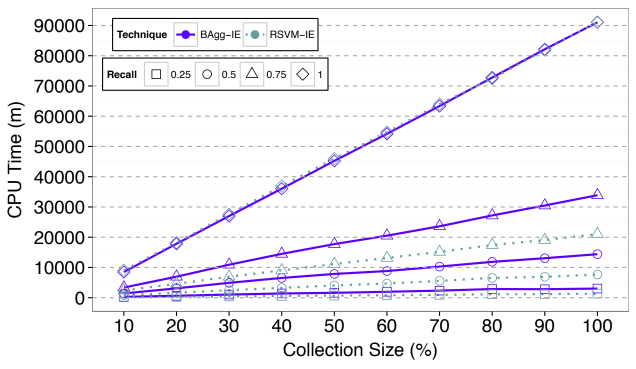

Figure 10: Average CPU time of our techniques as a function of the collection size for different target recall values, for the Natural Disaster–Location relation.

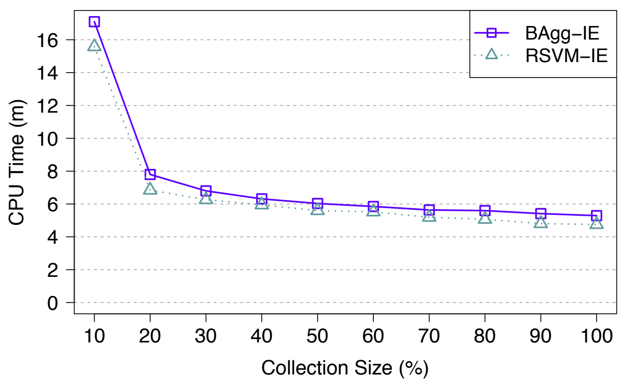

Figure 11: Average CPU time to find a target number of documents (i.e., the number of useful documents in the subset with 10% of the collection) for the Person–Organization Affiliation relation, as a function of the collection size.

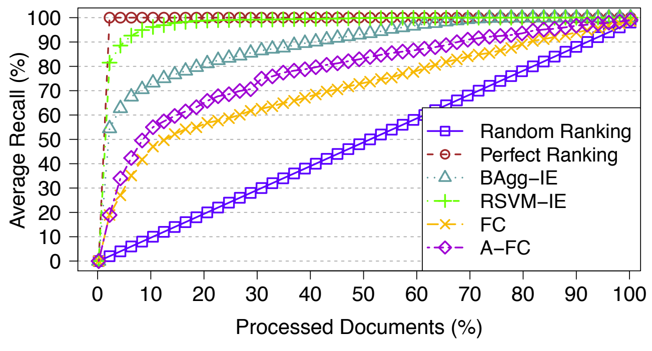
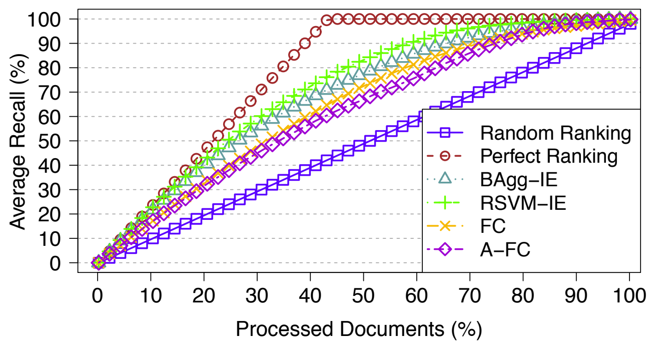
strategies scale with the document collection size, we produced 10 subsets of the test collection with different sizes (from 10% to 100% of the total collection) and we measured (i) the time overhead for producing the ranking and (ii) the extraction time needed to reach a (fixed) target number of useful documents in each subset. Figure 10 shows how the size of the collection affects the CPU time needed to perform the ranking and extraction tasks with our techniques for the Natural Disaster–Location relation: the CPU time needed to perform an extraction task with our techniques grows approximately linearly with the collection size, which is desirable. Additionally, Figure 11 shows—for the Person–Organization Affiliation relation—that the time needed to find and process a target number of useful documents significantly drops as we increase the size of the collection. In this figure, the target number of useful documents corresponds to that in the subset of the collection that only contains 10% of the documents. As shown, the time becomes almost constant when the number of useful documents in the subset is large enough for the ranking to reach the target number at very early phases of the extraction process.

Comparison with State-of-the-Art Ranking Strategies: We now compare our best performing ranking approaches with the state-of-the-art approaches discussed in Section 4. We selected the best configuration for RSVM-IE and BAgg-IE according to the previous experiments, which involve CQS sampling and Mod-C update detection. Then, we ran this configuration over the test set to compare with FC and A-FC. We performed this experiment in the search interface access scenario as well, with similar conclusions. We compare the techniques on ranking quality and efficiency.



(a) Disease–Outbreak



(b) Person–Career

Figure 12: Average recall for different ranking approaches in the full-access scenario.

Table 4 shows the average precision and AUC of the four techniques that we compare, for all relations and over the full access scenario: RSVM-IE and BAgg-IE generally outperform the FactCrawl baselines by a large margin, and RSVM-IE consistently outperforms BAgg-IE. Interestingly, our adaptive version of FactCrawl, A-FC, does not exhibit the same significant improvement compared to FC that we observed between the adaptive and base versions of RSVM-IE and BAgg-IE above: A-FC is unable to properly model the usefulness of the documents when new features emerge, since it only relies on a small number of features.

To understand the effects of the relation characteristics, we studied the performance of the techniques over both sparse (Figure 12a) and dense (Figure 12b) relations. The performance gap is more evident for sparse relations than it is for dense relations: The vocabulary around mentions of sparse relations tends to be reduced and specific, which makes it easier to model and prioritize the useful documents. Conversely, dense relations are scattered across diverse documents, thus co-occurring with a large variety of words, which makes it difficult to select a set of features that

(b) Person–Organization Affiliation

Figure 13: CPU time to obtain a target recall value.

precisely identifies useful documents. Regardless, RSVM-IE and BAgg-IE still outperform the other techniques, since they are able to handle feature spaces of variable sizes.

We evaluate efficiency by measuring the time—including both ranking and extraction time—that each technique requires to achieve different values of recall. We show the results for two relations that exhibit substantially different extraction times according to their respective information extraction system: (i) Natural Disaster–Location, which takes an average of 6 seconds per document (Figure 13a); and (ii) Person–Organization Affiliation, which takes an average of 0.01 seconds per document (Figure 13b). RSVM-IE outperforms the others, in agreement with our earlier findings. The results for Person–Organization Affiliation are, in contrast, slightly different. For this fast extraction task, the overhead of the ranking technique can be problematic since it may easily become larger than the extraction time per se. We can observe such behavior for A-FC, which is less efficient than a random ranking technique with no overhead: A-FC (and, correspondingly, FC) relies on features that are expensive to compute [7], which is problematic for the adaptive case. However, the other techniques behave similarly as for the more expensive relations, with RSVM-IE resulting in the most efficient extraction process. Interestingly, for extraction tasks that incur lengthier extraction time, as is the case for Natural Disaster–Location, the quality of the ranking has a higher impact on efficiency than for other extraction tasks.

Overall, our experiments show that RSVM-IE outperforms all other techniques in all settings and extraction tasks. More specifically, RSVM-IE produces better rankings, while incurring very little overhead. Finally, when combined with Mod-C, RSVM-IE achieves much lower extraction times than the alternative strategies that we studied. Indeed, even with fast information extraction systems, adaptively ranking documents with RSVM-IE remained the best choice. Additionally, we evaluated the scalability of our techniques and confirmed that as the size of the collection grows, so does the positive impact of our approach, making it a substantial step towards scalable information extraction.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we presented an adaptive, lightweight document ranking approach for information extraction. Our approach enables effective and efficient information extraction over large document collections. Specifically, our approach relies on learning-to-rank techniques that learn in a principled way the fine-grained characteristics of the useful documents for an extraction task of interest. Our techniques incorporate (i) online learning algorithms, to enable a principled, efficient, and continuous incorporation of new relevant evidence as the extraction process progresses and reveals the real usefulness of documents; and (ii) in-training feature selection, to enable the learning of ranking models that rely on a small, discriminative set of features. Our experiments show that our approach exhibits higher recall and precision than state-of-the-art approaches, while keeping the overhead low. Overall, our document ranking approach is a substantial step towards scalable information extraction.

As future work, we plan to study how to estimate the recall of the alternative document ranking approaches for an information extraction task of interest. Through such estimates, we could in turn estimate the extraction cost, as a function of the number of processed documents, to achieve a target recall value with each ranking approach. We could then explore the recall-extraction cost tradeoff in a robust, quantitative manner, and substantially enhance recent optimization efforts for information extraction programs (e.g., [31]) by integrating our approach as an alternative document selection technique. As another direction for future work, we plan to continue studying our document ranking approaches along other dimensions, so that, for example, we can characterize ranking models according to the diversity of the tuples that they tend to produce. Finally, we aim at exploring parallelization approaches that, combined with the ranking-based approach described in this paper, can further speed up the execution of information extraction systems over large volumes of text data.

ABSTRACT

We consider the problem of processing similarity queries over a set of top-k rankings where the query ranking and the similarity threshold are provided at query time. Spearman's Footrule distance is used to compute the similarity between rankings, considering how well rankings agree on the positions (ranks) of ranked items (i.e., the L1 distance). This setup allows the application of metric index structures such as M- or BK-trees and, alternatively, enables the use of traditional inverted indices for retrieving rankings that overlap (in items) with the query. Although both techniques are reasonable, they come with individual drawbacks for our specific problem. In this paper, we propose a hybrid indexing strategy, which blends inverted indices and metric space indexing, resulting in a structure that resembles both indexing methods with tunable emphasis on one or the other. To find the sweet spot, we propose an assumption-lean but highly accurate (empirically validated) cost model through theoretical analysis. We further present optimizations to the inverted index component, for early termination and minimizing bookkeeping. The performance of the proposed algorithms, hybrid variants, and competitors is studied in a comprehensive evaluation using real-world benchmark data consisting of Web-search–result rankings and entity rankings based on Wikipedia.

1. INTRODUCTION

One common way to counter the information deluge is the formation of concise rankings that allow users and algorithms to effectively and efficiently inspect the best performing items within a certain category. Ranking schemes are used to impose an order between items—such as Google's PageRank or more traditional OLAP-style aggregation and ranking functions used in databases for business intelligence and other forms of insight-seeking analyses. Besides tangible facts and objective ranking schemes, rankings are often also crowd-sourced through mining user polls on the Web, in portals such as IMDB (for movie ratings) or rankopedia.com, or specifically created by users in form of favorite lists on personal websites or used in dating portals for matchmaking. A core characteristic of such rankings is that they are rather tiny in length, compared to the global domain of items that could be ranked—consider the top-10 movies of all time compared to the total number of produced movies or the top-10 Web search results for Britney Spears compared to more than 100 million documents about her in Google's index. Access to rankings can serve ad-hoc information demands or give access to deeper analytical insights. Consider for instance the task of query suggestion in web search engines that is based on finding historic queries by their result lists with respect to the currently issued query, or dating portals that let users create favorite lists that are used to search for similarly minded mates.

As a generic access substrate for such services, we consider querying sets of top-k rankings by means of distance functions. That is, retrieving all rankings that have a distance to the query less than or equal to a user-provided threshold. We specifically focus on Spearman's Footrule that is the L1 distance metric between two rankings. Fagin et al. [18] show that there is a metric Spearman's Footrule adaptation for top-k rankings, whose ranked items do not necessarily match or overlap at all. Dealing with metrics immediately suggests employing metric data structures like M-trees [14] for indexing and similarity search. On the other hand, similar rankings, for reasonable query thresholds, should in fact overlap in some (or all) of the items they rank. Searching overlapping sets for ad-hoc queries [22, 30] or joins [25] is a well studied research topic. Inverted indices or signature trees are used to indexing tuples based on their set-valued attributes [22]. Such indices are very efficient to answer contained-in, equal-to, or overlaps-with queries, but do not exploit the distances between the indexed rankings as metric index structures do. In this work, we study a hybrid index structure that smoothly blends an inverted index with metric space indexing. With an assumption-lean but highly accurate theoretic cost model, we further show that the estimated sweet spot reaches runtime performances almost identical to the manually tuned one.

1.1 Problem Statement and Setup

As **input** we are provided with a set $\mathcal{T}$ of rankings τ_i (Table 1). Each ranking has a domain D_{τ_i} of items it contains. We consider fixed-length rankings of size k, i.e., $|D_{\tau_i}| = k$, but investigate the impact of various choices of k on the

*This work has been partially supported by the Excellence Cluster on Multimodal Computing and Interaction (MMCI) and the German Research Foundation (DFG) under grant MI 1794/1-1.

$\mathcal{T}$	
ranking id	**ranking content**
τ_1	$[2, 5, 4, 3]$
τ_2	$[1, 4, 5, 9]$
τ_3	$[0, 8, 5, 7]$

Table 1: Sample set $\mathcal{T}$ of rankings (items are represented by their ids).

query performance. The considered rankings do not contain any duplicate items.

Rankings are represented as arrays or lists of items, where the left-most position denotes the top ranked item. Without loss of generality, in the remainder of the paper, we assume that items are represented by their ids. The rank of an item i in a ranking τ is given as $\tau(i)$.

A distance function d quantifies the distance between two rankings—the larger the distance the less similar the rankings are. Therefore, for a given query ranking q, distance function d, and distance threshold θ, we want to find all rankings in $\mathcal{T}$ with distance below or equal to θ, that is,

$$\{\tau_i | \tau_i \in \mathcal{T} \wedge d(\tau_i, q) \leq \theta\}$$

In this work, we focus on the computation of Spearman's Footrule distance, but the proposed coarse index can be applied to any metric distance function. A more detailed introduction to rankings specifically top-k rankings, metric distance functions, and how to work with items i that are not in a ranking τ is described in Section 3.

The objective of this work is to study in-memory indexing and query processing techniques, with the overall aim to decrease the average query response time. We consider adhoc similarity queries over rankings, where the query ranking and query similarity threshold are specified at query time.

1.2 Contributions and Outline

In this work, we make the following contributions:

- we present a coarse index and a cost model that allows automated tuning of the coarsening threshold for optimal performance
- we derive distance bounds for early stopping / pruning inside position-augmented inverted indices—concepts that are largely orthogonal to each other and can be combined
- we show the results of a carefully conducted experimental evaluation involving a suite of algorithms and hybrids under realistic workloads derived from real-world rankings

The remainder of this paper is organized as follows. Section 2 discusses related work. Section 3 presents background information on rankings and discusses distance functions for rankings. Section 4 introduces a coarse, hybrid index that indexes partitions of rankings. Section 5 describes a cost model that allows picking the sweet spot between inverted-index-access time and result-validation time. Section 6 shows how to compute distance bounds and to enable effective pruning of entire index lists at runtime. Section 7 presents the experimental evaluation, while Section 8 concludes the paper.

2. RELATED WORK

There is an ample work on computing relatedness between ranked lists of items, such as to mine correlations or anti-correlations between lists ranked by different attributes; like age and weight. Arguably, the two most prominent similarity measures are Kendall's tau and Spearman's Footrule. Fagin et al. [18] study comparing top-k lists, that is, lists capturing a subset of a global set of items, rendering the lists incomplete in nature. In the scenarios motivating our work, like similarity search of favorite/preference rankings, the lists are naturally incomplete, capturing, e.g., only the top-10 movies of all times. In this work, we focus on the computation of Spearman's Footrule distance, for which Fagin et al. [18] show that it retains its metric properties also for incomplete rankings under certain assumptions (cf., Section 3).

We primarily distinguish two indexing paradigms for handling ranked lists. First, considering the similarity metric among them and applying indexing techniques for metric spaces. Second, treating ranked lists as plain sets and indexing them using methods like inverted indices.

Helmer and Moerkotte [22] present a study on indexing set-valued attributes as they appear for instance in object-oriented databases. Retrieval is done based on the query's items; the result is a set of candidate rankings, for which the distance function can be computed. For metric spaces, data-agnostic structures for indexing objects are known, like the M-tree by Ciaccia et al. [14, 37]. For discrete metrics, the tree structure proposed by Burkhard and Keller [10] resembles an n-ary search tree, called BK-tree, where subtrees group items according to their (discrete) distance to the parent node. Similarly, Ganti et al. [21] present single-pass algorithms for clustering data in metric distance space using a R*-tree–style [7] structure for mapping objects to (evolving) clusters. The vantage-point tree [32, 36] partitions the space by choosing vantage points (pivots) that segment the space into two areas, similar to the k-d tree [8]. Chávez and Navarro [12] describe an algorithm to create non-overlapping partitions of data in a metric space based on pivots and fixed-diameter or fixed-size partitions; several ways to choose pivots are studied. We consider indexing clusters of rankings to shrink the size of the inverted index, by considering partitions of rankings within a pre-determined distance threshold (Section 4)—effectively trading-off cluster retrieval time and final result validation cost. The partitioning can be done in any of the above ways; we choose the BK-tree [10]. The book by Hanan Samet [26] gives a comprehensive overview of indexing techniques for metric spaces. The recent work by Wang et al. [34] propose MapReduce [16] algorithms for all-pairs similarity search in metric spaces. Previously, Jacox and Samet [24] proposed sequential algorithms for the similarity join problem in metric spaces.

Augmenting the inverted index with rank information allows computing the Footrule distance on the fly. For score-ordered index lists used in top-k query processing, there is a large variety of work. Most prominently, the family of threshold algorithms [18] and variants like the work by Bast et al. [4] that is emphasizing on disk-I/O optimal access. For k nearest neighbor (KNN) or similarity queries, the per-dimension information of the indexed objects is not pre-sorted by "score" as this depends on the query that is not known a priori. Work on KNN search in databases [9] transforms the KNN problem into a range query over the involved dimensions, that can be answered using standard database

τ	A ranking
$\tau(i)$	The rank of item i in ranking τ
$F(\tau_i, \tau_j)$	Footrule distance between τ_i and τ_j
$d(\tau_i, \tau_j)$	Distance between τ_i and τ_j
d_{max}	maximum distance between two rankings
$\mathcal{T}$	Set of rankings to be indexed
k	Size of rankings
$\mathcal{D}_\tau$	Items contained in ranking τ
$\mathcal{D}$	Global domain of items
q	Query ranking
θ	Similarity threshold, set at query time
θ_C	Maximum pairwise similarity within a partition
$\mathcal{P}_i$	A partition of rankings. Partitions are pairwise disjoint.

Table 2: Overview of notation used in this paper

indices that support range queries, like B+ trees [6]. Work on similarity join in databases [2, 27, 28] focuses on defining and implementing the similarity join as relational operators. Mamoulis [25] addresses processing joins between sets (relations) of tuples with set-valued attributes. Terrovitis et al. [29] considers containment queries over sets with skewed data distributions. The work in [30] proposes combination of trees and inverted files to answer superset, subset and equality queries over set-valued attributes. Recently, the most prominent technique for answering set similarity joins are the prefix-filtering based methods [35, 5, 11]. The main idea behind this method is to reduce the size of the inverted index. This is done by imposing a total ordering of the elements in the universe $\mathcal{U}$ (or what we refer to as the dictionary $\mathcal{D}$), sorting the elements in the records, and then, based on the threshold value, indexing only a prefix, and not the complete records. Similarly, we propose a technique for dropping some of the elements in the query (Section 6), however, our technique does not require the threshold value to be known during index construction. Additionally, we do not require a global ordering to be imposed on the items in the rankings, i.e., the rankings keep their original structure. Wang et al. [33] propose the AdaptJoin algorithm that improves on previous prefix filtering work by using variable length prefix scheme and a cost model that selects the most efficient prefix length for each object. They further propose the AdaptSearch algorithm for processing ad-hoc queries using the same adaptive framework. As rankings can also be seen as plain sets, AdaptSearch can be applied for computing relatedness between rankings as well.

When processing top-k, KNN, or similarity queries, the ultimate goal is to identify the final result objects as soon as possible, without exhaustive evaluation of scores/distances. In the NRA algorithm by Fagin et al. [19] over score-sorted index lists, this is achieved by maintaining score bounds for each seen object. We come back to this in Section 6.

3. BACKGROUND ON RANKINGS AND DISTANCE FUNCTIONS

Pairwise similar rankings can be retrieved by means of distance functions, like Kendall's Tau or Spearman's Footrule distance, over all pairs or selectively for a given query ranking. We first discuss metrics over complete rankings over a single domain and then we discuss results on computing distances for top-k lists (incomplete rankings).

Complete rankings are considered to be permutations over a fixed domain $\mathcal{D}$. We follow the notation by Fagin et al. [18] and references within. A permutation σ is a bijection from the domain $\mathcal{D} = \mathcal{D}_\sigma$ onto the set $[n] = \{1, \dots, n\}$. For a permutation σ, the value $\sigma(i)$ is interpreted as the rank of element i. An element i is said to be ahead of an element j in σ if $\sigma(i) < \sigma(j)$. For two permutations σ_1, σ_2 over the same domain, the Kendall's tau $K(\sigma_1, \sigma_2)$ and Spearman's Footrule $F(\sigma_1, \sigma_2)$ measures are two prominent ways to compute the distance between σ_1 and σ_2. Both measures are distance metrics, that is, they have symmetry property, i.e., $d(x, y) = d(y, x)$, are regular, i.e., $d(x, y) = 0$ iff $x = y$, and suffice the triangle inequality $d(x, z) \leq d(x, y) + d(y, z)$, for all x, y, z in the domain. Spearman's Footrule metric is the L_1 distance between two permutations, i.e., $F(\sigma_1, \sigma_2) = \sum_i |\sigma_1(i) - \sigma_2(i)|$ and in this work we specifically focus on this metric, but the proposed coarse index can be applied to any metric distance function. We refer the reader to Table 2 for an overview of the notation used in this paper.

We consider incomplete rankings, called top-k lists in [18]. Formally, a top-k list τ is a bijection from D_τ onto $[k]$. The key point is that individual top-k lists, say τ_1 and τ_2 do not necessarily share the same domain, i.e., $D_{\tau_1} \neq D_{\tau_2}$. Fagin et al. [18] discuss how the above two measures can be computed over top-k lists.

There exists a Spearman's Footrule adaptation that is also a metric for top-k lists by considering an artificial rank l for items not contained in a ranking, i.e., $\tau(i) = l$ if $i \notin D_\tau$. Consider the rankings $\tau_1 = [2, 5, 6, 4, 1], \tau_2 = [1, 4, 5]$, and $\tau_3 = [0, 8, 4, 5, 7]$. For a rank $l = 6$ for not-contained items, we obtain $F(\tau_1, \tau_2) = 15$, $F(\tau_2, \tau_3) = 17$, and $F(\tau_1, \tau_3) = 22$.

In this work, we assume that $\tau(i)$ takes values from 0 to $k - 1$ (instead of 1 to k), and we fix the value of l to k as suggested in [18]. It is clear that this does not affect our algorithms. We further consider only rankings of same size k, thus the largest possible value of the Footrule distance is $k \times (k + 1)$ and occurs if two disjoint rankings are compared. The smallest distance is 0, for the compared rankings are identical. In the rest of the paper, for ease of presentation, we use normalized values for the Footrule distance and θ, ranging from 0 to 1, i.e., $d_{max} = 1$.

4. FRAMEWORK

Rankings can be considered as plain sets and accordingly indexed in traditional inverted indices [22] that keep for each item a list of rankings in which the item appears. At query time such a structure allows efficiently finding those rankings that have one or more items in common with the query ranking. A compact example is given below:

$$\text{item a} \longrightarrow <\tau_1, \tau_5, \tau_7> \qquad \textit{inverted index}$$
$$\text{item b} \longrightarrow <\tau_4, \tau_9, \tau_{12}, \tau_{19}>$$

The key point of using inverted indices is their ability to efficiently reduce the global amount of all rankings to potential candidates by eliminating the rankings with maximum distance d_{max} to the query. This is done in the first query processing phase, namely the **filtering phase**. In this phase, for a given query ranking q and a user defined threshold θ, the inverted index is queried for each item in $\mathcal{D}_q$. The obtained index lists are merged to identify all rankings that have at least one overlapping item with the query ranking q. These are considered candidates.

For each of them, the distance function $d(q, \tau)$ is evaluated to identify the true results, i.e., the rankings where $d(q, \tau) \leq \theta$. This is done in the **validation phase**. We refer to this as the Filter and Validate (F&V) algorithm. Naturally, we assume that the query threshold θ is strictly smaller than the maximum possible distance d_{max}.

Although the inverted index is good for finding rankings (sets) that intersect with the query, the F&V comes with two drawbacks:

(i) It naively indexes all rankings and, hence, is of massive size, despite the fact that often rankings are (near) duplicates

(ii) The validate phase evaluates the distance function on each ranking separately, although known metric index structures suggest pre-computing distances among (similar) rankings for faster identification of true results

While directly using metric index structures, like M-Trees [14] or BK-Trees [10], appears promising at first glance, they are not ideal for boiling down the space to intersecting rankings. In fact, we show in our experiments that using metric data structures is an order of magnitude slower than using pure inverted indexes.

To harness the pruning power of inverted indices but at the same time not to ignore the metric property of the Footrule distance, we present a hybrid approach that blends both performance sweet spots by representing near duplicate rankings by one representative ranking, which is then put into an inverted index. That way, depending on how aggressive this coarsening is, the inverted index drastically shrinks in size, hence, lower response time, and the validation step is benefiting from the fact that near duplicate rankings are represented by a metric index structure.

Below, we describe more formally how such an index organisation is realized and how queries are processed on top of it. We present a highly accurate cost model that allows trading-off the coarsening threshold to find the optimal trade-off between the inverted index cost and the cost to validate rankings in the metric index structure.

4.1 Index Creation

The aim is to group together rankings that are similar to each other—with a quantifiable bound on the maximum distance. That is, partitions $\mathcal{P}_i$ of similar rankings are created, and each represented by one $\tau_m \in \mathcal{P}_i$, the so called medoid of the partition. It is guaranteed that $\forall \tau_i \in \mathcal{P} : d(\tau_m, \tau) \leq \theta_C$. The distance bound θ_C is called the partitioning threshold. We write $\tau_m \prec \tau$ to denote that ranking τ is represented by ranking (medoid) τ_m.

To find partitions of rankings, we employ a BK-tree [10], an index structure for discrete metrics, such as the Footrule distance. Figure 1 depicts the general shape of such a BK-tree. Ignoring for a moment the different colors and black, solid circles: each node represents an object (here, ranking) and maintains pointers to subtrees whose root has a specific, discrete distance. We create such a BK-tree for the given rankings. Then, in order to create partitions of similar rankings, the tree is traversed and, for each node, the children with distance above θ_C are considered in different partitions. The procedure continues recursively on these children. The children within distance $\leq \theta_C$ are forming a partition with their root node, which acts as the medoid. In Figure 1, each partition is illustrated by its root (representative ranking) shown as a black, solid circle, and the green subtrees below it (those with distance 1 or 2). A partition is not represented as a plain set (or list) of rankings, but by the corresponding subtree of the BK-tree. The immediate benefit is that these subtrees (that are full-fledged BK-tree themselves) are used to process the original query (with threshold θ) on the clusters, without the need to perform an exhaustive evaluation of the partition's rankings. Alternatively, any algorithm that creates (disjoint) partitions of objects within a fixed distance bound can be used, such as the approach by Chávez and Navarro [12], which randomly picks medoids, assigns objects to medoids, and continues this procedure until no object is left unassigned. We use this simple model to reason about the trade-offs of our algorithm below.

Irrespective of the way to find medoids and their partitions, medoids are rankings, too, and can be indexed using inverted indices. In Section 6 we further propose techniques for more efficient retrieval of the rankings indexed with an inverted index.

4.2 Query Processing

LEMMA 1. *For given query threshold θ and partitioning threshold θ_C, at query time, for query ranking q, all medoids τ_m with distance $d(\tau_m, q) \leq \theta + \theta_C$ need to be retrieved in order not to miss a potential result ranking.*

Lemma 1 ensures that rankings $\{\tau_i | \tau_m \prec \tau_i \wedge d(\tau_i, q) \leq \theta \wedge d(\tau_m, q) > \theta\}$ will not be omitted from the result set. In other words, Lemma 1 avoids missing result rankings with distance $\leq \theta$, which are represented by a medoid with distance $> \theta$. On the other hand, since the medoids are indexed using an inverted index, we assume that $\theta + \theta_C < 1$. This is needed because medoids τ_m that are not overlapping with q at all, cannot be retrieved from the inverted index.

For each of the found medoids τ_m (i.e., $d(\tau_m, q) \leq \theta + \theta_C$), the rankings $\mathcal{R} := \{\tau | \tau_m \prec \tau\}$ are potential result rankings. For each such candidate ranking $\tau_i \in \mathcal{R}$ it needs to be checked if in fact $d(q, \tau_i) \leq \theta$. The rankings $\tau_i \in \mathcal{R}$ with $d(q, \tau_i) > \theta$ are so called *false positives* and according to Lemma 1 there are *no false negatives.* As for each affected medoid τ_m, the rankings in $\mathcal{R}$ are represented in form of a BK-tree (or any other metric index structure), it is the task of this tree to identify the true result rankings (i.e., eliminating the false positives).

Algorithm 1, depicts the querying using the relaxed query threshold, and the subsequent retrieval of result rankings. In this algorithm, as well as in the actual implementation, the partitions, represented by the medoids, are arranged as BK-trees, created at partitioning time.

It is clear that the partitioning threshold θ_C affects the cost for querying the metric index structure: The larger the partitions are (i.e., the larger θ_C is) the larger is the tree to be queried. On the other hand, then, there are less medoids to be indexed in the inverted index. This apparent tradeoff is theoretically investigated in the following section to find the design sweet spot between the naive inverted index and the case of indexing the entire set of rankings in one metric index structure.

```
method: processCoarse
input: QueryProcessor over Medoids qp, double $\theta$, $\theta_C$,
       Map:Int→ BK-Tree map
output: list of query results rlist
1  rTemp ← qp.execute($\theta$+$\theta_C$) ▷ query with relaxed threshold
2  for each id ∈ rTemp
3      tree ← map[id]
4      rList.addAll(tree.execute($\theta$))
5  return rList
```

Algorithm 1: Query processing using the coarse index.

5. PARAMETER TUNING

Setting the clustering threshold θ_C allows tuning the performance of the coarse index. For a clustering threshold $\theta_C = 0$, only duplicate rankings are grouped together, whereas for $\theta_C = 1$ there is only one large group that consists of all rankings. That means, for larger θ_C the inverted index becomes smaller, with more work to be done at validation time inside the retrieved clusters. For smaller θ_C the inverted index is larger, but clusters are smaller, hence, less work to be done in the validation phase. There are, hence, two separate costs: **filtering cost**—the cost for querying the inverted index, and, **validation cost**—the cost for validating the partitions represented by the medoids returned as results by the inverted index, in order to get the final query answers.

We try to make as few assumptions as possible and for now we assume we know only the distribution of pairwise distances. That is, for a random variable X that represents the distance between two rankings, we know the cumulative distribution function $P[X \leq x]$, hence, we know how many rankings of a population of n rankings are expected to be within a distance radius r of any ranking, i.e., $n \times P[X \leq \theta_C]$. We assume that medoids are also just rankings (by design) and are accordingly distributed. According to the clustering method described by Chávez and Navarro [12], we randomly select medoids, one after the other. After each selected medoid, all rankings that are not yet assigned to any medoid before and that are within distance θ_C to the current medoid are assigned to it. The process ends as soon as no ranking is left unassigned:

The radius r of the created partitions around the medoids is modeled as $P[X \leq \theta_C]$. We are interested in the number of medoids that need to be created to capture all rankings in the database. This resembles the *coupon collector problem* [20]. The solution to this problem describes how many coupons a collector needs to buy, in expectation, to capture all distinct coupons available. The first acquired coupon is unique with probability 1. The second pick is not seen before with probability $(c-1)/c$; c denoting the total number of distinct coupons. The third pick with probability $(c-2)/c$, and so on. In the case of medoids and their partitions, we specifically consider the variant of the coupon collector problem with package size larger or equal to one, i.e., batches of coupons are acquired together. Within each such package, there are no duplicate coupons. Figure 2 depicts the generic sampling of the ranking space, where fixed-diameter circles are forming the partitions around the medoid at the center. The deviation from the standard coupon collectors problem is that for picking medoids, in each round of picks, the medoid itself has not been selected before. Thus, the number

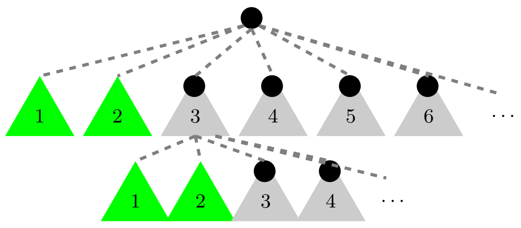

Figure 1: Creating partitions based on the BK-tree. The green (distance 1 and 2) subtrees are indexed by their parent node (medoid, as black dot). Distance 0 is not shown here.

of "coupons" that need to be acquired to get the i^{th} distinct coupon, given package size $p = P[X \leq \theta_C] \times n$, and a total of c distinct coupons, which in our case is the number of distinct rankings n is then:

$$h(n,i,p) = \begin{cases} 1, & \text{if } i \,\mathbf{mod}\, p = 0 \\ \frac{n-(i \,\mathbf{mod}\, p)}{n-i}, & \text{otherwise} \end{cases} \quad (1)$$

And overall, the number of medoids (packages) is given as

$$M(n,\theta_C) = p^{-1} \sum_{i=0}^{n-1} h(n,i,p) \quad (2)$$

This gives us the expected number of medoids indexed by the inverted index. Next, we first reason about the cost for validating the partitions, and then we discuss the filtering cost, i.e., the cost for querying the inverted index.

Cost for Validating Partitions

The number of medoids retrieved is following again the given distribution of pairwise distances. Since we query the inverted index with threshold $\theta + \theta_C$ we obtain

$$E[\textit{retrieved medoids}] = P[X \leq \theta + \theta_C] \times M \quad (3)$$

where M, for brevity, denotes $M(n, \theta_C)$.

Assuming that the retrieved medoids have the same size on average, i.e., n/M for a total number of rankings n, we have

$$E[\textit{candidate rankings}] = P[X \leq \theta + \theta_C] \times n \quad (4)$$

candidate rankings retrieved that need to be checked against the distance to the query ranking. This is also very intuitive.

For the case of brute-force evaluation of such candidate rankings this is multiplied with the cost of computing the distance measure. The cost of representing the partitions by full-fledged BK-tree is expected to be lower, but it introduces a complexity to the model. Our goal is to provide an easy to compute, and yet accurate model. For a more complex reasoning about the cost of querying the BK-tree we refer the reader to [3].

Cost for Retrieving Partitions

When querying the inverted index with a threshold $\theta + \theta_C$ to find the resulting medoids, the overall cost is based on the average index list length and the final medoids to be checked against the threshold. We should first estimate the average size of an index list in an inverted index.

We assume that the popularity of items in the rankings follows Zipf's law with parameter s. Sorting all items by their popularity (frequency of appearance in the rankings),

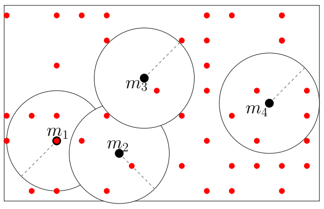

Figure 2: Four medoids with fixed-diameter partitions.

the law states that the frequency of the item at rank i is given by $f(i; s, v) = \frac{1}{i^s H_{v,s}}$, where $H_{v,s}$ is the generalized harmonic number and v is the total number of items. The size of the index list for an item is equal to the number of rankings that contain the item, i.e., $n \times f(i; s, v)$ for the i^{th} most popular item; where n is the number of indexed rankings. Consider a random variable Y representing sizes y_i of index lists for items i. We are interested in $E[Y] = \sum_i y_i\, P[y_i]$ and assume that the chance of item i, that is the i^{th} most popular item, to be selected as a query item is following the same Zipf distribution, $f(k; s, v)$. That means, the items appearing frequently in the data are also used often in the queries. The average size of an index list is then given as $E[Y] = \sum_i n \times f(i; s, v)^2$. This is a generic result for inverted indices, which in our cost model is applied on an inverted index over M medoids (not n rankings) that together have v' distinct items; v' is derived thereafter, so the expected length of an inverted list for the inverted index is:

$$E[\mathit{index\ list\ length}] = \sum_i M \times f(i; s, v')^2 \tag{5}$$

For each query, k such index lists need to be accessed. This is one part of the cost caused by the retrieval of the medoids. For these $k \times E[\mathit{index\ list\ length}]$ medoids, we have to compute the distance function, assuming that there are no duplicate medoids retrieved.

The expectation of distinct items v' within the medoids is derived as follows. The probability that an item, out of a global domain of v items, is not selected into a single ranking of size k is $(\frac{v-1}{v})^k$, but we do know that a ranking does not contain duplicate items, hence, $P[\neg \mathit{selected}] = \frac{v-1}{v} \times \frac{v-2}{v-1} \cdots \frac{v-k}{v-k+1} = \Pi_{i=0}^{k} \frac{v-i}{v-i+1} = 1 - (\frac{k}{v})$. The probability that an item, out of a global domain of v items, is not selected into a single ranking of size k, knowing that the items in the ranking are unique, is $P[\neg \mathit{selected}] = 1 - (\frac{k}{v})$. The probability *not* to be selected in *any* of the M medoid rankings is then $(1 - \frac{k}{v})^M$. And thus

$$E[v'] = v \times \left(1 - \left(1 - \frac{k}{v}\right)^M\right) \tag{6}$$

To compute the overall cost, the above estimates are combined as shown in Table 3. To bring both parts of the overall cost to a comparable unit, we precompute the cost (runtime) of a single Footrule computation $Cost_{Footrule}(k)$ (for various k) and the cost (runtime) to merge k lists of a certain size, $Cost_{merge}(k, size)$.

Figure 3 shows the model for vary θ_C for the two datasets used in the experimental evaluation (we refer the reader to Section 7 for a description of the datasets). We empirically estimated the skewness parameter s from samples of the datasets—$s = 0.87$ for the New York Times dataset (left plot) and $s = 0.53$ for the Yago dataset (right plot)—and fitted it in the above estimate of the expected index list length.

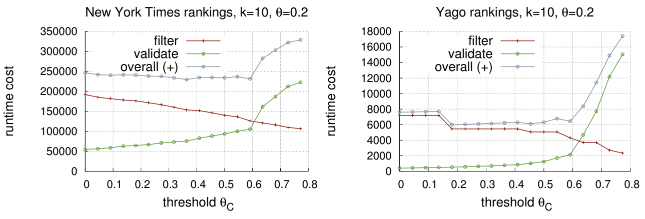

Figure 3: The behavior of the theoretically derived performance for varying θ_C.

Find medoids for query:	
Inv. Index Cost:	$Cost_{merge}(k, \sum_i f(i; s, v')^2 \times M)$
	$+$
Validation Cost:	$k\left(\sum_i f(i; s, v')^2 \times M\right) \times Cost_{Footrule}(k)$
Validation of retrieved rankings:	
Validation Cost:	$n \times P[X \leq \theta + \theta_C] \times Cost_{Footrule}(k)$

Table 3: Model of query performance (∼runtime) of the coarse index.

6. INV. INDEX ACCESS & OPTIMIZATIONS

Medoids are rankings as well and thus they can be indexed using inverted indices. In this section, two optimizations over inverted indices are presented.

First, a minimum-overlap criterion is derived; it indicates how many of the k index lists can be dropped from consideration, guaranteeing that no true result ranking can possibly be missed.

For the second optimization, for a query ranking of size k, the k corresponding index lists are accessed one after the other, and the contained information in each list in the form of $(\tau_i, \tau(i))$ are continuously aggregated for each (seen) ranking. For each ranking observed during accessing the index lists, upper and lower bounds for the true distance are derived, to allow accepting or rejecting final result rankings early.

6.1 Pruning by Query-Ranking Overlap

Consider a ranking τ with $\mathcal{D}_\tau \cap \mathcal{D}_q = \emptyset$, i.e., the items in τ are not at all overlapping with the query's items. It is easy to see that the Footrule distance is $F(\tau, q) = k \times (k+1) = L(k)$, considering rankings of length k. $L(k)$ is used to denote this lowest possible distance[1]. In the case of zero overlap, $L(k)$ is also the exact distance. In general, considering an overlap of size ω between $\mathcal{D}_q$ and $\mathcal{D}_\tau$, the smallest possible Footrule distance $L(k, \omega)$ in that case is given when the ω overlapping items are perfectly matched and positioned in the top of both lists, hence, $L(k, \omega) = L(k - \omega)$. For a given query threshold θ, rankings with an overlap of ω items can be safely ignored if $L(k, \omega) > \theta$. In practice, this means that some index lists can be entirely omitted from being accessed.

[1]We use the naming lower and upper bounds for distances instead of best and worst distances, for clarity.

It is immediately clear how to turn this insight into enhancements of algorithms that work with an inverted index: Solving $L(k, \omega) = \theta$ for ω tells that rankings τ with $F(\tau, q) \leq \theta$ must not have an overlap smaller than $\omega = \lfloor 0.5(1 + 2k - \sqrt{1 + 4\theta}) \rfloor$. From this it immediately follows that $k - \omega + 1$ index lists are sufficient to retrieve all the candidate lists since a ranking missing from these lists must have an overlap smaller than ω.

If we further take into consideration the position of the ω overlapping items, i.e., that they are positioned at the top of both lists, then we can ensure correctness by retrieving $k-\omega$ lists if at least one of the retrieved lists is of an item positioned in the top ω places. In this case, we can miss rankings that have an overlap of ω with the query, but we will never miss rankings that have overlap of ω where these ω items are positioned at the top ω places. This leads immediately to the following lemma.

LEMMA 2. *For given query threshold θ and ranking size k, $k - \omega$ index lists are sufficient to retrieve all the candidate rankings τ with $F(\tau, q) \leq \theta$, where $\omega = \lfloor 0.5(1 + 2k - \sqrt{1 + 4\theta}) \rfloor$.*

This is a generic result, independent of the actual choice of the index lists that can be dropped. Still, the expected impact of the candidate pruning is larger if the largest lists are dropped. In fact, experiments will show that specifically for the query-log–based benchmark, drastic performance gains can be enjoyed, literally for free. For the remaining lists and rankings within, the exact distance still needs to be determined, as there are obviously so called *false positives* with distance larger than the query threshold. But the above lemma guarantees that there are *no false negatives*, i.e., no ranking τ with $F(\tau, q) \leq \theta$ is missed.

Algorithms that make use of this dropping of entire index lists carry the suffix **+Drop** in the title.

6.2 Partial Information

Instead of having only ranking ids stored in the inverted index, such that an additional lookup is required to get the actual ranking content, we can augment the inverted index to make it hold the rank information as well, such that the true distance can be directly computed.

inverted index w/ ranks

item a $\longrightarrow$ <(τ_1 : 3),(τ_5 : 1),(τ_7 : 4)>

item b $\longrightarrow$ <(τ_4 : 2),(τ_9 : 11),(τ_{12} : 1),(τ_{19} : 2)>

In a **List-at-a-Time** fashion, the individual index lists determined by the query are accessed one after the other. Similarly to the NRA algorithm by Fagin et al. [19], for a ranking τ that has been seen only in a subset of the index lists, we can compute bounds for its final distance. This is done by keeping track of the common elements seen between the query q and ranking τ. The lower and upper bounds are computed by reasoning about the yet unseen elements: A lower bound distance $L(\tau, q)$ is given by assuming the best configuration of the unseen elements, that is, the remaining elements are common to both q and τ, and are additionally present in the same ranks in both rankings. Thus, their partial contribution to the Footrule distance is zero.

The upper bound distance $U(\tau, q)$ is obtained when none of the (yet) unseen elements in τ will be present in the query q. The partial distance contribution of such an item i, at rank $\tau(i)$ in τ is $|k - \tau(i)|$, and overall we have

$\tau_0 = [1, 2, 3, 4, 5]$	$\tau_5 = [4, 5, 1, 2, 3]$
$\tau_1 = [1, 2, 9, 8, 3]$	$\tau_6 = [1, 6, 2, 3, 7]$
$\tau_2 = [9, 8, 1, 2, 4]$	$\tau_7 = [7, 1, 6, 5, 2]$
$\tau_3 = [7, 1, 9, 4, 5]$	$\tau_8 = [2, 5, 9, 8, 1]$
$\tau_4 = [6, 1, 5, 2, 3]$	$\tau_9 = [6, 3, 2, 1, 4]$

Table 4: Sample set $\mathcal{T}$ of rankings

$$U(\tau, q) = L(\tau, q) + \sum_{i\, unseen} |k - \tau(i)|$$

The bounds allow pruning of candidates: If $L(\tau, q) > \theta$ we know that τ is not a result ranking, since $L(\tau, q)$ is monotonically non-decreasing. Similarly, if $U(\tau, q) \leq \theta$, we report τ as the result, as $U(\tau, q)$ is monotonically non-increasing. For small values of θ, many candidates can be evicted early on in the execution phase. For larger values of θ, candidate results can be reported early—reducing bookkeeping costs.

Consider for instance the set $\mathcal{T}$ of the rankings presented in Table 4 and a query $q = [7, 6, 3, 9, 5]$. The index list for item 7 is:

item 7 $\longrightarrow$ <(τ_3 : 0),(τ_6 : 4),(τ_7 : 0)>

We can compute the bounds for the seen rankings, τ_3, τ_6, and τ_7. For all these rankings, we know the seen element is item 7 and we have 4 unseen elements, since $k = 5$. Thus, $L(\tau_3, q) = L(\tau_7, q) = 0$ and $L(\tau_6, q) = 4$, as $\tau_3(7) - q(7) = \tau_7(7) - q(7) = 0$, and $\tau_6(7) - q(7) = 4$ and for the unseen items we assume they are on the same position in all rankings. $U(\tau_3, q) = U(\tau_7, q) = 20$ and $U(\tau_6, q) = 24$, as we assume that all of the unseen elements are not present in τ_3, τ_6, and τ_7.

These distance bounds are used in the following online aggregation algorithm that encounters partial information. Algorithms that make use of this pruning for partial information carry the suffix **+Prune** in their title.

6.3 Blocked Access on Index Lists

When index lists are ordered according to the rank values, since the ranks are integers, there might be a sequence of index lists whose ranks are the same. We refer to this sequence of index lists as a block of index lists. Formally, we let the block $\mathcal{B}_{i@j}$ to denote the set of rankings in which item i appears at position j. We additionally have a secondary index, one for each index list, which stores the offsets of the individual blocks.

The advantage with such an index list organization strategy is that processing the entire index list can be avoided in many cases. We describe this in detail. It is obvious that result candidates which have a partial distance greater than θ can be pruned out. In such an index organization approach, we avoid processing blocks which would produce candidates with a partial distance greater than θ. Given a query $q = [q_1, \ldots, q_k]$ with a threshold θ, all result candidates obtained while traversing the block $\mathcal{B}_{i@j}$ have a partial distance of at least $|j - i|$. Thus, we modify the List-at-a-Time algorithm so that blocks, $\mathcal{B}_{i@j}$, where $|j - i| > \theta$ are omitted, avoiding processing the bulk of the index list.

Consider for instance the inverted index in Figure 4, constructed according to the rankings in Table 4. For the query $q = [3, 2, 1]$ and $\theta = 1$, blocks $\mathcal{B}_{3,1}$ need to be accessed for item 3, $\mathcal{B}_{2,1}$, $\mathcal{B}_{2,1}$ and $\mathcal{B}_{2,3}$ for item 2. Finally, blocks $\mathcal{B}_{1,2}$, $\mathcal{B}_{1,3}$ and $\mathcal{B}_{1,4}$ for item 1. In the process 17 out of 28 index item 1$\rightarrow$ $\boxed{(\tau_0:0), (\tau_1:0), (\tau_6:0)}, \boxed{(\tau_3:1), (\tau_4:1), (\tau_7:1), (\tau_{10}:1)}, \boxed{(\tau_2:2), (\tau_5:2)}, \boxed{(\tau_9:3)}, \boxed{(\tau_8:4)}$

item 2$\rightarrow$ $\boxed{(\tau_8:0)}, \boxed{(\tau_0:1), (\tau_1:1)}, \boxed{(\tau_6:2), (\tau_9:2)}, \boxed{(\tau_2:3), (\tau_4:3), (\tau_5:3), (\tau_{10}:3)}, \boxed{(\tau_7:4)}$

item 3$\rightarrow$ $\boxed{(\tau_9:1)}, \boxed{(\tau_0:2)}, \boxed{(\tau_6:3)}, \boxed{(\tau_1:4), (\tau_4:4), (\tau_5:4)}$

lists are processed which accounts for less than 50% index lists being accessed.

7. EXPERIMENTS

We implemented the described algorithms in Java 1.7 and report on the setup and results of an experimental study. The experiments are conducted on a quad-core Intel Xeon W3520 @ 2.67GHz machine (256KiB, 1MiB, 8MiB for L1, L2, L3 cache, respectively) with 24GB DDR3 1066 MHz (0.9 ns) main memory.

Datasets

Yago Entity Rankings: We have mined top-k entity rankings out of the Yago knowledge base, as described in [23]. The facts, in form of subject/predicate/object triples, are used to define constraints, for which the qualifying entities are ranked according to certain criteria. For instance, we generate rankings by focusing on type building and predicate located in New York, ranked by height. This dataset, in total, has 25,000 rankings.

NYT: We executed 1 million keyword queries, randomly selected out of a published query log of a large US Internet provider, against the New York Times archive [31] using a unigram language model with Dirichlet smoothing as a scoring model. Each query together with the resulting documents represents one ranking.

The two datasets are naturally very different: while the Yago dataset features real world entities that each occur in few rankings, the NYT dataset has many popular documents that appear in many query-result rankings.

Algorithms under Investigation

- the baseline approaches Filter and Validate (**F&V**) and Merge of Id-Sorted Lists (**ListMerge**) both described below
- filter and validate technique combined with the optimization based on dropping entire index lists (**F&V+ Drop**)
- blocked access with pruning (**Blocked+Prune**)
- blocked access with pruning based on both overlap and pruning (**Blocked+Prune+Drop**)
- query processing on the coarse index using the F&V technique (**Coarse**)
- query processing on the coarse index using the F&V+ Drop technique (**Coarse+Drop**)
- a competitor **AdaptSearch**, and **Minimal F&V** algorithm, both described below

Next to the actual algorithms, we implemented a minimal Filter and Validate algorithm (**Minimal F&V**) that has for each query materialized a single index list in an inverted index that contains exactly the true query-result rankings. For each of these, the Footrule distance is computed. The cost for the single index lookup and the Footrule computations serves as a lower bound for the performances of the discussed algorithms.

We also implemented **AdaptSearch** [33] as the most recent and competitive work on ad-hoc set similarity search in main memory. We implemented AdaptSearch by following the C++ implementation of the AdaptJoin algorithm available online[2]. We computed the size of the prefix of the query using the overlap threshold ω derived in Section 6. In the validation phase, AdaptSearch computes the Footrule distance for each of the candidate rankings.

The implementation of the M-tree is obtained from [15]. We implemented the BK-tree ourselves, according to the original work in [10]. The inverted index implementations make use of the Trove library[3].

Merge of Id-Sorted Lists with Aggregation: If the information within each index list is sorted by ranking id, and further contains rank information, the problem of computing the actual distances of the rankings to the query ranking can be achieved using a classical merge "join" of id-sorted lists. This is very efficient, in particular as the index lists do not contain any duplicates. Cursors are opened to each of the lists, and the distances of each ranking is finalized on the fly. There is no bookkeeping required as, at any time, only one ranking is under investigation (the one with the lowest id, if sorted in increasing order). Rankings do either qualify the query threshold or not. It is clear that this algorithm is threshold-agnostic, that is, its performance is not influenced by the query threshold θ; the index lists have to be read entirely.

We mainly focus on rankings of size 10 since in a previous study [1] we observed that at ranker.com most common are rankings of size 10.

Performance Measures

- Wallclock time: For all algorithms we measure the wallclock time needed for processing 1000 queries.
- Distance function calls: For the filter&validate algorithms, specifically F&V, F&V+Drop, Blocked+Prune+Drop, Coarse, and Coarse+Drop, we measure the number of distance function computations performed.

For the coarse index processing techniques, we also investigate the performance of the individual phases.

7.1 Query Processing Performance

Inverted Index vs. Metric Index Structures

We first compare the two main concepts of processing similarity queries over top-k rankings: First, the use of met-

[2]https://github.com/sunlight07/similarityjoin
[3]http://trove.starlight-systems.com/

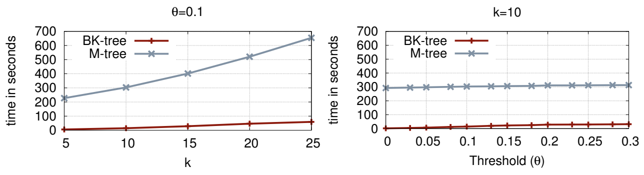

Figure 5: Performance of the M-tree vs. BK-tree (NYT)

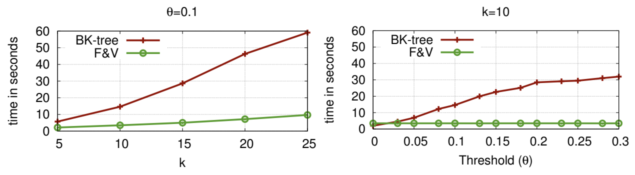

Figure 6: Performance of the BK-tree vs. the performance of inverted index (NYT)

ric index structures is compared, here, represented by the BK-tree and the M-tree [37] (Figure 5). Second, the use of inverted indices is compared to the BK-tree (Figure 6).

Figure 5 reports the query performance of the BK-tree compared to the M-tree and Figure 6 on the query performance of the BK-tree index structure versus the plain query processing using the inverted index with subsequent validation, i.e., filter and validate, F&V. We see that the inverted index performs orders of magnitudes better than the M-tree. Although the M-tree is a balanced index structure it still performs worse than the BK-tree. Chávez et al. [13] show that balanced index structures perform worse than unbalanced ones in high dimensions—we calculated the intrinsic dimensionality of both datasets to be around 13 (cf. [13] for the definition of intrinsic dimensionality). Despite the better performance of the BK-tree, the inverted index still outperforms it. Hence, only techniques using the inverted index paradigm are further studied.

Coarse Index Performance Based on θ_C

Next, we studied the performance of the coarse index for different θ_C values. We focus on the performance of the coarse index combined with the F&V technique as this combination resembles the model presented in Section 4 most. In Figure 7, the filtering and validation times are shown when varying θ_C and fixed $k = 10$, for both datasets. We see that the curves resemble the ones plotted for the cost model in Figure 3. Both dataset show a similar behavior of the execution time. The filtering time is reducing as we increase the value of θ_C, since the number of indexed medoids reduces. The validation time, on the other hand, is rising, since the size of the partitions is increasing proportionally with θ_C. Most importantly, we see that we can find a specific value of θ_C for which the coarse index performs optimally and this value depends on the value of $\theta + \theta_C$ as modeled in Section 4.

Cost Model Correctness

The performance of the coarse index if the trade-off value of θ_c as computed by the model is chosen, is shown in the plots in Figure 7 as a small rectangle. The vertical line denotes the difference between the performance of the coarse index in case of the two trade-off θ_c values—the modeled optimal one and the real optimal one. We observe that except for $\theta = 0.1$, for the NYT dataset, the difference in performance

	$\theta = 0.1$	$\theta = 0.2$	$\theta = 0.3$
NYT	29.47	10.23	4.75
Yago	3.28	0.41	2.38

Table 5: Difference in ms between the minimal performance of the coarse index, and the performance for the theoretically computed best value of θ_c ($k = 10$)

is smaller than 11ms (Table 5). For $\theta = 0.1$ the difference is 29.47ms. For the Yago dataset, the difference in performance is less than 4ms for any value of θ.

As we are considering the task of processing ad-hoc queries, even choosing the optimal value of θ_C for some previously defined maximum value of θ would result in a performance close to the optimal one, as the performance of the coarse index remains stable in this region. The major increase in the performance happens for very small values of θ_C or larger than the optimal θ_C. We show this in the experiments comparing different algorithms, where we set $\theta_C = 0.5$—the optimal value for $\theta = 0.3$.

We also measure the performance of the coarse index combined with the F&V+Drop technique as this should result in even bigger performance gains. For this technique, we measured the optimal value for θ_C to be 0.06, since for smaller values of $\theta + \theta_C$ we can drop more index lists.

Comparison of Different Algorithms

Next, we study the performance of different query processing methods performed over the two datasets; for rankings of size 10 and 20 and θ ranging from 0 to 0.3. First, in Figure 8 we compare the performance of the coarse index with the remaining techniques, for the NYT dataset. For a better visibility, we group the algorithms in the plots in two groups. The first (left) group contains the Coarse and Coarse+Drop techniques, the two baseline approaches F&V and ListMerge, and the competitors AdaptSearch and Minimal F&V. The second (right) group contains the remaining hybrid techniques.

We see that for all threshold values the coarse index, with and without dropping index list, significantly outperforms the AdaptSearch algorithm. In fact, the Coarse+Drop index outperforms the competitor by at least factor of 34. The coarse index outperforms the Minimal F&V technique by a factor of up to 7, since the number of Footrule distance function calls reduces significantly as shown in Figure 10. Dropping entire lists from the query even further boosts the performance of the coarse index, and results in up to 24 times better performance than the Minimal F&V. The baseline approaches, although threshold agnostic, perform worse than the rest of the algorithms. Increasing the values of θ degrades the performance of all the processing techniques except for the baseline F&V and ListMerge techniques, as they are threshold agnostic. In fact, because of its simple and efficient implementation, the ListMerge even outperforms the AdaptSearch algorithm for $\theta \geq 0.1$ for rankings with $k = 10$. For $k = 20$, since we increase the number of lists that need to be merged, the performance of the ListMerge is worse and thus the AdaptSearch outperforms it for all values of θ.

For rankings of size 10, all hybrid techniques outperform AdaptSearch, but not the coarse index. The Blocked+Prune algorithm dynamically computes the best score for the yet unseen blocks to decide when to terminate further schedul-

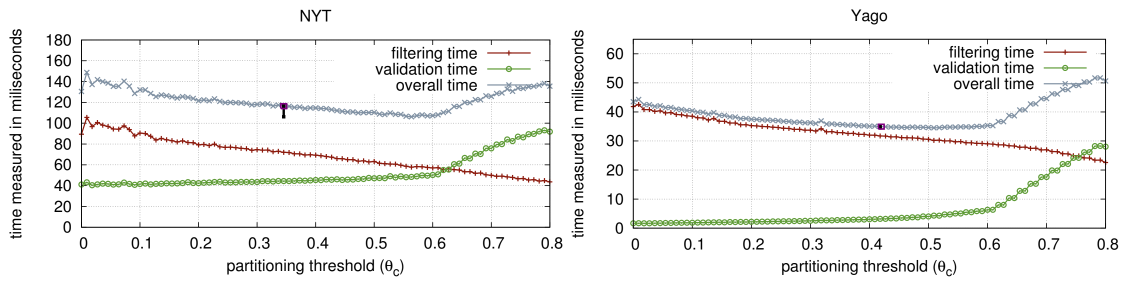

Figure 7: Trend of the filtering and validation time of the coarse index for $k = 10$, $\theta = 0.2$ and varying θ_C. The small rectangle depicts the performance of the coarse index if θ_C was chosen by the model and the vertical line the difference in performance.

ing of blocks. In cases where the best blocks will not result in similar rankings, Blocked+Prune terminates early. Thus, when searching for exact matches, the Blocked+Prune technique performs especially well, outperforming AdaptSearch by a factor of 1.2. Same as for the coarse index, dropping lists further improves the performance of the Blocked+ Prune technique. Increasing the values of θ degrades the performance of all the processing techniques. The Blocked+ Prune+Drop technique performs worse than the F&V+Drop, because sorting the lists adds some overhead to the processing while the pruning is not so effective. The F&V+Drop technique is performing very well, in fact we measured its performance to be very close to the Minimal F&V, especially for small values of θ. Although they are both based on the same concept, F&V+Drop performs better than AdaptSearch, first because it drops one index list more than AdaptSearch, and second, because we are processing relatively short rankings, thus the simple algorithms perform well.

Most of the query processing techniques display the same behavior in the experiments performed on the Yago dataset (Figure 9). What is different here is that none of the processing techniques perform as good as the Minimal F&V, which shows a runtime close to zero. This is due to the fact that the items in the Yago dataset are more equally distributed. In this dataset we have small clusters of similar rankings. However, the clusters seem to be different among them, allowing more rankings to be pruned early on. Moreover, for the Yago dataset the Blocked+Prune technique performs very poorly. We believe this is because the overhead of sorting the index list is too big for the small index size. In fact, we measured that for 35% of the queries sorting of the index lists accounts for a third of the execution time, when $k = 10$. The percentage increases as we increase k. The simple baseline ListMerge technique surprisingly outperforms the coarse index and the AdaptSearch algorithm. We believe that this happens because of the small data size and the size of the rankings. Still, ListMerge does not perform better than the Coarse+Drop technique, except for $\theta = 0.3$ and $k = 10$. For this dataset, the AdaptSearch algorithm shows better performance, performing better than the coarse index in most of the cases. However, the Coarse+Drop technique and some of the hybrid techniques still outperform the competitor, AdaptSearch.

Distance Function Computations

The difference in performance between the Coarse, Coarse+ Drop, F&V+Drop and Blocked+Prune+Drop algorithms can be explained by looking at the number of distance functions calls, shown in Figure 10. We see that for the Yago dataset

	size in MB		**construction time in sec.**	
	NYT	Yago	NYT	Yago
Plain Inverted Index	480	24	3.37	0.03
Augmented Inverted Index	661	38	5.72	0.11
Delta Inverted Index	417	35	3.63	0.086
BK-tree	276	11	1206.75	12.11
M-tree	265	11	35.00	0.47
Coarse Index	367	26	1392.35	19.57

Table 6: Size and construction time of indices for $k = 10$

the final result set is very small, practically almost 1, and the number of distance function computations performed by all the algorithms is significantly larger than the final result set. On the other hand, for the NYT data set—where we have a skewed distribution of the items—the number of false positives is very small, resulting in a very good performance of the F&V+Drop and Blocked+Prune+Drop processing techniques. Combining these with the coarse index even further reduces the number of distance function computations, i.e., the number of distance function computations is smaller than the final result set. This is because for the exact matching rankings in one partition, the Footrule distance is not computed again during query processing time.

7.2 Index Size and Construction Time

In Table 6 the size and the index construction time is shown for both datasets for $k = 10$. Delta Inverted Index is the index used in the AdaptSearch algorithm. For the coarse index, we set $\theta_C = 0.5$. We see that all the indices are smaller than 1GB. All indices store the complete rankings, thus their sizes do not differ significantly. The rank-augmented inverted index requires the most storage as it keeps both the complete rankings, and the position augmented index lists to support different processing techniques.

The construction time of the coarse index is the most expensive one, as we need to build a BK-tree, partition it and add the medoids to the inverted index. The construction of the BK-tree is expensive as the tree is unbalanced and in worst case, we need $O(n^2)$ distance computations. The M-tree index construction time is lower than the BK-tree. Both construction times are worse than the one of the inverted index; creating the inverted index does not imply making any distance computations. However, the construction time of the plain inverted index is cheaper than the augmented one, as we do not consider the position of the rankings.

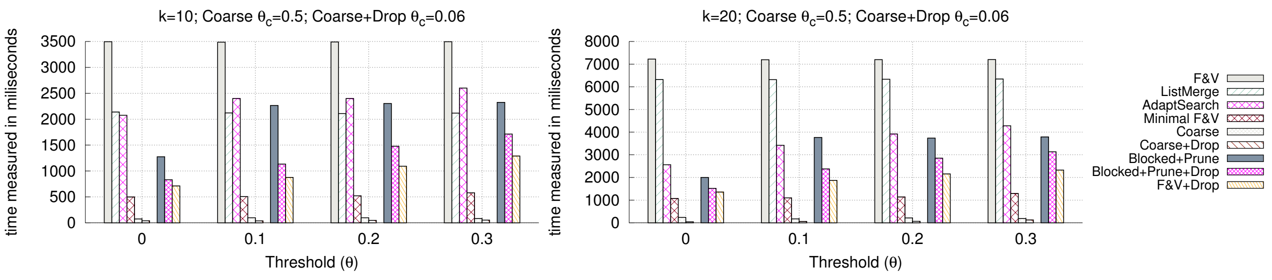

Figure 8: Comparing query processing over coarse index with baseline and competitor approaches (left block) and with other hybrid methods over inverted index (right block) (NYT).

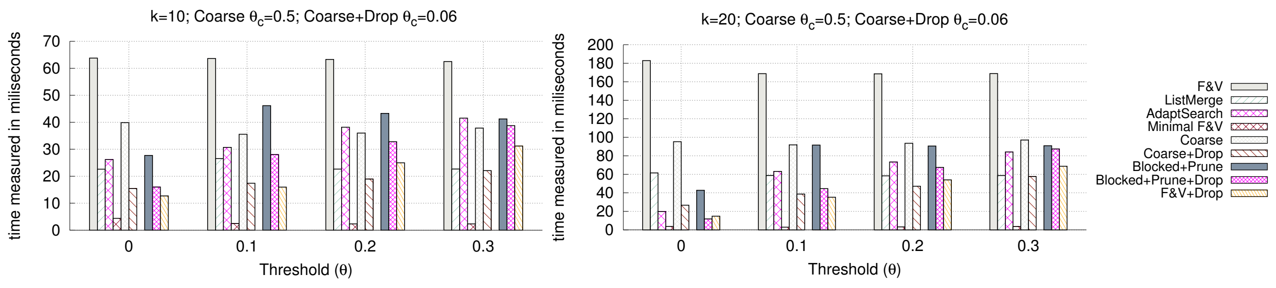

Figure 9: Comparing query processing over coarse index with baseline and competitor approaches (left block) and with other hybrid methods over inverted index (right block) (Yago).

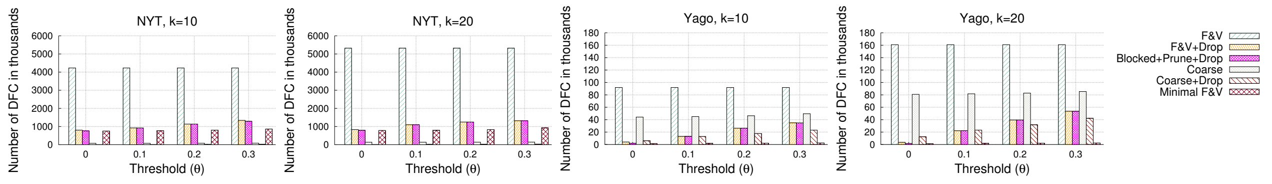

Figure 10: # of distance function calls (DFC) for different query processing methods (Coarse θ_c=0.5; Coarse+Drop $\theta_c = 0.06$)

It is difficult to compare the complexity of the construction time of the different index structures, since the complexity of the metric index structures is usually measured in distance function computation, as this is the most costly operation. On the other hand, in the case of the inverted index there are no distance functions performed during construction at all.

Lessons Learned

Combining the coarse index with the proposed optimizations on the inverted index always leads to performance improvements, independent of the distribution of the items in the dataset. The experiments demonstrate that the Coarse+ Drop technique outperformed state-of-the-art algorithm for similarity search, AdaptSearch, for both datasets. The simple yet accurate model for picking the optimal trade-off point (cf., Section 4) leads close to the best performance of the coarse index. When the query threshold is not known, we can tune the coarse index for the maximum query threshold that we might have. In these cases, the coarse index shows to perform better for a skewed dataset. When having a dataset where the items are unevenly distributed, the F&V+Drop algorithm alone results in huge gains as we only process the smallest index lists. These, as the distribution of the items is skewed, can often contain only few false positives. On the contrary, when the dataset contains chunks of rankings similar to each other, i.e, we have more evenly distributed items, the effect of the early pruning of rankings is most expressed. Thus in these cases, using the Blocked+Prune+Drop algorithm, which combines the early pruning with dropping of entire index lists, leads to the biggest benefits, for small values of θ. Varying the size of the rankings does not have a great impact on the different algorithms. Only when having very small ranking sizes, for instance k=5, the simple baseline ListMerge shows to perform well.

8. CONCLUSION AND OUTLOOK

In this paper, we addressed indexing mechanisms and query processing techniques for ad-hoc similarity search inside sets of rankings. We specifically considered Spearman's Footrule distance for top-k rankings and investigated the trade-offs between metric index structures and inverted indices, known in the literature for indexing set-valued attributes. The presented coarse index synthesizes advantages of metric-space indexing and the ability of inverted indices to immediately dismiss non-overlapping rankings. To understand and automatically tune the necessary partitioning of the rankings, we developed an accurate theoretic cost model; and showed by experiments that it allows reaching performance close to the optimal trade-off point. Further, we presented an algorithm that avoids accessing blocks of an index list during query processing thereby improving performance. We derived upper and lower distance bounds for such an online processing and, further, studied the impact of dropping entire parts of the query depending on the tightness of the query threshold. The presented approaches are to a large extent orthogonal and, by a comprehensive performance evaluation using two real-world datasets, we showed that the individual benefits add up, showing better performance than the competitor, AdaptSearch.

As ongoing work we consider processing large batches of queries, instead of the single ad-hoc queries we addressed in this work. We believe that an approach similar to the coarse indexing can be fruitful here: the query batch can be partitioned into related medoid rankings to prune the search space of potential result rankings.

Optimizing Reformulation-based Query Answering in RDF

Damian Bursztyn[§,⋆] François Goasdoué[†,§] Ioana Manolescu[§,⋆]

[§]INRIA, France [⋆]Université Paris-Sud, France [†]Université Rennes 1, France

firstname.lastname [§]@inria.fr [⋆]@lri.fr [†]@irisa.fr

ABSTRACT

Reformulation-based query answering is a query processing technique aiming at answering queries under constraints. It consists of reformulating the query based on the constraints, so that evaluating the reformulated query directly against the data (i.e., without considering any more the constraints) produces the correct answer set.

In this paper, we consider optimizing reformulation-based query answering in the setting of *ontology-based data access*, where SPARQL conjunctive queries are posed against RDF facts on which constraints expressed by an RDF Schema hold. The literature provides query reformulation algorithms for many fragments of RDF. However, reformulated queries may be complex, thus may not be efficiently processed by a query engine; well established query engines even fail processing them in some cases.

Our contribution is (i) to generalize prior query reformulation languages, leading to investigating a *space of reformulated queries* we call `JUCQ`s (joins of unions of conjunctive queries), instead of a single reformulation; and (ii) an effective and efficient *cost-based algorithm* for selecting from this space, the reformulated query with the lowest estimated cost. Our experiments show that our technique enables reformulation-based query answering where the state-of-the-art approaches are simply unfeasible, while it may decrease its cost by orders of magnitude in other cases.

1. INTRODUCTION

The Resource Description Framework (RDF) [1] is a graph-based data model promoted by the W3C as the standard for Semantic Web applications. As such, it comes with an ontology language, *RDF Schema* (RDFS), that can be used to enhance the description of RDF *graphs*, i.e., RDF datasets. The W3C standard for querying RDF graphs is the SPARQL Protocol and RDF Query Language (SPARQL) [2].

Answering SPARQL queries requires to handle the *implicit information* modeled in RDF graphs, through the essential RDF reasoning mechanism called *RDF entailment*. Query answers are defined based on both the explicit and the implicit content of an RDF graph. Thus, ignoring implicit information leads to incomplete answers [2].

Two main methods exist for answering SPARQL queries against RDF graphs, both of which consists of a *reasoning* step, either on the graphs or on queries, followed by a *query evaluation* step. A popular reasoning method is *graph saturation* (a.k.a. *closure*). This consists of pre-computing and adding to an RDF graph all its implicit information, to make it explicit. Answering queries through saturation, then, amounts to evaluating the queries on the saturated graph. While saturation leads to efficient query processing, it requires time to be computed, space to be stored, and must be recomputed upon updates. The alternative reasoning step is *query reformulation*. This consists in turning a query into a *reformulated query*, which, evaluated against a non-saturated RDF graph, yields the exact answers to the original query. Since reformulation takes place at query time, it is intrinsically robust to updates; the query reformulation process in itself is also typically very fast, since it only operates on the query, not on the data. However, reformulated queries are often syntactically more complex than the original ones, thus their evaluation may be costly or even unfeasible.

Saturation-based query answering has been well studied by now; efficient saturation algorithms have been proposed, including incremental ones [3, 4, 5, 6]. Most RDF data management systems use saturation-based query answering, either by providing such a reasoning service on RDF graphs, like 3store, OWLIM, Sesame, etc., or by simply assuming that RDF graphs have been saturated prior to loading. Most systems built on top of relational data management systems (RDBMSs, in short) or RDBMS-style engines [7, 8, 9] fall in this category.

Reformulation-based query answering has also been the topic of many works [6, 10, 11, 12, 13], including ours [4, 14, 15]. Existing techniques apply to the Description Logics (DL) [16] fragment of RDF, the conjunctive subset of SPARQL subset and extensions thereof [10, 11, 14, 15, 17, 18, 19], including the "database fragment" of RDF we introduced in [4], the most expressive RDF fragment to date. Only a few RDF data management systems, such as AllegroGraph, Stardog or Virtuoso, use reformulation, in some cases incomplete. The main reason is that state-of-the-art techniques produce reformulated queries whose evaluation is *inefficient*. A query is typically reformulated into an equivalent *large* union of conjunctive queries (`UCQ`), maximally contained in the original query w.r.t. the RDF Schema constraints [4, 6, 10, 11, 12, 14, 15, 17, 18], or in languages for

10.5441/002/edbt.2015.24

which no well established off-the-shelf query engine exists, such as nested SPARQL [19]. The technique of [13], when translated to the RDF setting, reformulates a conjunctive query into a so-called *semi-conjunctive query* (SCQ), which is a join of unions of atomic queries. While in many cases this performs better than the UCQ reformulations used in prior work, we show that the reformulation of [13] is only another point in a space, in which we automatically identify the most efficient alternative. Finally, a mix of saturation- and reformulation-based query answering has been investigated in [11]. Only RDF Schema contraints are saturated (thus need maintenance), which allows to avoid generating as part of the reformulation, empty-answer subqueries. This may reduce its syntactic size, but (depending on the ability of the underlying engine to detect empty-answers queries early on) the resulting reformulated query may still be hard to evaluate.

This work focuses on *optimizing reformulation-based query answering in RDF.*

We consider the setting in which *conjunctive queries (*CQ*), once reformulated into unions of conjunctive queries (*UCQ*) or semi-conjunctive queries (*SCQ*), are handled for evaluation to a query evaluation engine*, which can be an RDBMS, a dedicated RDF storage and query processing engine, or more generally any system capable of evaluating *selections*, *projections*, *joins* and *unions*. As our experiments show, the evaluation of reformulated queries may be very challenging even for well-established relational or native RDF processors, which may handle them inefficiently or simply fail to handle them, even on moderate-size datasets.

The approach we take is the following. Given a SPARQL conjunctive query q and a query reformulation algorithm $\mathcal{A}$ which turns a CQ into a UCQ, we explore a novel, large *space of alternative reformulations* of q that we term JUCQ (for *joins of unions and conjunctive queries*, and pick the JUCQ reformulation with the lowest estimated cost. Each JUCQ reformulation is obtained based on a carefully chosen set of invocations of the algorithm $\mathcal{A}$, guided by our cost model.

Contributions. The contributions we bring to the problem of efficiently answering SPARQL queries, through reformulation, can be outlined as follows (see Figure 1):

1. We generalize the query reformulation approach, by considering a large *space of alternative (equivalent)* JUCQ *reformulations*. This space corresponds to the yellow-background box in Figure 1; it includes and significantly generalizes the prior works based on UCQ or SCQ reformulation. We characterize the size of our space of alternatives, and show that it is oftentimes too large to be completely explored.
2. We define a *cost model* for estimating the evaluation performance of our reformulated queries through a relational engine; other functions can be used instead, and we show that an RDBMSs' internal cost model can easily be used, too.
3. We devise a novel *algorithm* which selects one alternative reformulated query, namely q^{best} in Figure 1, which (*i*) computes the same result as the UCQ reformulated query q^{ref}, and (*ii*) reduces significantly the query evaluation cost (or simply makes it possible when evaluating the plain reformulation fails!)
4. We implemented this algorithm and deployed it on top of three well-established RDBMSs, which we show differ significantly in their ability to handle UCQ and SCQ reformulations proposed in the previous work. Our experiments confirm that our algorithm *makes the most out of each of these engines* by leveraging their strengths and avoiding their weaknesses thanks to the usage of our cost model, which we calibrate separately for each system. This makes reformulation feasible when UCQ and/or SCQ fail, and brings performance improvements of several orders of magnitude w.r.t. UCQ.
5. Finally, we compare our reformulation-based query answering technique against saturation-based query answering, both through an RDBMS and the native RDF platform Virtuoso. These experiments confirm the robustness and performance of our technique, showing in particular that in some cases its performance approaches that of saturation-based query answering.

In the sequel, Section 2 introduces RDF, SPARQL conjunctive queries, query reformulation and the performance issues raised by the evaluation of reformulated queries. Section 3 characterizes our solution search space and formalizes our problem statement. In Section 4, we present our cost model and solution search space exploration technique, which we evaluate through experiments in Section 5. We discuss related work in Section 6, then we conclude.

2. PRELIMINARIES

In Section 2.1 we introduce *RDF graphs*, modeling RDF datasets. Section 2.2 presents the SPARQL conjunctive queries, a.k.a. *Basic Graph Pattern queries.* In Section 2.3, we recall the query reformulation algorithm from [4] used in the present work, chosen because the RDF fragment it applies to is the largest known to date. However, as previously explained, our optimization technique can use any CQ to UCQ reformulation algorithm among those applicable to RDF.

2.1 RDF Graphs

An *RDF graph* (or *graph*, in short) is a set of *triples* of the form s p o. A triple states that its *subject* s has the *property* p, and the value of that property is the *object* o. We consider only well-formed triples, as per the RDF specification [1], using uniform resource identifiers (URIs), typed or un-typed literals (constants) and blank nodes (unknown URIs or literals).

Blank nodes are essential features of RDF allowing to support *unknown URI/literal tokens.* These are conceptually similar to the variables used in incomplete relational databases based on *V-tables* [20, 21], as shown in [4].

Notations. We use s, p, o and $\_{:}b$ in triples as placeholders. Literals are shown as strings between quotes, e.g., "*string*". Finally, the set of values – URIs (U), blank nodes (B), and literals (L) – of an RDF graph G is denoted Val(G).

Figure 2 (top) shows how to use triples to describe resources, that is, to express class (unary relation) and property (binary relation) assertions. The RDF standard [1] provides a set of built-in classes and properties, as part of the rdf: and rdfs: pre-defined namespaces. We use these namespaces exactly for these classes and properties, e.g., rdf:type specifies the class(es) to which a resource belongs.

Example 1 (**RDF graph**). *The RDF graph* G *below comprises information about a book, identified by* doi_1*: its author (a blank node* $\_{:}b_1$ *related to the author name, which is a literal), title and date of publication.*

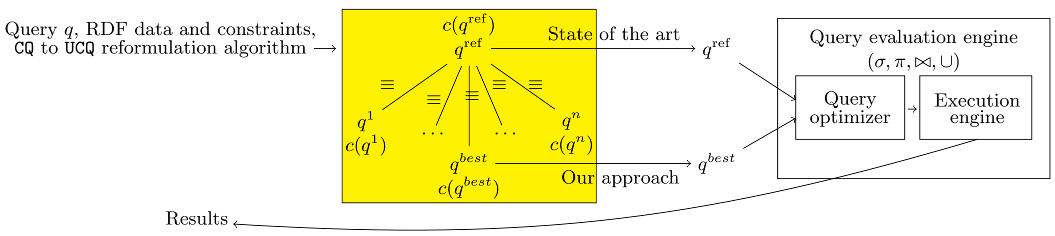

Figure 1: Outline of our approach for efficiently evaluating reformulated SPARQL conjunctive queries.

Assertion	Triple	Relational notation
Class	`s rdf:type o`	$\mathtt{o(s)}$
Property	`s p o`	$\mathtt{p(s, o)}$

Constraint	Triple	OWA interpretation
Subclass	`s rdfs:subClassOf o`	$\mathtt{s} \subseteq \mathtt{o}$
Subproperty	`s rdfs:subPropertyOf o`	$\mathtt{s} \subseteq \mathtt{o}$
Domain typing	`s rdfs:domain o`	$\Pi_{\text{domain}}(\mathtt{s}) \subseteq \mathtt{o}$
Range typing	`s rdfs:range o`	$\Pi_{\text{range}}(\mathtt{s}) \subseteq \mathtt{o}$

Figure 2: RDF (top) & RDFS (bottom) statements.

$$\mathtt{G} = \begin{array}{l}\{\text{doi}_1 \text{ rdf:type Book},\\ \text{doi}_1 \text{ writtenBy } \_{:}b_1,\\ \text{doi}_1 \text{ hasTitle ``Game of Thrones''},\\ \_{:}b_1 \text{ hasName ``George R. R. Martin''},\\ \text{doi}_1 \text{ publishedIn ``1996''}\}\end{array}$$

RDF Schema. A valuable feature of RDF is RDF Schema (RDFS) that allows enhancing the descriptions in RDF graphs. RDFS triples declare *semantic constraints* between the classes and the properties used in those graphs.

Figure 2 (bottom) shows the allowed constraints and how to express them; *domain* and *range* denote respectively the first and second attribute of every property. The RDFS constraints (Figure 2) are interpreted under the open-world assumption (OWA) [20]. For instance, given two relations R_1, R_2, the OWA interpretation of the constraint $R_1 \subseteq R_2$ is: any tuple t in the relation R_1 *is considered as being also in the relation* R_2 (the inclusion constraint *propagates* t *to* R_2). More specifically, when working with the RDF data model, if the triples hasFriend rdfs:domain Person and Anne hasFriend Marie hold in the graph, then so does the triple Anne rdf:type Person. The latter is due to the rdfs:domain constraint in Figure 2.

RDF entailment. *Implicit triples* are an important RDF feature, considered part of the RDF graph even though they are not explicitly present in it, e.g., Anne rdf:type Person above. W3C names *RDF entailment* the mechanism through which, based on a set of explicit triples and some *entailment rules*, implicit RDF triples are derived. We denote by $\vdash^{i}_{\text{RDF}}$ *immediate entailment*, i.e., the process of deriving new triples through a *single* application of an entailment rule. More generally, a triple $\mathtt{s\ p\ o}$ is entailed by a graph $\mathtt{G}$, denoted $\mathtt{G} \vdash_{\text{RDF}} \mathtt{s\ p\ o}$, if and only if there is a sequence of applications of immediate entailment rules that leads from $\mathtt{G}$ to $\mathtt{s\ p\ o}$ (where at each step of the entailment sequence, the triples previously entailed are also taken into account).

Example 2 (**RDFS**). *Assume that the RDF graph* $\mathtt{G}$ *in Example 1 is extended with the following constraints.*

- *books are publications:*
  Book rdfs:subClassOf Publication
- *writing something means being an author:*
  writtenBy rdfs:subPropertyOf hasAuthor

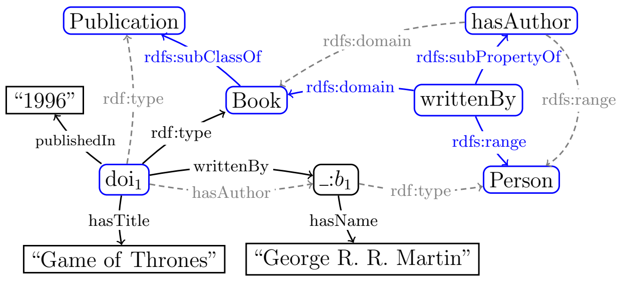

Figure 3: Sample RDF graph.

- *books are written by people:*
  writtenBy rdfs:domain Book
  writtenBy rdfs:range Person

The resulting graph is depicted in Figure 3. Its implicit triples are those represented by dashed-line edges.

Saturation. The immediate entailment rules allow defining the finite *saturation* (a.k.a. closure) of an RDF graph $\mathtt{G}$, which is the RDF graph $\mathtt{G}^\infty$ defined as the fixed-point obtained by repeatedly applying $\vdash^{i}_{\text{RDF}}$ rules on $\mathtt{G}$.

The saturation of an RDF graph is unique (up to blank node renaming), and does not contain implicit triples (they have all been made explicit by saturation). An obvious connection holds between the triples entailed by a graph $\mathtt{G}$ and its saturation: $\mathtt{G} \vdash_{\text{RDF}} \mathtt{s\ p\ o}$ if and only if $\mathtt{s\ p\ o} \in \mathtt{G}^\infty$.

RDF entailment is part of the RDF standard itself; in particular, *the answers to a query posed on* $\mathtt{G}$ *must take into account all triples in* $\mathtt{G}^\infty$, since *the semantics of an RDF graph is its saturation* [2].

2.2 BGP Queries

We consider the well-known subset of SPARQL consisting of (unions of) *basic graph pattern* (BGP) queries, modeling the SPARQL conjunctive queries. Subject of several recent works [4, 22, 23, 24], BGP queries are the most widely used subset of SPARQL queries in real-world applications [24]. A BGP is a set of *triple patterns*, or triples/atoms in short. Each triple has a subject, property and object, some of which can be variables.

Notations. In the following we use the conjunctive query notation $q(\bar{x})$:- $t_1, \ldots, t_\alpha$, where $\{t_1, \ldots, t_\alpha\}$ is a BGP; the query head variables $\bar{x}$ are called *distinguished variables*, and are a subset of the variables occurring in $t_1, \ldots, t_\alpha$; for boolean queries $\bar{x}$ is empty. The head of q is $q(\bar{x})$, and the body of q is $t_1, \ldots, t_\alpha$. We use x, y, z, etc. to denote variables in queries. We denote by $\mathtt{VarBl}(q)$ the set of variables *and* blank nodes occurring in the query q.

Query evaluation. Given a query q and an RDF graph $\mathtt{G}$, the *evaluation of* q *against* $\mathtt{G}$ is:

$$q(\mathtt{G}) = \{\bar{x}_\mu \mid \mu : \mathtt{VarBl}(q) \to \mathtt{Val}(\mathtt{G}) \text{ is a total assignment}$$

$$\text{such that } t_1^\mu \in \mathtt{G}, t_2^\mu \in \mathtt{G}, \ldots, t_\alpha^\mu \in \mathtt{G}\}$$

where we denote by t^μ the result of replacing every occurrence of a variable or blank node $e \in \mathtt{VarBl}(q)$ in the triple t, by the value $\mu(e) \in \mathtt{Val}(\mathtt{G})$.

Note that evaluation *treats the blank nodes in a query exactly as it treats non-distinguished variables* [25]. Thus, in the sequel, without loss of generality, we consider queries where all blank nodes have been replaced by (new) distinct non-distinguished variables.

Query answering. The evaluation of q against G uses only G's explicit triples, thus may lead to an incomplete answer set. The (complete) *answer set* of q against G is obtained by the evaluation of q against $\mathtt{G}^\infty$, denoted by $q(\mathtt{G}^\infty)$.

Example 3 (**Query answering**). *The following query asks for the names of authors of books somehow connected to the literal 1996:*

$q(x_3)$:- x_1 hasAuthor x_2, x_2 hasName x_3, x_1 x_4 "1996"

Its answer against the graph in Figure 3 is $q(\mathtt{G}^\infty) = \{\langle\text{"George R. R. Martin"}\rangle\}$. *The answer results from* $\mathtt{G} \vdash_{\mathrm{RDF}}$ doi$_1$ hasAuthor _:b_1 *and the assignment* $\mu = \{x_1 \leftarrow \text{doi}_1, x_2 \leftarrow \_{:}b_1, x_3 \leftarrow \text{"George R. R. Martin"}, x_4 \leftarrow \text{publishedIn}\}$. *Observe that evaluating q directly against* G *leads to the empty answer, which is obviously incomplete.*

2.3 Query answering against RDF databases

The *database (DB)* fragment of RDF [4] is, to the best of our knowledge, the most expressive RDF fragment for which both *saturation-* and *reformulation-based RDF query answering* has been defined and practically experimented. The fragment is thus named due to the fact that query answering against any graph from this fragment, called an *RDF database*, can be easily implemented on top of any RDBMS. This DB fragment is defined by:

- *Restricting RDF entailment* to the RDF Schema constraints only (Figure 2), a.k.a. RDFS entailment. Consequently, the DB fragment focuses only on the application domain knowledge, a.k.a. ontological knowledge, and not on the RDF meta-model knowledge which mainly begets high-level typing of subject, property and object values found in triples with abstract RDF built-in classes, e.g., rdf:Resource, rdfs:Class, etc.
- *Not restricting RDF graphs in any way.* In other words, any triple allowed by the RDF specification is also allowed in the DB fragment.

Saturation-based query answering amounts to precomputing the saturation of a database db using its RDFS constraints in a forward-chaining fashion, so that the *evaluation* of every incoming query q against the saturation yields the correct answer set [4]: $q(\mathtt{db}^\infty) = q(\textbf{Saturate}(\mathtt{db}))$. This technique follows directly from the definitions in Section 2.1 and Section 2.2, and the W3C's RDF and SPARQL recommendations.

Reformulation-based query answering, in contrast, leaves the database db untouched and reformulates every incoming query q using the RDFS constraints in a backward-chaining fashion, $\textbf{Reformulate}(q, \mathtt{db}) = q^{\mathrm{ref}}$, so that the *relational evaluation* of this reformulation against the (non-saturated) database yields the correct answer set [4]: $q(\mathtt{db}^\infty) = q^{\mathrm{ref}}(\mathtt{db})$. The **Reformulate** algorithm, introduced in [23] and extended in [4], exhaustively applies a set of 13 reformulation rules. Starting from the incoming BGP query q to answer against db, the algorithm produces a *union of BGP queries* retrieving the correct answer set from the database, even if the latter is not saturated.

Triple	#answers	#reformulations	#answers after reformulation
(t_1)	18,999,082	188	33,328,108
(t_2)	0	4	3,223
(t_3)	396	3	683

Table 1: Characteristics of the sample query q_1.

Example 4 (**Query reformulation**). *The reformulation of* $q(x,y)$:- x rdf:type y *w.r.t. the database* db *(obtained from the RDF graph* G *depicted in Figure 3), asking for all resources and the classes to which they belong, is:*

(0)	$q(x,y)$:- x rdf:type y	$\cup$
(1)	$q(x,\text{Book})$:- x rdf:type Book	$\cup$
(2)	$q(x,\text{Book})$:- x writtenBy z	$\cup$
(3)	$q(x,\text{Book})$:- x hasAuthor z	$\cup$
(4)	$q(x,\text{Publication})$:- x rdf:type Publication	$\cup$
(5)	$q(x,\text{Publication})$:- x rdf:type Book	$\cup$
(6)	$q(x,\text{Publication})$:- x writtenBy z	$\cup$
(7)	$q(x,\text{Publication})$:- x hasAuthor z	$\cup$
(8)	$q(x,\text{Person})$:- x rdf:type Person	$\cup$
(9)	$q(x,\text{Person})$:- z writtenBy x	$\cup$
(10)	$q(x,\text{Person})$:- z hasAuthor x	

The terms (1), (4) *and* (8) *result from* (0) *by instantiating the variable y with classes from* db*, namely* {Book, Publication, Person}*. Item* (5) *results from* (4) *by using the subclass constraint between books and publications.* (2), (6) *and* (9) *result from their direct predecessors in the list, and are due to the domain and range constraints. Finally,* (3), (7) *and* (10) *result from their direct predecessors and the sub-property constraint present in the database.*

Evaluating this reformulation against db *returns the same answer as* $q(\mathtt{G}^\infty)$*, i.e., the answer set of q.*

3. OPTIMIZED REFORMULATION

We first introduce, by examples, the performance issues raised by the evaluation of state-of-the-art reformulated queries. We then introduce our novel reformulation search space and formalize our optimization problem.

Motivating Example 1. *Consider the three triples query q_1 shown below:*

$$\begin{array}{lll} q_1(x,y) \text{ :- } & x \text{ rdf:type } y, & (t_1) \\ & x \ \mathit{ub{:}degreeFrom} \ \text{“}\mathit{http://www.Univ532.edu}\text{”}, & (t_2) \\ & x \ \mathit{ub{:}memberOf} \ \text{“}\mathit{http://www.Dept1.Univ7.edu}\text{”} & (t_3) \end{array}$$

Table 1 gives some intuition on the difficulty of answering q_1 over an 10^8 triples LUBM [26] benchmark dataset:

The state-of-the-art CQ *to* UCQ *reformulation-based query answering needs to evaluate a reformulated query q_1', which is a union of* 2,256 *conjunctive queries, each of which consists of three triples (one for the reformulation of each triple in the original q_1). This query appears in Table 2, where all the triples t_1, t_2, t_3 are reformulated together by a* CQ *to* UCQ *reformulation algorithm denoted $(.)^{ref}$. Observe that in q_1', many sub-expressions are repeated; for instance, the join over the single triples resulting from the reformulation of triples (t_2) and (t_3) will appear for each of the* 188 *reformulations of triple (t_1). Evaluating q_1' on the* 100 *million triples LUBM dataset takes more than* ***6 seconds****, in the same experimental setting.*

	Joins of UCQs	#reformulations	exec.time (ms)
q_1'	$(t_1,t_2,t_3)^{ref}$	2,256	6,387
q_1''	$(t_1)^{ref} \bowtie (t_2)^{ref} \bowtie (t_3)^{ref}$	195	1,074,026
	$(t_1,t_2)^{ref} \bowtie (t_3)^{ref}$	755	1,968
	$(t_1)^{ref} \bowtie (t_2,t_3)^{ref}$	200	846,710
q_1'''	$(t_1,t_3)^{ref} \bowtie (t_2)^{ref}$	568	554
	$(t_1,t_2)^{ref} \bowtie (t_1,t_3)^{ref}$	1,316	2,734
	$(t_1,t_2)^{ref} \bowtie (t_2,t_3)^{ref}$	764	2,289
	$(t_1,t_3)^{ref} \bowtie (t_2,t_3)^{ref}$	576	588

Table 2: Sample reformulations of q_1.

Triple	#answers	#reformulations	#answers after reformulation
(t_1)	18,999,082	188	33,328,108
(t_2)	18,999,082	188	33,328,108
(t_3)	476	1	476
(t_4)	509	1	509
(t_5)	7,299,701	3	7,803,096
(t_6)	7,299,701	3	7,803,096

Table 3: Characteristics of the sample query q_2.

Alternatively, one could consider the equivalent query $q_1'' = (t_1)^{ref} \bowtie (t_2)^{ref} \bowtie (t_3)^{ref}$*, which joins the* CQ *to* UCQ *reformulation of each query's triple. In other terms,* q_1'' *first reformulates each triple (into, respectively, a union of* 188*,* 4*, and* 3 *queries), and then joins these unions. This query corresponds to the simple semi-conjunctive queries (*SCQ*) alternative proposed in [13]. While this avoids the repeated work, its performance is much worse: it takes about* ***1074 seconds*** *to evaluate.*

Let us now consider the following equivalent query $q_1''' = (t_1,t_3)^{ref} \bowtie (t_2)^{ref}$ *where* t_1, t_2, t_3 *are the triples of the query* q_1*. Evaluating* q_1''' *in the same experimental setting takes* ***554 ms****, more than* ***10 times faster*** *than the initial reformulation. The performance improvement of* q_1''' *over* q_1'' *is due to the intelligent grouping of the triples* t_1 *and* t_3 *together. Such grouping of triples reduce the cardinality of the respective reformulated queries. Thus,* $(t_1,t_3)^{ref}$ *has* 2,045 *answers and* 564 *reformulations. Table 2 shows the number of reformulations and execution time for all the eight possible combinations of triples.*

Motivating Example 2. *Consider now the six triples query* q_2 *shown below:*

$q_2(x,u,y,v,z)$:-
- x rdf:type u, (t_1)
- y rdf:type v, (t_2)
- x *ub:mastersDegreeFrom* "$http://www.Univ532.edu$", (t_3)
- y *ub:doctoralDegreeFrom* "$http://www.Univ532.edu$", (t_4)
- x *ub:memberOf* z (t_5)
- y *ub:memberOf* z (t_6)

Statistics on the query triples, when evaluated over a 100 *million triples LUBM dataset, appear in Table 3. The* CQ *to* UCQ *reformulation of* q_2*, on the other hand, leads to a query* q_2' *corresponding to a union of* 318,096 *six triples queries. Due to its complexity,* q_2' ***could not be evaluated*** *in the same experimental setting*[1].

[1]Concretely, a *stack depth limit exceeded error* was thrown by the DBMS. Further, other queries presented I/O exceptions thrown by the DBMS, in connection with a failed attempt to materialize an intermediary result. While it may be possible to tune some parameters to make the evaluation of such queries possible, the same error was raised by many large-reformulation queries, a signal that their peculiar shape is problematic.

Now consider the query $q_2'' = (t_1)^{ref} \bowtie (t_2)^{ref} \bowtie (t_3)^{ref} \bowtie (t_4)^{ref} \bowtie (t_5)^{ref} \bowtie (t_6)^{ref}$*, where* $t_1, \ldots, t_6$ *are the triples of* q_2*; again, this corresponds to the* SCQ *reformulation proposed in [13].* q_2'' *is equivalent to* q_2^{ref}*, and in the same experimental setting, it is evaluated in* ***229 seconds****. This is due to the large results of the (syntactically smal) subqueries* $(t_1)^{ref}, \ldots, (t_6)^{ref}$ *(especially the first two, each with* 33,328,108 *results), which required some time to join.*

Finally, consider the query $q_2''' = (t_1,t_3)^{ref} \bowtie (t_3,t_5)^{ref} \bowtie (t_2,t_4)^{ref} \bowtie (t_4,t_6)^{ref}$*, also equivalent to* q_2'*. Evaluating* q_2''' *takes* ***524 ms****, more than* ***430 times faster*** *than one-triple reformulation. As in the previous example,* q_2''' *gains over* q_2'' *by first, reducing repeated work, and second, intelligently grouping triples so that the query corresponding to each triple group can be efficiently evaluated and returns a result of manageable size. In particular, the biggest-size triples* (t_1) *and* (t_2) *had been grouped with* (t_3) *and* (t_4) *respectively, resulting in smaller intermediate results of* 2,296 *and* 2,475 *rows respectively, and improving the perfomance. Grouping triples* (t_3) *and* (t_4) *with the* (t_5) *and* (t_6) *respectively, yields analogous performance improvements.*

As the above examples illustrate, generalizing the state-of-the-art query reformulation language of UCQs [4, 6, 10, 11, 12, 14, 15, 17, 18] or of SCQs [13], to that of *joins* of UCQs, offers a great potential for improving the performance of reformulated queries. We introduce:

Definition 3.1 (JUCQ). *A* Join of Unions of Conjunctive Queries (JUCQ) *is defined as follows:*
- *any conjunctive query (*CQ*) is a* JUCQ*;*
- *any union of* CQ*s (*UCQ*) is a* JUCQ*;*
- *any join of* UCQ*s is* JUCQ.

In this work, we address the challenge of finding the best-performing JUCQ *reformulation* of a BGP query against an RDF database, among those that can be derived from a *query cover.* We define these notions as follows:

Definition 3.2 (JUCQ reformulation). *A* JUCQ reformulation $q^{\mathtt{JUCQ}}$ *of a BGP query* q *w.r.t. a database* $\mathtt{db}_1$ *is a* JUCQ *such that* $q^{\mathtt{JUCQ}}(\mathtt{db}_2) = q(\mathtt{db}_2^\infty)$*, for any RDF database* $\mathtt{db}_2$ *having the same schema as* $\mathtt{db}_1$.

Recall that two RDF databases have the same schema iff their saturations have the same RDFS statements.

BGP query covering is a technique we introduce for exploring a space of JUCQ reformulations of a given query. The idea is to *cover* a query q with (possibly overlapping) subqueries, so as to produce a JUCQ reformulation of q by joining the (state-of-the-art) CQ to UCQ reformulations of these subqueries, obtained through any reformulation algorithm in the literature (e.g., [4]). Formally:

Definition 3.3 (BGP query cover). *A* cover *of a BGP query* $q(\bar{x})$:- $t_1, \ldots, t_n$ *is a set* $C = \{f_1, \ldots, f_m\}$ *of non-empty subsets of* q*'s triples, called* fragments*, such that* $\bigcup_{i=1}^m f_i = \{t_1, \ldots, t_n\}$*, no fragment is included into another, i.e.,* $f_i \not\subseteq f_j$ *for* $1 \le i,j \le m$ *and* $i \neq j$*, and: if* C *consists of more than 1 fragment, then any fragment joins at least with another, i.e., they share a variable.*

For example, a cover of our query q_1 is $\{\{t_1,t_2\},\{t_2,t_3\}\}$.

Definition 3.4 (Cover queries of a BGP query). *Let* $q(\bar{x})$:- $t_1, \ldots, t_n$ *be a BGP query and* $C = \{f_1, \ldots, f_m\}$ *one of its covers. A* cover query $q_{|f_i, 1 \le i \le m}$ *of* q *w.r.t.* C

is the subquery whose body consists of the triples in f_i and whose head variables are the distinguished variables $\bar{x}$ of q appearing in the triples of f_i, plus *the variables appearing in a triple of f_i that are shared with some triple of another fragment $f_{j,1\leq j\leq m,j\neq i}$, i.e., on which the two fragments join.*

For example, the cover $\{\{t_1\},\{t_2,t_3\}\}$ of our query q_1 leads to the cover queries $q_{|f_1}(x,y)$:- x rdf:type y, and $q_{|f_2}(x)$:- x *ub:degreeFrom* "*http* : //*www.Univ*532.*edu*", x *ub:memberOf* "*http* : //*www.Dept*1.*Univ*7.*edu*".

Query evaluation through an RDBMS is typically much more efficient when all the atoms of the query are connected through joins (in which case, properly optimized queries oftentimes run in linear time in the size of the data), than when the query comprises a cartesian product (which leads to unavoidable quadratic or higher complexity in the size of the data). Therefore, in this work, we only consider fragments which do not feature a cartesian product.

The theorem below states that evaluating a query q as the join of the cover queries resulting from one of its covers, yields the answer set of q:

Theorem 3.1 (Cover-based reformulation). *Let $q(\bar{x})$:- $t_1,\ldots,t_n$ be a BGP query and $C=\{f_1,\ldots,f_m\}$ be any of its covers,*

$$q^{\texttt{JUCQ}}(\bar{x})\text{:- } q^{\texttt{UCQ}}_{|f_1}\bowtie\cdots\bowtie q^{\texttt{UCQ}}_{|f_m}$$

is a JUCQ *reformulation of q w.r.t. any database* db*, where every $q^{\texttt{UCQ}}_{|f_i}$ is a* UCQ *reformulation of the cover query $q_{|f_i}$, for $1\leq i\leq m$.*

An *upper bound* on the size of the cover-based reformulation space for a given query of n triples is given by the number of *minimal covers* of a set $\mathcal{S}$ of n elements [27], i.e., a set of non-empty subsets of $\mathcal{S}$ whose union is $\mathcal{S}$, and whose union of all these subsets but one is not $\mathcal{S}$. This bound grows rapidly as the number n of triples in a query's body increases, e.g., 1 for $n=1$, 49 for $n=4$, 462 for $n=5$, 6424 for $n=6$ (`http://oeis.org/A046165`). In practice, however, we require each fragment to share a variable with another (if any), so that cover queries, hence *cover-based reformulations do not feature cartesian products.* Therefore, the number of cover-based reformulations is smaller than the number of minimal covers.

In order to select the best performing cover-based reformulation within the above space, we assume given a *cost function* c which, for a JUCQ q, returns the cost $c(q(\texttt{db}))$ of evaluating it through an RDBMS storing the database db. Function c may reflect any (combination of) query evaluation costs, such as I/O, CPU etc. As customary, we rely on a *cost estimation* function c^{ϵ}, which statically provides an approximate value of c. For simplicity, in the sequel we will use c to denote the estimated cost.

The problem we study can now be stated as follows:

Definition 3.5 (Optimization problem). *Let* db *be an RDF database and q be a BGP query against it. The* optimization problem *we consider is to find a* JUCQ *reformulation $q^{\texttt{JUCQ}}$ of q w.r.t.* db*, among the cover-based reformulations of q with lowest (estimated) cost.*

Optimized queries vs. optimized plans. As stated above and illustrated in Figure 1, we seek the best *query* that is an optimized reformulation of q against db; we do not seek to optimize its *plan*, instead, we take advantage of existing query evaluation engines for optimizing and executing it. Alternatively, one could have placed this study *within an evaluation engine* and investigate *optimized plans.* We comment more the two alternatives in Section 6.

4. EFFICIENT QUERY ANSWERING

We present now the ingredients for setting up our cost-based query answering technique. We introduce, in Section 4.1, our cost model for JUCQ reformulation evaluation through an RDBMS. We then provide, in Section 4.2, an exhaustive algorithm that traverses the search space of reformulated queries, looking for a cover-based reformulation with lower cost. Finally, in Section 4.3, we introduce a greedy, anytime algorithm that outputs a best query cover of the input BGP query, found so far. This one is then used to evaluate the query as stated by Theorem 3.1.

4.1 Cost model

In this section we detail the cost of evaluating a JUCQ (reformulation) sent to an RDBMS. Such a query is a join of UCQs subqueries of the form: $q^{\texttt{JUCQ}}(\bar{x})$:- $q^{\texttt{UCQ}}_1\bowtie\cdots\bowtie q^{\texttt{UCQ}}_m$.

The evaluation cost of $q^{\texttt{JUCQ}}$ is

$$c(q^{\texttt{JUCQ}})=c_{\texttt{db}}+\sum_{q_i^{\texttt{UCQ}}\in q^{\texttt{JUCQ}}}(c_{eval}(q_i^{\texttt{UCQ}})+c_{join}(q^{\texttt{UCQ}}_{i,1\leq i\leq m})+ c_{mat}(q^{\texttt{UCQ}}_{i,1\leq i\leq m,i\neq k}))+c_{unique}(q^{\texttt{JUCQ}})\quad(1)$$

reflecting:

(*i*) the fixed overhead of connecting to the RDBMS $c_{\texttt{db}}$;
(*ii*) the cost to *evaluate* each of its UCQ sub-queries $q_i^{\texttt{UCQ}}$;
(*iii*) the cost of eliminating duplicate rows from each of its UCQ sub-query results;
(*iv*) the cost to *join* these sub-query results;
(*v*) the *materialization* costs: the SQL query corresponding to a JUCQ may have many sub-queries. At execution time, some of these subqueries will have their results materialized (i.e., stored in memory or on disk) while at most one sub-query will be executed in pipeline mode. We assume without loss of generality, that the largest-result sub-query, denoted $q_k^{\texttt{UCQ}}$, is the one pipelined (this assumption has been validated by our experiments so far); and
(*vi*) the cost of eliminating duplicate rows from the result.

In the above, duplicates are eliminated because existing reformulation algorithms (and accordingly, our work) operate under *set semantics*.

Notations. For a given query q over a database db, we denote by $|q|_t$ the estimated number of tuples in q's answer set. Recall that $q_{|\{t_i\}}$ stands for the restriction of q to its i-th triple. Using the notations above, the number of tuples in the answer set of $q_{|\{t_i\}}$ is denoted $|q_{|\{t_i\}}|_t$.

Duplicate elimination costs are estimated using well-known textbook formulas [28]; more details appear in [29].

UCQ evaluation costs are estimated by summing up the estimated costs of the CQs:

$$c_{eval}(q_i^{\texttt{UCQ}})=c_{unique}(q_i^{\texttt{UCQ}})+\sum_{q^{\texttt{CQ}}\in q_i^{\texttt{UCQ}}}c_{eval}(q^{\texttt{CQ}})$$

The cost of evaluating *one* conjunctive query $c_{eval}(q^{\texttt{CQ}})$, where $q^{\texttt{CQ}}(\bar{x})$:- $t_1,\ldots,t_n$, through the RDBMS is made of the *scan* cost for retrieving the tuples for each of its triples, and the cost of *joining* these tuples:

$$c_{eval}(q^{\texttt{CQ}})=c_{scan}(q^{\texttt{CQ}})+c_{join}(q^{\texttt{CQ}})$$

We estimate the *scan cost* of $q^{\texttt{CQ}}$ to:

$$c_{scan}(q^{\texttt{CQ}}) = c_t \times \sum_{t_i \in q^{\texttt{CQ}}} |q^{\texttt{CQ}}_{|\{t_i\}}|_t$$

where c_t is the fixed cost of retrieving one tuple.

The *join* cost of $q^{\texttt{CQ}}$ represents the respective CPU and I/O effort; assuming efficient join algorithms such as hash- or merge-based etc. are available [28], this cost is linear in the total size of its inputs:

$$c_{join}(q^{\texttt{CQ}}) = c_j \times \sum_{t_i \in q^{\texttt{CQ}}} |q^{\texttt{CQ}}_{|\{t_i\}}|_t$$

Therefore, we have:

$$c_{eval}(q_i^{\texttt{UCQ}}) = (c_t + c_j) \times \sum_{q^{\texttt{CQ}} \in q_i^{\texttt{UCQ}}} \sum_{t_i \in q^{\texttt{CQ}}} |q^{\texttt{CQ}}_{|\{t_i\}}|_t \quad (2)$$

UCQ join cost. As before, we consider the join cost to be linear in the total size of its inputs:

$$c_{join}(q^{\texttt{UCQ}}_{i,1\leq i \leq m}) = c_j \times \sum_{q_i^{\texttt{UCQ}}} \sum_{q^{\texttt{CQ}} \in q_i^{\texttt{UCQ}}} \sum_{t_i \in q^{\texttt{CQ}}} |q^{\texttt{CQ}}_{|\{t_i\}}|_t \quad (3)$$

UCQ materialization cost. Finally, we consider the materialization cost associated to a query q is $c_m \times |q|_t$ for some constant c_m:

$$c_{mat}(q^{\texttt{UCQ}}_{i,1\leq i \leq m, i\neq k}) = c_m \times \sum_{q_i^{\texttt{UCQ}}, i\neq k} \sum_{q^{\texttt{CQ}} \in q_i^{\texttt{UCQ}}} \sum_{t_i \in q^{\texttt{CQ}}} |q^{\texttt{CQ}}_{|\{t_i\}}|_t \quad (4)$$

where $q_k^{\texttt{UCQ}}$ is the largest-result sub-query, and the one which is picked for pipelining (and thus not materialized).

Injecting the equations 2, 3 and 4 into the global cost formula 1 leads to the estimated cost of a given JUCQ. This formula relies on estimated cardinalities of various subqueries of the JUCQ, as well as on the system-dependent constants $c_{\texttt{db}}$, c_{scan}, c_{join} and c_{mat}, which we determine by running a set of simple calibration queries on the RDBMS being used. The details are straightforward and we omit them here.

4.2 Exhaustive query cover algorithm (ECov)

As a yardstick for the *quality* of the query covers we find, we developed an exhaustive query cover finding algorithm, called ECov, that traverses the search space of reformulated queries and outputs a query cover leading to a cover-based reformulation with lowest cost.

Given a BGP query q and a database db, ECov enumerates all the possible query covers, estimates the cost of the corresponding cover-based reformulations, and returns a query cover with the lowest estimated cost. We use this cover as "golden standard", i.e., the best solutions based on our cost estimation function,

4.3 Greedy query cover algorithm (GCov)

We now present our optimized query cover finding algorithm (GCov). Intuitively, GCov attempts to identify query covers such that the estimated evaluation cost of each cover fragment (once reformulated), together with the estimated cost of joining the results of these reformulated fragments, is minimized. Performance benefits in this context are attained from two sources: (*i*) avoiding the explosion in the size of the reformulated queries that results when many triples, each having many reformulations, are in the same fragment, and (*ii*) avoiding reformulated fragments with very large results, since materialising and joining them is costly. The key intuition for reaching these goals is to *include highly selective, few-reformulations triples in several cover fragments.* Observe that this is different from (and orthogonal to) join ordering, which the underlying query evaluation engine (RDBMS in this study) applies independently to each reformulated subquery.

Algorithm 1: Greedy query cover algorithm (**GCov**)

```
Input  : BGP query $q(\bar{x}\text{:- } t_1, \ldots, t_n)$, database db
Output: Cover $C_{best}$ for the BGP query $q$
1  $C_0 \leftarrow \{\{t_1\}, \{t_2\}, \ldots, \{t_n\}\}$;
2  $T \leftarrow \{t_1, t_2, \ldots, t_n\}$;
3  $C_{best} \leftarrow C_0$; $moves \leftarrow \emptyset$; $analysed \leftarrow \emptyset$;
4  foreach $f \in C_0, t \in T$ s.t. $t \notin f \wedge connected(f, \{t\})$
     $\wedge\, C_0.add(f,t) \notin analysed$ do
5      $analysed \leftarrow analysed \cup C_0.add(f,t)$;
6      if $C_0.add(f,t)$ est. cost $\leq C_{best}$ est. cost then
7          $moves \leftarrow moves \cup (C_0, f, t)$;
8  while $moves \neq \emptyset$ do
9      $(C, f, t) \leftarrow moves.head()$;
10     $C' \leftarrow C.add(f,t)$;
11     if $C'$ est. cost $\leq C_{best}$ est. cost then
12         $C_{best} \leftarrow C'$;
13         foreach $f \in C', t \in T$ s.t. $t \notin f \wedge$
           $connected(f, \{t\}) \wedge C'.add(f,t) \notin analysed$ do
14             $analysed \leftarrow analysed \cup C'.add(f,t)$;
15             if $C'.add(f,t)$ estimated cost $< C_{best}$
               estimated cost then
16                 $moves \leftarrow moves \cup (C', f, t)$;
17 return $C_{best}$;
```

GCov (Algorithm 1) starts with a simple cover C_0 consisting of *one triple fragments*, and explores possible *moves* starting from this state. A *move* consists of adding to one fragment, an extra triple connected to it by at least one join variable, such that the estimated cost associated to the cover-based reformulation thus obtained is smaller than that before the addition. A move may reduce the cost in two ways: (*i*) by making a fragment more selective, and/or (*ii*) by leading to the removal of some fragments from the cover. For instance, let $\{\{t_1,t_2\},\{t_1,t_3\},\{t_3,t_4\}\}$ be a cover of a four-triples query. The move which adds t_4 to the first fragment, also renders $\{t_3,t_4\}$ redundant. Thus, the cover resulting from the move is: $\{\{t_1,t_2,t_4\},\{t_1,t_3\}\}$.

Possible moves based on the initial cover C_0 are developed and added to the list *moves*, sorted in the increasing order of the estimated cost their bring. Next (line 8), GCov starts exploring possible moves. It picks the most promising one from the sorted *moves* list and applies it, leading to a new query cover C'. If its estimated cost is smaller than the best (least) cost encountered so far, the best solution is updated to reflect this C' (line 12), and possible moves based on C' are developed and added to the sorted *moves* list.

GCov explores query covers in breadth-first and *greedy* fashion, adding to the *moves* list the possible moves starting from the current best cover, and selecting the next move with smallest cost. In practice, one could easily change the stop condition, for instance to return the best found cover as soon as its cost has diminished by a certain ratio, or after a time-out period has elapsed etc.

5. EXPERIMENTAL EVALUATION

We now present an experimental assessment of our ap-

Table 4: Characteristics of the queries used in our study.

proach. Section 5.1 describes the experimental settings. Section 5.2 studies the effectiveness and efficiency of our optimized reformulation-based query answering technique. Section 5.3 widens our comparison to saturation-based query answering, then we conclude. For space reasons, more experiment descriptions are relegated to [29].

5.1 Settings

Software. We implemented our reformulation-based query answering framework in Java 7, on top of three well-known RDBMSs, namely: PostgreSQL v9.3.2, System A (last available free edition version), and System B (last available free edition version). For each RDBMS, we instantiated the cost formulas introduced in Section 4.1 with the proper coefficients, learned by running our calibration queries on that system.

Hardware. All the RDMBSs run on 8-core Intel Xeon (E5506) 2.13 GHz machines with 16GB RAM, using Mandriva Linux release 2010.0 (Official).

Data. We conducted experiments using DBLP (8 million triples) [30] and LUBM [26] with 1 and 100 millions triples.

In our experiments, RDFS constraints are kept in memory, while RDF facts are stored in a `Triples(s, p, o)` table, indexed by all permutations of the `s, p, o` columns, leading a total of 6 indexes. Our indexing choice is inspired by [8, 9], to give the RDBMS efficient query evaluation opportunities. Further, as in [4, 8, 9, 23], for efficiency, the `Triples(s, p, o)` table's data are dictionary-encoded, using a unique integer for each distinct value (URIs and literals). The dictionary is stored as a separate table, indexed both by the code and by the encoded value.

Queries. We used 28 and 10 BGP queries for our evaluation on LUBM and DBLP data sets, respectively. The queries can be found in [29], while their main characteristics (number of union terms in their `UCQ` reformulation, denoted $|q^{ref}|$, as well as the number of results when evaluated on our data sets) are shown in Table 4.

Some queries are modified versions of LUBM benchmark queries, in order to remove redundant triples[2]. We designed the others so that (*i*) they have an intuitive meaning, (*ii*) they exhibit a variety of result cardinalities, (*iii*) they exhibit a variety of reformulations, some of which are syntactically complex, to allow a study of the performance issues involved and (*iv*) none of their triples is redundant.

[2]A query triple is redundant when it can be inferred from the others based on the RDFS constraints. For instance, when looking for x such that x is a person and x has a social security number, if we know that only people have such numbers, the triple "x is a person" is redundant.

All measured times are averaged over 3 (warm) executions. Moreover, queries whose evaluation requires *more than 2 hours* were interrupted; we point them out when commenting on the experiments' results.

5.2 Optimized reformulation

In this section, we compare our reformulation-based query answering technique with those from the literature based on `UCQ`s and `SCQ`s.

Effectiveness: is an optimizer needed? The first question we ask is whether exploring the space of `JUCQ` alternatives is actually needed, or could one just rely on a simple (fixed) query cover?

The `UCQ` reformulation used in many prior works is a particular case of the `JUCQ` reformulations we introduced in this work; it corresponds to a cover of a single fragment made of all the query triples (recall q_1' in **Motivating Example 1**, Section 3). From a database perspective, it corresponds to *pushing the joins below a single (potentially large) union.* At the other extreme, the `SCQ` reformulation proposed in [13] is a particular case of `JUCQ` reformulation obtained from a cover where each query triple is alone in a fragment (recall q_1'' in the same example). The `SCQ` reformulation can thus be thought of as *pushing all unions below a the joins.* Both the `UCQ` and `SCQ` reformulations correspond to a cover where *each triple appears in exactly one fragment*, whereas our `JUCQ`s do not have this constraint; further, the `UCQ` and `SCQ` reformulations *do not take into account quantitative information* about the data and query.

We compared the performance of query answering through: (*i*) `UCQ` reformulation; (*ii*) `SCQ` reformulation; (*iii*) the `JUCQ` recommended by the exhaustive ECov algorithm; (*iv*) the `JUCQ` recommended by our greedy GCov algorithm.

Figure 4 shows the evaluation times for LUBM queries on the 100M dataset, on the three RDBMSs we tested; observe the logarithmic time axis. Missing bars correspond to executions which timed out or were infeasible. Figure 4 shows that neither `UCQ` nor `SCQ` reformulation are reliable options. Indeed, `UCQ` *is the slowest* for many queries on System Aand Postgres, sometimes by more than an order of magnitude, and it *fails* for $Q_9, Q_{15}, Q_{18}(forLUBM100M), Q_{19}$ and Q_{28} on System A, to which we add Q_6, Q_{14} and Q_{16} on Postgres (for LUBM 100M). `SCQ` *is very inefficient* on System B, and also on Postgres for Q_1, Q_2, Q_3, Q_8 etc.; it is almost always the worst choice for System B. In contrast, the GCov-chosen `JUCQ` *always completes* and is *the fastest overall* in all but Q_{24}, Q_{25} and Q_{27} on Postgres. Figure 4 also shows that the GCov `JUCQ` performs as well as the ECov one, thus the greedy is making smart choices. In Figure 4, the GCov `JUCQ` is *up to 4 orders of magnitude faster than the* `SCQ` *reformulation* and *two orders of magnitude faster than* `UCQ` (on

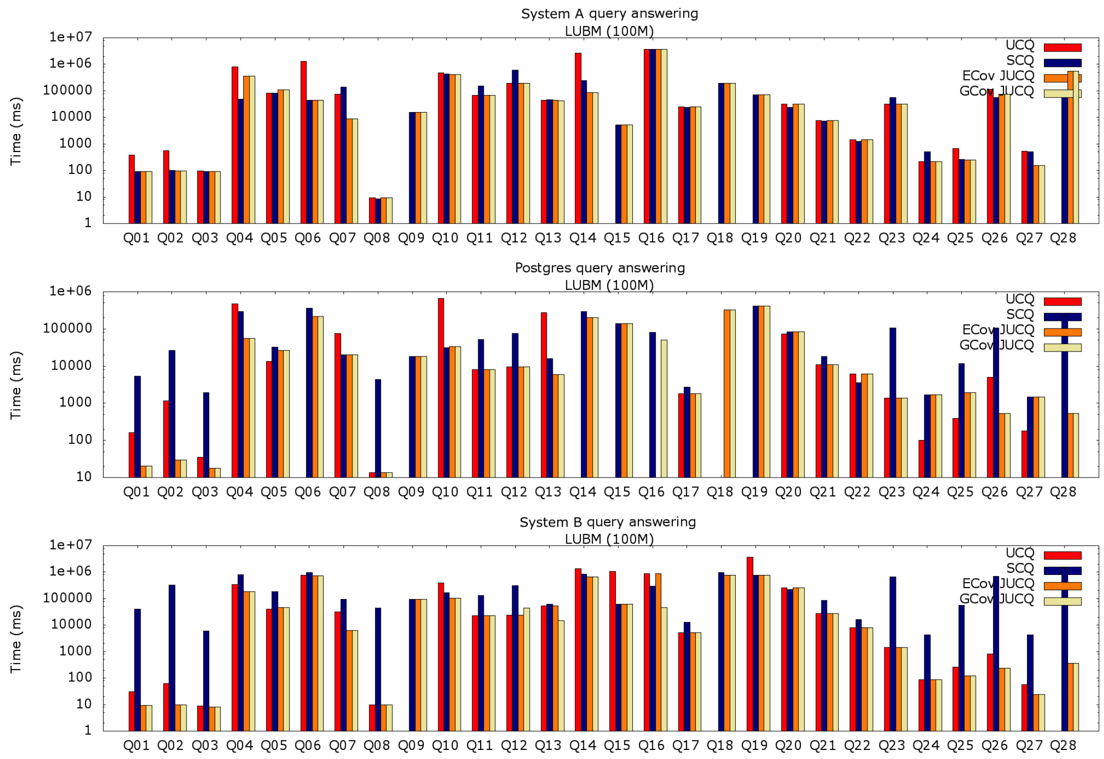

Figure 4: LUBM 100M query answering through `UCQ`, `SCQ`, ECov and GCov `JUCQ` reformulations, against System A, Postgres and System B.

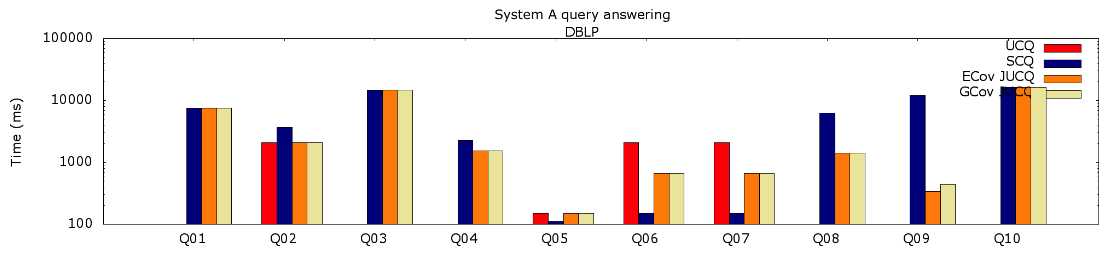

Figure 5: DBLP query answering through `UCQ`, `SCQ`, ECov and GCov `JUCQ` reformulation, against System A.

LUBM 1M, it wins by 3 orders of magnitude w.r.t. `UCQ` [29]). We end by noting that the Q_{16} cover chosen by ECov for Postgres has failed to execute due to insufficient memory in our runtime environment; we believe this could be avoided by further tuning the server execution parameters etc.

Figure 5 further highlights that no fixed reformulation technique is always the best, not even if one fixes the system and the dataset. In this figure, `SCQ` performs very well for Q_6 and Q_7, and very poorly for Q_8 and Q_9; on the latter, `UCQ` times out. In contrast, `JUCQ` performance is robust, the best in all cases but Q_6 and Q_7, and for those it is not very far from the optimum. These experiments highlight the interest of the `JUCQ` reformulation space, and the usefulness of our cost model in guiding ECov and GCov search.

GCov performance We now turn to considering *the number of covers*: overall (as explored by the exhaustive ECov), and the subset traversed by our greedy GCov; these are depicted in Figure 6 also in logarithmic scale. While the search space can be very large (e.g., for LUBM Q_2, Q_9 or Q_{12}), GCov only explores a small subset thereof. The same figure also shows *the running time* of GCov, ECov, and the time to build the `UCQ` and `SCQ` reformulations respectively (again, observe the logarithmic time axis). The time is spent to: obtain the statistics necessary for estimating the number of results of various fragments; reformulate each fragment, estimate its cost, and all other steps shown in Algorithm 1. We see that GCov's running time may be one order of magnitude less than the one of ECov; building the (cost-ignorant) `UCQ` and `SCQ` is faster, but we have seen that their evaluation may be very inefficient. Our algorithms last longest for queries with a huge `UCQ` reformulation (such as LUBM Q_{28}, recall Section 5.1) and/or on queries with *many joins between triples*, such as LUBM Q_{12}: such queries enable many possibilities to add an triple to a fragment, leading to a new cover (recall from Definition 3.3 that a fragment in a cover is not allowed to contain a cartesian product).

Alternative: using the RDBMS cost estimation The second question we study is the quality of our cost estimation, that is crucial in guiding GCov decisions. The golden standard one can compare against is the RDBMS's internal cost estimation function: this is because any cover we chose is evaluated by sending it (as a SQL statement) to the system which optimizes it according to its internal cost model. Thus, the cost function used by GCov should be as close as possible to the RDBMS one.

For this comparison, whenever we needed to estimate the

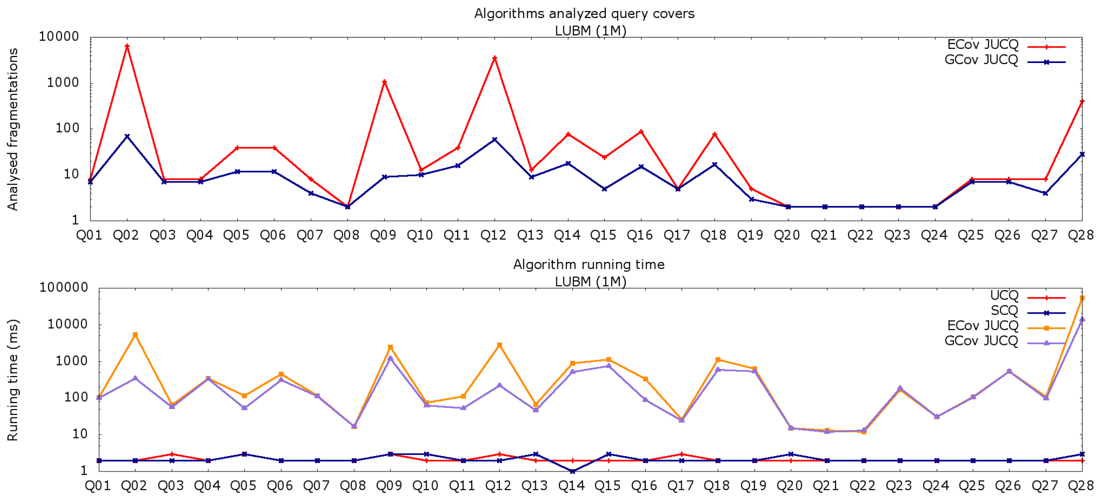

Figure 6: Number of query covers explored by the algorithms (top) and algorithm running times (bottom) for the LUBM queries.

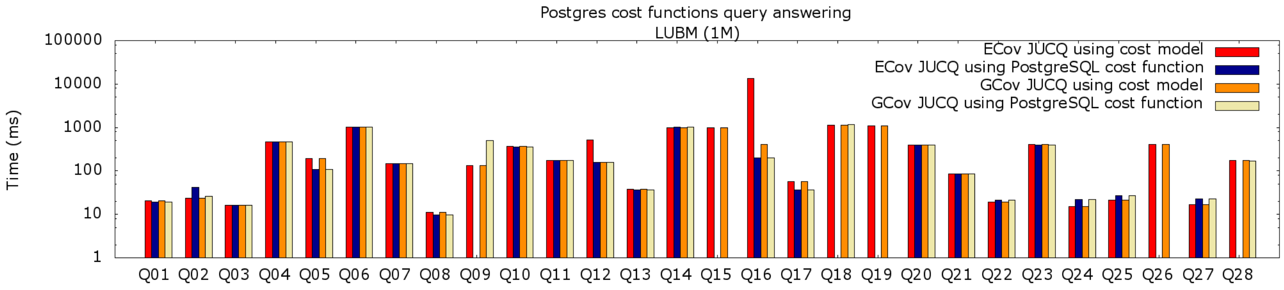

Figure 7: Cost model comparison.

cost of a cover, we sent to Postgres an `explain` statement for the corresponding cover-based reformulation, and extracted from its result Postgres' cost estimation[3]

Figure 7 shows the evaluation time of the `JUCQ` reformulations chosen by ECov and GCov, based on one hand on our cost function, and on the other hand on the Postgres one. Most of the time, the results are similar, demonstrating that our cost model is indeed close to the one of Postgres. In a few cases (LUBM Q_{12} and Q_{16}), using Postgres' cost model helped avoid bad ECov decisions; however, for the LUBM queries Q_9, Q_{15}, Q_{18}, Q_{19}, Q_{26} and Q_{28}, the ECov `JUCQ` chosen based on Postgres' cost estimation was unfeasible.

Figure 7 demonstrates that our cost model (Section 4.1) has lead our algorithm to evaluation choices very similar to the ones that Postgres made, validating its accuracy.

5.3 Comparison with saturation

As explained in the Introduction, graph saturation and query reformulation are the two main techniques for answering queries under constraints. Saturation-based query answering can be very efficient, once the data is saturated; however, if the RDF graph is updated, the cost of maintaining the saturation may be very high [4]. In contrast, query reformulation is performed directly at query time, and so it naturally adapts to the current state of the database. The performance trade-off between saturation- and reformulation-based query answering depends on the schema, on the nature of updates, and on the data statistics [4].

In this section, we show how our optimized `JUCQ` reformulation-based query answering technique impacts the performance comparison with saturation-based query answering. Figure 8 compares on the LUBM 1M dataset: (i) `UCQ` reformulation; (ii) saturation-based query answering based on Postgres; (iii) saturation-based query answering based on Virtuoso v6.1.6 (open-source, multithreaded edition); and (iv) our GCov-chosen `JUCQ`. As expected, `UCQ` reformulation performs much worse than saturation-based query answering, and worse than the GCov `JUCQ` by up to three orders of magnitude. On some queries, such as Q_{15} or $Q_{23} - Q_{28}$, saturation keeps its advantage even compared to our optimized `JUCQ` reformulation. However, on queries such as $Q_3 - Q_{14}$ and $Q_{16} - Q_{22}$, the `JUCQ` reformulation *is close to (competitive with) saturation-based query answering*, which is remarkable given that reformulation reasons at query time, and considering the performance gap observed between the two in previous works, e.g., [4].

5.4 Experiment conclusion

Our experiments lead to the following conclusions. **(1).** Confirming the intuition given by our example in Section 3, the space of `JUCQ` reformulation comprises alternative reformulations of a given BGP query w.r.t. the RDFS constraints, whose evaluation is (i) *feasible when* `UCQ` *reformulation fails*, and (ii) up to *4 orders of magnitude more efficient* than a fixed reformulation strategy, such as `UCQ` or `SCQ`. **(2).** While ECov is slow for large-reformulation queries, GCov identifies covers leading to efficient reformulations quite fast, confirming the feasibility of our optimized reformulation technique at query time. **(3).** The cost model

[3]Doing this for every examined cover slowed down our search significantly, thus we do not recommend actually running GCov *out* of a RDBMS based on the RDBMS's *internal* cost model.

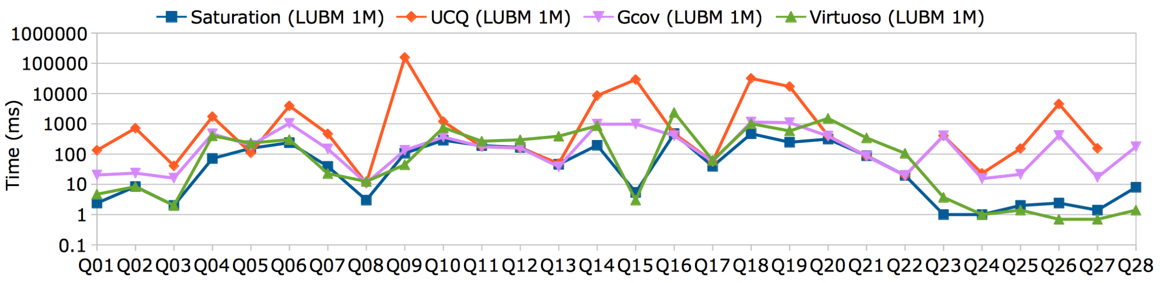

Figure 8: Query answering through Virtuoso and Postgres (via saturation, respectively, optimized reformulation).

on which our search is based performs globally well; in particular, when calibrated for Postgres, we have shown it leads to chosing covers very close to the ones obtained when relying on Postgres' internal cost model. **(4).** While saturation-based query answering has reasons to be much more efficient than reformulation techniques (*if one is willing to disregard the initial cost of saturating the database, as well as any cost related to saturation maintenance!*), our efficient reformulation technique is in many cases competitive with saturation-based query answering, *both through a relational server and through the native-RDF Virtuoso server.* This confirms the important performance improvement brought by our work to reformulation-based query answering in RDF; recall that any CQ to UCQ reformulation algorithm could be used with our cost-based GCov optimization technique.

6. RELATED WORK

The context of our work is the problem of answering conjunctive queries against RDF facts, in the presence of RDFS constraints. As mentioned in the introduction, solutions from the literature rely on RDF graph saturation, on query reformulation, or by mixing both [11]; our work focused on making query answering based on reformulation performant. Below, we position our work w.r.t. these two techniques.

Saturation-based query answering. When using graph saturation, all the implicit triples are computed and explicitly added to the database; query answering then reduces to query evaluation on the saturated database. Well-known SPARQL compliant RDF platforms such as 3store [31], Jena [32], OWLIM [33], Sesame [34], Oracle Semantic Graph [35] support saturation-based query answering, based on (a subset of) RDF entailment rules.

RDF platforms originating in the data management community, such as Hexastore [9] or RDF-3X [8], ignore entailed triples and only provide query *evaluation* on top of the RDF graph, which is assumed to be already saturated.

The drawbacks of saturation w.r.t. updates have been pointed out in [3], which proposes a *truth maintenance* technique implemented in Sesame. It relies on the storage and management of the *justifications* of entailed triples (which triples beget them). This technique incurs a high overhead of handling justifications when their number and size grow. Therefore, [36] proposes to compute only the relevant justifications w.r.t. an update, at maintenance time. This technique is implemented in OWLIM, however [33] points out that updates upon RDFS constraint deletions can lead to poor performance. More efficient saturation maintenance techniques are provided in [4, 6] based on the *number of times* triples are entailed.

Reformulation-based query answering. When using query reformulation, a given BGP query is reformulated based on the RDFS constraints into a target language, such that evaluating the reformulated query through an appropriate engine yields the query answer.

UCQ reformulation [4, 6, 10, 11, 12, 14, 15, 17, 18] applies to various fragments of RDF, ranging from the Description Logics (DL) one up to the Database one, the largest for which this technique have been considered so far. UCQ reformulation corresponds in this work to a JUCQ reformulation obtained from a single fragment query cover. SCQ reformulation [13] was defined for the DL fragment of RDF. In our setting, it corresponds to a JUCQ reformulation obtained from a query cover in which each triple is alone in a fragment. Our experiments have shown that the evaluation performance for both UCQ or SCQ reformulation can be very poor.

Among popular RDF data management systems, the only ones supporting reformulation-based query answering are Stardog, Virtuoso (which supports only the rdfs:subClassOf and rdfs:subPropertyOf RDFS rules) and AllegroGraph [37] which supports the four RDFS rules but whose reasoning implementation is incomplete[4]. Virtuoso is based on SCQ reformulation, while Stardog uses UCQ reformulation; we found no information about AllegroGraph's query reformulation language. Nested SPARQL is the target reformulation language in [19]; in contrast, we focus on translating into a commonly supported language such as JUCQs which in turn can be efficiently evaluated by an SQL engine. In [11], the schema is maintained saturated and reformulation is applied at runtime. Our approach could apply in that setting, to improve their reformulation performance.

Datalog has also been used as a target reformulation language. For instance, Presto [12, 38] reformulates queries in a DL-Lite setting into non-recursive Datalog programs. These DL-Lite formalisms are strictly more expressive from a semantic constraint viewpoint than the RDFS constraints we consider. Thus, their method could be easily transferred (restricted) to the DL fragment of RDF which, as previously mentioned, is a subset of the database fragment of RDF that we consider. However, these works did not consider cost-driven performance optimization based on data statistics and a query evaluation cost model as in our work.

From a *database optimization* perspective, the performance advantage we gain by adding selective triples next to very large ones within query covers' fragments is akin to the semi-join reducers technique, well-known from the distributed database context [39]. It has been shown e.g., in [40] that semi-join reducers can also be beneficial in a centralized context by reducing the overall join effort. In this work, we use a technique reminiscent of semi-joins in order to pick the best *query-level* formulation of a reformulated query, to make its

[4]As stated at http://franz.com/agraph/support/documentation/v4/reasoner-tutorial.html#fnr0-2014-09-16

evaluation possible and efficient; this contrasts with the traditional usage of semi-joins *at the level of algebraic plans*. On one hand, working at the plan level enables one to intelligently combine traditional joins and semi-joins to obtain the best performance. On the other hand, producing (as we do) an output at the *query (syntax)* level (recall Figure 1) enables us to take advantage of any existing system, and of its optimizer which will figure out the best way to evaluate such queries, a task at which many systems are good once the query has a "reasonable" shape and size. Further, expressing optimized reformulations as queries allows us *not* to (re-)explore the search space of join orders etc. together with the (already large) space of possible reformulated queries.

7. CONCLUSION

Our work is placed in the setting of query answering against RDF graphs in the presence of RDF Schema constraints. In particular, we focus on *improving the performance of reformulation-based RDF query answering.*

We have identified a space of alternative JUCQ reformulations, whose evaluation (based on a standard, semantics-unaware query processor) may be (*i*) feasible even when the prominent UCQ reformulation is not, and (*ii*) more efficient by up to three orders of magnitude. Further, we have presented a cost model for such JUCQ alternatives, and proposed an anytime greedy cost-based algorithm capable of identifying such efficient alternatives. Our technique may be used with any CQ-to-UCQ query reformulation algorithm (recall Figure 1) and thus we consider it a big step forward toward making reformulation-based query answering efficient. This is particularly useful in contexts when the data and/or constraints are updated, and saturation-based techniques incur high maintenance costs as illustrated e.g., in [4]; in contrast, applying at query time, reformulation-based query answering is naturally robust to updates, and (through cost-based techniques such as the one described in our work) close to saturation-based performance but without its drawbacks.

ABSTRACT

XML semantic-aware processing has become a motivating and important challenge in Web data management, data processing, and information retrieval. While XML data is semi-structured, yet it remains prone to lexical ambiguity, and thus requires dedicated semantic analysis and sense disambiguation processes to assign well-defined meaning to XML elements and attributes. This becomes crucial in an array of applications ranging over semantic-aware query rewriting, semantic document clustering and classification, schema matching, as well as blog analysis and event detection in social networks and tweets. Most existing approaches in this context: i) ignore the problem of identifying ambiguous XML nodes, ii) only partially consider their structural relations/context, iii) use syntactic information in processing XML data regardless of the semantics involved, and iv) are static in adopting fixed disambiguation constraints thus limiting user involvement. In this paper, we provide a new XML Semantic Disambiguation Framework titled *XSDF* designed to address each of the above motivations, taking as input: an XML document and a general purpose semantic network, and then producing as output a semantically augmented XML tree made of unambiguous semantic concepts. Experiments demonstrate the effectiveness of our approach in comparison with alternative methods.

Categories and Subject Descriptors

H.3.3 [**Information Storage and Retrieval**]: Information Search and Retrieval - Content Analysis and Indexing; I.7.1 [**Document and Text Processing**]: Document and Text Editing – *Document management*; I.7.2 [**Document Preparation**]: Document Preparation – *Markup languages*.

General Terms

Algorithms, Measurement, Performance, Design, Experimentation.

Keywords

XML semantic-aware processing, ambiguity degree, sphere neighborhood, XML context vector, semantic network, semantic disambiguation.

1. INTRODUCTION

In the past decade, there has been extensive research around XML data processing taking advantage of the semi-structured nature of XML documents to improve the quality of Web-based information retrieval and data management applications [28]. The majority of existing approaches use syntactic information in processing XML data, while ignoring the semantics involved [48]. Yet, various studies have highlighted the impact of integrating semantic features in XML-based applications, ranging over semantic-aware query rewriting and expansion [11, 40] (expanding keyword queries by including semantically related terms from XML documents to obtain relevant results), XML document classification and clustering [49, 53] (grouping together documents based on their semantic similarities, rather than performing syntactic-only processing), XML schema matching and integration [13, 55] (considering the semantic meanings and relations between schema elements and data-types), and more recently XML-based semantic blog analysis and event detection in social networks and tweets [2, 7]. Here, a major challenge remains unresolved: *XML semantic disambiguation*, i.e., how to resolve the semantic ambiguities and identify the meanings of terms in XML documents [23], which is central to improving the performance of XML-based applications. The problem is made harder with the volume and diversity of XML data on the Web.

Usually, heterogeneous XML data sources exhibit different ways to annotate similar (or identical) data, where the same real world entity could be described in XML using different structures and/or tagging, depending on the data source at hand (as shown in Figure 1, where two different XML documents describe the same *Hitchcock movie*). The core problem here is lexical ambiguity: a term (e.g., an XML element/attribute tag name or data value) may have multiple meanings (homonymy), it may be implied by other related terms (metonymy), and/or several terms can have the same meaning (synonymy) [23]. For instance (according to a general purpose knowledge base such as WordNet [14]) the term *"Kelly"* in XML document 1 of Figure 1 may refer to *Emmet Kelly: the circus clown*, *Grace Kelly: Princess of Monaco*, or *Gene Kelly: the dancer*. However, looking at its context in the document, a human user can tell that *"Kelly"* here refers to *Grace Kelly*. Yet while seemingly obvious for humans, such semantic ambiguities remain extremely complex to resolve with automated processes.

Figure 1. Sample documents with different structures and tagging, yet describing the same information.

In this context, *word sense disambiguation* (WSD), i.e., the computational identification of the meaning of words in *context* [39], could be central to automatically resolve the semantic ambiguities and identify the meanings of XML element/attribute

10.5441/002/edbt.2015.25

tag names and data values, in order to effectively process XML documents. While WSD has been widely studied for flat textual data [20, 39], yet, the disambiguation of structured XML data remains largely untouched. The few existing approaches to XML semantic-aware analysis (cf. Section 2) have been directly extended from traditional flat text WSD, and thus show several limitations, motivating this work:

- **Motivation 1:** Completely ignoring the problem of *semantic ambiguity*: most existing approaches perform semantic disambiguation on all XML document nodes (which is time consuming and sometimes needless) rather than only processing those nodes which are most ambiguous,
- **Motivation 2:** Only partially considering the structural relations/context of XML nodes (e.g., solely focusing on parent-node relations [52], or ancestor-descendent relations [50]). For instance, in Figure 1, processing XML node *"cast"* for disambiguation: considering (exclusively) its parent node label (i.e., *"picture"*), its root node path labels (i.e., *"films"* and *"picture"*), or its node sub-tree labels (i.e., *"star"*), remains insufficient for effective disambiguation.
- **Motivation 3:** Making use of syntactic processing techniques such as the *bag-of-words* paradigm [49, 52] (commonly used with flat text) in representing XML data as a plain set of words/nodes, thus neglecting XML structural and/or semantic features as well as compound node labels,
- **Motivation 4:** Existing methods are mostly static in adopting a fixed context size (e.g., parent node [52], or root path [50]) or using preselected semantic similarity measures (e.g., edge-based measure [29], or gloss-based measure [50]), such that user involvement/system adaptability is minimal.

The main goal of our study is to provide an effective method to XML semantic analysis and disambiguation, overcoming the limitations mentioned above. We aim to transform traditional *syntactic XML trees* into *semantic XML trees* (or graphs, when hyperlinks come to play), i.e., XML trees made of concept nodes with explicit semantic meanings. Each concept will represent a unique lexical sense, assigned to one or more XML element/attribute labels and/or data values in the XML document, following the latter's structural context. To do so, we introduce a novel XML Semantic Disambiguation Framework titled *XSDF*, a fully automated solution to semantically augment XML documents using a machine-readable semantic network (e.g., WordNet [14], Roget's thesaurus [60], FOAF [2], etc.), identifying the semantic definitions and relationships among concepts in the underlying XML structure. Different from existing approaches, *XSDF* consists of four main modules for: i) linguistic pre-processing of XML node labels and values to handle compound words (neglected in most existing solutions), ii) selecting ambiguous XML nodes as primary targets for disambiguation using a dedicated *ambiguity degree* measure (unaddressed in existing solutions), iii) representing target nodes as special *sphere neighborhood* vectors considering a comprehensive XML structure context including all XML structural relations within a (user-chosen) range (in contrast with partial context representations using the *bag-of-words* paradigm), and iv) running *sphere neighborhood* vectors through a hybrid disambiguation process, combining two approaches: *concept-based* and *context-based* disambiguation, allowing the user to tune disambiguation parameters following her needs (in contrast with static methods). We have implemented *XSDF* to test and evaluate our approach. Experimental results reflect our approach's effectiveness in comparison with existing solutions.

The remainder of this paper is organized as follows. Section 2 reviews the background and related works. Section 3 develops our XML disambiguation framework. Section 4 presents experimental results. Section 5 concludes the paper with future works.

2. BACKGROUND & RELATED WORKS

2.1 Word Sense Disambiguation

WSD underlines the process of computationally identifying the senses (meanings) of words in context, to discover the author's intended meaning [20]. The general WSD task consists of the following main elements: i) selecting words for disambiguation, ii) identifying and representing word contexts, iii) using reference knowledge sources, and iv) associating senses with words.

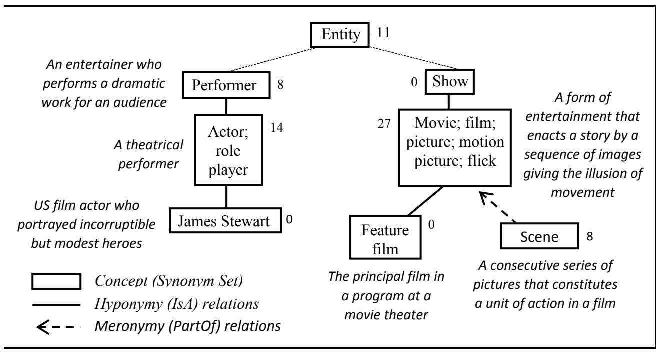
Selecting words for disambiguation: two possible methods exist: i) *all-words*, or ii) *lexical-sample*. In all-words WSD, e.g., [10, 44], the system is expected to disambiguate all words in a (flat) textual document. In lexical-sample WSD, e.g., [18, 44], specific target words are selected for disambiguation, which are usually the most ambiguous words, chosen using supervised learning methods trained to identify salient words in phrases [39].

Identifying and representing context: the *context* of a word in traditional flat textual data usually consists of the set of terms in the word's vicinity, i.e., terms occurring to the left and right of the considered word, within a certain predefined window size [26]. Thus, the traditional *bag-of-words* paradigm to represent context terms is broadly adopted with flat textual data [20, 39].

Using reference knowledge sources: distinguished as *corpus-based* or *knowledge-based*. The corpus-based approach, e.g., [3, 4, 11], considers previously disambiguated words, and requires supervised learning from sense-tagged corpora (e.g., SemCor [36]) to enable predictions for new words. Knowledge-based methods, e.g., [33, 39, 49], use machine-readable knowledge bases (i.e., ontologies, thesauri and/or taxonomies, e.g., WordNet [14], Roget's thesaurus [60], ODP [28], etc.) providing ready-made sense inventories to be exploited in WSD.

Associating senses with words: categorized as *supervised* or *unsupervised*. Supervised methods, e.g., [31, 39, 57], use machine-learning techniques with *corpus-based* training data provided to a learning algorithm that induces rules to be used for assigning meanings to words. Unsupervised methods, e.g., [29, 43, 48], are usually *knowledge-based* where reference knowledge bases (e.g., WordNet) are processed as *semantic networks* made of concepts representing word senses, and links connecting concepts, representing semantic relations (hyponymy, meronymy, etc., [14, 46], cf. Figure 2). Here, WSD consists in identifying the semantic concept (word sense) in the semantic network that best matches the semantic concepts of terms appearing in the context of the target word, using a measure of *semantic similarity* [9, 42].

Semantic similarity measures in a semantic network: can be classified as *edge-based*, *node-based*, and *gloss-based* [9]. Edge-based methods [25, 59] estimate similarity as the shortest path (in edges, weights, or number of nodes) between concepts being compared. Node-based approaches [27, 45] estimate similarity as the maximum amount of information content concepts share in common, based on the statistical distribution of concept (term) occurrences in a text corpus (e.g., the Brown corpus [15]). Gloss-based methods [5, 6] evaluate word overlap between the glosses of concepts being compared, a gloss underlining the textual definition describing a concept (e.g., the gloss of the 1st sense of word *Actor* in WordNet is *"A theatrical performer"*, cf. Figure 2).



Entity 11
An entertainer who performs a dramatic work for an audience
Performer 8
0 Show
A form of entertainment that enacts a story by a sequence of images giving the illusion of movement
A theatrical performer
Actor; role player 14
27 Movie; film; picture; motion picture; flick
US film actor who portrayed incorruptible but modest heroes
James Stewart 0
Feature film 0
Scene 8
Concept (Synonym Set)
Hyponymy (IsA) relations
Meronymy (PartOf) relations
The principal film in a program at a movie theater
A consecutive series of pictures that constitutes a unit of action in a film

Figure 2. Extract of the (weighted) WordNet semantic network. Numbers next to concepts represent concept frequencies (based on the Brown text corpus [15]). Sentences next to concepts represent concept glosses.

Note that *unsupervised/knowledge-based* WSD has been largely investigated recently (including most methods targeting XML data), in comparison with *supervised* and *corpus-based* methods, which usually require extensive training and large test corpora [39], and thus do not seem practical for the Web. The reader can refer to [20, 39] for reviews on traditional WSD.

2.2 XML Semantic Disambiguation

Few approaches have been developed for semantic disambiguation of XML and semi-structured data. The main challenges reside in the notion of XML (structural) contextualization and how it is processed, as described below.

2.2.1 XML Context Identification

While the context of a word in traditional flat textual data consists of the set of terms in the word's vicinity [26], yet there is no unified definition of the context of a node in an XML document tree. Different approaches have been investigated: i) *parent node*, ii) *root path*, iii) *sub-tree*, and iv) *versatile structural context*.

Parent node context: The authors in [51, 52] consider the *parent node* to be the context of an XML data element, and process a parent node and its children as one (canonical) entity, deemed as the simplest semantically meaningful structural entity. The authors utilize context-driven search techniques (structure pruning, identifying relatives, etc.) to determine the relations between canonical trees. These are used to assign semantic node labels using a reference ontology [47], generalizing/specializing node concepts following their labels and positions in the XML tree.

Root path context: In [49, 50], the authors extend the notion of XML node context to include the whole XML root path, i.e., the path consisting of the sequence of nodes connecting a given node with the root of the XML document (or document collection). They perform per-path sense disambiguation, comparing every node label in each path with all possible senses of node labels occurring in the same path (using gloss-based and edge-based semantic similarity measures from [6, 59] applied on WordNet) to select the appropriate sense for the node label being processed.

Sub-tree context: The authors in [56] consider the set of XML node labels contained in the sub-tree rooted at a given element node to describe the node's XML context. The authors apply a similar paradigm to identify the contexts of all possible node label senses in WordNet. Consequently, they compare the XML label context to all candidate sense contexts in WordNet, identifying the sense (concept) with the highest context similarity.

Versatile structural context: In [29], the authors combine the notions of parent context and descendent (sub-tree) context in disambiguating generic structured data (e.g., XML, web directories, and ontologies). They propose various edge-weighting measures (namely a Gaussian decay function) to identify *crossable* edges, such that nodes reachable from a target node through any *crossable* edge belong to the target node's context. Then, they compare the target node label with each candidate sense (concept) corresponding to the labels in the target node's context (using edge-based semantic similarity [24] applied on WordNet) in order to identify the highest matching concept.

2.2.2 XML Context Representation and Processing

Another concern in XML-based WSD is how to effectively process the context of an XML node (once it has been identified) considering the structural positions of XML data. Most existing WSD methods - developed for flat textual data (Section 2.1) and/or XML-based data [49-52] - adopt the *bag-of-words* model where context is processed as a set of words surrounding the term/label (node) to be disambiguated. Hence, all context nodes are treated the same, despite their structural positions in the XML tree. One approach in [29] extends the traditional *bag-or-words* paradigm with additional information considering distance weights separating the context and target nodes: identified as *relational information model* [29]. The authors employ a specially tailored Gaussian decay function estimating edge weights such as the closer a node (following a user-specified direction), the more it influences the target node's disambiguation [29].

2.2.3 Associating Senses with XML Nodes

Once the contexts of XML nodes have been determined, they can be handled in different ways. Two interesting approaches, both *unsupervised* and *knowledge-based*, have been adopted in this context, which we identify as: *concept-based* and *context-based*. On one hand, the concept-based approach adopted in [49, 50] consists in evaluating the semantic similarity between target node senses (concepts) and those of its context nodes, using measures of semantic similarity between concepts in a semantic network, selecting the target sense with maximum similarity. On the other hand, the context-based approach introduced in [56] consists in building context vectors for each target node sense (concept) in the semantic network, and building a context vector for the target node in the XML document tree, and then comparing context vectors to select the target sense with maximum vector similarity.

A hybrid approach in [29] combines variants of the two preceding approaches to disambiguate generic structured data (including XML). Yet while producing quality results, the authors do not compare their solution with XML disambiguation methods.

Wrapping up: we identify four major limitations motivating our work (which have been highlighted in Section 1): most existing methods i) completely ignore the problem of *semantic ambiguity*, ii) only partially consider the structural relations/context of XML nodes (e.g., parent-node [52] or ancestor-descendent relations [50]), ii) neglect XML structural/semantic features by using syntactic processing techniques such as the *bag-of-words* paradigm [49, 52], and iv) are static in choosing a fixed context (e.g., parent node [52], or root path [50]) or preselected semantic similarity measures, thus minimizing user involvement.

3. XML DISAMBIGUATION FRAMEWORK

In order to address all motivations above and provide a more complete and dynamic XML disambiguation approach, we introduce *XSDF* as an unsupervised and knowledge-based solution to resolve semantic ambiguities in XML documents. *XSDF*'s overall architecture is depicted in Figure 3. It is made of four modules: i) linguistic pre-processing, ii) nodes selection for disambiguation, iii) context definition and representation, and iv) XML semantic disambiguation. The system receives as input: i) an XML document tree, ii) a semantic network (noted *SN*), and iii) user parameters (to tune the disambiguation process following her needs), and produces as output a semantic XML tree.

Semantic XML Tree

Figure 3. Overall *XSDF* architecture.

We develop *XSDF*'s main modules in the following, starting with the XML and semantic data models adopted in our study.

3.1 XML and Semantic Data Models

XML documents represent hierarchically structured information and can be modeled as *rooted ordered labeled trees* (Figure 4.a and b), based on the Document Object Model (DOM) [58].

Definition 1 - Rooted Ordered Labeled Tree: It is a rooted tree in which the nodes are labeled and ordered. We denote by $T[i]$ the i^{th} node of T in preorder traversal, $T[i].\ell$ its label, $T[i].d$ its depth (in number of edges), and $T[i].f$ its out-degree (i.e., the node's fan-out). $R(T)$=[0] designates the root node of tree T[1] ●

An XML document can be represented as a *rooted ordered labeled tree* where nodes represent XML elements/attributes, labeled using element/attribute tag names. Element nodes are ordered following their order of appearance in the XML document. Attribute nodes appear as children of their containing element nodes, sorted[2] by attribute name, and appearing before all sub-elements [41, 61]. Element/attribute text values are stemmed and decomposed into tokens (using our linguistic pre-processing component), mapping each token to a leaf node labeled with the respective token, appearing as a child of its container element/attribute node, and ordered following their order of appearance in the element/attribute text value (Figure 4.a).

Note that element/attribute values can be disregarded (*structure-only*) or considered (*structure-and-content*) in the XML document tree following the application scenario at hand. Here, we believe integrating XML structure and content is beneficiary in resolving ambiguities in both element/attribute tag names (structure) and data values (content). For instance, in the document of Figure 1.a, considering data values *"Kelly"* and *"Stewart"* would be beneficial to disambiguate tag label *"cast"*. The same applies the other way: *"cast"* can help disambiguate *"Kelly"* and *"Stewart"*. Also, we provide the formal definition of a semantic network, as the semantic (knowledge base) data model adopted in our study[3].

Definition 2 – Semantic network: It is made of concepts representing groups of words/expressions designating word senses, and links connecting the concepts designating semantic relations, and can be represented as $SN=(C, L, G, E, R, f, g)$:

- C: set of nodes representing concepts in *SN* (*synsets* as in WordNet [14]),
- L: set of words describing concept labels,
- G: set of glosses describing concept definitions,
- E: set of edges connecting concept nodes, $E \subseteq C \times C$,
- R: set of semantic relations, R = {*Is-A*, *Has-A*, *Part-Of*, *Has-Part*…}, the synonymous words/expressions being integrated in the concepts themselves,
- f: function designating the labels, sets of synonyms, and glosses of concept nodes, f: $C \rightarrow L, L^n, G$ where n designates the number of synonyms per concept,
- g: function designating the labels of edges, g: $E \rightarrow R$.

Note that $c \in SN$ designates a semantic concept with $c.\ell$ its label, $c.syn$ its set of synonymous words, and $c.gloss$ its gloss. We also designate by $\overline{SN}$ a weighted semantic network: augmented with concept frequencies (cf. Figure 2) statistically quantified from a given text corpus (e.g., the Brown corpus [15]) ●

In our current study and tests, we adopt WordNet [14] as a reference semantic network, being a commonly used lexical reference for the English language. Yet, any other knowledge base can be used based on the application scenario, e.g., ODP [28] for describing semantic relations between Web pages, or FOAF [2] to identify relations between persons in social networks.

Note that after disambiguation, target nodes in the XML document tree would consist of semantic concept identifiers extracted from the reference semantic network, where non-target XML nodes remain untouched (cf. Figure 4.b).

3.2 Linguistic Pre-Processing

Linguistic pre-processing consists of three main phases: i) tokenization, ii) stop word removal, and iii) stemming, applied on each of the input XML document's element/attribute tag names and text values, to produce corresponding XML tree node labels. Here, we consider three possible inputs:

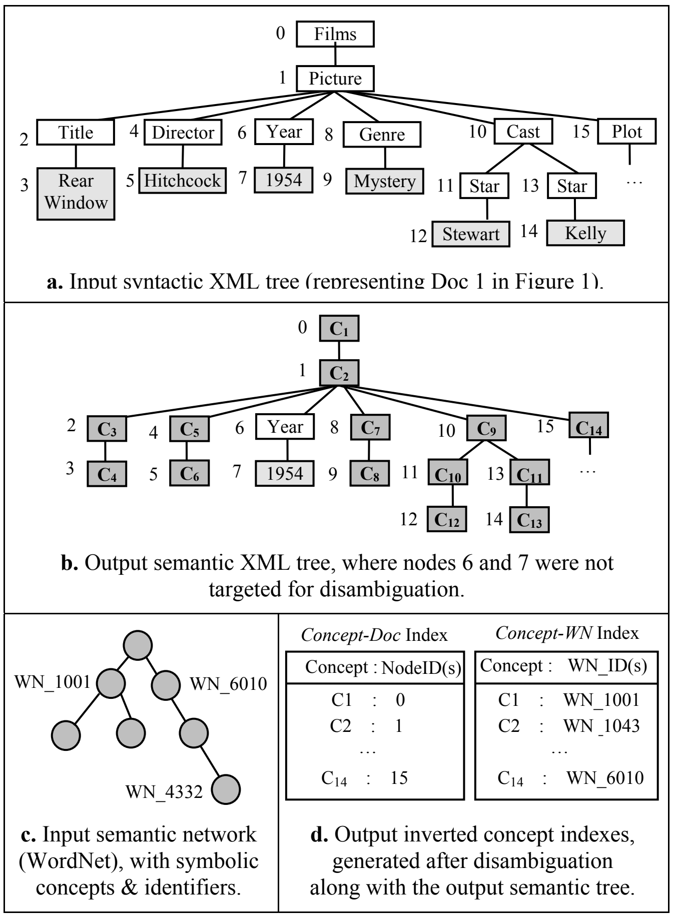
- Element/attribute tag names consisting of individual words,
- Element/attribute tag names consisting of compound words, usually made of two individual terms (t_1 and t_2)[4] separated by special delimiters (namely the underscore character, e.g., "*Directed_By*"), or the use of upper/lower case to distinguish the individual terms (e.g., "*FirstName*"),
- Element/attribute text values consisting of sequences of words separated by the space character.

[1] *Tree* and *rooted ordered labeled tree* are used interchangeably hereafter.

[2] While the order of attributes (unlike elements) is irrelevant in XML [1], yet we adopt an ordered tree model to simplify processing [44, 58].

[3] *Knowledge base* & *semantic network* are used interchangeably hereafter.

[4] More than two terms per XML tag name is unlikely in practice [59].



a. Input syntactic XML tree (representing Doc 1 in Figure 1).

b. Output semantic XML tree, where nodes 6 and 7 were not targeted for disambiguation.

c. Input semantic network (WordNet), with symbolic concepts & identifiers.

d. Output inverted concept indexes, generated after disambiguation along with the output semantic tree.

Figure 4. Sample input (syntactic) XML tree and output (semantic) XML trees.

Considering the first case, no significant pre-processing is required, except for stemming (when the word is not found in the reference semantic network). Considering the second case (i.e., compound words, usually disregarded in existing methods), if t_1 and t_2 match a single concept in the semantic network (i.e., a synset in WordNet, e.g. *first name*), they are considered as a single token. Otherwise, they are considered as two separate terms, and are processed for stop word removal and stemming. Yet, they are kept within a single XML node label (ℓ) in order to be treated together afterward, i.e., one sense will be finally associated to ℓ, which is formed by the best combination of t_1 and t_2's senses (in contrast with studies in [29, 56] which process token senses separately as distinct labels). As for the third case, we apply traditional tokenization (i.e., the text value sentence is broken up into a set of word tokens t_i), processed for stop word removal and stemming, and then represented each as an individual node (x_i) labeled with the corresponding token ($x_i.\ell = t_i$), and appearing as children of the containing element/attribute node.

3.3 Node Selection for Disambiguation

Given an input XML tree, the first step is to select target nodes to disambiguate, which (we naturally assume) are the most ambiguous nodes in the document tree. Thus we aim to provide a mathematical definition to quantify an XML node ambiguity degree which can be used to select target nodes for disambiguation (answering *Motivation 1*). To do so, we start by clarifying our assumptions about XML node ambiguity:

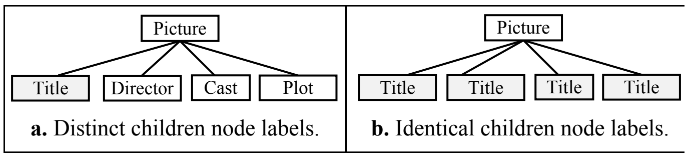
- **Assumption 1:** The semantic ambiguity of an XML node is related to the number of senses of the node's label: i) the more senses it has, the more ambiguous the node is, ii) the less senses it has, the less ambiguous the node is.
- **Assumption 2:** The semantic ambiguity of an XML node is related to its distance from the root node of the document tree: i) the closer it is to the root, the more ambiguous it is, ii) the farther it is from the root, the less ambiguous it is.

Assumption 2 follows the nature of XML and semi-structured data, where nodes closer to the root of the document tend to be more descriptive of the whole document, i.e., having a broader meaning, than information further down the XML hierarchy [8, 61]. In other words, as one descends in the XML tree hierarchy, information becomes increasingly specific, consisting of finer details [54], and thus tends to be less ambiguous.

- **Assumption 3:** The semantic ambiguity of an XML node is related to its number of children nodes having distinct labels: i) the lesser the number of distinct children labels, the more ambiguous the node is, ii) the more the number of distinct children labels, the less ambiguous the node is.

Assumption 3 is highlighted in the sample XML trees in Figure 5. One can clearly identify the meaning of root node label *"Picture"* (i.e., *"motion picture"*) in Figure 5.a., by simply looking at the node's distinct children labels. Yet the meaning of *"Picture"* remains ambiguous in the XML tree of Figure 5.b (having several children nodes but with identical labels). Hence, we believe that distinct children node labels can provide more hints about the meaning of a given XML node, making it less ambiguous.

- **Assumption 4:** An XML node which label has only one possible sense is considered to be unambiguous (i.e., semantic ambiguity is minimal), regardless of its distance from the tree root and its number of distinct children labels.



a. Distinct children node labels.

b. Identical children node labels.

Figure 5. Sample XML document trees.

While our goal is to quantify XML semantic ambiguity, yet this can be done in many alternative ways that would be consistent with the above assumptions. Hence, we first provide a set of propositions that map to the above assumptions, which we will utilize to derive our ambiguity degree measure.

Proposition 1: The ambiguity degree of an XML node x in tree T increases when the number of senses of $x.\ell$ is high in the reference semantic network *SN*, or else it decreases such that:

$$\text{Amb}_{Polysemy}(\text{x}.\ell, \text{SN}) = \frac{senses(\text{x}.\ell) - 1}{\text{Max}(senses(\text{SN})) - 1} \in [0,1] \quad \textbf{(1)}$$

where *Max*(*senses*(*SN*)) is the maximum number of senses of a word/expression in *SN* (e.g., in WordNet 2.1 [14], $Max_{polysemy}$ = 33, for the word *"head"*) □

Proposition 2: The ambiguity degree of an XML node x in tree T increases when the distance in number of edges between x and $R(T)$ is low, or else it decreases such that:

$$\text{Amb}_{Depth}(\text{x, T}) = 1 - \frac{\text{x.d}}{\text{Max}(depth(\text{T}))} \in [0,1] \quad \textbf{(2)}$$

where *Max*(*depth*(*T*)) is the maximum depth in *T* □

Proposition 3: The ambiguity degree of an XML node *x* in tree *T* increases when the number of children nodes of *x* having distinct labels, designated as $\overline{x.f}$, is low, or else it decreases:

$$\text{Amb}_{Density}(\text{x, T}) = 1 - \frac{\overline{\text{x.f}}}{\text{Max}(\overline{fan\text{-}out(\text{T})})} \in [0,1] \quad \textbf{(3)}$$

where $Max(\overline{fan\text{-}out(\text{T})})$ is the maximum number of children nodes with distinct node labels in *T*. We identify this factor as node density factor to distinguish it from traditional node fan-out: number of children nodes (regardless of label, cf. Definition 1) □

From the above propositions, we can derive a general definition for XML ambiguity degree:

Definition 3 – XML Node Ambiguity Degree: Given an XML tree *T*, a node *x* ∊ *T*, and a reference semantic network *SN*, we define the ambiguity degree of *x*, *Amb_Deg*(*x*), as the ratio between $Amb_{Polysemy}(x.\ell, SN)$ on one hand, and the sum of 1-$Amb_{Depth}(x, T)$ and 1-$Amb_{Density}(x, T)$ on the other hand:

$$\text{Amb\_Deg(x, T, SN)} = \frac{\text{w}_{\text{Polysemy}} \times \text{Amb}_{Polysemy}(\text{x}.\ell, \text{SN})}{\text{w}_{\text{Depth}} \times (1-\text{Amb}_{Depth}(\text{x, T})) + \text{w}_{\text{Density}} \times (1-\text{Amb}_{Density}(\text{x, T})) + 1} \in [0,1] \quad \textbf{(4)}$$

where $w_{Polysemy}$, w_{Depth}, $w_{Density}$ ∊ [0, 1] are independent weight parameters allowing the user to fine-tune the contributions of polysemy, depth, and density factors respectively ●

Lemma 1: The ambiguity degree measure *Amb_Deg* in Definition 3 varies in accordance with Propositions 1-3, and conforms to Assumptions 1-4 □

Proofs of Propositions 1-3 and Lemma 1 have been omitted for space limitations, and can be found in [38].

Special case: When the label of node *x* consists of a compound word made of tokens t_1 and t_2, we compute *Amb_Deg*(*x*) as the average of the ambiguity degrees of t_1 and t_2.

Amb_Deg is computed for all nodes in the input XML tree. Then, only the most ambiguous nodes are selected as targets for disambiguation following an ambiguity threshold $Thresh_{Amb}$ automatically estimated or set by the user, i.e., nodes having $Amb\_Deg(x, T, SN) \geq Thresh_{Amb}$, whereas remaining nodes are left untouched. Note that the user can disregard the ambiguity degree measure: i) by setting $w_{Polysemy} = 0$ so that all nodes end up having *Amb_Deg* = 0 regardless of constituent polysemy, depth, and density factors, or ii) by setting $Thresh_{Amb} = 0$ so that all nodes are selected for disambiguation regardless of their ambiguity degrees.

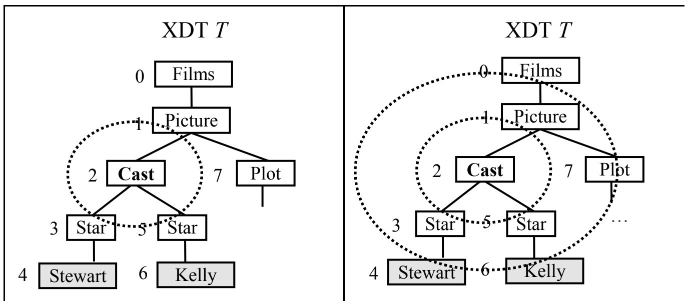
Note that the fine-tuning of parameters is an optimization problem such that parameters should be chosen to maximize disambiguation quality (through some cost function such as *f-measure*, cf. Section 4). This can be solved using a number of known techniques that apply linear programming and/or machine learning in order to identify the best weights for a given problem class, e.g., [19, 30, 37]. Providing such a capability, in addition to manual tuning, would enable the user to start from a sensible choice of values (e.g., identical weight parameters to consider all ambiguity features equally, i.e., $w_{Polysemy} = w_{\text{Depth}} = w_{\text{Fan-out}} = 1$, with a minimal threshold $Thresh_{Amb} = 0$ to consider all results initially) and then optimize and adapt the disambiguation process following the scenario and optimization (cost) function at hand. We do not further address the fine-tuning of parameters here since it is out of the scope of this paper (to be addressed in an upcoming study).

3.4 Context Definition and Representation

3.4.1 XML Sphere Neighborhood

For each target node selected from the previous phase, node contexts have to be defined and processed for disambiguation. While current approaches only partly consider the semi-structured nature of XML in defining disambiguation contexts (*Motivation 2*), we introduce the XML *sphere neighborhood* context model, inspired from the sphere-search paradigm in XML IR [17][5], taking into account the whole structural surrounding of an XML target node (including its ancestors, descendants, and siblings) in defining its disambiguation context. We define the notion of XML ring as the set of nodes situated at a specific distance from the target node. An XML sphere would encompass all rings included at distances less or equal to the size (radius) of the sphere.

Definition 4 – XML Ring: Given an XML tree *T* and a target node *x* ∊ *T*, we define an XML ring with center *x* and radius *d* as the set of nodes located at distance *d* from *x*, i.e., $R_d(x) = \{x_i \in T \mid Dist(x, x_i) = d\}$ ●



a. XML ring $R_1(T[2])$ centered around node *T*[2] of label *"cast"*.

b. XML sphere $S_2(T[2])$ centered around node *T*[2] of label *"cast"*.

Figure 6. Sample XML (ring and) sphere neighborhoods.

The distance between two XML nodes in an XML tree, $Dist(x_i, x_j)$, is typically evaluated as the number of edges separating the nodes. For instance, in tree *T* of Figure 6.a, the distance between nodes *T*[2] and *T*[6] of labels "*cast"* and *"Kelly"* respectively is equal to 2. Hence, the XML ring $R_1(T[2])$ centered around node *T*[2] (*"cast"*) at distance 1 consists of nodes: *T*[1] (*"Picture"*), *T*[3] (*"star"*) and *T*[5] (*"star"*). Note that our approach can be straightforwardly extended to consider different kinds of tree node distance functions (including edge weights, density, or direction, etc. [16, 21]). Yet, we restrict ourselves to the most intuitive notion of node distance here, and report the investigation of other distance functions to a dedicated study.

[5] While comparable with the concept of *XML sphere* exploited in [19], the latter consists of an XML retrieval paradigm for computing TF-IDF scores to rank XML query answers, which is orthogonally different, in its use and objectives, from our disambiguation proposal.

Definition 5 – XML Sphere[6]**:** Given an XML tree *T*, a target node $x \in T$, and a set of XML rings $R_{d_j}(x) \subseteq T$, we define an XML sphere with center *x* and radius *d* as the set of nodes in the rings centered around *x* at distances less or equal to *d*, i.e., $S_d(x) = \{x_i \in T \mid x_i \in R_{d_j}(x) \wedge d_j \leq d\}$ ●

In Figure 6.b, the XML sphere $S_2(T[2])$ centered around node *T*[2] of label *"cast"* with radius 2 consists of: ring $R_1(T[2])$ of radius 1 comprising nodes *T*[1] (*"picture"*), *T*[3] (*"star"*) and *T*[5] (*"star"*), and ring $R_2(T[2])$ of radius 2 comprising nodes *T*[0] (*"Films"*), T[4] (*"Stewart"*), T[6] (*"Kelly"*), and *T*[7] (*"Plot"*). The size (radius) of the XML sphere context is tuned following user preferences and/or the nature of the XML data at hand (e.g., XML trees might contain specialized and domain-specific data, and thus would only require small contexts to achieve good disambiguation, whereas more generic XML data might require larger contexts to better describe the intended meaning of node labels and values, cf. experiments in Section 4).

3.4.2 Context Vector Representation

Having identified the context of a given XML target node, we need to evaluate the impact of each of the corresponding context nodes in performing semantic disambiguation (in contrast with existing methods using the *bag-of-words* paradigm where context is processed as a set of words/nodes disregarding XML structure: *Motivation 3*). Here, we introduce a *relational information* solution based on the general vector space model in information retrieval [32] (in comparison with the specific decay function used in [29]), designed to consider the structural proximity/relations among XML nodes in computing disambiguation scores following our sphere neighborhood model. Our mathematical formulation follows two basic assumptions:

- **Assumption 5:** XML context nodes closer to the target node should better influence the latter's disambiguation, whereas those farther away from the target node should have a smaller impact on the disambiguation process.

This is based on the structured nature of XML, such as nodes closer together in the XML hierarchy are typically more related than more separated ones.

- **Assumption 6:** Nodes with identical labels, occurring multiple times in the context of a target node, should better influence the latter's disambiguation in comparison with nodes with identical labels occurring a lesser number of times.

This is based on the notion of context in WSD, where words occurring multiple times in the context of a target word have a higher impact on the target's meaning. Therefore, we represent the context of a target XML node *x* as a weighed vector, which dimensions correspond to all distinct node labels in its sphere neighborhood context, weighted following their structural distances from the target node.

Definition 6 – XML Context Vector: Given a target node $x \in$ XML tree *T*, and its sphere neighborhood $S_d(x) \in T$, the corresponding context vector $\overrightarrow{V_d(x)}$ is defined in a space which dimensions represent, each, a single node label $\ell_r \in S_d(x)$, such as $1 < r < n$ where *n* is the number of distinct node labels in $S_d(x)$. The coordinate of a context vector $\overrightarrow{V_d(x)}$ on dimension ℓ_r, $w_{\overrightarrow{V_d(x)}}(\ell_r)$, stands for the weight of label ℓ_r in sphere $S_d(x)$ ●

Definition 7 – XML Node Label Weight: The weight $w_{\overrightarrow{V_d(x)}}(\ell_r)$ of node label ℓ_r in context vector $\overrightarrow{V_d(x)}$ corresponding to the sphere neighborhood $S_d(x)$ of target node *x* and radius *d*, consists of the structural frequency of nodes $x_i \in S_d(x)$ having label $x_i.\ell = \ell_r$. It is composed of a normalized occurrence frequency factor $Freq(\ell_r, S_d(x))$ (based on Assumption 6) defined using a structural proximity factor $Struct(x_i, S_d(x))$ (based on Assumption 5). Formally, given $|S_d(x)|$ the cardinality (in number of nodes) of $S_d(x)$:

$$w_{\overrightarrow{V_d(x)}}(\ell_r) = \frac{\text{Freq}(\ell_r, \text{S}_\text{d}(\text{x}))}{\text{Max}_\text{Freq}} = \frac{2 \times \text{Freq}(\ell_r, \text{S}_\text{d}(\text{x}))}{|\text{S}_\text{d}(\text{x})| + 1} \in [0,1] \quad \textbf{(5)}$$

$Freq(\ell_r, S_d(x))$ underlines the total number of occurrences of nodes $x_i \in S_d(x)$ having label $x_i.\ell = \ell_r$, weighted w.r.t. structural proximity, formally:

$$\text{Freq}(\ell_r, \text{S}_\text{d}(\text{x})) = \sum_{\substack{x_i \in S_d(x) \,/ \\ x_i.\ell = \ell_r}} \text{Struct}(\text{x}_\text{i}, \text{S}_\text{d}(\text{x})) \quad \in \left[\frac{1}{d+1}, \frac{|\text{S}_\text{d}(\text{x})|+1}{2}\right] \quad \textbf{(6)}$$

$Struct(x_i, S_d(x))$ underlines the structural proximity between each context node $x_i \in S_d(x)$ having $x_i.\ell = \ell_r$, and the target (sphere center) node *x*, formally:

$$\text{Struct}(\text{x}_\text{i}, \text{S}_\text{d}(\text{x})) = 1 - \frac{\text{Dist}(\text{x}, \text{x}_\text{i})}{\text{d}+1} \quad \in \left[\frac{1}{\text{d}+1}, 1\right] \quad \textbf{(7)}$$

The denominator in $Struct(x_i, S_d(x))$ is incremented by 1 (i.e., *d*+1) to allow context nodes occurring in the farthest ring of the sphere context $S_d(x)$, i.e., the ring $R_d(x)$ of radius *d*, to have a non-null weight in $\overrightarrow{V_d(x)}$, and thus a non-null impact on the disambiguation of target node *x* ●

For instance, given the XML tree in Figure 6, Figure 7 shows context vectors of sphere neighborhoods $S_1(T[2])$ and $S_2(T[2])$ centered around node *T*[2] of label *"Cast"*. One can realize that label weights in Figure 7 increase as nodes occur closer to the target node (Assumption 5), and as the number of node label occurrences increases in the sphere context (Assumption 6, e.g., in $\overrightarrow{V_1(T[2])}$, $w_{\overrightarrow{V_1(\text{“}Cast\text{”})}}(\text{“}Star\text{”}) = 2\times\ w_{\overrightarrow{V_1(\text{“}Cast\text{”})}}(\text{“}Picture\text{”})$ since node label "*Star*" occurs twice in $S_1(T[2])$ while "*Picture*" occurs once; also in $\overrightarrow{V_2(T[2])}$). Formally:

Lemma 2: The context vector weight measure $w_{\overrightarrow{V_d(x)}}(\ell_r)$ in Definition 7 varies in accordance with Assumptions 5 and 6 □

The lemma's proof is omitted here, and can be found in [38], along with detailed computation examples.

In short, context nodes are weighted based on their labels' occurrences as well as the sizes (radiuses) of the sphere contexts to which they correspond, varying context node weights and thus their impact on the target node's disambiguation accordingly.

[6] The notion of *sphere* here is equivalent to that of a *disk* in 2D space. Yet, we adopt the *sphere* nomination for clearness of presentation.

	Cast	*Picture*	*Star*
$\overrightarrow{V_1}(T[2])$	0.4	0.2	0.4

	Cast	*Picture*	*Star*	*Films*	*Stewart*	*Kelly*	*Plot*
$\overrightarrow{V_2}(T[2])$	0.25	0.1667	0.3334	0.0835	0.0835	0.0835	0.0835

Figure 7. Sample sphere context vectors based on the sphere neighborhoods in Figure 6.

3.5 XML Semantic Disambiguation

Once the contexts of XML nodes have been determined, we process each target node and its context nodes for semantic disambiguation. Here, we propose to combine two strategies: the *concept-based* approach and the *context-based* approach. The former is based on semantic concept comparison between target node senses (concepts) and those of its sphere neighborhood context nodes, whereas the latter is based on context vector comparison between the target node's sphere context vector in the XML tree and context vectors corresponding to each of its senses in the reference semantic network. The user will be able to combine and fine-tune both approaches (answering *Motivation 4*).

3.5.1 Concept-based Semantic Disambiguation

It consists in comparing the target node with its context nodes, using a combination of semantic similarity measures (*edge-based*, *node-based*, and *gloss-based*, cf. Section 2.1) in order to compare corresponding semantic concepts in the reference semantic network. Then, the target node sense with the maximum similarity (relatedness) score, w.r.t. context node senses, is chosen as the proper target node sense. To do so, we propose an extension of context-based WSD techniques (cf. Section 2.2.3) where we:

- Build upon the sphere neighborhood context model, to consider XML structural proximity in evaluating the semantic meanings of context nodes (in comparison with the traditional *bag-of-words* context model),
- Allow an extensible combination of several semantic similarity measures, in order to capture semantic relatedness from different perspectives (in comparison with most existing methods which exploit pre-selected measures).

Definition 8 – Concept-based Semantic Score: Given a target node $x \in$ XML tree T and its sphere neighborhood $S_d(x) \in T$, and given s_p as one possible sense for x.ℓ in a (weighted) reference semantic network $\overline{SN}$, we define *Concept_Score*(s_p, $S_d(x)$, $\overline{SN}$) to quantify the semantic impact of s_p as the potential candidate for the intended sense (meaning) of $x.\ell$ within context $S_d(x)$ in T w.r.t. $\overline{SN}$, computed as the average of the weighted maximum similarities between s_p and context node senses:

$$\text{Concept\_Score}(s_p, S_d(x), \overline{SN}) = \sum_{x_i \in S_d(x)} \frac{\underset{s_j^i \to x_i.\ell}{\text{Max}}\left(\text{Sim}(s_p, s_j^i, \overline{SN})\right) \times w_{\overrightarrow{V_d(x)}}(x_i.\ell)}{|S_d(x)|} \in [0,1] \quad \textbf{(8)}$$

where s_j^i designates the *j*th sense of context node $x_i.\ell \in S_d(x)$, and $Sim(s_p, s_j^i, \overline{SN})$ designates the semantic similarity measure between senses s_p and s_j^i w.r.t. $\overline{SN}$ ●

Definition 9 – Semantic Similarity Measure: It quantifies the semantic similarity (relatedness) between two concepts (i.e., word senses) c_1 and c_2 in a reference (weighted) semantic network $\overline{SN}$[7], computed as the weighted sum of several semantic similarity measures[8]. Formally:

$$\begin{aligned}\text{Sim}(c_1, c_2, \overline{SN}) = {} & w_{Edge} \times \text{Sim}_{Edge}(c_1, c_2, SN) + \\ & w_{Node} \times \text{Sim}_{Node}(c_1, c_2, \overline{SN})) + \\ & w_{Gloss} \times \text{Sim}_{Gloss}(c_1, c_2, SN)) \in [0, 1]\end{aligned} \quad \textbf{(9)}$$

where:

- $w_{Edge} + w_{Node} + w_{Gloss} = 1$ and $(w_{Edge}, w_{Node}, w_{Gloss}) \geq 0$
- Sim_{Edge} is a typical edge-based measure from [59],
- Sim_{Node} is a typical node-based measure from [27],
- Sim_{Gloss} is a normalized extension of a typical gloss-based measure from [6] ●

Special case: If the target node label $x.\ell$ is a compound word consisting of two tokens t_1 and t_2 for which no single match was found in the reference semantic network $\overline{SN}$ (cf. Section 3.2), an average score for each possible combination of senses (s_p, s_q) corresponding to each of the individual token senses (s_p for token t_1, and s_q for t_2) is computed to identify the sense combination which is most suitable for the compound target node label:

$$\text{Concept\_Score}((s_p, s_q), S_d(x), \overline{SN}) = \sum_{x_i \in S_d(x)} \frac{\underset{s_j^i \to x_i.\ell}{\text{Max}}\left(\text{Sim}((s_p, s_p), s_j^i, \overline{SN})\right) \times w_{\overrightarrow{V_d(x)}}(x_i.\ell)}{|S_d(x)|} \in [0,1] \quad \textbf{(10)}$$

where

$$\text{Sim}((s_p, s_p), s_j^i, \overline{SN}) = \frac{\text{Sim}(s_p, s_j^i, \overline{SN}) + \text{Sim}(s_q, s_j^i, \overline{SN})}{2} \in [0,1]$$

Note that a compound context node label $x_i.\ell$ which tokens t_1^i and t_2^i do not match any single concept in $\overline{SN}$, is processed similarly to a compound target node label.

3.5.2 Context-based Semantic Disambiguation

It consists in comparing the target node sphere neighborhood in the XML tree with each of its possible sense (concept) sphere neighborhoods in the reference semantic network. To do so, we adopt the same notions of sphere neighborhood and context vector (Definitions 4-7) defined for XML nodes in an XML tree, to build the sphere neighborhood and context vector of a semantic concept in the semantic network. The only difference here is that sphere rings in the semantic network are built using the different kinds of semantic relations connecting semantic concepts (e.g., hypernyms, hyponyms, meronyms, holonyms, cf. Definition 2), in contrast with sphere rings in an XML tree which are built using XML structural containment relations (Definition 1). Here, given

7 $\overline{SN}$ designates a semantic network *SN* weighted with corpus statistics needed to compute a *node*-based similarity measure [29, 48]. Yet, the original non-weighted semantic network *SN* is sufficient to compute typical *edge*-based and *gloss*-based measures (cf. Section 2.1).

8 Here, we use three typical semantic similarity measures, yet any other semantic similarity measure can be used, or combined with the latter.

a reference semantic network *SN*, a semantic concept $c \in SN$, and a radius d, we designate by $R_d(c)$, $S_d(c)$, and $\overrightarrow{V_d(c)}$ the ring, sphere, and context vector of radius d corresponding to concept c in *SN* respectively. Note that linguistic pre-processing (cf. Section 3.2) can be applied to concept labels (when needed[9]) before building context vectors and computing vector weights. Formally:

Definition 10 – Context-based Semantic Score: Given a target node $x \in$ XML tree T, its sphere neighborhood $S_d(x) \in T$ and context vector $\overrightarrow{V_d(x)}$, and given s_p as one possible sense for $x.\ell$ in a reference semantic network *SN*, with its sphere neighborhood $S_d(s_p) \in SN$ and context vector $\overrightarrow{V_d(s_p)}$, we define *Context_Score*(s_p, $S_d(x)$, *SN*) to quantify the semantic impact of s_p as the potential candidate designating the intended sense (meaning) of $x.\ell$ within context $S_d(x)$ in T w.r.t. *SN*, computed using a vector similarity measure between $\overrightarrow{V_d(x)}$ and $\overrightarrow{V_d(s_p)}$:

$$\text{Context\_Score}(s_p, S_d(x), SN) = \cos(\overrightarrow{V_d(x)}, \overrightarrow{V_d(s_p)}) \in [0, 1] \quad \textbf{(11)}$$

where *cos* designates the *cosine* vector similarity measure[10] ●

<u>Special case</u>: If the target node label $x.\ell$ is a compound word consisting of tokens t_1 and t_2 for which no single match was found in the reference semantic network *SN*, an integrated score for each possible combination of senses (s_p, s_q) corresponding to each of the individual token senses (s_p for token t_1, and s_q for token t_2) is computed. Here, the sphere neighborhoods and context vectors of individual senses s_p and s_q are combined together to represent the context sphere of the combination of senses (s_p, s_q) in *SN*:

$$\text{Concept\_Score}((s_p, s_q), S_d(x), SN) = \cos(\overrightarrow{V_d(x)}, \overrightarrow{V_d(s_p, s_q)}) \in [0,1] \quad \textbf{(12)}$$

where $\overrightarrow{V_d(s_p, s_q)}$ is a compound context vector generated based on compound sphere neighborhood $S_d(s_p, s_q) = S_d(s_p) \bigcup S_d(s_q)$.

3.5.3 Combined Semantic Disambiguation

While *concept-based* and *context-based* disambiguation can be applied separately as described in the above sections, yet we allow the user to combine and fine-tune both approaches (answering *Motivation 4*), producing a combined score as the weighted sum of concept-based and context-based scores:

$$\begin{aligned} &\text{Concept\_Score}(s_p, S_d(x), \overline{SN}) = \\ &w_{Concept} \times \text{Concept\_Score}(s_p, S_d(x), \overline{SN}) + \\ &w_{Context} \times \text{Context\_Score}(s_p, S_d(x), SN) \quad \in [0, 1] \end{aligned} \quad \textbf{(13)}$$

where $w_{Concept} + w_{Context} = 1$ and $(w_{Concept}, w_{Context}) \geq 0$

Note that disambiguation algorithms have been omitted for space limitations. Overall complexity simplifies to the sum of the complexities of *concept-based* and *context-based* disambiguation processes, i.e., $O(|senses(x.\ell)| \times |S_d(x)| \times |senses(x_i.\ell)|)$, and $O(|senses(x.\ell)| \times (|S_d(x)| + |S_d(s_p)|)$ respectively (cf. details in [38]).

[9] This depends on the semantic network (not required with WorldNet).

4. EXPERIMENTAL EVALUATION

We have developed a prototype titled *XSDF*[11] to test and compare our approach with its most recent alternatives. We have evaluated two criteria: i) *semantic ambiguity* and ii) *disambiguation quality*.

4.1 Experimental Test Data

We used a collection of 80 test documents gathered from several data sources having different properties (cf. Table 3), which we describe and organize based on two features: i) *node ambiguity*, and ii) *node structure* (cf. Table 1). The former feature highlights the average amount of ambiguity of XML nodes in the XML tree, estimated using our *ambiguity degree* measure, $Amb\_Deg \in [0, 1]$. The latter feature describes the average amount of structural richness of XML nodes, in terms of node *depth*, *fan-out*, and *density* in the XML tree, estimated as the sum of normalized node depth (1-Amb_{Depth}), fan-out, and density (1-$Amb_{Density}$) factors, averaged over all nodes in the XML tree, formally:

$$\text{Struct\_Deg}(x, T) = \frac{w_{Depth} \times x.d}{\text{Max}(\mathit{depth}(T))} + \frac{w_{Fan\text{-}out} \times x.f}{\text{Max}(\mathit{fan\text{-}out}(T))} + \frac{w_{Density} \times \overline{x.f}}{\text{Max}(\overline{\mathit{fan\text{-}out}(T)})} \in [0,1] \quad \textbf{(14)}$$

where $w_{Depth} + w_{Fan\text{-}out} + w_{Density} = 1$ and $(w_{Depth}, w_{Fan\text{-}out}, w_{Density}) \geq 0$. In other words, high node depth, fan-out, and/or density here indicate a highly structured XML tree, whereas low node depth, fan-out, and/or density indicate a poorly structured (relatively flat) tree. In our experiments, we set equal weights $w_{Depth} = w_{Fan\text{-}out} = w_{Density} = 1/3$ when measuring *Struct_Deg* (cf. Table 1). In this study, we do not address the issue of assigning weights, which could be performed using optimization techniques (e.g., linear programming and/or machine learning [19, 30, 37]) to help fine-tune input parameters and obtain optimal results (cf. Section 3.3). Such a study would require a thorough analysis of the relative effect of each parameter on disambiguation quality, which we report to a dedicated subsequent study.

Table 1. XML test documents organized based on average node *ambiguity* and *structure*.

	Structure +	Structure –
Ambiguity +	**Group 1** *Amb_Deg* = 0.1127 & *Struct_Deg* = 0.6803	**Group 2** *Amb_Deg* = 0.1378 & *Struct_Deg* = 0.6621
Ambiguity –	**Group 3** *Amb_Deg* = 0.0625 & *Struct_Deg* = 0.612	**Group 4** *Amb_Deg* = 0.0447 & *Struct_Deg* = 0.5515

4.2 XML Ambiguity Degree Correlation

We compare XML node ambiguity ratings produced by human users with those produced by our system (i.e., via our *ambiguity degree* measure, *Amb_Deg*, cf. Section 3.3), using *Pearson's correlation coefficient*, $pcc = \delta_{XY}/(\sigma_X+\sigma_Y)$ where: x and y designate user and system generated ambiguity degree ratings respectively, σ_X and σ_Y denote the standard deviations of x and y respectively, and δ_{XY} denotes the covariance between the x and y variables. The values of $pcc \in [-1, 1]$ such that: -1 designates that one of the variables is a decreasing function of the other variable (i.e., values deemed ambiguous by human users are deemed unambiguous by the system, and visa-versa), 1 designates that one of the variables is an increasing function of the other variable

[10] We adopt *cosine* since it is widely used in IR [35]. Yet, other vector similarity measures can be used, e.g., Jaccard, Pearson corr. coeff., etc.

[11] Available online at http://sigappfr.acm.org/Projects/XSDF/

(i.e., values are deemed ambiguous/unambiguous by human users and the system alike), and 0 means that the variables are not correlated. Five test subjects (two master students and three doctoral students, who were not part of the system development team) were involved in the experiment. Manual ambiguity ratings (integers ∈ [0, 4], i.e., ∈ [*min*, *max*] ambiguity) where acquired for 12-to-13 randomly pre-selected nodes per document, i.e., a total of 1000 nodes (during an average 10 hours rating time per tester) and then correlated with system ratings, computed with variations of *Amb_Deg*'s parameters to stress the impact of its factors ($Amb_{Polysemy}$, Amb_{Depth}, and $Amb_{Density}$): i) Test #1 considers all three factors equally ($w_{Polysemy} = w_{Depth} = w_{Density} = 1$), ii) Test #2 focuses on the polysemy factor ($w_{Polysemy} = 1$ while $w_{Depth} = w_{Density} = 0$), iii) Test #3 focuses on the depth factor ($w_{Depth} = 1$ while $w_{Polysemy} = 0.2$ and $w_{Density} = 0$), iv) Test #4 focuses on the density factor ($w_{Density} = 1$, $w_{Polysemy} = 0.2$ and $w_{Depth} = 0$).

Results compiled in Table 2 highlight several observations. First, XML ambiguity seems to be perceived and evaluated similarly by human users and our system – obtaining maximum positive correlation between human and *Amb_Deg* scores – when highly ambiguous and highly structured XML nodes are involved (e.g., Group 1). Second, ambiguity seems to be evaluated differently by users and our system when less ambiguous and/or poorly structured XML nodes are involved, attaining: negative or close to null correlation when low ambiguity and/or poorly structured XML nodes are evaluated (e.g., Groups 2, 3, and 4). This might be due to the intuitive understanding of semantic meaning by humans, in comparison with the intricate processing done by our automated system. For instance, in the case of documents of Dataset 9 of Group 4 (conforming to the *personnel.dtd* grammar of the Niagara XML document collection, cf. [38]), the meaning of child node label "*state*" under node label "*address*" was obvious for our human testers (providing an ambiguity score of 0/4). Yet, the interpretation of the meaning of "*state*" is not so obvious for a machine, especially using a rich lexical dictionary such as WordNet where word "*state*" has 8 different meanings. Here, a label considered relatively unambiguous form the user's point of view was assigned a higher ambiguity score by the system based on the expressiveness of the lexical reference.

Concerning *Amb_Deg*'s parameter weight variations (for $w_{Polysemy}$, w_{Depth}, and $w_{Density}$) with tests 2, 3, and 4, all three parameters seem to have comparable impacts on ambiguity evaluation. Note that evaluating XML node ambiguity is not addressed in existing approaches (they do not select target nodes, but simply disambiguate all of them, which can be complex and needless).

4.3 XML Semantic Disambiguation Quality

In addition to evaluating our XML ambiguity degree measure, we ran a series of experiments to evaluate the effectiveness of our XML disambiguation approach. We used the same test datasets described previously. Target XML nodes were first subject to manual disambiguation (12-to-13 nodes were randomly pre-selected per document yielding a total of 1000 target nodes, allowing the same human testers to manually annotate each node by choosing appropriate senses from WordNet, which required an average 22 hours per tester) followed by automatic disambiguation. We then compared user and system generated senses to compute *precision*, *recall* and *f-value* scores.

4.3.1 Testing with Different Configurations

We first tested the effectiveness of our approach considering its different features and possible configurations, considering: i) the properties of XML data (w.r.t. ambiguity and structure), ii) context size (sphere neighborhood radius), and iii) the disambiguation process used (concept-based, context-based, and the combined approach). We only show *f-value* levels in Figure 8 for space limitation (*precision* and *recall* levels follow similar patterns). Several interesting observations can be made here.

Table 2. Correlation between human ratings and system generated ambiguity degrees (cf. graphs in [38]).

		Test #1 *All factors*	**Test #2** *Polysemy*	**Test #3** *Depth*	**Test #4** *Density*
Group 1	Doc 1	0.394	0.411	0.335	**0.439**
Group 2	Doc 2	**0.017**	0.181	0.243	0.139
Group 3	Doc 3	-0.087	-0.139	-0.071	-0.138
	Doc 4	0.408	0.438	0.390	0.398
	Doc 5	-0.184	-0.185	-0.131	-0.235
Group 4	Doc 6	-0.284	-0.291	-0.243	-0.316
	Doc 7	-0.177	-0.190	-0.254	-0.143
	Doc 8	-0.119	-0.025	0.033	-0.156
	Doc 9	-0.452	-0.301	-0.251	**-0.456**
	Doc 10	-0.258	0.180	0.412	0.276

1) Considering ***XML data properties***, one can realize that our approach produced consistent *f-value* levels ∈ [0.55, 0.69] over all the tested configurations. The highest levels were reached with Dataset 1 of Goup1 having *high ambiguity* and *rich structure*, which resonates with the node ambiguity results discussed in the previous section (highly ambiguous and structurally rich XML nodes seem to be most effectively processed by our approach).

2) Considering ***context size***, optimal *f-value* levels are obtained with the smallest sphere neighborhood radius *d*=1 with Group 1 (*high ambiguity* and *rich structure* XML nodes), whereas optimal levels are obtained with larger contexts having *d*=3 with Groups 2, 3, and 4 (*low ambiguity* and/or *poor structure*). This is expected since increasing context size with highly ambiguous/structure rich XML would increase the chances of including noise (e.g., unrelated/heterogeneous XML nodes) in the disambiguation context and thus disrupt the process. Yet, increasing context size with less ambiguous/poorly structured XML could actually help in creating a large-enough and/or rich-enough context to perform effective disambiguation.

3) Considering the ***disambiguation process***, one can realize that the *concept-based* approach[12] generally produces higher *f-value* levels in comparison with the *context-based* approach, the latter appearing to be more sensitive to context size. This is expected since the context-based approach primarily depends on the notion of context and context nodes, in both the XML document and semantic network, and thus increasing/decreasing context size would disturb its effectiveness. The effect of context size here could be aggravated when using a rich semantic network (such as WordNet) where a small increase in sphere neighborhood radius could include a huge number of concepts (synsets) in the semantic network context vector, thus adding considerable noise.

To sum up, the above results emphasize the usefulness and need for a flexible approach (such as ours), allowing the user to fine-tune the disambiguation process in order to optimize disambiguation following the nature and properties of the data.

[12] When applying the concept-based approach, semantic similarity measures were considered with identical parameter weights ($w_{Edge} = w_{Node} = w_{Gloss} = 1/3 = 0.3334$), since evaluating the effectiveness of different semantic similarity measures is out of the scope of this paper.

Table 3. Characteristics of test documents.

Groups	Datasets	Source dataset	Grammar	N# of docs	Avg. N# of nodes per doc	Node label polysemy (N# of senses)		Node Depth		Node Fan-out		Node Density

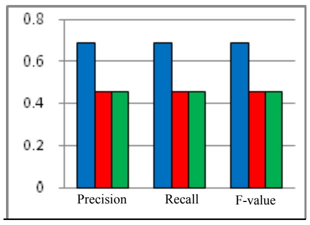
▢ d = 1 🟦 d = 3 ■ d = 5 (or d=4 if *Max*(Depth(T)) = 4)

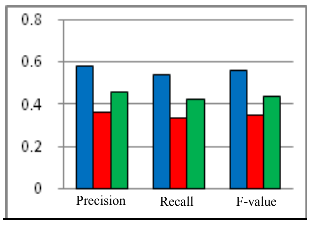
Figure 8. **Average *f-value* scores considering different features and configurations of our approach.**

4.3.2 *Comparative Study*

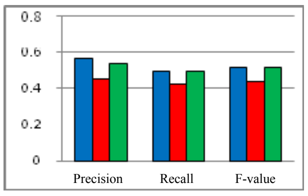
In addition, we evaluated the effectiveness of our approach in comparison with two of its most recent alternatives: *RPD* (Root Path Disambiguation) [50], and *VSD* (Versatile Structure Disambiguation) [29]. A qualitative comparison is shown in Table 4. We ran a battery of tests considering the different features and configurations or our approach. Here, we provide a compiled presentation considering optimal input parameters for our approach[19] (i.e., context size *d*=1 when processing Group 1, *d*=3 when processing Groups 2, 3, 4, using the *concept-based* disambiguation process with all groups) and its alternatives (as indicated in corresponding studies). Results in Figure 9 show that our method yields *precision, recall,* and *f-value* levels higher than those achieved by its predecessors, with almost all test groups except with Group 4 where *RPD* produces better results. In fact, XML nodes in Group 4 are less ambiguous and poorly structured in comparison with remaining test groups. Hence, choosing a simple context made of root path nodes has proven to be less noisy in this case, in comparison with the more comprehensive context models used with our approach and with VSD.



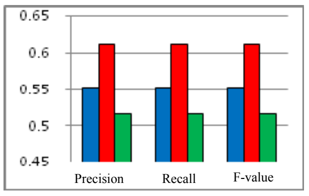
a. Results with Group 1.



b. Results with docs of Group 2.



c. Results with Group 3.



d. Results with Group 4.

🟦 XSDF (our approach) 🟥 RPD 🟩 VSD

Figure 9. **Average *PR*, *R* and *F-value* scores comparing our approach with RPD [50] and VSD [29].**

One can also realize that our method produces highest *precision*, *recall*, and *f-value* levels with Group 1 (*high ambiguity* and *rich structure* XML nodes), with an average 35% improvement over *RDP* and *VSD* (Figure 9.a), in comparison with average 25%, 5%, and almost 0% improvements with Groups 2, 3, & 4 respectively. This concurs with our results of the previous section: our method is more effective when dealing with highly ambiguous nodes within a rich XML structure, in comparison with less ambiguous/poorly structured XML.

5. CONCLUSION

This paper introduces a novel XML Semantic Disambiguation Framework titled *XSDF*, to semantically annotate XML documents with the help of machine-readable lexical knowledge base (e.g., WordNet), which is a central pre-requisite to various applications ranging over semantic-aware query rewriting [11, 40], XML document classification and clustering [49, 53], XML schema matching [13, 55], and blog analysis and event detection in social networks [2, 7]. *XSDF* covers the whole disambiguation pipeline from: i) linguistic pre-processing of XML node labels to handle compound words (neglected in most existing solutions), to ii) selecting ambiguous nodes for disambiguation using a dedicated *ambiguity degree* measure (unaddressed in most solutions), iii) representing target node contexts as comprehensive and flexible (user chosen) *sphere neighborhood* vectors (in contrast with partial and fixed context representations, e.g., parent node or sub-tree context), and iv) running a hybrid disambiguation process, combining two (user chosen) methods: *concept-based* and *context-based* (in contrast with static methods). Experimental results w.r.t. user judgments reflect our approach's effectiveness in selecting ambiguous XML nodes and identifying node label senses, in comparison with existing solutions.

We are currently investigating different XML tree node distance functions (including edge weights, density, direction, etc. [16, 21]), to define more sophisticated neighborhood contexts. Fine-tuning user parameters using dedicated optimization techniques [19, 30] is another work in progress. We are also investigating the use of additional/alternative lexical knowledge sources such as Google [22], Wikipedia [12], and FOAF [2] to acquire a wider word sense coverage, and thus explore our approach in practical applications, namely semantic blog and wiki document clustering.

ABSTRACT

In the age of statistical and scientific databases, there is an emerging trend of integrating analytical algorithms into database systems. Many of these algorithms are based on linear algebra with large, sparse matrices. However, linear algebra expressions often contain multiplications of more then two matrices. The execution of sparse matrix chains is nontrivial, since the runtime depends on the parenthesization and on physical properties of intermediate results. Our approach targets to overcome the burden for data scientists of selecting appropriate algorithms, matrix storage representations, and execution paths. In this paper, we present a sparse matrix chain optimizer (SpMachO) that creates an execution plan, which is composed of multiplication operators and transformations between sparse and dense matrix storage representations. We introduce a comprehensive cost model for sparse-, dense- and hybrid multiplication kernels. Moreover, we propose a sparse matrix product density estimator (SpProdest) for intermediate result matrices. We evaluated SpMachO and SpProdest using real-world matrices and random matrix chains.

G.1.3 [**Numerical Linear Algebra**]: Sparse, structured, and very large systems

General Terms

sparse linear algebra, optimization

1. INTRODUCTION

In the era of big data and data deluge, scientists and data analysists are confronted with a time-consuming implementation overhead, when they want to scale and speed up their existing, handcrafted code that has been working for years on small data sets. This set the way for new database applications in the fields of scientific computations and advanced analytics on large data. However, since most of the algorithms in science and data mining are composed of linear algebra expressions, conventional SQL-based relational database management systems (RDBMS's) did not match the requirements. On the other hand, numerical algebra systems like R are known for efficient linear algebra algorithms, but they lack scalability and data manipulation capabilities. As a consequence, the demand of data scientists for a scalable system that provides a basic set of efficient linear algebra primitives attracted the attention of the database community [11]. Recently emerged systems like SciDB [8] or SystemML [6] reacted by providing a R or R-like interface and deep integrations of linear algebra primitives, such as sparse matrix-matrix and matrix-vector multiplications.

In business environments, data analysts often load data from a relational database into a numerical algebra system to perform their analysis by means of linear algebra. For example, financial analysts that use a RDBMS for storing stock price data need the functionality of SQL, e.g., in order to get the average stock prizes, or to find all stocks that belong to a certain group. On the other side, they might want to use matrix multiplications to find correlations [24] of stocks and derivatives.

Matrices as first-class citizens have been integrated in many systems, for example in array DBMS's [8], data warehouses [19], or in-memory column stores [20], but only little has been done in the direction of optimizing the execution of linear algebra expressions. In this paper, we focus on optimizing the execution of sparse linear algebra expressions based on physical properties. The idea is the following: next to the RDBMS optimizer that creates optimized execution plans from SQL expressions, we propose a component (Fig. 1) that generates an optimal execution plan for linear algebra, which is using the native storage and execution engine of the system, and additional operators for linear algebra, such as a matrix multiplication operator.

As most of the big matrices occurring in the real world are *sparse*, linear algebra expressions often contain multiplications of three or more sparse, or mixed dense and sparse matrices, e.g. in transitive closure computations, Markov chains [27], linear transformation [13], or linear discrete dynamical systems [4]. An efficient execution of sparse matrix chain multiplications is nontrivial, in particular, if intermediate result matrices become dense. In many situations

10.5441/002/edbt.2015.26

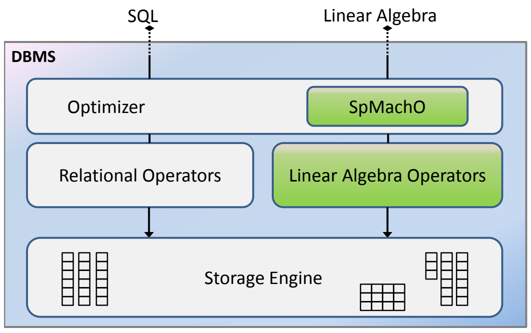

Figure 1: DBMS example architecture.

the runtime performance can be significantly improved by changing the execution order, or by switching from a sparse to a dense multiplication algorithm in later stages. Since data scientists are usually not familiar with algorithmic details of multiplication kernels and system parameters, and do not have profound knowledge of the characteristics of their matrices, it makes sense to leave these decisions to the system.

In particular, the contributions of this work are:

- **SpMachO**, a general matrix chain multiplication optimizer based on a dynamic programming approach, which leverages density estimations of intermediate results and different multiplication kernels to minimize the total execution runtime. The optimization problem and the SpMachO algorithm are presented in sections 2 and 3.
- **SpProdest**, a sparse matrix density estimator, which predicts the density structure of intermediate and final result matrices, by using a novel skew-aware stochastic density propagation method. It is described in detail in sections 4 and 5.
- An extensive evaluation and comparison of the execution runtime of the SpMachO-generated plan against alternative execution strategies and other numerical algebra systems, which is presented in section 6.

Finally, we will discuss the related work in section 7, followed by the conclusion in section 8.

2. EXPRESSION OPTIMIZATION

A lot of data scientists work with numeric algebra systems to run their linear algebra algorithms. However, the user is often let alone with the execution order, although the way of executing large sparse matrix expressions contains a significant optimization potential.

Consider a set of linear algebra expressions that consist of matrix multiplication and addition on general $\mathcal{R}^{m\times n}$ matrices. Further operations, like subtraction or division by a matrix $\boldsymbol{A}$ can be represented by using the corresponding inverse of addition $(-\boldsymbol{A})$, or inverse of multiplication $\boldsymbol{A}^{-1}$, respectively. Thus, the expression can be reduced to a form:

$$\boldsymbol{C} = \boldsymbol{A}_0 + \boldsymbol{A}_1 \cdot \boldsymbol{A}_2 \cdot ... \cdot \boldsymbol{A}_p + \boldsymbol{A}_{p+1} \cdot ...\boldsymbol{A}_l + ...,$$

From a mathematical perspective, the number of operations needed for the element-wise addition of intermediate results, or any element-wise operation in general, is independent from the execution order, thus, it is the same for $(\boldsymbol{A}+\boldsymbol{B})+\boldsymbol{C}$ as

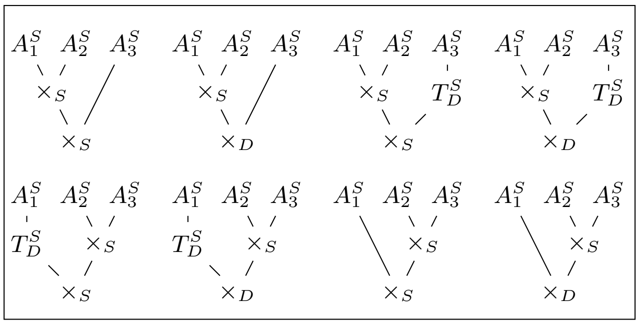

Figure 2: Eight of the possible 128 execution plans for the multiplication of three sparse matrices $\boldsymbol{A}_1 \cdot \boldsymbol{A}_2 \cdot \boldsymbol{A}_3$. $\times$ are binary multiplication operators, S/D denotes the internal *sparse/dense* representation type of matrices, and T are unary storage type transformations of matrices.

for $\boldsymbol{A}+(\boldsymbol{B}+\boldsymbol{C})$. Although this indifference might not hold in practise, when different physical representations are used, the addition part in the computation of $\boldsymbol{C}$ is rather cheap, since the complexity is at most $\mathcal{O}(mn)$ for dense matrices. Most of the execution time is spent in the computation of multiplications

$$\boldsymbol{A}_1 \cdot \boldsymbol{A}_2 \cdot ... \cdot \boldsymbol{A}_{p-1} \cdot \boldsymbol{A}_p, \quad \boldsymbol{A}_i \in \mathcal{R}^{m_i \times m_{i+1}}, \tag{1}$$

so the work of this paper focus on the optimization of matrix chain multiplications. The algebraic degree of freedom to execute expression (1) consists in the setting of parenthesis, since matrix multiplications are associative. Altering the parenthesization does not change the result, but the number of operations required in the computation of the complete chain can vary significantly. Finding the optimal parenthesization for a dense, non-square matrix chain multiplication is well understood and serves as a text book example for the use of dynamic programming [16, 12]. The idea is to iteratively construct the optimal parenthesization as a combination of optimal sub-parenthesizations, by minimizing a cost recurrence expression with respect to the split point k

$$C_{\pi^{\mathrm{B}}(ij)} = \min_{i\leq k<j} \{C_{\pi^{\mathrm{B}}(ik)} + C_{\pi^{\mathrm{B}}((k+1)j)} + \mathtt{TM}\left(\boldsymbol{A}_{[i...k]}, \boldsymbol{A}_{[k+1...j]}\right)\}. \tag{2}$$

For the mathematical formulation, we introduce

- $\pi(ij)$: a parenthesization for the matrix (sub)chain $\boldsymbol{A}_{[i...j]}$
  $\pi^{\mathrm{B}}(ij)$ denotes the optimal ("best") one.
- C_π: the cost for executing the matrix chain multiplication, given a certain parenthesization π.
- $\mathtt{TM}\left(\boldsymbol{A}_{[i...k]}, \boldsymbol{A}_{[k+1...j]}\right)$: the cost function for multiplying the two matrices that result from the subchains $\boldsymbol{A}_{[i...k]}$ and $\boldsymbol{A}_{[k+1...j]}$

In the textbook case, the combination cost $\mathtt{TM}\left(\boldsymbol{A}_{[i...k]}, \boldsymbol{A}_{[k+1...j]}\right)$ is set equal with the number of flops for multiplying the two dense intermediate result matrices. By using the classical inner product algorithm the costs can be exactly determined a priori as $m_i m_{k+1} m_{j+1}$.

However, the dense matrix case has certain limitations that restricts its relevance in practice. Most important, many of the real-world matrices in big data environments are sparse. A sparse matrix is not only defined by its row and column dimensions m and n, but also by the number and the pattern of non-zero elements N_{nz}, or the *density*[1] $\rho = \frac{N_{nz}}{mn}$. As a matter of fact, algorithms on sparse matrices have a different complexity: unlike the naive inner product algorithm for dense matrices, the cost of a multiplication of two sparse matrices rather depends on the number of non-zero elements than on their dimensions. Moreover, sparse matrices are stored in a different data structure than dense matrices, which leads to different actual costs depending on the characteristics of the physical representation. Most of the related work on matrix chain multiplications consider either dense-only [16, 12] or sparse-only [9] multiplications, being agnostic to the fact that the densities of the intermediate result matrices can vary significantly from the initial matrices. For example, the density of the result matrix $\boldsymbol{C} = \boldsymbol{A} \cdot \boldsymbol{B}$ can be much higher, or even less than that of both $\boldsymbol{A}$ and $\boldsymbol{B}$ (see Fig. 5). Despite the mathematical complexity, it is in many cases more efficient to continue using algorithms on dense matrix representations, if the density exceeds a certain threshold. This can be reasoned with the efficient and well-tuned implementations of dense matrix multiplication kernels in BLAS[2].

Our idea is to take the individual differences of the different matrix representations and multiplication kernels into account, and to exploit the potential performance benefits from changing the physical implementation of the initial matrices or intermediate results. We construct an execution plan for the chain expression that can contain dense, sparse and mixed dense/sparse matrix multiplications. Furthermore, the execution plan can contain conversions from a sparse into a dense representation. Therefore, we adopted the idea of dynamic programming and modified it in such a way that it incorporates the physical properties of the matrices. We extended the recurrence (2) by adding the input and output storage types as independent dimensions, and added cost functions for the storage type conversions:

$$\begin{aligned} &C_{\Pi^{\mathrm{B}}(ij)S^o} = \\ &\min_{\substack{i \le k < j \\ S^l, S^r, S^1, S^2 \in \mathcal{S}}} \Big\{ C_{\Pi^{\mathrm{B}}(ik)S^l} + C_{\Pi^{\mathrm{B}}((k+1)j)S^r} + \mathtt{TT}_{S^1}\left(\boldsymbol{A}_{[i..k],S^l,\rho}\right) \\ &+ \mathtt{TT}_{S^2}\left(\boldsymbol{A}_{[k+1..j],S^r,\rho}\right) + \mathtt{TM}_{S^o}\left(\boldsymbol{A}_{[i..k],S^1,\rho}, \boldsymbol{A}_{[k+1..j],S^2,\rho}\right) \Big\} \end{aligned} \tag{3}$$

- $\Pi(ij)$: execution plan for a matrix (sub)chain multiplication. It contains the execution order as well as all storage transformations. Π^{B} denotes the optimal plan.

- S^X: storage type, which is either dense or sparse. The superscript X labels each of the five matrices that are considered per execution node. $X = l$: left subplan output-, r: right subplan output-, 1: left input-, 2: right input-, o: current product output matrix .

- $\mathtt{TT}_{S^Y}\left(\boldsymbol{A}_{[i..k],S^X}\right)$: cost function for the conversion of a matrix from type S^X into type S^Y.

[1]In the remainder of this paper, we refer to the non-zero structure using ρ rather than N_{nz}

[2]Basic Linear Algebra Subprograms, http://www.netlib.org/blas/

Since the cost functions TM in equation (3) depend on the storage types of the input and output matrices, as well as their densities, it could be beneficial to convert a matrix from one into the other representation prior to the multiplication because conversions are usually less costly than multiplications. For example, if the initial matrices are in a sparse representation, and the dense multiplication kernel plus the conversion has a far lower cost than the sparse multiplication, then they are first converted into the dense representation. As a matter of fact, the value of the conversion cost $\mathtt{TT}_S(A, S)$ equals zero for identity transformations, i.e., when a matrix is already in the optimal representation. Hence, besides the parenthesization split point k, we vary the input and output storage types for each step in recurrence (3).

Some of the parameters that contribute to the cost functions $\mathtt{TM}/\mathtt{TT}(\cdot)$, for example the density ρ of intermediate results, are not known prior to the execution and have to be estimated. Therefore, we developed the sparse matrix product density estimator SpProdest, which is described in section 4 and 5 of this paper. The resulting costs derived from recurrence (3) are minimal, given that the estimated costs encoded in TM and TT are determined precisely. In particular, the optimality, or *goodness*, of SpMachO depends on two parts, which potentially contain uncertainties: first, the accuracy of the quantitative cost model of the multiplication kernels, and second, the precision of the density estimates provided by SpProdest.

The total number of the possible execution plans using our model (3) for a matrix chain multiplication of length p is

$$\mathcal{C}_{p-1} \cdot 2^{3(p-1)}, \tag{4}$$

where $\mathcal{C}_{p-1}$ denotes the Catalan number $\mathcal{C}_n = \frac{(2n)!}{(n+1)!n!}$.

$\mathcal{C}_{p-1}$ reflects the number of possible parenthesizations, which is the same as for the textbook case [12]. The second factor is related to the 2^3 {left input-, right input-, output-} storage type combinations that are connected with each of the $p-1$ type multiplication nodes. The number in (4) resembles the size of the search space, which grows exponentially. To give an example, it yields 2560 for a matrix chain of length $p = 4$ and already 1376256 for $p = 6$. As in [12], SpMachO solves the recurrence (3) in $\mathcal{O}(p^3)$ time using a bottom-up dynamic programming approach.

3. SpMachO

The pseudocode of SpMachO is sketched in Algorithm 1. The cost of the optimal sub-chain multiplications and the relevant plan information (split points and storage types per sub-chain) are cached in three-dimensional array structures. For each combination in the inner loop, the method chkMemLimit checks if the total memory consumption of the matrices and intermediate results in the current plan configuration would exceed the system limit. The memory required for dense $m \times n$ matrices is $\mathcal{O}(mn)$, and $\mathcal{O}(N_{nz} = mn\rho)$ for sparse matrices. Since SpMachO optimizes the runtime performance, the plan may contain conversions from sparse into dense matrix representations whenever the dense kernel leads to a lower overall runtime, due to the efficient dense kernel implementation. However, the conversions into dense representations potentially increase the memory consumption compared to a sparse-only plan. Our strategy is that every conversion is allowed, as long as the total memory consumption at every point in time does not exceed a hard memory

Algorithm 1 SpMachO

```
 1: function spMacho(MatrixChain $\boldsymbol{A}_{[1..p]}$, TM, TT)
 2:     $\hat{\boldsymbol{\rho}}[][] \leftarrow$ spProdest($\boldsymbol{A}_{[1..p]}$)
 3:     for $1 \leq j < p, j > i \geq 0$ do
 4:         for $i \leq k < j$ do
 5:             for types $\in$ {sparse, dense} do
 6:                 if !chkMemLimit($A, k, \rho$, types) then
 7:                     continue
 8:                 $q \leftarrow$ TT($\boldsymbol{A}_{[i..k..j]}, \hat{\boldsymbol{\rho}}[][]$, types)
 9:                 $q \leftarrow q +$ TM($\boldsymbol{A}_{[i..k..j]}, \hat{\boldsymbol{\rho}}[][]$, types)
10:                 if $q <$ cost[$i$][$j$][$S^o$] then
11:                     cost[$i$][$j$][$S^o$] $\leftarrow q$
12:                     plan[$i$][$j$][$S^o$] $\leftarrow$ k, types
13:     if cost[1][$p$][$\cdot$] $\geq$ MAXVAL] then
14:         /* memory exceed exception */
15:     else
16:         return min(plan[1][p][sparse], plan[1][p][dense])
```

limit. Execution paths that would exceed the memory limit are automatically skipped (line 6). We assume that there is at least one plan that does not exceed the memory limit. If not, SpMachO returns with an exception (line 13). Finally, the resulting plan, which can be converted into a directed acyclic graph representation as of Fig. 2, is returned to the system for execution.

The complexity of Algorithm 1 is $\mathcal{O}(p^3)$, which can be derived from the dynamic programming loop and is the same as in the dense-only problem. The additional complexity by the introduction of storage type transformations yields a constant factor, since the inner loops over the storage types do not depend on the chain length p. A few pruning methods can be applied to reduce the execution plan space, for example, by excluding that the product of two dense can be sparse. However, they do not lower the asymptotic complexity of the algorithm.

The system executes the plan using the corresponding transformation and matrix multiplication operators. While the unary transformation operator either performs a dense-to-sparse or a sparse-to-dense storage transformation, the eight-fold multiplication operator delegates the execution to one of the multiplication kernels. We implemented all algorithms in our prototype using row-major 2D-arrays for dense- and the columnar compressed sparse row layout (CSR) for sparse matrices, since they are to our notion the most common physical representations, and are used in many numerical libraries, e.g. the Intel Math Kernel Library [1]. As mentioned in the beginning, we already showed in [20] that these representations can be mapped onto a columnar storage layout of an in-memory columnar DBMS.

3.1 Multiplication Kernels

There are eight different **ge**neral **m**atrix **m**ultiply (gemm) kernels that are used in our system. We will use the notation *xyz_gemm* to denote a multiplication kernel, where x is the left-hand input-, y is the right-hand input type and z the output matrix storage type, which can be either sparse (*sp*) or dense (*d*). Some of the kernels, for example the standard BLAS *ddd_gemm*, or *spdd_gemm*, are implemented by vendor-tuned C++ libraries, so we call the library instead of providing an own implementation. As of the current status, this is done only for *ddd_gemm*, for which we use the Intel MKL implementation.

Table 1: The matrix multiplication kernels for the product $C^{m\times n} = A^{m\times k} \cdot B^{k\times n}$ and their cost functions used in SpMachO. $N_\times$ denotes the number of actual multiplications, the hat indicates the corresponding estimated value. α, β, γ are constant parameters.

Kernel	Cost Function
ddd_gemm	$\alpha(mkn)$
spdd_gemm	$\alpha\hat{N}_\times$
dspd_gemm	$\alpha(mk) + \beta\hat{N}_\times$
spspd_gemm	$\alpha N^A_{\text{nz}} + \beta\hat{N}_\times$
ddsp_gemm	$\alpha\hat{N}_\times + \beta\hat{N}^C_{\text{nz}} + \gamma(mn)$
spdsp_gemm	$\alpha N^A_{\text{nz}} + \beta\hat{N}_\times + \gamma\hat{N}^C_{\text{nz}}$
dspsp_gemm	$\alpha\hat{N}_\times + \beta\hat{N}^C_{\text{nz}} + \gamma(mk)$
spspsp_gemm	$\alpha N^A_{\text{nz}} + \beta\hat{N}_\times + \gamma\hat{N}^C_{\text{nz}}$

Table 1 lists the kernels that are used in our system. In order to obtain the optimal execution plan via solving recurrence (3), the cost model and its corresponding parameters have to be determined accurately for each multiplication kernel. Since the actual runtime depends on many parameters and external influences, an exact determination cannot be guaranteed. However, even for small variations, the plan generated by SpMachO is still near-optimal, which we verified in the evaluation in section 6.

3.2 Execution Time Cost Model

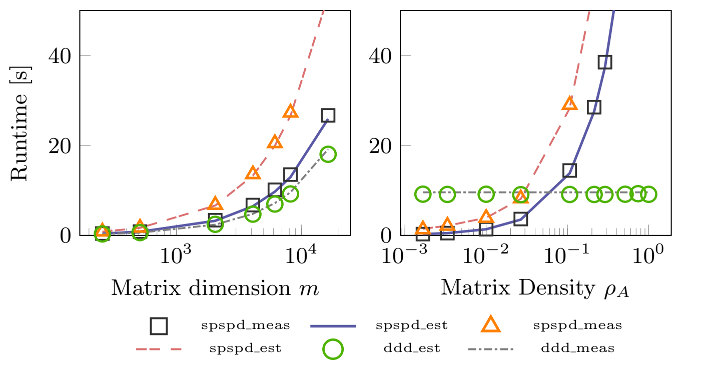
The cost for multiplying two dense or sparse matrices generally depends on the matrix dimensions m, k, n, the number and pattern of non-zero elements of both the input and the result matrices, and the implementation details of the corresponding kernel algorithm. The idea is to reduce the dimensions to a set of only a few, significant dimensions, and create the cost model based on the reduced dimension set. On average, it is a fair approximation to assume that the runtime of a single multiplication only depends on the number of non-zero elements, and not on the individual non-zero pattern variations. Hence, we are able to reduce the parameter space to the dimensions m, k, n, ρ_A, ρ_B, and $\hat{\rho}_C$, which corresponds to the product density estimation, which is determined by SpProdest.

As an example, we will examine the *spspsp_gemm* kernel that uses the popular Gustavson algorithm [18]. The algorithm is based on the *sparse accumulator* method, which is still commonly used for sparse matrix implementations [15]. In order to not repeat the algorithm description in detail, we only sketch the derivation of our cost model for *spspsp_gemm*, which we consider as the most interesting kernel.

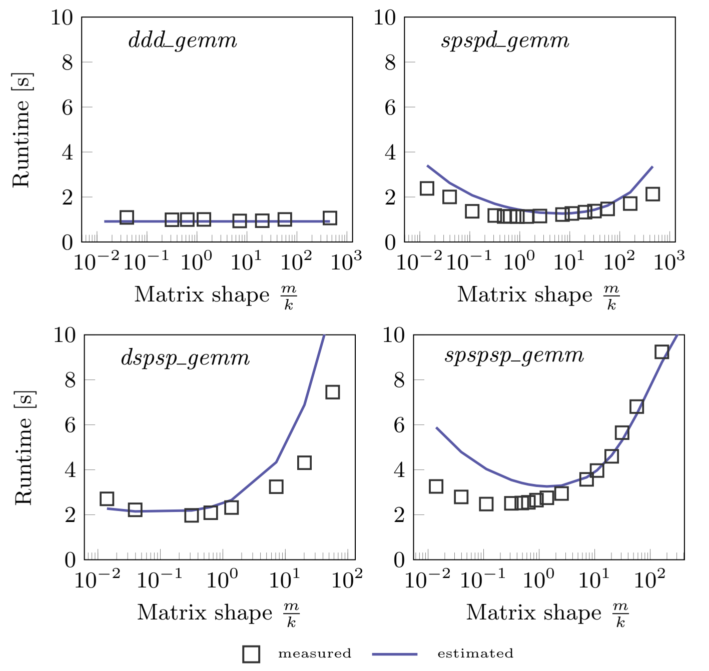
For reasonably large sparse matrices, the runtime of sparse kernels is often dominated by main memory bandwidth. Hence, mainly the memory accesses contribute to the runtime of an algorithm, which is in conformance to the external memory (I/O) model. For *spspsp_gemm*, the access pattern can be formulated as

$$\texttt{TM}(m, k, n, \rho_A, \rho_B) = m \times (\text{read}_{rowA} + k\rho_A \times (\text{read}_{colA,rowB} + n\rho_B \times (\text{read}_{colB,valA,valB} + \text{write}_{colC,valC})) + n\hat{\rho}_C \text{write}_{colC,valC}),$$

where the read/write denote the accesses to the respective data structures (*rowA, rowB,* etc.) in memory. For example,



(a) Scaling behavior: varying the dimension (left) and density (right). Other dimensions are fixed: $k = 8192, n = 8192, \rho_B = 0.1$



(b) Varying the matrix shape m/k. $N_\times$ is fixed in each plot.

Figure 3: Measured runtimes (markers) and time estimates (lines) for different matrix multiplication kernels.

a read on *colA* has a higher average cost than a read on *colB*, since a complete row of matrix $\boldsymbol{B}$ is touched in-between two consecutive *colA*-reads, thus, the system has most probably evicted the cache line of *colA* and has to fetch it again. The exact number of cycles, and hence, the required time per read or write access depends on whether the addressed cache line resides in the system cache. However, since we consider large matrices with sizes that are by factors larger than the last level system cache, we approximate the read and write accesses as fixed time constants in our model. Moreover, instead of determining the individual time constants for the $\text{read}_X/\text{write}_X$ access, we abstracted them into few parameters, which can then be determined empirically. Therefore, we expand the expression of `TM` and accumulate the time constants of the read/write accesses into the constant parameters α, β, γ, and obtain a simple time approximation for the

Wall-clock time

$$T \approx \alpha(\underbrace{m \cdot k \cdot \rho_A}_{N^A_{\text{nz}}}) + \beta(\underbrace{m \cdot k \cdot \rho_A \cdot n \cdot \rho_B}_{\hat{N}_\times}) + \gamma(\underbrace{m \cdot n \cdot \hat{\rho}_C}_{\hat{N}^C_{\text{nz}}}),$$

which only depends on the constant parameters

$$\alpha = T(\mathit{read}_{colA,rowB})$$
$$\beta = T(\mathit{read}_{colB,valA,valB} + \mathit{write}_{colC,valC})$$
$$\gamma = T(\mathit{write}_{colC,valC})$$

and the *derived* dimensions:

- N^A_{nz}: the number of non-zeros in matrix $\boldsymbol{A}$
- $\hat{N}_\times$: the estimated number of multiplications
- $\hat{N}^C_{\text{nz}}$: the estimated number of non-zero elements in the result matrix

For the other kernels, the cost function can be deduced in a similar manner. Because of space limitations, we will not discuss them in this paper. Table 1 lists the cost function for each kernel. Each cost function is a linear combination of different derived dimensions, weighted by constant parameters α, β, γ. The constant parameters are estimated for each kernel by a multilinear least-squares fit. Since they are dependent on the system hardware, the fit has to be done once for each system configuration.

Fig. 3a shows the scaling behavior of the matrix multiplication kernels *spspsp_gemm*, *spspd_gemm* and *ddd_gemm* with respect to matrix dimension and density. We observe that our cost models (lines) conform well with the actual algorithm runtimes (markers). From the right plot in Fig. 3a we can infer the following example scenarios: if the density ρ_A has a higher value than about 0.1, then it can be worthwhile to convert A into a dense representation and continue with the dense kernel – of course only if the dense representation does not exceed the available memory. If the density is below, it is probably best to select the *spspd_gemm* kernel. For $\rho_A \ll 0.01$ and depending on the following multiplications and the estimated intermediate result densities, it might be best to take with the *spspsp_gemm* kernel.

In Fig. 3b, we fixed the densities ρ_A, ρ_B and the product $(m \cdot k \cdot n)$, and only varied the relative matrix shapes $\frac{m}{k} \equiv \frac{k}{n}$. At both edges of each plot the matrices are extremely rectangular. The deviation of the actual times from our estimates shows that our cost model has limited accuracy in these extreme cases. However, the deviation is still acceptable, since the times are always overestimated. Overestimation is more robust than underestimation, because SpMachO would then just select another multiplication kernel, whereas in the latter case the deviation would propagate into the overall estimation. It is worthwhile mentioning that one conclusion we deduce from Fig. 3b is that simplistic cost models, which solely depend on the number of non-zero multiplications $N_\times$, are not able to describe the shape dependency, since $N_\times \equiv$ *const.* is fixed in each plot.

4. DENSITY ESTIMATION

The estimation of the intermediate result matrix densities is a crucial part of the SpMachO optimizer, since the cost models of the sparse multiplication kernels primarily depend on the number of non-zero elements, and hence, the matrix densities ρ. Our approach is to encode the non-zero structure into the smallest possible set of values without losing too much information.

a)
$$\begin{pmatrix} 0 & 2 & 0 & 0 \\ 5 & 0 & 0 & 8 \\ 0 & 0 & 8 & 0 \\ 4 & 0 & 0 & 0 \end{pmatrix} \quad \rho = \begin{pmatrix} \frac{5}{16} \end{pmatrix}$$

b)
$$\begin{pmatrix} 0 & 2 & 0 & 0 \\ 3 & 9 & 0 & 1 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 2 & 0 \end{pmatrix} \quad \begin{pmatrix} \rho_{11} & \rho_{12} \\ \rho_{21} & \rho_{22} \end{pmatrix} = \begin{pmatrix} 0.75 & 0.25 \\ 0 & 0.75 \end{pmatrix}$$

Figure 4: Assignment of non-zero population densities for two different matrices using a) scalar density, b) density map.

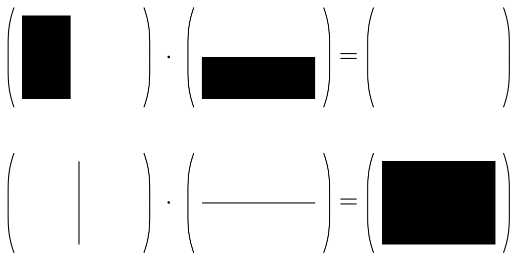


Figure 5: Product density in extreme non-uniform cases. The upper row shows how two half-populated matrices cancel to zero. The lower row shows how two, almost empty sparse matrices produce a full matrix (outer vector product).

4.1 Scalar Density

A matrix can be considered as a two-dimensional object which has a certain population density ρ of non-zero matrix elements. As an example, Fig. 4 a) shows a 4×4 matrix, which has five non-zero elements, and thus, a total population density of $\rho = 5/16 \approx 0.31$. The scalar density value does not reflect any patterns in the matrix, but it contains all relevant information if, and only if, the matrix is *uniformly* populated with non-zero elements. Then, the probability of a randomly picked matrix element for being non-zero is $p((A)_{ij} \neq 0) = \rho$, which is 0.31 in the example of Fig. 4 a).

Lemma 4.1. *Under the condition that the non-zero elements are uniformly distributed, the density estimate $\hat{\rho}$ of a product of two matrices $\boldsymbol{C} = \boldsymbol{A} \cdot \boldsymbol{B}$ can be calculated using probabilistic propagation*

$$\hat{\rho}_C = \hat{\rho}_{A \cdot B} = 1 - (1 - \rho_A \rho_B)^k. \tag{5}$$

The estimate of Eq. (5) is unbiased, i.e. $E[\hat{\rho}_C] \equiv \rho_C$.

For the sake of simplicity, we denote the operation in Eq. (5) with the symbol $\odot$, thus, $\hat{\rho}_C = \rho_A \odot \rho_B$. Lemma 4.1 can be derived as follows: using the inner product formulation, the elements c_{ij} of the result matrix are calculated as $\sum_k a_{ik} b_{kj}$. The probability for a_{ik} being non-zero is $p(a_{ik} \neq 0) = \rho_A$, for b_{kj} accordingly: $p(b_{kj} \neq 0) = \rho_B$. Thus, every summand $a_{ik} b_{kj}$ is nonzero with probability $p_{nz}(a_{ik}) \wedge p_{nz}(b_{kj}) = \rho_A \rho_B$. c_{ij} is non-zero if any of the summands $a_{ik} b_{kj}$ is non-zero. We leverage the inverse probability and obtain $p(c_{ij} = 0) = \Pi_k (1 - \rho_A \rho_B)$. Finally, with $p(c_{ij} \neq 0) = 1 - p(c_{ij} = 0)$ and $p(c_{ij} \neq 0) = \rho_C$, equation (5) results. We remark that we are assuming *no cancellation*, i.e., a sum of products of overlapping non-zero elements never cancel to zero, which is a very common assumption in the mathematical programming literature [10].

Eq. (5) can be used as an $\mathcal{O}(1)$ estimator for the result density prediction of a multiplication of two matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ that have uniform non-zero patterns. Hence, the prediction of a chain multiplication of p matrices has a linear time complexity $\mathcal{O}(p)$. Moreover, the density prediction is independent of the parenthesization.

4.2 Estimation Errors

However, the obvious disadvantage of maintaining a scalar density is that $\hat{\rho}$ is only valid for matrices with uniformly distributed non-zero elements. Although the uniform assumption holds for many matrices to a certain degree, there are many matrices that have distinguishable non-zero patterns, i.e. a topology with some regions that are significantly more dense than others. For these matrices, a density prediction according to equation 5 does not provide an accurate, unbiased result.

In extreme non-uniform cases, equation (5) could produce an asymptotic maximum error of 100%. Fig. 5 shows two example cases where the $\hat{\rho}$ estimate according to (5) fails significantly: In the first case, the product of two $n \times n$ matrices with each $\rho = 0.5$ cancel out into an empty matrix with $\rho = 0$, whereas the naive estimate according to Eq. 5 is $\hat{\rho} = 1 - (0.75)^n \xrightarrow{n \to \infty} 1$. Hence, the density value is maximal overestimated. The second example is a multiplication of two sparse $\rho = \frac{1}{n}$ matrices, which are zero except one column in $\boldsymbol{A}$ and the matching row in $\boldsymbol{B}$. The resulting full matrix has $\rho = 1$, whereas the naive prediction gives $\hat{\rho} = 1 - (1 - \frac{1}{n^2})^n \xrightarrow{n \to \infty} 0$.

In order to lower the average estimation error, we estimate matrix densities on a finer granularity. SpProdest uses a *density map* for non-uniform sparse matrices, which is able to reflect a $2D$ matrix pattern on a configurable, granular level.

4.3 Density Map

The density map $\boldsymbol{\rho}_A$ of a $m \times n$ sparse matrix $\boldsymbol{A}$ is effectively a $\frac{m}{b} \times \frac{n}{b}$ density histogram. It consists of $\left(\frac{mn}{b^2}\right)$ density values $(\rho)_{ij}$, each referring to the density of the corresponding block $\boldsymbol{A}_{ij}$ of size $b \times b$ in matrix $\boldsymbol{A}$. As an example, Fig. 4b) shows the density map of a 4×4 matrix with blocks of size 2×2.

In the following we sketch how the density map $\hat{\boldsymbol{\rho}}_C$ of the result matrix $\boldsymbol{C}$ are estimated from the density maps $\boldsymbol{\rho}_A$ and $\boldsymbol{\rho}_B$ of its factor matrices. Therefore, it is necessary to take a glance at blocked matrix multiplication. Assuming square blocks, the product matrix $\boldsymbol{C}$ can be represented as

$$\boldsymbol{C} = \begin{pmatrix} \boldsymbol{A}_{11} \cdot \boldsymbol{B}_{11} + \boldsymbol{A}_{12} \cdot \boldsymbol{B}_{21} & \boldsymbol{A}_{11} \cdot \boldsymbol{B}_{12} + \boldsymbol{A}_{12} \cdot \boldsymbol{B}_{22} \\ \boldsymbol{A}_{21} \cdot \boldsymbol{B}_{11} + \boldsymbol{A}_{22} \cdot \boldsymbol{B}_{21} & \boldsymbol{A}_{21} \cdot \boldsymbol{B}_{12} + \boldsymbol{A}_{12} \cdot \boldsymbol{B}_{22} \end{pmatrix}. \tag{6}$$

First, we define an estimator for the *addition* of two matrices:

Lemma 4.2. *Under the condition that the non-zero elements are uniformly distributed, the density estimate $\hat{\rho}$ of the addition of two matrices $\boldsymbol{C} = \boldsymbol{A} \cdot \boldsymbol{B}$ can be calculated using probabilistic propagation*

$$\hat{\rho}_{A+B} = \rho_A + \rho_B - (\rho_A \rho_B) \equiv \rho_A \oplus \rho_B. \tag{7}$$

The derivation of Lemma 4.2 is similar to that of Lemma 4.2, which is why we leave it out for space reasons.

Then, combining Eq. (6) with (5) and (7), one obtains

$$\hat{\boldsymbol{\rho}}_C = \begin{pmatrix} \rho_{A_{11}} \odot \rho_{B_{11}} \oplus \rho_{A_{12}} \odot \rho_{B_{21}} & \rho_{A_{11}} \odot \rho_{B_{12}} \oplus \rho_{A_{12}} \odot \rho_{B_{22}} \\ \rho_{A_{21}} \odot \rho_{B_{11}} \oplus \rho_{A_{22}} \odot \rho_{B_{21}} & \rho_{A_{21}} \odot \rho_{B_{12}} \oplus \rho_{A_{22}} \odot \rho_{B_{22}} \end{pmatrix}$$

for the density propagation of a 2×2 map. Density maps of a finer granularity, i.e. with more than four blocks, are calculated accordingly.

As a result, the average density estimation error is significantly lowered when using density maps compared to the scalar density estimation, which we verified empirically in the evaluation section (Fig. 6.) As a matter of fact, the smaller the block size and the higher the granularity, the more information is stored in the density map and finer structures can be resolved. However, the runtime of the density map estimation also grows with the granularity, since its complexity is in $\mathcal{O}(\left(\frac{n}{b}\right)^3)$, and hence, $\mathcal{O}(p\left(\frac{n}{b}\right)^3)$ for a chain estimation of length p. For infinitesimal block sizes $b \to 1 \times 1$, the estimation error vanishes completely, but the determination of $\hat{\boldsymbol{\rho}}_C$ is then equivalent with the corresponding boolean matrix multiplication of $\boldsymbol{A} \cdot \boldsymbol{B}$, and has the same problem complexity as the actual multiplication. Thus, the block size configuration is generally a trade-off between accuracy and runtime of the prediction.

However, we employ a greedy strategy, which reduces the runtime by using density maps only for matrices with a skewed non-zero distribution, and the scalar density for matrices with an approximately uniform distribution. To decide whether a given matrix has an uniformly distributed or a skewed non-zero pattern we define a quantitative disorder measure for sparse matrices.

4.4 Matrix Disorder Measures

We introduce two measures to quantify how the non-zero pattern of a sparse matrix deviates from an (approximate) uniform distribution. Since we already introduced the density map that involves blocks of different densities, it is natural to approach the problem from same the block-granular level.

4.4.1 *Variance Analysis*

One way of deciding whether or not a matrix is approximately uniformly distributed is to make use of a statistical hypothesis testing method. The scalar density propagation formulas as shown in Lemmas 4.1 and 4.2 are based on the assumption that every element of the matrix has the same probability to be populated, and the probability is equal to the overall density ρ. Using this assumption as the null hypothesis H_0, the number of non-zero elements in each $b \times b$-block would follow a binomial distribution $\mathcal{B}(N, p)$ with $N = b^2$ and $p = \rho$. This can be deduced in the same way as a coin toss experiment, where the number of experiments N is equal to the number of potential elements in a block, and the *success* probability $p = \rho$ equals the global population density. From elementary statistics [7] we get

$$E[N_{\text{nz}}^{b\times b}] = b^2\rho, \qquad E[V(N_{\text{nz}}^{b\times b})] = b^2\rho(1-\rho) \tag{8}$$

for the expectation values of for the number of non-zero elements N_{nz} in one $b \times b$ and the variance of $N_{nz}^{b\times b}$ when assuming a binomial distribution $\mathcal{B}(b^2, \rho)$.

The (dis-)conformance of the null hypothesis H_0 with the reality can be determined using a simple one-factorial variance analysis. Therefore, we use the F-test [7], a likelihood quotient test, which checks the conformance of the observed variance of two random, normally distributed[3] variables X and Y. If the test statistic $f = V_X/V_Y$ (ratio of variances in X and Y) exceeds a critical value f_{crit} according to an α-quantile of the F-distribution, then H_0 is rejected, meaning that X and Y are not of the same distribution with probability 1-α.

For a matrix with N_B $b \times b$ blocks, we define

$$V_{\text{observed}} = \frac{1}{N_B - 1} \sum_{ij} (N_{\text{nz}}(ij) - E[N_{nz}^{b\times b}])^2 \tag{9}$$

$$f = \left(\frac{V_{\text{observed}}}{V_{\text{expected}}}\right) = \left(\frac{V_{\text{observed}}}{E[V(N_{nz}^{b\times b})]}\right) \tag{10}$$

For uniformly distributed matrices, f has the expectation value $E[f] = 1$. The exact choice of the threshold, however, depends on the sample size, i.e. the number of blocks N_B and the desired accuracy.

4.4.2 *Entropy*

A known measure for the disorder of elements is the entropy

$$\sum_i^N -p_i \ln p_i, \tag{11}$$

which is defined over a space with N entities (or states) i that have a relative probability p_i. The entropy is used in a variety of contexts. To name an example, the Shannon entropy [26] is used in information theory to quantify the information content of a message with N characters as entities. In a similar manner, we can define and quantify the information content of the non-zero pattern of a sparse matrix, by identifying the p_i with the local block density ρ_{ij}.

The entropy (11) is maximal if each entity has the same probability. In the terms of sparse matrices, the theoretical disorder is maximized if every block has the same local density $\rho_{ij} \equiv \rho$. The scaled entropy

$$\tilde{H} = \frac{H}{H_{\max}} = \frac{\sum_{ij}^{N_B} \rho_{ij} \ln \rho_{ij}}{N_B \rho \ln \rho} \in [0, 1] \tag{12}$$

is sensitive to the matrix density skew, which we evaluated in section 6. However, in contrast to f, the entropy is rather suited for measuring *relative* changes in the non-zero disorder, and it is hard to interpret the absolute value of $\tilde{H}$.

5. SpProdest

SpProdest is sketched in algorithm 2. First, the disorder measure $\delta = \sqrt{1/f}$ is retrieved (getDisorder) for each matrix, which is a modified version of f according to Eq. (10). Then, δ is used to decide whether to store a only scalar density value, or a density map (line 4). If δ is lower than a certain threshold δ_T, then the density map is created, if the disorder is higher, then a scalar density is chosen. Finally, the density estimates are calculated by using the probabilistic density propagation method (EstProdDensity), according to equations (5) and (7). Note that instead of calculating δ and $\hat{\boldsymbol{\rho}}$ for each expression (line 4-7), they can be cached as matrix statistics in the system, and reused for further multiplications.

The complexity of SpProdest depends on the actual granularity of the density map. Assuming a chain multiplication

[3]for sufficiently large N and $Np \to$ const., the binomial distribution can be approximated by a normal distribution

Algorithm 2 SpProdest

```
1: function spProdest(MatrixChain $\boldsymbol{A}_{[1..p]}$)
2:     $\hat{\boldsymbol{\rho}}[][] \leftarrow 0$
3:     for Matrix $\boldsymbol{A}_i \in \boldsymbol{A}_{[1..p]}$ do
4:         $\delta \leftarrow$ getDisorder($\boldsymbol{A}_i$)
5:         if $\delta < \delta_T$ then
6:             $\hat{\boldsymbol{\rho}}[i][i] \leftarrow$ scalarDensity($\boldsymbol{A}_i$)
7:         else
8:             $\hat{\boldsymbol{\rho}}[i][i] \leftarrow$ densityMap($\boldsymbol{A}_i$)
9:     for $1 < j < p$ do
10:        for $j > i > 0$ do
11:            $\hat{\boldsymbol{\rho}}[i][j] \leftarrow$ estProdDensity($\hat{\boldsymbol{\rho}}[i][j-1], \hat{\boldsymbol{\rho}}[j][j]$)
       return $\hat{\boldsymbol{\rho}}[][]$
```

of p square matrices, the time complexity would be in the best case $\mathcal{O}(p)$ (no map) and in worst case $\mathcal{O}(p(\frac{n}{b})^3)$, which is equal to the chain multiplication of p $\frac{n}{b} \times \frac{n}{b}$ matrices, where $\frac{n}{b}$ is the dimension of the density grids. Analogously, the space complexity of SpProdest is best case $\mathcal{O}(p)$, worst case $\mathcal{O}(p(\frac{n}{b})^2)$. In practice, the overhead of the SpProdest component is negligible against the potential speedup gained by the SpMachO, which is manifested in our evaluation in section 6.3.

6. EVALUATION

In this section, we first evaluate the accuracy of spProdest according to the deviation in the result sparse matrix densities. Second, we apply SpMachO on different matrix chains and compare the execution runtime against R and a popular commercial numerical algebra system for matrix computations (called system A here), and two further execution approaches. The platform for our prototype implementation is a two-socket Intel Xeon X5650 CPU with 2 × 6 cores with 2.66 GHz and a total of 48 GB RAM.

6.1 Density Estimate Accuracy

As mentioned in section 4, the density ρ_C of a matrix $\boldsymbol{C} = \boldsymbol{A} \cdot \boldsymbol{B}$ depends not only on the densities of the factor matrices ρ_A and ρ_B, but also on their non-zero patterns, especially on the pattern skew. To show the effect of the non-zero pattern skew on the density estimation, we generated a set of matrices with increasing skew. The skew parameter ξ in our example defines the slope of a linear ascend in the density distribution with increasing row number r: $\rho(r) = \xi \cdot r$. We fixed the total density of $\boldsymbol{A}$, thus, N_{nz} =const.

The left-hand plot in Fig. 6 shows the actual density ρ_C and the estimated densities using the scalar density and the density map approach with different block sizes. In our example, the density of the product matrix ρ_C decreases with increasing pattern skew. This conforms with our notion, that in most cases a higher skew at constant density leads to a lower density of the result matrix, although there are cases which show the opposite behavior, for example, as in Fig. 5.

Nevertheless, it is clearly observable that a finer granularity of the density map, and thus, a smaller block size, results in a better density estimation. The idea is to choose the block size as large as possible, since a finer granular density grid negatively influences the runtime performance of spProdest. We chose a block size of 256 × 256 as a good compromise between accuracy and estimation runtime. The right-hand plot of Fig. 6 confirms that the disorder measures are both

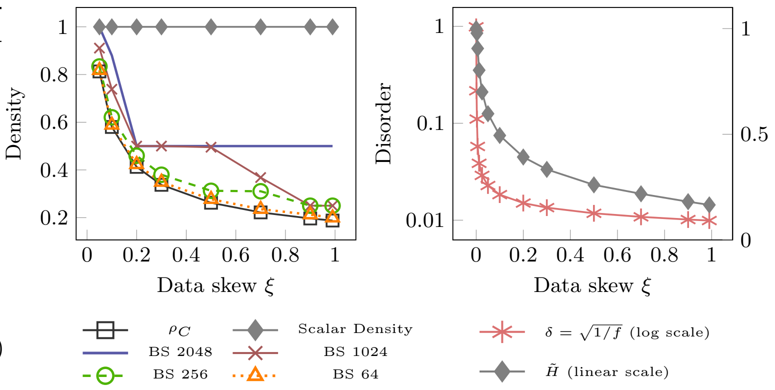

Figure 6: Left: Estimated density $\hat{\rho}_C$ vs. actual density (ρ_C) of the product matrix $\boldsymbol{C} = \boldsymbol{A} \cdot \boldsymbol{B}$ using the scalar and the density map estimation with different grid block sizes (BS). Matrices: $\boldsymbol{A} \in \mathcal{R}^{4096 \times 2048}, \boldsymbol{B} \in \mathcal{R}^{2048 \times 4096}$ and average density $\langle\rho\rangle = 0.1$. Right: Influence of the matrix $\boldsymbol{A}, \boldsymbol{B}$ nonzero skew on the disorder measures $\delta, \tilde{H}$.

sensitive to the nonzero skew, but the teststatistic-based disorder measure δ is much more sensitive to the skew than the entropy-based $\tilde{H}$. In particular we can observe that the trivial scalar density provides a sufficient accuracy for approximately uniform nonzero patterns ($\xi \to 0$).

6.2 Plan Ranking

In this experiment we evaluate the total cost model accuracy of SpMachO by comparing the estimated runtime against the actual runtime of each possible plan. Hence, SpMachO is optimal if the plan with the lowest actual runtime has also the lowest estimated runtime. However, this experimental verification of optimality requires to run all possible execution plans, which is not feasible for longer matrix chains due to the exponentially growing number of plans according to Eq. (4). Thus, we did a "brute-force evaluation" only for matrix chains of length $p = 3$:

$$\boldsymbol{A}_1^S \cdot \boldsymbol{A}_2^S \cdot \boldsymbol{A}_3^S. \tag{13}$$

Although there are only two ways of setting the parenthesis in this expression, with all the possible storage type transformations per multiplication node, one obtains 128 different execution plans. Fig. 2 shows some of the possible plans, to illustrate the problem complexity. The execution plans are composed of

- **multiplication operators** ${}^{D/S}\times^{D/S}_{D/S}$, which can either produce a *sparse* result matrix or a *dense* one. For a chain of length p there are exactly $p-1$ multiplication operators.
- **transformation operator** $T^{S/D}_{S/D}$ that transforms the intermediate result from one storage representation into another (which is either dense or sparse.) There can be none or up to 2^{3p-1} transformation operators.

SpMachO estimates the cost for each operator via the cost functions `TM`,`TT` described in section 2. As a consequence, each operator estimation potentially contributes to the absolute execution runtime error.

In this experiment, we first executed all 128 plans and measured the *actual* execution runtime. Thereafter, we computed the runtime estimations using SpMachO's cost model

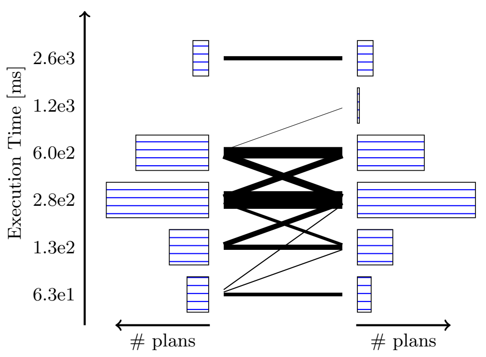

Figure 7: Vertical histogram of the actual (bars on left-hand side) and estimated (bars on right-hand side) runtimes of all 128 possible execution plans. The edges denote the plan (dis-)placement, the linewidth correlates with the corresponding number of plans. The vertical time axis has a logarithmic scale.

for each plan. Fig. 7 shows the histograms for the actually measured (left-hand side) and the estimated (right-hand side) execution runtimes. Note that the vertical axis has a logarithmic scale, hence, the width of the upper bins refers to a larger time interval than the width of the lower bins. The connecting edges in-between the bins of the two histograms show where the plans of the actual runtime histogram are placed in the estimated runtime histogram. If there is an ascending edge, for example from the lowest bin in the left histogram to the second lowest bin of the right histogram, then there is at least one plan, whose runtime was overestimated. If the edge is horizontal, then the estimated runtimes of all plans corresponding to this edge are within the same time interval as their actual runtimes. The width of the edges indicates how many plans are affected. It is worthwhile mentioning that for the selection of the best execution plan, the quantitative estimation of execution runtimes could potentially differ arbitrarily from the actual runtimes, as long as the estimated *order* of the plans preserves the actual runtime order correctly. This condition is only violated for the edges that are crossing another edge. If the total runtime for a plan is significantly under- or overestimated, its corresponding edge crosses multiple other edges. Indeed, the goodness of the cost model can be defined by the number of edges crossings, weighted by the number of plans per crossing edge.

The majority of estimations, which are shown in Fig. 7, are in the correct corresponding time bin. Although there are quite a few crossings, especially in the middle part, most of the edges only span over to the neighboring bin. Moreover, for the selection of the most efficient plan, only the lower part of Fig. 7 is relevant. In particular, the plan with the lowest estimated runtime, which is generated by SpMachO, should be contained in the lowest bin of the actual runtime histogram. Since all edges of the lowest estimated time bin originate from the lowest actual time bin, we observe that the SpMachO selected plan is at least among the top k plans, if not the best.

6.3 Performance Comparison

We compared the absolute execution runtime of a matrix chain multiplication expression using the optimized plan by SpMachO against R and the commercial system A. Both systems contain classes and algorithms for dense and sparse matrices. In R (V3.0.0) we used the Cran R matrix package[2] (V1.0.12), in system A we used the native sparse matrix representation. In addition,we included the following alternative execution approaches to the measurement:

- **Left-deep, sparse only:** All matrices are multiplied using a sparse-sparse into sparse multiplication using the *spspsp_gemm* kernel (${}^{S}\times^{S}_{S}$), starting with the first left pair and proceeding into the right direction.
- **Right-deep, sparse-dense-dense:** The outermost right pair is multiplied using sparse-sparse into dense multiplication (${}^{S}\times^{S}_{D}$). Then, the matrices on the left are consecutively multiplied with the right-hand dense intermediate result matrix using the sparse-dense into dense multiplication kernel (*spdd_gemm*, ${}^{S}\times^{D}_{D}$).

Both approaches use the same infrastructure as SpMachO. The reason why we chose exactly these two specific execution strategies is that either of them turned out to be good (or even optimal) for a reasonable large fraction of matrix chains. In particular, they yield good performance if the inter-matrix skew is low, i.e., the dimensions and the densities do not differ, since in these cases, the impact of parenthesization on the optimization is less significant. We also tried other alternatives to the dynamic programming approach of SpMachO, for example, a method that picks an execution plan based on the metaheuristic simulated annealing. However, due to the high dimensionality of the search space and the large discrepancy in the runtimes, it turned to be out to be far worse in most cases, hence, we did not include it in the measurements.

6.3.1 Data Set

Since there are currently no standardized benchmarks for large scale linear algebra expressions, it is generally difficult to provide a comprehensive performance comparison. Therefore, we created two performance experiments: first, we took real world-matrices of different domains and compared the execution runtime of self-multiplication chains (matrix powers). Thereafter, we generated random matrices of different dimension and density skews in order to study the systematic behavior of SpMachO.

Table 2: Sparse matrices of different dimensions and population densities. The $\rho = N_{nz}/(n \times n)$ value denotes the population density (rounded) of each matrix. All matrices are square ($n \times n$.)

Name	Matrix Domain	Dim.	N_{nz}	$\rho \cdot 10^2$ [%]
NCSM1	Nuclear Physics	3440	2.930 M	24.7
PWNET	Power Eng.	8140	2.017 M	3.0
JACO1	Econometric	9129	56 K	0.07

Tab. 2 lists the matrix data sets which we used in the evaluation. The first matrix NCSM1 is taken from a nuclear physics group, the other two (PWNET, JACO1) are from the Florida Sparse Matrix Collection[4].

In our prototype system, some of the multiplication kernels are implemented single-threaded, whereas other kernels have parallel implementations. Although we emphasize that the

[4]`http://www.cise.ufl.edu/research/sparse/matrices/`

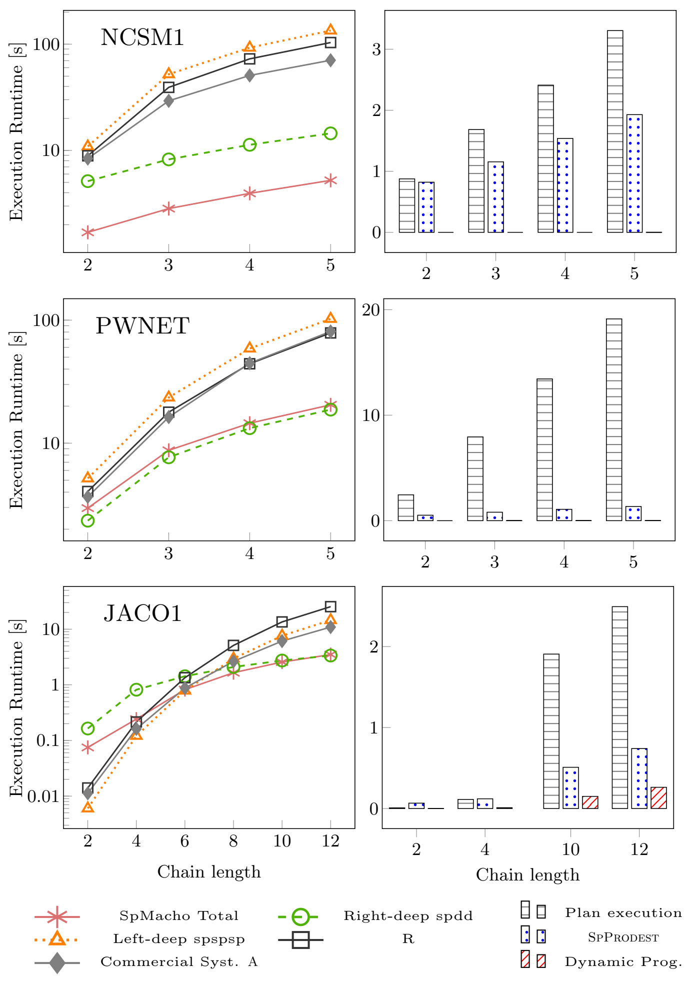

Figure 8: *Left Column*: Measurement of the execution runtime of sparse matrix chains (matrix powers). *Right*: The total runtime of SpMacho is visually separated into its components: the plan execution, the SpProdest runtime and the dynamic programming part.

conceptual execution plan optimization of SpMacho works orthogonal to the individual performance of the multiplication kernels, the absolute execution runtime does obviously also depend on the low level implementation of each algorithm. Hence, there is still potential to reduce the overall runtime further by switching completely to massively parallelized multiplication kernels. However, although we use mostly sequential kernels in the prototype, our algorithm was still able to outperform R and the commercial system A.

6.3.2 Self Multiplications

In this part we discuss the performance of matrix self multiplications (matrix powers), which is for example used for the calculation of Markov chains models.

The left column of Fig. 8 shows the absolute runtimes using SpMacho versus R, commercial system A, and the right-deep *spspsp* and left-deep *spdd* approaches. The first notion is that the relative performance speedup of SpMacho becomes more significant with increasing chain length. For matrices with a relatively high density, e.g. NCSM1, SpMacho outperforms the other systems even for a single multiplication already by several factors. In this case, SpMacho recognizes that it is worth to convert the matrix into dense representations prior to the multiplication. For the second matrix chain (PWNET), the performance gap is increasing with the chain length up to a speedup factor of five. Only in the third plot (JACO1), the overhead of SpMacho amortizes not before a chain length of four. In this relatively simple case of matrix self multiplications, the speedup is related to the density evolution of the intermediate results. When the matrix reaches a relatively high density in an early stage of the execution plan, SpMacho is likely to choose dense formats and proceed with dense multiplication kernels, whereas the use of sparse-only kernels will have a poor performance for every additional multiplication. That also explains why the right-deep *spdd_gemm* strategy is often optimal, e.g. for the PWNET matrix chain.

The right column in Fig. 8 shows the separate runtimes of each component of SpMacho, which are: the plan execution, the SpProdest runtime, and the dynamic programming loop. The runtime of the dynamic programming part is negligible and only visible for longer chains (10-12). Note that we the SpProdest cost can be further reduced, if we cache the density maps. As of now, they are created once prior to each expression execution, consuming most of SpProdest's runtime.

As a side note, the R and commercial system A runtimes show astonishing similarity with our left-deep *spspsp_gemm* approach. We assume that they use a similar way of execution.

6.3.3 Random Matrix Chains

In the next experiment, we used three different, randomly created matrices. Products of *three* matrices are very common in many applications, for example in algorithms that contain matrix factorizations.

In order to observe the systematic influence of the data skew on the execution runtime, we varied three skew dimensions: the matrix shape skew, the inter-matrix density skew and the matrix intra-density skew (as of section 6.1). For each skew dimension, we varied a parameter $\xi \in [0, 1]$ that quantifies the skew in a range from zero (no skew) to one (maximum skew). More precisely, the parameter dimensions $(m/n)_i$, ρ_i and the intra-density skews ξ_i, are randomly picked from a <*min*, *max*, *average*> distribution, where ξ corresponds to the deviation from the *average* value.

Since we created the matrices randomly for each skew parameter configuration, one single configuration can have various random instances, which results in a potentially large variety of different runtimes. This is reasoned by the fact that a skew in the matrices can affect the execution runtime in both directions – increasingly or decreasingly. Generally speaking, a large skew in the data can dramatically slow down naive execution approaches, but also reveals a large optimization potential for SpMacho by exploiting the skew. In contrast to the previous self-multiplication experiment, a skew in the matrices leads to a higher influence of the parenthesization, and the selection of storage representations and algorithms.

To be independent of particular random matrix instances, we repeated the measurement multiple times, hence, we took 25 different randomly created sparse matrix chains of length three per configuration. Fig. 9 shows for each skew configuration a box plot with the corresponding median, lower quartile,

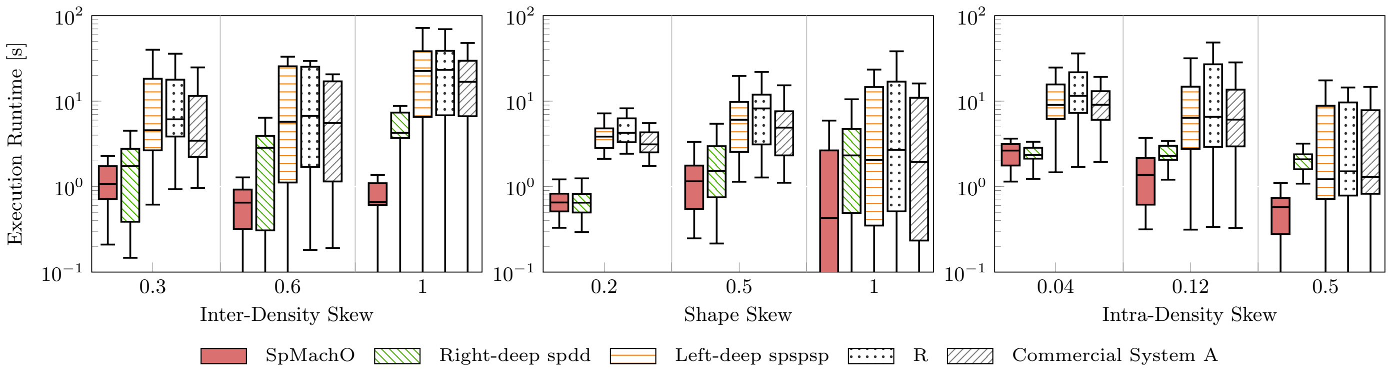

Figure 9: Average (log scale) runtime and variance comparison of SpMachO vs. the right-deep spdd and left-deep spspsp approaches, R, and the commercial system for a multiplication of the expression $\boldsymbol{A}_1 \cdot \boldsymbol{A}_2 \cdot \boldsymbol{A}_3$. We varied in x-direction: the inter-density skew (left), the shape skew (middle) and the intra-density skew (right). The bounding *<min,max,avg>* distributions for the data skew are *<0.001, 0.5, 0.025>* for matrix densities, and *<32, 16384, 3072>* for the matrix dimensions. The intra-density skew ξ was chosen according to Fig. 6 with values ranging from 0 to 0.5.

upper quartile and whiskers of the execution runtimes. Note that our measured runtime of SpMachO includes the time for the density estimation (SpProdest). We observe the following characteristics: First, for low skew parameters, both SpMachO and the right-deep spdd outperform the other approaches for most of the instances. For unskewed matrices, this underlines the result that we already obtained in the previous experiment for matrix chains with similar densities, i.e. that the right-deep spdd multiplication execution is optimal if intermediate results are rather dense. Second, and more interesting, is the development of the runtime distributions with higher data skews. In the inter-density skew experiment (left plot), the median execution time in R, the commercial system A and the left-deep spspsp approach increases, whereas the SpMachO median time stays low and gets even lower for $\xi = 1$. Moreover, the variance in time of SpMachO grows notably slower than these of the other systems. In the other two plots, we see a similar picture, although most of the median execution times decrease slightly in the shape skew experiment (middle plot), and more significantly in the intra-density skew experiment (right plot). Here, the increased intra-density skew leads in the majority of cases to a reduced execution runtime, which conforms to our notion. Still, in quite a few cases the runtime of the other systems explodes, leading to the observed high variance and scattering of the execution times. The right-deep spdd approach is more robust, but not optimal for high skews. In contrast, SpMachO is able to reveal the skew and exploit it for optimization. As a result, we observe that SpMachO has a by far better worst-case behavior than the established systems.

7. RELATED WORK

As this work has overlaps with multiple research areas, we subdivide the discussion into the major subtopics:

7.1 Optimization of Linear Algebra Expressions

Despite the optimization potential, we did not find that common numerical algebra systems optimize the execution of linear algebra expressions based on matrix sparsity and dimension characteristics. In contrast, the idea of optimizing linear algebra operations on system level has been mentioned in SystemML [14, 6], which describes a Hadoop-based machine-learning framework with an *R*-like declarative language. However, the cost model they describe in [6] is based on independent, one-dimensional scaling functions, and they assume full density ($\rho = 1$) for intermediate results. In [5] they mention that they optimize by assuming “independence with regard to the sparsity of intermediates”. In contrast, we observed that particularly in situations with large density differences (inter-density skew) the density of intermediate results influences the optimization significantly. Since simple models are unable to reconstruct the complicated runtime behaviour of matrix multiplication kernels, we also put our focus on accurate cost models from an algorithmic perspective. In addition, our cost analysis revealed that matrix dimensions and the matrix sparsity can not be regarded as independent parameters.

7.2 Matrix Chain Multiplication and Density Estimation

In contrast to dense matrix chain multiplication, which has been discussed thoroughly in the past decades, e.g. in [12, 16, 21], there is little work about sparse matrix chain multiplications. Interesting work that should be mentioned in this context is from Cohen [9, 10], who extended the dynamic programming approach idea to sparse matrices. In her work, she minimizes the overall number of floating point operations that are needed to compute the matrix chain product by predicting the non-zero structure for intermediate result matrices on row/column-level. The density prediction algorithm of [10] is based on random number propagation in a layered graph, and has a fixed complexity $\Theta(\sum N_{nz,i})$. However, as observed in section 2, the actual runtime cost of sparse matrix multiplication kernels are not just proportional to number of floating point operations. Moreover, coming from a real system perspective, we consider not only pure sparse-sparse matrix multiplications, but leverage sparse-dense transformations and the coexistence of sparse and dense matrices to optimize on a more complete level.

7.3 Join Optimization

The problem of sparse matrix chain multiplication is related to join enumeration and cardinality estimation in a relational database management system RDBMS. This connection is more obvious when sparse matrices are represented as $\langle row, col, val \rangle$ triple tables [20]. In fact, a multiplication can then be expressed as a join aggregation [3]. The use of dynamic programming in join optimization [25, 22] and join plan generation with respect to physical table properties [17] were inspiring for this work, as well as the use of multidimensional histograms [23] for the optimization of queries on multidimensional data. Although the mathematical characteristics of matrices and multiplications require a slightly different perspective, it is an interesting aspect that some of the ideas of relational join optimization can be used for linear algebra.

8. CONCLUSION

In times of emerging analytical and scientific databases, many systems [8, 6] started to deeply integrate linear algebra. This work shows that integrating linear algebra operations, such as matrix multiplications, is not just adding algorithms to the database engine. In fact, due to different matrix representations, algorithms, and the presence of data skew, we observed that a naive execution of sparse matrix products can be up to orders of magnitude slower than an optimized one.

In this paper we presented SpMachO, which optimizes sparse, dense and mixed matrix multiplications of arbitrary length, by creating an execution plan that consists of transformation and multiplication operators. By using detailed cost functions of different sparse, dense and mixed matrix multiplication kernels, SpMachO leads to a faster and more robust execution compared to widely used algebra systems. Moreover, our density prediction approach SpProdest with an entropy-based skew awareness enables accurate memory consumption and runtime estimates at each stage in the execution plan.

To put it in a nutshell, we showed how methods inspired from database technology can improve linear algebra computations, and took a step into the direction of taking complexity from data scientists – who should not be required to have profound knowledge about the connections between mathematical optimizations, matrix characteristics, algorithmic complexities and the hardware parameters of their system.

ABSTRACT

In this paper, we present a method for the efficient evaluation of threshold queries of derived fields for large numerical simulation datasets stored in a cluster of relational databases. The datasets produced by these simulations are in the TB and even PB ranges. Data-intensive computations that examine entire time-steps of the simulation data are impractical to perform locally by the user, taking days or months to iterate over the entire dataset. The integrated method for the evaluation of threshold queries that we have developed achieves scalability through data-parallel execution of the computations on the nodes of an analysis database cluster. We extend the scientific analysis environment with the introduction of an application-aware cache for query results, building on the concept of semantic caching. The cache has little overhead and improves query performance by over an order of magnitude for queries that hit the cache. Caching the results of threshold queries preserves both the I/O and computation effort used to obtain them. In the case of computational turbulence, this allows scientists to quickly focus on the most intense events and interesting regions in any time-step or the dataset as a whole, which greatly speeds up the rate of scientific exploration and discovery.

1. INTRODUCTION

Better instruments, faster and bigger supercomputers and easier collaboration and sharing of data in the sciences have introduced the need to manage increasingly large datasets. Data-intensive systems and architectures have been developed with the goal of storing and providing fast access to such datasets. Examples of such analysis environments include the GrayWulf and Data-Scope clusters [31, 10] at Johns Hopkins, which have capacity of 1.1PB and 11PB respectively. One of their missions is to provide persistent storage and public access to world-class numerical simulation data. These systems differ from the traditional HPC environments in that they aim to achieve high aggregate throughput by balancing computation capabilities with I/O and network bandwidth. The computing systems and services developed on top of these platforms are more than pure storage engines and usually have complex analysis routines built-in, which has largely been driven by the "move the computation to the data" paradigm [14]. These built-in analysis routines are most often not novel themselves. They implement core scientific functionality for the study of the particular scientific phenomena, which was observed or simulated in the first place. The analysis routines however require novel evaluation strategies and methods for their execution. They have to operate on large array datasets distributed across multiple nodes of a cluster of relational databases. In order to reduce their running times, they have to make efficient use of the cluster resources and incorporate leading data management techniques.

Finding the locations or regions of highest vorticity or those with the largest norms of the velocity or other fields of interest enables new insights in the study of fluid dynamics. Analysis of this kind coupled with the ability to analyze time-series datasets both forward and backward in time has transformed our understanding of turbulence [12]. Furthermore, threshold, top-k queries and similarity search in general are important in many different disciplines. We introduce an efficient evaluation strategy for threshold queries over time-series datasets stored in a cluster of relational databases. Our method evaluates not only threshold queries of the vector or scalar field data stored in the database, but also performs thresholding of *derived* fields.

The main challenge that our approach tackles is that the data-intensive computation of *derived* fields has to be carried out on-demand for extremely large array datasets stored in an analysis cluster environment comprised of multiple

10.5441/002/edbt.2015.27

database nodes. We focus on the evaluation of threshold queries of fields derived from the data stored in the cluster as these queries are the most interesting scientifically. However, our approach applies to the evaluation of top-k queries, rollup queries and data-reducing queries in general. The established data management techniques that our approach combines make the approach easy to understand. It can be applied to other scientific analysis environments, which manage large datasets in a database management system. Examples include the Sloan Digital Sky Survey [28], the Millennium Simulation [23] and the Open Connectome Project [6].

Evaluating threshold queries within the database cluster allows scientists with modest computational and network capability to narrow down on and examine some of the most interesting regions and features in the dataset and focus on the subsequent analysis needed to understand these events. It is impractical to materialize all possible derived fields and store them alongside the raw data due to the large size of the datasets and the limits of available storage. Obtaining the derived field and thresholding locally by the user requires not only the computation of the derived field over an entire time-step server-side but also the transfer of a large amount of data over the network, most of which are subsequently discarded. One of our collaborators reported that such a local evaluation of a threshold query over an entire time-step took over 20 hours. It would take months to iterate over the entire dataset. This highlighted the need for providing the capability through an integrated approach, which performs the evaluation server-side.

Database, operating and file system caches are effective at speeding up access to the large amounts of data stored on disk. However, this might not be sufficient for some applications, because these application-independent caches cannot exploit dataset-specific structure and application-level information [20]. Moreover, even if the data are available in one or more of these application-independent caches the computation associated with the derived field still needs to be performed for each point on the grid, because results of previous computations are not cached. We will demonstrate that an integrated approach, which computes the derived fields on-demand in a data-parallel manner, performs the evaluation over an entire time-step in a few minutes. Storing the query results in an application-aware semantic cache further reduces the running times to several seconds.

Thresholding allows scientists to obtain and examine the regions containing the most intense events and features in the dataset in the case of turbulence. These are often the locations that have the largest vorticity norms and have intense vortices or reconnection events. In magnetohydrodynamics, the locations of largest electric current are of great interest for similar reasons. It is important that threshold queries are evaluated in an efficient manner, because often further subsequent examination and analysis is required to understand the physics that drive these intense events.

There are several challenges that arise during the evaluation of threshold queries of derived fields in an analysis database cluster. The field variables have to be evaluated *on-demand* from the array data stored in the database cluster. The evaluations are data-intensive as they perform kernel computations on extremely large multidimensional array datasets. A kernel computation computes the value at a grid location using the data points at a set of neighboring locations. Kernel computations have to be performed at each location on the grid as opposed to at a particular number of target locations. The evaluation needs to be distributed across the nodes of the database cluster to avoid the unnecessary movement of data over the network and to achieve scalability. Techniques that target the traditional supercomputing environments do not translate directly to the distributed database setting of an analysis cluster environment.

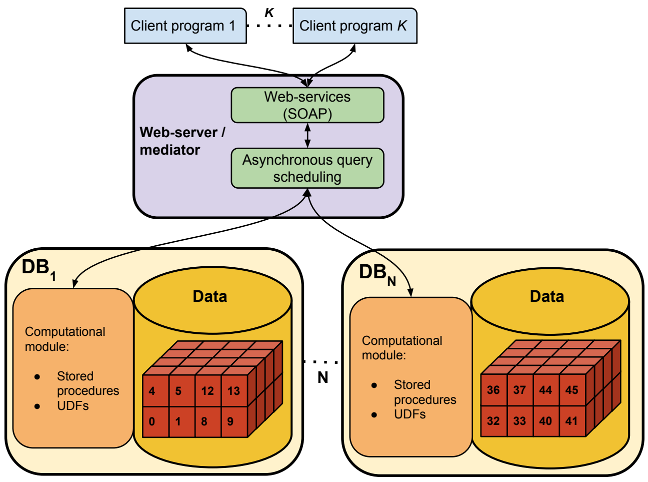

Figure 1: Architecture of the JHTDB.

We present a method for the efficient evaluation of threshold queries over fields derived from the raw vector or scalar fields of the numerical simulation stored in the database. Our method makes effective use of the cluster resources and achieves high throughput and scalability. We exploit the parallelism available in the cluster by means of data-parallel execution of the computations. We extend the database management system with an application-aware cache for query results. We build on the idea of an application-aware cache introduced by Lopez et al. [20] and more broadly on the concept of semantic caching [9]. Rather than caching just data as is the case in system caches and the tree-cache described by Lopez et al., we cache query results along with query metadata and subsequent queries are evaluated against the cache. This leads to query performance improvement of over an order of magnitude.

The contributions of this paper are the following:

- Computing derived fields of large simulation data on-demand and evaluating threshold queries on them at extreme scale. This provides large data analytics capabilities that examine entire time-steps of the simulation transparently to the user in a production analysis environment.
- Achieving this through the combination of existing data management techniques such as data parallelism and semantic caching as well as taking advantage of heterogeneous scientific cluster architectures (sharded relational DBMS with several SSDs per node).
- Evaluating the proposed method on data-intensive workloads in a live production environment and showing scalability results on datasets hundreds of terabytes in size.

2. JOHNS HOPKINS TURBULENCE DATABASES

Data-intensive architectures and compute clusters built from commodity hardware rely on parallel I/O to multiple disks and high network bandwidth to achieve high throughput. Such systems have only recently been deployed for the storage of large numerical simulation datasets. The virtual laboratories built on these systems make use of relational database system technology to store and manage large array datasets. Relational database systems however often do not support all of the functionality that scientists are interested in out of the box. It is either up to the user to develop more sophisticated analysis routines locally or such capabilities have to be built into the database through user-defined functions or stored procedures.

The method that we have developed for the evaluation of threshold queries of derived fields was deployed and integrated into the Johns Hopkins Turbulence Databases (JHTDB) [19, 26]. It solves a pressing problem in a production scientific analysis environment, which differs from the traditional supercomputing environments and provides large data analytics capabilities transparently to the public. The JHTDB, built on top of the GrayWulf and Data-Scope clusters, serves as a public virtual laboratory for the study of turbulent phenomena. The JHTDB stores several datasets, which are the output of high-resolution numerical simulations of turbulence. The 3d time-series data are partitioned into small subcubes and stored in relational databases distributed across the nodes of the cluster. Access to the data is provided by means of Web-services and a variety of analysis functions have been implemented and can be executed through Web-service calls (Fig. 1). At present the service hosts four datasets, which are available publicly. The data are the output of numerical simulations of forced isotropic turbulence, magnetohydrodynamics (MHD), channel flow turbulence and homogenous buoyancy driven turbulence. The total amount of space occupied by the datasets is over 230 TB.

The database nodes are part of the GrayWulf [31] and Data-Scope [10] clusters. Each node is running Windows Server 2008 and SQL Server 2008 R2. The data for each dataset reside on a regular three-dimensional spatial grid with the exception of the channel flow data, which has an irregular y dimension. The data are partitioned spatially across 4 to 8 database nodes, and each database node hosts one or more databases. We use the Morton z-order space-filling curve to distribute the data across nodes and databases [26]. Each time-step is spatially subdivided into database atoms, which are of size 8^3. Each such atom is indexed by the time-step, which it belongs to and by the Morton code of it's lower left corner. This combination of index and data forms a record in the database. Queries to the data and derived fields, such as derivatives and filtered quantities are evaluated through stored procedures or user-defined functions implemented in the Common Language Runtime (CLR) framework.

The Web-services are hosted on a front-end Web-server, which handles user requests and hosts the main Web-page portal. The Web-server acts as a mediator sending the users' requests to the database nodes and initiating their distributed evaluation. Each request is broken down into multiple parts based on the spatial layout of the data. Each part is asynchronously submitted for evaluation to the database which stores the data needed for the evaluation. The Web-server assembles the results from the distributed computation and sends them back to the client.

The JHTDB provides a variety of data-intensive analysis routines that are executed on the database nodes. These include interpolation, differentiation, particle tracking and spatial filtering. These tasks are often data-intensive and in order to leverage the capabilities of the cluster we have developed data-driven batch processing techniques for their evaluation [17, 16]. Most of these tasks usually operate on subsets of the space or a collection of individual target locations within a time-step.

In contrast, threshold and top-k queries usually have to examine the entire data volume of a time-step or a signification portion of it. Furthermore, the data product of threshold queries is much smaller in relation to the amount of data that need to be examined. This fact combined with the fact that subsequent queries can reuse previously computed results makes the query results suitable to caching.

3. SCIENTIFIC USE CASES

One of the applications of thresholding in turbulence is to find the locations of maximum vorticity in a particular time-step or the dataset as a whole. The locations of maximum vorticity are usually associated with the most intense vortices in the dataset and often have interesting and complex reconnection events associated with them. Once obtained from the service, these locations can be clustered in both 3d and 4d. This allows scientists to examine their evolution with the flow and make subsequent analysis queries as needed in order to study these events. The relationship between different "worms" (see Figure 3) that connect and reconnect at those locations is of the most interest.

The vorticity is computed from the velocity field by taking its curl:

$$\begin{aligned}\vec{\omega} = \vec{\nabla} \times \vec{v} &= \left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z}\right) \times (v_x, v_y, v_z) \\ &= \left(\frac{\partial v_z}{\partial y} - \frac{\partial v_y}{\partial z}, \frac{\partial v_x}{\partial z} - \frac{\partial v_z}{\partial x}, \frac{\partial v_y}{\partial x} - \frac{\partial v_x}{\partial y}\right). \qquad (1)\end{aligned}$$

We use finite differencing methods of different orders for the evaluation of the curl. For example, with 4th-order centered

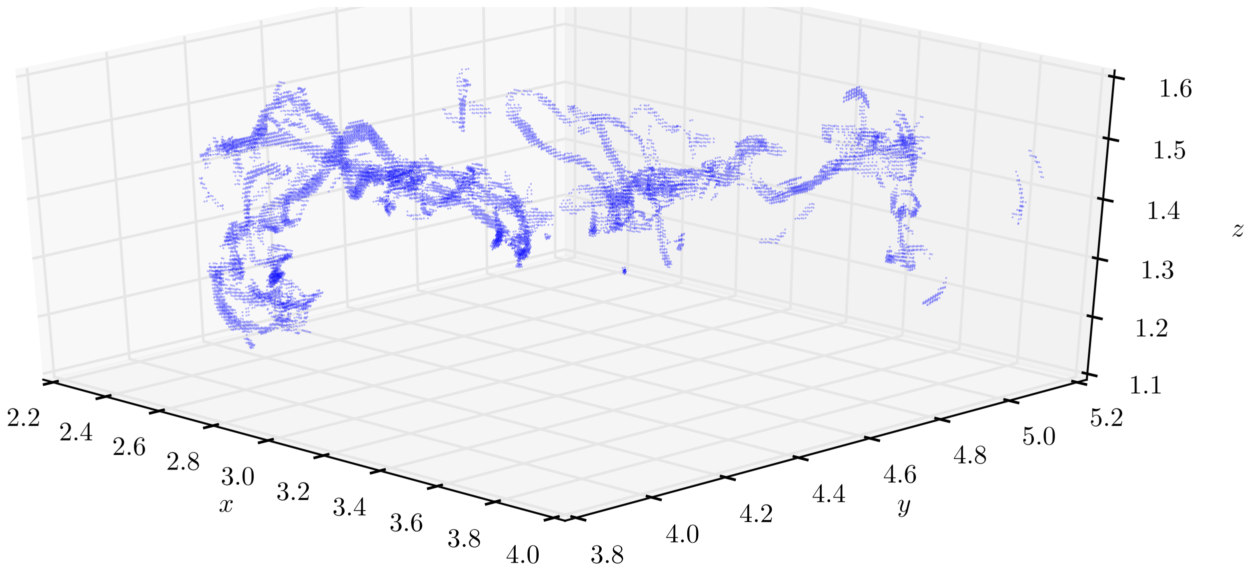

Figure 3: 3D (single time-step) cut through the 4D cluster containing the most intense event.

finite differencing each partial derivative is evaluated from the 4 adjacent grid node values as follows:

$$\left.\frac{df}{dx}\right|_{x_n} = \frac{2}{3\Delta x}[f(x_{n+1}) - f(x_{n-1})] - \frac{1}{12\Delta x}[f(x_{n+2}) - f(x_{n-2})], \qquad (2)$$

where f denotes any one of the three components of the velocity and Δx is the width of the grid in the x direction. The partial derivatives along y and z are computed in the same fashion. Figure 2 shows the distribution of the values of the norm of the vorticity field in the MHD dataset for a representative time-step. This is indicative of how the values are distributed in the dataset as a whole. This coarse view of the data can be used by scientists to guide the selection of threshold values.

Figure 3 shows the most intense event observed in the forced isotropic turbulence dataset. The locations of maximum vorticity in the dataset were clustered in this case in 4d using a friends-of-friends algorithm. It is interesting to note that the cluster containing the most intense event in the entire dataset develops from nothing (i.e. it does not appear in the first few time-steps) and it takes less than the timespan stored in the database for it to develop. Figure 3 also shows that most interactions between worms are not simple. There are several worms interacting in a complex way at the same time. Similar type of analysis and the fact that the entire time history of the simulation is available in a database cluster, which provides built-in sophisticated analysis routines revealed flux-freezing breakdown in MHD turbulence [12], showing why solar flares last minutes rather than the millions of years that conventional theory would predict.

In addition to obtaining the regions of largest vorticity, there is substantial interest in studying the regions with highest values for other fields, such as the second and third velocity gradient invariants (Q and R). These invariants are scalar quantities whose values contain information about the topology of the flow and the rates of vortex stretching and rotation. In MHD, finding the locations with largest values for the electric current can lead to new insights into the development of the most intense reconnection events of magnetic field sheets in the simulated plasma. Similarly to the vorticity, the electric current is derived from the magnetic field by taking its curl. The list of fields of interest, on which scientists would like to perform threshold queries certainly does not stop here and is indicative of how valuable this functionality is in the study of turbulence and fluid dynamics.

4. THRESHOLD QUERY EVALUATION

Threshold queries of derived fields submitted to the JHTDB are evaluated using a data-parallel execution strategy and the query results are cached in an application-aware semantic cache. In addition to query results, the cache stores their semantic descriptions and query metadata and parameters used to obtain them. The evaluation strategy for queries that do not hit the cache is driven by the spatial partitioning of the data across the nodes of the cluster.

Derived fields computation: The databases store only the raw field data from the simulation (e.g. velocity, pressure, magnetic field etc.). However, the threshold queries of most interest to science users produce all locations where the values of a *derived* field are above a given threshold. Thus, the derived field in question has to be computed from the raw data first. For most derived fields of interest, this computation has local support. It has an associated localized kernel of computation around each grid node. Therefore, the value of the derived field at each grid node depends on the value of the stored field at all of the grid locations, which are part of the kernel of computation.

Distributed data-parallel execution: In most cases threshold queries operate over an entire time-step. Each such query is subdivided by the mediator into queries submitted to each of the database nodes. Each node evaluates the query over the data that it has stored locally. Only a

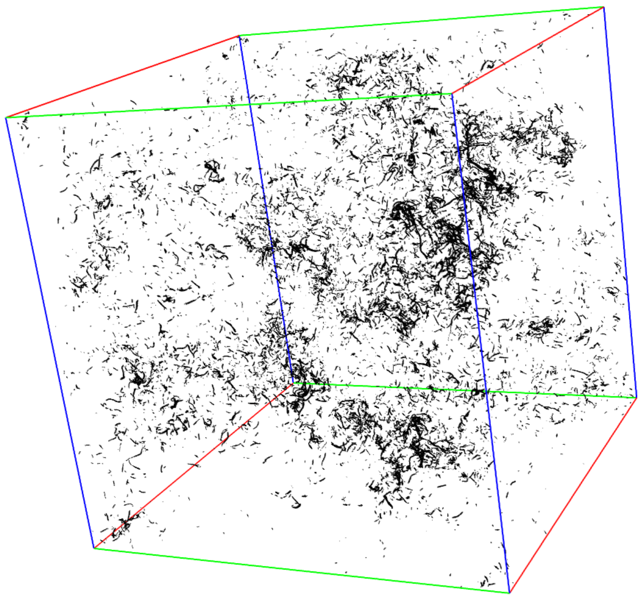

Figure 4: Points with values above 7 times the root mean square value of the vorticity for a single time-step.

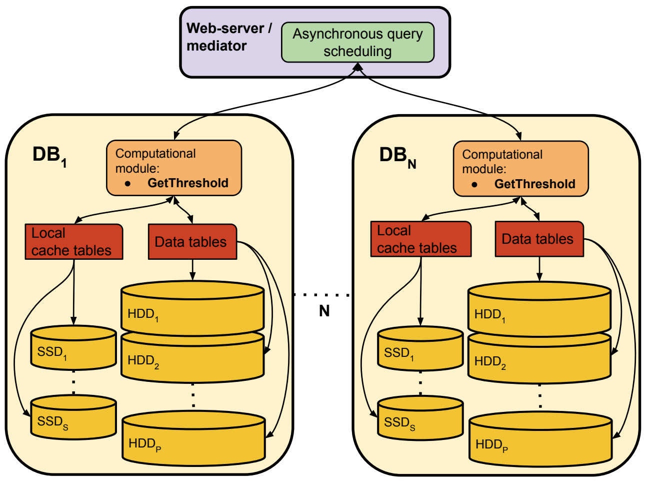

Figure 5: Distributed evaluation of threshold queries and architecture of the application-aware cache. Each database node has local cache tables, which reside on solid-state drives attached to the node.

small amount of data along the boundary need to be requested from adjacent nodes. The size of the band of data that may not be available locally is equal to a kernel half-width. Such a band is needed on each of the sides of the box forming the domain of the computation. The data are read into memory and the particular field requested is computed at each of the locations on the grid. The same strategy applies when utilizing multiple processes per node. The norm or absolute value of the derived field at each location is compared against the specified threshold and if the value is higher, it is maintained along with the spatial coordinates of the location in a list.

We impose a limit on the maximum number of locations that can be returned as a result of a threshold query in order to prevent having to return the entire time-step or a significant fraction of it for queries with thresholds that are set too low. Currently this limit is set conservatively to 10^6 locations, which is sufficient to examine a time-step in detail. In the case of the vorticity, the values above 8 times the root mean square value, which is about 25% of the maximum, are contained within 2.6×10^5 points in each time-step. Figure 4 shows all the points in a single time-step with values above 7 times the root mean square value. There are 2.4×10^5 points in the figure. Given that we are interested in extreme events, obtaining the locations with values even within 50% of the maximum would be sufficient. At the same time this also limits the amount of data that have to be returned to the user over the network as well as the amount of data that have to be cached. Users receive an error message notifying them if their request has a threshold that is set too low. If a user is interested in obtaining more data he or she can request the values of the derived field directly. Alternatively, if they are interested in the density distribution of values they can examine the probability density function (e.g. Fig. 2), which is computed using a similar strategy to threshold queries.

Application-aware cache for query results: A central part of the evaluation strategy for threshold queries that we have developed is the introduction of an application-aware cache for query results (Fig. 5). The results of these queries are small compared to the amount of data that need to be examined and the results can be used to answer subsequent queries as long as they are within the same region and specify the same or higher threshold. Each database node has a local cache. Cache entries are indexed by the field, time-step, spatial region and the threshold requested. We use a least recently used cache replacement policy. All modifications of and queries to the cache are executed within a transaction with snapshot isolation level to avoid dirty-reads or an inconsistent view of the cache.

Caching the query results preserves the computational effort in addition to substantially reducing I/O. The cached data are for the particular derived field that was queried and not the raw data of the simulation fields. Thus, we do not have to derive the requested field from the raw data for queries that hit the cache. This results in a substantial improvement in query performance as we only have to scan a small set of data and do not need to perform any additional computation.

Not all query results are suitable to caching. Most of the queries submitted to the JHTDB other than threshold queries request data at a collection of target locations. Given that there are 1024^4 possible locations for three of the datasets and $6 * 1024^4$ locations for the channel-flow dataset the chance of reuse for the results of these queries is extremely small. This is why the cache currently stores only the results of threshold queries. Nevertheless, it can easily be extended to cache the results of other query types as well if that becomes advantageous.

The cached query results are stored in a table in the database and the overall size of the cache is limited by the amount of available SSD disk space, not memory. Given a limit of $\sim 10^6$ points per time-step for a threshold query, the space required to cache the maximum number of points including the index space and database overhead is ∼40MB. Therefore for a dataset containing 1024 time-steps, as is the case for the isotropic turbulence and MHD datasets part of the JHTDB, a cache size of 40GB is sufficient to cache the query results for threshold queries of a derived field over the entire dataset. The currently available SSD disk space per node is ∼200GB, which will be sufficient to maintain the threshold results for nearly five derived fields over the entire dataset. In contrast, computing and materializing a scalar derived field for the entire dataset would require ∼5TB (15TB for vector fields).

Algorithm 1 Get points above threshold using cache

```
Require: Dataset $d$, Field $f$, Timestep $t$, Threshold $k$,
    Query box $q = [x_l, y_l, z_l, x_u, y_u, z_u]$
 1: procedure GetThreshold

25:         end if
26:     else
27:         $updateCache \leftarrow true$
28:     end if
29:     if $updateCache$ then
30:         Retrieve data covering $q$ from DB.
31:         for all $p \in q$ do
32:             Compute $f$ at $p$.
33:             if $\|f(p)\| \geq k$ then
34:                 $points.Add(new\ Point(p, \|f(p)\|))$
35:             end if
36:         end for
37:         Update cacheInfo and cacheData tables.
38:     end if
39:     return $points$
40: end procedure
```

The entire cache is comprised of two database tables. The *cacheInfo* table stores metadata for the cached entries. It stores information about the dataset, field, time-step, start and end coordinates of the spatial region examined and the threshold value used. The *cacheData* table stores the locations of all of the grid points, for which the field queried has a norm higher than the specified threshold. The *cacheData* table is foreign key constrained with the ordinal of the *cacheInfo* table. This allows us to quickly find a record in the *cacheInfo* table and retrieve all of the cached entries using an index lookup.

Overall execution of threshold queries: Algorithm 1 illustrates the process of obtaining all points with norms of the specified field above the given threshold from the database in the presence of a cache. The mediator submits a query to each of the database nodes storing the raw data asynchronously. Each node begins evaluation of the query by executing Algorithm 1. First a cache lookup is performed. If the data for the requested field, time-step and spatial region are available in the cache and if the specified threshold is higher than the one stored in the cache the query can be answered from there. The records are retrieved from the cache and the ones that have a higher value are returned to the mediator and subsequently back to the user. If the data stored in the cache have a higher threshold than the one requested the cache needs to be updated. Similarly, if the cache does not have an entry for the specified parameters the query needs to be evaluated from the raw data. In those cases the raw data are read into memory with data along the boundary requested from adjacent nodes as needed. The specified field is derived at each location on the grid and the norm or absolute value of the field is compared against the threshold. The locations where the values are higher than the threshold need to then be stored in the cache. If the cache does not have enough space for the new records, space is freed up by removing the least recently used data across all quantities. Reading from, updating or modifying the cache is done within a transaction with snapshot isolation level. Snapshot isolation allows us to avoid locking the tables that serve as the cache for each transaction. This provides for a higher degree of parallelism and avoids any potential deadlocks from queries running in parallel.

5. EXPERIMENTAL RESULTS

We evaluate the developed method for the execution of threshold queries to large numerical simulation datasets with the goal of analyzing the benefits and overhead from the introduction of the application-aware cache. We also analyze the scaling properties of the method. Finally, we show that an integrated method that performs the evaluation on the database nodes near the data is several orders of magnitude faster than the user requesting the derived filed of interest from the database and evaluating the threshold locally.

5.1 Experimental Setup

The experiments were run on the production database nodes of the JHTDB through a development Web-server hosting the Web-services. We used the MHD dataset (Sec. 2) for the experimental runs. This dataset is partitioned across 4 database nodes according to spatial regions in the Morton z-order. The database nodes are 2.66 GHz dual quad-core Windows 2008 servers with SQL Server 2008 R2 and 24 GB of memory. Each node has 24 2TB SATA disks arranged as a set of four RAID-5 arrays. The database files are striped across the nodes and their associated disk arrays. The tables storing the data are partitioned spatially along

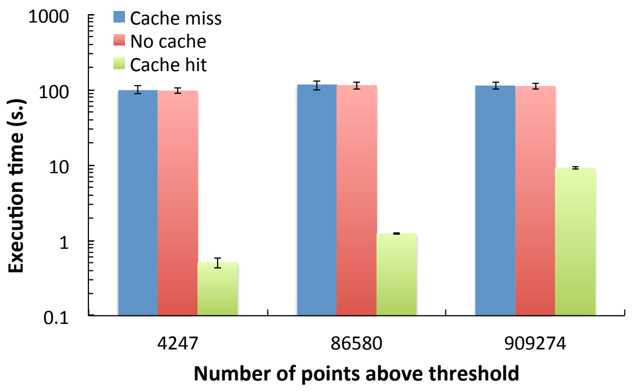

Figure 6: Execution time for threshold queries at different threshold levels compared with the execution time of the same queries in the absence of a cache.

contiguous ranges of the Morton z-curve and the data for each partition reside in one database file.

For this evaluation we looked at the performance of threshold queries to the vorticity field. The vorticity field is representative of derived fields that have to be computed from the stored data. It is defined as the curl of the velocity field. As described in section 3 thresholding the vorticity field is important in the study of fluid dynamics and obtaining the locations of maximum vorticity can lead to new insights into the development of the most intense vortices observed in the dataset.

5.2 Evaluation of cache effectiveness

The central part of the strategy that we have developed for the evaluation of threshold queries of derived fields is the application-aware cache, which stores the results of these queries. We first evaluate the overhead associated with the introduction and maintenance of the cache. Figure 6 compares the execution time of queries in the absence of a cache with the execution time of the same queries, which interrogate the cache first (blue and red bars in the figure). The execution times are also shown in Table 1. For these experiments we requested the locations with norms of the vorticity above thresholds at different levels. We refer the reader to Figure 2, which shows the distribution of values of the norm of the vorticity field in the MHD dataset to get an appreciation of the different threshold values used in the experiments. For the first set the threshold was set high (80.0) and only ∼4,300 points (or 0.0004% of all points) were above the threshold. For the second set a medium threshold (60.0) was chosen and ∼87,000 points (or 0.0081% of all points) were above the threshold. Finally, a low threshold (44.0) was chosen for the last set and there were ∼900,000 points (or 0.0847% of all points) above the threshold. For each set a random time-step was chosen and the queries were run against that time-step. The measurements were taken from the point of view of the end user.

As we can see from the results shown in Figure 6 the overhead associated with querying the cache first is minimal, less than 3% and within the margin of error. The cache was initially populated by executing several hundred unrelated queries and contained several million entries. During the "cache-miss" runs cache entries for the particular time-step queried were dropped before each run, making sure that each query would produce a cache miss and would have to be evaluated from the raw data. The execution times were averaged over 10 runs. We utilized 4 processes per database node for the evaluation of each query. The method shows stable running time across different time-steps and threshold levels in the absence of a cache and during cache misses. The running time increases slightly only because of the larger result set that has to be returned to the user.

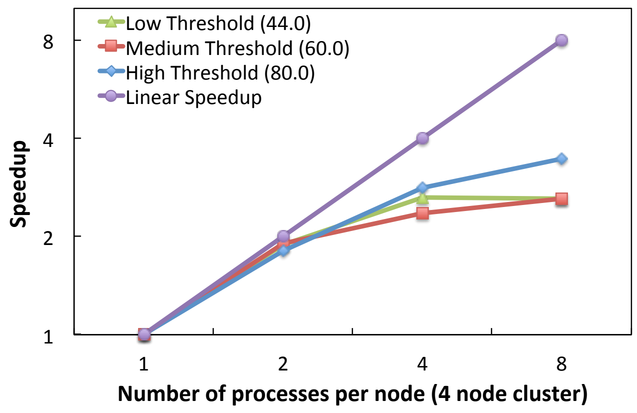
Vorticity threshold	Points above threshold	Average Running time (s.)		
		No cache	With cache (miss)	With cache (hit)
80.0	4247	97.1	100.2	0.5
60.0	86580	113.7	115.9	1.2
44.0	909274	111.6	115.0	9.1

Table 1: Effectiveness of caching.

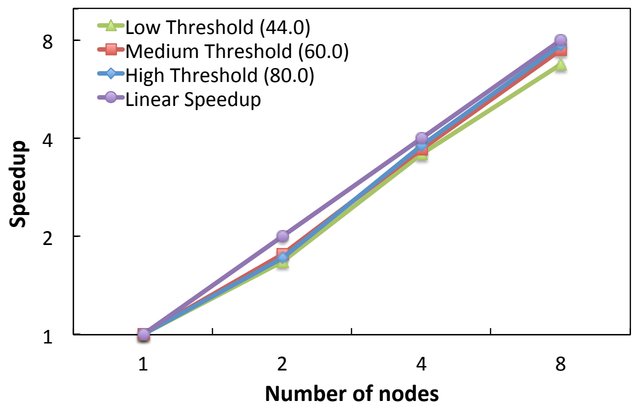
Cache hits reduce the running time of threshold queries by over an order of magnitude as shown in Figure 6 and Table 1. This is because we do not have to compute the requested derived field from the raw data, which eliminates the associated I/O. Only the cache entries need to be looked-up, which is substantially less data than the raw vector or scalar field data. For the queries with large result sets it is actually the network time taken to transfer the results to the user that dominates the overall execution as opposed to the I/O or computation time as we show later. Cache hits are evaluated by first warming up the cache by submitting the same set of threshold queries of the vorticity field as before. We then submit several more unrelated queries with different time-steps and threshold values in order to pollute the cache. Finally, we issue the original set of queries and measure their running times. Let us focus on the query with low threshold, which returns ∼900,000 points. Given that valid threshold values are limited to those that result in no more than 1,000,000 points it is likely that all subsequent queries to this time-step will result in a cache hit as their threshold is likely to be equal or higher than the cached one. Currently we observe fairly high cache-hit ratios as the workload is very structured and queries tend to examine the same regions in space and time.

5.3 Scaling and Distributed Evaluation

The evaluation of threshold queries of derived fields from the raw data is both I/O and computationally bound. These queries examine the entire data volume of a simulation time-step and are, therefore, good candidates for a data-parallel distributed evaluation. Our data-parallel implementation exhibits good vertical and nearly ideal horizontal scaling as shown in Figure 7. For the scale-up experiments (Fig. 7(a)), we used the same queries and threshold values as for the runs shown in Figure 6 and Table 1 but with varying number of processes per node. Cache entries for the time-step queried were again dropped before each run in order to evaluate the scaling properties of the computation of the derived field from the stored data. The computations for all of the derived fields of interest (such as the vorticity) at each grid point need data from adjacent grid points only. Therefore, each node of the cluster is able to compute the derived field



(a) Scale-up with multiple processes per node



(b) Scale-out to multiple nodes

Figure 7: Execution time for threshold queries at different threshold levels – high, medium and low. The scale-up evaluation was performed utilizing 1-8 processes per server on a 4-node cluster. The scale-out evaluation was performed on 1 through 8 nodes.

from data available locally with only a small amount along the boundary of each region having to be retrieved from adjacent nodes. Each computation is independent and embarrassingly parallel. This allows us to make use of multiple processes per node and scale out to multiple database nodes.

We observe nearly a two times speedup when going from a single process per node to two processes per node (Fig. 7(a)). The speedup diminishes to 1.4 times when going to 4 processes and little speedup is observed with 8 processes per node. While the computation time scales with increased process count, the time to perform I/O does not as the data on each node reside in the same database table and on the same set of disks. Additionally, I/O redundancy increases as the process count increases as data along the boundary of each region are requested by multiple processes. SQL Server already utilizes parallelism to perform the I/O even when data are retrieved utilizing a single query. Finally, the experiments were run on the live production database nodes, which were also servicing other user queries in addition to operating system and other SQL Server processes. Nevertheless, running with 4 processes per node is nearly 2.6 times faster when compared to running with a single process.

The scale-out experiments show a nearly perfect linear speedup as the evaluation is distributed to an increasing number of database nodes (Fig. 7(b)). For these experiments we issued queries with the same threshold levels as before to a cold cache. We utilized a single process per database node to evaluate the horizontal scaling of the computation. The evaluation benefits not only from the additional computational resources with the addition of database nodes to the cluster but also from the increased memory size. The data needed for the computation of each derived field are read into memory and the larger memory size means that there is less contention with other system and application processes and it is less likely that virtual memory needs to be used. SQL Server also benefits from a larger buffer pool, which reduces the I/O time.

As expected, we observe even weaker speedup when the queries perform nothing but I/O and the number of processes per node is increased. Figure 8 compares the running time of the queries with a medium threshold and executed

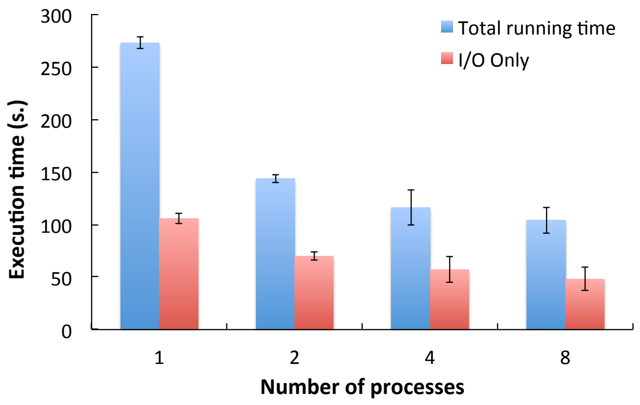


Figure 8: Execution time for threshold queries evaluated utilizing different number of processes per server compared with the time taken to perform the I/O only.

with varying number of processes per node with the time taken to perform the I/O only. The I/O time is about half of the total running time for these queries. SQL Server already makes use of parallelism internally and the data have to be retrieved from the same set of disks. Nevertheless, the I/O time does decrease with additional processes, this is because the data reside in a partitioned table and the data in each partition are placed in a separate file on one of the disk arrays. Depending on how the data requests are scheduled in SQL Server this allows for the disks arrays to be driven in parallel. Additionally, with more processes per node the data can also be consumed faster. It is worth noting that the total running time for the queries evaluated with 4 or 8 processes is about the same as the time it takes to perform the I/O only with a single process.

So far we have presented the effectiveness of evaluating threshold queries of derived fields on the database cluster storing the raw simulation data. The data-parallel computation of the derived fields allows us to evaluate a threshold

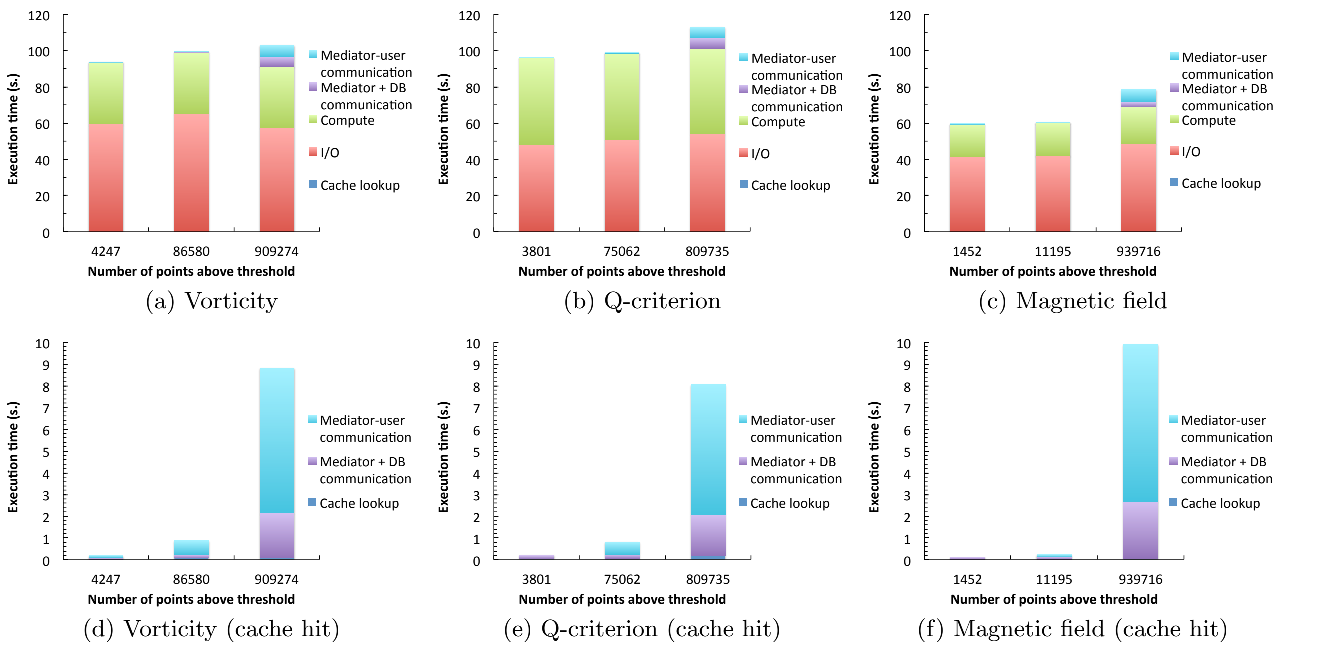

Figure 9: Breakdown of the execution time for threshold queries requesting different fields and at different threshold levels – high, medium and low.

query over an entire 1024^3 time-step part of a 20TB dataset in less than two minutes. The introduction of an application-aware cache for the query results of these queries reduces this time to several seconds when there is a cache hit. In contrast, one of our science collaborators reported that his evaluation of this functionality performed locally would take over 20 hours to complete. To perform the evaluation locally the user requests the derived field of interest from the database by submitting multiple queries over subregions of a time-step. This is necessary as requesting a derived field over an entire time-step will overload the network. Derived fields may have even more components than the scalar or vector field stored in the database. For example, the velocity gradient (needed for the computation of the vorticity) has 9 components compared with the 3 components of the velocity. Given a single-precision floating-point representation, this makes the velocity gradient of an entire time-step at least 36GB in size. A Web-service request will be much larger due to the overhead of wrapping the data in an xml format. After the field of interest is obtained locally the user has to threshold it to get the final result, which is reasonably fast, but discards most of the data that have been requested to yield a small in size result.

5.4 Evaluation of Additional Fields

The data-parallel evaluation of threshold queries shows stable execution time for different derived fields in addition to the different threshold levels and time-steps queried. The execution times depend on the complexity of the computation needed to evaluate the particular derived field requested. Figures 9(a), 9(b) and 9(c) show a breakdown of the execution time of threshold queries of different derived fields, which are evaluated from the raw data and a cold cache using 4 processes per node on a 4 node cluster. Almost the entire time is spent performing the I/O and computation associated with the derived field requested.

The vorticity field and the Q-criterion have similar I/O requirements as they have the same kernels of computation and are both derived from the velocity gradient. The vorticity has 3 components and its computation only examines 6 of the 9 components of the velocity gradient, which are also examined in pairs (see Eq. 1). On the other hand, even though the Q-criterion is a scalar value, it is computed through a non-linear combination of all 9 of the components of the velocity gradient. This means that the velocity gradient has to be computed at each grid location before the Q-criterion is evaluated, which is reflected in the increased computation time that we observe for the Q-criterion. The magnetic field is one of the raw fields of the magnetohydrodynamics dataset that are stored in the database. Therefore, there is no additional computation needed to derive it from the data, every data point has to be simply compared with the threshold level specified. This is why the computation time is much smaller compared to the queries for the vorticity and the Q-criterion. The I/O time for the magnetic field is also smaller. This is because its kernel of computation is a single point and therefore there are no additional data along the boundary that have to be requested from adjacent nodes. In that case all of the data needed are available locally for each database node.

In all of these cases, the time taken to interrogate the cache is negligible. The mediator time to distribute the queries and assemble the results as well as the time to transfer them to the user are also substantially smaller than the I/O and computation times. As expected they increase proportionally to the number of points in the result set.

It is interesting to note that the time taken to perform a cache lookup is relatively small even in the case of a cache hit as can be seen in Figures 9(d), 9(e) and 9(f). This is because the cache tables reside on SSDs attached to each database node (see Fig. 5) and retrieving the data is always done through a clustered index lookup. In the cases of a cache hit, the majority of the time is spent simply transferring the results from the database nodes to the mediator and then back to the user. These times remain more or less constant between the cases of cache misses and cache hits (top row and bottom row of Fig. 9). Caching the results of threshold queries effectively preserves the I/O and computational effort spent during their initial evaluation and results in over an order of magnitude speedup for all the different fields requested as we can see in Figure 9.

6. RELATED WORK

Only select few database systems offer support for arrays as first-class citizens. Even fewer provide the fault-tolerance, scalability and availability guarantees necessary for a system managing multi-terabyte datasets in a production setting. This is part of the reason why we have chosen to represent the array data in the JHTDB as a collection of binary large objects in a relational DBMS and perform the array manipulation tasks necessary at the application level. The systems that provide support for arrays and aim to handle large array data efficiently are RasDaMan [5], SciDB [30] and MonetDB/SciQL [34]. RasDaMan partitions raster objects into tiles, which are stored in a traditional relational database system. This approach is similar to how the numerical simulation data are handled in the JHTDB. RasDaMan provides RasQL [4], which is a SQL-92 based query language for the manipulation of raster images. SciDB is an array database system build from the ground up. Array attributes are partitioned vertically and each attribute array is decomposed into overlapping chunks. SciDB provides a declarative Array Query Language (AQL) and an Array Functional Language (AFL). Users can create arrays with named dimensions with AQL and make use of the functional operators defined in AFL, such as SLICE, SUBSAMPLE, SJOIN, FILTER and APPLY. SciQL's focus is on language design and integration with SQL:2003 syntax and semantics. It is implemented within the MonetDB framework [24].

Database systems support rollup queries, including top-k queries, but in most cases these queries apply only simple linear score functions on the attribute values of individual records. Additionally, many top-k query evaluation techniques rely on the score functions being monotone in order to perform early pruning (see [15] for a survey of top-k evaluation strategies). This is an assumption that we cannot make for the functions used to compute all the different possible derived fields of interest in fluid mechanics. Even approaches that aim to work with general score functions [11, 33] assume that the function operates on the attributes of a single record. In contrast, our approach performs a kernel computation at each grid location in order to obtain the value of a *derived* field at that location and examines the vector or scalar array data at all neighboring locations, which are within the kernel of the computation. The functions used to derive the field may even be non-linear. Finally, a top-k approach may not be suitable in the cases where scientists are interested in performing threshold queries at different time-steps as the same threshold level will produce different number of points in the result set for different time-steps.

The processing of top-k queries has been studied extensively in the context of distributed and relational database systems. A survey of different techniques in the case of centralized processing is given in [15]. In the case of distributed processing different approaches focus on horizontally [3, 32] or vertically [7, 8, 13, 21, 22] distributed data. None of these approaches deal with array data stored in a relational database system. Zhao et al. propose an algorithm for the processing of top-k queries in large-scale distributed environments called BRANCA [35]. They build on the idea of semantic caching [27] and make use of branch caches, which store results of previous top-k queries with respect to the data stored on each server. The caching mechanism that we use is similar in that regard, but the queries that are evaluated in our system operate on derived fields, which are computed at each location by accessing data from a surrounding region. The queries described in [35] operate over the attributes of individual records only using simple linear score functions.

Aßfalg et al. introduce the concept of threshold queries in time-series databases [2]. Their definition of threshold queries differs from the threshold queries described in this paper. They are concerned with determining the time-series, which exceed a user-defined threshold at time frames similar to the time-series specified in the query. Thus, their definition of threshold queries is concerned with the temporal relationship between the time-series stored in the database (usually one dimensional sequence of measurements) and the time-series given in the query. In contrast, our approach focuses on reporting all of the spatial locations of a multidimensional field where the norm or absolute value of the field exceeds a user prescribed threshold.

In a system called the tree cache, Lopez et al. [20] make use of a small application-aware cache to reduce access time to large datasets stored on disk. The tree cache stores individual octants of octree datasets and exploits application-specific information to determine which octants to cache and to perform query reordering. This work has inspired the use of an application-aware cache for the evaluation of threshold queries. In contrast to the tree cache, we do not cache raw data objects, but rather query results. Caching query results preserves the computational effort in addition to reducing I/O, which has a much bigger impact on query performance and substantially reduces the size of the cache. Additionally, the cache that we introduce resides on disk rather than in memory, which greatly increases its potential size. Lopez et al. also explore approximate querying through aggregation, which can be fairly easily supported by our system but is of limited use as scientists performing threshold queries are usually interested in obtaining the exact locations where a field is at its highest values.

Sampling approaches [29, 25] offer an alternative to the on-demand computation of derived fields and the evaluation of threshold queries on them. The goal of both techniques is to not return large data volumes, but focus on the most intense events and interesting regions in the dataset. The computation of derived fields is carried out on the nodes of the database cluster and takes a look at the dataset as a whole, while the user obtains only a small subset of the data, where the derived field in question is above the prescribed threshold. Sampling approaches can potentially omit some locations and while useful for generating initial impressions may not be suitable if the exact locations where a field is at its highest values are desired.

Andrade et al. [1] describe a database system and an optimization framework build on the concept of *active se-*

mantic caching. An active semantic cache aims to fully or partially reuse cached query results or aggregates through automated transformations of these aggregates. Similarly to our work they focus on real scientific data-analysis applications. The method that we have developed for the evaluation of threshold queries complements the active semantic caching approach and could be used in that framework. Our work has focused on extending a relational database system (Microsoft's SQL Server) as opposed to designing a new database system from the ground up as described by Andrade et al. [1].

7. CONCLUSIONS AND FUTURE WORK

We have presented an efficient strategy for the evaluation of threshold queries of derived fields in large numerical simulation datasets. The thresholded fields are derived from the stored simulation data in a distributed data-parallel manner. The computations scale with the cluster resources and are performed on the database nodes, where the data are stored. This new capability allows researches to quickly obtain and focus on regions of special interest even if they lack the computing capabilities or data transfer rates necessary to examine entire time-steps or large parts of the entire dataset.

We have introduced an application-aware cache for the query results of threshold queries. Cache hits reduce query running times by over an order of magnitude. The cache adds minimal overhead during the evaluation of queries even if there is a cache miss and has modest storage requirements. The cache is represented as a set of database tables and resides on disk rather than in memory. Each database node has local cache tables, which allows the cache to scale-out as the cluster grows.

The introduction of an application-aware cache for query results lays the groundwork for the creation of a landmark database. Such a database can store the locations of the highest vorticity regions in the dataset or more broadly regions of interest and their associated statistics.

The Web-services approach to archived numerical simulation datasets provides public access to high quality simulation data to anyone with an internet connection. The Web-services methods can be called from any modern programming language and we provide C, Fortran and Matlab client libraries for the JHTDB. The evaluation of each query submitted through a Web-service call is carried out on the nodes of the database cluster by means of a stored procedure or a user-defined function that has been implemented and deployed to handle these requests. This allows us to fine-tune the execution of these procedures and handle all requests transparently to the user. However, this approach also has drawbacks. Adding new functionality means adding to a long list of Web-service calls and requires substantial implementation effort. In the case of threshold queries the stored procedure performing the evaluation must have an implementation for each derived field of interest even though the execution is handled by the same Web-service call.

In the future, we plan to develop declarative and graphical user interfaces that will allow users to combine existing building blocks and perform computations that have not been explicitly implemented. Additionally, we plan on deploying a server-side computing environment for users similar to the CasJobs service for the Sloan Digital Sky Survery [18]. In such an environment users can run queries in batch mode and save their results in a personal database called MyDB, which resides on the servers near the data. This will allow for much greater flexibility in the type of computations that can be performed in addition to substantially decreasing the network overhead.

ABSTRACT

In this paper, we consider large graphs that evolve over time, such as graphs that model social networks. Given two instances of the graph at two points in time, we ask to identify the top pairs of nodes whose shortest path distance has decreased the most. We call these pairs *converging*. The straightforward way to address this problem is by computing the shortest path distances of all pairs at both instances and keeping the ones with the largest differences. Since for large networks this is computationally infeasible, we consider a budgeted version of the problem, where given a fixed budget of single-source shortest path computations, we seek to identify nodes that participate in as many converging pairs as possible. We evaluate a number of different approaches for our problem, that employ centrality-based, dispersion-based, and landmark-based distance estimation metrics. We also consider a classification-based approach that builds a classifier that combines the above features for predicting whether a node participates in one of the top converging pairs. We present experimental results using real-world datasets that show that we are able to identify the large majority of the top converging pairs on a very small budget.

1. INTRODUCTION

A variety of natural or man-made complex systems can be modeled as networks. Prominent examples include the Internet, the Web, transportation networks, online social networks such as Facebook, Twitter and LinkedIn, biological systems such as protein interactions or metabolic pathways, the global economy, and many more. All these systems consist of individual entities that are interconnected to form a complex system. Understanding them is not possible without understanding the underlying network. The network carries a significant amount of information about the functionality of the system as a whole as well as for its individual entities [9].

A central piece of information revealed through the network is that of *proximity*. Using the network structure, we can determine how close two individuals are in a social network, or how easy it is to navigate between different web pages. There are several ways of measuring proximity, or similarity, within the network (see, for example [6] for a recent survey). A commonly used proximity measure is the length of the shortest path distance between two nodes in the graph. Although simple, the shortest path distance is still the first notion of proximity we want to compute when examining the relationship of two individual entities. In many cases, it also provides an actionable piece of information: It is the path by which we want to route information between two individuals; the path we want to follow when moving from one place to another in a traffic network; the quickest way to create a connection within a professional network.

A succinct characteristic of real-life networks is their continuous evolution. New nodes and edges are added, often at an exponential pace. Even when observing a fixed set of nodes, their relationship can change dramatically by the addition of new edges among nodes in the set, or to other nodes outside the set. As a result, new shortest paths are created and the relationships between individuals are constantly updated.

Identifying the pairs of nodes that came the closest to each other is important in our understanding of the network, and it may be crucial for some applications. For example, in social networking sites such as *Facebook* or *LinkedIn*, if two distant users come closer over time, this could imply the appearance of similar interests or activities between them.

10.5441/002/edbt.2015.28

Hence, this further knowledge can help in making more suitable friendship recommendations. In economic networks, the decrease of the shortest path between two major players could signal a change of strategy, or have future implications for their growth. In a criminal or terrorist network, it is critical to know which suspects have come closer to each other; such moves may be indications of future actions or coalitions.

There could be also an application of this problem in protein-protein interaction networks, where the nodes are proteins within a cell and they are connected by edges if there is a possible interaction between them [3]. As new experiments reveal new connections, for two given proteins, the knowledge that they came closer together in the graph makes them candidates for an upcoming interaction. Furthermore, if a certain protein comes closer to multiple others, they may be part of the same community [12], with all underlying proteins having the same specific function within the cell.

In this paper, we address the following problem. Given two snapshots of an evolving network, we ask for the k pairs of nodes whose shortest path distance has decreased the most between the two snapshots. We call such pairs of nodes *converging*. There is a simple polynomial-time solution to our problem: Compute the all-pair shortest path distances in the two graph instances and find the pairs with the largest distance change. However, even if we used fast algorithms that approximate shortest path computation, e.g., [20], it would still require time quadratic in the size of the graph for just producing the pairs. Given that real graphs have size in the order of thousands or millions, we need solutions that scale linearly with the size of the graph.

Despite its significance, the problem of identifying the top-k converging pairs has received limited attention. The only related work we are aware of is the work in [14] which provides an approach based on the endpoints of the new edges in the second snapshot. In this paper, we address the problem from a different perspective, by predicting the nodes of the converging pairs. We formally define good candidate nodes as those nodes that belong to a *cover* of the set of the top-k converging pairs. We also introduce a novel budget formulation of the problem, where to achieve the required result, we are given a fixed budget of $m \ll n$ single-source shortest-path computations. We propose a suite of algorithms for identifying good candidate nodes based purely on the structural properties of the two graph instances. These algorithms are based on node centrality, node dispersion and landmark-based distance estimations. Then, we build a classifier that combines the proposed algorithms to effectively identify the approach that is the most appropriate for each setting. By further extending the classifier to include features of the graph, such as the graph density, we were able to build a "global" classifier that works on any graph. The classifier takes advantage of our novel method of characterizing good candidate nodes.

Our experiments with four real datasets show that we can identify most of the converging pairs with a budget equal to a very small percentage of the graph nodes. For example, for the *Internet links* dataset, with a budget of just 0.5% of the nodes, we are able to locate over 90% of the top-k converging pairs for various values of k. Furthermore, our classifiers are successful in identifying converging pairs and match the performance of the best algorithm for each dataset.

In summary, in this paper we make the following contributions:

- We formalize the problem of finding the top-k converging pairs in a graph under budget constraints as a problem of finding a vertex cover of an appropriately defined graph over the set of these pairs.
- We propose a suite of methods for identifying candidate nodes that best cover the set given a fixed budget of shortest path computations.
- We show how to combine our techniques into a single algorithm that makes use of all the proposed features.
- We perform extensive experiments that show that our techniques work well in practice, being able to find the top-k converging pairs with only a small number of shortest path computations. Compared to the approach in [14] our algorithms are more effective in identifying converging pairs, while having strong budget guarantees.

The rest of this paper is structured as follows. In Section 2, we present related work. In Section 3, we introduce the problem of identifying the top-k converging pairs and formulate it as a vertex cover problem. In Section 4, we present a suite of algorithms for identifying candidate nodes for the converging pairs. Experimental results are presented in Section 5. Finally, in Section 6, we provide conclusions and directions for future work.

2. RELATED WORK

Dynamic social network analysis has received a lot of attention, including research on community evolution, e.g., [2], and on graph generation models, e.g., [15]. In this paper, we focus on a different aspect. Given two graph instances, we ask what are the pairs of nodes that came closer to each other. This problem is different from the problem of incrementally maintaining shortest path distances in dynamic graphs, e.g., [7, 23]. Here we just want to identify the k pairs of nodes whose shortest path distance has changed the most, without re-estimating the distances for all pairs. Recent work also addresses the problem of monitoring the proximity of nodes in bipartite time-evolving social graphs [21]. The authors propose pre-computing and storing all pair distances for a small number of nodes so as to incrementally update distances and maintain the top-k most closely connected pairs, or the most central nodes. In contrast here, we consider general graphs (non bipartite) and search for the top-k pairs with the largest decrease in their shortest path distance.

Another line of research addresses graph augmentation problems that ask to find a set of edges to add to a graph so as the graph satisfies specific properties including ones involving shortest path distances. In the context of social networks, recent work considers augmentation problems within the context of improving content propagation. The authors of [22] ask which edges to add or delete in a graph so as to improve the information dissemination process and in particular to increase the leading eigenvalue of the adjacency matrix of the graph. Other recent work addresses the problem of recommending edges to add so as to maximize content spread but in addition ensure that the recommendations are also relevant [4]. The authors of [18] study the problem of selecting a k-size subset of the non-existing or ghost edges of a graph such that if they are added to the graph will minimize the average all pairs shortest path distances. The authors of [19] study the same problem as in [18] but the added edges are selected from a given set of candidate edges (e.g., the edges added between two snapshots). Different to this work, we do not assume that we can select edges to decrease the shortest paths, but rather that edges have already been added as part of the evolution of the network, and we want to find the pairs that were most affected.

The work most closely related to ours is that of [14] that studies essentially the same problem. However, their work does not impose a budget constraint on the shortest path computations. Algorithmically, their work focuses on the endpoints of new edges and relies on identifying critical edges that lie in the shortest paths of many pairs. Such notions necessitate the use of betweenness measures [9], which in general are expensive to compute. In comparison, our work introduces the idea of allocating a fixed budget of m shortest path computations, as well as the formalization of good candidate endpoints as the ones belonging to the maximum cover of the top-k converging pairs. The latter can also form the basis for building effective classifiers for the problem. We compare with the approach in [14] in our experiments.

There is a rich literature in using landmarks for shortest path estimation in large graphs, e.g., [20, 23, 25]. Various approaches for selecting landmarks have been proposed, including the ones used here. However, the problem addressed in our work is different from previous work in that we want to estimate shortest path changes rather than actual shortest paths. It is interesting to consider additional methods for selecting landmarks, such as the approach proposed in Orion [25] that maps graphs into a multi-dimensional Euclidean coordinate space, but it is beyond the scope of this work.

A different point of view in the point-to-point distance estimation problem, which bears some similarity with our approach, is considered in [5]. They propose the use of machine learning techniques for predicting the distance between two nodes of a graph. Aiming to answer real-time point-to-point distance queries, they propose to use linear functions that combine vertex-based attributes, such as the closeness centrality with landmark-based attributes, while incorporating different approaches on selecting lower bound and upper bound landmarks.

Finally, there is a large body of research on link prediction (e.g., [16]) that asks to predict which pairs of nodes will be connected in future snapshots. In this work, we are given the future snapshot, and we are interested in the efficient computation of converging pairs of nodes, not predicting direct links.

3. PROBLEM DEFINITION

We consider undirected (weighted) graphs that change over time. Let $G_t = (V_t, E_t)$ denote the graph at time instant t. As is the most common case with social networks, we consider only node and edge insertions. Thus, a dynamic graph can be seen as a sequence of slices $S_1, S_2, \dots S_t, \dots,$ of node and edge insertions. $G_t = (V_t, E_t)$ is the graph that results by aggregating all slices up until t.

For two nodes u, v, and time instant t, we use $d_t(u, v)$ to denote their shortest path distance in G_t. We call a pair of nodes $u, v \in V_t$, connected if u, v belong to the same connected component of G_t.

Now assume two graph instances, $G_{t_1} = (V_{t_1}, E_{t_1})$ and $G_{t_2} = (V_{t_2}, E_{t_2})$, with $t_2 > t_1$. Take two connected nodes u, v in G_{t_1} that are at distance $d_{t_1}(u, v)$. When considering the graph G_{t_2} the addition of new nodes and edges can only decrease the distance between u, and v. Let $\Delta_{t_1,t_2}(u, v) = d_{t_1}(u, v) - d_{t_2}(u, v)$ denote the decrease in distance between u and v. We are interested in identifying the pairs of connected nodes for which we have a sharp decrease in distance, that is $\Delta(u, v)$ is large. We focus on connected nodes since the distance between non-connected nodes is infinite, and thus, in this case, the problem comes down to finding the disconnected components that got connected.

More formally, we define our problem as follows.

Problem 1 (top-k converging pairs). *Given two graph instances G_{t_1} and G_{t_2}, at time instants t_1 and t_2, respectively, $t_2 > t_1$, and a value k, find the k connected pairs u, v of nodes in G_{t_1} with the largest $\Delta_{t_1,t_2}(u, v)$ value among all pairs of connected nodes in G_{t_1}. We call these pairs of nodes the top-k converging pairs.*

There is a simple polynomial-time solution for our problem. We compute the shortest paths of all (connected) pairs of nodes in G_{t_1} and G_{t_2} and we find the ones that have the largest decrease. Regardless of how fast we compute the shortest paths – there are fast algorithms for approximate shortest path computation, e.g., [20] – just outputting the paths for all pairs requires time $O(n^2)$, where n is the number of nodes in G_{t_1}. For networks with millions of nodes this is impractical both in terms of storage and time. We need solutions that scale linearly with the number of nodes in the graph.

To address this issue, we want to reduce the number of nodes for which we need to compute the shortest paths. We view a shortest path computation (SP computation) as a unit of computational cost, and we assume that we have a fixed computational budget that we can use for our task. This is the number m of SP computations we can perform, which is dictated by our resources and our application. We want to retrieve as many of the top-k converging pairs as possible, under the budget constraints.

We will first establish what is the minimum possible number of shortest path computations. Let P denote the set of the top-k converging pairs that we want to compute. Assume that we are given a set C such that for every pair $(u, v) \in P$, either $u \in C$, or $v \in C$. If we compute all shortest paths for the nodes in C in G_{t_1} and G_{t_2}, and we keep the top-k ones with the highest Δ_{t_1,t_2} value, then we obtain again the set P. The space and time requirements for this algorithm is $O(n|C|)$. Note that the size of the set C is at most k, so the complexity of the problem would be linear in the size of the graph. The set C is a *cover* for the set of pairs in P.

To formalize the definition of the set C, given G_{t_1}, G_{t_2} and k, we define a new graph $G_k^p = (V_1, P)$, defined over the nodes V_1 of graph G_1, $V_1 \subseteq V_{t_1}$, such that there is an edge between two nodes u and v in G_k^p, if and only if, (u, v) is a top-k converging pair. The set C described above is a *vertex cover* of the graph G_k^p, since for every edge $(u, v) \in P$ of G_k^p at least one of the endpoints of the edge belongs to C. That is, every edge is *covered* by at least one vertex. Given a vertex cover of the graph G_k^p, we can obtain the set P of the top-k converging pairs efficiently.

Obviously, when tackling Problem 1, we do not have access to graph G_k^p, or its cover, i.e., the set C. Actually, even if we knew graph G_k^p, obtaining a vertex cover C of minimum size is an NP-hard problem. However, using G_k^p, we can now reformulate our problem as follows.

Problem 2 (budgeted path cover). *Given two graph instances G_{t_1} and G_{t_2}, at time instants t_1 and t_2 respectively, with $t_2 > t_1$, a value k, and a budget m, find a set of nodes $M \subseteq V_{t_1}$ of size m such that the number of edges of G_k^p covered by M is maximized.*

We note again that we do not have access to the graph G_k^p. Problem 2 is a harder version of Problem 1, where our computational budget is limited. However, the definition of Problem 2 dictates our approach for solving Problem 1. Our goal is to identify a set of candidate nodes M that are likely to be in the cover of G_k^p. Towards this end, we have a fixed computational budget which is defined by the number m of nodes for which we can compute the single-source shortest paths distances in G_{t_1} and G_{t_2}.

Note that even if we had access to the graph G_k^p finding the minimum vertex cover, or the set of m nodes that maximize coverage is an NP-hard problem. However, it is known [24] that the greedy algorithm that each time selects the node that covers the largest number of the uncovered edges provides a solution with a logarithmic approximation ratio, that works well in practice. The greedy algorithm also has an approximation ratio for the *max-coverage* problem, where given a budget of m vertices we want to find the ones that maximize the coverage of edges. In our experiments, when we want to compare against a "good" solution, we use the vertex cover produced by the greedy algorithm. We will often refer to the greedy solution as the cover of the G_k^p graph.

4. ALGORITHMIC TECHNIQUES

We now outline a generic algorithm for finding the top-k converging pairs. As an intermediate step, our algorithm addresses Problem 2, finding a set M of nodes that cover the largest number of the top-k converging pairs. We propose a suite of algorithms for solving Problem 2. In the following, we shall use the term candidate nodes and candidate endpoints interchangeably to denote the nodes in M.

4.1 Finding the Top-k Converging Pairs

In Algorithm 1, we describe a generic algorithm for finding the top-k converging pairs. The algorithm relies on the function ComputeCandidateEndpoints that returns a set M of candidate endpoints of size m. We discuss the candidate generation below. The number of candidate endpoints m is small and thus it is feasible to compute all shortest path distances between M and the nodes in V_{t_1} in graphs G_{t_1} and G_{t_2}. Given these distances, we can compute the $\Delta_{t_1,t_2}(u, v)$ values for the pairs in $M \times V_{t_1}$ and select the top-k pairs with the highest values.

4.2 Candidate Endpoint Generation

We now describe the algorithms for generating candidate endpoints, that is, identifying nodes that best cover the top-k converging pairs, i.e., the edges of G_k^p. Our algorithms take as input the two graph instances, G_{t_1} and G_{t_2}, and the value m, and produce as output a set $M \subset V_{t_1}$ of m nodes. We want to select M such that M covers the largest number of the top-k converging pairs. The size m of M is determined by our resource budget: it is the number of nodes for which we can afford to compute the single-source shortest paths in G_{t_1} and G_{t_2}.

Algorithm 1 Generic top-k Algorithm.

```
Input: Graph snapshots $G_{t_1} = (V_{t_1}, E_{t_1})$, $G_{t_2} = (V_{t_2}, E_{t_2})$,
    $k$, $m$
Output: The set of the top-$k$ converging pairs
1: $M \leftarrow$ ComputeCandidateEndpoints($G_{t_1}$,$G_{t_2}$, $m$)
2: $D_1 \leftarrow m \times n$-dimensional array with shortest path distances in $G_{t_1}$ between the nodes in $M$ and $V_{t_1}$.
3: $D_2 \leftarrow m \times n$-dimensional array with shortest path distances in $G_{t_2}$ between the nodes in $M$ and $V_{t_2}$.
4: $\Delta_{t_1,t_2} \leftarrow D_1 - D_2$.
5: return the top-$k$ pairs $(i, j)$ with the highest values in $\Delta_{t_1,t_2}$.
```

We consider the following approaches in selecting the nodes for the set M:

- **Centrality-based:** In this case, we select nodes based on their degree or the change in their degree.
- **Dispersion-based:** In this case, we select nodes that are highly dispersed in the graph G_{t_1}, that is, they are far apart from each other. These nodes are likely to participate in a large number of top-k converging pairs, since they were far apart in the first place.
- **Landmark-based:** In this case, we select a small sample $L \subset V_{t_1}$ of the nodes in G_{t_1} to act as *landmarks*. We select the candidate endpoints based on the changes of their shortest path distances from these landmarks.
- **Hybrid:** In this case, we use again a landmark-based approach, but instead of sampling randomly the set of landmarks L, we use a dispersion-based approach to guide our choice.
- **Classification-based:** In this case, we use features provided from the previous algorithms to build a classifier that predicts whether a node is a good candidate endpoint.
- **The Incidence family of algorithms:** In this case, we consider some of the algorithms in [14] for selecting the candidate endpoints.

We now discuss each of the above approaches in detail.

4.2.1 Centrality-based selection

With this approach, we use the centrality of nodes in the graph G_{t_1} to guide us in the selection of candidate nodes. The motivation is that nodes central in graph G_{t_1} are likely to be part of the shortest paths for many nodes. Thus they seem a reasonable choice as candidate endpoints. Furthermore, we consider also nodes that had a large increase in their centrality, either in absolute terms or relative to the original value.

A simple and easy to compute centrality measure is the node degree. Formally, let $\deg_t(u)$ denote the degree of node u in graph G_t. The algorithm DEGREE ranks nodes in descending order of $\deg_{t_1}(u)$ and selects the top-m nodes. The algorithm DEGDIFF ranks nodes in descending order of $\deg_{t_2}(u) - \deg_{t_1}(u)$ and selects the top-m nodes. Finally, the DEGREL ranks nodes in descending order of $(\deg_{t_2}(u) - \deg_{t_1}(u))/\deg_{t_1}(u)$ and selects the top-m nodes.

4.2.2 *Dispersion-based selection*

With this approach, we want to select as candidates the m nodes in G_{t_1} that are the furthest apart from each other. That is, we want M to contain the most dispersed set of nodes. We define this in two different ways.

The first approach is to select nodes such that the average distance between all pair of selected nodes is maximized:

$$M = \arg \max_{\substack{S \subseteq V_{t_1} \\ |S|=m}} \frac{1}{\binom{m}{2}} \sum_{v_i, v_j \in S} d_{t_1}(v_i, v_j) \qquad (1)$$

This approach tends to select nodes in the perimeter of the graph.

Alternatively, we can select nodes such that the minimum distance between any two pairs of the selected nodes is maximized:

$$M = \arg \max_{\substack{S \subseteq V_{t_1} \\ |S|=m}} \min_{v_i, v_j \in S} d_{t_1}(v_i, v_j) \qquad (2)$$

This approach tends to select nodes that "cover" the graph.

Even if we had the pairwise distances between all nodes, finding the optimal set of nodes for both cases is an NP-hard problem (for example, see [13] for a recent discussion on this topic). We thus use a greedy algorithm that at each step selects the node that maximizes the dispersion with respect to the nodes selected so far. We refer to the algorithm that maximizes the average distance as MAXAVG and to the algorithm that maximizes the minimum distance as MAXMIN.

4.2.3 *Landmark-based selection*

With this approach, we make use of a set $L \subset V_{t_1}$ of ℓ nodes that we call *landmarks* and compute the distances of all nodes in G_{t_1} and G_{t_2} from the nodes in L. We select our candidates based on how close they came to the landmarks in graph G_{t_2}.

Specifically, let $L = (w_1, \ldots, w_\ell)$ be an ordered set of landmark nodes of graph G_{t_1}, with $\ell \ll |V_{t_1}|$. We associate with each node $u \in V_{t_1}$, two ℓ-dimensional vectors, $DL_1(u)$ and $DL_2(u)$, where $DL_1(u)[i] = d_{t_1}(u, w_i)$ and $DL_2(u)[i] = d_{t_2}(u, w_i)$. The vector $\Delta L_{t_1,t_2}(u) = DL_1(u) - DL_2(u)$ captures the change in the shortest path distance from u to the landmarks in L.

We now select as candidate endpoints the nodes that came "closest" to the landmarks L in the graph G_{t_2}. To measure the degree of distance change, we use the L_1 and L_∞ norms of the vector $\Delta L_{t_1,t_2}(u)$.

$$\|\Delta L_{t_1,t_2}(u)\|_1 = \sum_{i=1}^{\ell} \Delta L_{t_1,t_2}(u)[i] \qquad (3)$$

$$\|\Delta L_{t_1,t_2}(u)\|_\infty = \max_{i=1}^{\ell} \Delta L_{t_1,t_2}(u)[i] \qquad (4)$$

Table 1: Shortest-path computations for different approaches

Approach	Candidate Generation	top-k Pairs
Degree-based	0	$2m$
Dispersion-based	m	m
Landmark-based	2ℓ	$2m - 2\ell$
Hybrid	2ℓ	$2m - 2\ell$
Classification-based	$3 \cdot 2\ell$	$2m - 3 \cdot 2\ell$

In the SUMDIFF algorithm, we select the m nodes with the largest L_1-norm, while in the MAXDIFF algorithm, we select the m nodes with the largest L_∞-norm. The intuition is that these are nodes that became more central in the graph G_{t_2} and thus are likely to participate in many changed shortest paths. The SUMDIFF algorithm is somewhat related in motivation to the greedy algorithm for finding the minimum vertex cover. The node with the largest L_1-norm value is the node that covers the most of the distance changes in the $(\ell \times n)$-matrix $\Delta L_{t_1,t_2}$.

4.2.4 *Hybrid selection*

With the hybrid approach, we attempt to get the best of both worlds by combining the dispersion-based approach with the landmark based approach. Specifically, we use the dispersion-based techniques to select the ℓ landmarks, and then apply the landmark based approach.

This hybrid approach is motivated by two factors. First, in order to obtain the landmark distances in the graphs G_{t_1} and G_{t_2}, we need to pay a cost of ℓ shortest path computations in each graph. When selecting a set of random landmarks this cost comes with no payoff since it is unlikely that the randomly selected nodes will cover any of the converging pairs. Using the nodes selected from the dispersion based algorithm guarantees that we will obtain some benefit from the landmark selection. Second, intuitively, it seems that dispersed nodes should work better as landmarks since they cover different parts of the graph, and thus we can better capture the fact that a node came closer to some part of the graph.

Depending on the algorithm that we use for the landmark selection policy, and the norm we use for measuring the change in the distance to the landmarks, we get four different algorithms, namely the MAXAVG-SUMDIFF (MASD), MAXAVG-MAXDIFF (MAMD), MAXMIN-SUMDIFF (MMSD) and MAXMIN-MAXDIFF (MMMD) algorithms.

4.2.5 *Classification-based selection*

Our goal in the candidate endpoint generation is to identify nodes that are likely to cover the largest number of converging pairs. We can think of most of the previous algorithms as methods for identifying features that characterize good candidates. A natural extension of the above approach is to combine all these features into a single algorithm using a classifier that will try to predict whether a node is a "good" endpoint or not. The benefit of such an approach is that it combines multiple features instead of one, and it automatically finds the appropriate features to use for each dataset without manual inspection. However, we need to allocate resources for training the classifier.

An important question in this setting is how to determine the positive class for the classifier. What do we mean by

Table 2: Dataset Characteristics

Dataset	No of nodes		No of edges		diameter		max Δ_{t_1,t_2}	not-connected
	G_{t_1}	G_{t_2}	G_{t_1}	G_{t_2}	G_{t_1}	G_{t_2}		G_{t_1}
Actors	1,851	1,886	45,584	56,981	5	5	3	0
Internet links	21,835	25,526	83,857	104,824	12	11	6	80
Facebook	4,436	4,734	25,197	31,498	12	11	7	27
DBLP	15,391	17,992	38,866	48,618	17	15	9	3,864

"good" endpoint? For this task we make use of the vertex cover of the graph G_k^p, that we obtain with the greedy algorithm. This is a collection of nodes that concisely cover the changed paths, and thus it is reasonable to use them as the positive class for our classification task. As features, we use features employed by our algorithms such as the degree of the nodes in G_{t_1}, and G_{t_2}, the degree difference, and the relative degree difference, the L_1 and L_∞ norm of the distances to random landmarks and landmarks selected accordingly to the MaxMin and MaxAvg algorithms. We train one such classifier for each dataset as described in the experiments. We refer to this classifier, as the *local* classifier of the dataset.

We also consider a classifier that can operate on *any* dataset. For this classifier, we extend the feature set with features characteristic of the dataset. In particular, we consider the density, and the maximum degree of the two graph snapshots. The resulting classifier, termed *global* classifier, once trained, can be used to generate candidate endpoints for the top-k converging pairs for any two snapshots of any graph.

For the classification, we use logistic regression. The benefit of the logistic regression algorithm is that it outputs a probability for a node to belong to a given class, in our case to the vertex cover. We sort the nodes in decreasing order of this probability and we output the top-m nodes.

4.2.6 *Incidence Algorithm*

To the best of our knowledge, the first paper that addresses the problem of identifying the top converging pairs in evolving social networks, is [14]. In this paper, the nodes that receive new edges in the second timestamp are called *active* and are considered as the most probable nodes to participate in the top converging pairs. The *Incidence Algorithm* is introduced, where after constructing the set of the *active* nodes A, a number of $|A|$ shortest path computations is performed on both instances of the graph, in order to obtain the pairs with the maximum distance difference.

There are two variations of the *Incidence Algorithm*. In the first one, called *Selective Expansion*, the neighbors of the endpoints in A are also considered as candidates. Every neighbor is evaluated according to the number of its *important* edges. For this purpose, the notion of edge *importance* in a social network is introduced, which is an estimate of the edge betweenness centrality, computed using a randomly selected set of shortest path trees. In our experiments, we used the actual edge betweenness centrality, giving an advantage to the *Incidence* algorithm. In this variation, the algorithm proceeds iteratively, inserting to A new neighbors, and executing *Incidence*, until there are no more new pairs discovered.

The second variation of the *Incidence Algorithm* proposes a number of rank strategies for the *active* nodes, in order to choose the top few of them that are likely to participate in the converging pairs. The rank policies are divided to degree-based and betweeness-based. Among other strategies concerning weighted social graphs (which we do not consider in our work), the authors of [14] rank the *active* nodes using four different policies: their degree in G_{t_2}, their degree difference between the two graph instances, the sum of the *importance* of the edges that a node received in G_{t_2} and finally the difference of the last measure among G_{t_1} and G_{t_2}.

4.3 Complexity

Recall that the value m is not only the number of candidate endpoints, but also the computational budget we have in terms of time and space, that determines how many single-source shortest-path computations we can afford to perform on graphs G_{t_1} and G_{t_2}. Therefore, all algorithms perform exactly $2m$ shortest path computations. Table 1 demonstrates how these computations are allocated in the different phases of the algorithm, for different selection policies. The first phase concerns the shortest path computations required for selecting the candidate endpoints. The second phase involves the computation of the single-source shortest-paths for the candidate endpoints, in both snapshots. For the generated pairs, we compute the decrease in their shortest paths, and select the k ones whose distance decreased the most.

Note that the dispersion based methods need to compute shortest paths only in the graph G_{t_1}, in order to select the candidate endpoints. We still need to compute the shortest paths on G_{t_2} though, in order to output the top-k pairs. Also the classifier requires $3 \cdot 2\ell$ shortest path computations for computing the landmarks in three different ways, in order to produce the features.

5. EXPERIMENTAL EVALUATION

In this section, we compare the performance of the various algorithms and classifiers in terms of identifying the actual top-k converging pairs for various values of the available budget m.

5.1 Datasets and Setting

To evaluate the performance of our algorithms, we need to be able to compute the true top-k converging pairs. Therefore, we use datasets of manageable size, for which it is feasible to compute all-pairs shortest paths. We consider the following four real datasets:

- The *Actors* dataset, where the nodes are actors and there is a connection between two film actors if they both appeared in the same movie. The dataset was obtained from the IMDB web site[1], and it spans the years from 1998 to 2010.

[1]http://www.imdb.com

Table 3: Characteristics of the G_k^p graphs (number of nodes and edges) and their maximum vertex cover (number of nodes).

Dataset	$i = 0$			$i = 1$			$i = 2$		
Actors	$\delta = 3$			$\delta = 2$			$\delta = 1$		
	endpoints	pairs	maxcover	endpoints	pairs	maxcover	endpoints	pairs	maxcover
	35	27	10	1,350	4,081	446	1,851	202,899	9

	4	2	2	44	37	16	409	591	60
DBLP	$\delta = 9$			$\delta = 8$			$\delta = 7$		
	endpoints	pairs	maxcover	endpoints	pairs	maxcover	endpoints	pairs	maxcover
	6	4	2	68	68	12	289	462	46

- The *Internet links* dataset is an undirected graph representing the AS-level connectivity of the Internet [17, 10] (an Autonomous System (AS) represents a single administrative domain on the Internet). Each node in the graph is an AS and an edge between two nodes represents a message that was exchanged between them, using the inter-domain routing protocol.

- The *Facebook* dataset, where nodes are users of Facebook, and edges between two nodes denote friendship. The dataset contains 31,498 connections, which were created sequentially in 31,498 different time points.

- The *DBLP* dataset, where nodes are authors and there is an edge between two authors if they wrote a paper together. The dataset was obtained from the *DBLP* site[2] and includes articles of 14 top conferences in data mining, databases, theory and the WWW from 1983 to 2013.

Each dataset was divided into two snapshots, so that the initial snapshot, G_{t_1}, contains 80 percent of the edges, and the second snapshot, G_{t_2}, contains the entire graph. Table 2 provides a summary of the characteristics of each dataset.

In selecting the values of k on which to evaluate our algorithms, we note that for any given k, there are many ties, that is, there are many pairs with the same shortest path change. This means that there are many different sets of top-k converging pairs and G_k^p graphs. We set k to a value that guarantees a single optimal solution. Specifically, for two graph instances G_{t_1} and G_{t_2}, let Δ be the maximum distance decrease over all connected pairs of nodes in G_{t_1}. We test our algorithms by assigning values to k that correspond to the number of pairs whose distance change is at least equal to δ, where δ takes values Δ, $\Delta - 1$, and $\Delta - 2$. Setting k as above makes the problem harder, since there is a single optimal solution that we must retrieve that includes *all* converging pairs with shortest path distance change at least δ. For smaller values of the given k, our algorithms work even better, since in this case, retrieving any of (many) tying pairs suffices.

In Table 3, we report for each dataset the number of pairs whose path distance change is at least $\delta = \Delta - i$, for $i = 0, 1, 2$, the number of distinct endpoints involved in these pairs, and the size of the maximum cover as computed by the greedy algorithm. For example, for the DBLP dataset, for $\delta = 8$ ($\Delta - 1$), there are 68 pairs whose distance was reduced by at least 8. These pairs involved 68 distinct nodes, and they can be covered with 12 nodes. When running our algorithms we set $k = 68$, that is, we look for the top-68 converging pairs.

The main parameter of our algorithms is the available budget expressed through parameter m, i.e., the number of candidate endpoints for which we can compute shortest paths. The performance of an algorithm is measured in terms of *coverage*: The percentage of top-k converging pairs that are retrieved by the algorithm. Note that these are pairs with at least one endpoint in the candidate set produced by the algorithm. The goal of the experiments is to study the cost-coverage tradeoff. We want to understand how the coverage grows as we increase the budget, and the maximum coverage we can obtain with a small budget ($m = 100$). For simplicity, we fix the number ℓ of landmarks to 10 for all algorithms. A larger number of landmarks did not improve the performance.

In Table 4 we give an overview of the algorithms we consider, and a quick index for the algorithm names.

5.2 Single Feature Algorithms

In this experiment, we evaluate the performance of the proposed single-feature algorithms (all algorithms, except for the classification-based algorithms). Our evaluation is in terms of coverage of the top-k converging pairs.

We first evaluate the coverage of our algorithms (percentage of top-k converging pairs found) for a fixed budget $m = 100$ and various values of k. Table 5 reports the coverage of converging pairs with distance change at least δ for various δ, which corresponds to a number of different k values, ranging from $k = 2$ for Facebook and $\delta = 7$ to $k = 202{,}899$ for Actors and $\delta = 1$. The bold entries correspond to the best performing algorithm for a particular input.

As shown, the *centrality-based algorithms* (based on degree) achieve the lowest coverage almost always for all datasets but for *Actors*. The algorithm that orders the candidate endpoints according to their degree in the original graph has actually almost zero coverage for all datasets, indicating that degree is negatively correlated with participation to changed shortest paths. It appears that nodes with very high degree are already central in the graph, and thus most of their shortest paths are already short. Surprisingly the degree difference is also an ineffective feature for selecting good candidates. This can be explained from the prefer-

[2]http://dblp.uni-trier.de/

Table 4: Overview of Candidate Selection Algorithms.

DEGREE	Selects the m nodes with the largest $\deg_{t_1}(u)$.
DEGDIFF	Selects the m nodes with the largest $\deg_{t_2}(u) - \deg_{t_1}(u)$.
DEGREL	Selects the m nodes with the largest $(\deg_{t_2}(u) - \deg_{t_1}(u))/\deg_{t_1}(u)$.
MAXMIN	Selects greedily m nodes in the first snapshot, such that each new node maximizes the minimum distance to the already selected nodes.
MAXAVG	Selects greedily m nodes in the first snapshot, such that each new node maximizes the average distance to the already selected nodes.
SUMDIFF	Selects the m nodes with the largest sum of distance decreases from a set of random landmarks L.
MAXDIFF	selects the m nodes with the largest maximum distance decrease from a set of random landmarks L.
MMSD	MAXMIN-SUMDIFF: Uses MAXMIN for landmark selection, and SUMDIFF for selecting the m nodes.
MMMD	MAXMIN-MAXDIFF: Uses MAXMIN for landmark selection, and MAXDIFF for selecting the m nodes.
MASD	MAXAVG-SUMDIFF: Uses MAXAVG for landmark selection, and SUMDIFF for selecting the m nodes.
MAMD	MAXAVG-MAXDIFF: Uses MAXAVG for landmark selection, and MAXDIFF for selecting the m nodes.
INCDEG	Selects the m of the *active* nodes with the largest $\deg_{t_2}(u) - \deg_{t_1}(u)$ [14].
INCBEET	Selects the m of the *active* nodes with the largest increase in the total betweenness of their incident edges [14].

ential attachment principle [1]: nodes with high degree are more likely to obtain new links. We indeed observed strong correlation between degree and degree change. Relative degree difference mitigates the effect of high degree to some extent, and this is why it performs better than degree and degree difference on all datasets. Still it underperforms compared to other algorithms. The poor performance of the centrality-based algorithms indicates that approaches based on the endpoints of the new edges as the one in [14] are less efficient than selecting candidate nodes based on other features.

The exception to the above observations is the *Actors* dataset. For this dataset, DEGREL is among the best algorithms. We note that this is a dense dataset where many of the top changed shortest paths are reduced to single edges. In this setting, the addition of new edges to a node has a stronger effect on the shortest path changes.

The *dispersion-based algorithms* are relatively successful in discovering the converging pairs. MAXAVG outperforms MAXMIN in almost all cases. MAXAVG gives preference to nodes in the outskirts of the graph while MAXMIN tends to select nodes that cover the different clusters in the graph [8]. Peripheral nodes are more likely to come significantly closer to other nodes in the graph. The satisfactory performance of the dispersion-based algorithms and the fact that they do not require knowledge of the second snapshot indicates that dispersion techniques could also be used as predictors of converging pairs.

From the two *landmark-based algorithms*, SUMDIFF works consistently better than MAXDIFF. SUMDIFF considers nodes that came closer to many landmarks and thus discovers nodes that become central in the new graph. We think of the SUMDIFF algorithm as a sampling of the distance changes of the nodes in the graph. Nodes with high SUMDIFF value are likely to have come close to many nodes in the graph. Thus, in some sense, SUMDIFF is trying to approximate the methodology of the greedy algorithm for finding a vertex cover for G_k^p.

Finally, among the *hybrid algorithms*, the best coverage is attained in most cases by MAXMIN-SUMDIFF (MMSD). The MAXMIN-SUMDIFF algorithm exploits the ability of the MAXMIN algorithm to select representative landmarks that cover the initial graph and the ability of SUMDIFF to select nodes that come closer to all these representative nodes. Note that although in general MAXAVG is a better dispersion algorithm than MAXMIN, MAXMIN-based landmark selection tends to outperform MAXAVG-based selection. This is reasonable, since, for landmark selection, it is better to select nodes that cover the graph rather than peripheral nodes.

We now study the coverage achieved for different values of the budget m. Figure 1 shows the coverage achieved by the landmark-based algorithms for various values of m for all datasets. In general, the algorithms based on SUMDIFF converge faster confirming our intuition that they cover many pairs. The plot also demonstrates that landmark-based algorithms waste part of their computational budget in computing shortest path distances for the $l = 10$ random nodes selected as landmarks that are not likely to be endpoints. Thus, these algorithms obtain no coverage for this computation. On the other hand, the hybrid algorithms benefit from the fact that they choose meaningful candidates as landmarks, and as a result the effort for the landmark shortest path computations is not wasted. Also, notice that MASD and MMSD attain 90% coverage for m smaller than 50.

We also look into the set of candidate endpoints generated by our algorithms to see to what extent this set consists of (1) nodes in G_k^p and (2) nodes in the vertex cover of G_k^p produced by the greedy algorithm. We refer to the second set as greedy-cover. For this experiment we use the Facebook dataset and $\delta = 6$ (k = 37). We study the best-performing algorithms for this dataset: the landmark-based and hybrid algorithms. Figure 2(a) reports the percentage of the candidate nodes that belong to G_k^p and Figure 2(b) the percentage that belongs to greedy-cover for various values of m. Similar behavior is noticed for the other datasets and algorithms. Not surprisingly, we observe that algorithms that cover many paths also have high intersection with both sets. It is interesting to note that the algorithms based on SUMDIFF have the largest intersection with the greedy-cover, that is, they discover high-quality candidate nodes.

5.3 Classification-based methods

In our experiments, we observed that different algorithms perform well for different datasets. A natural question is whether we can combine the individual algorithms to generate better candidate endpoints and if so, how we should weight the contribution of each individual algorithm. To this end, we view the above algorithms as features and use them

Table 5: Coverage: percentage of converging pairs found for $m = 100$.

to build a classifier to predict whether a node is a "good" candidate endpoint or not. More precisely we use the following features: the degree of the nodes in the first snapshot; the degree difference; the degree relative difference; the L_1 and L_∞ norm of the distances to random landmarks and landmarks selected accordingly to the MaxMin and the MaxAvg algorithms. All features are normalized in the interval [-1,1]. An important benefit of using a classifier is that it automatically finds the appropriate features for each dataset.

For the positive class of the classifier, that is for the class that corresponds to "good" endpoints, we use the vertex cover computed by the greedy algorithm for the graph G^p_k. As shown by our experiments, participation of a node in the vertex cover is a strong indication that a node is a good candidate. We also experimented with using all endpoints in G^p_k, and the results were very similar.

We use the *LIBLINEAR* implementation of the logistic regression classifier [11]. The logistic regression classifier outputs a probability for every node to belong to the positive class. Using this probability, we order the nodes according to their likelihood of being good endpoints. We sort the nodes in descending order of this probability and we output the top-m nodes.

For the evaluation of the classifier, we split each dataset into four snapshots. To train the classifier, we use snapshots $G^0_{t_1}$ that includes 40 percent of the edges and $G^0_{t_2}$ that includes 60 percent of the edges. To test the classifier, we use snapshots G_{t_1} that includes 80 percent of the edges and G_{t_2} that includes the full graph, that is, the same snapshots used for the evaluation of the single-feature algorithms. This allows for a direct comparison of the results. We used the same δ for both training and testing.

We consider two types of classifiers. A *local* classifier build for each dataset which we denote as L-Classifier, and a *global* classifier that can work for any dataset which we denote as G-Classifier. For the global classifier, we extract additional features from all datasets. In particular, we compute the density and the maximum node degrees of the training graph snapshots that we normalize appropriately within the interval [-1, 1]. We create the global classification model using training data from all four datasets in equal proportions.

Figure 3 compares the coverage achieved by L-Classifier and G-Classifier, with the best algorithm for each dataset. Note that the best algorithm is different for each dataset. The classification algorithm is able to automatically detect the appropriate features and produce a solution that has high coverage for each dataset. Note that the classifiers are handicapped by the set-up cost of the landmark computation (the first 30 shortest-path computations). Still, they are able to catch up with the best algorithm.

The only case where this does not happen is for the *Actors* dataset, when using G-Classifier. The poor performance can be explained by the differentiation of *Actors* dataset compared to the other datasets (Section 5.2). Since 75% of the training set for G-Classifier consists of features extracted from the *Facebook*, *Internet links*, and *DBLP* datasets, and only 25% of *Actors* features, the G-Classifier fails to produce a high coverage.

5.4 The Incidence algorithms

Finally, we compare our work to the approach in [14]. For this comparison, we implemented the original version of the Incidence algorithm, which does not use any kind of budget in the shortest path computations. This algorithm achieves very high coverage as shown in Table 6. However the set of the *active* nodes A, which is the set of nodes for which we need to compute the shortest paths, is a large fraction of the original graph. The smallest set A is computed for the *DBLP* dataset, and it is 11.66% of the G_{t_1} size ($m = 1{,}794$). In comparison our budget ($m = 100$) does not exceed 0.65% of the graph size. The largest set A is computed for the *Facebook* dataset, and it is around 66% of G_{t_1}, while our budget of $m = 100$ candidates is just 2.25% of the graph. Given the large number of candidates used by Incidence, the algorithm achieves almost complete coverage. At the same, time the time complexity is excessively high. For efficiency reasons, we did not test the effectiveness of *Selective Expansion*, as it is a recursive process that is very time consuming. It would lead us to use a very large set of candidate nodes and eventually to solve the problem by performing the baseline algorithm (computing all-pairs shortest paths), which is prohibitively expensive.

We also compare with the approach of [14] under budget constraints. Table 5 shows the best of the degree-based policies, IncDeg, where the *active* nodes are ranked by their

(d) *Pair coverage for DBLP*

Figure 3: Coverage of the top-k converging pairs, achieved by best algorithm, G-Classifier, L-Classifier trained with the vertex cover computed by the greedy algorithm, for the (a) *Actors* dataset and $\delta = 3$ ($k = 27$), (b) *Internet links* dataset and $\delta = 6$ ($k = 46$), (c) *Facebook* dataset and $\delta = 6$ ($k = 37$), and (d) *DBLP* dataset and $\delta = 8$ ($k = 68$).

degree change and IncBeet, where active nodes are ranked by the increase of the betweeness centrality of the edges incident to the nodes. We compute the actual edge betweenness centrality instead of estimating it, giving an advantage to the IncBeet algorithm. We can observe in Table 5 that IncDeg and IncBet have low performance. In particular, for the *Internet links* dataset, with $\delta = 4$ and $m = 100$ (0.5% of G_{t_1} size), MMSD achieves almost 96% coverage, while the coverage of IncBet does not exceed 1%. In almost all of our experiments, with exception the case of the *DBLP* dataset with $\delta = 9$, both of the two best variations of the Incidence algorithm underperform in term of coverage, as they can not discover more than 50% of the top converging pairs.

6. CONCLUSIONS AND FUTURE WORK

In this paper, we focus on the problem of identifying top-k converging pairs of nodes, that is, pairs of nodes that came closer together between two snapshots of an evolving social graph. We address the problem using purely structural properties of the two graph instances. Since a brute-force method for computing all pair shortest path distances in the two instances is not cost effective, we tackle the problem from a different angle, by predicting the endpoints of such pairs. In doing so, we introduce two novel ideas: (1) allocating a fixed budget of m shortest-path computations and (2) formally defining good candidate endpoints as those belonging to the vertex cover of the top-k converging pairs. We propose a suite of algorithms for selecting candidate nodes and build a classifier that combines them to effectively identify the most appropriate algorithm for each setting. The classifier takes advantage of our novel method of characterizing good candidate endpoints.

For future work, an interesting variation of the problem to consider is the converging pair prediction task, where we are given only the initial graph snapshot and we are asked to "predict" the converging pairs. This problem can be seen as an extension of the link prediction problem which asks whether a single edge will be added between a pair of nodes. Finally, our work can be extended by considering non structural properties, such as additional attributes of the edges or nodes.

ABSTRACT

Outlier or anomaly detection in large data sets is a fundamental task in data science, with broad applications. However, in real data sets with high-dimensional space, most outliers are hidden in certain dimensional combinations and are relative to a user's search space and interest. It is often more effective to give power to users and allow them to specify outlier queries flexibly, and the system will then process such mining queries efficiently. In this study, we introduce the concept of query-based outlier in heterogeneous information networks, design a query language to facilitate users to specify such queries flexibly, define a good outlier measure in heterogeneous networks, and study how to process outlier queries efficiently in large data sets. Our experiments on real data sets show that following such a methodology, interesting outliers can be defined and uncovered flexibly and effectively in large heterogeneous networks.

1. INTRODUCTION

Heterogeneous networks are the networks composed of multi-typed, interconnected vertices and links. Since the real world information entities are interconnected, forming numerous, gigantic networks, heterogeneous information networks are ubiquitous and form the basic semantic structure of interconnected data. Thus, detecting anomalies or finding outliers in such networks becomes an important task in network analysis. Although outlier detection has been studied extensively in data mining and various application fields [5, 14], outlier detection in heterogeneous information networks poses several unique challenges:

1. Unlike many outlier analysis methods that work on homogeneous datasets (*e.g.*, find anomalous communications in a communication network), this new endeavor needs fundamental changes on the definition and detection of outliers since it involves heterogeneously typed vertices and links.

2. In a gigantic network, and particularly in a heterogeneous network, it is unrealistic to discover all outliers using "global" techniques. The variety of vertex types, edge types, and paths connecting particular vertices creates many potential viewpoints from which outliers may be classified. These views are difficult to compare and possibly conflicting.

3. Data analysts (as users) need to obtain results promptly to react to outliers or further elaborate their queries. This creates a big challenge to efficiently process outlier queries in heterogeneous information networks.

Based on the above observations, we propose a new outlier detection task, called *query-based outlier detection in heterogeneous information networks*, by facilitating users to compose various kinds of outlier queries flexibly in heterogeneous networks via a novel query language; defining a new outlier measure, called NetOut, to measure the outlierness in such heterogeneous networks; and developing an efficient network detection algorithm for this task. The following is an example that illustrates our ideas.

Motivating example. The DBLP network is a network generated from the computer science bibliographic publication database[1] that consists of a set of vertex types: paper (P), venue (V), author (A), and term (T). A research publication entry essentially generates a set of links of the types $P-V$, $P-A$, and $P-T$, each connecting in the network a paper with its publication venue, set of authors and set of terms, respectively.

It is unrealistic and meaningless to find outliers with respect to all types of the vertices in the entire heterogeneous network. However, it is more interesting to give users freedom to specify what they want. For example, a user can confine the outliers to be among the coauthors of Christos Faloutsos (*i.e.*, all the authors connected with Christos via at least one joint paper).

Even for this author set, it is still unclear what aspect the outliers should be judged by: should the outliers be judged based on their publication venues or their collaborators? The former may lead to finding those who publish multiple papers in rather different venues than the majority of Christos' coauthors; whereas the latter may find those who have rather different collaboration behavior than the majority of his coauthors. Different judgment criteria lead to rather different results, which makes it essential to

*The first two authors made equal contributions.

[1]`http://www.informatik.uni-trier.de/~ley/db`

ask users to specify the criteria explicitly. Furthermore, a user may like to find outliers among Christos' coauthors, not compared within this coauthor set itself but compared with another explicitly specified set, such as prolific EDBT authors (*e.g.*, those who have published at least 10 papers in EDBT).

From this example, one can see that it is necessary to provide an outlier query language with which a user can specify the candidate set (*e.g.*, Christos' coauthors), the aspect (*e.g.*, publishing venues) by which the outliers will be judged, and sometimes the reference set (*e.g.*, prolific EDBT authors). With such primitives, a user can flexibly and unambiguously specify the outliers to be mined in a heterogeneous network.

Besides providing flexible ways for users to interact with the system to specify outlier queries in networks, another important issue is how to define the outlier measures for heterogeneous networks. Taking the query, "finding outlying co-authors of Christos in terms of their publishing venues", it is important to work out a good outlier measure in heterogeneous networks so that one can readily identify the outliers among Christos' co-authors who published multiple papers at rather different venues than that by the majority coauthors of Christos. Such intuition may help us work out a new definition of outlier measure in heterogeneous networks.

In this study, we work on this interesting problem and have made the following contributions.

1. We introduce the concept of query-based outlier in heterogeneous information networks, formalize different components for an outlier query in such networks, and develop a user-friendly, meta-path based outlier query language that allows users to interact with the outlier detection system using their intuition;
2. We introduce a new outlier measure, NetOut, which defines query-based outlierness in heterogeneous information networks, with respect to the queries specified by users;
3. We develop an efficient computation method to find query-based outliers in heterogeneous information networks and analyze our performance improvement in the efficiency study.

The rest of the paper is organized as follows. Section 2 discusses the related work. Section 3 introduces the basic concepts. Section 4 introduces the formal definition of outlier query, and designs a query language as an interface for users to specify outlier queries. Section 5 develops a new outlier measure, NetOut, and shows its effectiveness. Section 6 outlines the implementation of the proposed outlier detection system as well as several query optimization techniques. The performance study of the comparative methods, as well as the efficiency study are reported in Section 7. We present an overall discussion in Section 8 and provide concluding remarks in Section 9.

2. RELATED WORK

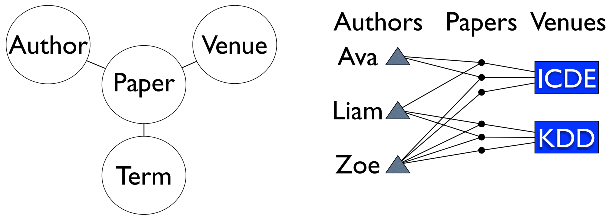
Outlier detection. The field of outlier detection has been explored for years. A good overview of outlier detection techniques can be found in surveys [5, 14].

Our work is most related to the thread of research on networked data outlier detection. There are some early explorations on network outlier detection on bipartite graphs [23]. But most existing studies are confined to homogeneous networks. For example, Gao *et al.* [6] studied contextual outliers in (homogeneous) networks, *i.e.* outliers deviating from their closely connected peers; Akoglu *et al.* [1] proposed OddBall, which takes several network structural properties as features to identify outliers in weighted graphs; Gupta *et al.* [8] studied outliers in terms of their abnormal dynamics among communities; Perozzi *et al.* [19] and Li *et al.* [18] explored outlier detection in attributed graphs. Zong *et al.* [30] studied how to detect abnormal network events and their possible sources. However, these methods are not applicable to heterogeneous information networks. For heterogeneous networks, Gupta *et al.* [7] proposed to measure outlierness based on community distribution of each vertex in the network; Gupta *et al.* [9] also studied outlier detection based on assumption of association-based cliques in networks.

Although a great variety of research has been done on outlier detection given a data set, few of them really consider doing outlier detection in a query-based fashion. Gupta *et al.* [11] proposed using a template subgraph as a query for finding outlier subgraphs, but the definition of a query in this work is not general enough to be extended to most common use cases. Efficient mining of top-k outliers in large databases has been studied in early research. For example, Ramaswamy *et al.* [20] proposed a partition-based algorithm to mine top-k outliers in very large databases, using a distance-based outlier detection algorithm [17]; Jin *et al.* [15] presented an algorithm based on "micro-clusters" to find top-k outliers using the local outlier factor (LOF) measure [4]. Nevertheless, they only optimize for a certain type of outlier definition on the entire data set. Schubert *et al.* [22] proposed a generalized point of view for local outlier detection, but it does not explicitly consider the query-based scenario. In this work we generalize the outlier detection framework and give users flexibility to specify their own definition of an outlier.

Query languages for heterogeneous networks. Managing data organized in heterogeneous information networks is a challenging problem. Compared to a traditional relational database, data is organized in an arbitrary and potentially more complicated graphical structure. There are several different threads of research on developing graph query languages and optimizing queries. A comparison of different graph database models can be found in [2, 3]. Research related to the semantic web usually organizes information into machine-readable web information represented in a language called Resource Description Framework (RDF) [12]. Optimization of the RDF query language SPARQL is studied in [21]. Cypher[2] is another query language utilized by open-source graph database Neo4j; while GraphQL [13] is another query language which supports querying by graph structure. For graph query optimization, Yan *et al.* [26, 27] and Zhao *et al.* [29] proposed indexing strategies to efficiently process graph queries. As knowledge graphs have attracted more studies in recent years, there is also some recent research on querying schema-less graphs. Kasneci *et al.* [16] studies keyword search on knowledge graphs; Yang *et al.* [28] propose an SQL framework where users do not need to specify the querying graph schema/structure precisely. Gupta *et al.* [10] proposed a method to efficiently find the top-k most inter-

[2]`http://docs.neo4j.org/chunked/stable/cypher-introduction.html`



(a) Schema (b) Instantiated network

Figure 1: Bibliographic network schema and instantiated network.

esting subgraphs in a heterogeneous network. However, as far as we know, none of the current graph query languages explicitly support queries for outlier detection in graphs.

3. PRELIMINARIES

Real-world informational or abstract entities are often interconnected, forming multiple gigantic networks. When such networks can be structured around a small number of entity/link types, many interesting properties can be explored systematically. Here we introduce a few related concepts.

Definition 1 (Heterogeneous information network). *A heterogeneous information network [25] is an information network with multiple types of vertices. Without loss of generality, it can be defined as a directed network $G = (\mathcal{V}, \mathcal{E}; \phi, \mathcal{T})$ where $\mathcal{V}$ is the set of vertices, and $\mathcal{E}$ is the set of edges. There is a vertex type mapping function $\phi : \mathcal{V} \to \mathcal{T}$ where $\mathcal{T}$ is the set of types, i.e., each vertex $v \in \mathcal{V}$ belongs to a particular type $T \in \mathcal{T}$. For undirected cases, an undirected edge can be viewed as two symmetric directed edges. When there exists only one vertex type, the network reduces to a homogeneous information network.*

A bibliographic network, such as DBLP, is a heterogeneous information network where there are four types of vertices: paper (P), venue (V), author (A), and term (T), and an edge type represents a type of link between two vertex types (*e.g.*, $P-V$ represents that paper P was published in venue V).

To formalize the relationships between two vertices in a heterogeneous network, meta-paths [24] have been used to represent semantic links at the schema level.

Definition 2 (Meta-path). *In a heterogeneous network G, a meta-path is an ordered sequence of vertex types, denoted as $\mathcal{P} = (T_0 - T_1 - \ldots - T_l)$, or $\mathcal{P} = (T_0T_1 \ldots T_l)$, where $T_x \in \mathcal{T}$.*

In a bibliographic network, $\mathcal{P}_{ca} = (APA)$ is a meta-path, representing the coauthorship between two authors.

We also introduce two basic operators for meta-paths.

Definition 3 (Reversal of a meta-path). *A meta-path $\mathcal{P} = (T_0T_1 \ldots T_l)$ can be reversed, where the reversed path is denoted as $\mathcal{P}^{-1} = (T_lT_{l-1} \ldots T_0)$.*

As an example, if $\mathcal{P} = (APV)$, then its reversal $\mathcal{P}^{-1} = (VPA)$.

Definition 4 (Concatenation of meta-paths). *Given two meta-paths $\mathcal{P}_1 = (T_{1,0} \ldots T_{1,l})$ and $\mathcal{P}_2 = (T_{2,0} \ldots T_{2,l'})$. If $T_{1,l} = T_{2,0}$, then $\mathcal{P}_1$ can be concatenated by $\mathcal{P}_2$, where the concatenated meta-path is denoted as $(\mathcal{P}_1\mathcal{P}_2) = (T_{1,0} \ldots T_{1,l}T_{2,1} \ldots T_{2,l'})$.*

For example, if we have two meta-paths $\mathcal{P}_1 = (APV)$ and $\mathcal{P}_2 = (VPT)$, $\mathcal{P}_1$ can be concatenated by $\mathcal{P}_2$, and the concatenated meta-path $(\mathcal{P}_1\mathcal{P}_2) = (APVPT)$.

Meta-paths provide the schema to instantiate actual paths in a heterogeneous network.

Definition 5 (Meta-path instantiation). *We say an instantiation of $\mathcal{P}$ is a path in G, denoted as $p = (v_0v_1 \ldots v_l)$, satisfying $\phi(v_x) = T_x, \forall x = 0, 1, \ldots, l$. A meta-path can be instantiated by different paths. We represent the set of all path instances of meta-path $\mathcal{P}$ between vertices v_i and v_j by $\pi_{\mathcal{P}}(v_i, v_j)$.*

As an example, for authors Ava and Liam in Figure 1(b), the number of instantiations of meta-path $\mathcal{P}_{ca} = (APA)$ connecting them represents the number of papers they have coauthored, denoted as $|\pi_{\mathcal{P}_{ca}}(\text{Ava, Liam})| = 1$. Similarly, for authors Liam and Zoe, the number of instantiations of meta-path $\mathcal{P}_{ca}$ connecting them is $|\pi_{\mathcal{P}_{ca}}(\text{Liam, Zoe})| = 2$.

Based on the definition of a meta-path, we can define the "neighbors" of a vertex in a heterogeneous network. Different from traditional homogeneous networks, immediate neighbors of a certain vertex could be of different types and therefore have different semantics. Also, vertices that are multiple hops away from the given vertex can be meaningful "neighbors". For the sake of generality, we define the neighborhood of a vertex with respect to a given meta-path. Formally,

Definition 6 (Neighborhood). *In a heterogeneous network G, we define the neighborhood of a certain vertex v_i with regard to a given meta-path $\mathcal{P}$ as $N_{\mathcal{P}}(v_i) = \{v_j | \pi_{\mathcal{P}}(v_i, v_j) \neq \emptyset\}$.*

For example, the set of coauthors of author Zoe in Figure 1(b) can be represented by $N_{\mathcal{P}_{ca}}(\text{Zoe}) = \{\text{Ava, Liam}\}$.

Every vertex v_j, in the neighborhood of vertex v_i, is connected to v_i by at least one instantiation of the specified meta-path. However, multiple instantiations may exist. To better characterize the neighborhood of a vertex, we further define a vector representation of the neighborhood as a "neighbor vector".

Definition 7 (Neighbor vector). *We define a function $\sigma_{\mathcal{P}} : V \mapsto \mathbb{N}^{|V|}$ as the neighbor vector function. With regard to a given meta-path $\mathcal{P}$, it returns the neighbor vector given a certain vertex as input, where the j-th dimension is the count of paths instantiated by $\mathcal{P}$ between v_i and v_j. More precisely,*

$$\sigma_{\mathcal{P}}(v_i) = \Big[|\pi_{\mathcal{P}}(v_i, v_1)|, \ldots, |\pi_{\mathcal{P}}(v_i, v_n)|\Big]$$

For example, given meta-path $\mathcal{P}_{ca}$, Zoe's neighbor vector contains the count of papers co-authored with each of her coauthors, $\sigma_{\mathcal{P}_{ca}}(\text{Zoe}) = [\text{Ava} : 1, \text{Liam} : 2, \text{Zoe} : 5]$. Alternatively, Zoe's neighbor vector given meta-path $\mathcal{P}_v = (APV)$ is the count of papers that she has published in each venue, $\sigma_{\mathcal{P}_v}(\text{Zoe}) = [\text{ICDE} : 2, \text{KDD} : 3]$.

4. OUTLIER QUERIES

In this section, we formalize the definition of a query in the context of outlier detection in heterogeneous information networks. We also design a query language for users to specify queries.

4.1 General Formalization

Generally, a declarative query for outliers consists of two parts, a candidate set containing all the candidates that are potentially meaningful outliers, and a reference set providing a reference for outliers to be compared. In most outlier detection frameworks, the candidate set and the reference set are both assumed to be the entire data set. In our query-based outlier detection framework, users are provided with the flexibility to specify the candidate and reference sets of their interest, which enables our framework to be applicable to a broader range of scenarios.

Another important part of a user query is how the vertices should be compared. In a heterogeneous network, vertices can be compared in many different ways. For example, a pair of authors in a bibliographic information network can be compared based on how much their coauthors overlap, or how many common conferences they attend. Users should be given the flexibility to determine how they would like to compare two vertices.

There are two alternative ways to formulate the comparison method in a query. One is to directly ask the user to define a comparison function $\kappa : S_c \times S_r \mapsto \mathbb{R}$ to compare vertices in the candidate and reference sets; another is to ask the user to declare how a vertex should be characterized, and leave the implementation of the comparison method to the system. In most cases users are clear about the semantics of the desired outliers (*e.g.* comparing two authors based on their coauthors), but do not necessarily understand how to formulate a comparison function accordingly (*e.g.* comparing two authors by the number of their common coauthors), so we adopt the second query formulation where users specify how to characterize vertices using a meta-path based language.

Based on the principles above, we assemble a query for outlier detection with the following modules: the candidate set, the reference set, feature meta-path(s) to specify how a vertex is characterized in the context of outlier detection, and an optional vector used to weight feature meta-paths. To be precise,

DEFINITION 8 (GENERAL OUTLIER QUERY). *An outlier query in a heterogeneous network G is denoted by $Q = (S_c, S_r, \mathbf{P}, \mathbf{w})$, where $S_c \subset V$ is the candidate set of vertices, from which the outliers will be chosen; $S_r \subset V$ is the reference set of vertices, serving as the reference of normal vertices; $\mathbf{P} = (\mathcal{P}_1, \dots, \mathcal{P}_m)$ is a collection of feature meta-paths, describing the user's intuition of which aspects should characterize candidate vertices; $\mathbf{w} \in \mathbb{R}^m$ is a weighting vector for feature meta-paths, and by default is an all-one vector if not specified by users. The outlier detection algorithm should return outliers as a subset of the candidate set, i.e. $\Omega \subset S_c$, that are significantly different from vertices in S_r, in terms of the given meta-paths and weighting vector.*
