A second dimension is **how the source (or local) schemas are connected to the global (integration) schema**, using *mappings* [23]. There are three types of mappings, each corresponding to a column in Table 1. The simplest mappings define each element of the global schema, e.g., each relation (if the global schema is relational), as a view over the local schemas; this is known as Global-As-View, or **GAV** in short. In a GAV system, a query over the global (virtual) schema is easily transformed into a query over the local schemas, by *unfolding* each global schema relation, i.e., replacing it with its definition. In contrast, Local-As-View (**LAV**) mappings define elements of the local schemas as views over the global one. Query answering in this context requires *rewriting the query with the views* describing the local sources [31]. Global-Local-As-View (**GLAV**) data integration generalizes both GAV and LAV. A GLAV mapping pairs a query q_1 over one or several local schemas to a query q_2 over the global schema, having the same answer variables. The semantics is that for each answer of q_1, the integration system exposes the data comprised in a corresponding answer of q_2. *GLAV maximizes flexibility*, or, equivalently, *integration expressive power*: unlike LAV, a GLAV mapping may expose only part of a given source's data, and may combine data from several sources; unlike GAV, a GLAV mapping may include joins or complex expressions over the global schema.

In this work, we study **GLAV mediation supporting SPARQL queries over the data and the ontology**. We pick GLAV for its highest expressive power, RDF for its wide adoption, and aim at querying the data and the ontology in order to fully benefit from the flexibility and expressivity of RDF. As Table 1 shows, our system is *the first capable of integrating multiple data sources through GLAV mappings, for SPARQL querying over the data and the ontology*; further, it supports *heterogeneous* data sources (of different data models). A benefit of our using GLAV is the ability to support a form of *incomplete information*, naturally present in RDF through the so-called *blank nodes*, in the virtual RDF graph exposed by the mediator (see Section 3.1).

Our closest competitors only support GAV mappings, even though some support more expressive ontologies and/or queries [16, 33, 44]. Formal OBDA frameworks based on GLAV mappings have been defined, e.g., [18], without concretely deployed systems. A technique for simulating GLAV mappings through GAV ones under certain conditions is suggested in [21], however this solution has many drawbacks; we defer a detailed discussion to Section 6.

Contributions and novelty The contributions we make in this work are as follows.

(1). RIS Formalism We formally define **RDF Integration Systems** (RIS, in short), OBDA mediators capable of exposing data from heterogeneous sources of virtually any data model through GLAV mappings, under the form of an RDF graph endowed with an RDFS ontology. We formalize the problem of BGP (basic graph pattern) RDF query answering over the RDF data and ontology exposed in such systems.

(2). Novel RIS query answering techniques We describe several RIS query answering methods based on transforming *mappings into LAV view definitions*, and on reducing query answering to rewriting it using views. Our first method combines known techniques; the other two methods are novel, and rely on a form of *mapping saturation*. We show that a smart decomposition of reasoning between offline precomputation and query time makes one of these methods much faster than the others.

The paper is organized as follows. Section 2 recalls a set of preliminary notions we build upon. Then, Section 3 defines our RIS and formalizes RIS query answering. Section 4 describes RIS query answering methods. Section 5 presents our experiments, then we discuss related work and conclude.

2 PRELIMINARIES

We present the basics of the RDF graph data model (Section 2.1), of RDF entailment used to make explicit the implicit information RDF graphs encode (Section 2.2), and how RDF graphs can be queried using the widely-considered SPARQL Basic Graph Pattern queries (Section 2.3).

Then, we recall two techniques, namely *query reformulation* (Section 2.4) and *view-based query rewriting* (Section 2.5), which will serve as building blocks for our query answering techniques.

2.1 RDF Graphs

We consider three pairwise disjoint sets of values: $\mathscr{I}$ of IRIs (resource identifiers), $\mathscr{L}$ of literals (constants) and $\mathscr{B}$ of blank nodes modeling unknown IRIs or literals, a.k.a. *labelled nulls* [3, 29]. A *(well-formed) triple* belongs to $(\mathscr{I} \cup \mathscr{B}) \times \mathscr{I} \times (\mathscr{L} \cup \mathscr{I} \cup \mathscr{B})$, and an *RDF graph* G is a set of (well-formed) triples. A triple $(\mathsf{s}, \mathsf{p}, \mathsf{o})$ states that its *subject* s has the *property* p with the *object* value o [47]. We denote by $\mathrm{Val}(G)$ the set of all values (IRIs, blank nodes and literals) occurring in an RDF graph G, and by $\mathrm{Bl}(G)$ its set of blank nodes. In triples, we use _:b (possibly with indices) to denote blank nodes, and quoted strings to denote literals.

Schema triples	Notation
Subclass	$(\mathsf{s}, \prec_{sc}, \mathsf{o})$
Subproperty	$(\mathsf{s}, \prec_{sp}, \mathsf{o})$
Domain typing	$(\mathsf{s}, \hookleftarrow_{d}, \mathsf{o})$
Range typing	$(\mathsf{s}, \hookrightarrow_{r}, \mathsf{o})$
Data triples	Notation
Class fact	$(\mathsf{s}, \tau, \mathsf{o})$
Property fact	$(\mathsf{s}, \mathsf{p}, \mathsf{o})$ s.t. $\mathsf{p} \notin \{\tau, \prec_{sc}, \prec_{sp}, \hookleftarrow_{d}, \hookrightarrow_{r}\}$

Table 2: RDF triples.

Within an RDF graph, we distinguish **data** triples from **schema** ones. The former describe data (either attach a type, or a class, to a resource, or state the value of a certain data property of a resource). The latter state ontological constraints using RDF Schema (RDFS), which relate classes and properties: **subclass** (specialization relation between types), **subproperty** (specialization of a binary relation), typing of the **domain** (first attribute) of a property, respectively, **range** (typing of the second attribute) of a property. Table 2 introduces short notations we adopt for these schema properties.

From now on, we denote by $\mathscr{I}_{\mathrm{rdf}}$ the *reserved* IRIs from the RDF standard, e.g., the properties τ, $\prec_{sc}$, $\prec_{sp}$, $\hookleftarrow_{d}$, $\hookrightarrow_{r}$ shown in Table 2. The rest of the IRIs are application-dependent classes and properties, which are said *user-defined* and denoted by $\mathscr{I}_{\mathrm{user}}$. Hence, $\mathscr{I}_{\mathrm{user}} = \mathscr{I} \setminus \mathscr{I}_{\mathrm{rdf}}$.

We will consider RDF graphs with *RDFS ontologies* made of schema triples of the four above flavours. More precisely:

Definition 2.1 (RDFS ontology). An *ontology triple* is a schema triple whose subject and object are user-defined IRIs from $\mathscr{I}_{\mathrm{user}}$. An *RDFS ontology* (or ontology in short) is a set of ontology triples. Ontology O *is the ontology of an RDF graph* G if O is the set of schema triples of G.

Above, ontology triples are not allowed over blank nodes. This is only to simplify the presentation; we could have allowed them, and handled them as in [29]. More importantly, we forbid ontology triples from altering the common semantics of RDF itself. For instance, we do not allow $(\hookleftarrow_{d}, \prec_{sp}, \hookrightarrow_{r})$, which would impose that the range of every property shares all the types of the property's domain! This second restriction can be seen as common-sense; it underlies most ontological formalisms, in particular description logics [8] thus the W3C's Web Ontology Language (OWL), Datalog± [15] and existential rules [39], etc.

Example 2.2 (Running example, based on [12]). Consider the following RDF graph:

$G_{\mathrm{ex}} = \{$(:worksFor, $\hookleftarrow_{d}$, :Person), (:worksFor, $\hookrightarrow_{r}$, :Org),
(:PubAdmin, $\prec_{sc}$, :Org), (:Comp, $\prec_{sc}$, :Org),
(:NatComp, $\prec_{sc}$, :Comp), (:hiredBy, $\prec_{sp}$, :worksFor)
(:ceoOf, $\prec_{sp}$, :worksFor), (:ceoOf, $\hookrightarrow_{r}$, :Comp),
(:p$_1$, :ceoOf, _:b_c), (_:b_c, τ, :NatComp),
(:p$_2$, :hiredBy, :a), (:a, τ, :PubAdmin)$\}$

The ontology of G_{ex}, i.e., the first eight schema triples, states that people work for organizations, some of which are public administrations or companies. Further, national companies are a kind of companies. Being hired by or being CEO of an organization are two ways of working for it; in the latter case, this organization is a company. The facts of G_{ex}, i.e., the four remaining data triples, state that :p$_1$ is CEO of some unknown company represented by the blank node _:b_c, which is a national company, and :p$_2$ is hired by the public administration :a.

	Rule [48]	Entailment rule	
$\mathcal{R}$	`rdfs5`	$(\mathsf{p}_1, \prec_{sp}, \mathsf{p}_2), (\mathsf{p}_2, \prec_{sp}, \mathsf{p}_3) \rightarrow (\mathsf{p}_1, \prec_{sp}, \mathsf{p}_3)$	$\mathcal{R}_c$
	`rdfs11`	$(\mathsf{s}, \prec_{sc}, \mathsf{o}), (\mathsf{o}, \prec_{sc}, \mathsf{o}_1) \rightarrow (\mathsf{s}, \prec_{sc}, \mathsf{o}_1)$	
	`ext1`	$(\mathsf{p}, \hookleftarrow_d, \mathsf{o}), (\mathsf{o}, \prec_{sc}, \mathsf{o}_1) \rightarrow (\mathsf{p}, \hookleftarrow_d, \mathsf{o}_1)$	
	`ext2`	$(\mathsf{p}, \hookrightarrow_r, \mathsf{o}), (\mathsf{o}, \prec_{sc}, \mathsf{o}_1) \rightarrow (\mathsf{p}, \hookrightarrow_r, \mathsf{o}_1)$	
	`ext3`	$(\mathsf{p}, \prec_{sp}, \mathsf{p}_1), (\mathsf{p}_1, \hookleftarrow_d, \mathsf{o}) \rightarrow (\mathsf{p}, \hookleftarrow_d, \mathsf{o})$	
	`ext4`	$(\mathsf{p}, \prec_{sp}, \mathsf{p}_1), (\mathsf{p}_1, \hookrightarrow_r, \mathsf{o}) \rightarrow (\mathsf{p}, \hookrightarrow_r, \mathsf{o})$	
	`rdfs2`	$(\mathsf{p}, \hookleftarrow_d, \mathsf{o}), (\mathsf{s}_1, \mathsf{p}, \mathsf{o}_1) \rightarrow (\mathsf{s}_1, \tau, \mathsf{o})$	$\mathcal{R}_a$
	`rdfs3`	$(\mathsf{p}, \hookrightarrow_r, \mathsf{o}), (\mathsf{s}_1, \mathsf{p}, \mathsf{o}_1) \rightarrow (\mathsf{o}_1, \tau, \mathsf{o})$	
	`rdfs7`	$(\mathsf{p}_1, \prec_{sp}, \mathsf{p}_2), (\mathsf{s}, \mathsf{p}_1, \mathsf{o}) \rightarrow (\mathsf{s}, \mathsf{p}_2, \mathsf{o})$	
	`rdfs9`	$(\mathsf{s}, \prec_{sc}, \mathsf{o}), (\mathsf{s}_1, \tau, \mathsf{s}) \rightarrow (\mathsf{s}_1, \tau, \mathsf{o})$	

Table 3: Sample RDFS entailment rules.

2.2 RDF Entailment Rules

An *entailment rule* r has the form body(r) $\rightarrow$ head(r), where body(r) and head(r) are RDF graphs, respectively called *body* and *head* of the rule r. In this work, we consider the **RDFS entailment rules** $\mathcal{R}$ shown in Table 3, which are the most frequently used; in the table, all values except RDF reserved IRIs are blank nodes. For instance, rule `rdfs5` reads: whenever in an RDF graph, a property p_1 is a subproperty of a property p_2, and further p_2 is a subproperty of p_3 (body of `rdfs5`), it follows that p_1 is a subproperty of p_3 (head of `rdfs5`). Similarly, rule `rdfs7` states that if p_1 is a subproperty of p_2 and a resource s has the value o for p_1, then s also has o as a value for p_2. The triples $(\mathsf{p}_1, \prec_{sp}, \mathsf{p}_3)$ and $(\mathsf{s}, \mathsf{p}_2, \mathsf{o})$ in the above examples are called **implicit**, i.e., they hold in a graph thanks to the entailment rules, even if they may not be **explicit**ly present in the graph. Following [12], we view $\mathcal{R}$ as partitioned into two subsets: the rules $\mathcal{R}_c$ lead to implicit schema triples, while rules $\mathcal{R}_a$ lead to implicit data triples[1]. The **direct entailment** of an RDF graph G with a set of RDF entailment rules $\mathcal{R}$, denoted by $C_{G,\mathcal{R}}$, is the set of implicit triples resulting from rule applications that use solely the explicit triples of G. For instance, the rule `rdfs9` applied to the graph G_{ex}, which comprises (:NatComp, $\prec_{sc}$, :Comp), (_:b_c, τ, :NatComp), leads to the implicit triple (_:b_c, τ, :Comp). This triple belongs to $C_{G_{\text{ex}},\mathcal{R}_a}$ (hence also to $C_{G_{\text{ex}},\mathcal{R}}$). The **saturation** of an RDF graph allows materializing its semantics, by iteratively augmenting it with the triples it entails using entailment rules, until reaching a fixpoint; this process is finite [48]. Formally:

Definition 2.3 (RDF graph saturation). Let G be an RDF graph and $\mathcal{R}$ a set of entailment rules. We recursively define a sequence $(G_i)_{i\in\mathbb{N}}$ of RDF graphs as follows: $G_0 = G$, and $G_{i+1} = G_i \cup C_{G_i,\mathcal{R}}$ for $i \geq 0$. The *saturation* of G w.r.t. $\mathcal{R}$, denoted $G^{\mathcal{R}}$, is G_n for n the smallest integer such that $G_n = G_{n+1}$.

Example 2.4 (Saturation). The saturation of G_{ex} w.r.t. the set $\mathcal{R}$ of RDFS entailment rules shown in Table 3 is attained after the following *two* saturation steps:

$(G_{\text{ex}})_1 = G_{\text{ex}} \cup$
{(:NatComp, $\prec_{sc}$, :Org),
(:hiredBy, $\hookleftarrow_d$, :Person), (:hiredBy, $\hookrightarrow_r$, :Org),
(:ceoOf, $\hookleftarrow_d$, :Person), (:ceoOf, $\hookrightarrow_r$, :Org),
(:p$_1$, :worksFor, _:b_c), (_:b_c, τ, :Comp),
(:p$_2$, :worksFor, :a), (:a, τ, :Org)}

$(G_{\text{ex}})_2 = (G_{\text{ex}})_1 \cup$
{(:p$_1$, τ, :Person), (:p$_2$, τ, :Person), (_:b_c, τ, :Org)}

2.3 Basic Graph Pattern Queries

A popular RDF query dialect consists of **basic graph pattern queries**, or **BGPQs**, in short. Let $\mathscr{V}$ be a set of variable symbols, disjoint from $\mathscr{I} \cup \mathscr{B} \cup \mathscr{L}$. A basic graph pattern (BGP) is a set of *triple patterns* (triples in short) belonging to $(\mathscr{I} \cup \mathscr{B} \cup \mathscr{V}) \times (\mathscr{I} \cup \mathscr{V}) \times (\mathscr{I} \cup \mathscr{B} \cup \mathscr{L} \cup \mathscr{V})$. For a BGP P, we denote by Var(P) the set of variables occurring in P, by Bl(P) its set of blank nodes, and by Val(P) its set of values (IRIs, blank nodes, literals and variables).

Definition 2.5 (BGP Queries). A *BGP query* q is of the form $q(\bar{x}) \leftarrow P$, where P is a BGP (also denoted by body(q)), and $\bar{x} \subseteq$ Var(P) are the answer variables of q.

To ease the presentation, and without loss of generality, we consider BGPQs *without* blank nodes, as it is well-known that these can be replaced by non-answer variables [46].

For query answering based on query reformulation (see Section 2.4), it is convenient to slightly generalize BGPQs into **partially instantiated BGPQs** [12, 29]. Starting from a BGPQ q, partial instantiation may replace *some* variables with values from $\mathscr{I} \cup \mathscr{L} \cup \mathscr{B}$, as specified by a substitution σ. Due to σ, and in contrast with standard BGPQs, some answer variables of the resulting query q_σ can be bound:

Example 2.6 (Partially instantiated BGPQ). Consider the BGPQ asking for *who is working for which kind of company* $q(x, y) \leftarrow (x, \text{:worksFor}, z), (z, \tau, y), (y, \prec_{sc}, \text{:Comp})$ and the substitution $\sigma = \{x \mapsto \text{:p}_1\}$. The corresponding partially instantiated BGPQ is: $q(\text{:p}_1, y) \leftarrow (\text{:p}_1, \text{:worksFor}, z), (z, \tau, y), (y, \prec_{sc}, \text{:Comp})$. In it, the first answer variable has been bound to :p$_1$.

For simplicity, below we use the term "query" to designate either a standard BGPQ or a partially instantiated BPGQ.

The semantics of a BGPQ on an RDF graph is defined through standard **homomorphisms** from the query body to the queried graph. We recall that a homomorphism from a BGP P to an RDF graph G is a function φ from Val(P) to Val(G) such that for any triple $(s, p, o) \in P$, the triple $(\varphi(s), \varphi(p), \varphi(o))$ is in G, with φ the identity on IRIs and literals. Next, we distinguish **query evaluation**, whose result is just based on the explicit triples of the graph, i.e., on BGP-to-RDF graph homomorphisms, from **query answering** that also accounts for the implicit graph triples, resulting from entailment. Formally:

Definition 2.7 (Evaluation and answering). The *answer set* to a BGPQ q on an RDF graph G w.r.t. a set $\mathcal{R}$ of RDF entailment rules is: $q(G, \mathcal{R}) = \{\varphi(\bar{x}) \mid \varphi \textit{ homomorphism from } \text{body}(q) \textit{ to } G^{\mathcal{R}}\}$. If $\bar{x} = \emptyset$, q is a *Boolean* query, in which case q is false when $q(G, \mathcal{R}) = \emptyset$ and true when $q(G, \mathcal{R}) = \{\langle\rangle\}$, i.e., the answer to q is the empty tuple.

The *evaluation* of q on G, denoted $q(G, \emptyset)$ or $q(G)$ in short, is obtained from homomorphisms from body(q) to G alone (not $G^{\mathcal{R}}$). It can be seen as a particular case of query answering when $\mathcal{R} = \emptyset$.

Example 2.8 (Evaluation and answering). Consider again the BGPQ q from the preceding example. Its evaluation on G_{ex} is empty because G_{ex} has no explicit :worksFor assertion, while its answer set on G_{ex} w.r.t. $\mathcal{R}$ is $\{\langle \text{:p}_1, \text{:NatComp}\rangle\}$ because :p$_1$ being CEO of _:b_c, :p$_1$ implicitly works for it, and _:b_c is explicitly a company of the particular type :NatComp.

The above notions and notations naturally extend to *unions* of (partially instantiated) BGPQs, or **UBGPQ**s in short.

We end this section by pointing out that many RDF data management systems use *saturation-based query answering*, which directly follows the definition of query answering: an RDF graph G is first saturated with the set $\mathcal{R}$ of entailment rules, so that the

[1]In the notations $\mathcal{R}_c$ and $\mathcal{R}_a$, c and a respectively stand for "constraint triples" (called schema triples here) and "assertion triples" (data triples).

answer set to an incoming query q is obtained through query evaluation as $q(G^{\mathcal{R}})$.

2.4 Query Reformulation

Reformulation-based query answering is an alternative technique to the widely adopted saturation-based query answering. It consists in *reformulating* a query using $\mathcal{R}$, so that evaluating the reformulated query on G yields the answer set to the original query on G w.r.t. $\mathcal{R}$. Intuitively, reformulation injects the ontological knowledge into the query, just as saturation injects it into the RDF graph. We rely here on the very recent algorithm from [12], which takes into account all the entailment rules from Table 3. The process is decomposed into *two steps* according to the partition of $\mathcal{R}$ into $\mathcal{R}_a$ and $\mathcal{R}_c$.
(i) The first step reformulates a BGPQ q w.r.t. an RDFS ontology O and the set of rules $\mathcal{R}_c$ into a UBGPQ, say Q_c, which is guaranteed not to contain ontology triples. Intuitively, this step generates new BGPQs obtained from q by instantiating variables that query the ontology with all their possible bindings; for instance, y in a query triple $(y, \prec_{sc}, \text{:Comp})$ is bound to the IRIs of all explicit and implicit subclasses of :Comp in O. This step, alone, is sound and complete w.r.t. $\mathcal{R}_c$ for query answering, i.e., for any graph G with ontology O, $q(G, \mathcal{R}_c) = Q_c(G)$.
(ii) The second step reformulates Q_c w.r.t. O and $\mathcal{R}_a$, and outputs a UBGPQ, say $Q_{c,a}$. This step, alone, is sound and complete w.r.t. $\mathcal{R}_a$ for query answering, i.e., for any graph G with ontology O, $Q_c(G, \mathcal{R}_a) = Q_{c,a}(G)$. Furthermore, a key property is that $q(G, \mathcal{R}) = Q_c(G, \mathcal{R}_a)$, i.e., only $\mathcal{R}_a$ needs to be considered to answer Q_c with respect to the entire set of rules $\mathcal{R}$. This is the fundamental reason why the sucessive application of these two reformulation steps leads to a sound and complete reformulation-based query answering technique: $q(G, \mathcal{R}) = Q_{c,a}(G)$.

Example 2.9 (Two-step reformulation). Consider the query $q(x, y) \leftarrow (x, \text{:worksFor}, z), (z, \tau, y), (y, \prec_{sc}, \text{:Comp})$ from the preceding example and the ontology O in Example 2.2. The first reformulation step instantiates the triple $(y, \prec_{sc}, \text{:Comp})$ on O, leading to:
$Q_c = q(x, \text{:NatComp}) \leftarrow (x, \text{:worksFor}, z), (z, \tau, \text{:NatComp})$.
Then, Q_c is reformulated into $Q_{c,a}$ =
$q(x, \text{:NatComp}) \leftarrow (x, \text{:worksFor}, z), (z, \tau, \text{:NatComp}) \cup$
$q(x, \text{:NatComp}) \leftarrow (x, \text{:hiredby}, z), (z, \tau, \text{:NatComp}) \cup$
$q(x, \text{:NatComp}) \leftarrow (x, \text{:ceoOf}, z), (z, \tau, \text{:NatComp})$
by specializing :worksFor according to its subproperties in O. It can be checked that $Q_{c,a}(G_{\text{ex}}) = q(G_{\text{ex}}, \mathcal{R}) = q(G_{\text{ex}}^{\mathcal{R}}) = \{\langle \text{:p}_1, \text{:NatComp}\rangle\}$, obtained here from the third BGPQ in $Q_{c,a}$.

2.5 Query Rewriting-based Data Integration

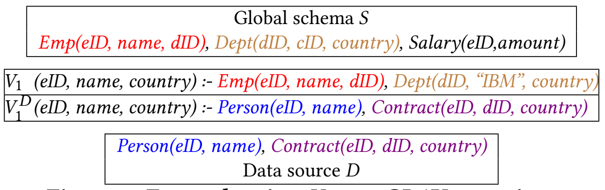
We recall now the basics of relational view-based query rewriting (Section 2.5.1), which has been extensively studied [23, 31]. Then we present a generalization of the notion of views as mappings [35] (Section 2.5.2).

2.5.1 View-based (LAV) Data Integration.

An integration system $\mathcal{I}$ is made of a *global schema* S (a set of relations) and a set $\mathcal{V}$ of *views*. An instance of $\mathcal{I}$ assigns a set of tuples to each relation of S and to each view of $\mathcal{V}$. The data stored in a view is called its *extension*. Further, to each view V is associated a query $V(\bar{x})$:- $\psi(\bar{x})$ over the global schema S, specifying how its data fits into S. Accordingly, this framework is called local-as-view (LAV) data integration. For instance, let S consist of three relations *Emp(eID, name, dID), Dept(dID, cID, country), Salary(eID,amount)*, where *eID*, *dID* and *cID* are respectively identifiers for employees, departments and companies.
Consider the views V_1*(eID, name, country) :- Emp(eID, name, dID), Dept(dID, "IBM", country)* providing the names of IBM employees and where they work, and V_2*(eID, amount) :- Emp(eID, name, "R&D"), Salary(eID,amount)*, which indicates the salaries of employees in R&D departments. Typically, no single view is expected to bring *all* information of a given kind; for instance, V_1 brings *some* IBM employees, but other views may bring others, e.g., V_2, possibly overlapping with V_1; this is called the "Open World Assumption" (OWA).
In an OWA setting, we are interested in *certain answers* [31], i.e., those that are sure to be part of the query result, knowing the data present in the views. Such answers can be computed by *rewriting* a query over S, into one over the views $\mathcal{V}$; evaluating the rewriting over the view extensions produces the answers.
Ideally, a rewriting should be equivalent to the query over S, i.e., compute exactly the same answers. However, depending on the views and queries, such a rewriting may not exist. For instance, the query $q(n, a)$:- $Emp(e, n, d), Dept(d, c, \text{"France"}), Salary(e, a)$ does not have an equivalent rewriting using V_1 and V_2, because V_1 only provides IBM employees working in France, while V_2 only has salaries of employees of R&D departments. A *maximally contained rewriting* brings all the query answers that can be obtained through the given set of views; the rewriting may be not be equivalent to q (but just contained in q). In our example, $q_r(n, a)$:- $V_1(e, n, \text{"France"}), V_2(e, a)$ is a maximally contained rewriting of q; it returns employees of French IBM R&D departments with their salary, clearly a subset of q answers.
A remarkable result holds for *(unions of) conjunctive queries ((U)CQs)*, *conjunctive views* (views V such that the associated query $V(\bar{x})$:- $\psi(\bar{x})$ is a CQ) and *rewritings that are UCQs*: any maximally contained rewriting computes exactly the certain answers [2]; we will build upon this result for answering queries in our RDF integration systems.

2.5.2 GLAV Data Integration.

The above setting has been generalized to views that are not necessarily stored as such, but just queries over some *underlying data source*. For instance, assuming a data source D holds the relations *Person(eID, name)* and *Contract(eID, dID, country)* (see Figure 1) with people and their work contracts at IBM, the view V_1 from the above example may be *defined on* D by the query V_1^D over the D schema shown in the figure (note that V_1^D hides the department from system $\mathcal{I}$); V_1^D provides the extension of V_1. Similarly, view V_2 may be defined as a query over some data source (or sources).



Global schema S
Emp(eID, name, dID), Dept(dID, cID, country), Salary(eID,amount)
V_1 *(eID, name, country) :- Emp(eID, name, dID), Dept(dID, "IBM", country)*
V_1^D*(eID, name, country) :- Person(eID, name), Contract(eID, dID, country)*
Person(eID, name), Contract(eID, dID, country)
Data source D

Figure 1: Example: view V_1 as a GLAV mapping.

Query rewriting is unchanged, whether the views are stored or defined by source queries. In the latter case, to obtain answers, a view-based rewriting needs to be *unfolded*, replacing every occurence of a view symbol V with the body of the source query defining that view. Executing the resulting query (potentially over different data sources) computes the answers. This integration setting, which considers views as intermediaries between sources and the integration schema, has been called "global-local-as-view" (GLAV) [26]. An association of a query q_1 over the data sources and another query q_2 over the global schema, both with the same answer variables, e.g., $q_1 = V_1^D$ and $q_2 = V_1$ above, is commonly called a *GLAV mapping* (denoted $q_1(\bar{x}) \rightsquigarrow q_2(\bar{x})$).

Historically, two restrictions of GLAV mappings have been investigated. First, *global-as-view* (or GAV) mappings define global schema relations as views over the local schemas. Specifically, a GAV mapping $q_1(\bar{x}) \rightsquigarrow q_2(\bar{x})$, q_2 defines a single element of the global schema (hence $body(q_2)$ is restricted to a single atom if q_2 is a CQ, or a single triple pattern if q_2 is a BGPQ) and its variables are exactly $\bar{x}$. Second, *local-as-view* (LAV) mappings express elements of the local schema as views over the global schema, similarly to the views described in Section 2.5.1.

Importantly, unlike GAV mappings, GLAV ones do not require all variables of q_2 to be answer variables (e.g., *dID* in V_1 in Figure 1); this makes integration more powerful. For example, suppose that ⟨1,*"John Doe"*,*"France"*⟩ is an answer to V_1^D above. Then, V_1 exposes this tuple in the global schema as: *Emp*(1,*"John Doe"*,x), *Dept*(x,*"IBM"*,"France"), stating that John Doe works for a department x located in France. Here, x is an existential variable (called "labeled null" in [3]); the GLAV mapping *states the existence* of such a department in the global schema, even if its identifier is unknown (because it is not provided by V_1). Therefore, John Doe is a certain answer to a query asking for all employees in IBM departments, based on the above GLAV mapping. This answer cannot be found using GAV mappings.

3 PROBLEM STATEMENT

In this section, we first formalize the notion of *RDF integration system* (Section 3.1). Then, we state the associated query answering problem (Section 3.2), for which Section 4 provides solutions.

3.1 RDF integration system (RIS)

In an RDF integration system (RIS in short), data from heterogeneous sources, each of which may have its own data model and query language, is integrated into an RDF graph, consisting of an (RDFS) ontology and of data triples derived from the sources by means of GLAV-style mappings. Mappings allow (*i*) specifying the data made available from the sources, and (*ii*) organizing it according to the RIS ontology.

Definition 3.1 (RIS mappings and extensions).
A *RIS mapping* m is of the form $m = q_1(\bar{x}) \rightsquigarrow q_2(\bar{x})$ where q_1 and q_2 are two queries with the same answer variables, and q_2 is a BGPQ whose body contains only triples of the forms:

- $(\mathsf{s}, p, \mathsf{o})$ where $p \in \mathscr{I}_{\text{user}}$,
- (s, τ, C) where $C \in \mathscr{I}_{\text{user}}$.

The *body* of m is q_1 and its *head* is q_2. The *extension* of m is the set of tuples $\text{ext}(m) = \{V_m(\delta(v_1), \dots, \delta(v_n)) \mid \langle v_1, \dots, v_n \rangle \in q_1(D)\}$, where $q_1(D)$ is the answer set of q_1 on the data source D that m integrates and δ is a function that maps source values to RDF values, i.e., IRIs, blank nodes and literals.

Intuitively, m specifies that the result of query q_1 on D transformed in RDF, i.e., the extension of m, is exposed to the RIS as the result of the (BGP) query q_2.

Example 3.2 (Mappings). Consider the two mappings:
m_1 with head $q_2(x) \leftarrow (x, \text{:ceoOf}, y), (y, \tau, \text{:NatComp})$ and
m_2 with head $q_2(x, y) \leftarrow (x, \text{:hiredBy}, y), (y, \tau, \text{:PubAdmin})$.
Suppose that the body of m_1 returns $\langle p^{D_1} \rangle$ as its results, and that the δ function maps the value $p_1^{D_1}$ from the data source D_1 to the IRI :p$_1$. Then, the extension of m_1 is: $\text{ext}(m_1) = \{V_{m_1}(\text{:p}_1)\}$. Further, suppose that the body of m_2 returns $\langle p_2^{D_2}, a^{D_2} \rangle$, and that δ maps the values $p_2^{D_2}, a^{D_2}$ from the data source D_2 to the IRIs :p$_2$, :a. Then, the extension of m_2 is: $\text{ext}(m_2) = \{V_{m_2}(\text{:p}_2, \text{:a})\}$.

Given a set of RIS mappings $\mathcal{M}$, the *extent* of $\mathcal{M}$ is the union of the mappings' extensions, i.e., $\mathcal{E} = \bigcup_{m \in \mathcal{M}}$ *ext(m)*, and we denote by $\text{Val}(\mathcal{E})$ the set of values occurring in $\mathcal{E}$. We can now define the RIS data triples *induced* by some mappings and an extent thereof. These are *all the data which is exposed (can be queried) through a RIS.*

Definition 3.3 (RIS data triples). Given a set $\mathcal{M}$ of RIS mappings and an extent $\mathcal{E}$ of $\mathcal{M}$, the *RIS data triples* induced by $\mathcal{M}$ and $\mathcal{E}$ form an RDF graph defined as follows:

$$G_{\mathcal{E}}^{\mathcal{M}} = \bigcup_{m = q_1(\bar{x}) \rightsquigarrow q_2(\bar{x}) \in \mathcal{M}} \{\text{bgp2rdf}(\text{body}(q_2)_{[\bar{x} \leftarrow \bar{t}]})) \mid V_m(\bar{t}) \in \mathcal{E}\}$$

where

- $\text{body}(q_2)_{[\bar{x} \leftarrow \bar{t}]}$ is the BGP $\text{body}(q_2)$ in which the answer variables $\bar{x}$ are bound to the values in the tuple $V_m(\bar{t})$, part of $\mathcal{E}$;
- $\text{bgp2rdf}(\cdot)$ is a function that transforms a BGP into an RDF graph, by replacing each variable with a fresh blank node.

Observe that, because we use GLAV mappings, RIS data triples may include fresh blank nodes, as exemplified below; these correspond to the existential variables allowed in GLAV mappings, as discussed at the end of Section 2.5.2.

Example 3.4. Reusing the mappings from Example 3.2, let $\mathcal{M} = \{m_1, m_2\}$ and its extent $\mathcal{E} = \{V_{m_1}(\text{:p}_1), V_{m_2}(\text{:p}_2, \text{:a})\}$. The RIS data triples they lead to are:

$$G_{\mathcal{E}}^{\mathcal{M}} = \{(\text{:p}_1, \text{:ceoOf}, \_\text{:}b_c), (\_\text{:}b_c, \tau, \text{:NatComp}), (\text{:p}_2, \text{:hiredBy}, \text{:a}), (\text{:a}, \tau, \text{:PubAdmin})\}$$

In particular, the first and second triples contain the blank node $\_\text{:}b_c$, introduced by bgp2rdf instead of the variable y in the head (query q_2) of m_1. Importantly, only non-answer variables in a mapping head lead to blank nodes introduced this way: by Def. 3.3, answer variables (here x for m_1 and x, y for m_2) are replaced with values from $V_m(\bar{t})$, thus from $\text{Val}(\mathcal{E})$.

Finally, we **define a RIS** as a tuple $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E} \rangle$ stating that S allows to access (query), with the reasoning power given by the set $\mathcal{R}$ of RDFS entailment rules, the RDF graph comprising the ontology O and the data triples induced by the set of mappings $\mathcal{M}$ and their extent $\mathcal{E}$.

3.2 Query answering problem

The problem we consider is answering BGPQs in a RIS. We define certain answers in a RIS setting as follows:

Definition 3.5 (Certain answer set). The *certain answer set* of a BGPQ q on a RIS $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E} \rangle$ is:
$\text{cert}(q, S) = \{\varphi(\bar{x}) \mid \varphi$ *homomorphism from* $\text{body}(q)$ *to* $(O \cup G_{\mathcal{E}}^{\mathcal{M}})^{\mathcal{R}}\}$
where $\varphi(\bar{x})$ comprises only values from $\text{Val}(\mathcal{E})$.

The certain answer set $\text{cert}(q, S)$ is thus the subset of $q(O \cup G_{\mathcal{E}}^{\mathcal{M}}, \mathcal{R})$ restricted to tuples fully built from source values, i.e., we exclude tuples with blank nodes introduced by the mappings (see Def. 3.3). Note, however, that blank nodes can be exploited to answer queries, as shown below.

Example 3.6 (Certain answers). Consider the RIS S made of the ontology O of G_{ex} in Example 2.2, the set $\mathcal{R}$ of entailment rules shown in Table 3, and the set of mappings $\mathcal{M}$ together with the extent $\mathcal{E}$ from Example 3.4.

Let $q(x, y) \leftarrow (x, \text{:worksFor}, y), (y, \tau, \text{:Comp})$ be the query asking "who works for which company", while the query $q'(x) \leftarrow (x, \text{:worksFor}, y), (y, \tau, \text{:Comp})$ asks "who works for some company". The only difference between them is that y is an answer variable in q and not in q'. The certain answer set of q is $\emptyset$,

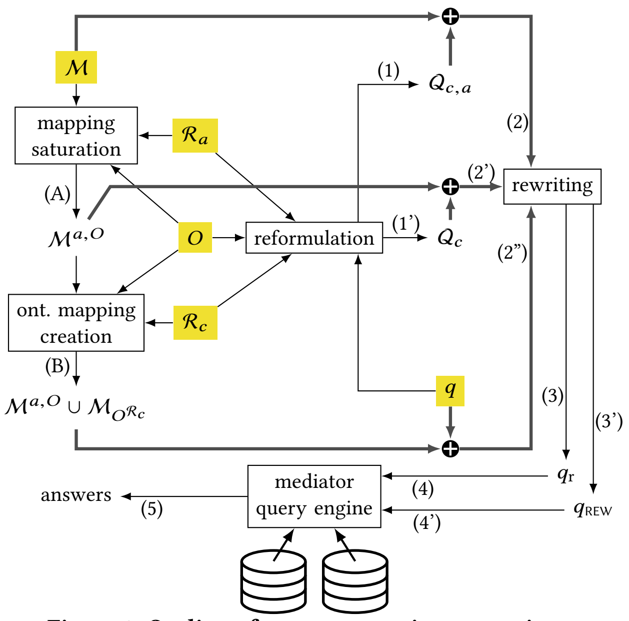


Figure 2: Outline of query answering strategies.

while the certain answer set of q' is $\{\langle :\text{p}_1 \rangle\}$. This answer results from the RIS data triples $(:\text{p}_1, :\text{worksFor}, \_:b_c)$, $(\_:b_c, \tau, :\text{Comp})$, which are entailed from:

- the $G_{\mathcal{E}}^{\mathcal{M}}$ triples $(:\text{p}_1, :\text{ceoOf}, \_:b_c)$, $(\_:b_c, \tau, :\text{NatComp})$, with the blank node $\_:b_c$ discussed in Example 3.4, and:
- either the O triples $(:\text{ceoOf}, \prec_{sp}, :\text{worksFor})$, $(:\text{ceoOf}, \hookrightarrow_r, :\text{Comp})$ together with the $\mathcal{R}$ rules `rdfs3`, `rdfs7`, or the O triples $(:\text{ceoOf}, \prec_{sp}, :\text{worksFor})$, $(:\text{NatComp}, \prec_{sc}, :\text{Comp})$ together with the $\mathcal{R}$ rules `rdfs3`, `rdfs9`.

The query q has no answer because it requires a value not available from the source: the company for which $:\text{p}_1$ works; the RIS only knows the existence of such value through the blank node $\_:b_c$ begotten by bgp2rdf in its data triples. In contrast, q' allows finding out that $:\text{p}_1$ works for (as CEO of) some (national) company, even though the mapping m_1 (the only one involving companies) does not expose the company IRI through the RIS.

The problem we study in the next section is:

Problem 1. *Given a RIS S, compute the certain answer set of a BGPQ q on S, i.e.,* cert(q, S).

4 QUERY ANSWERING IN A RIS

Since we adopt a mediator-style approach, the RIS data triples $G_{\mathcal{E}}^{\mathcal{M}}$ are not materialised, hence the saturation of $O \cup G_{\mathcal{E}}^{\mathcal{M}}$ cannot be computed to answer queries as defined above. Instead, queries are rewritten in terms of the remote heterogeneous sources, based on the RIS ontology O, reasoning power $\mathcal{R}$ and mappings $\mathcal{M}$. We present three query answering strategies, which differ in how the ontological reasoning is incorporated: we may have *all*, *some* or *no* reasoning performed at query time, as outlined in Figure 2.

All reasoning at query time The first strategy will be detailed in Section 4.1. First, it reduces the RIS query answering problem to *standard query evaluation* in an RDF data management system, by reformulating (step (1) in Figure 2) the query q based on the RIS ontology O and entailment rules $\mathcal{R} = \mathcal{R}_c \cup \mathcal{R}_a$. The obtained reformulated query $Q_{c,a}$ thus yields the expected certain answers when evaluated on the RIS data triples (recall Section 2.4), provided that answers with blank nodes introduced by the *bgp2rdf* function are discarded (recall Section 3.2). Since these data triples are not materialized, the RDF query evaluation problem is in turn reduced to *relational view-based query answering*, by rewriting $Q_{c,a}$ using the RIS GLAV mappings $\mathcal{M}$ seen as LAV views (step (2)). This produces a relational rewriting q_r over the mappings extension (step (3)), whose evaluation with a mediator query engine provides the desired certain answers (steps (4) and (5)).

Some reasoning at query time The second strategy (detailed in Section 4.2) is a main contribution of this paper. First, it reduces the RIS query answering problem to *saturation-based query answering* by reformulating (step (1')) the query q based on O and $\mathcal{R}_c$ only (not $\mathcal{R} = \mathcal{R}_c \cup \mathcal{R}_a$ as above). The obtained reformulation Q_c thus yields the expected certain answer set when evaluated on the RIS data triples *saturated with* $\mathcal{R}_a$ (recall Section 2.4), again provided that the answers with blank nodes introduced by the *bgp2rdf* function are discarded (as above). Since these triples are not materialized in a RIS, hence cannot be saturated with $\mathcal{R}_a$, the saturation-based query answering problem is in turn reduced to *relational view-based query answering*, by rewriting Q_c using the RIS GLAV mappings *saturated O and $\mathcal{R}_a$*, seen as LAV views. These saturated mappings, denoted $\mathcal{M}^{a,O}$, are obtained (step (A)) from the original ones by adding to their head queries (q_2) all the implicit data triples they model w.r.t. O and $\mathcal{R}_a$. Then, the partially reformulated query Q_c is rewritten using $\mathcal{M}^{a,O}$ (step (2')) and the resulting query (step (3)) is evaluated as in the first strategy (steps (4) and (5)). Importantly, mappings are saturated offline, and need to be updated only when some mapping changes. This limits both the reasoning effort at query time *and* the complexity of the reformulated query to rewrite, hence the rewriting time needed to obtain a rewriting q_r over the data sources, as our experiments show (Section 5).

No reasoning at query time Finally, the third strategy (detailed in Section 4.3) reduces the RIS query answering problem directly to view-based query answering. Here, the mappings are saturated offline as above (step (A)), in order to model all explicit and implicit RIS data triples. Also, these mappings are complemented with a set of mappings, noted $\mathcal{M}_{O^{\mathcal{R}_c}}$ (step (B)), comprising all the explicit and implicit RIS schema triples w.r.t. O and $\mathcal{R}$; since only $\mathcal{R}_c$ rules entail new schema triples (Table 3), $O^{\mathcal{R}}$ is actually equal to $O^{\mathcal{R}_c}$. This second set of mappings is also computed offline, and only needs to be updated when the ontology changes. A query q just needs to be rewritten based on the above mappings $\mathcal{M}^{a,O} \cup \mathcal{M}_{O^{\mathcal{R}_c}}$ seen as LAV views (step (2")), in order to obtain, as above, a rewriting q_{REW} over the data sources (step(3'), followed by the evaluation steps (4') and (5)).

Before going into the technical details of the above strategies, we introduce a set of simple functions. The *bgp2ca* function transforms a BGP into a conjunction of atoms with ternary predicate T (standing for "triple") as follows: $bgp2ca(\{(\text{s}_1, \text{p}_1, \text{o}_1), \ldots, (\text{s}_n, \text{p}_n, \text{o}_n)\}) = T(\text{s}_1, \text{p}_1, \text{o}_1) \wedge \cdots \wedge T(\text{s}_n, \text{p}_n, \text{o}_n)$. The *bgpq2cq* function transforms a BGPQ $q(\bar{x}) \leftarrow body(q)$ into a CQ $q(\bar{x}) \leftarrow bgp2ca(body(q))$. Finally, the function *ubgpq2ucq* function transforms a UBGPQ $\bigcup_{i=1}^{n} q_i(\bar{x}_i)$ into a UCQ by applying the above *bgpq2cq* function to each of its q_i.

4.1 Rewriting Fully-Reformulated Queries using Mappings as Views: REW-CA

Based on [12], the first step of this strategy, (1) in Figure 2, reformulates a query q w.r.t. O and $\mathcal{R} = \mathcal{R}_c \cup \mathcal{R}_a$ into a query $Q_{c,a}$. This allows obtaining the certain answers directly from the RIS data triples, and not from their saturation after they have been augmented with O (recall Definition 3.5). Indeed, the correctness of the reformulation ensures that the certain answers of q on the RIS S correspond precisely to those of $Q_{c,a}$ asked on S when disregarding O and $\mathcal{R}$, as formally expressed in the next lemma. Of course, this still does not provide a concrete solution to obtain the desired certain answers using standard query evaluation, since the RIS data triples $G^{\mathcal{M}}_{\mathcal{E}}$ are not materialized.

Lemma 4.1. *Let $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E}\rangle$ be a RIS, q be a BGPQ and $Q_{c,a}$ its UBGPQ reformulation w.r.t. $O, \mathcal{R} = \mathcal{R}_c \cup \mathcal{R}_a$ using [12]. Then:*

$$\text{cert}(q, S) = \text{cert}(Q_{c,a}, \langle \emptyset, \emptyset, \mathcal{M}, \mathcal{E}\rangle)$$

The proof of this and our following claims can be found in [13]. Recall that the RIS data triples are defined from the mappings $\mathcal{M}$ by, for every mapping $m = q_1(\bar{x}) \rightsquigarrow q_2(\bar{x}) \in \mathcal{M}$, (i) evaluating the mapping body $q_1(\bar{x})$ on the data source to produce its extension $\text{ext}(m) \in \mathcal{E}$, and then (ii) instantiating the mapping head $q_2(\bar{x})$ with its extension. At the same time, this is also how the instance of a data integration system based on LAV views and their extensions is defined in a relational setting (Section 2.5.1)! Based on this analogy, we *recast the RIS query answering problem* of the above Lemma, into a *relational view-based query answering* one. To this aim, we treat our mappings as LAV views:

Definition 4.2 (Mappings as relational LAV views). Let $m = q_1(\bar{x}) \rightsquigarrow q_2(\bar{x})$ be a mapping. Its corresponding relational LAV view is: $V_m(\bar{x}) \leftarrow \mathit{bgp2ca}(\text{body}(q_2))$.

Example 4.3. The relational LAV views corresponding to the mappings m_1, m_2 from Example 3.2 are:

- $V_{m_1}(x) \leftarrow T(x, \text{:ceoOf}, y), T(y, \tau, \text{:NatComp})$
- $V_{m_2}(x, y) \leftarrow T(x, \text{:hiredBy}, y), T(y, \tau, \text{:PubAdmin})$

We denote the set of views derived from all the mappings $\mathcal{M}$ by Views($\mathcal{M}$). Crucially, the extent $\mathcal{E}$ of the mapping set $\mathcal{M}$ is also an extent for the corresponding set of views Views($\mathcal{M}$).

Based on the above Lemma 4.1, treating mappings and their extent as relational LAV views and their extent, and seeing (U)BGPQs as (U)CQs with the help of the functions introduced in the beginning of Section 4, we reduce the RIS query answering problem to view-based query answering:

Theorem 4.4 (REW-CA correctness). *Let $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E}\rangle$ be a RIS and q be a BGPQ. Let $Q_{c,a}$ be the reformulation of q w.r.t. O and $\mathcal{R}$ using [12]. Then:*

$$\text{cert}(q, S) = \text{cert}(\mathit{ubgpq2ucq}(Q_{c,a}), \text{Views}(\mathcal{M}), \mathcal{E})$$

where $\text{cert}(\mathit{ubgpq2ucq}(Q_{c,a}), \text{Views}(\mathcal{M}), \mathcal{E})$ *denotes the certain answer set of* $\mathit{ubgpq2ucq}(Q_{c,a})$ *over* Views($\mathcal{M}$) *and* $\mathcal{E}$.

Importantly, this provides an effective solution to RIS query answering problem by using state-of-the-art view-based query rewriting techniques [31], in particular for step (2) in Figure 2.

Example 4.5 (REW-CA query answering). Consider again the RIS in Example 3.6 and the query $q(x, y) \leftarrow (x, y, z), (z, \tau, t), (y, \prec_{sp}, \text{:worksFor}), (t, \prec_{sc}, \text{:Comp}), (x, \text{:worksFor}, a), (a, \tau, \text{:PubAdmin})$ asking "who works for some public administration, and what working relationship he/she has with some company". Its UBGPQ reformulation, seen as a UCQ, is shown in Figure 3. Its maximally-contained rewriting based on the views obtained from the RIS mappings is: $q_r(x, \text{:ceoOf}) \leftarrow V_{m_1}(x), V_{m_2}(x, y)$, obtained from the second CQ in the above union. This becomes clear when the views are replaced by their bodies: $q(x, \text{:ceoOf}) \leftarrow T(x, \text{:ceoOf}, y_1), T(y_1, \tau, \text{:NatComp}), T(x, \text{:hiredBy}, y_2), T(y_2, \tau, \text{:PubAdmin})$. Note that the other CQs cannot be rewritten given the available views. With the current RIS, this rewriting yields an empty certain answer set to q, i.e., $\text{cert}(q, S) = \emptyset$, because the extent of the mappings, hence of the views, is: $\mathcal{E} = \{V_{m_1}(\text{:p}_1), V_{m_2}(\text{:p}_2, \text{:a})\}$. However, if we add $V_{m_2}(\text{:p}_1, \text{:a})$ to $\mathcal{E}$, then $\text{cert}(q, S) = \{\langle \text{:p}_1, \text{:ceoOf}\rangle\}$.

$$\begin{aligned}
Q_{c,a} = \quad & q(x, \text{:ceoOf}) \leftarrow && T(x, \text{:ceoOf}, z), T(z, \tau, \text{:NatComp}),\\
& && T(x, \text{:worksFor}, a), T(a, \tau, \text{:PubAdmin})\\
\cup\ & q(x, \text{:ceoOf}) \leftarrow && T(x, \text{:ceoOf}, z), T(z, \tau, \text{:NatComp}),\\
& && T(x, \text{:hiredBy}, a), T(a, \tau, \text{:PubAdmin})\\
\cup\ & q(x, \text{:ceoOf}) \leftarrow && T(x, \text{:ceoOf}, z), T(z, \tau, \text{:NatComp}),\\
& && T(x, \text{:ceoOf}, a), T(a, \tau, \text{:PubAdmin})\\
\cup\ & q(x, \text{:hiredBy}) \leftarrow && T(x, \text{:hiredBy}, z), T(z, \tau, \text{:NatComp}),\\
& && T(x, \text{:worksFor}, a), T(a, \tau, \text{:PubAdmin})\\
\cup\ & q(x, \text{:hiredBy}) \leftarrow && T(x, \text{:hiredBy}, z), T(z, \tau, \text{:NatComp}),\\
& && T(x, \text{:hiredBy}, a), T(a, \tau, \text{:PubAdmin})\\
\cup\ & q(x, \text{:hiredBy}) \leftarrow && T(x, \text{:hiredBy}, z), T(z, \tau, \text{:NatComp}),\\
& && T(x, \text{:ceoOf}, a), T(a, \tau, \text{:PubAdmin})
\end{aligned}$$

Figure 3: Sample reformulation for Example 4.5.

4.2 Rewriting Partially-Reformulated Queries using Saturated Mappings as Views: REW-C

In constrast with the REW-CA strategy that performs *all* the reasoning w.r.t. O and $\mathcal{R} = \mathcal{R}_c \cup \mathcal{R}_a$ at query time, our second strategy called REW-C splits the reasoning work between offline preprocessing and query time.

The first step of this strategy, labeled (1') in Figure 2, reformulates a query q using [12], but *solely* w.r.t. $O, \mathcal{R}_c$, producing a UBGPQ denoted Q_c. From the correctness of this reformulation step, and the fact that only $\mathcal{R}_a$ needs to be considered to answer Q_c with respect to the entire set of rules $\mathcal{R}$ (recall Section 2.4), the certain answer set of q asked on the RIS S is exactly the certain answer set of Q_c asked on S when disregarding $\mathcal{R}_c$. Formally:

Lemma 4.6. *Let $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E}\rangle$ be a RIS, q be a BGPQ and Q_c its reformulation w.r.t. $O, \mathcal{R}_c$ [12]. Then:*

$$\text{cert}(q, S) = \text{cert}(Q_c, \langle O, \mathcal{R}_a, \mathcal{M}, \mathcal{E}\rangle)$$

In other words, the desired answer set could be obtained by evaluating Q_c on the RIS data triples $G^{\mathcal{M}}_{\mathcal{E}}$ saturated by $\mathcal{R}_a$. Again, since the RIS data triples are not materialized, this does not provide a concrete solution. To account for the impact of the ontology O and the entailment rules $\mathcal{R}$ on these "virtual" data triples, we rely on *BGPQ saturation* [25]: given a BGPQ q, O and $\mathcal{R}$, the *saturation* $q^{\mathcal{R},O}$ *is q augmented with* all *the triples q implicitly asks for, given the ontology O and the rules $\mathcal{R}$*. BGPQ saturation is exemplified below:

Example 4.7 (BGPQ saturation). Consider the ontology O of G_{ex} and the query $q(x) \leftarrow (x, \text{:hiredBy}, y), (y, \tau, \text{:NatComp})$ asking who has been hired by a national company. Its saturation w.r.t. $\mathcal{R}_a, O$ is: $q^{\mathcal{R}_a,O}(x) \leftarrow \text{body}(q), (x, \text{:worksFor}, y), (x, \tau, \text{:Person}), (y, \tau, \text{:Comp}), (y, \tau, \text{:Org})$.

We use BGPQ saturation to saturate the RIS mapping heads w.r.t. $\mathcal{R}_a, O$, so that the *saturated* mappings together with $\mathcal{E}$ model the *saturated RIS data triples w.r.t.* $\mathcal{R}_a, O$. To compute $q^{\mathcal{R}_a,O}$ we (1) saturate body(q) $\cup\ O$ using $\mathcal{R}_a$, then (2) add to the body of q all triples thus inferred.

Definition 4.8 (Mappings saturation). The saturation of a set $\mathcal{M}$ of RIS mappings w.r.t. entailment rules $\mathcal{R}_a$ and ontology O is:

$$\mathcal{M}^{a,O} = \bigcup_{m \in \mathcal{M}} \{q_1(\bar{x}) \rightsquigarrow q_2^{\mathcal{R}_a,O}(\bar{x}) \mid m = q_1(\bar{x}) \rightsquigarrow q_2(\bar{x})\}$$

We saturate mappings offline, and just need to update them when O or the mapping heads change.

Example 4.9 (Saturated mappings). Consider the RIS of Example 3.6, the mapping heads in $\mathcal{M}^{a,O}$ are (added implicit triples are in blue):

$$\begin{aligned}
m_1: \quad & q_2^{\mathcal{R}_a,O}(x) \leftarrow && (x, \text{:ceoOf}, y), (y, \tau, \text{:NatComp}) \\
& && (x, \text{:worksFor}, y), (y, \tau, \text{:Comp}) \\
& && (x, \tau\text{:Person}), (y, \tau, \text{:Org}) \\
m_2: \quad & q_2^{\mathcal{R}_a,O}(x, y) \leftarrow && (x, \text{:hiredBy}, y), (y, \tau, \text{:PubAdmin}) \\
& && (x, \text{:worksFor}, y), (y, \tau, \text{:Org}) \\
& && (x, \tau, \text{:Person})
\end{aligned}$$

From the above Lemma and the use of saturated RIS mappings instead of the original ones, we show:

Lemma 4.10. *Let $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E}\rangle$ be a RIS, q be a BGPQ and $\mathcal{Q}_c$ its reformulation w.r.t. $O, \mathcal{R}_c$ [12]. Then:*

$$\text{cert}(q, S) = \text{cert}(\mathcal{Q}_c, \langle \emptyset, \emptyset, \mathcal{M}^{a,O}, \mathcal{E}\rangle)$$

This result allows solving the RIS query answering problem by relational view-based query rewriting (step (2') in Figure 2):

Theorem 4.11 (REW-C correctness). *Let $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E}\rangle$ be a RIS, q be a BGPQ and $\mathcal{Q}_c$ its reformulation w.r.t. $O, \mathcal{R}_c$.Then:*

$$\text{cert}(q, S) = \text{cert}(ubgpq2ucq(\mathcal{Q}_c), \text{Views}(\mathcal{M}^{a,O}), \mathcal{E})$$

Example 4.12 (REW-CA). Consider again the RIS in Example 3.6 and the query q of Example 4.5. Its reformulation $\mathcal{Q}_c$ w.r.t. $O, \mathcal{R}_c$, seen as a UCQ, is:

$$\begin{aligned}
& q(x, \text{:ceoOf}) \leftarrow && T(x, \text{:ceoOf}, z), T(z, \tau, \text{:NatComp}), \\
& && T(x, \text{:worksFor}, a), T(a, \tau, \text{:PubAdmin}) \\
\cup\ & q(x, \text{:hiredBy}) \leftarrow && T(x, \text{:hiredBy}, z), T(z, \tau, \text{:NatComp}), \\
& && T(x, \text{:worksFor}, a), T(a, \tau, \text{:PubAdmin})
\end{aligned}$$

This reformulation is therefore rewritten using the RIS views as: $q_r(x, \text{:ceoOf}) \leftarrow V_{m_1}(x), V_{m_2}(x, y)$. It is obtained from the first CQ in the above; the second one has no rewriting based on the available RIS views. We remark that this rewriting is equivalent to the one obtained in Example 4.5, hence yields the same answers.

4.3 Rewriting Queries using Saturated Mappings and Ontology Mappings as Views: REW

This strategy does not reason at query time at all. Instead, it rewrites a query q based on the saturated RIS mappings $\mathcal{M}^{a,O}$ as above, *and* on a specific set of ontology mappings we build to model the *saturated RIS ontology as a data source*:

Definition 4.13 (Ontology mappings). The set of *ontology mappings* for a RIS ontology O is:

$$\mathcal{M}_{O^c} = \bigcup_{x \in \{\prec_{sc}, \prec_{sp}, \hookleftarrow_d, \hookrightarrow_r\}} \{m_x \mid m_x = q_1(\text{s}, \text{o}) \rightsquigarrow q_2(\text{s}, \text{o})\}$$

with $q_2(\text{s}, \text{o}) \leftarrow (\text{s}, x, \text{o})$. The *extension* of an ontology mapping m_x is $\text{ext}(m_x) = \{V_{m_x}(\text{s}, \text{o}) \mid (\text{s}, x, \text{o}) \in O^{\mathcal{R}_c}\}$. The *extent* of $\mathcal{M}_{O^c}$ is denoted $\mathcal{E}_{O^c}$.

We compute ontology mappings offline, and only need to update them when the ontology changes. The ontology mapping extensions $\mathcal{E}_{O^c}$ store all the explicit and implicit RIS ontology triples (recall from Section 2.2 that only $\mathcal{R}_c$ lead to such triples). Importantly, this leads to the observation that a query triple that refers to the ontology (schema) can be evaluated on the ontology mapping extensions alone. Formally:

$$\begin{aligned}
& q(x, \text{:ceoOf}) \leftarrow && V_{m_1}(x), V_{m_{\prec_{sp}}}(\text{:ceoOf}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:NatComp}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & q(x, \text{:ceoOf}) \leftarrow && V_{m_1}(x), V_{m_{\prec_{sp}}}(\text{:ceoOf}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:Comp}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & q(x, \text{:ceoOf}) \leftarrow && V_{m_1}(x), V_{m_{\prec_{sp}}}(\text{:ceoOf}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:Org}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & q(x, \text{:worksFor}) \leftarrow && V_{m_1}(x), V_{m_{\prec_{sp}}}(\text{:worksFor}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:NatComp}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & q(x, \text{:worksFor}) \leftarrow && V_{m_1}(x), V_{m_{\prec_{sp}}}(\text{:worksFor}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:Comp}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & q(x, \text{:worksFor}) \leftarrow && V_{m_1}(x), V_{m_{\prec_{sp}}}(\text{:worksFor}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:Org}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & q(x, \text{:hiredBy}) \leftarrow && V_{m_2}(x, z), V_{m_{\prec_{sp}}}(\text{:hiredBy}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:PubAdmin}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & q(x, \text{:hiredBy}) \leftarrow && V_{m_2}(x, z), V_{m_{\prec_{sp}}}(\text{:hiredBy}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:Org}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & q(x, \text{:worksFor}) \leftarrow && V_{m_2}(x, z), V_{m_{\prec_{sp}}}(\text{:worksFor}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:PubAdmin}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & q(x, \text{:worksFor}) \leftarrow && V_{m_2}(x, z), V_{m_{\prec_{sp}}}(\text{:worksFor}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:Org}, \text{:Comp}), V_{m_2}(x, a) \\
\cup\ & \textstyle\bigcup_{\text{r} \in \{\prec_{sc}, \prec_{sp}, \hookleftarrow_d, \hookrightarrow_r\}} q(x, \text{r}) \leftarrow && V_{m_\text{r}}(x, z), V_{m_2}(v, z), \\
& && V_{m_{\prec_{sp}}}(\text{r}, \text{:worksFor}), \\
& && V_{m_{\prec_{sc}}}(\text{:PubAdmin}, \text{:Comp}), \\

\end{aligned}$$

Figure 4: Sample rewriting for Example 4.17.

Lemma 4.14. *Let $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E}\rangle$ be a RIS and q be a BGPQ. Then:*

$$\text{cert}(q, S) = \text{cert}(q, \langle O, \mathcal{R}_a, \mathcal{M}_{O^c} \cup \mathcal{M}, \mathcal{E}_{O^c} \cup \mathcal{E}\rangle)$$

This lemma effectively "pushes" $\mathcal{R}_c$ reasoning in the set of mappings (to which we add $\mathcal{M}_{O^c}$) and the extent (to which we add $\mathcal{E}_{O^c}$). Next, we rely (as we did for REW-CA) on mappings saturation with $O, \mathcal{R}_a$ to also push $\mathcal{R}_a$ reasoning in the mappings, leading to:

Lemma 4.15. *Let $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E}\rangle$ be a RIS and q be a BGPQ. Then:*

$$\text{cert}(q, S) = \text{cert}(q, \langle \emptyset, \emptyset, \mathcal{M}_{O^c} \cup \mathcal{M}^{a,O}, \mathcal{E}_{O^c} \cup \mathcal{E}\rangle)$$

This allows to reduce RIS query answering to relational view-based query rewriting (step (2") in Figure 2):

Theorem 4.16 (REW correctness). *Let $S = \langle O, \mathcal{R}, \mathcal{M}, \mathcal{E}\rangle$ be a RIS and q be a BGPQ. Then:*

$$\text{cert}(q, S) = \text{cert}(bgpq2cq(q), \text{Views}(\mathcal{M}_{O^c} \cup \mathcal{M}^{a,O}), \mathcal{E}_{O^c} \cup \mathcal{E})$$

Example 4.17 (REW). Consider again the RIS in Example 3.6 and the query q of Example 4.5 seen as a CQ:

$$\begin{aligned}
q(x, y) \leftarrow\ & T(x, y, z), T(z, \tau, t), T(y, \prec_{sp}, \text{:worksFor}), \\
& T(t, \prec_{sc}, \text{:Comp}), T(x, \text{:worksFor}, a), \\
& T(a, \tau, \text{:PubAdmin})
\end{aligned}$$

Its maximally-contained rewriting q_{REW} based on the views obtained from the RIS *saturated* mappings and *ontology* mappings appears in Figure 4. This rewriting is much larger than the ones of the two preceding techniques: this is due to the ontology mappings. If we assume that $\mathcal{E}$ also contains $V_{m_2}(\text{:p}_1, \text{:a})$, as we did in

Example 4.5, we obtain again $\text{cert}(q, S) = \{\langle :p_1, :\text{ceoOf}\rangle\}$, which results from the evaluation of the first CQ in the UCQ rewriting; the other CQs yield empty results because some required $\prec_{sc}$ or $\prec_{sp}$ contraints are not found in the views built from the RIS ontology mappings.

How do our strategies compare? Since they are all correct, they lead to the same RIS certain answer set, however they do not necessarily compute the same view-based rewritings. Indeed, REW considers the additional set $\mathcal{M}_{O^c}$ of ontology mappings. Hence, for queries over the ontology, i.e., featuring in a property position $\prec_{sc}$, $\prec_{sp}$, $\hookleftarrow_d$, $\hookrightarrow_r$, or a variable, a REW rewriting is larger than a REW-CA or REW-C rewriting and, to be answered, requires the additional ontology source. In contrast, REW-CA and REW-C yield logically equivalent rewritings; we minimize them both to avoid possible redundancies, thus they become identical (up to variable renaming). Hence, REW-CA and REW-C do not differ in how these rewritings are evaluated. Instead, they differ in how the rewritings are *computed*, or, equivalently, on *the distribution of the reasoning effort on the data and mappings, across various query answering stages.* As our experiments show, given the computational complexity of view-based query rewriting [42], this difference has a significant impact on their performance.

5 EXPERIMENTAL EVALUATION

We now describe our experiments with RIS query answering. In addition to our strategies based on query rewriting, we include in our comparison a simple **alternative strategy, based on materialization and denoted MAT**. Offline (before answering queries), this strategy materializes the RIS data triples and saturates them with the rule set $\mathcal{R}$. The materialization is stored and saturated in an **RDF data management system (RDFDB, in short)**. Then, MAT query answering amounts to query evaluation on the saturated materialization. Therefore, MAT query answering can be seen as a lower bound for query answering through other strategies.

5.1 Experimental settings

Software Our platform is developed in Java 1.8, as follows. Our RDFDB is OntoSQL[2], a Java platform providing efficient RDF storage, saturation, and query evaluation on top of an RDBMS [14, 29], relying on Postgres v9.6. To save space, OntoSQL encodes IRIs and literals into integers, and a dictionary table which allows going from one to the other. It stores all resources of a certain type in a one-attribute table, and all (subject, object) pairs for each property (including RDFS schema properties) in a table; the tables are indexed. OntoSQL is used in the MAT strategy, and it also provides the RDF query reformulation algorithm [12].
We rely on the Graal engine [9] for **view-based query rewriting**. Graal is a Java toolkit dedicated to query answering algorithms in knowledge bases with existential rules (a.k.a. tuple-generating dependencies). Since the relational view $V_m(\bar{x}) \leftarrow bgp2ca(\text{body}(q_2))$ corresponding to a GLAV mapping m (recall Def. 4.2) can be seen as a specific existential rule of the form $V_m(\bar{x}) \rightarrow bgp2ca(\text{body}(q_2))$, the query reformulation algorithm of Graal can be used to rewrite the UCQ translation of a BGPQ with respect to a set of RIS mappings. To **execute queries against heterogeneous data sources**, we use Tatooine [4, 10], a Java-based mediator (or polystore) system, capable both of pushing queries in underlying data sources and (unlike other polystores, e.g., [24]) of evaluating joins within the mediator engine. Query rewritings produced by Graal are unfolded into queries on the data sources (using the q_1 parts of the mappings, see Section 2.5.2) and passed to Tatooine. We implemented the RIS query answering methods described here in Java 1.8 on top of these tools.
Hardware We used servers with 2,7 GHz Intel Core i7 processors and 160 GB of RAM, running CentOs Linux 7.5.

5.2 Experimental scenarios

RDF Integration Systems (RIS) used Our first interest was to study scalability of RIS query answering, in particular in the *relational* setting studied in many prior works. To achieve this, we used the BSBM benchmark relational data generator[3] to build databases consisting of 10 relations named producer, product, offer, review etc. Using two different benchmark scale factors, we obtained a data source DS_1 of 154.054 tuples across the relations, respectively, DS_2 of 7.843.660 tuples; both are stored in Postgres. We used two RDFS ontologies O_1 respectively O_2, containing, first, subclass hierarchies of 151 (resp. 2011) product types, which come with DS_1, respectively, DS_2. To O_1 and O_2, we add a natural RDFS ontology for BSBM composed of 26 classes and 36 properties, used in 40 subclass, 32 subproperty, 42 domain and 16 range statements.
Relational-sources RIS We devised two sets $\mathcal{M}_1, \mathcal{M}_2$ of 307, respectively, 3863 mappings, which expose the relational data from DS_1, respectively, DS_2 as RDF graphs. The relatively high number of mappings is because: (*i*) each product type (of which there are many, and their number scales up with the BSBM data size) appears in the head of a mapping, enabling fine-grained and high-coverage exposure of the data in the integration graph; (*ii*) we also generated more complex GLAV mappings, partially exposing the results of join queries over the BSBM data; interestingly, these mappings expose incomplete knowledge, in the style of Example 3.4.
The mapping sets lead to the **RIS graphs of** $2.0 \cdot 10^6$, respectively, $108 \cdot 10^6$ triples. Their **saturated** versions comprise respectively $3.4 \cdot 10^6$ and $185 \cdot 10^6$ triples. Our first two RIS are thus: $S_1 = \langle O_1, \mathcal{R}, \mathcal{M}_1, \mathcal{E}_1\rangle$ and $S_2 = \langle O_2, \mathcal{R}, \mathcal{M}_2, \mathcal{E}_2\rangle$, where $\mathcal{E}_i$ for i in $\{1, 2\}$ are the extents resulting from DS_i and $\mathcal{M}_i$.
Heterogeneous-sources RIS Second, going beyond relational-sources OBDA [16, 17, 44], our architecture extends to *heterogeneous data sources*. For that, we converted a third (33%) of DS_1, DS_2 into JSON documents, and stored them into MongoDB, leading to the JSON data sources denoted $DS_{j,1}, DS_{j,2}$; the relational sources $DS_{r,1}, DS_{r_2}$ store the remaining (relational) data. Conceptually, for i in $\{1, 2\}$, the extension based on $DS_{r,i}$ and extension based on $DS_{j,i}$ form a partition of $\mathcal{E}_i$. We devise a set of **JSON-to-RDF mappings** to expose $DS_{j,1}$ and $DS_{j,2}$ into RDF, and denote $\mathcal{M}_3$ the set of mappings exposing $DS_{r,1}$ and $DS_{j,1}$, together, as an RDF graph; similarly, the mappings $\mathcal{M}_4$ expose $DS_{r,2}$ and $DS_{j,2}$ as RDF. Our last two RIS are thus: $S_3 = \langle O_1, \mathcal{R}, \mathcal{M}_3, \mathcal{E}_3\rangle$ and $S_4 = \langle O_2, \mathcal{R}, \mathcal{M}_4, \mathcal{E}_4\rangle$, where $\mathcal{E}_3$ is the extent of $\mathcal{M}_3$ based on $DS_{r,1}$ and $DS_{j,1}$, while $\mathcal{E}_4$ is the extent of $\mathcal{M}_4$ based on $DS_{r,2}$ and $DS_{j,2}$. *The RIS data and ontology triples of S_1 and S_3 are identical; thus, the difference between these two RIS is only due to the heterogeneity of their underlying data sources.* The same holds for S_2 and S_4.
Queries We devised a set of 28 BGP queries having from 1 to 11 triple patterns (5.5 on average), of varied selectivity (they return between 2 and $330 \cdot 10^3$ results in S_1 and S_3 and between 2 and $4.4 \cdot 10^6$ results in S_2 and S_4); 6 among them query the data *and* the ontology (recall Example 2.6), a capability which most

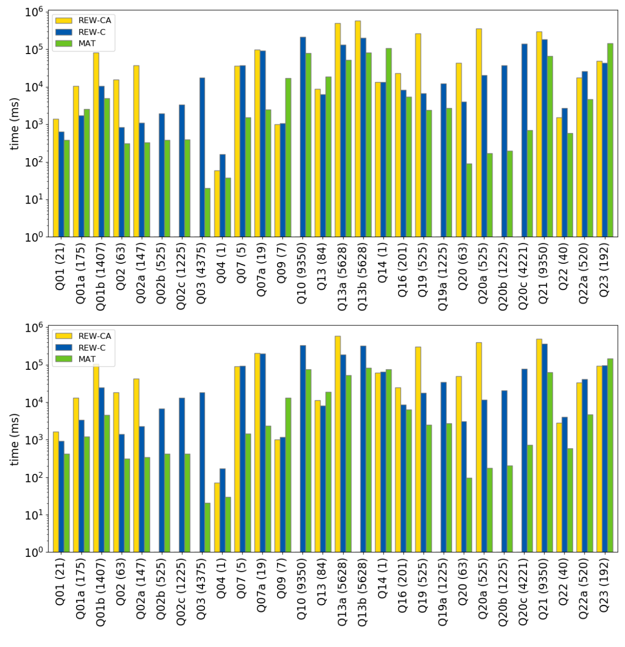

Figure 6: Query answering times on the larger RIS S_2 (top, relational sources) and S_4 (bottom, heterogeneous sources).

competitor systems lack (see Section 6). Table 4 reports three query properties impacting query answering performance: the number of induced triples (N_{TRI}), the number of BGPQ reformulations on the ontology ($|\mathcal{Q}_{c,a}|$, ranging from 1 to 1225; this strongly determines the performance of answering such large union queries, recall Example 4.5), and its number of answers (N_{ANS}) on the two RIS groups (S_1, S_3 and S_2, S_4). To further study the impact of the ontology on query evaluation complexity, we created *query families* denoted Q_X, Q_{Xa} etc. by replacing the classes and properties appearing in Q_X with their super classes or super properties in the ontology. In such a family, Q_X *is the most selective, and queries are sorted in the increasing order of their number of reformulations.*

Our ontologies, mappings, queries, and experimental details are available online[4].

5.3 Query answering performance

REW inefficiency We have conducted experiments[4] using our six queries on ontological triples showing, as in Example 4.17 and Figure 4, an explosion of the size of the rewriting (number of CQs), compared to the rewriting produced by the two other approaches. *On queries (also) over the ontology,* as explained in Section 4.3, we noted that the size of the rewriting produced by REW is larger (by a multiplicative factor of 29 to 74 in S_1 and S_3, and of 33 to 969 in S_2 and S_4) than the rewritings of the two other strategies, which led to an explosion of the time spent minimizing the rewriting, and made REW overall unfeasible; the details of these tests can be found online[4]. *On queries that do not carry over the ontology,* REW produces the same rewritings as the other methods. Thus, we do not report further REW performance below.

Query answering time comparison Figure 5 depicts the query answering times, on the smaller RIS, of REW-CA, REW-C and MAT. *The size of (number of BGPQs in) the reformulation of each query w.r.t. $\mathcal{R}$, $|\mathcal{Q}_{c,a}|$ appears in parentheses after the query name, in the labels along the x axis.* Given that S_1, S_3 have the same RIS data triples, the MAT strategy coincides among these two RIS. Figure 6 shows the corresponding times for the largest RIS S_2 and S_4; the same observations apply. Note the logarithmic time axes.

A first observation is that *our query set is quite diverse*; their answering times range from a few to more than 10^5 ms.

As expected, query answering in MAT *is the fastest in most cases,* since it has no reasoning work to do at query answering time. However, it required, for S_1, S_3, $1.2 \cdot 10^5$ ms to build the materialization and $1.49 \cdot 10^5$ ms more to saturate it, whereas for S_2, S_4, these times are 14h46 ($5.31 \cdot 10^7$ ms), respectively, 1h28 ($5.28 \cdot 10^6$

[4]Experiment web site: https://gitlab.inria.fr/mburon/org/blob/master/projects/het2onto-benchmark/bsbm/

ms). Not only these are *orders of magnitude more than all query answering times*; recall also that materializing $G_{\mathcal{E}}^{\mathcal{M}}$ requires maintaining it when the underlying data changes, and its saturation $(G_{\mathcal{E}}^{\mathcal{M}} \cup O)^{\mathcal{R}}$ needs a second level of maintenance. Thus, MAT is not practical when data sources change. We were surprised to see REW-C and REW-CA somehow faster than MAT for queries Q_{09} and Q_{14}. Answering these queries through MAT within OntoSQL leads to producing many results that involve *mapping-generated blank nodes*, tuples which should not appear in our certain answers, as per Definition 3.5. We remove such tuples in post-processing mode, which leads to a performance overhead for MAT. REW-C and REW-CA, in contrast, are answered by evaluating rewritings, and do not have to apply such a result pruning. It remains to be seen if this pruning could be pushed in an RDFDB; note that not *all* answers including blank nodes should be pruned, only those whose blank nodes are due to mappings.

In each scenario, we observe that REW-C is faster or takes as long as REW-CA. Since the two approaches produce the same rewritings, the difference is due to steps before the step (3) in Figure 2. It turns out it is due to the rewriting time, which in turn strongly depends on the size of the reformulation it receives as input. In REW-C, the reformulations w.r.t. $\mathcal{R}_c$ are of size 1 (no union, just one BGP) for queries on data triples only, and never exceed 64 in S_1 and S_3 and 200 in S_2 and S_4, whereas, in REW-CA the reformulation sizes are much larger. REW-C is most often faster than REW-CA, by up to two orders of magnitude e.g., for Q_{02a}, Q_{19} and Q_{20a} on S_2, the latter two on S_4 etc. One order of magnitude speed-up is noticeable even on the smaller RIS S_1, S_3 (Figure 5) for Q_{02a}. As a consequence, REW-C completes successfully in all scenarios we study, whereas REW-CA fails to complete for many queries with timeout set to 10min (missing yellow bars in Figure 6), in close correlation with the increased number of reformulations.

Scaling in the data size As stated in Section 5.2, there is a *scale factor of about 50* between S_1, S_3 on one hand, and S_2, S_4 on the other. Figures 5 and 6 show that the query answering times generally grow by less than 50, when moving from S_1 to S_2, and from S_3 to S_4. This is mostly due to the good scalability of PostgreSQL (in the all-relational RIS), Tatooine (itself building on PostgreSQL and MongoDB, in the heterogeneous RIS), and OntoSQL (for MAT). As discussed above, computation steps we implemented outside these systems are strongly impacted by the *mappings, ontology and query*; intelligently distributing the reasoning effort, as REW-C does, avoids the heavy performance penalties that from which REW-CA and REW sometimes suffer.

Impact of heterogeneity REW-CA and REW-C incur a (modest) overhead when combining data from PostgreSQL and MongoDB (heterogeneous RIS) w.r.t. the relational-sources RIS. Part of this is due to the cost of marshalling data across system boundaries; the rest is due to imperfect optimization within Tatooine. Overall, the comparison demonstrates that RIS query answering is feasible and quite efficient even on heterogeneous data sources.

5.4 Experiment conclusion

In a setting where the data, ontology and mappings do not change, MAT is an efficient and robust query answering technique, at a rather high cost to materialize and saturate the RIS instance. In contrast, in a dynamic setting, REW-C *smartly combines partial reformulation and view-based query rewriting to efficiently compute query answers.* The changes it requires when the ontology and mappings change (basically re-saturating mapping heads) are light and likely to be very fast. Thus, we conclude that REW-C is the best query answering strategy for dynamic RIS.

6 RELATED WORK AND CONCLUSION

Ontologies have been used to integrate relational or heterogeneous data sources in mediators [49] with LAV views based on description logics [1, 37] or their combination with Datalog [28, 30]. Semantics have been used at the integration level since e.g., [20] for SGML and soon after for RDF [6, 7]; data is considered represented and stored in a flexible object-oriented model, thus no mappings are used.

Our work follows the OBDA paradigm introduced in [41]. This paradigm was conceived to enhance access to relational data by mappings to an ontology expressed in a dialect of the DL-Lite description logic family (typically DL-Lite$_{\mathcal{R}}$ underpinning the OWL 2 QL profile of the W3C ontological language OWL 2). Mature DL-based systems include Mastro[5] [17] and Ontop[6] [16, 43]. Another notable OBDA system, namely Ultrawrap^{OBDA} [44], is based on an extension of RDFS to inverse and transitive properties. All these systems rely on GAV mappings.

Compared to these, our main novelty is to handle GLAV mappings and provide query answering algorithms for the resulting novel RIS setting. Note that formal OBDA frameworks with GLAV mappings have long been defined, e.g., in [18], but not put into practice. Regarding the other components of OBDA, we consider a simpler ontological language than existing OBDA systems, but support BGPQs on both data and ontological triples, a feature hardly found in these systems (an exception is [33]).

As explained in the introduction, GLAV mappings maximize the expressive power of the integration system. In particular, they allow to expose a form of *incomplete* information (recall Example 3.6). To some extent, GLAV mappings may be simulated by GAV mappings provided with so-called Skolem functions on answer variables, as suggested for instance in [21]. To illustrate, consider the GLAV mapping $m_1 = q_1(\bar{x}) \rightsquigarrow q_2(\bar{x})$ with head $q_2(x) \leftarrow (x, \text{:ceoOf}, y), (y, \tau, \text{:NatComp})$ from Example 3.2. The non-answer variable y could be replaced by a Skolem function $f(x)$, which would yield two GAV mappings, namely $m_{1_1} = q_1(\bar{x}) \rightsquigarrow q_{2_1}(\bar{x})$ and $m_{1_2} = q_1(\bar{x}) \rightsquigarrow q_{2_2}(\bar{x})$, with respective head $q_{2_1}(\bar{x}) \leftarrow (x, \text{:ceoOf}, f(x))$ and $q_{2_2}(\bar{x}) \leftarrow (f(x), \tau, \text{:NatComp})$. Note that Skolem functions would have to produce syntactically correct RDF values in a materialization scenario. Still in a materialisation scenario, query answering would require some post-processing to prevent the values built by the Skolem functions to be accepted as answers, while in a query rewriting sceSkolemnario functional values would also have to be dealt with in a special way, which in particular prevents to use off-the-shelf view-based query rewriting algorithms. Hence, value invention would be simulated here at the price of technically more complex mappings and processing. Second, the break-up of GLAV mappings into several GAV mappings would lead to higher conceptual complexity since intrinsically connected triples, as those associated with $(x, \text{:ceoOf}, y)$ and $(y, \tau, \text{:NatComp})$ in the example, could not be exposed together by a single mapping. Last but not least, query rewriting would be considerably slowed down and would produce highly redundant rewritings, as demonstrated in the seminal paper [42].

Our mapping saturation (Definition 4.8) is inspired by a query saturation technique introduced in [25] to compute least general generalizations of BGPQs under RDFS background knowledge.

[5] http://obdasystems.com/mastro/
[6] https://ontop.inf.unibz.it/

It can be seen as a generalization to GLAV mappings of the $\mathcal{T}$-mapping technique introduced in [43] (and further developed in [44]) to optimize query rewriting in a classical OBDA context. The $\mathcal{T}$-mapping technique consists of completing the original set of GAV mappings with new ones, encapsulating information inferred from the DL ontology. For instance, given a GAV mapping $m = q_1(x) \rightsquigarrow q_2(x) \leftarrow C(x)$ with C a class, and a DL constraint specifying that C is a subclass of D, a new mapping $m' = q_1(x) \rightsquigarrow q_2'(x) \leftarrow D(x)$ is created by composing m and the DL constraint. On this example, we would saturate the head of m into $q_2(x) \leftarrow C(x) \wedge D(x)$, which is semantically equivalent to adding the mapping m'. However, when mappings are GLAV and not GAV, one cannot simply add new mappings. For instance, consider the GLAV mapping $m_1 = q_1(\bar{x}) \rightsquigarrow q_2(\bar{x})$ with head $q_2(x) \leftarrow (x, \text{:ceoOf}, y), (y, \tau, \text{:NatComp})$; given the entailment rule `rdfs9` and the ontological triple $(\text{:NatComp}, \prec_{sc}, \text{:Comp})$, the saturation adds the triple $(y, \tau, \text{:Comp})$ to the body of q_2; creating instead a new mapping of the form $m_1' = q_1(\bar{x}) \rightsquigarrow q_2'(\bar{x})$ with head $q_2'(x) \leftarrow (y, \tau, \text{:Comp})$ would be unsatisfactory as y in m_1' should correspond to the same object as y in m_1.
Our mapping saturation technique could be extended to more general entailment rules, in which the head of the rules may include blank nodes that are not in their body, possibly shared by several triples. This is part of our future research agenda.

ABSTRACT

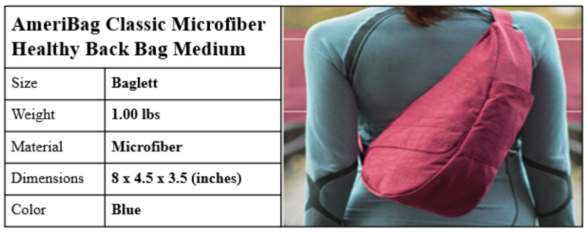
Current work to detect data errors often uses (semi-)automatic solutions. In this paper, however, we argue that there are many real-world scenarios where users have to detect data errors *completely manually*, and that more attention should be devoted to this problem. We then study one instance of this problem in depth. Specifically, we focus on the problem of *manually verifying the values of a target attribute*, and shows that the current best solution in industry, which uses crowdsourcing, has significant limitations. We develop a new solution that addresses the above limitations. Our solution can find a much more accurate ranking of the data values in terms of their difficulties for crowdsourcing, can help domain experts debug this ranking, and can handle ambiguous values for which no golden answers exist. Importantly, our solution provides a unified framework that allows users to easily express and solve a broad range of optimization problems for crowdsourcing, to balance between cost and accuracy. Finally, we describe extensive experiments with three real-world data sets that demonstrate the utility and promise of our solution approach.

1 INTRODUCTION

Data cleaning has received significant recent attention (e.g., [5, 7, 10, 46]), due to the explosion of data science applications, which often need data cleaning before analysis can be carried out. Most recent data cleaning works focus on detecting and repairing data errors [5, 7, 10, 46] (e.g., outliers, incorrect values, duplicate tuples, and constraint violations). In this paper we focus on *detecting* errors.

To detect data errors, current work often employs semi-automatic solutions, which use machine learning or hand-crafted data quality rules (e.g., "age must be between 18 and 80" and "any employee in NYC earns no less than any non-NYC employee at the same level" [5]). In certain cases the user can be involved, e.g., to provide feedback to the solutions or verify that the data instances reported by the solutions are indeed errors.

In practice, however, *there are many scenarios where users still have to detect data errors completely manually*. First, to detect data errors we often need to extract the values of certain attributes. Such extraction can be very difficult for today algorithms, but much easier for human users. This often happens when an attribute value is buried in a picture or text.



AmeriBag Classic Microfiber Healthy Back Bag Medium	
Size	Baglett
Weight	1.00 lbs
Material	Microfiber
Dimensions	8 x 4.5 x 3.5 (inches)
Color	Blue

Figure 1: An example of manual error detection.

Example 1.1. Consider the product in Figure 1. A data quality rule is "the value of attribute color *should be consistent with the color of the product in the picture". There is no algorithm today that can reliably extract the color of the product from the picture. Here the picture shows not just the product, a bag, but also a woman wearing a bag, making the extraction of the bag's color even more difficult. A human user however can quickly detect that the bag's color in the picture is red. This is inconsistent with the value of attribute* color *in the text, which is blue, suggesting a data error.*

Even if an attribute's values are present (so no extraction is required), it can still be difficult for algorithms to judge if those values are correct. For example, there is no good algorithm today to detect if a given URL is indeed the correct URL for a given business (especially where multiple fake URLs exist for a business). So detecting incorrect business URLs (e.g., to clean business listings) is still done largely by human users. Another example is verifying if the category of a product is "athletic (man)", which typically requires a human user to read the product description, examine the picture, etc.

Finally, an algorithmic solution may exist (e.g., extracting a person's gender from a picture can be done reliably today using deep learning [24]), but the business may have no one qualified to develop, debug, and run it. Or there is someone qualified, but developing and debugging the algorithm would take weeks, whereas the cleaning work must be done within days. In such cases, businesses often resort to detecting data errors completely manually, using human users.

In this paper we consider manually detecting data errors. As a first step, we consider the common setting in which *users must manually check the correctness of the values of a target attribute* (e.g., color, category). This problem is often called *manual data validation* [5, 7, 10, 46]. It is pervasive, yet no published work has addressed it in depth, as far as we can tell.

Using in-house experts to do manual data validation is not practical for large amounts of data: it takes too long and is not a good use of their limited time. So companies often use *crowdsourcing*, where the crowd can be for instance contractors or

Mechanical Turk workers. A common solution formulates each error detection as a question, sends it to the crowd, solicits k answers (e.g., $k = 5$), then takes a majority vote. For example, if three out of five workers answer "no" to the question "is the color of this product indeed blue?" for the product in Figure 1, then we can report that product as potentially having a data error.

The above solution is conceptually simple, but inefficient. Intuitively, different data values pose different levels of difficulties to human users. For example, most people know the color "blue", and so can answer questions about this color with high accuracy. But fewer people know the color "chartreuse". So we may want to solicit fewer answers for questions involving "blue" (e.g., 3 answers per question), but more answers for questions involving "chartreuse" (e.g., 7). Such crowdsourcing strategies, which are sensitive to the difficulties of different data regions, can significantly reduce the crowdsourcing cost while achieving the same level of error detection accuracy.

Indeed many companies have now employed such *adaptive crowdsourcing strategies*. A very common solution (e.g., employed at WalmartLabs, Facebook, Johnson Controls, and elsewhere) works as follows:

(1) Compute a ranking K of the data values (in decreasingly order of their difficulties),
(2) Examine K to assign to each data value v a number of answers n_v (such that a data value placed higher in K is assigned a higher number of answers), then
(3) Solicit n_v answers for each question with value v.

Obtaining the ranking K is important for many purposes. For example, after crowdsourcing to obtain answers for all questions, companies often take a sample and manually check the accuracies of the questions in the sample, for quality assurance purposes. The ranking K allows them to bias the sample, e.g., intentionally sample more items with values in the top-10 of K, to check how well crowdsourcing works for these difficult values. Example 4.1 lists other usages of ranking K.

While the above solution has been quite popular in industry, it has several important limitations. In this paper we address those and significantly advance this line of research in several ways.

First, obtaining *a good ranking of the data values* in terms of their difficulties is critical. To do so, the above solution estimates the difficulty score of a data value to be *the average worker accuracy* for a sample set S of questions with that value. To estimate these scores accurately, the size of sample set S must be quite large. But this incurs a lot of domain expert's effort, because he or she must label all data instances in S (as having data errors or not).

Here we show that we do not need a large sample S. Our key idea is that if the average time it takes for a worker to answer questions is high, or if the disagreement among workers is high, then those also indicate that a data value is likely to be difficult. Consequently, *we use all three factors (i.e., worker accuracy, average answer time, and worker disagreement) to directly rank the data values, using a machine learning approach.* We show how to minimize the domain expert's effort, by iteratively expanding sample S and stopping when a convergence condition is met.

Second, once the ranking has been created, domain experts often want to examine, debug, and modify it. To address this problem, *we develop a solution to help a domain expert debug the ranking.* Specifically, he or she can request explanations on why a data value v is considered difficult. Among others, our solution can explain that v is not difficult, but appears so due to spammers, low-quality workers, or careless mistakes from the workers; or that v is indeed difficult, because the value is hard to understand (e.g., "chartreuse"), or the item description is incomplete, or the description has confusing/conflict information, etc.

Third, the existing solution considers only the problem of *minimizing the crowdsourcing cost while achieving the same detection accuracy* (as the baseline solution of soliciting the same number of answers regardless of the data value). We show that in practice, users want to consider a far broader range of problems. Examples include minimizing cost given that the accuracy exceeds a threshold, maximizing accuracy given a budget on the cost, improving the overall accuracy of a set of data items having difficult values, and more. *We develop a unified framework that allows users to easily express and solve a broad range of such optimization problems*, all of which find crowdsourcing strategies that adapt to the data value difficulties.

Finally, the existing solution assumes *golden answers* exist for the questions with each data value (otherwise the worker accuracy for that value cannot be computed). In practice, surprisingly, we found that there are many cases where there are no such golden answers. For example, a product description may show the picture of a bag in sand color, with the value for attribute "color" being "desert sand". So the question for the crowd is "is the color of this product 'desert sand'?". But nobody knows what "desert sand" means. There is no such color. Or more accurately, this is an *ambiguous* color invented by the marketing team. As such, there is no correct, i.e., golden answer to the above question. (In our experiments, 2/3 of workers answer yes, and the rest answer no.) Clearly, this problem of *ambiguous values* must be addressed, before the above adaptive crowdsourcing solution can be applied. In this paper we develop a simple but effective solution to this problem.

Contributions: To summarize, in this paper we make several fundamental contributions to the problem of manually detecting errors for data cleaning:

- We argue that the above problem is pervasive, and needs more attention. As far as we can tell, this is the first work that studies this problem in depth.
- We focus on the problem of manually verifying the values of a target attribute, and shows that the current best solution has significant limitations.
- We develop a new solution that addresses the above limitations and significantly advances the state of the art. Our solution can find a much more accurate ranking of the data values, can help domain experts debug this ranking by providing explanations on why a data value is considered difficult, and can handle ambiguous values for which no golden answers exist. Importantly, our solution provides a unified framework that allows users to easily express and solve a broad range of optimization problems.
- We describe extensive experiments with three real-world data sets that demonstrate the utility and promise of our solution approach.

2 PROBLEM DEFINITION

We now describe the problem of manual detection of data errors considered in this paper.

Data Items, Attributes, and Values: For manually detecting data errors, many problem types exist. As a start, in this paper we will consider the problem of manually verifying the correctness of the categorical values of a target attribute. Specifically, let $D = \{d_1, \ldots, d_n\}$ be a set of data items, such as books, papers, products, etc. We assume that each item is encoded as a tuple of attribute-value pairs, i.e., $d_i = \langle a_1 = v_{i1}, \ldots, a_m = v_{im} \rangle$. For example, a product may be encoded as $\langle category = shirt, gender = male, color = blue \rangle$. We will use $a_j(d_i)$ to refer to the attribute a_j of d_i.

We assume that each attribute $a_j(d_i)$ has a set of correct values $V_j^*(d_i)$. For example, a course about discrete math is suitable for students from both mathematics and computer science departments, therefore its subject contains at least two values: mathematics and computer science. We say that $a_j(d_i)$ is correct if and only if its value v_{ij} is in $V_j^*(d_i)$.

Further, we assume that all attributes of each data item d_i are correct, except one attribute, which is referred to as the *target attribute* and whose values we will need to verify. Without loss of generality, we assume that the target attribute is the last attribute a_m.

Manual Validation of the Target Attribute: Let c_i be the context of d_i, defined as "all other attributes and their values": $c_i = \langle a_1 = v_{i1}, \ldots, a_{m-1} = v_{i(m-1)} \rangle$.

Our problem is to verify $a_m(d_i)$ for all items d_i in D. For each item d_i, verifying whether the value of a_m is correct is equivalent to answering the following question q_i: "is the value of $a_m(d_i)$ indeed v_{im}, given the context c_i and any other background knowledge B that the worker may have?" (we discuss examples of background knowledge B below).

Then the problem of verifying the target attribute a_m for items in D can be translated into answering the set of questions $Q = \{q_1, \ldots, q_n\}$, where the answer for each question q_i is yes or no. If the answer is yes, then our confidence that $a_m(d_i)$ is correct is increased. If the answer is no, then it is likely that there is a data error in d_i (in practice, the error may not be in a_m, but the error must exist because $a_m(d_i)$ is inconsistent with c_i). In this case, d_i is sent for further verification by an expert.

Suppose we have golden answers for all questions in Q, then for any solution to the above validation problem, we can define its overall accuracy to be the fraction of questions whose answers are correct, i.e., n_0/n, where n_0 is the number of questions whose answers match the golden answers, and $n = |Q|$.

Current Manual Solutions: Today, such questions are often answered manually, on a GUI, by an expert or a small set of experts, e.g., data analysts at an e-retailer, data scientists in an R&D group. To give the expert the maximal context information, a question will typically display the entire description of the item, e.g., all attribute-value pairs (see Figure 1).

If the expert still cannot decide after examining these attribute-value pairs, he or she may try to find more information, e.g., examining the same product at a different e-retailer, looking for any new information that can help answer the question. For the question "is the color of this product chartreuse?", the expert may have to first look up the meaning of "chartreuse" on the Web, and so on. We refer to such externally acquired knowledge as *the background knowledge B*.

Clearly, this manual solution is tedious and time consuming. As a result, many real-world applications have turned instead to crowdsourcing to verify attribute values.

Current Crowdsourcing Solutions: The simplest crowdsourcing (CS) solution solicits k answers from crowd workers for each question $q \in Q$, then combines these answers using majority voting to obtain a final answer for q.

Note that we can combine worker answers using more sophisticated strategies, e.g., estimating each worker's accuracy, then taking a weighted sum [19, 22, 27, 39]. Many real-world applications, however, still use majority voting, which is easy to understand, debug, and maintain. This is especially important when there is a high personnel turnover. Further, the application may need to contract with a crowdsourcing company and this may be the only solution being offered by that company. Finally, as far as we know, there is no published conclusive evidence yet that more sophisticated strategies to combine answers work much better in practice. Thus, in this paper we will focus on the above majority-voting solution to verify attribute values, leaving more sophisticated solutions for future research.

The above CS solution, while faster than manual solutions, can incur high monetary costs, especially if the application wants high accuracy for crowdsourcing.

Example 2.1. Suppose an e-retailer A must verify the attributes of 50K newly arrived products. To ensure that product details on its Web pages are error-free as much as possible, A wants crowdsourcing to have an accuracy of at least 95%. To reach this accuracy, soliciting 3 answers per question is often insufficient, A would need to solicit 5, 7, or more answers. Assuming 3 cents per answer, if A solicits 5, 7, or 9 answers per question, crowdsourcing 5 attributes of 50K products costs $37.5K, $52.5K, and $67.5K, respectively.

Thus, it is important that we develop solutions to minimize the crowdsourcing cost, while achieving the same verification accuracy. As discussed in the introduction, intuitively, different data regions often have different degrees of difficulty for human verification. So if we can estimate these difficulty levels, we can adjust the degree of redundancy (i.e., the number of answers solicited for each question in a region). For example, a set of products D can be split into data regions where all products with the same color form a region. Then for each question in the region with "red" color, we only need to solicit 3 answers, say; whereas for each question in the region with the "acid yellow" color, which is more difficult, we would solicit 7 answers.

Indeed many companies have now employed such *adaptive CS strategies.* A very common solution works as follows:

(1) Compute a ranking of the data regions (in decreasingly order of their difficulties),
(2) Examine the ranking to assign to each region a number of answers (such that a region placed higher in the ranking is assigned a higher number of answers), then
(3) Solicit that number of answers for each question in the region.

It is important that this solution outputs both a ranking and a crowdsourcing plan (which specifies how many answers to solicit for each question in a data region). Outputting a ranking serves many important purposes, as discussed in the introduction (see also Example 4.1).

The above solution is appealing, but has significant limitations. (1) The ranking that it computes is often inaccurate, because the solution uses only the average worker accuracy to find the ranking. (2) Domain experts often cannot debug the ranking, e.g., understand why a data region is considered difficult. (3) The task of assigning to each data region a number of answers is often done in an ad-hoc "eyeballing" way, by examining where the data region is in the ranking. (4) It is difficult to express and solve a broad range of optimization problems regarding crowdsourcing costs and accuracy, even though users often have such needs. (5) Finally, this solution cannot handle "ambiguous" data values (e.g., "desert sand"), for which there are no golden answers.

In the rest of this paper we introduce our solution, called VChecker, which addresses the above limitations.

3 RANKING THE DATA REGIONS

In VChecker, we first obtain a ranking of the data regions, in decreasing order of their difficulties. In this section we discuss how we split the data into different regions, then rank them. (The next two sections describe how to debug the ranking, then how to use it to formulate and solve a broad range of optimization problems, to find good crowdsourcing plans.)

3.1 Splitting Data into Regions

We consider scenarios where for each data instance d_i, the difficulty in verifying the target attribute a_m only depends on its value v_{im}. Such scenarios are common in practice. For instance, for products such as the one described in Figure 1, the difficulty of verifying the attribute color only depends on its value (e.g., red, blue, acid yellow, etc.).

In such cases, the expert will split the data such that all questions with the same target attribute value form a region (because all such questions share the same difficulty level). Formally, let $D = \{d_1, \ldots, d_n\}$ be the set of data instances, a_m be the target attribute, $Q = \{q_1, \ldots, q_n\}$ be the set of questions "is the value of attribute a_m of instance d_i indeed v_{im}?", and $V = \{v_1, \ldots, v_r\}$ be the set of all values of a_m for instances in D. Then we can split the set of questions Q into r sets such that all questions (and only these questions) in a set Q_i share the same value for attribute a_m. We refer to each such set as a data region. In general, it is not always possible to so simply split the data into regions. This raises the interesting problem of how to help the expert do so, which we leave for future work.

3.2 Learning to Rank the Regions

To rank the data regions, a common solution in industry is to compute for each region an *average worker accuracy*, then rank the regions in increasing worker accuracy (thus in decreasing difficulties).

Specifically, let Q_i be a data region, i.e., the set of questions (in Q) with the same value v_i for the target attribute a_m. The current solution assumes that all crowd workers have the same probability of answering any question in Q_i correctly (a reasonable assumption in many real-world scenarios). It then takes this probability to be the average worker accuracy for Q_i, denoted as $a(Q_i)$.

To estimate $a(Q_i)$, the solution randomly takes a set x of questions in Q_i, solicits y answers from the crowd for each question, then computes $a(Q_i)$ as the fraction of xy answers that are correct. To determine answers' correctness, the solution uses the golden answers to the x questions, as provided by an expert. Finally, the solution ranks the data regions in increasing order of the computed average worker accuracy $a(Q_i)$.

While conceptually simple, this solution is limited in several important ways. First, it provides no way to determine x and y. If they are set to large values, then we waste a lot of crowdsourcing money and expert time (to provide golden answers). If they are set to small values, then it is difficult to estimate $a(Q_i)$ *accurately*. Second, it fails to exploit extra information that can help better

V = {black, red, iris, lavender, chartreuse}
(a)

$G = \{\langle \text{black}, f_1 \rangle, \langle \text{red}, f_2 \rangle, \langle \text{chartreuse}, f_5 \rangle\}$
(c)

$$F = \{f_1 = \langle 1, 2.3, 0 \rangle, \; f_2 = \langle 1, 2.4, 0.05 \rangle, \; f_3 = \langle 0.7, 5.1, 0.1 \rangle, \; f_4 = \langle 0.6, 8.4, 0.1 \rangle, \; f_5 = \langle 0.7, 11.2, 0.15 \rangle\}$$

Figure 2: Creating training data for SVM Rank.

rank the data regions. Finally, the solution does not provide any way to solicit and incorporate knowledge from the expert, even though he or she often has such knowledge about the difficulties of the various data regions.

Key Ideas of Our Solution: Our solution exploits three key ideas. First, we observe that if a value is difficult, it often takes a worker longer to provide an answer (e.g., for a question involving the value "acid yellow", he or she may need to consult the Web to understand its meaning before being able to answer the question). It also often causes more disagreement among the workers. As a result, we capture and exploit these two types of information and use them together with the worker accuracy to learn to rank the values in decreasing order of their difficulties.

Second, to learn the ranking, we ask the expert to provide training data in the form of (v_i, v_j) such that v_i is ranked more difficult than v_j. We also allow the expert to debug the ranking and manually edit it if necessary (see Section 4). Thus, our solution provides a natural way for the expert to provide domain knowledge about the difficulties of the data regions.

Finally, to minimize the crowdsourcing and expert cost, we develop a solution in which we iteratively explore larger values for x (the number of questions sampled per value) and y (the number of answers solicited per question), and stop when a condition is met. We now describe the above ideas in detail.

1. Defining the Problem of Ranking the Values: Let $V = \{v_1, \ldots, v_r\}$ be the set of all values of the target attribute for all data instances in D. Our goal is to find a total ranking K of the values in V, such that v_i being ranked higher than v_j means that v_i is judged more difficult than v_j.

2. Learning the Ranking: For each value $v_i \in V$, we start by sampling x questions from the corresponding region Q_i, then solicit y answers for each question from the crowd (we explain later how to select x and y). This produces a total of xy answers.

Next, we create a feature vector $f_i = \langle a_i, t_i, e_i \rangle$, where a_i is the worker accuracy for v_i, computed as the fraction of xy answers that are correct. To determine if an answer is correct, the expert must provide the golden answers for the x questions. t_i is the time it takes for a worker to answer the questions, averaged over the xy answers. Finally, e_i is the disagreement among the workers in answering the questions, measured as $1 - |N_{yes} - N_{no}|/(xy)$, where N_{yes} and N_{no} are the total numbers of yes/no answers from the workers, respectively (and $N_{yes} + N_{no} = xy$).

Example 3.1. Consider the five colors in set V in Figure 2.a. Figure 2.b shows five feature vectors created for these colors, after sampling x questions from each color region and soliciting y answers from the crowd for each question.

At this point, we have obtained a set of feature vectors $F = \{f_1, \ldots, f_r\}$, one for each value. We now learn to rank the values, using these feature vectors. To do so, we use SVM Rank, a well-known ML algorithm that can be used to rank examples [38].

To use SVM Rank, we create training data as follows. First, we randomly sample a set G of feature vectors (FVs) from F. Next, we need to rank the FVs in G (in terms of the difficulty of their corresponding values). Abusing notation, we use "$f_i \geq f_j$" to indicate that FV f_i is ranked the same or higher than FV f_j (i.e., the value corresponding to f_i is the same or more difficult than that of f_j).

Ideally, we want to create a total ranking on G, i.e., for any pair $(f_i, f_j) \in G \times G$, either $f_i \geq f_j$ or $f_j \geq f_i$, then use this total ranking as training data. However, creating a total ranking is very expensive and often quite difficult for the expert, so we ask him or her to create only a partial ranking. Specifically, the expert merely divides G into two groups U and V based on his or her domain knowledge such that for any $f_i \in U$ and $f_j \in V$, $f_i \geq f_j$.

Then for each $f_i \in U$, we create a training example $(f_i, 1)$. Similarly, for each $f_j \in V$, we create a training example $(f_j, 2)$. Here we assume that an example associated with rank 1 is more difficult than any example associated with rank 2. We output the set S of all these examples as the training data for SVM Rank.

Example 3.2. Continuing with Example 3.1, suppose we have selected the three colors black, red, and chartreuse for creating the training data (see Figure 2.c). Suppose the expert specifies that chartreuse is considered more difficult than both black and red (Figure 2.d). Then we can create the training set S in Figure 2.e for SVM Rank.

SVM Rank then uses S to learn a regression model that assigns a score to each example, such that the higher the score, the higher the example is ranked. Finally, we apply SVM Rank to FVs in F to compute for each FV a score and use these scores to rank the FVs. This produces a total ranking K for the values in V, such that a higher ranked value is said to be more difficult than a lower-ranked one.

The expert can then optionally examine, debug, and edit the ranking K, as we discuss later in Section 4.

3. Determining Parameters x and y: Recall that for each value v_i we take x questions from the set of questions with that value Q_i, then solicit y answers per question from the crowd. We now discuss how to set x and y. Our solution is to start with the smallest x and y, iteratively increase them, computing rankings along the way, then stop when these rankings have "converged". This way, we hope to minimize the cost of the expert (who needs to answer $x|V|$ questions and the crowd (who needs to answer $xy|V|$ questions).

Specifically, we start with (2,2), i.e., $x = 2$ and $y = 2$ (the smallest values that allow us to meaningfully compute feature vectors), and compute the ranking of the values $K(2, 2)$, as described earlier. Next, we increase y to consider (2,3), and compute $K(2, 3)$. Then we consider (3,3) and compute $K(3, 3)$, and so on. To compute a new ranking, say $K(3, 3)$, using SVM Rank, the expert needs to label, i.e., provide golden answers to the new questions, and we need to solicit crowd answers for these questions. But we do not have to create any additional training data.

We use the Spearman score [48], which ranges from 1 to -1, to measure the correlation between any two rankings. Consider three consecutive rankings $K(x_{n-2}, y_{n-2})$, $K(x_{n-1}, y_{n-1})$, $K(x_n, y_n)$. If it is the case that the score Spearman$(K(x_{n-2}, y_{n-2}), K(x_{n-1}, y_{n-1}))$ and the score Spearman$(K(x_{n-1}, y_{n-1}), K(x_n, y_n))$ are both exceeding a pre-specified threshold, or if x_n and y_n reach pre-specified maximal values, then we stop, returning $K(x_n, y_n)$ as the desired ranking. Algorithm 1 shows the pseudo code of the entire process to rank the data regions.

4 DEBUGGING THE RANKING

Recall from the previous section that at the start, we enlist the expert and the crowd workers to create a ranking K of the values in V, in decreasing order of difficulties. In practice, it turns out that the ranking K can be used for many important purposes.

Example 4.1. The ranking K can be used to re-calibrate the worker accuracies of the values (see Section 5.2). It can be used in formulating optimization problems, e.g., a user may want to focus on the top-10 most difficult values in K and try to maximize the average accuracy of those values (see Section 5.1). Finally, K can also be used in quality assurance (QA). For example, after we have crowdsourced to obtain answers for all questions, we may want to take a sample and manually check the accuracies of the questions in the sample, for QA purposes. The ranking K allows us to bias the sample, e.g., intentionally sample items with values in the top-10 of K, to check how well the crowdsourcing process works for these difficult values.

As a result, *it is important to make the ranking K as accurate as possible.* Once K has been created (see Section 4), the expert often wants to examine, debug, and modify it. Currently, however, there is no debugging support. To address this problem, as a first step, in this paper we will develop a way to generate explanations, which can help the expert debug K.

Specifically, given a value v placed high in the ranking K, indicating that it is difficult, the expert can ask for an explanation on why v is judged difficult by the system.

Example 4.2. When asked why "acid yellow" is judged difficult, our system may return explanations that state that this value is actually not difficult, but appears to be difficult due to spammers and low-quality (i.e., bad) workers who gave many incorrect answers. Or the system may return explanations that state that the value is indeed difficult because it is unfamiliar to many workers. Other explanations may include "the product description contains incomplete or confusing information" and "the description is hard to understand", among others.

Clearly, such explanations can significantly help the expert understand and debug the ranking K. To generate such explanations, we first develop a model M on how a crowd worker answers a question. Next, we analyze M to create a taxonomy T of possible explanations. Finally, we develop a procedure that, when given a value v, analyzes answers solicited from the crowd to identify the most likely explanations in T for v. We now discuss these steps in more details.

Developing a User Model for Answering Questions: There are many possible ways to model how a worker answers our questions. For this paper we use the following simple yet reasonable model. Suppose a worker U has to answer a question q, which has a value v for the target attribute and a context c (which is the rest of the description of the data item). Then U first tries to understand v. Next, U tries to understand c. Finally, U determines if v and c are consistent, returning "yes" or "no" if

Algorithm 1 Learning to Rank the Data Regions

```
Input: $Q$: set of questions, $V$: set of values, $x_{\max}$: max num of sampled questions,
    $y_{\max}$: max num of answers to be collected per sampled question, $(x_0, y_0)$: initial
    value for $(x, y)$, $\epsilon$: convergence threshold for ranking, $n_0$: number of training
    examples for SVM Rank
Output: A ranking $K$ of values
 1: $V_t \leftarrow$ Randomly sample $n_0$ values from $V$
 2: $O \leftarrow$ CreatePartialOrder($V_t$)
 3: $P \leftarrow$ GenerateConfigs($x_0, y_0, x_{\max}, y_{\max}$)
 4: $Q_s, A_s, T_s, G_s \leftarrow \emptyset$
 5: $(x_c, y_c) \leftarrow (0, 0)$ // current $(x, y)$
 6: $L \leftarrow [\ ]$ // list of rankings
 7: for $(x, y) \in P$ do
 8:     Sample $x - x_c$ new questions per value and add them to $Q_s$
 9:     Collects needed answers and time data and add them to $A_s$
        and $T_s$
10:     Find golden answers for newly sampled questions and add
        them to $G_s$
11:     Compute set of features $F$ from $A_s, T_s, G_s$
12:     $K(x, y) \leftarrow$ SVMRank values in $V$ using $F$, $O$
13:     $(x_c, y_c) \leftarrow (x, y)$
14:     Append $K(x, y)$ to $L$
15:     if IsRankingConverged($L$, $\epsilon$) then
16:         break
17:     end if
18: end for
19: $K \leftarrow K(x_c, y_c)$
20: $W \leftarrow$ Improve estimated worker accuracy using $K$ in Equation 4
21: return $K$, $W$

22: procedure CreatePartialOrder($V_t$)
23:     The expert partitions $V_t$ into two groups $U$, $V$ such that each
        value in $U$ is more difficult than each value in $V$
24:     $O \leftarrow \emptyset$
25:     for $v \in U$ do
26:         Add $(v, 1)$ into $O$
27:     end for
28:     for $v \in V$ do
29:         Add $(v, 2)$ into $O$
30:     end for
31:     return $O$
32: end procedure

33: procedure GenerateConfigs($x_0, y_0, x_{\max}, y_{\max}$)
34:     $P \leftarrow [(x_0, y_0)]$
35:     $n = \min(x_{\max} - x_0, y_{\max} - y_0)$
36:     for $i = 1, 2, \ldots, n$ do
37:         Append $(x_0 + i - 1, y_0 + i)$ and $(x_0 + i, y_0 + i)$ to $P$
38:     end for
39:     if $x_0 + n == x_{\max}$ then
40:         $m = y_{\max} - y_0 - n$
41:         for $i = 1, 2, \ldots, m$ do
42:             Append $(x_0 + n, y_0 + n + i)$ to $P$
43:         end for
44:     else if $y_0 + n == y_{\max}$ then
45:         $m = x_{\max} - x_0 - n$
46:         for $i = 1, 2, \ldots, m$ do
47:             Append $(x_0 + n + i, y_0 + n)$ to $P$
48:         end for
49:     end if
50:     return $P$
51: end procedure

52: procedure IsRankingConverged($L$, $\epsilon$)
53:     if $len(L) < 3$ then
54:         return False
55:     else
56:         Let $K_{n-2}, K_{n-1}, K_n$ be the last three rankings in $L$
57:         $s_1 \leftarrow$ Spearman($K_{n-2}, K_{n-1}$)
58:         $s_2 \leftarrow$ Spearman($K_{n-1}, K_n$)
59:         if $s_1 \geq \epsilon$ and $s_2 \geq \epsilon$ then
60:             return True
61:         else
62:             return False
63:         end if
64:     end if
65: end procedure
```

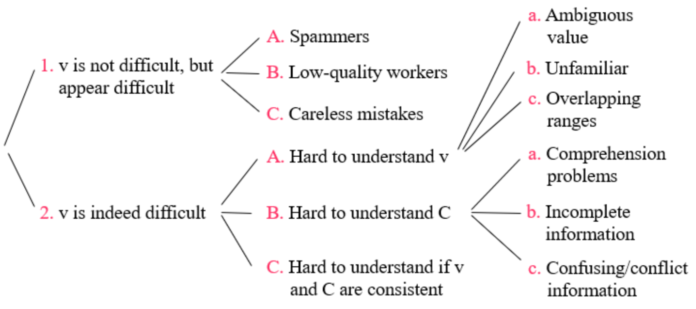

Figure 3: A taxonomy of explanations.

Algorithm 2 Generating Explanations

```
Input: $v$: the value to be explained
Output: $E_v$: the set of possible explanations for value $v$
 1: Collect data $S = \{Q_x, A, W\}$ where $Q_x$ is all $x|V|$ questions sam-
    pled in difficulty estimation stage, $A$ is all answers and their time
    stats for questions in $Q_x$, $W$ is the set of all workers for $A$
 2: Compute accuracy $\alpha$ and average time $t$ for $A$
 3: for each $w \in W$ do
 4:     Apply a procedure on $R_w$ using $\alpha$, $t$ to classify $w$ as spammers,
        low-quality workers, or regular workers
 5: end for
 6: Let $W_v$ be the set of workers who answer at least one question with
    value $v$
 7: $E_w \leftarrow$ GenWorkerExplanations($W_v$)
 8: Update $S$ to $S^+$ by removing answers and the time stats from spam-
    mers and low-quality workers
 9: Apply a procedure on $R_v$ using $S^+$, $\alpha$, $t$ to classify the nature $N_v$
    of value $v$ (i.e., ambiguous, unfamiliar, overlapping)
10: $E_v \leftarrow$ GenValueExplanations($N_v$)
11: Let $Q_v$ be the set of questions in $Q_x$ with value $v$
12: for each $q \in Q_v$ do
13:     Apply a procedure on $R_q$ using $\alpha$, $t$ to classify the nature of $q$
        (i.e., comprehension, incomplete, confusing/conflict)
14: end for
15: Let $N_q$ be the set of natures for questions in $Q_v$
16: $E_q \leftarrow$ GenQuestionExplanations($N_q$)
17: $E_v \leftarrow E_w \cup E_v \cup E_q$
18: return $E_v$
```

U can make this determination with high confidence. Otherwise U returns the answer ("yes" or "no") judged most likely.

Creating a Taxonomy of Explanations: Analyzing the above user model produces the taxonomy of explanations in Figure 3. Observe that the explanations fall into several clean groups. The first group concerns the *workers:* if they are spammers, bad workers, etc., then the value may not be difficult but will appear difficult. The second group concerns the *nature of the value v itself:* is it ambiguous, unfamiliar, etc? If so, it may explain why v is ranked difficult. The final group concerns the *nature of the question/the description of the data item/the context.* Is the description understandable (e.g., in English)? Is it complete? As we will see below, we can develop solutions to explore each of the above groups of explanations.

Generating Explanations for a Value v: Given a value v, we now seek to generate explanations for why v is difficult. We refer to each node in the above taxonomy (see Figure 3) as an *explanation.* Our solution will return a set of such explanations (in future work we will explore ranking them). To do so, the solution proceeds in the following steps (see Algorithm 2 for the pseudo code).

(1) Collect data S: We first collect data that can be analyzed to generate explanations. This data S consists of Q_x, the set of all questions generated for the difficulty score estimation process, A, the set of all answers solicited for questions in Q_x, and W, the set of all workers who have given at least one answer in A.

(2) Use S to classify the workers: We use a rule-based procedure to classify workers in W into spammers, bad workers, and regular workers. For example, we classify a worker w as a spammer if w's accuracy is significantly lower than the average accuracy, and w's response time is much faster than the average response time (as computed from data S).

(3) Generate explanations regarding the nature of the workers: Next, we identify likely explanations regarding the nature of the workers in the taxonomy T. For example, if a certain percentage of workers that have answered questions involving v are spammers, then we will identify node "1.A (Spammers)" of T as an explanation.

(4) Update data S into S^+: Next, we remove the data involving the spammers and bad workers from S, so that we can work with more accurate statistics in subsequent steps.

(5) Use S^+ to classify the nature of value v: Similar to Step 2, here we use a rule-based procedure to analyze S+, to classify the value v as ambiguous, unfamiliar, etc. For example, if the average worker accuracy for v is high and the average response time is low, then we determine that v is not unfamiliar.

(6) Generate explanations regarding the nature of value v: Again, similar to Step 3, we identity explanations in taxonomy T that involve the nature of value v. This step is straightforward.

(7) Use S^+ to classify the nature of the questions and generate explanations: We proceed similarly to Steps 2-3. For example, if a certain percentage of the questions involving v is confusing, then we will identify node "2.B.c" of T as an explanation. Finally, we return all identified explanations as the set of explanations for value v.

It is important to note that our rule-based procedures for the above steps have been created, only once. They are not dependent on the particular application domain. However, the rules employed do use various parameters (e.g., thresholds). These parameters are set based on analyzing the data S (but can also be tuned by the domain expert).

5 FINDING GOOD PLANS

We now discuss finding good crowdsourcing plans. We begin by considering the *types of problems* that the user wants to solve. As discussed in Section 1, a common baseline crowdsourcing (CS) plan is to solicit t_b answers per question, then take the majority vote to be the final answer. The existing solution has considered a single problem: minimize the total CS cost while keeping the accuracy the same as that of the baseline plan.

In practice, however, we observe that *users often want to express a wide range of other CS problems*. Examples include minimizing cost given that the accuracy exceeds a threshold, maximizing accuracy given a budget on the cost, improving the overall accuracy of a set of data items having difficult values, and more.

As a result, in this section we develop a unified framework in which users can easily express a variety of such CS problems. Some of these problems make use of the ranking K (e.g., maximizing the average accuracy of the values in the top-5 of K). Next, we show how to solve these problems using integer linear programming (ILP). Our solutions often involve the average worker accuracy per data value. Finally, we show how to use the ranking K to improve our estimations of these average worker accuracies.

5.1 Expressing Crowdsourcing Problems

Let $D = \{d_1, \ldots, d_n\}$ be a set of data items to be validated. Let $V = \{v_1, \ldots, v_r\}$ be the set of values for the target attribute of the items in D. We define a crowdsourcing plan p to be a tuple $\langle\langle v_1, t_1\rangle, \ldots, \langle v_r, t_r\rangle\rangle$, where for each question involving the value v_i, plan p will solicit t_i answers from the crowd ($i \in [1, r]$).

Let $S \subseteq V$ be a set of values. We define $acc(S, p)$ to be the accuracy of plan p for the values in S, i.e., the fraction of questions with value $v \in S$ that receive a correct (aggregated) answer when p is executed. We define $cost(S, p)$ to be the total number of answers solicited from the crowd for the questions with value $v \in S$.

We can now define a general CS problem template as follows *"Given a set of plans P and a set of values $\mathcal{S}$, return the plan that maximizes or minimizes an objective O, subject to a constraint C, where O and C involve P and $\mathcal{S}$, and optionally a ranking K of values".* In this paper we consider the following concrete CS problems that follow the above template.

Finding Plans That Outperform a Baseline Plan: In many scenarios there exists already a baseline plan p_b. The user however wants a plan p that is better than p_b in some aspects. While numerous problem variations exist, in this paper we consider the following variations:

T_1: Minimize cost while achieving the same accuracy

Return the plan p that minimizes $cost(V, p)$, subject to constraints $acc(V, p) \geq acc(V, p_b)$ and $cost(V, p) \leq cost(V, p_b)$. This is the problem considered by PBA [14].

T_2: Maximize accuracy while keeping the same cost

Return the plan p that maximizes $acc(V, p)$, subject to constraints $cost(V, p) \leq cost(V, p_b)$ and $acc(V, p) \geq acc(V, p_b)$.

T_3: Maximize the individual accuracy

In many cases the overall accuracy $acc(V, p)$ can be high, say 95%, yet certain individual accuracies (e.g., $acc(v, p)$ for certain v-s) may be quite low, say 60%. For example, the overall accuracy for color verification can be 95%. Yet the accuracy for "chartreuse" is only 60%.

In such cases, the user often wants to improve the accuracies of the values *across the board* as much as possible, while keeping the overall accuracy at least as high as that of p_b and keeping the overall cost at most as high as that of p_b. To do this, the user can try to solve the following problem: Return the plan p that maximizes $min_{v_i \in V} acc(v_i, p)$, subject to $acc(V, p) \geq acc(V, p_b)$ and $cost(V, p) \leq cost(V, p_b)$. Intuitively, if a plan increases $min_{v_i \in V} acc(v_i, p)$, then it would increase the accuracies of all individual values.

Solving problems $T_1 - T_3$ for only a subset of values

The above problems $T_1 - T_3$ consider all values in V. In certain cases, the user may be interested in optimizing for only a subset of values $S \subseteq V$, such as the top 10 most difficult values, according to the ranking K. In such cases, we can formulate problems similar to $T_1 - T_3$, but replace V with S where appropriate.

Finding Plans That Satisfy General Constraints: In certain cases, the user does not have a baseline plan p_b to compare against. Instead, he or she just wants to find an "optimal" plan that satisfies certain constraints about cost and accuracy. Many variations exist. In this paper we consider the following:

T_4: Minimize cost while keeping accuracy above a threshold

Return the plan p that minimizes $cost(V,p)$, subject to constraint $acc(V,p) \geq \alpha$.

T_5: Maximize accuracy while keeping cost below a threshold

Return the plan p that maximizes $acc(V,p)$, subject to constraint $cost(V,p) \leq \beta$.

Solving problems $T_4 - T_5$ for only a subset of values

Again, in certain cases, the user may be interested in optimizing for only a subset of values $S \subseteq V$. In such cases, we can formulate problems similar to $T_4 - T_5$, but replace V with S where appropriate.

5.2 Solving Crowdsourcing Problems

We have described how users can express a variety of CS problems for detecting data errors. We now discuss how to solve them. The main idea is to formulate them as integer linear programming (ILP) optimization problems, solve these problems to find an optimal CS plan $p* = \langle\langle v_1, t_1\rangle, \ldots, \langle v_r, t_r\rangle\rangle$, then execute $p*$.

In what follows we discuss how to carry out the above idea for problem type T_1, then briefly discuss problem types $T_2 - T_5$. Recall that in problem type T_1, we want to find the plan p that minimizes $cost(V,p)$, subject to constraints $acc(V,p) \geq acc(V,p_b)$ and $cost(V,p) \leq cost(V,p_b)$. We now discuss how to estimate the quantities $cost(V,p)$, $cost(V,p_b)$, $acc(V,p_b)$, and $acc(V,p)$.

Estimating $cost(V,p)$ and $cost(V,p_b)$: It is straightforward to compute $cost(V,p_b)$, the crowdsourcing cost of the baseline solution. Recall that V is the set of values. Suppose each value v_i has n_i questions, then the total number of questions is $\sum_{i=1}^{r} n_i$. Since t_b answers need to be collected per question, $cost(V,p_b) = t_b \sum_{i=1}^{r} n_i$.

To compute $cost(V,p)$, recall that in our solution, for each value v_i, we have sampled x questions and collected y answers per sampled question. If plan p states that t_i answers will be collected for each remaining question, then the cost spent on value v_i will be $t_i(n_i - x) + xy$. Then the total cost on V can be computed as $cost(V,p) = \sum_{i=1}^{r}(t_i(n_i - x) + xy)$.

However, we cannot use t_i's as variables in the resulting ILP optimization problem (because constraints involving them will not be linear). To handle this problem, we use a set of indicator variables to represent t_i. Specifically, suppose $t_{\min}$ and $t_{\max}$ are the min and max number of answers to be collected per question (these two values are pre-specified; $t_{\min}, t_{\max}$ need to be odd positive integers since majority vote is used for aggregation). Let $A = \{t_{\min}, t_{\min} + 2, \ldots, t_{\max}\}$. Clearly, all t_i's are in A. To represent t_i, for each $j \in A$ we create an indicator variable h_{ij}. That is, if $j = t_i$, then $h_{ij} = 1$; otherwise $h_{ij} = 0$ for all $j \neq t_i$. We have $t_i = \sum_{j \in A} j h_{ij}$ and $cost(V,p) = \sum_{i=1}^{r}((\sum_{j\in A} j h_{ij})(n_i - x) + xy)$. As we will see shortly, our ILP formulation uses this formula for $cost(V,p)$.

Estimating $acc(V,p_b)$: Let m_i be the number of questions with value v_i whose aggregated answers are correct, then $acc(V,p_b) = (\sum_{i=1}^{r} m_i)/(\sum_{i=1}^{r} n_i)$, where n_i is the number of questions for value v_i.

To estimate m_i, for each question q with value v_i we need to compute the probability that q's aggregated answer is correct, which depends on the number of collected answers. Recall that we assume that all questions with value v_i have the same difficulty and workers are i.i.d. (i.e., identically independently distributed) for each value. When we collect the same number of answers per question for a value, the aggregated answers of those questions will have the same probability of being correct.

We define $f_{i,t}$ as the probability that for any question q with value v_i, q's aggregated answer is correct when t answers are collected per question. So if the baseline approach collects t_b answers per question, then $m_i = n_i f_{i,t_b}$, where n_i is the number of questions in region i (for value v_i). We now describe how to compute $f_{i,t}$ for any i and t.

To compute $f_{i,t}$, we use the worker accuracy a_i for value v_i. Since we assume that workers are i.i.d. for value v_i, when t answers are collected for question q in region i, these answers are independent and each answer has the probability a_i of being correct. So the number of correct answers follows the binomial distribution $B(t, a_i)$. Since we use majority voting, q's aggregated answer is correct if and only if more than half of the collected answers of q are correct. So we can compute

$$f_{i,t} = \sum_{j=\lceil t/2 \rceil}^{t} \binom{t}{j} a_i^j (1 - a_i)^{t-j} \tag{1}$$

For each value v_i, we compute f_{i,t_b} using (1), then estimate m_i's and $cost(V,p_b)$ as described above. (At the end of this subsection we will describe how we use the rankings from Section 4 to adjust a_i's for all v_i's.)

Estimating $acc(V,p)$: Recall that $A = \{t_{\min}, t_{\min} + 2, \ldots, t_{\max}\}$ and $f_{i,t}$ is the probability that for any question q with value v_i, q's aggregated answer is correct when t answers are collected per question. Using the indicator variables described earlier, the expected probability that q's aggregated answer is correct can be estimated as $\sum_{j\in A} h_{ij} f_{i,j}$. Then the overall accuracy of our approach is computed as $acc(V,p) = \frac{\sum_{i=1}^{r}(x+(n_i-x)(\sum_{j\in A} h_{ij} f_{i,j}))}{\sum_{i=1}^{r} n_i}$.

Formulating T_1 as an ILP Problem: We now can formulate problem T_1 as the following ILP problem:

$$\begin{aligned}
\underset{\substack{h_{ij} \forall j \in A,\\ i=1,2,\ldots r}}{\text{minimize}} \quad & \sum_{i=1}^{r}(xy + (\sum_{j\in A} j h_{ij})(n_i - x)) \\
\text{subject to} \quad & \frac{\sum_{i=1}^{r}(x + (n_i - x)(\sum_{j\in A} h_{ij} f_{i,j}))}{\sum_{i=1}^{r} n_i} \geq \alpha_b \\
& \sum_{i=1}^{r}(xy + (\sum_{j\in A} j h_{ij})(n_i - x)) \leq t_b \sum_{i=1}^{r} n_i \\
& \sum_{j\in A} h_{ij} = 1 \quad \forall i = 1, 2, \ldots, r \\
& h_{ij} \in \{0, 1\} \quad \forall j \in A, \forall i = 1, 2, \ldots, r
\end{aligned} \tag{2}$$

The objective function is the total number of answers to be collected, which should be minimized. The first constraint ensures that the overall accuracy is same or better than that of the baseline approach (here α_b is $acc(V,p_b)$). The second constraint ensures that the total cost is no more than that of the baseline. The third constraint ensures that for each value, only one indicator variable is equal to 1. Finally, we solve the above ILP problem using the Gurobi solver [1], and return any solution found to the user, as the crowdsourcing plan p to be executed. We have

Proposition 5.1. *Let t_{min} and t_{max} be the minimal and maximal number of answers that the user wants to solicit for each question. Let t_b be the number of answers that the baseline solution solicit for each question, and x be the number of questions that we sample per value for the difficulty estimation step. If $t_{min} \leq t_b \leq t_{max}$ and $t_b \geq x$, then Equation 2 always has at least one solution.*

Solving Problems $T_2 - T_5$: So far we have discussed solving problem T_1. Problems T_2, T_4, and T_5 can be transformed similarly. For T_2, we only need to change the objective to maximize $acc(V, p)$ (which is the left side part of first constraint in problem T_1). For T_4 (or T_5), we only need to replace the estimated baseline accuracy (or cost) with the given accuracy (or cost) threshold from problem T_1 (or T_2) and remove the unnecessary constraint on cost (or accuracy).

Solving T_3, which maximizes $\min_{v_i \in V} acc(v_i, p)$, is a bit more involved. Let z be the minimum value accuracy among values in V, then the objective function of the transformed optimization is simply to maximize z, and it must add a constraint for each value v_i in V to ensure the accuracy of v_i is at least z (Constraint 3 in Equation 3). Therefore, we formulate problem T_3 as

$$\begin{aligned}
\underset{\substack{z, h_{ij} \forall j \in A,\\ i=1,2,\ldots r}}{\text{maximize}} \quad & z \\
\text{subject to} \quad & \frac{\sum_{i=1}^{r}(x + (n_i - x)(\sum_{j \in A} h_{ij} f_{i,j}))}{\sum_{i=1}^{r} n_i} \geq \alpha_b \\
& \sum_{i=1}^{r}(xy + (\sum_{j \in A} j h_{ij})(n_i - x)) \leq t_b \sum_{i=1}^{r} n_i \\
& \frac{x + (n_i - x)(\sum_{j \in A} h_{ij} f_{i,j})}{n_i} \geq z \qquad \forall v_i \in V \\
& \sum_{j \in A} h_{ij} = 1 \quad \forall i = 1, 2, \ldots, r \\
& h_{ij} \in \{0, 1\} \quad \forall j \in A, \forall i = 1, 2, \ldots, r
\end{aligned} \tag{3}$$

We have described how to solve problems $T_1 - T_5$ in the cases where they involve the set of all values V. It is easy to see that these problems can be solved in a similar fashion if they involve only a subset of values $S \subseteq V$.

Using the Ranking to Adjust Worker Accuracies: Recall that for each value $v_i \in V$, we have obtained xy answers from the crowd, and have estimated the worker accuracy for v_i as a_i, the fraction of the xy answers that are correct.

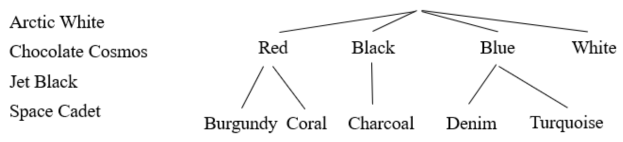
However, a_i is often not a good estimation of the true worker accuracy for v_i, because the set of xy answers is often small (e.g., $x = 4$ and $y = 5$ for 20 answers total). Thus, we seek to improve these estimations, using the ranking K. Our key idea is that if v_i is ranked higher than v_j, thus being perceived as being more difficult, then the worker accuracy for v_i should be no higher than that of v_j. If this is not the case, then we can adjust such worker accuracies so that they become more consistent with the ranking K.

Specifically, suppose K assigns to each value $v_i \in V$ a rank $k_i \in [1, r]$, where a smaller k_i indicates a value closer to the top of the ranked list. Then we model the task of improving the worker accuracies a_i's as the following optimization problem:

$$\begin{aligned}
\underset{z_1, z_2, \ldots, z_r}{\text{minimize}} \quad & \sum_{i=1}^{r}(z_i - a_i)^2 \\
\text{subject to} \quad & 0 \leq z_i \leq z_j \leq 1 \quad \forall i, j \in [1, r] \text{ s.t. } k_i < k_j
\end{aligned} \tag{4}$$

Here z_i is the improved worker accuracy for value v_i, and the cost function is the sum of the squares of $z_i - a_i$ (also known as L_2 cost function). Its constraint ensures that each value has the same or less worker accuracy than any easier value. This model is a simple Isotonic Regression problem, which always has a solution. It can be efficiently solved in $O(r)$ time [23], where r is the number of values. We solve it using Gurobi [1]. We then set $a_i = z_i$ and use a_i's as the worker accuracies in formulating ILP problems, as discussed earlier in this section.

Table 1: An example of handling ambiguous colors.



6 MANAGING AMBIGUOUS VALUES

As discussed in Section 1, in practice, there are many cases when the value for the target attribute is inherently ambiguous, such as "desert sand" and "arctic white". In such cases even the expert has trouble determining what should be the correct answer to the question, let alone asking the crowd workers. Such cases are surprisingly common, and no existing work has addressed them, as far as we can tell.

In this paper we provide a simple yet effective solution to this problem, based on what we have seen working well in industry. Briefly, we ask the expert E to first create a taxonomy Z of only unambiguous values, such as the one in Figure 1. Then the expert E examines each value v in V (the set of all values for the target attribute in the data set D). If E judges v to be inherently ambiguous, E should map v to a value $m(v)$ in Z.

Example 6.1. Table 1 shows a set of values (on the left side of the figure) that are ambiguous. The expert can map "Arctic White" to node "White" in the taxonomy, "Chocolate Cosmos" to "Burgundy", and so on.

A question such as "is the color of this product indeed chocolate cosmos?" is then transformed into "is the color of this product indeed burgundy?", which is unambiguous for crowd workers to answer.

7 EMPIRICAL EVALUATION

We now evaluate our solution. First, we crawled online sources to obtain the three datasets shown under "Datasets A" in Table 2. Their schemas are shown at the top of the table, with the target attribute underlined. Column "# Items" lists the number of data items in each dataset, and column "# Values" lists the number of values for the target attribute.

Since it would be too expensive to crowdsource all items in all datasets, we downsample all three datasets (using stratified sampling in which for each value of the target attribute, we randomly retain only 20% of the data items with that value). The new datasets are listed under "Datasets B" in the same table. Our experiments with real crowd workers are performed on these new datasets. We used Amazon Mechanical Turk for crowdsourcing, and used common turker qualifications, such as allowing only turkers with at least 100 approved HITs and 95% approval rate.

7.1 Learning to Rank

We first examine the performance of learning to rank. Recall that for each dataset, we sample x questions for each value, and then solicit y answers for each question. Thus, the expert must provide golden answers for $x|V|$ questions (where V is the set of

	7	4,830	2,866	40.7	98.36	97.97
	9	6,210	3,202	48.4	98.84	98.02

all values for the target attribute), and the crowd must provide $xy|V|$ answers. So it is highly desirable that we minimize these two quantities, to minimize the workload of the expert and the crowd workers.

For our current three datasets, (x, y) are $(4, 5)$, $(5, 5)$, $(5, 5)$ for Products, Courses, and Apparel, respectively. Our iterative expansion process (to find x and y) converged for Products and Courses. These results suggest that indeed VChecker spends relatively little expert and crowd effort to compute the difficulty scores.

Next, we examine the quality of the ranking K of the values that we have obtained. To do so, we need a "golden" ranking $K*$. We obtain $K*$ as follows. First, for each value v, we collect A_v, the set of all answers obtained from the crowd for all questions involving v. Since we have obtained at least 9 answers for each question, this is usually a large number (in the hundreds). Next, we have identified the correct answer for all questions in our datasets, so we can compute the worker accuracy for v as the fraction of answers in A_v that is correct. Since A_v is a large set of answers, we take this worker accuracy to be the golden worker accuracy. Finally, we sort the values in decreasing order of these golden accuracies, to obtain a golden rank $K*$ of the values, in decreasing order of difficulties.

We now compare ranking K with $K*$. Direct comparison turns out to be difficult, because we often have two values v_i and v_j such that v_i is ranked above v_j in K and the reverse applies in $K*$, yet their difficulty scores differ by less than 0.01, say. In such cases, where the difficulty scores differ by less than a small ϵ threshold, we say the two values are not comparable. We translate ranking $K*$ into a set of $S(K*)$ of all (v_i, v_j) pairs that are comparable, and translate ranking K into a similar set $S(K)$.

Table 3 compares these sets. Consider the last three cells of the first row (the cells under "VChecker"). The cell under "Precision" is 68.64%, meaning 68.64% of pairs in $S(K)$ appear in $S(K*)$. The cell under "Recall" means 68.47% of pairs in $S(K*)$ appear in $S(K)$. These two numbers produce a F_1 score of 68.56%. Thus, for Products, the ranking K approximates the golden rank $K*$ quite well, with high precision and recall (though there is still room for improvement). Similar results are shown for Courses and Apparel.

Recall that the current popular solution in industry uses the average worker accuracy to rank the data values. Table 3 shows that the ranking produced by this solution is worse than the VChecker ranking (see the first three columns of the table, under "WAK", shorthand for "worker accuracy-based ranking", which show lower F_1 values). This result suggests that VChecker is indeed able to exploit additional information such as the response time and the worker disagreement to obtain a better ranking of value difficulties than the current existing solution.

7.2 Generating Explanations

To evaluate our explanation generator, for each dataset we select 3 values in the top part of the ranking K, then ask for their explanations. For comparison purposes, we also ask a domain expert to manually generate explanations, after carefully examining all the answers solicited from the crowd.

Table 4 lists the explanations for VChecker vs those generated by the experts. "2Ab" for example is the explanation at node "2.A.b" in the taxonomy of explanations in Figure 3 ("v is indeed difficult because it is unfamiliar"). The table shows that the two sets of explanations share large overlaps (see the last column of the table), suggesting that VChecker is effective in generating explanations to explain why a value is considered difficult.

7.3 Finding Good Crowdsourcing Plans

We now show that VChecker can find good crowdsourcing plans for a variety of problem types. Table 5 compares VChecker to the baseline plan of soliciting the same number t_b of answers for each data value. We call this plan UCS, shorthand for "uniform crowdsourcing".

To explain, consider the third row of this table. It shows that for dataset Products, if UCS solicits $t_b = 3$ answers per question, then it incurs a total crowdsourcing cost of 6,393 answers. If

Table 6: VChecker vs UCS in solving problem T_3.

Dataset	Min Value Accuracy		Avg Value Accuracy	
	UCS	VChecker	UCS	VChecker
Products	68.45	83.33	92.34	96.11
Courses	72.45	74.68	96.11	96.81
Apparel	92.23	95.58	97.46	98.30

we solve the CS problem T_1 (as described in Section 5.1; we experiment with other CS problem types below) to find a better CS plan, which would minimize this cost while keeping accuracy at least equal or better than that of UCS, then the cost of this new plan (listed under column "VChecker") is 4,435. This produces a reduction of 30.6% in cost. The last two cells of this row show that the accuracies of UCS and VChecker are comparable (96.1 vs 95.53) [1]. (We obtained these accuracy numbers by executing both plans on Amazon Mechanical Turk.) Subsequent rows are similar, but for different values of t_b.

The table shows that VChecker can significantly reduce the cost of the baseline solution UCS, by 22.7-53.4% in all cases, except two cases where the reduction is a more modest 2.6% and 2.9%. It also shows that the accuracy of VChecker is comparable to that of UCS (with the difference in the range [-1.17%, 0.43%]).

Solving Other Types of CS Problems: Earlier we have shown how VChecker solves CS problems of type T_1. We now show that VChecker is effective in helping users solve other types of CS problems.

In Section 5.1 we discuss problem T_3, where the user wants to improve the accuracies of the values *across the board* as much as possible, while keeping the overall accuracy at least as high as that of the baseline plan p_b and keeping the overall cost at most as high as that of p_b. The goal is to return the plan p that maximizes $min_{v_i \in V} acc(v_i, p)$, subject to $acc(V, p) \geq acc(V, p_b)$ and $cost(V, p) \leq cost(V, p_b)$.

Table 6 shows how well VChecker performs for this problem. The column "UCS" shows the minimal value accuracy (i.e., the lowest accuracy among those of all values) when it solicits 3 answers for each question. The column "VChecker" shows that VChecker is able to improve this minimal accuracy significantly, while keeping the cost no higher than the cost of UCS. The last two columns show that even the average value accuracy (i.e., averaged over all values) of VChecker is higher than that of UCS.

In Section 5.1 we also discuss the problem of maximizing the accuracy of k most difficult values, as taken from the ranking K. Table 7 shows that VChecker is effective for solving this problem, improving the accuracy of the top 5 most difficult values per dataset significantly.

7.4 Additional Experiments

Sensitivity Analysis: In the current VChecker system we set $x_{max} = 5$ and $y_{max} = 5$, meaning that the iterative exploration process (see Section 3.2) never goes beyond these values. Figure 4 shows how iterative exploration is sensitive to varying these values. It shows that this process converges between 3 and 6 for all three datasets, suggesting that setting the values to 5 is a reasonable choice.

[1]When solving the ILP problem, we specified the constraint that VChecker has the same or better accuracy than UCS. When executing the found plan on Mechanical Turk, however, this constraint may not hold, due to spammers, careless workers, etc. Nevertheless, our experiments show that the accuracies of VChecker and UCS differ by a very small range.

Table 7: Maximizing accuracy of 5 most difficult values.

Dataset	Values	Value Accuracy		
		UCS	VChecker	% Improved
Products	Coral	68.45	83.33	14.88
	Denim	81.07	100.00	18.93
	Taupe	76.96	100.00	23.04

	Socks	96.87	96.90	0.03
	Swimwear	99.34	97.35	-1.99

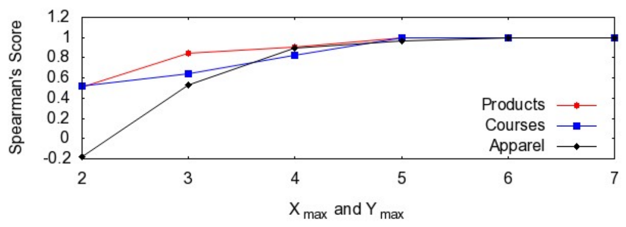

Figure 4: Convergence in iterative exploration.

Managing Ambiguous Values: Finally, we briefly discuss examples of managing ambiguous values. In our experiments it turns out that Products has ambiguous values. Specifically, it has a total of 173 values, 110 of which are considered ambiguous and have to be mapped to 63 values in a taxonomy of unambiguous values. Examples of such mappings include Arctic White mapped to White, Fluorescent Orange mapped to Orange Red, and Saddle Brown mapped to Brown. This clearly suggests that managing such ambiguous values is critical in real-world verification of attribute values.

8 RELATED WORK

Data cleaning has received enormous attention (e.g., [2–4, 6, 9, 11, 12, 16, 32–37, 40–45, 50]). See [5, 7, 10, 46] for recent tutorials, surveys, and books. However, as far as we can tell, no published work has examined the problem of manually detecting data errors in categorical attributes, as we do in this paper.

In recent years, crowdsourcing (CS) has received significant attention and has also been applied to many data cleaning problems (e.g., [8, 14, 15, 20, 22, 25, 28, 30, 31, 47, 49]). Among these, the work [14] also discusses the idea of adapting crowdsourcing strategies to the difficulties of data regions. However, it considers this idea in the setting of crowdsourcing for active learning. Further, it does not consider learning to rank the data regions, nor debugging the ranking, as we do this paper.

A critical challenge in CS is that the quality of workers varies. Researchers have proposed many methods to differentiate workers, such as filtering out spammers [25, 47], measuring the reliability and quality of workers [19, 22, 27, 39], and finding the right group of workers for a given task [17]. These methods usually assume that all the questions are of the same difficulty. In contrast, VChecker utilizes the difficulty heterogeneity among the questions while assuming that all workers have the same quality.

VChecker uses majority voting to aggregate the collected answers of each question. Many other aggregation methods have been proposed [19, 22, 27, 39]. They usually assign higher weights to answers from workers with good quality, then perform weighted aggregation. Many build probabilistic models [22, 39] to iteratively update the estimation of worker quality and weights. However, as far as we can tell, there is no published work yet showing conclusive evidence that these methods can achieve higher accuracy than majority voting, especially when we can only collect a small number of answers per question due to limited budget, as in our setting here.

Researchers also propose other methods to reduce CS cost, e.g., early-stopping strategies [13, 21, 29]. They stop collecting more answers for a question when they realize that collecting more answers will not change the aggregated answer. Such methods can also be used in VChecker to further reduce our cost, when we use the best plan returned by VChecker to crowdsource all the questions.

Finally, most CS works only collect answers from the crowd. [26] also collects the self-reported confidence from workers to improve the accuracy of aggregated answers. However, they also notice that workers have the tendency to overestimate or underestimate their confidence. Recently [18] proposes to collect the time spent by workers to measure CS effort. VChecker also collects the response times, but use these (and other data) to estimate question difficulty.

9 CONCLUSIONS

Detecting data errors completely manually is a ubiquitous problem in data cleaning, yet it has not received much attention. In this paper we have shown that the current common solution of crowdsourcing the above problem using the same number of answers per question can be improved by detecting the difficulties of data regions, then adjusting the number of answers required for each region based on its difficulty. We showed that current work using this idea has several significant limitations. We proposed VChecker, a novel solution to address these limitations, and described extensive experiments with three real-world data sets that demonstrate the promise of our solution. For future work, we plan to improve VChecker in multiple ways, including developing solutions to partition the input data into regions, better solutions to estimate and rank the data regions' difficulties, and better solutions to generate explanations for domain experts.

ABSTRACT

Millions of videos are ubiquitously generated and shared everyday. Releasing videos would be greatly beneficial to social interactions and the community but may result in severe privacy concerns. To the best of our knowledge, most of the existing privacy preserving techniques for video data focus on detecting and blurring the sensitive regions in the video. Such simple privacy models have two major limitations: (1) they cannot quantify and bound the privacy risks, and (2) they cannot address the inferences drawn from the background knowledge on the involved objects in the videos. In this paper, we first define a novel privacy notion *ϵ-Object Indistinguishability* for all the predefined sensitive objects (e.g., humans and vehicles) in the video, and then propose a video sanitization technique VERRO that randomly generates utility-driven synthetic videos with indistinguishable objects. Therefore, all the objects can be well protected in the generated utility-driven synthetic videos which can be disclosed to any untrusted video recipient. We have conducted extensive experiments on three real videos captured for pedestrians on the streets. The experimental results demonstrate that the generated synthetic videos lie close to the original video for retaining good utility while ensuring rigorous privacy guarantee.

1 INTRODUCTION

Millions of videos are ubiquitously generated and shared everyday via video surveillance devices, traffic cameras, smart phones, among others. Sharing such video data would greatly benefit human interactions and the community. For instance, surveillance cameras in buildings capture possible threats to the corporate assets (such videos are shared for analysis in many cases [44]). Traffic videos contribute to monitoring the street traffic and traffic analysis applications such as vehicle counting and traffic flow analysis [3] as well as pedestrian behavior analysis.

However, these scenarios have often raised severe privacy concerns since human faces, bodies, identities, activities and other sensitive information can be recorded in such videos [8, 44]. Thousands of vehicles are involved in a traffic monitoring video, and drivers may not be willing to share their vehicle plate, make, model, locations and trajectories [2]. In addition, video surveillance systems monitor specific areas of interests with the following goals: law enforcement, personal safety, resource planning, and security of assets [44]. While ensuring safety and deterrence, it may also compromise the privacy of innocent individuals. Thus, privacy preserving solutions for videos have attracted significant interests recently.

To the best of our knowledge, most of the existing privacy preserving techniques for addressing the privacy concerns in video data (e.g., [1, 6, 20, 24, 42]) focus on detecting and blurring the sensitive regions in the videos (e.g., faces and bodies). Such simple privacy models have two major limitations: (1) they cannot quantify the bound of privacy risks, and (2) they cannot address the inferences drawn from the background knowledge on the involved objects. For instance, the video recipient may have known that an individual lives near the scene, and he/she usually wears red clothes as well as likes running at a specific side of the street. In this case, even if all the humans can be detected and blurred before video disclosure, they can be readily re-identified by the adversary with the above background knowledge.

ϵ-Object Indistiguishability. To tackle such critical limitations, we define a novel privacy notion for protecting the objects (and the corresponding individuals) in the videos – "*ϵ-Object Indistinguishability*", which is extended from the emerging *differential privacy* in local setting [4, 10, 16]. Specifically, in the past decade, the notion of differential privacy has emerged essentially as the de facto privacy standard for bounding the privacy risks while sanitizing different data [7, 13, 25]. Adversaries cannot infer if a certain individual is included in the input or not from the noisy aggregated result (perturbed by a trusted aggregator) regardless of their background knowledge [13]. More recently, local differential privacy (LDP) models have been proposed to privately perturb data by each individual such that the collected (random) data from different individuals can be *indistinguishable.* Inspired by the LDP models, our privacy notion also ensures *indistinguishability* for all the objects in the randomized output video, and thus the perturbed video can be safe to be disclosed to any untrusted video recipient.

Recall that videos differ from many other data (e.g., statistical databases [13], location data [32], and search logs [26]). A local video may include numerous objects corresponding to multiple different individuals, e.g., many pedestrians are recorded in a single video, and many vehicles are recorded in the same video. A video includes the "local data" of many individuals (e.g., humans) which will be shared to the untrusted recipients via the video owner. Thus, the primary difference between *ϵ-Object Indistinguishability* and the original definition of LDP [4, 10, 16] is that the video owner locally perturbs data for all the objects rather than letting the objects execute perturbation (see Figure 1).

Contributions. With the privacy notion of *ϵ-Object Indistinguishability*, we propose a video sanitization technique that randomly generates a synthetic video by the video owner (e.g., the agency which captures the video) while ensuring *ϵ-Object Indistinguishability* and good utility.

Specifically, we design a novel random response scheme (by optimizing the RAPPOR [16]) that randomly generates different objects in the video by maximizing the utility of random response

[16] applied to the objects. Thus, we name our proposed technique as *"Video with Randomly Responded Objects* (VERRO)". As a result, we boost the utility of VERRO in two folds: (1) for each object, optimizing its random response in different frames, and (2) interpolating the trajectories of objects in the video [17] (without additional privacy leakage [14], see Section 4). Thus, the synthetic video can be disclosed to any untrusted recipient. Finally, we summarize the major contributions of this paper as below:

- To the best of our knowledge, we define the first rigorous privacy notion for all the sensitive objects (predefined by the video owner) in the video data, which ensures that all the objects are *indistinguishable* in the randomized output video against arbitrary background knowledge.
- We propose a novel video sanitization technique VERRO that randomly generates utility-driven synthetic videos in which any two sensitive objects are ϵ-*Object Indistinguishable.*[1] The video owner can also specify its privacy budget ϵ for all the objects in its video.
- The proposed novel random response scheme (by optimizing RAPPOR [16]) in VERRO that optimally picks frames of the video to randomly generate objects (while satisfying indistinguishability). The utility of the synthetic video is further improved using computer vision techniques.
- We have conducted extensive experiments on real videos to validate the performance of VERRO. The experimental results demonstrate that VERRO can effectively generate private synthetic videos with high utility.

The remainder of this paper is organized as follows. Section 2 introduces some preliminaries. Section 3 illustrates the first phase of VERRO and analyzes the privacy guarantee. Section 4 presents the second phase of VERRO (for further boosting the utility) and its privacy guarantee. Section 5 gives discussions for VERRO. Section 6 demonstrates the experimental results. Section 7 and 8 present the literature and conclusions.

2 PROBLEM FORMULATION

In this section, we first describe the adversary model, then define our privacy notion, and finally provide a general overview of our proposed approach.

2.1 Adversary Model

Denote a video as $\mathcal{V}$ which is captured by a video owner, e.g., a hospital or a company equipped with CCTV surveillance, and an agency which captures the video on the street. Video $\mathcal{V}$ (all the frames) includes a set of n sensitive objects $\mathbb{O} = \{O_1, O_2, \cdots, O_n\}$ (e.g., humans and vehicles). Assume that the video owner would like to share $\mathcal{V}$ to an external party for analysis (viz. the adversary). To ensure privacy, our proposed VERRO (randomly) generates a synthetic video $\mathcal{V}^*$ which is close to $\mathcal{V}$, such that:

- Each sensitive object in all the frames satisfies ϵ-*Object Indistinguishability* – the adversary cannot distinguish any two objects from the output synthetic video $\mathcal{V}^*$ with arbitrary background knowledge.
- The synthetic video $\mathcal{V}^*$ retains good utility (close to $\mathcal{V}$).

In VERRO, we assume that the adversaries can possess arbitrary background knowledge on each object (e.g., object contents, trajectories, at-scene times, and gathering groups of objects). To retain the output utility, VERRO does not change the background scene(s), but the privacy model can break the linkage between each object and the background scene(s) via *indistinguishability.*

With privacy guarantee for all the objects (making them indistinguishable), VERRO regularly generates synthetic videos for videos including sensitive objects w.r.t. multiple individuals (e.g., pedestrians and vehicles). In case that a video includes only one sensitive object, the adversary still cannot re-identify the object (see Section 5). In addition, VERRO only addresses the visual privacy concerns, assuming that the adversary cannot identify objects from the audio or audio is not captured (e.g., traffic monitoring and video surveillance).

2.2 Privacy Notion

2.2.1 Traditional Privacy Model. Video $\mathcal{V}$ includes multiple sensitive objects $O_1, \ldots, O_n$, which can be detected and tracked in all the frames [48, 49]. Specifically, it first detects all the sensitive objects in each frame with the detection algorithms (e.g., HOG for human [51] and SVM for vehicles [22]). Each detected object can be accurately tracked with the same ID if they highly overlap in multiple frames.

The traditional privacy models are defined to blur all the detected objects [1, 6, 20, 24, 42]. An alternative solution could be replacing the detected objects with "synthetic objects" [28, 43]. Each object can be replaced by a unique synthetic object: for instance, a red synthetic human and a purple synthetic human can be used to represent two different pedestrians in all the frames involving them. Then, the inferences and re-identification visually from the objects can be greatly mitigated.

2.2.2 ϵ-Object Indistinguishability for Sensitive Objects. Recall that only replacing the objects with synthetic objects in the video cannot address the re-identification based on the adversaries' background knowledge (as discussed in Section 1). Thus, we need to ensure *indistinguishability* for not only objects themselves (can be achieved by synthetic objects) but also their moving trajectories [50] in the video.

To this end, inspired from the indistinguishability provided by the ϵ-LDP, we define a novel privacy notion ϵ-*Object Indistinguishability* by considering each object's trajectory in the video (coordinates at different frames) as its "local data". Specifically, in the standard LDP definition [4, 10, 16], there are a set of users, each of which has its own data. After each user locally perturbs its data, the obfuscated output can be directly disclosed to any untrusted recipient/aggregator, where the randomized data collected from any two different users are indistinguishable [10, 16]. Migrating the LDP model to the objects in any video $\mathcal{V}$, we define the ϵ-*Object Indistinguishability* as below:

Definition 2.1 (ϵ-Object Indistinguishability). A randomization algorithm $\mathcal{A}$ satisfies ϵ-*Object Indistinguishability*, if and only if

[1]As formally defined in Definition 2.1, ϵ-*Object Indistinguishability* ensures a similar privacy guarantee as ϵ-*local differential privacy* [4, 10, 16].

Synthetic Objects
Background Scene(s)

Figure 2: VERRO for Utility-Driven Synthetic Video Generation with Object Indistinguishability

for any two input objects $O_i, O_j \in \mathbb{O}$ in the input video $\mathcal{V}$, and for any output object of $\mathcal{A}$ in the synthetic video $\mathcal{V}^*$ (denoted as y), we have $Pr[\mathcal{A}(O_i) = y] \le e^{\epsilon} \cdot Pr[\mathcal{A}(O_j) = y]$.

Similar to ϵ-LDP [16], *ϵ-Object Indistinguishability* also focuses on the indistinguishability of randomizing any two objects, rather than the indistinguishability of randomizing any two neighboring inputs (whether any object is included or not included in the input) in traditional differential privacy [13]. Privacy budget ϵ decides the degree of indistinguishability (identical to LDP [16]).

Definition 2.1 guarantees that the randomly perturbed output of any two objects in $\mathcal{V}$ (both the object contents and the trajectories in all the frames) are ϵ-indistinguishable in $\mathcal{V}^*$. It also ensures *plausible deniability* for every object [5]. Since *ϵ-Object Indistinguishability* also requires all the objects to be visually indistinguishable (object contents), VERRO randomly assigns synthetic objects (e.g., the same shape but different colors) to replace the original distinct objects while generating the synthetic video $\mathcal{V}^*$. The synthetic objects are generated and placed by considering the distance of the object to the camera (e.g., the synthetic object size is larger if getting closer to the camera) [31].

2.3 VERRO Framework

The major components of VERRO (see Figure 2) consist of:

(1) **Preprocesssing**: all the objects are detected and tracked, and background scene (for each frame) is extracted using computer vision techniques [11, 48, 49].
(2) **Phase I**: for each object, its presence or absence in different frames/segments of the video are randomly generated (by random response) to be indistinguishable. Before executing random response, VERRO reduces the frame dimension in the video by detecting the key frames. Then, the utility can be improved by allocating optimal budgets for different dimensions. Furthermore, we also formulate a utility maximizing random response problem (optimizing RAPPOR [16]) to retain the optimal object presence information after Phase I. Note that Phase I satisfies *ϵ-Object Indistinguishability*: all the objects' presence in all the frames are indistinguishable (see details in Section 3).
(3) **Phase II**: with the randomly generated presence/absence information for each object, VERRO generates the synthetic video by inserting the synthetic objects into the video (background scene(s)). Specifically, the coordinates (where to insert the synthetic objects) are assigned, and computer vision techniques are applied to interpolate object moving trajectories between two assigned coordinates in the synthetic video. We also shown that Phase II does not leak any additional information (as a post-processing step [14]), and then VERRO satisfies *ϵ-Object Indistinguishability* (see details in Section 4).

3 PHASE I: OPTIMAL OBJECT PRESENCE

As the "local data" of each object (e.g., a pedestrian or vehicle) in the video $\mathcal{V}$, the object trajectory includes its presence or absence information in each frame and the coordinates in the frame (if present). In this section, we illustrate the Phase I of VERRO that first generates indistinguishable object presence.

3.1 Poor Utility with Random Response

We first define a bit vector for each object to indicate if such object is included in different frames or not:

Definition 3.1 (Object Presence Vector). Given video $\mathcal{V}$ which includes m different frames $F_1, \dots, F_m$ and n distinct objects $\mathbb{O} = \{O_1, ..., O_n\}$, whether each object $O_i, i \in [1, n]$ is present in frame $F_k, k \in [1, m]$ or not (all m frames) can form a bit vector: $B_i = (b_i^1, .., b_i^m) \in \{0, 1\}^m$ for object O_i.

It has been proven that a classic randomized response (RR) technique (e.g., RAPPOR [4, 16]) can be adapted to ensure ϵ-LDP for locally randomizing bit vectors. Similarly, a naive solution of ensuring *ϵ-Object Indistinguishability* for the object presence vectors is to directly the random response mechanism (*we will discuss how to optimize the utility in Section 3.2 and 3.3*). For each object $O_i \in \mathbb{O}, i \in [1, n]$, if object O_i exists in frame F_k, we set $b_i^k = 1, k \in [1, m]$. Otherwise, $b_i^k = 0$ holds in the vector B_i. Then, we flip one bit in vector $B_i, i \in [1, n]$ with a certain probability to report the true value. Then, all the perturbed bits in the object presence vector B_i can be combined as the output object presence vector for object O_i. Thus, the vectors $B_1, \dots, B_n$ (of all the objects) can be indistinguishable. Algorithm 1 shows the details of directly applying random response for object presence.

Algorithm 1 Random Response for Object Presence [16]

```
1: detect all the objects $\mathbb{O} = \{O_1, \dots, O_n\}$ in $\mathcal{V}$
2: for each $O_i, i \in [1, n]$ do
3:     collect the object presence vector $B_i = (b_i^1, .., b_i^m)$ in $\mathcal{V}$
4:     for each frame $F_k, k \in [1, m]$ do
5:         equally allocate budget $\epsilon/m$ to frame $F_k$
6:         random response for bit $b_i^k$ with the probability $\frac{e^{\epsilon/m}}{1+e^{\epsilon/m}}$
7:     end for
8:     $B_i \leftarrow (b_i^1, \dots, b_i^m)$
9: end for
10: Return $\forall i \in [1, n]$, $B_i$
```

Theorem 3.2. *Algorithm 1 randomly generates object presence vectors for objects with ϵ-Object Indistinguishability.*

Proof. *ϵ-Object Indistinguishability* can be proven by following the proof of ϵ-LDP with random response [16]. Given the object presence vectors $B_i = \{b_i^1, \dots, b_i^m\}$ and $B_j = \{b_j^1, \dots, b_j^m\}$ of any two objects $O_i, O_j \in \mathbb{O}$, for any possible output m-bit vector $y = (y^1, \dots, y^m)$, we have:

$$\frac{Pr[\mathcal{A}(B_i) = y]}{Pr[\mathcal{A}(B_j) = y]} = \frac{Pr(b_i^1 = y^1)}{Pr(b_j^1 = y^1)} \cdots \frac{Pr(b_i^m = y^m)}{Pr(b_j^m = y^m)} \tag{1}$$

Since each bit is allocated with an equal privacy budget ϵ/m, the flipping probability would be $\frac{e^{\epsilon/m}}{1+e^{\epsilon/m}}$ [16]. For $k \in [1, m]$, if $b_i^k = b_j^k$ (either 0 or 1), then $\frac{Pr(b_i^k = y^k)}{Pr(b_j^k = y^k)}$ always equals 1. If $b_i^k \neq b_j^k$ and $b_i^k = y_k$, thus we have:

$$\frac{Pr(b_i^k = y^k)}{Pr(b_j^k = y^k)} = \frac{e^{\frac{\epsilon}{m}}}{1 + e^{\frac{\epsilon}{m}}} \cdot (1 + e^{\frac{\epsilon}{m}}) = e^{\frac{\epsilon}{m}} \tag{2}$$

Similarly, if $b_i^k \neq b_j^k$ and $b_j^k = y_k$, we have $\frac{Pr(b_i^k = y^k)}{Pr(b_j^k = y^k)} = e^{-\epsilon/m}$. Then, we have $\forall k \in [1, m]$, $\frac{Pr(b_i^k = y^k)}{Pr(b_j^k = y^k)} \leq e^{\epsilon/m}$ (equals one of 1, $e^{\epsilon/m}$ and $e^{-\epsilon/m}$). Combining all m bits, we have:

$$\frac{Pr[\mathcal{A}(B_i) = y]}{Pr[\mathcal{A}(B_j) = y]} \leq e^{\epsilon} \tag{3}$$

Thus, the generated presence bit vectors satisfy *ϵ-Object Indistinguishability*. This completes the proof. □

Poor Utility. Although Algorithm 1 satisfies *ϵ-Object Indistinguishability*, the utility of synthetic video would be extremely low since the total number of frames in a video m can be thousands or more, and then the allocated budget for each frame would be negligible. It destroys the utility of random response (i.e., RAPPOR [16]). For instance, a vehicle occurs in 100 frames out of a 1000-frame video, then the privacy budget for each frame is $\epsilon/1000$, which makes the flipping probability close to 0.5. Then, each of the 1000 frames would have 50% probability to include the vehicle (and other vehicles), then the objects in the video are too random (extremely low utility at this time). Thus, we explore an alternative solution for the video data in Section 3.2 and 3.3.

3.2 Dimension Reduction in the Video

Recall that the limited utility in Algorithm 1 results from the high dimensions in the video (considering each frame as a dimension). Most existing LDP techniques (e.g., RAPPOR [16], LDPMiner [40], and PLDP [9]) have reduced the dimension (e.g., bloom filter reduces the bits dimension for RAPPOR [16], top k frequent items reduces the dimension of items in LDPMiner [40], and Johnson-Lindenstrauss transform reduces the dimension of location data [9]). In videos, since difference between two consecutive frames is very small, we extract the key frames [12, 19, 30] out of m frames from $\mathcal{V}$ to reduce dimension in VERRO.

3.2.1 Key Frame Extration.

In computer vision, many existing key frame extraction algorithms have been proposed based on the boundary method [19], motion analysis [12], clustering [30], among others. Since algorithms based on clustering has been shown to generate more accurate results [30], we integrate it into VERRO for dimension reduction. The basic idea is to divide the video into several groups of similar frames.

The algorithm [39] first transforms each pixel RGB value to construct the HSV (hue, saturation, value) histogram for each frame, and then calculates the pixel distribution in terms of hue, saturation, value, respectively. Each cluster is initialized with a new frame, and expanded by adding new consecutive frames which are similar to the existing frames (measured by the HSV histograms). After the clustering, each cluster includes a group of consecutive frames, which can be considered as a segment of the video. Finally, a key frame can be extracted from each cluster/segment. The details are illustrated in Algorithm 2.

As a result, the key frame can be utilized to represent every segment. Then, the m-bit object presence vectors (for all the objects) can be reduced to ℓ-bit vectors. For instance, key frames $\mathcal{F}_1, \dots, \mathcal{F}_\ell$ (where ℓ denotes the number of key frames, and $\ell \ll m$ in general) are extracted from $\mathcal{V}$. Object O_i's presence vector B_i can be reduced to $B_i' = (kb_i^1, \cdots, kb_i^\ell)$.

Algorithm 2 Segmentation and Key Frame Extraction

```
1:  initialize the first segment $S_1 = F_1$, segment index $i = 1$
2:  equally partition $H, S, V$ value ranges to $h$, $s$ and $v$ parts
3:  for each frame $F_k$, $k \in [2, m]$ do
4:      for each part $\hat{h}, \hat{s}, \hat{v}$ in H, S, V do
5:          construct the histograms $H(\hat{h})$, $S(\hat{s})$, $V(\hat{v})$ in frame $F_k$
6:      end for
7:      $Sim_H(F_k, S_i) = \sum_{\hat{h}=1}^{h} \min\{H(\hat{h}), S_i[H(\hat{h})]\}$
8:      $Sim_S(F_k, S_i) = \sum_{\hat{s}=1}^{s} \min\{S(\hat{s}), S_i[S(\hat{s})]\}$
9:      $Sim_V(F_k, S_i) = \sum_{\hat{v}=1}^{v} \min\{V(\hat{v}), S_i[V(\hat{v})]\}$
        $\{\alpha, \beta, \gamma$: weights for H, S, V; similarity threshold: $\tau\}$
10:     if $(\alpha \cdot SI_H + \beta \cdot SI_V + \gamma \cdot SI_S) \geq \tau$ then
11:         $S_i \leftarrow S_i \cup F_k$
12:     else
13:         $i = i + 1$ and initialize a new segment $S_i$
14:         $S_i \leftarrow S_i \cup F_k$
15:     end if
16: end for
17: for each segment $S_i$ do
18:     compute the maximum frame entropy $Entropy(F)$:
19:     max $\{-\alpha \cdot \sum_{\hat{h}=1}^{h}[H(\hat{h}) \log H(\hat{h})] - \beta \cdot \sum_{\hat{s}=1}^{s}[S(\hat{s}) \log S(\hat{s})] - \gamma \cdot \sum_{\hat{v}=1}^{v}[V(\hat{v}) \log V(\hat{v})]\}$
20:     extract the key frame with maximum entropy $\mathcal{F}_i$ in $S_i$
21: end for
22: return all the segments and key frames
```

3.2.2 Random Response.

After dimension reduction, random response can be implemented based on the RAPPOR framework [16] for each object. Each bit kb_i^k in ℓ-bit vector of object O_i is randomly flipped into 0 or 1 using the following rules:

$$kb_i^k = \begin{cases} kb_i^k, \text{ with the probability of } (1-f) \\ 1, \text{ with the probability of } \frac{f}{2} \\ 0, \text{ with the probability of } \frac{f}{2} \end{cases} \tag{4}$$

Theorem 3.3. *The random response (with rules in Equation 4) $\ell \log(\frac{2-f}{f})$-Object Indistinguishability.*

Proof. Again, object indistinguishability can be proven by following the proof of LDP [16]. Specifically, the RAPPOR [16] satisfies $2h \log(\frac{2-f}{f})$-LDP with the output size of the hash function in the bloom filter h and the flipping probability f. Maximum difference sizes are $2h$ between two input values. Thus, the random response (with rules in Equation 4) make ϵ equal to $\ell \log(\frac{2-f}{f})$ since size difference in any two presence vector is at most ℓ (by replacing the encoded bit vectors of bloom filter as the object presence vectors in RAPPOR [16]), which satisfies $\ell \log(\frac{2-f}{f})$-*Object Indistinguishability.*

□

3.3 Optimizing RAPPOR for Object Presence

Although ℓ is far less than m, the number of key frames ℓ may still be large depending on the background scene(s), activity motion and light density. To solve this, we can further reduce the dimension by choosing a subset of key frames out of ℓ key frames to allocate the privacy budget. Indeed, determining whether each key frame is picked for allocating the privacy budget or not can be formulated as an optimization problem (*maximizing the utility of generating the synthetic video using the random object presence vectors in Phase II*).

3.3.1 Optimization Problem. For each key frame $\mathcal{F}_k, k \in [1,\ell]$, we define a binary variable $x_k \in \{0,1\}$ to represent if key frame $\mathcal{F}_k$ is picked for budget allocation or not. Then, the total number of picked key frames is referred as $\sum_{k=1}^{\ell} x_k$. Per the Theorem 3.3, we have the random response satisfies $\sum_{k=1}^{\ell} x_k \log(\frac{2-f}{f})$-*Object Indistinguishability.*

Figure 3: Dimension Reduction, Utility Maximization and Random Response

An example for dimension reduction, utility maximization and random response is given in Figure 3. Considering the n objects $O_1, \dots, O_n$, after dimension reduction, all the n object presence vectors are reduced to n different ℓ-bit vectors. Our goal is to accurately retain more objects in the video, thus we aim at minimizing the distance between $\forall i \in [1,n], B_i'$ (extracted from $\mathcal{V}$) and $\forall i \in [1,n], R_i$ (denoted as the ℓ-bit vectors by applying random response to $\forall i \in [1,n], B_i'$).

Specifically, since $\forall i \in [1,n], R_i$ are randomized bit vectors (the kth entry in all the vectors are 0 if $x_k = 0$), we should measure the difference between the expectation $\forall i \in [1,n], E(R_i) = E[(R_i^1, \dots, R_i^{\ell})]$ and $B_i' = (kb_i^1, \dots, kb_i^{\ell})$.

We first learn the expectation of R_i^k (the kth entry in R_i). If $x_k = 0$, then $\forall i \in [1,n], R_i^k = 0$ hold. Thus, we have:

$$E(R_i^k) = x_k \cdot [Pr(R_i^k = 1) \cdot 1 + Pr(R_i^k = 0) \cdot 0] \tag{5}$$

There are two cases for R_i^k (in case of $x_k = 1$):

(1) If $kb_i^k = 1$, per Equation 4, we have $E[R_i^k] = 1 \cdot [(1-f) \cdot 1 + \frac{f}{2} \cdot 0 + \frac{f}{2} \cdot 1]$.

(2) If $kb_i^k = 0$, we have $E[R_i^k] = 1 \cdot [(1-f) \cdot 0 + \frac{f}{2} \cdot 0 + \frac{f}{2} \cdot 1]$.

Thus, the expectation can be summarized as following:

$$\begin{cases} E(R_i^k) = \frac{f}{2}, \text{ if } x_k = 1 \text{ and } kb_i^k = 0 \\ E(R_i^k) = 1 - \frac{f}{2}, \text{ if } x_k = 1 \text{ and } kb_i^k = 1 \\ E(R_i^k) = 0, \text{ if } x_k = 0 \text{ and } kb_i^k = 0 \text{ or } 1 \end{cases} \tag{6}$$

The objective function can be formulated as:

$$\min: \sum_{k=1}^{\ell} [x_k \sum_{i=1}^{n} |E(R_i^k) - kb_i^k|] \tag{7}$$

Furthermore, for accurately interpolating the objects in different frames in Phase II, the number of key frames picked for budget allocation should be no less than 2. Therefore, we formulate the optimization problem as below:

$$\begin{aligned} &\min: \sum_{k=1}^{\ell} [x_k \sum_{i=1}^{n} |E(R_i^k) - kb_i^k|] \\ &s.t. \begin{cases} 2 \le \sum_{k=1}^{\ell} x_k \le \ell \\ \forall k \in [1,\ell], x_k \in \{0,1\} \end{cases} \end{aligned} \tag{8}$$

Detailing expectation $E(R_i^k)$ with the flipping probability, the optimization problem can be converted to:

$$\begin{aligned} &\min: \sum_{k=1}^{\ell} (x_k | \frac{n \cdot f}{2} - f \cdot \sum_{i=1}^{n} kb_i^k |) \\ &s.t. \begin{cases} 2 \le \sum_{k=1}^{\ell} x_k \le \ell \\ \forall k \in [1,\ell], x_k \in \{0,1\} \end{cases} \end{aligned} \tag{9}$$

3.3.2 Complexity and Solver. Since f and $\forall k \in [1,\ell], \forall i \in [1,n], kb_i^k$ are constants, $\forall k \in [1,\ell], |\frac{n \cdot f}{2} - f \cdot \sum_{i=1}^{n} kb_i^k|$ are constants. Then, Equation 9 is a binary integer programming (BIP) problem. Although solving the BIP problems can be NP-hard [27], we can approximately solve Equation 9 using linear programming (LP) since the objective function and the constraints are *linear*: (1) letting the binary variable $\forall k \in [1,\ell], x_k$ be continuous in $[0,1]$, (2) solving the problem using standard LP solvers (e.g., the Simplex algorithm), and (3) in the optimal solution of the LP problem, $\forall k \in [1,\ell]$, if $x_k \in [0, 0.5)$, we assign $x_k = 0$; if $x_k \in [0.5, 1]$ we assign $x_k = 1$ as the approximated optimal solution of the BIP problem.

3.3.3 Addressing Possible Privacy Leakage in Optimization. Compared to randomly picking a number of key frames for budget allocation, computing the optimal frames for budget allocation may result in some minor privacy leakage since the total number of objects in the kth key frame $\sum_{i=1}^{n} kb_i^k, k \in [1,\ell]$ (which is used in the optimization) might be different. Such privacy leakage is generally minor due to a small sensitivity Δ of the object count in each frame (e.g., $\Delta = 1$ for protecting the presence/absence of each object in every frame). Thus, it can be addressed by injecting a small amount of generic Laplace noise $Lap(\frac{\Delta}{\epsilon'})$ into $\sum_{i=1}^{n} kb_i^k, k \in [1,\ell]$ before formulating the optimization problem. Although adding such small amount of noise may slightly deviate the optimality, this could guarantee end-to-end indistinguishability (differential privacy). Since such privacy guarantee is well studied in literature [13], we do not discuss it in this paper due to space limitation.

3.4 Privacy Guarantee

After solving the optimization problem, as shown in Figure 3, each of the picked key frames will be allocated with a privacy budget $\epsilon/\sum_{k=1}^{\ell} x_k$. In the meanwhile, VERRO utilizes the optimal solution $\forall k \in [1, \ell], x_k$ n to derive the optimal presence vectors ($\sum_{k=1}^{\ell} x_k$-bit), denoted as $B_1^*, \dots, B_n^*$. Next, random response is applied to $B_1^*, \dots, B_n^*$ to generate output presence vectors $R_1, \dots, R_n$.

Theorem 3.4. *Phase I satisfies ϵ-Object Indistinguishability.*

Proof. Phase I derives the presence bit vectors B_i^* and B_j^* for any two objects O_i and O_j after the optimization. Then, random response is applied to B_i^* and B_j^* and generate random vectors R_i and R_j. Per Theorem 3.3, Phase I satisfies ϵ-*Object Indistinguishability* where $\epsilon = \sum_{k=1}^{\ell} x_k \ln \frac{2-f}{f}$ (note that the privacy guarantee for utility maximization has been discussed in Section 3.3.3). □

It is worth noting that the presence of objects in the remaining $(m - \sum_{k=1}^{\ell} x_k)$ frames and the coordinates of the objects in all m frames in the synthetic video $\mathcal{V}^*$ will be generated in Phase II.

4 PHASE II: VIDEO GENERATION

In this section, we illustrate the details of Phase II.

4.1 Background Scene(s)

As discussed in Section 2, video preprocessing includes detecting/tracking objects and background scene(s) extraction. While removing objects from digital images (e.g., each frame of a video), the pixels within the objects are missing in the frame and need to be reconstructed for the background scene(s). In VERRO, we utilize an efficient algorithm [11] to fill the blank area by considering both texture and structure.

First, the quality of the output image/frame highly depends on the order of filling different parts of the blank areas. The algorithm provides a filling strategy by prioritizing them using the combination of the continuation of strong edges and high-confidence surrounded pixels. The priority is computed for every border patch, with distinct patches for each pixel on the boundary of the blank areas. Then, we always start filling at the border pixels with the highest priority.

Second, while filling the pixel p, the algorithm places it at the centroid of a patch with certain size (e.g., 3×3). Then, we traverse all the background pixels, and the centroid pixel of the most similar patch from the source background region will be filled in p, where the similarity is measured by the sum of squared errors. Some reconstructed background scenes are demonstrated in Section 6.

4.2 Randomly Generating Object Coordinates

Phase I generates indistinguishable presence information (in different frames) for all the objects. Next, we need to insert synthetic objects into the background scene (each frame) to generate the synthetic video $\mathcal{V}^*$. Specifically, we denote all the frames in the synthetic video $\mathcal{V}^*$ as $\{F_1^*, \dots, F_m^*\}$, and the frames in $\mathcal{V}^*$ corresponding to the original key frames as $\{\mathcal{F}_1^*, \dots, \mathcal{F}_\ell^*\}$. We then discuss different cases of generating coordinates for the objects in each frame.

4.2.1 $R_i = \emptyset$. If all the entries in any object presence vector are 0, such random vector output R_i would result in object loss (the synthetic video will lose one object), and it is unnecessary to identify the coordinates for them in this case. We have evaluated such utility loss in Section 6, and most of the objects can be retained by VERRO in practice.

4.2.2 $R_i \neq \emptyset$. If there exists at least one non zero entry in R_i, then an object will be inserted to the synthetic video $\mathcal{V}^*$. A critical and challenging question is that where to insert the object. We employ the coordinates of all the objects in the original video $\mathcal{V}$ as "Candidate Coordinates" to generate the coordinates in each frame of the synthetic video.

Specifically, in each key frame of the synthetic video $\forall k \in [1, \ell], \mathcal{F}_k^*$, the number of objects inserted into key frame $\mathcal{F}_k^*$ is $\sum_{i=1}^{n} R_i^k$ (derived in Phase I). Denoting the number of objects in the kth key frame of $\mathcal{V}$ as $c_k, k \in [1, \ell]$ where $c_k = 0$ if $x_k = 0$, we thus have:

- *Sufficient candidate coordinates*: if $\sum_{i=1}^{n} R_i^k \le c_k$, the number of required objects in $\mathcal{F}_k^*$ is no greater than the number of candidate coordinates in $\mathcal{F}_k$. Then, VERRO randomly picks $\sum_{i=1}^{n} R_i^k$ out of c_k candidate coordinates for $\sum_{i=1}^{n} R_i^k$ different objects in the background scene (frame $\mathcal{F}_k^*$). Please see the left example in Figure 4.
- *Insufficient candidate coordinates*: if $\sum_{i=1}^{n} R_i^k > c_k$, the number of required objects in $\mathcal{F}_k^*$ is greater than the number of candidate coordinates in $\mathcal{F}_k$. For instance, in the right example in Figure 4, we expand the set of candidate coordinates by adding the candidate coordinates in $\mathcal{F}_k$'s neighboring frames in the same segment. Then, VERRO randomly picks $\sum_{i=1}^{n} R_i^k$ out of c_k' candidate coordinates (c_k' is expanded from c_k where $c_k < \sum_{i=1}^{n} R_i^k \le c_k'$) to insert $\sum_{i=1}^{n} R_i^k$ different objects into the background scene (frame $\mathcal{F}_k^*$).

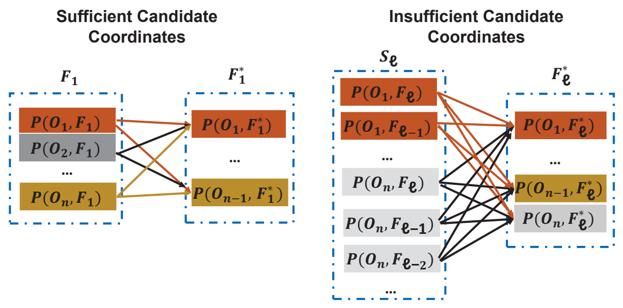

Figure 4: Random Coordinates Assignment (before Interpolation)

After assigning coordinates to the key frames (where $R_i^k = 1$), we obtain at least 1 frame with the corresponding coordinates for any O_i (if the corresponding object is retained in the synthetic video) – the retained object has been assigned with coordinates in at least two frames in almost all the cases in our experiments in Section 6. With such randomly assigned coordinates in some key frames, we can interpolate the coordinates in other frames (out of m frames in total) between such key frames. For instance, given coordinates in two key frames F_1 and F_{10} for object O_i, then its coordinates between F_1 and F_{10} can be estimated. In literature, there are many interpolation methods for moving object trajectories data, such as nearest neighbor interpolation [21] and Lagrange interpolation [17]. In VERRO, we adopt the Lagrange interpolation to estimate such trajectories with the randomly generated positions.

Finally, after interpolation, we define the first frame in which any object first occurs as "head" and the frame where such object last occurs as "end" in the interpolated trajectory. The head and end generally involve such object on the border of the frame. Thus, the interpolation terminates as each object's head and end are identified on the border of the frame (*objects do not occur in all the frames in general*).

Theorem 4.1. *VERRO (Phase I and Phase II) satisfies ϵ-Object Indistinguishability.*

Proof. Given any two objects O_i and O_j, their randomly generated presence vectors R_i and R_j are proven to be *ϵ-Object Indistinguishable* (after Phase I). We now examine the randomly assigned coordinates in the key frames and two full interpolated trajectories in the synthetic video $\mathcal{V}^*$.

Specifically, given any output presence vector y and any output trajectory $t = \{t_1, \dots, t_m\}$ in $\mathcal{V}^*$, for simplicity of notation, we also denote the trajectories of O_i and O_j in $\mathcal{V}^*$ as $O_i = \{T_i^1, \dots, T_i^m\}$ and $O_j = \{T_j^1, \dots, T_j^m\}$, respectively.

$$\frac{Pr[\mathcal{A}(O_i) = t]}{Pr[\mathcal{A}(O_j) = t]}$$
$$= \frac{Pr[\mathcal{A}(B_i') = y]}{Pr[\mathcal{A}(B_j') = y]} \cdot \frac{Pr[\mathcal{A}(T_i^1) = t_1]}{Pr[\mathcal{A}(T_j^1) = t_1]} \cdots \frac{Pr[\mathcal{A}(T_i^m) = t_m]}{Pr[\mathcal{A}(T_j^m) = t_m]}$$

On one hand, we have $\frac{Pr[\mathcal{A}(B_i')=y]}{Pr[\mathcal{A}(B_j')=y]]} \leq e^\epsilon$ (Phase I). On the other hand, if $\forall k \in [1, m], R_i^k = R_j^k = 1$, two objects are present in the same frame F_k (and F_k^*). In this case, since the same randomization is applied to O_i and O_j to pick the coordinates from the same set of candidates, we have $\forall k \in [1, m], Pr[\mathcal{A}(T_i^k) = t_k] = Pr[\mathcal{A}(T_j^k) = t_k]$. If $\forall k \in [1, m], R_i^k = R_j^k = 0$ (the coordinates are interpolated from the coordinates randomly assigned in the previous case [14]), we also have $\forall k \in [1, m], Pr[\mathcal{A}(T_i^k) = t_k] = Pr[\mathcal{A}(T_j^k) = t_k]$.

To sum up the above three cases, we have:

$$\frac{Pr[\mathcal{A}(O_i) = t]}{Pr[\mathcal{A}(O_j) = t]} \leq e^\epsilon \tag{10}$$

where $\epsilon = \sum_{k=1}^{\ell} x_k \log(\frac{2-f}{f})$, as analyzed in Theorem 3.3 and Section 3.3. This completes the proof. □

Finally, we summarize the procedures and privacy guarantee in VERRO. Given an video, the presence of objects in all the frames are indistinguishable via random response. Then, adversaries cannot identify specific objects by the frame presences with any background knowledge. Furthermore, we randomly generate synthetic positions of objects. Therefore, we claim that any object in the input $\mathcal{V}$ can possibly generate any object in the output $\mathcal{V}^*$ (with random response in Phase I and random coordinates assignment in Phase II).

5 DISCUSSION

Distributed Framework: LDP techniques [4, 16] are deployed in distributed setting where each user perturbs its local data to share. Our object-based privacy model ensures indistinguishability at the object level where all the "distributed" local data can be perturbed by a "local agent" (aka. video owner) and shared as $\mathcal{V}^*$ to untrusted recipients.

Different video owners can also share their perturbed videos to any untrusted recipient (all the objects in each video are still well protected). Note that VERRO does not ensure video level indistinguishability (all the videos are indistinguishable). We will investigate the utility of the video level indistinguishability in practice and explore the LDP solutions in the future.

Noise Cancellation: in VERRO, objects and their trajectories are generated in the sanitized video. Thus, the individual noises resulted from random response for all the objects may not be directly canceled in the output video. Indeed, after random response and random coordinates assignment, there exists trajectories in the sanitized video which are close to the original trajectories (as shown in Figure 6-8 in our experiments). Also, such noise can be cancelled in data aggregation applications [9] (e.g., object counting, as shown in Figure 12 and 13).

Multiple Object Types: in this paper, we use pedestrians and vehicles as concrete examples to show their indistinguishability in the publishable synthetic video. It is worth noting that other objects can also be protected with the defined privacy notion in VERRO by replacing the detecting algorithms and synthetic objects. Furthermore, if any video includes multiple types of objects (e.g., pedestrians and vehicles), VERRO can generate the synthetic video for different types of objects, respectively. For instance, it first randomly generates pedestrians, and then randomly generates the vehicles. All the pedestrians are *ϵ-Object Indistinguishable* while all the vehicles are *ϵ-Object Indistinguishable*, assuming that it does not leak additional information across different object types (as all the objects have been replaced with random synthetic objects in the same type).

Protection for One-Object Video: VERRO can generate synthetic videos in which all the objects are ϵ-indistinguishable. In case that the video includes only one sensitive object, VERRO can also protect such object against re-identification. In existing LDP techniques [4, 16], if only one user perturbs its Object data and discloses it to the untrusted aggregator, the original data cannot be identified from its perturbed data. Similar to such works (e.g., RAPPOR [16]), the objects and the trajectories cannot be identified from the perturbed presence in the synthetic video even if the adversary has arbitrary background knowledge on the presence of individuals at specific times.

Imperfect Background Scene(s): as discussed in Section 4, background scene(s) is extracted from the original video. The reconstructed scene may not be as perfect as the original frame (e.g., human/vehicle silhouette or duplicated/blurred region may occur). Thus, imperfect background scene(s) may leak some privacy about "there exists some object in the silhouette or blurred regions in the original video". However, adversaries cannot infer that "who is in that region or which object is in that region" since all the objects are indistinguishable from end to end.

System Deployment: the proposed VERRO can be implemented as an application, and deployed as a component to generate utility-driven synthetic videos by processing the videos captured by each camera (e.g., in the surveillance system, integrated with the traffic monitoring facilities, in smart phones or other mobile devices) where *ϵ-Object Indistinguishability* can be guaranteed.

6 EXPERIMENTS

In this section, we present the performance evaluations.

6.1 Experimental Setup

We conduct our experiments on three real videos in the repository of multiple object tracking benchmark[2]. To benchmark the results, we choose three pedestrian videos, two videos are captured by static cameras while the third video is recorded by a moving camera (where multiple background scenes are extracted):

(1) MOT16-01 (people walking around a large square, denoted as "MOT01") [35]: 23 distinct pedestrians are sensitive objects in 450 frames (static camera).
(2) MOT16-03 (pedestrians on the street at night, denoted as "MOT03") [35]: 148 distinct pedestrians are sensitive objects in 1,500 frames (static camera).
(3) MOT16-06 (street scene from a moving platform, denoted as "MOT06") [35]: 221 distinct pedestrians are sensitive objects in 1,194 frames (moving camera).

Table 1: Characteristics of Experimental Videos

Video	Resolution	Frame #	Objects	Camera
MOT16-01	1920 × 1080	450	23	static
MOT16-03	1920 × 1080	1,500	148	static
MOT16-06	640 × 480	1,194	221	moving

We implement the detecting/tracking algorithm [48, 49] to identify all the objects (pedestrians). Objects are detected in each frame, and the same object is marked with the same ID in the entire video. Computer vision technique [11] is also utilized to extract/reconstruct the background scene(s) from the input video $\mathcal{V}$. All the programs are implemented in Python 3.6.4 with the OpenCV 3.4.0 library and tested on an HP PC with Intel Core i7-7700 CPU 3.60GHz and 32G RAM.

6.2 Generic Utility Evaluation

We first evaluate the utility of our synthetic videos. The proposed VERRO is a two-phase LDP approach. In Phase I, it randomly generates the object presence in all the frames of the synthetic video ("1" or "0"). In Phase II, we interpolate the trajectories. Thus, we evaluate two different types of utility: (1) the retained utility after Phase I (Random Response), and (2) the utility of synthetic video after Phase II.

6.2.1 Utility for Phase I. Phase I generates "presence bit vectors" for all the objects with frame dimension reduction, optimization ("OPT") and random response ("RR"). Some objects might not be included in the key frames, and/or might not be generated in the random response. Then, such objects cannot be generated in the synthetic video (all the entries in the corresponding vectors are 0) since they cannot be interpolated without any object presence in Phase I (also treated as noise). Thus, we evaluate the count of distinct objects (pedestrians) in Phase I.

First, Table 2 shows some results after detecting key frames for frame dimension reduction. In video MOT01, there are 22 key frames, and 19 out of 23 objects are present in the key frames. In video MOT03, 52 key frames are extracted, and 124 out of 148 objects are present in such key frames. In video MOT06, 191 out of 221 objects are captured in the identified 48 key frames. We can observe that frame dimension reduction results in less utility loss (retaining $\sim$ 80% distinct objects).

Figure 5(a), 5(c) and 5(e) present the count of distinct objects in original video, after optimization ("OPT"), and random response ("RR"). We set the flipping probability f from 0.1 to 0.9 for random response. In Figure 5(a), approximately 17 distinct objects can be retained in 10 key frames (optimized). f only slightly affects the optimization: the count of distinct objects increases a little bit

[2]https://motchallenge.net/

Table 2: Distinct Objects after Key Frame Extraction

Video	Frame #	Objects #	Key Frame #	Remaining #
MOT01	450	23	22	19
MOT03	1,500	148	52	124
MOT06	1,194	221	48	191

as f grows. To evaluate how f affects the random response, we can observe that one or two objects are not randomly generated in RR as f grows to a large flipping probability (e.g., 0.8). This matches the fact that higher f results in worse utility in random response (Theorem 3.2) – such utility loss is indeed minor in our experiments. In addition, we can draw similar observations in Figure 5(c) and 5(e) where the utility loss of random response is even less for videos MOT03 and MOT06. Thus, Phase I retains a high percent of distinct objects via their random presence vectors, which means less side effect introduced by RR (this facilitates the interpolation in Phase II for boosting utility).

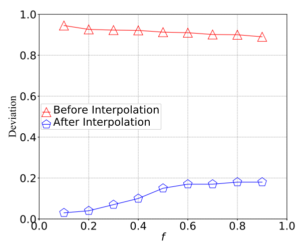
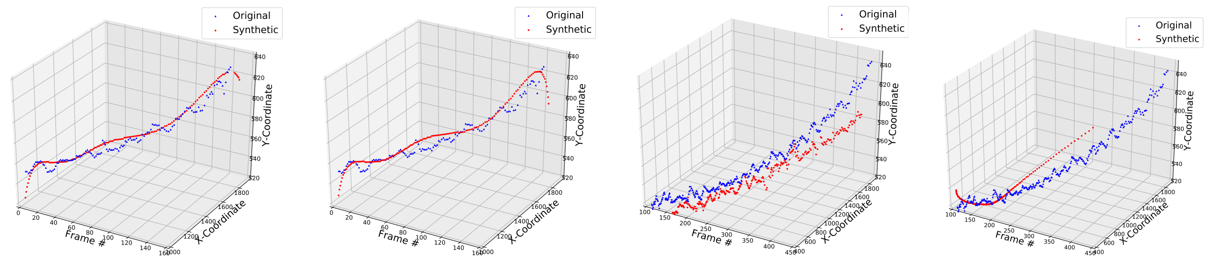
(e) Count of Distinct Ojects



(f) Deviation of Object Trajectories

Figure 5: Utility Evaluation of Phase I & II of MOT01 (MOT03 and MOT06)

6.2.2 Utility for Phase II. Since the synthetic video generated in Phase II includes the synthetic objects at the same scene, the corresponding synthetic object of each original object (e.g., pedestrian) may have different coordinates in the same frame.



(a) Object #2 (f=0.1) (b) Object #2 (f=0.9) (c) Object #9 (f=0.1) (d) Object #9 (f=0.9)

Figure 8: Trajectories of Two Randomly Selected Objects in MOT06

All the coordinates in different frames may form a trajectory in the synthetic video. Thus, we also measure the deviation for the trajectories of all the objects in the original video and synthetic video: $\sum_{i=1}^{n}\sum_{k=1}^{m}\frac{P(O_i,F_k)-P(O_i,F_k^*)}{P(O_i,F_k)}$, where $P(O_i, F_k)$ and $P(O_i, F_k^*)$ are the center coordinates of object O_i in the kth frame of the input video and the synthetic video.

In Figure 5(b), 5(d) and 5(f), we can observe that the deviation before Phase II is higher than 0.9, since each object is only generated in a few frames. The deviation of trajectories increases as the flipping probability f gets larger since more flips occur more frequently (e.g., "0" to "1", or vice-versa). In such three figures, after Phase II, the deviation can be significantly reduced (e.g., in $[0.1, 0.2]$ for video MOT01, in $[0.02, 0.2]$ for video MOT06).

More specifically, we randomly select two objects (e.g., pedestrians) from each of the three videos, and extract their trajectories in the original video $\mathcal{V}$. In addition, we also extract their corresponding trajectories in the synthetic video $\mathcal{V}^*$. Figure 6, 7 and 8 demonstrate the trajectories of those objects in the input videos and synthetic videos, where 3-dimensional axes refer to the frame ID and coordinates (X, Y) in videos. As $f = 0.1$, the trajectories of the objects lie closer to the original ones (compared to $f = 0.9$). It is worth noting that any object (pedestrian) in the original video can generate the corresponding trajectory of any object (e.g., the plotted trajectories corresponding to Object #2 and Object #9 in Figure 6). This is ensured by the ϵ-indistinguishable presence bit vectors randomly generated from all the objects in VERRO.

6.3 Visual & Aggregated Results

We also randomly pick a frame from each of the three experimental videos, and present the generated background scenes and the corresponding frames in the synthetic videos. For video MOT01, Figure 9(a) shows the input frame and the detected objects in the frame. Also, we use a background interpolation algorithm [11] to fill the missing pixels (after removing all the detected objection), as shown in Figure 9(b). Similarly, a randomly picked frame (with the detected objects) and the generated background

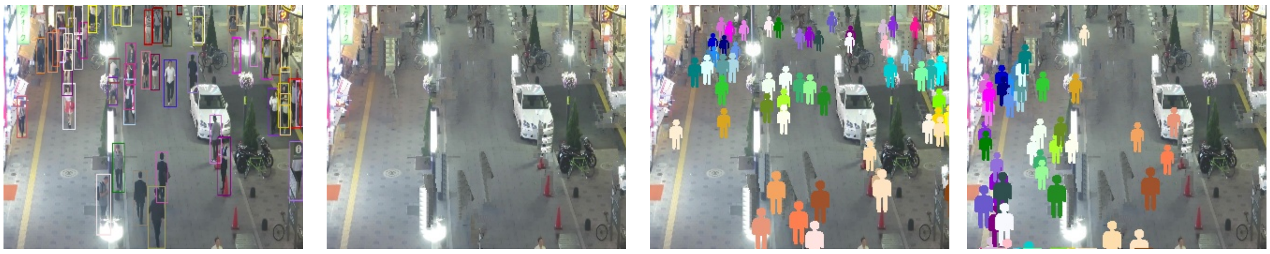
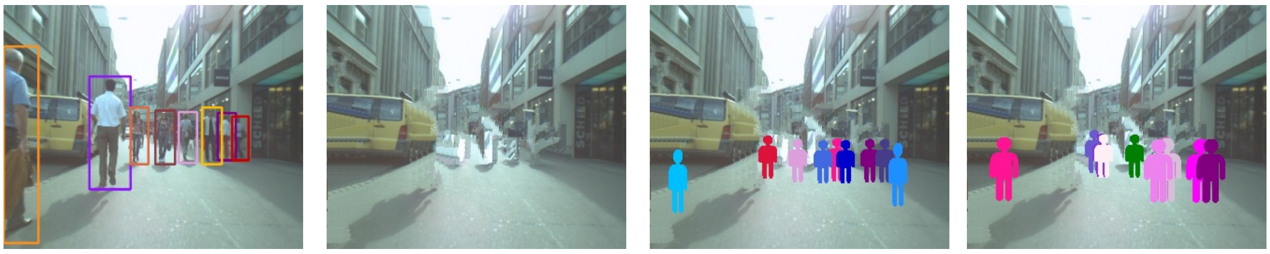
Figure 9: Representative Frames in MOT01 and the Generated Synthetic Video



(a) Frame 134 (b) Background Scene (c) Synthetic Frame (f=0.1) (d) Synthetic Frame (f=0.9)

Figure 10: Representative Frames in MOT03 and the Generated Synthetic Video



(a) Frame 216 (b) Background Scene (c) Synthetic Frame (f=0.1) (d) Synthetic Frame (f=0.9)

Figure 11: Representative Frames in MOT06 and the Generated Synthetic Video

scenes in MOT03 and MOT06 are given in the first two subfigures of Figure 10 and 11. Some human silhouettes still exist in the background scenes. Clearly, the silhouettes cannot be associated to any objects in the synthetic video (as shown in Figure 10(c), 10(d), 11(c) and 11(d)). This confirms the discussion for imperfect background scene in Section 5.

In the synthetic videos, we use different colors for different synthetic objects. Compare to $f = 0.1$ (shown in Figure 9(c), 10(c) and 11(c)), $f = 0.9$ would lead to more coordinates/trajectory deviation (as shown in Figure 9(d), 10(d) and 11(d)). However, accurate count of objects (pedestrians) can be retained in the synthetic frames even if the flipping probability f is specified as 0.9 (small privacy bound). Thus, we can still use such synthetic videos to function specific application based on the count of objects, e.g., head counting and crowd density [23, 34]. To confirm such observation, we also detect and count all the pedestrians in each frame of the synthetic videos ($f = 0.1$ and $f = 0.9$).

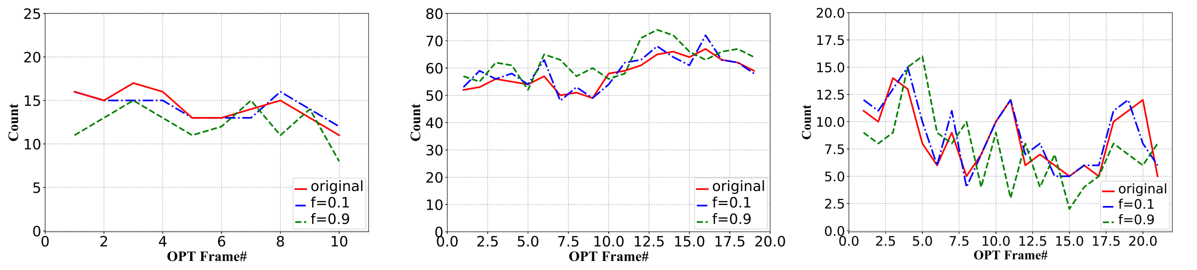
Figure 12 shows the pedestrian counts in the (optimized) key frames (after Phase I). The aggregated result lies very close to the original result when f is small. When f goes larger, the aggregated result is slightly more fluctuated, and more objects are generated in the frames. Figure 13 demonstrates the aggregated counts of pedestrians in each frame (after Phase II). Note that many objects (with the coordinates outside the frames; not between the “head” and “end”) are suppressed in Phase II, making the object counts in different frames more accurate. Note that if multiple cameras capture more videos (e.g., surveillance or traffic monitoring cameras for the smart city) for joint analysis, the noise can be further cancelled in the applications.

6.4 Overheads

We evaluate the overheads of VERRO. Table 3 presents the runtime of the two phases and the required bandwidth for sending the synthetic videos to an untrusted recipient.

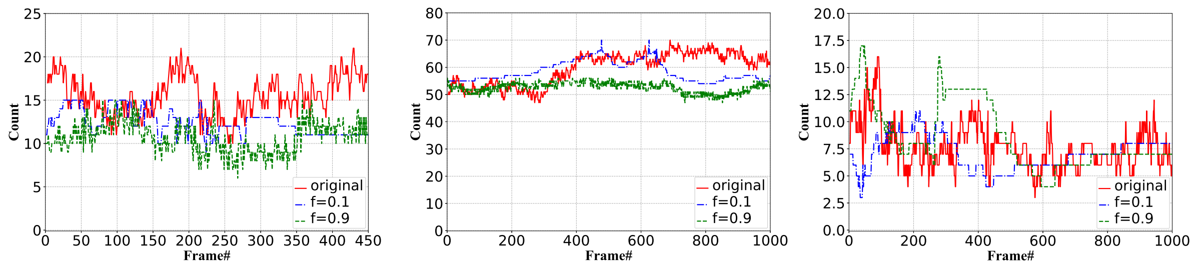
Table 3: Computational and Communication Overheads

Video	Phase I (Sec)	Phase II (Sec)	Bandwidth (MB)
MOT01	0.89	34.78	9.58
MOT03	1.56	36.12	16.6
MOT06	1.57	43.12	19.4



(a) MOT01 (b) MOT03 (c) MOT06

Figure 12: Object Counts in the Optimized Key Frames (by each frame)



(a) MOT01 (b) MOT03 (c) MOT06

Figure 13: Object Counts in the Synthetic Videos (by each frame)

The computational cost increases as the count of distinct objects increases (MOT01 has the least pedestrians while MOT06 has the most pedestrians). The results reflect a *sublinear* increase trend, which enables VERRO to be scaled to generate synthetic videos for longer videos (with more frames). In addition, although MOT06 has a lower resolution (less pixels) than MOT01 and MOT03, it is captured by a moving camera. Since more background scenes have to be interpolated, it requires longer runtime (but still efficient). Note that the runtime for object detecting and background scene(s) generation (1-2 minutes in our experiments) can be considered as computational costs for preprocessing.

Finally, the communication overhead for sharing three synthetic videos is almost identical to the original video size.

7 RELATED WORK

In the context of privacy preserving video publishing, many solutions have been proposed in literature (e.g., [6, 20, 41, 42, 44]). Saini et al. [41] have categorized such works in terms of the sensitive attributes obfuscated in the sanitization. These sensitive attributes include the evidence types *bodies, what*(activity), *where* (location where the video is recorded) and *when* (time when the video is recorded). In general, most of these works employ a *detect* and *blur* policy for only body attributes [6, 20, 42, 44] and some of them [15, 41, 47] aims at preserving the privacy against other three implicit inference channels.[3]

Specifically, these techniques often leverage computer vision techniques [20, 29] to first *detect* faces and/or other sensitive regions in the video frames and then *obscure* them. However, such *detect-and-protect* solutions have some limitations. For instance, the *detect-and-protect* techniques cannot formally quantify and bound the privacy leakage. In addition, blurred regions might still be reconstructed by deep learning methods [33, 37]. Last but not least, these techniques often use naive measures for quantifying the privacy loss in videos. For instance, in [20, 36], if faces are present, then it is considered as complete privacy loss, otherwise no privacy loss is reported. Fan [18] applied Laplace noise to randomly perturb the pixels in an image to ensure differential privacy for protecting specific regions of an image. However, the quality of the image is significantly deviated in the sanitized results. Our proposed privacy notion and the VERRO technique have addressed all the above limitations.

On the other hand, in the context of privacy preserving data publishing, the notion of differential privacy has emerged as a standard specification during past decade. This strong notion of privacy was first proposed by Dwork [13] to guarantee *indistinguishability* in the published data against an adversary armed with arbitrary background knowledge. Although differential privacy has been widely used to sanitize and release data in statistical databases [13], numeric data [45], location data [38], and search logs [25], to the best of our knowledge, no attempt has yet been made to benefit from differential privacy in video databases. Furthermore, to fully utilize differential privacy for sanitizing videos, we have defined our privacy notion based on a recently proposed locally implemented notion of differential privacy in which individuals in the videos (i.e., as objects) can directly interact with the sanitized result to ensure trustworthiness and fine-grained privacy. The emerging local differential privacy (LDP) models [4, 10, 16] have been utilized in a wide variety of applications (e.g., heavy hitters or histogram construction [4, 16], and frequent itemset mining [46]), but cannot be directly applicable to local video perturbation. VERRO complements the literature with strong privacy protection for (local) objects in the video against arbitrary background knowledge.

[3]The synthetic videos generated by VERRO can preserve the information of "where and when the videos are captured" while ensuring indistinguishability of objects (the linkage between every object and such inference channels can be broken to avoid leakage in the disclosure of the background scene).

8 CONCLUSION

Privacy concerns arise in considerable number of real world videos. To the best of our knowledge, we take the first cut to pursue indistinguishability for objects in the video by defining a novel privacy notion *ϵ-Object Indistinguishability*. We propose a two-phase video sanitization technique VERRO that locally perturbs all the objects in the video and generates a utility-driven synthetic video with indistinguishable objects, which can be directly shared to any untrusted recipient. In the synthetic videos, not only the object contents (e.g., different humans, and vehicle make/model/color), but also their moving trajectories in the video (e.g., a series of coordinates in different frames) can be effectively protected since every synthetic object and its trajectory can be possibly generated from any object in the original video. Experiments performed on real videos have validated the effectiveness and efficiency of VERRO. In the future, we will comprehensively study the utility of the synthetic videos in more application scenarios, and explore rigorous protection for objects which can be tracked in multiple videos.

PrefDiv: Efficient Algorithms for Effective Top-k Result Diversification

ABSTRACT

The ever-increasing supply of data is bringing renewed attention to result diversification, a technique usually studied with result relevance for a given task. Together, they produce a subset of results that are relevant to the user query and contain less redundant information. In this work, we formulate an extended version of the result diversification problem, considering three objectives—relevance, diversity, and coverage—and present a novel approach and algorithms that produce better-diversified results. Our approach takes a large set of possible answers generated from a user query and outputs a representative subset of results that are highly ranked according to the preference of the user. The data items contained in the representative set are diverse, such that each item is different from the rest and provides good coverage of the underlying aspects of the original results. Our approach also suggests a set of appropriate parameters for each user query to achieve a balance between our conflicting objectives and is efficient enough to ensure an interactive experience. We study the complexity of our algorithms and experimentally evaluate them in terms of normalized relevance, coverage, and execution time. Our evaluation indicates a speedup of up to 159x, and outperforms the state-of-the-art algorithms on multiple fronts.

1 INTRODUCTION

Motivation With the exponential increase in the amount of data being generated every second, the term "Big Data" that is adopted to represent the challenge of large-scale data processing is currently mentioned frequently in everyday life [20]. This reflects the fact that people are increasingly reliant on using data as an integral part of their daily activities (e.g., decisions and collaborations).

The challenge of scalable data processing can be examined from two viewpoints. Traditionally, scalability has been seen from a *systems point of view*, where challenges can be attributed to an increasing rate of data on the one hand, and network bandwidth, processing power, and storage limitation on the other hand. Scalability can also be viewed from a *human point of view* [23]. Given the exponential volume of data, the challenge here is how to avoid overwhelming users with irrelevant results.

Query personalization is a well-known technique for dealing with scalability challenges from a human point of view, which often happens at two different levels:

- *Ranking* – Ranking techniques utilize user *preferences* with the aim of providing the most relevant results to the users (e.g., [33]). These techniques can be distinguished as *quantitative-based*, *qualitative-based*, or *hybrid*, based on the type of user preferences that they can support.
- *Diversification* – Diversification techniques aim to reduce the amount of redundant information in the results. These techniques typically group data in sets that are most "dissimilar" with each other (e.g., [3, 12]).

Since highly-ranked items can be similar, result diversification [31] has recently drawn significant attention as a technique to facilitate applications such as keyword search, recommendation systems, and online shopping. The key idea of result diversification is to output a subset of representative results from the original in an informative way, since the user most probably will not view results beyond a small number. This requires the representative top-k results to be relevant, diverse, and maintain good coverage of the original answers (i.e., able to cover different underlying aspects of the original results). One thing to note is that the definitions of both relevance and diversity are subjective; thus, they can vary depending on the query and the user.

Goal In this paper, we present an approach to efficiently compute the representative result set for arbitrary top-k queries under user-definable relevance and diversity definitions. We name this as the *Diversified Top-k (DT-k)* problem.

Challenges Below, we will illustrate the challenges to our proposed approach by means of three examples.

Example 1.1. Assume a tourist who is currently visiting Athens wants to find an affordable restaurant with great taste. So she visits a publicly available database that contains the relation RESTAURANT (Name, Food Type, Cost, Score), where *Name* indicates the official name of the restaurant; *Food Type* indicates the type of food (e.g., Greek, Japanese, Chinese); *Cost* is the average expense per person, and *Score* is a numeric number between 1 and 10 that indicates the quality of the food and services offered at the restaurant. To find the ideal place for dinner, she, therefore, enters the following SQL-like query:

*SELECT * FROM RESTAURANT*
WHERE Score $\geq$ 6 *AND Cost* $\leq$ 20
ORDER BY Cost ASC;

However, these kinds of queries may produce thousands of results, among which the top 5 and bottom 5 results are listed in Table 1. The problem is that users are typically only interested in seeing a small portion of these results, not to mention many of these results are, in fact, redundant (e.g., differ only in the name). Simply fetching a certain top number (e.g., top 5) of results does not help improve their usefulness. Instead, the user might be better served with the right amount of diverse (i.e., dissimilar) items from the original answer with good coverage of different aspects (e.g., Food Type, Cost, Score). Furthermore, among those representative subsets with good diversity and coverage, the one that is most relevant to the user's interest should be preferred, such that the relevance refers to criteria that can be used to rank the answers. These may be obtained by interoperating the SQL-like query itself (e.g., through the "Order By" predicates), or derived from external user profiles (e.g., query histories, crowdsourcing).

One immediate challenge raised is how to define diversity, which clearly changes based on the user and the query being performed. In our work, we associate diversity with the similarity between pairs of answers (i.e., data items). To address this challenge, we propose a tunable definition that can be adjusted with a set of diversity thresholds DIV. Each threshold div in DIV is a real number between $[0, 1]$, which specifies the threshold between "similar" and "dissimilar" data items with respect to the normalized distance given by the specified distance measure (e.g., Euclidean, Manhattan, and Hamming) and attributes. $|DIV| = 0$ results in the traditional top-k query, while more diversity thresholds with higher values increase the diversity of the result set.

Name	Food Type	Cost	Score
McDonald	Fast Food	8	7
KFC	Fast Food	8	7
Burger King	Fast Food	8	7
Arby's	Fast Food	8	7
Oinomageireio H Epirus	Greek	8	9
......			
Scala Vinoteca	Greek	20	9
Ta Karamanlidika tou Fani	Greek	20	10
A Little Taste of Home	Greek	20	9
Liondi Traditional Greek	Greek	20	9
Dio Dekares i Oka	Greek	20	9

Table 1: Top-5 and bottom-5 tuples with respect to the cost.

Name	Food Type	Cost	Score
McDonald	Fast Food	8	7
Beer Garden Ritterburg	German	8	9
Nolan	Japanese	9	8
Oinomageireio H Epirus	Greek	10	10
Dosirak	Korean	12	6

Table 2: Top-5 tuples based on cost that are diversified respect to attributes "Food Type" and "Score".

Example 1.2. With the above diversity parameter, the previous sample query in Example 1.1 could be expanded accordingly:

*SELECT * FROM* RESTAURANT
WHERE Score ≥ 6 *AND* (*Cost* ≤ 20)
ORDER BY Cost *DESC*
DIVERSE BY div = 0.2 *ON* 'Food Type' (Hamming)
AND div = 0.3 *ON* 'Score' (Euclidean) *LIMIT* 5;

where Food Type and Score are the attributes on which the diversity is calculated, and Hamming and Euclidean are the corresponding distance measures. The idea here is to generate a set of results that follow the diversity constraints *DIV* specified within the query [1]. The result of the above query is illustrated in Table 2. Although the above example produces some compelling results with its information representative subset, it could be difficult to see how the coverage is contributing differently to the results than the dissimilarity. To illustrate the importance of the coverage, let us consider a simple example:

Example 1.3. Consider the nodes in Figures 1 and 2. In these two figures, each node represents an item in the dataset, and an edge exists between a pair of nodes iff the similarity between these two nodes are close enough according to some pre-defined threshold. On the one hand, in Figure 2, a set of dissimilar items $\{v_5, v_4\}$ is selected. However, only $\{v_1, v_5, v_4\}$ are considered to be covered by $\{v_5, v_4\}$, as $\{v_2, v_3\}$ are not connected with either v_5 or v_4. On the other hand, in Figure 1, a single vertex v_1 is connected to all four vertices, hence achieving 100% coverage. In this case, one can see that vertex v_1 better represents the entire graph when compared with $\{v_5, v_4\}$, thus indicating coverage is another valuable aspect to the quality of the representative results.

The above two examples (i.e., Example 1.2 and 1.3) illustrate the key advantages and desired features of an effective approach that provides a meaningful and representative subset of the original query results. First, the representative subset is relevant to the intention of the query and contains items that would be ranked highly in the original results. Second, the chosen representative items are diverse, each contributing additional novelty to the answer. Third, the representative items are selected in a way that most items in the original answers are reachable with a small distance (i.e., change) from one of the representative answers. Clearly, simply applying ranking, diversification, or clustering on the original result sets could not achieve the above properties. Thus, techniques that clearly consider multiple aspects of the representative results are needed to address this challenge.

[1]Note that our PrefDiv algorithms take the set of diversity constraints *DIV* as one of their inputs, and it is up to the design of the actual system that integrates the PrefDiv to determine how *DIV* will be integrated with its user query.

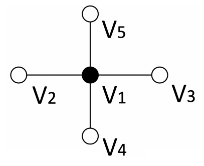

Figure 1: Single vertex v_1 with 100% coverage.

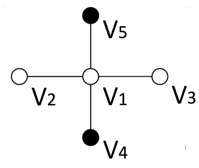

Figure 2: A set of vertices $\{v_4, v_5\}$ with 60% coverage.

Unfortunately, as we will discuss in more detail in Section 2.2.3, finding the optimal solution that maximizes both the "relevance" and "diversity" is an NP-Hard problem by itself, let alone with the addition of the other aspect "coverage" that should also be considered when producing the representative results.

Our Approach To overcome these challenges, we propose an extremely efficient online algorithm, called *Preferential Diversity* (PrefDiv) [13] , for producing representative result sets with sufficient relevance, diversity, and coverage of the original answers. PrefDiv is a top-k bounded general diversification approach that can be applied to any existing relevance ranking model and datasets to retrieve a diversity-aware top-k representative subset of results. PrefDiv starts to construct the representative result set with the k most relevant results (according to the ranking method), then gradually refine this representative set by eliminating pairs of items that do not satisfy the constraints specified by the set of diversity thresholds *DIV*. This is achieved by identifying pairs of items in the representative result set that violate one or more diversity thresholds, and then, among the two items contained in the pair, one with lower relevance will be replaced with an item from the database that improves diversity and coverage. In the end, PrefDiv produces k representative results balanced between relevance, diversity, and coverage.

To the best of our knowledge, PrefDiv is the first general approach to deliver representative results that explicitly consider relevance, diversity, and coverage with an interactive speed that is independent of the underlying database and data set.

However, in order to optimize multiple conflicting objectives such as relevance and diversity, a common approach taken by most diversification algorithms, including our PrefDiv, is to utilize a number of tunable parameters. This could be a major drawback for an algorithm, because with the increase of the number of required parameters, the complexity of the algorithm increases as well, making it more difficult to use in real-world scenarios.

In this paper, we extend and present a family of PrefDiv algorithms based on the vanilla PrefDiv. These includes two novel algorithms that automatically determine: 1) the corresponding diversity thresholds $DIV = \{div_1, div_2, ..., div_n\}$ given the set of diversity constraints Ψ, and 2) the tunable parameters A that balance the trade-off between the relevance and diversity, respectively.

Contributions To achieve the solution as described above, this paper makes the following contributions.

- We formulate the *Diversified Top-k (DT-k)* problem, provide a theoretical analysis of its complexity, and show NP-hardness results. (Section 2)
- We provide a detailed description of the design of PrefDiv, which is an efficient online result diversification algorithm.

Table 3: LIST OF NOTATIONS USED IN THE PAPER

Symbol	Explanation
R_Q	a set of initial query results
R	a set of representative results
k	the number of item in the result-set
$\mathcal{L}$	the number of iterations to obtain R with PrefDiv
Ψ	a set of diversity constraints
ψ	the diversity constraint
div	a diversity threshold
div_{opt}	an optimal diversity threshold
Δ	a set of dimensions
A	a relevance parameter
v	a self-adjustable relevance parameter
I_x	the intensity value of item x
$U(x)$	a utility function that produces the I_x
$sim_\Psi(x_i, x_j)$	x_i and x_j are similar w.r.t Ψ
$dissim_\Psi(x_i, x_j)$	x_i and x_j are dissimilar w.r.t Ψ

- We introduce the concept of Relevance Proportionality (RP), that dynamically balances the trade-off between relevance and diversity during the retrieval of the top-k representative results based on the given query and dataset.
- We propose a novel greedy algorithm that automatically finds the optimal diversity threshold, which maximizes the coverage of the representative result set produced by the PrefDiv.
- We perform extensive experimental evaluations with two real-world datasets, Cameras [10] and Foursquare [7]. Our experimental results show that PrefDiv and its optimizations outperform the most similar state-of-the-art competitors, as suggested in [34], by a significant margin. Compared to other alternatives (discussed in Section 5), our algorithm achieves up to 159x speedup and produces a representative subset that better covers the original answers with a negligible performance decrease in relevance. (Section 4)

2 PROBLEM FORMULATION

In our work, we assume that the database DB is composed of N data items over a D-dimensional space $(d_1, d_2, ..., d_D)$, where each dimension $d \in D$ can be either numerical or categorical attributes. Note that the above assumption enables us to handle any data type (e.g., structured, semi-structured, unstructured) as long as they are vectorized. The user specifies a query Q that aims to retrieve a set of k representative items from DB over a subset of dimensions S, such that $S \leq D$. The goal here is to produce a set of k items that maximizes the *relevance* while ensuring the *diversity* (i.e., ensuring each item is diverse with respect to one another). Below, we will first provide the necessary background and basic concepts of our problem, and then present our problem definition and analyze its complexity. The list of symbols used in the following sections of the paper is shown in Table 3.

2.1 Background

2.1.1 Relevance. The relevance of R represents the degree of the relevancy of each data item $x \in R$ and is typically represented with a utility function $U(x)$ that measures the "goodness" of each data item with respect to certain metrics.

Definition 1. *Relevance* – Given a database DB and a utility function $U(x)$, the relevance is measured as the outcome of $U(x)$, which is an *intensity value* $I_x \in (0, 1) \subset \mathbb{R}$ for item $x \in$ DB that is used to express the degree of benefit from retrieving x.

A higher intensity value indicates that a data item is more desired than those items with a lower intensity value.

The intensity value (i.e., relevance score) enables database systems to produce a total order of each data item in a given data set and thus allow the extraction of top-k data items. This is simply achieved by retrieving k data items with the highest intensity value.

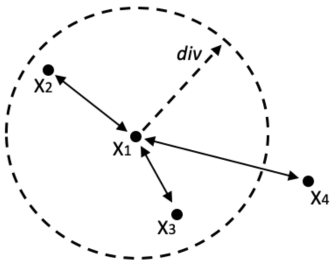

Figure 3: Illustration of similarity and dissimilarity.

2.1.2 Diversity. In our work, the diversity of a set of data items R is achieved by enforcing each pair of data items in R to be *dissimilar* with respect to each other, such that two data items x_i, and x_j are said to be dissimilar if for a given set of user-specified diversity constraints Ψ, x_i and x_j satisfy all constraints $\psi \in \Psi$. Formally, we can define a diversity constraint as follows:

Definition 2. *Diversity Constraint* – For a given pair of items x_i and x_j, a set of attributes Δ, a distance threshold div, and a distance function $dist(x_i, x_j, \Delta)$ that measures the distance between x_i and x_j with respect to the set of dimensions specified in Δ. A diversity constraint ψ is satisfied iff $dist(x_i, x_j, \Delta) > div$.

Based on the above definition of diversity constraints, we now define dissimilarity as:

Definition 3. *Dissimilarity* – Let X be a set of data items. For a given set of diversity constraints Ψ, two items x_i and $x_j \in X$ are dissimilar to each other, denoted as $dissim_\Psi(x_i, x_j)$, if they satisfy each diversity constraint ψ in Ψ.

Consequently, the similarity can simply be defined as the opposite of the dissimilarity, such that:

Definition 4. *Similarity* – Let X be a set of data items. For a given set of diversity constraints Ψ, two items x_i and $x_j \in X$ are similar to each other, denoted as $sim_\Psi(x_i, x_j)$, if they fail to satisfy at least one diversity constraint in Ψ.

Figure 3 illustrates the concept of similarity and dissimilarity with four 2-dimensional data items $x_1, .., x_4$, and a single diversity constraint that requires the Euclidean distance between each data object with respect to both dimensions (i.e., $\Delta = d_1, d_2$) to be at least div apart. Let us take point x_1 as an example. According to Definition 4, points $\{x_2, x_3\}$ are similar to x_1, since $dist(x_2, x_1, \Delta) \leq div$ and $dist(x_3, x_1, \Delta) \leq div$. In contrast, x_4 is dissimilar with respect to x_1, as $dist(x_4, x_1, \Delta) > div$.

2.1.3 Coverage. As pointed out in the previous literature [11], the coverage is another aspect that is important to the quality of the representative results. Since the size of the representative results is very restricted compared to the original answers, having a set of representative results with good coverage increases the chance for the user to get meaningful information from the selected representation items. Furthermore, coverage enables the system to organize all the answers in a cluster-like fashion, where each original answer of query Q can still be retrieved by "zoom-in" into one of the representative items. Such that the "zoom-in" operation will reveal all answers that are "similar" to the selected representative item. The actual implementation of this "zoom-in" operation has been well discussed in [11], thus it is omitted from the discussion of this paper.

Clearly, the coverage is defined completely based on the definition of the similarity and thus related heavily to the diversity constraints when the number of representative results is fixed to a certain number k. When k is fixed, a set of more relaxed diversity constraints (i.e., with higher diversity threshold) will help the representative set include more original answers into its coverage, and a set of stricter diversity constraints will certainly decrease the coverage of the representative set. In particular, given the definition of similarity, if item x_j satisfies $sim_\Psi(x_i, x_j)$, x_j is said to be covered by the item x_i. Consequently, we can define the coverage of a set of items as follows:

Definition 5. *Coverage* – Given a set of original answers R_Q and a representative result set R, where $R \subseteq R_Q$, the coverage of R corresponds to the percentage of items in R_Q that satisfies $sim_\Psi(x_i, x_j)$, such that $x_i \in R$ and $x_j \in R_Q$.

2.2 Diversified Top-k (DT-k) Problem

Based on the above discussions and definitions, we name our problem the *Diversified Top-k (DT-k)* problem.

2.2.1 Problem Formulation. Consider a database DB that consists of N data items distributed over a multi-dimensional space with mixed numeric and categorical dimensions. Given a query Q and its corresponding initial results set R_Q over DB, the desired result cardinality of k, a utility function $U(x)$, and a set of diversity constraints Ψ, the solution of DT-k produces a k-sized representative subset R from the original results R_Q, whose *relevance*, according to $U(x)$ is maximum, while satisfying the set of diversity constraints Ψ.

We name the above k-sized subset of representative results as Diversified Top-k (DT-k) set.

2.2.2 Problem Complexity. Finding the optimal DT-k Set for the Diversified Top-k problem is computationally hard, which can be shown by mapping it to the well-known *Maximum-weight Independent Set* problem [1]. We can achieve the mapping by forming a graph of G that corresponds to the original results R_Q. Each data item x_i in R_Q maps to a vertex v_i in G. An edge e is added between two vertices v_i and v_j if the distance between these two vertices is close enough such that not all diversity constraints are satisfied, and the intensity value I_{x_i} of an item x_i represents the weights of the corresponding vertex in G. Some tractable solutions have been proposed in the literature [18, 21], but these solutions require either a very specific type of graph (e.g., Outerstring graphs) or have strict restrictions (e.g., sparsity, outcome degree of each vertex). Thus, they are not practical in our environment.

2.2.3 Secondary Objective. As discussed above, coverage is another important aspect of result diversification, which is dependent completely on the diversity threshold specified inside each diversity constraint. Given that diversity constraints are typically defined by the user, this may lead to sub-optimal results if the user fails to define reasonable constraints. Consequently, our secondary objective is to address this challenge by automatically adapting the diversity constraints based on the type of the query being performed and the initial result set. Later, in Section 3.4, we will present a general optimization that helps determine the most suitable diversity constraints for different user queries.

3 PREFDIV ALGORITHMS

In this section, we introduce our solution to the Diversified Top-k problem. First, we start with the discussion of a naive approach to the problem and then propose our solution to this problem, namely, *Preferential Diversity* (PrefDiv) algorithm. Finally, we discuss some optimizations that improve the effectiveness of our proposed PrefDiv algorithm and reduce its number of tunable parameters.

3.1 Naive Solution

Before we discuss our solutions, one naive solution to the Diversified Top-k problem work as follows: given a new user query Q, a k, a set of initial results $R_Q = \{x_1, ..., x_t\}$, a utility function $U(x)$ and a set of diversity constraints Ψ, for each item in R_Q of q, we first compute and sort each item in R_Q according to the intensity value computed by the $U(x)$. We pick the item $x_i \in R_Q$ with the highest intensity value; for each remaining items x_j in R_Q, we mark them as "Eliminated" if they are similar to the x_i (i.e., $sim_\Psi(x_i, x_j)$). We then add x_i into the final result set R and remove x_i from R_Q. Afterwards, a new unmarked item with the highest intensity value will be picked from R_Q, and the previous steps will be repeated until either $|R| = k$ or all remaining items in $|R_Q|$ are marked as "Eliminated".

This naive solution is a greedy approach that will eventually produce a set of items that satisfy all diversity constraints with relatively high-intensity values. Clearly, the naive solution is computationally expensive, especially when the size of R_Q is large. Furthermore, it does not guarantee the resulting set to contain at least k items. However, we use this naive solution as a foundation and propose an efficient online solution that achieves better performance with much less computational cost.

ALGORITHM 1: PrefDiv

```
Require:
 1: Initial result set $R_Q$, result cardinality $k$, relevance
    parameter $A$, a set of diversity constraints $\Psi$
Ensure:
 2: One subset $R$ of $R_Q$
 3: $T \leftarrow \emptyset$
 4: while exists unexamined items in $R_Q$ and $|R| < k$ do
 5:   $T \leftarrow$ Pick $k$ items with highest intensity from $R_Q$
 6:   for all $x_i \in T$ do
 7:     if $Dissim_\Psi(x_i, x_j) : \forall x_j \in R$ then
 8:       $R \leftarrow R \cup x_i$
 9:     else
10:       Mark $x_i$ as "redundant"
11:   while number of promoted items in $R$ from $T < A * k$ do
12:     $R \leftarrow R \cup x_{max}$, s.t., $x_{max}$ is marked &
    $\forall x_j \in T, I_{x_{max}} \geq I_{x_j}$
13:     $T \leftarrow T - x_{max}$
14:   $A \leftarrow A/2$
15:   $R_Q = R_Q - T$
16: Return $R$
```

3.2 Preferential Diversity

Our Preferential Diversity algorithm is an online solution for the DT-k problem. As discussed in the previous section, finding the optimal solution to the DT-k problem is computationally expensive. Thus we chose a greedy approach in the PrefDiv design. To maximize the efficiency of PrefDiv, we need to develop it as an online algorithm that accesses database tuples (i.e., items) incrementally. The main idea underlying PrefDiv is minimizing as much as possible the number of data items being examined.

PrefDiv builds the DT-k set R by starting with a set of k highest ranked data item (with respect to the relevance score/intensity value), and then gradually replacing items that fail the diversity constraints with slightly less relevant but diverse items outside of R that satisfy the diversity constraints. This process continues until all items in R satisfy the specified diversity constraints.

One potential issue is that relevant items in the DT-k set tend to be similar to each other. Thus strictly enforcing diversity constraints may eliminate too many items that are highly beneficial to the user. To address this issue, we propose a *relevance parameter A* that allows PrefDiv to produce representative results with *partial* diversity. When $A = 1$, R would simply be the top k items from the initial set, i.e., the items with the k highest intensity values. When $A = 0$, R contains k dissimilar items from the initial set. When A is between 0 and 1 and given that PrefDiv is an iterative algorithm, considering k objectives each iteration, the final result will have at least $A * k$ items from every iteration, and in each iteration A will be divided by half. For example, when $A = 0.5$ and $k = 20$, the first iteration will select at least $20 * 0.5$ items for the final result set, the second iteration will select at least $20*(0.5*0.5)$ items, and so on. With this parameter, the user is able to control the trade-off between relevance *vs.* diversity by enabling partial diversity whenever necessary.

As illustrated in Algorithm 1, the basic logic of PrefDiv is as follows: PrefDiv takes as input, a set of initial results R_Q sorted according to the descending of their intensity value, the desired result cardinality of k, partial diversity parameter A, and a set of diversity constraints Ψ. It outputs a DT-k set that represents the original answers R_Q. In each iteration, PrefDiv fetches and removes k items with the highest intensity value from R_Q and places them in a temporary set T. Each of the items in T is then compared with items currently in R, such that any item in T that fails to satisfy all diversity constraints with respect to all items in R will be marked as “Redundant"; else, it will be added into R immediately. This process will continue until all items in T are either moved into R or marked as “Redundant". Once all k items fetched in the current iteration have been examined, PrefDiv will check if a sufficient number of items were moved into R according to parameter A. In case the number is not sufficient, the difference will be covered by the highest-ranked items (with respect to intensity value) that are marked as “Redundant" in the current iteration. Afterward, the above iteration will be repeated until k representative items are produced ($|R| = k$).

Time Complexity According to the above discussion, we can observe that the worst-case complexity of PrefDiv is $O(kN)$, since each of the N unlabeled items will be compared at most $k - 1$ times with the items that are currently in the result set before being included or discarded from the final result. Fortunately, as the size of k is usually a small number, PrefDiv should typically behave as a linear algorithm. Furthermore, as we will show in our empirical studies (Section 4), depending on the diversity constraints, PrefDiv typically does not need to examine all original items in R_Q. That is, a very small set of the item would be sufficient enough to produce R if Ψ are appropriately defined.

3.3 Relevance Proportionality

From the above discussions, it should be clear that having a good balance between relevance and diversity is important to the quality of the representative result set. In PrefDiv, we have introduced the relevance parameter A to enable the partial diversity, which helps preserve the relevance of the representative results. Our empirical study shows that such a parameter does help improve the quality of the result set R. However, it is up to the user to define A for any query, and this may increase user efforts when using our algorithm. This motivated us to introduce a new self-adjusted parameter v to replace the manual relevance parameter A, which led to a new variation of PrefDiv called *Preferneral Diversity with Proportional Relevance* (PrefDiv-PR). As illustrated in Algorithm 2, the idea here is to automatically compute the right amount of items that should be promoted into the final result set based on the proportion of the relevance of each iteration.

In particular, v adapts to the aggregated intensity value of all items in each iteration, and can be computed as follows: Assume a given set of original results R_Q, a DT-k subset $R \subseteq R_Q$ and a number of iterations $\mathcal{L}$ needed for PrefDiv to obtain the result set R. For each iteration ℓ., s.t. $\ell < \mathcal{L}$, a set of items with the highest intensity value from the remaining items of R_Q are reserved into a separated set B_ℓ, s.t. $B_\ell \subseteq R_Q$ and $|B_\ell| = k$. The v_ℓ of an

ALGORITHM 2: PrefDiv-PR

```
Require:
 1: Initial result set $R_Q$, result cardinality $k$, a set of diversity
    constraints $\Psi$
Ensure:
 2: One subset $R$ of $R_Q$
 3: $\mathcal{L} \leftarrow 0$
 4: $T \leftarrow \emptyset$
 5: while exists unexamined items in $R_Q$ and $|R| < k$ do
 6:     $T \leftarrow$ Pick $k$ items with highest intensity from $R_Q$
 7:     for all $x_j \in T$ do
 8:         if $Dissim_\Psi(x_j, x_t) : \forall x_t \in R$ then
 9:             $R \leftarrow R \cup x_j$
10:     $R_Q = R_Q - T$
11:     $B_\mathcal{L} \leftarrow T - R$
12:     Increase $\mathcal{L}$ by one
13: for $\ell = 1 \rightarrow \mathcal{L}$ do
14:     $v_\ell \leftarrow$ Compute $v_\ell$ according to Equation 1
15:     while the number of items in $R$ from $B_\ell < v_\ell * |R|$ do
16:         $R \leftarrow R - x_j$, s.t. $x_j \in R, I_{x_j} < I_{x_k} : \forall x_k \in R$
17:         $R \leftarrow R \cup x_i$, s.t. $x_i \in B_\ell, I_{x_i} \geq I_{x_t} : \forall x_t \in B_\ell$
18:         $B_\ell \leftarrow B_\ell - x_i$
19: Return $R$
```

iteration ℓ is calculated through the following equation:

$$v_\ell = \frac{\sum_{x \in B_\ell} I_x}{\sum_{j=1}^{\mathcal{L}} \sum_{x_c \in B_j} I_{x_c}} \quad (1)$$

Recall from Section 2.1.1, I_x is the intensity value of data item x. The idea here is that at least v_ℓ proportion (i.e., percent) of the item in the final representative result set should be extracted from iteration ℓ, as early iterations would always have a higher aggregated intensity value, and thus, would occupy a bigger portion of the final representative set R. Our empirical results show that by employing v to compensate for the loss of relevance, we can prevent too many relevant results from being dropped.

To actually generate the final representative results according to v_ℓ, PrefDiv-PR needs to first run PrefDiv to obtain the initial representative set R, as well as records the number of iterations $\mathcal{L}$ taken to obtained R. During each iteration of PrefDiv, the items that are initially extracted from R_Q (before applying the diversity constraints) will also be recorded into a separate set B_ℓ. Afterward, PrefDiv-PR will examine the set of items in R that are extracted from each B_ℓ with the corresponding v_ℓ to determine if additional items need to be extracted from B_ℓ and added into R. Note that if such extraction is necessary, depending on the number of items needed to be extracted, the set of items with the highest intensity value in B_ℓ that have not been included in R will be chosen from B_ℓ and placed in R. Finally, once all v are satisfied for each iteration, the set of k items with the highest intensity value in R will be retrieved as the final results.

3.4 Optimize Diversity Constraints for Coverage

As discussed previously in Section 2.1.3, coverage is yet another important property of the representative set. It gives us two major benefits. First, it helps to ensure that the underlying data space (i.e., the original set) has been well represented by the selected representative items. Second, it enables the possibility for the user to retrieve items that are not in the representative result set by performing “zoom-in” operations—each representative item can be seen as the leader of a set of similar items, and by

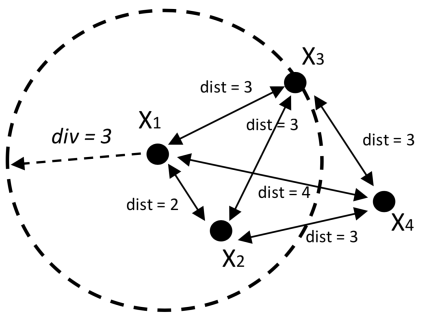

Figure 4: Illustration of the optimal radius, when $k = 2$

"zooming-in" to one of the leaders, similar items around the leader can be revealed.

Since the definition of coverage depends on the similarity between data objects, it is defined by the set of diversity constraints. In order to boost coverage, a set of appropriate diversity constraints must be defined. Below, we will discuss a general approach to determine such diversity constraints through an example.

Example 3.1. Consider a set of initial results R_Q that contains 100 items, each with two dimensions, $k = 30$, a single diversity constraint ψ that considers both dimensions, and the Euclidean distance as the diversity measure. Furthermore, assume that no partial diversity is allowed, meaning the final representative set produced must be a strict DT-k set. Obviously, whether it is possible to produce a DT-k set with 30 items is dependent on the definition of diversity constraints, such that if the diversity constraint consists of a diversity threshold that is beyond the maximum pair-wise distance between any pair of items in the original result set, then only a single item can be included in R, as the rest of the data items would be discarded due to the violation of the diversity constraint. Clearly, returning a result set with a single item when $k = 30$ is not ideal, and thus, the diversity threshold should be adjusted lower. In contrast, a minimum possible diversity threshold (i.e., 0) would lead to an arbitrary set of k items, which gives no guarantee of either diversity or coverage.

Clearly, from the example, an *optimal diversity constraint* should include a diversity threshold that exhibits the following properties: (1) be as large as possible to improve the coverage; and (2) be small enough to allow a strictly diverse representative set (i.e., DT-k set) with k mutually dissimilar items being formed.

With the above observations, we define the optimal diversity constraint as:

Definition 6. *Optimal Diversity Constraint.* For a given set of item R, an integer number k, and a distance function $dist(x_1,x_2)$, an optimal diversity constraint must contain the largest possible distance threshold, denoted as div_{opt}, that exists between a pair of items in R that can be used to generate a DT-k subset R_Q from R, such that $|R_Q| >= k$ and no two item in R_Q are similar according to $dist(x_1,x_2)$ and div_{opt}.

As illustrated in Figure 4, assume we have a set of points $P = \{x_1,...,x_4\}$, such that each point consists of a 2-D coordinate and a diversity constraint ψ that consist of both dimensions and uses Euclidean distance. In such case, if $k = 2$, then $div = 3$ will be the div_{opt} (i.e., optimal diversity threshold) for ψ. If any value less than 3 is chosen to be the div_{opt}, then at least three points will remain after removing all similar points because only p_2 and p_3 are considered to be similar with respect to a diversity threshold of 2. If any value larger than 3 is chosen to be the div_{opt}, then only one point will remain in P after removing all similar points. Thus, 3 is the only option for div_{opt}, as no other distance threshold would be able to produce a result with three items. Unfortunately, finding the optimal diversity threshold for a given distance measure and a set of attributes is NP-hard.

According to Definition 3, two items x_i,x_j are dissimilar iff they fail to satisfy a diversity constant Ψ with a diversity threshold div and distance function $dist(x_1,x_2)$. Since an item, x_i can be included in a DT-k subset R *if and only if* x_i satisfies all diversity constraints with respect to other items in R, the maximum distance d between any pair of items in R increases along with the diversity thresholds inside each diversity constraints. Based on the Definition 6 of the optimal diversity constraint, the problem of finding the optimal diversity thresholds (i.e., div_{opt}) for a given diversity constraint can be mapped to the MaxMin Diversity Problem, which aims to select a representative subset $R \subseteq R_Q$, such that $|R| = k$, and the minimum distance between any pair of items in R is maximized. As the MaxMin Diversity problem has been previously proven to be an NP-hard problem [4], finding the optimal diversity threshold is also an NP-hard problem.

Inspired by the MaxMin Diversity problem, we adopt a greedy heuristic (Algorithm 3), which automatically computes an approximation of the optimal diversity thresholds for a given set of diversity constraints. As illustrated in Algorithm 3, we first find a subset $S \subseteq R_Q$ that maximize the minimum distance between items in R (Lines 5 - 7). Then, we generate the optimal diversity threshold by comparing the pair-wise distance of all items that are in R_Q but not in S (Lines 8 - 11). The optimal diversity threshold is defined as the largest distance between a pair of items in R_Q that is smaller than the minimum distance between any pair of items in R. As proven in [30], the result produced by this greedy heuristic has a $\frac{1}{2}$ approximation of the optimal solution and a quadratic complexity, and no other polynomial algorithm can provide a better guarantee.

ALGORITHM 3: SearchOptimalDiversityThreshold

```
Require:
 1: A set of items $R_Q$, a size $k$, a set of attribute $\Delta$, and a
    distance function $dist(x_1,x_2,\Delta)$
Ensure:
 2: A diversity threshold $div_{opt}$
 3: $S \leftarrow$ an initial item $x \in R_Q$
 4: $div_{opt} \leftarrow \emptyset$
 5: while $|S| < k$ do
 6:     $x^* \leftarrow \arg\max_{x \in (R_Q - S)}(\min(dist(x,x_j,\Delta) : \forall x_j \in S))$
 7:     $S \leftarrow S \cup x^*$
 8: $\Theta \leftarrow$ minimum distance between any pair of items in S
 9: $x^R \leftarrow \arg\max_{x \in (R_Q - S)}(\min(dist(x,x_j,\Delta) : \forall x_j \in$
    $S, s.t. dist(x,x_j,\Delta) < \Theta))$
10: $div_{opt} \leftarrow \min(dist(x^R,x_j,\Delta) : \forall x_j \in R_Q)$
11: Return $div_{opt}$
```

4 EXPERIMENTAL EVALUATION

To study the effectiveness of our PrefDiv and PrefDiv-PR algorithms, we compare them to the two most effective diversified top-k algorithms, namely *Swap* [37] and *MMR* [5], as suggested in [34]. We also compare them to four diversity-focused algorithms, *MaxSum, MaxMin, K-Medoids*, and *DisC Diversity*, to assess how well diversity has been preserved when relevance is taken into account. All the algorithms in our evaluation are discussed in Section 5.

4.1 Experimental Testbed

We implemented all of the algorithms with JDK 8.0 on an Intel machine with Core i7 2.5Ghz CPUs, 16GB RAM, and 512GB SSD.

Algorithms. We implemented MMR and Swap based on their published descriptions [5] and [37], respectively. The MaxMin and MaxSum algorithms used in our experiments are based on Definitions 8 and 9 (in Section 5), respectively, and DisC Diversity is taken directly from the original author [10]. However, DisC Diversity is not top-k bounded algorithms, and the size of the result set that DisC Diversity produces is heavily dependent on the radius. To allow for a comparison, we modified the DisC Diversity to stop when the size of the result set equals k. We also included one well-known clustering algorithm, K-Medoids [26], which aims to group a set of data objects into clusters through some distance measure, so objects within a cluster are close to each other and objects outside of the cluster are unrelated to the objects inside the cluster.

In our experiment, we implemented K-Medoids based on [26]. Since K-Medoids does not capture the relevance in any regard, we improved the performance of K-Medoids in balancing the relevance *vs.* diversity trade-off by choosing the object with the highest intensity value as the final recommendation from each of its k clusters. This improvement significantly enhances the performance of the K-Medoids with respect to relevance, while exhibiting the minimum decrease in diversity.

Most of the diversification techniques involved in our experiments require some parameters, since finding the best parameters for each technique that are optimum under all situations would be too difficult. For the purpose of comparison, in all of our experiments, there is only one diversity constraint ψ for any given set of experiments, which is used by all algorithms that require a diversity constraint during its execution. We fixed the diversity threshold div used in ψ for each set of the experiments, which is computed with the optimal radius by Algorithm 3. All other parameters except ψ and r are fixed for all runs and adjusted according to the suggestion of the original authors, or based on the best overall performance. For MMR, we set $\lambda = 0.3$, for Swap, we set the $UB = 0.1$, and for PrefDiv, we set $A = 0.6$.

Datasets. We ran our tests on two real-world datasets: Cameras [10], and Foursquare. We selected these datasets in order to experiment with two different distance functions, *Hamming* with Cameras and *Euclidean* with Foursquare. The Cameras dataset consists of 579 records and 7 attributes per record. The Foursquare dataset is collected from the major location-based social network, Foursquare. We obtained real-life user preferences, used Foursquare's public venue API, and queried information for 14,011,045 venues. In order to build realistic user profiles for our evaluations, we used a dataset collected by Cheng et al. [7] that includes geo-tagged user-generated content from a variety of social media between September 2010 and January 2011. This dataset includes 11,726,632 check-ins generated by 188,450 users. Accordingly, each reading in our Foursquare dataset has the following tuple format: <ID, latitude, longitude, # check-ins, # unique users>. In our experiments, we consider only data items (i.e., venues) from New York City (NYC), which consists of 10912 items and San Francisco (SF), which consists of 7859 items.

User Preferences. The intensity values (I) for each individual dataset is generated as follows:

For the Cameras dataset, we generated 100 different sets of user preferences, such that in each profile the preference intensity value for each individual camera is generated based on a uniform distribution, and each individual user preference is represented as one unique query.

For the Foursquare dataset, we obtained the *real-life* user preferences based on the hierarchy of the Foursquare dataset, such that every individual venue v in the dataset is associated with a type T_v. For example, an Italian restaurant belongs to the category "Italian restaurant", which can belong to the higher level category "Restaurants", which can itself belong to the category "Food", and so on. In order to build highly personalized and specific profiles, we use the bottom layer of the hierarchy, as well as the specific venues visited. In particular, given the set of check-ins C_u of user u, we build a hierarchical profile $\mathcal{P}$ where at the top level, the preferences of the user are expressed in terms of the (normalized) frequencies of this user's visitations with respect to the types of venues. The second layer of the user profiles further provides the normalized frequencies of venues for the different types of locations visited by u. Since our user profile is sparsely gathered during a short period of time, to resemble a real-world user profile, we merged the 1000 sparse Foursquare user profiles to create one superuser profile. We performed our experiments by randomly selecting 50 query points from each city (100 query points in total). For each query point, we considered all venues located within a 1.5 kilometer radius of the query location.

4.2 Evaluation Metrics

In our experimental evaluation, we evaluate the performance of all models based on three well-known and commonly used metrics: *Normalized Relevance* [35], *Coverage* [10] (Definition 5), and *Execution Time*. Note, there are two other commonly used metrics for evaluating ranking algorithms such as DCG and Spearman rho. However, both metrics focus on measuring the correctness of the order of the results produced by the ranking algorithm. Thus, they are not the ideal evaluation metrics for evaluating the effectiveness of result diversification algorithms. As stated in previous sections, our proposed PrefDiv algorithms are post-processing steps of initial query results, which does not impact the relative order of the original result set. In other words, the produced representative result set of PrefDiv algorithms essentially follows the original order of the initial results. Thus, metrics that focus on the correctness of the ranking order do not fit the context of this evaluation.

Definition 7. *Normalized Relevance.* Let S be a set of items and $S_k^* \subseteq S$ such that $|S_k^*| = k$. The Normalized Relevance of a subset S_k^* is defined as the sum of the intensity value of items in S_k^* over the sum of k items with highest intensity value in S.

$$nRev(S_k^*) = \frac{\sum_{x \in S_k^*} I_x}{\max_{S_k \subseteq S, |S_k| = k} \sum_{x \in S_k} I_x} \quad (2)$$

In order to calculate the coverage for the Foursquare dataset, given that it is difficult to find a fixed radius that would work with any query location, we calculate the coverage with respect to the optimal radius generated by Algorithms 3 for every output size k. In the case of a Camera dataset, where the hamming distance is employed, the coverage is calculated with a fixed diversity threshold/radius $div = 3$ (which is the mid-point of the maximum distance allowed). For a fair comparison, all algorithms are evaluated with respect to the same diversity threshold/radius. Note that Normalized Relevance and Normalized Intensity Value would be used interchangeably in the following sections.

4.3 Experimental Results

Here we report the findings of our experimental evaluation.

4.3.1 Normalized Relevance. As demonstrated in Figures 5, 8, and 11, we can see a clear separation between two groups of algorithms for all datasets, where PrefDiv, PrefDiv-PR, Swap, MMR, and K-Medoids tend to group together, and MaxMin, MaxSum, and DisC Diversity form another group. The reason for this is that the second group does not take relevance into account; hence, it would be unlikely for them to retrieve a representative subset that has a high total intensity value. In contrast, the first group of algorithms takes relevance into account, and, as such, it

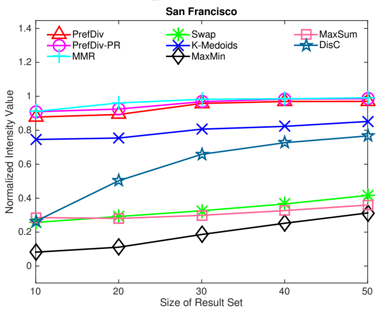

Figure 11: Normalized Intensity Value of Foursquare, SF

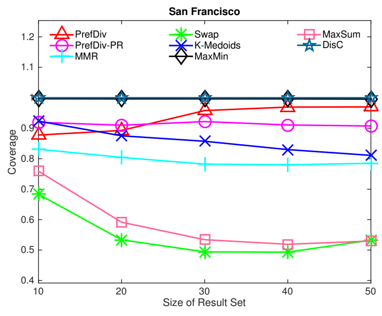

Figure 12: Coverage of Foursquare, SF

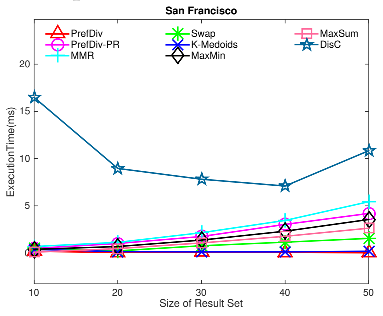

Figure 13: Execution Time of Foursquare, SF

achieves a significantly higher performance in terms of retrieving relevant items.

4.3.2 Coverage. Figures 6, 9, and 12 show that our PrefDiv and PrefDiv-PR exhibit better coverage on average when compared with MMR and Swap by 20% and 42%, respectively. The reason could be because both MMR and Swap optimize dissimilarity as their definition of diversity. In contrast, both PrefDiv and PrefDiv-PR are coverage-aware algorithms, which seek an optimal radius that directly improves the coverage of the representative result set. Therefore, both PrefDiv and PrefDiv-PR can perform much better than Swap and MMR. We also observed that on average PrefDiv is able to outperform MaxSum in terms of coverage by 160%, which could be explained because MaxSum as pure dissimilarity-based algorithm fails to cover the entire space of the dataset. K-Medoids demonstrates good coverages for both datasets. However, both PrefDiv and PrefDiv-PR still exhibit slightly better coverage in general.

The MaxMin algorithm performs well in terms of the Foursquare dataset, although the performance dropped significantly for the cameras dataset. The reason could be because in the Foursquare dataset the average number of venues around each query point is about 90 venues. In contrast, the Cameras dataset consists of 579 tuples. This shows that MaxMin is able to obtain good coverage with a relatively small dataset and Euclidean distance that takes a wide range of values as distance, but fails to cover the space with large datasets and hamming distance that only takes the number of attributes + 1 distinct values as distance. In both datasets, DisC Diversity demonstrated the highest coverage, which is to be expected since DisC Diversity is the only algorithm in the experiment that directly optimizes coverage as the only objective.

Another interesting observation is that, in the Foursquare dataset, except PrefDiv, PrefDiv-PR, and DisC Diversity, other algorithms appear to have a drop in coverage when the value of k increases, although, in general, with the increase in result size the coverage should increase as well. The reason for such behavior is that in the Foursquare dataset, we employed the optimal radius as the criterion for determining the similarity between items. Therefore, with the increase in result size, the optimal radius becomes smaller, thus leading to a decrease of coverage for some algorithms.

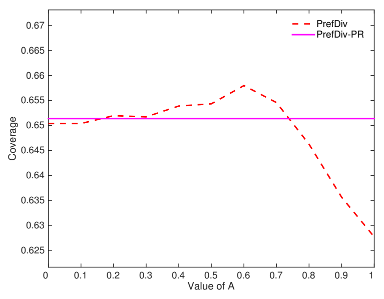

Figure 14: Coverage of different settings of A, with optimal radius and k = 30.

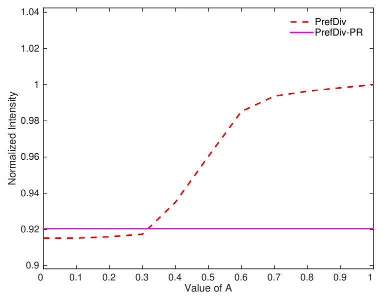

Figure 15: Normalized Relevance of different settings of A, with optimal radius and k = 30.

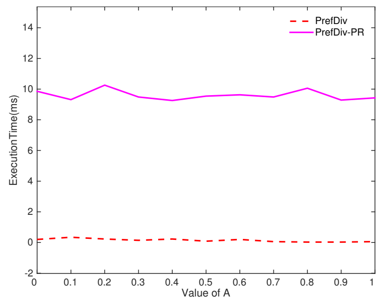

Figure 16: Execution Time of different settings of A, with optimal radius and k = 30.

4.3.3 Execution Time. We have measured the execution time required by all algorithms. As shown in Figures 7, 10, and 13, our PrefDiv and PrefDiv-PR appears to be the overall fastest algorithm when compared to all other alternatives. In general, PrefDiv and PrefDiv-PR perform near identically in terms of runtime, which is expected as the additional computation overhead introduced in PrefDiv-PR is negligible. To illustrate the efficiency of our proposed greedy heuristic for searching the optimal diversity threshold, we have included its runtime in the PrefDiv-PR, so the runtime difference between PrefDiv and PrefDiv-PR reflects the runtime of the search optimal diversity threshold algorithm. With that in mind, PrefDiv-PR is still on average faster than both MMR and Swap by up to 72% and 116%, respectively. Specifically, in the Camera dataset, PrefDiv is able to execute 57 times faster than K-Medoid, 127 times faster than MMR, and 159 times faster than Swap. In the Foursquare dataset, most algorithms tend to be faster when compared with Cameras, because the number of venues near each query point in Foursquare is much smaller than in the Cameras dataset. However, we still observed that, on average, PrefDiv is able to outperform MMR and Swap by 30 and 36 times, respectively. When compared to K-Medoid, which is also very efficient when dealing with this type of dataset, PrefDiv still appears to be 2.7 times faster than K-Medoid on average. As mentioned previously, if the optimal radius for most frequent queries is stored, PrefDiv-PR would not need to calculate the optimal radius for these queries again. Furthermore, for the fairness of the comparison, all of the algorithms run in a single-threaded mode. Since the optimal radius computation method that we adopted is fully parallelizable, it can take advantage of the modern multi-threaded CPU architecture to speed up the computations. In fact, we have observed linear speed up with respect to the number of CPU cores in the system up to 16 cores (the highest we have experimented). One interesting remark here is that, in the Foursquare dataset, the execution time of DisC Diversity drops when k increases from 10 to 20. The reason is that the runtime of DisC Diversity is also affected by the length of the radius, therefore, with smaller output sizes, the optimal radius will become larger, which leads to the relativity longer execution time of DisC.

4.3.4 Parameter A of PrefDiv. As illustrated in Figures 6 to 11, a performance difference between PrefDiv and PrefDiv-PR exists due to the existence of the accuracy parameter A in the PrefDiv algorithm. In this section, we conducted an experiment to study the effect of parameter A in PrefDiv with the Camera dataset and k = 30. As shown in Figures 14, 15, and 16, when A increases from 0 to 1, we observed an improvement of normalized relevance, albeit with a decrease in coverage. This is as expected since, with higher values of A, PrefDiv will select more relevant items, and with lower values of A, more diverse items will be selected that lead to an increase in coverage. However, this would be at the expense of lower relevance. The execution time appears to be stable regardless of the value of A. This is because, for each iteration, PrefDiv only requires a tiny amount of execution time. Therefore, the additional iterations introduced by the low value of *A* would not have a large impact on the overall runtime.

4.3.5 Relevancy vs. Diversity. Lastly, as a summary, we present three scatterplots that capture the trade-off between relevance and diversity. Each point in Figures 17 and 18 are corresponding to the average of over 50 different query locations with one value of k, and each point in Figures 19 are corresponding to the average of over 100 different user profiles with one value of k. As shown in the figures, we have Normalized Intensity Value as the y-axis and Coverage as the x-axis. Algorithms located in the upper left corner of the figure exhibit the best coverage result, while those in the lower right corner have the highest relevance scores. As we can observe, both PrefDiv and PrefDiv-PR are located towards the upper right corner (circled) for all three scatter plots, which indicates that both PrefDiv and PrefDiv-PR exhibit better ability to handle the trade-off between relevance and diversity with respect to both datasets and distance measures. One may notice that in the Camera dataset, the advantage of PrefDiv and PrefDiv-PR with respect to other alternatives is relatively smaller compared to that in the Foursquare dataset. This is because the Cameras dataset uses the Hamming distance as the distance measure, which has a much smaller domain than the Euclidean distance used in the Foursquare dataset, thus weakening the benefit of the optimal diversity threshold. These results also indicate that the relational proportionality introduced in PrefDiv-PR does effectively improve the quality of the result, since PrefDiv-PR is able to outperform (although slightly) the PrefDiv with manually configured relevance parameter *A*.

4.3.6 Additional Observations. Despite the fact that both PrefDiv and PrefDiv-PR run up to 159 times faster than other alternatives, the greedy heuristic (Algorithm 3) that we proposed for finding the optimal diversity threshold/radius runs at a quadratic time complexity, and thus, it is much slower. Although it is not required to run this heuristic before each execution of the PrefDiv/PrefDiv-PR, it certainly helps improve its performance. However, this is not an issue with our PrefDiv/PrefDiv-PR algorithm because other algorithms (e.g., DisC Diversity) also benefit from the optimal diversity threshold as much as PrefDiv/PrefDiv-PR.

Fortunately, this greedy heuristic only needs to run once for each query, and thus, it can simply be cached to boost the runtime of frequent queries significantly.

5 RELATED WORKS

In this section, we discuss works that are closely related to ours from multiple aspects.

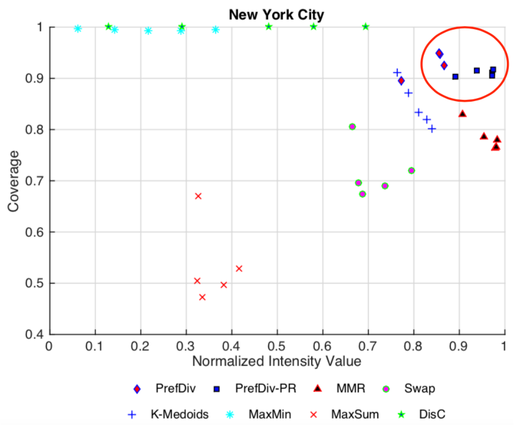

Figure 17: Relevance VS. Diversity (NYC).

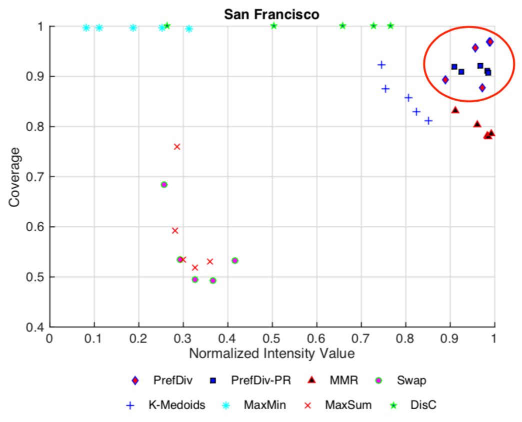

Figure 18: Relevance VS. Diversity (SF).

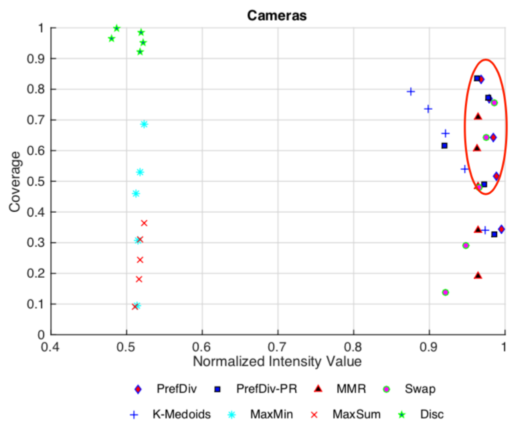

Figure 19: Relevance VS. Diversity (Cameras).

5.1 Relevance Ranking Techniques

Many ranking techniques using preference have been proposed. These are comprehensively surveyed in Stefanidis et al. [33]. As mentioned above, these techniques can be distinguished based on the type of preferences they support for filtering and ordering data. These techniques primarily handle only one type of preference, either *quantitative* or *qualitative*. However, each preference type has its own advantages and disadvantages. Hybrid schemes that support both qualitative and quantitative preferences have been proposed in an attempt to exploit the advantages of both types of preferences while eliminating their disadvantages [17, 22]. In this work, our proposed algorithms can work with any existing relevance ranking model that returns a set of sorted tuples/objects along with their scores/intensity values.

More recently, in [6], the author studied the problem of producing rankings while preserving a given set of fairness constraints. In particular, the proposed algorithm takes as input, a utility function, a collection of sensitive attributes (e.g., gender, race), and a collection of fairness constraints that restrict the number of items with each sensitive attribute that are allowed to appear in the final results. It outputs a ranking that maximizes the relevance with respect to the given utility function while respecting the fairness constraints. As mentioned previously, our proposed PrefDiv algorithms can leverage any existing relevance ranking model. Therefore, in the case where the required sensitive attributes and fairness constraints can be provided by the user, PrefDiv can be used in conjunction with the ranking produced in [6].

5.2 Diversity Techniques

Result diversification has been studied in many different contexts and with various definitions [10], such as similarity, semantic coverage [2], and novelty [8]. In our work, we focus on the similarity definition and use MaxMin and MaxSum, which are two widely used diversification models, as baselines.

The goal of these two diversification models is to select a subset S from the object space R, so that the minimum or the total pairwise distances of objects in S is maximized. Recently, a number of variations of the MaxMin and MaxSum diversification models have also been proposed (e.g., [9, 25]) to address the problem of diversifying continuous data. Formally, MaxMin and MaxSum are defined as follows:

Definition 8. *MaxMin* generates a subset of R with maximum $f = min_{p_i,p_j \in S} dt(p_i,p_j)$ where dt is some distance function $p_i \neq p_j$ for all subsets with the same size.

Definition 9. *MaxSum* generates a subset of R with maximum $f = \Sigma_{o_i,o_j \in S} dt(o_i,o_j)$ where dt is some distance function $o_i \neq o_j$ for all subsets with the same size.

DisC Diversity [10] is the most recently proposed diversity framework and solves the diversification problem from a different perspective. In DisC Diversity, the number of retrieved diverse results is not an input parameter. Instead, users define the desired degree of diversification in terms of a tuning parameter r (radius). DisC Diversity considers two objects o_i and o_j in the query result R to be similar objects if the distance between o_i and o_j is less than or equal to a tuning parameter r (radius). It selects the representative subset $S \in R$ according to the following conditions: (1) For any objects in R, there should be at least one similar object in S; and (2) All objects in S should be dissimilar to each other. These two conditions ensure both the coverage and the dissimilarity property of a diverse result set.

In addition, DisC Diversity also introduces two problems, *Covering* and *CoveredBy* [11]. These can be used to model the issue of generating a representative result set that is both diverse and relevant to a user's individual preference (without using preferences). The Covering problem is used to model the case where users want highly relevant items to cover a large area around them. In order to achieve this goal, a relatively larger radius is assigned to items with larger weights. The CoveredBy problem is used to model a case where a user wants to see more relevant objects. In that case, a smaller radius is assigned to items with larger weights. These two problems together illustrate the possibility of using DisC to handle relevance together with diversity.

The key differences between PrefDiv algorithms and DisC Diversity are: (1) PrefDiv algorithms follow the Top-k paradigm, which provides users with the option to specify the size of the final result set by assigning a value to parameter k, whereas DisC Diversity adjusts the size of the result set by changing its radius parameter r. (2) The PrefDiv algorithms focus on both the *relevance* of the result set with respect to the users' preference and the *diversity* of the result set. DisC Diversity focuses mainly on the most diverse representative subset with two scenarios that only illustrate the possibility of using DisC Diversity to handle such relevance-aware diversity requests; however, they do not mention any specific strategies on how one can dynamically change *r* with respect to Covering or CoveredBy. In addition, our implementation of PrefDiv-PR eliminates the need for identifying *r* (i.e., diversity threshold) manually by automatically finding the most suitable diversity threshold under any given situation.

Another way to generate a diverse, representative set of results is through clustering. One example of this would be *k-Medoids*, which is a well-known clustering algorithm that attempts to minimize the distance between points in a cluster and the center point (medoid element) of that cluster. The k-Medoids algorithm can be classified into two stages: In its first stage, it generates a set of k clusters C = {c1, c2, ..., ck} based on some distance function dt. In the second stage, one element from each cluster is selected to be part of the result set *R*. Several strategies for selecting an element from each cluster could be employed. For instance, one strategy is to choose the center point of each cluster that is expected to deliver high diversity, and another strategy would be to choose the point that has the highest intensity value for each cluster. However, since there is no parameter that can be tuned, either manually or automatically, to balance the trade-off between relevance and diversity, k-Medoids is unable to balance such a trade-off in fine granularity.

5.3 Multi-Criteria Objective Optimization

In the past, diversification and retrieval of relevant results have often been studied together as a multi-objective optimization problem with two objectives, where the first objective is relevance, and the second objective is dissimilarity [38]. The following are some representative techniques that are related to our work.

In [27], the authors considered the optimization of the diversified Top-K problem as finding the optimal solution for the maximum weight independent set problem, which has been proven to be an NP-hard problem. The authors proposed an approach, called *div-astar*, which uses a diversity graph that consists of N nodes, where each node corresponds to one item in the original data. This diversity graph is sorted according to the relevance score, and an a^* algorithm is used to find the optimal solution for diversifying Top-K Results. In addition to the div-astar solution, two enhancements have also been proposed, called *div-dp* and *div-cut*: div-dp takes advantage of dynamic programming to divide the initial graph into disconnected components, and div-cut is a cutpoint-based approach that further decomposes each disconnected component based on loosely connected sub-graphs. PrefDiv algorithms are different from div-astar [27] (Section 5.3), in that the main objective of div-astar is to find the exact solution for the maximum weight independent set; hence, even with all the enhancements and decompositions, each sub-problem is still NP-hard. On the other hand, although PrefDiv algorithms also consider the maximum weight independent set problem as part of the algorithm, they take advantage of greedy approximation with a relaxed constraint, which allows similar items to be included in the result set if the relevance distribution of the original data can be better reflected in the resulting set. Furthermore, such relaxed constraints allow PrefDiv to be more practical for border usage, especially for tasks that require a short response time.

One widely used approach that was targeted directly at optimizing the trade-off between diversity and relevance was introduced by [5]. In this work, the authors proposed the famous twin-objective function called *Maximal Marginal Relevance* (MMR), which combines both relevance and diversity aspects in a single, comprehensive objective function. Formally, MMR defines its objective function as:

$$\arg\max_{D_i \in R \setminus S}[\lambda(Sim_1(D_i, Q) - (1-\lambda)\max_{D_j \in S} Sim_2(D_i, D_j))] \tag{3}$$

Where λ is a scaling factor that specifies the preference between relevance and diversity. When $\lambda = 1$, the MMR function equals a standard relevance ranking function. When $\lambda = 0$, it computes a maximal diversity ranking. Comparing PrefDiv to MMR [5] approach, one can clearly see the difference: there are no comprehensive objective functions being used in the PrefDiv algorithms. Our approach addresses the combined problem of relevance and diversity through a combination of multiple steps, rather than solving it in one single function.

Recently, a new bi-criteria objective optimization approach based on MMR has been proposed [19]. This approach integrates *regret minimization* with traditional MMR to generate a new relevance score that takes into consideration the case of minimizing the disappointment of users when they see k representative tuples rather than the whole database. In this work, the authors proposed two approximation algorithms called *ReDi-Greedy* and *ReDi-SWAP*, which find the set of items consisting of k items having the highest score with respect to their MMR function.

In [32], the author has conducted a study on personalized, keyword-based search over relational databases, which includes the notion of diversity and coverage. Specifically, the author provided good discussions on modeling the relevance, user preferences, diversity, and coverage for keyword-based searches over relational databases by means of Join Tree of Tuples. Join Tree are trees of tuples connected through primary to foreign key dependencies. However, PrefDiv algorithms assume that a utility function F is given in advance to reflect the relevance and user preference, and thus does not focus on modeling the relevance and user preferences. Furthermore, PrefDiv algorithms are general, post-processing techniques for result diversification, and hence, do not restrict themselves to the keyword-based search over relational database settings. As long as proper utility functions and distance measures are given, PrefDiv algorithms can be applied to any data types (e.g., structured, unstructured, semi-structured). Consequently, the definition of coverage in [32] is also different than the definition of coverage in this work. Wheres [32] focuses on covering more user intents based on user profiles, PrefDiv algorithms focus on the proximity between the representative results and original results.

Swap is another recent Top-K diversification technique that is related to ours [37]; Swap starts with K items with the highest relevance scores. Among these K items, Swap picks an item with the lowest contribution to the diversity of the entire set, then swaps this item with the item that has the next highest relevance score. A candidate is successfully swapped with one of the items in the Top-K set if and only if it can contribute more in terms of the overall diversity of the result set. In order to preserve the relevance aspect, Swap introduces an optional pre-defined threshold called UB that specifies how much decrease in relevance can be tolerated. UB can serve as a terminal condition that stops the algorithm when the item with the highest relevance among the remaining set is no longer high enough for the algorithm to perform a swap operation. Our PrefDiv is different from the Swap, as Swap seeks diversity through pairwise distances of items among the result set, filters out items that contribute less to diversity, and ensures relevance by throwing out items that cause the relevance to drop below the pre-defined threshold. In contrast, PrefDiv algorithms seek diversity by eliminating similar items and ensuring relevance by using a relevance-focused greedy algorithm along with proportionality, which can reflect the relevance distribution of the original domain.

5.4 Data Summarization

Some recent works [24, 36] have studied the problem of providing interactive exploration and summarization support for tuples in a given table. The goal of this type of approach is to produce an informative hierarchy that organizes the underlying tuples essentially in k clusters. In order to display tuples as clusters, each cluster is folded into a single, representative tuple, with only the common attribute values among all members of the cluster being displayed. The rest of the attributes are shown as "?", which indicates that there are objects with different values with respect to these attributes inside the cluster. To explore each cluster, the user can gradually expand each "?" symbol contained in the current representative tuple of a cluster. Each time the user expands a "?" symbol, more tuples that contain a different value with respect to the corresponding attributes will be displayed. Clearly, these works are different than ours. We focus on producing a representative subset that is most informative to the user with adjustable size, rather than summaries of subsets of a table.

5.5 Impacts of PrefDiv

The efficiency of PrefDiv and its ability to balance the trade-offs between relevance, diversity, and coverage have already benefited the design of some real-world systems that need to produce highly informative representative subsets, or require interactive efficiency in producing the representative results (e.g., [14–16, 28, 29]) .

One example is a novel mobile recommendation service that provides a set of diverse points-of-interest (POI's) recommendations [14–16], where the interactive efficiency has been weighted equally important as the quality of the produced recommendations.

Another example is in the scientific domain and dimensionality reduction, which PrefDiv has been employ as a novel way to select subsets of highly informative dimensions for high-dimensional gene expression datasets [28, 29]. Those selected dimensions will then be used to enable effective downstream analysis in a variety of medical and bioinformatics researche.

6 CONCLUSIONS

Scalability from a human point of view is a very challenging problem as it consists of finding the perfect balance between the conflicting objectives of relevance and diversity. Traditional top-k result diversification approaches focus on producing a subset of results that balance the trade-off between selecting highly relevant items and items that are dissimilar with respect to each other. In order to achieve the above-mentioned objectives, most algorithms rely on a number of tunable control parameters, making them harder to configure (and be adopted). Coverage is another important factor of diversity, which has been mostly ignored in previous top-k result diversification algorithms.

In this work, we addressed these problems and proposed an efficient online solution called *Preferential Diversity* (PrefDiv). PrefDiv produces a set of high-quality representative items from a large set of initial answers, where each representative item is chosen to optimize both the *relevance* and *diversity* (i.e., dissimilarity, and coverage). We also proposed a number of optimizations that further improve PrefDiv's usability, efficiency, and effectiveness.

We theoretically analyzed and experimentally compared our algorithms to the state-of-the-art, top-k diversification algorithms. Our evaluation showed that our algorithms achieve similar performance in terms of normalized relevance, but outperforms the state-of-the-art algorithms in terms of coverage by a noticeable margin, while achieving a speedup of the runtime up to two orders of magnitude.

ABSTRACT

Connected mobility applications rely heavily on geospatial joins that associate point data, such as locations of Uber cars, to static polygonal regions, such as city neighborhoods. These joins typically involve expensive geometric computations, which makes it hard to provide an interactive user experience.

In this paper, we propose an adaptive polygon index that leverages *true hit filtering* to avoid expensive geometric computations in most cases. In particular, our approach closely approximates polygons by combining quadtrees with true hit filtering, and stores these approximations in a query-efficient radix tree. Based on this index, we introduce two geospatial join algorithms: an approximate one that guarantees a user-defined precision, and an exact one that adapts to the expected point distribution. In summary, our technique outperforms existing CPU-based joins by up to two orders of magnitude and is competitive with state-of-the-art GPU implementations.

1 INTRODUCTION

Connected mobility companies need to process vast amounts of location data in near real-time to run their businesses. For example, Uber needs to map locations of cars and passenger requests (points) to predefined zones (polygonal regions) for allocation and dynamic pricing purposes [40]. These polygonal regions are typically largely disjoint (non-overlapping) and mostly static. Points, on the other hand, are often not known a priori. Thus, the problem is how to efficiently find the polygons that contain an incoming point.

Traditionally, such point-polygon joins [19] follow the *filter and refine* approach. In this two-phase evaluation strategy, the filtering phase typically uses an index (e.g., an R-tree) on the minimum bounding rectangles (MBRs) of polygons and probes the index for each point to obtain a list of candidate join pairs. Then, in the refinement phase, expensive point-in-polygon (PIP) tests are performed to discard false matches.

We argue that the time has come to rethink this strategy: First, main memory is not a scarce resource anymore and modern machines offer multiple terabytes of memory. Combined with the city-centric model of geospatial applications (e.g., Uber), we show that it is possible to maintain highly fine-grained indexes for entire cities (e.g., Uber's operating zones) in main memory, dramatically reducing the number of CPU-intensive PIP tests. Second, geospatial positions, nowadays typically obtained by smartphones or wearables, are inherently imprecise [41]. Thus, we argue that it is in many cases admissible to trade off accuracy for performance. Based on these two insights, we transform the traditionally CPU-intensive problem of point-polygon joins into one that is bound by memory access latencies.

In contrast to the classical filter and refine approach, *true hit filtering* [9] identifies actual join pairs already in the filtering phase, and thus partially avoids expensive refinements. This is achieved by using additional approximations (such as inner rectangles [20]) to approximate the interior of polygons, so that when a point falls into an interior approximation, it can be safely deducted that the point is contained in the polygon.

Building on this seminal idea, we present an improved algorithm that combines true hit filtering with quadtrees [23] to *holistically* index an entire set of polygons. This is in contrast to existing implementations of true hit filtering that approximate polygons individually [15, 21] or use non-hierarchical (single-resolution) grids [6, 39, 49]. In our approach, polygons are translated into a *single* set of multi-resolution grid cells that approximates their boundary and interior areas. To support efficient queries, we store one-dimensional identifiers of the cells in a new in-memory radix tree (trie) named *Adaptive Cell Trie* (ACT). We show that ACT is more query-efficient than previous approaches for indexing cell identifiers (e.g., B-trees, like in [21]).

Another distinguishing feature of our approach is that it can entirely avoid the expensive refinement phase by refining cells in the boundary areas until a user-defined precision is guaranteed. Naturally, this comes at the cost of higher memory consumption than traditional filter and refine approaches. However, as stated above, we argue that we can nowadays actually afford this higher memory consumption in exchange for higher performance.

Our approach can also provide accurate results by performing expensive PIP tests for points that are potential hits. To reduce their number, we adapt (train) our index based on historical data points to provide higher precision where it is actually needed. As we show in our experiments, our accurate algorithm performs very few PIP tests. Compared to a filter based on the polygons' MBRs, our index (trained with 1 M historical points) reduces the number of required PIP tests by >97% for a join between NYC taxi pick-up locations and neighborhood polygons. This algorithm can also be used when ACT cannot guarantee the desired precision given a certain memory budget.

In summary, we make the following contributions:

- An algorithm that computes quadtree-based grid approximations for sets of polygons with precision guarantees
- A radix tree data structure (ACT) that is optimized for indexing cell identifiers: for a join of NYC's yellow taxi data with NYC's neighborhoods, we achieve a throughput of >50 M points/s per CPU core under a <4 m precision bound

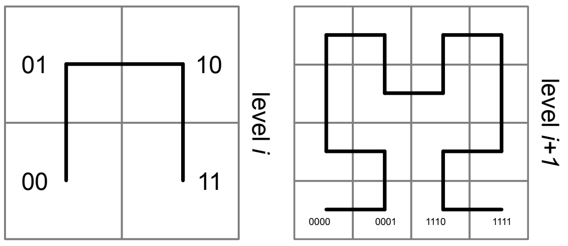

Figure 1: Quadtree-based cell decomposition and Hilbert curve-based enumeration.

- An evaluation of ACT in contrast to more traditional data structures, such as B-trees
- An accurate algorithm that trains the index structure based on historical data points
- An experimental comparison against state-of-the-art GPU-based point-polygon joins

In the remainder of this paper, we first give some background about the building blocks of our approach in Section 2. Section 3 describes our approach and Section 4 presents the evaluation with real-world and synthetic data. Finally, we summarize related work in Section 5 before concluding in Section 6.

2 BACKGROUND

Location Discretization. Our approach relies on a quadtree-based (hierarchical) decomposition of space (the surface of the Earth in this case). This decomposition is static and thus *data independent*. We enumerate the quadtree cells using a space-filling curve (e.g., the Hilbert or the Z curve) to index them in a one-dimensional data structure. Our approach does not depend on a concrete space-filling curve. For our indexing strategy to work, the cell enumeration must only fulfill the property that child cells share a common prefix with their parent cell.

Figure 1 shows the hierarchical decomposition of two cells at levels i and $i+1$ and the corresponding bitwise representations that encode the cells' positions along the Hilbert curve. Each cell consists of four sub cells, which it completely covers. Child cells share a common prefix with their parent cell, allowing us to compute *contains* relationships using efficient bitwise operations. In our implementation, we use the Google S2 library [32] for mapping latitude/longitude coordinates to 64-bit cell identifiers, which we call *cell ids* in the following. A cell id encodes up to 30 levels with two bits per level.

Polygon Approximations. To obtain fine-grained polygonal approximations, we need a method that maps polygons to sets of quadtree cells (possibly at different levels). In particular, our algorithms take as input approximations of the boundary and interior areas of *single* polygons. In our implementation, we use the S2 library to obtain these individual polygon approximations. Figure 2 illustrates a covering (in blue) and an interior covering (in green) of a polygon. A point contained in a covering cell is either within or outside of the polygon while points that match interior cells are known to be within the polygon (true hits). The cell marked with ① is one of the largest covering cells and only minimally intersects the polygon. Any point contained in this cell has at most a distance of $\sqrt{2} * \epsilon$ (with ϵ being the side length of the cell) to the polygon. To allow for an efficient search, S2 stores the cell ids of a covering in a sorted vector. Besides sorting the cell id vector, it allows for the covering to be *normalized*. A normalized covering contains neither conflicting nor duplicate cells. Two cells are conflicting when one cell contains the other. Only when the covering is normalized can cell containment checks be efficiently implemented using a binary search on the sorted vector ($O(\log n)$).

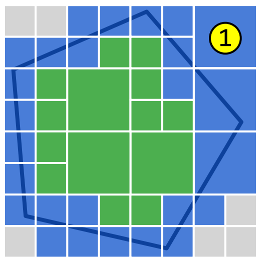

Figure 2: A covering (blue cells) and an interior covering (green cells) of an individual polygon.

While binary search on a sorted vector is a good strategy for querying small collections of cells (e.g., the covering cells of a single polygon), it is not the most efficient way to search larger collections (e.g., coverings of multiple polygons). In this work, we store large cell collections in ACT, a query-efficient radix tree, and evaluate its performance compared to alternative physical representations (including a sorted vector and a B-tree).

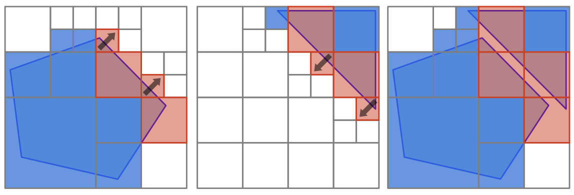
PIP Test. A point-in-polygon (PIP) test determines whether a point lies within a polygon. Typically such a test is performed using complex geometric operations, such as the *ray-tracing algorithm* [17], which involves drawing a line from the query point to a point that is known to be outside of the polygon and counting the number of edges that the line crosses. If the line crosses an odd number of edges, the query point lies within the polygon. The runtime complexity of this algorithm is $O(n)$, n being the number of edges. While there are many conceptual optimizations to the PIP test, this operation remains computationally expensive since it processes real numbers (e.g., latitude/longitude coordinates) and thus involves floating point arithmetics.

3 GEOSPATIAL JOIN APPROACH

In this work, we target the problem of mapping points to static, largely disjoint polygons. We show how to accelerate such joins by computing fine-grained cell-based approximations of sets of polygons and maintaining them in a query-efficient in-memory radix tree, which enables efficient cell lookups and significantly reduces (or even eliminates) expensive geometric tests.

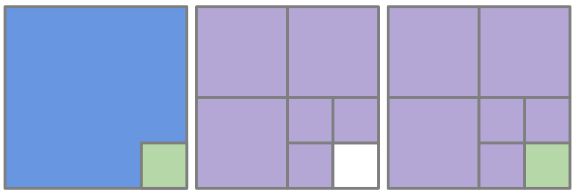
In contrast to techniques that first reduce the number of candidate polygons using an index, e.g., an R-tree on the polygons' MBRs, and then refine candidates using geometric operations, our approach leverages true hit filtering [9] and identifies most or even all join pairs in the filter phase. On a high level, our approach first computes cell-based approximations of all polygons, called coverings and interior coverings, and merges them to form a *super covering*. Then, it stores these approximations in a specialized in-memory radix tree (named ACT) which allows for efficient lookups. Finally, ACT is probed for every point to obtain a list of *true* and *candidate* point-polygon pairs. The candidate pairs are either refined by performing geometric computations to obtain an accurate result, or deemed to be part of the join result when small approximation errors can be tolerated.

The following provides more information about our indexing technique and the two geospatial join algorithms that are based on it: the approximate one that completely avoids expensive PIP tests while still guaranteeing a user-defined precision, and the exact one that reduces expensive computations by adapting to the expected point distribution. These algorithms allow us to trade memory consumption with precision (approximate approach) and performance (exact approach). Thus, they both favor



(a) Covering (b) Covering (c) Combined cov.

Figure 3: A combined covering may be less selective than two individual coverings. The arrows indicate that the cells will be expanded.



(a) c_1 and c_2 (b) Difference d (c) d and c_2

Figure 4: Precision preserving conflict resolution. c_1 is marked in blue, c_2 in green, and the cells in d in purple. Note that c_1 contains c_2.

modern hardware with large main memory capacities and high memory bandwidths. In summary, the key contribution of our indexing strategy is the novel combination of the super covering that approximates the polygons precisely, and the radix tree data structure that allows these approximations to be queried efficiently. With this design, we revisit the concept of true hit filtering in the context of modern hardware.

3.1 Adaptive Cell Trie (ACT) Indexing

3.1.1 Super Covering Computation. The super covering consists of a set of multi-resolution grid cells. All grid cells are disjoint in the sense that each geographical point is covered by at most one cell, even if two (or more) polygons overlap. A single cell of the super covering can therefore be associated with multiple polygons. The super covering maintains a list of *polygon references* for each individual cell. A polygon reference has two attributes:

polygon id The identifier of the polygon that this cell references.

interior flag Whether the cell is an interior or a boundary cell of the polygon.

The precision of the super covering determines the selectivity of the index. When combining the approximations of the individual polygons, we need to take special care of conflicting cells[1] to not lose precision. However, this is challenging for two reasons. First, conflicts may occur between the cells of a covering of a given polygon and the cells of its interior covering. The interior cells always overlap some (if not all) covering cells. Second, when different polygons overlap or are close to each other, conflicts may occur between the cells of their coverings.

One approach for retaining the precision would be to not resolve such conflicts at all and maintain all conflicting cells. However, this would have the consequence that a query point could match with more than one cell, which would affect lookup performance. In a radix tree, this would mean that we would need to keep searching lower levels once we found a match at a higher level.

Ensuring that cells are non-overlapping results not only in higher lookup performance, but also in a more compact radix tree. The reason is that for a given entry in a tree node, we only need to differentiate between a pointer (to a child node) and a value. With overlapping cells, we would have to store a pointer *and* a value.

There are two obvious solutions for resolving a conflict between two cells c_1 and c_2, where c_1 is an ancestor of c_2 in the quadtree (c_1 contains c_2). One is to replace c_2 with c_1, which leads to a precision loss as shown in Figure 3. Figures 3a and 3b show the coverings of two individual polygons. The red cells have conflicts with cells of the other covering. Figure 3c shows a combined covering, where the originally smaller cells are subsumed by larger cells, causing a precision loss. The other solution is to replace c_1 with a set of smaller cells at the same level (i.e., of the same size) as c_2. While this retains the precision, it can significantly increase the number of cells in the combined covering.

Without compromising on precision, we would like to reduce the number of cells introduced. To solve this problem, instead of storing both conflicting cells c_1 and c_2, we compute their difference d and store c_2 and d. This has the advantage that there will not be any overlap between the indexed cells, and thus an index lookup will return *at most* a single cell. The side effect is that the total number of cells will increase since d consists of at least three cells.

Figure 4 illustrates this precision preserving conflict resolution. Assume that c_1 (blue) and c_2 (green) are cells of two different coverings and that c_1 contains c_2. First, we compute d, which consists of six cells. We then copy all polygon references of c_1 to d and c_2 and omit c_1. Note that the cell count is increased by five. Overall, our approach retains the precision and the type (boundary or interior) of the individual cells as well as the mappings of cells to polygons.

Listing 1 outlines this algorithm. We iterate over all input cells and try to insert them into the super covering. When a cell already exists, this means that it is also part of another covering that has already been processed. When two cells conflict, this means that either the current cell covers the other cell or vice versa. These two cases may happen when polygons overlap or are close to each other, or when we first insert the cells of the covering of a given polygon and then the cells of its interior covering. To address these cases, we apply the precision preserving conflict resolution strategy described above. As mentioned earlier, this strategy increases the total number of cells. However, a more precise index reduces the number of expensive PIP tests and thus increases overall performance.

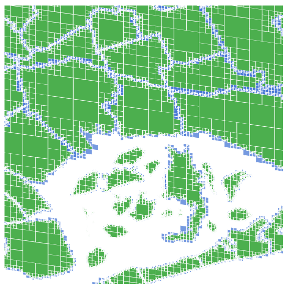


Figure 5: A super covering of neighborhoods in NYC's Jamaica Bay.

Figure 5 shows a super covering of neighborhoods in NYC's Jamaica Bay. Boundary (former covering) and interior cells are again marked in blue and green, respectively. Most of the area shown is covered by either interior cells or by no cells at all. Only

[1]Recall that a conflict between two cells exists if one cell contains the other. We do not consider duplicate cells as conflicting.

```
input:
 a list of coverings coverings // one per polygon
 a list of interior coverings interiors // one per polygon
output:
 // a list of (cell, polygon references)
 the super covering superCovering
procedure:
 for (covering in coverings) {
  for (cell in covering) {
   if (superCovering already contains cell) {
    add references of cell to existing cell
    continue
   }
   if (cell conflicts with existing cell in superCovering) {
    // cell is covered by existing cell or vice versa
    // resolve conflict
    $c_1$ = ascendant cell // may be cell or existing cell
    $c_2$ = descendant cell // may be cell or existing cell
    $d$ = difference of $c_1$ and $c_2$
    add references of $c_1$ to $d$ and $c_2$
    remove $c_1$ from superCovering // only required if the existing cell
      is the ascendant cell
    add $c_2$ and $d$ to superCovering
    continue
   }
   add {cell, {covering.polygonId, interior flag=false}} to superCovering
  }
 }
 // ... same code for interior coverings (with interior flag=true)
```

Listing 1: Build precision preserving super covering.

in the unlikely event that a query point hits a blue (boundary) cell, we may experience false positives (approximate approach) or we will need to enter the refinement phase (exact approach).

3.1.2 Data Structures. To store the super covering and enable efficient queries over it, we use two data structures: (i) a specialized radix tree (ACT) that indexes the cells of the super covering, and (ii) a lookup table that maintains the (variable-length) polygon references. Both data structures are designed for in-memory processing and are optimized for lookup performance.

Adaptive Cell Trie. ACT is a specialization of a textbook radix tree that indexes 64 bit cell ids. We call it adaptive for two reasons: (i) it indexes cells of adaptive sizes (to guarantee user-defined precision), and (ii) it can adapt to the expected point distribution. All adaptation is performed at build time. Once ACT is built, it is a static (immutable) data structure. We leave updates such as adding new polygons to an existing ACT for future work. However, we would like to point out that supporting updates is straightforward: In the build phase, cells of individual polygons are inserted one-by-one into ACT. The same procedure could be used to add new polygons at runtime, with appropriate synchronization between readers and writers. Code for removing polygons would follow the same logic, with the only difference being that we may want to (periodically) reorganize (i.e., compact) the lookup table.

We refer to the cell ids stored in the radix tree as *keys*. Each key denotes the path of a cell in the hierarchical grid. In the following, we first outline why a radix tree, in general, is a good choice for indexing quadtree cells, and we then explain how ACT differs from a general-purpose radix tree.

The main reasons why we choose a radix tree to index a super covering are (i) space efficiency and (ii) support for efficient prefix lookups. Compared to storing cell ids in a list, a radix tree avoids redundantly storing common prefixes, which reduces memory consumption. Prefix lookups, on the other hand, are required to find matching cells: The query point, which is a cell id at the most fine-grained grid level, is used to search for cell ids within the radix tree that share a common prefix (i.e., cover the query point). The runtime complexity of these lookups is in $O(k)$ with k being the key length, as opposed to the $O(\log n)$ of binary search that could be used on a sorted list. In other words, the number of node accesses in a radix tree is bounded by the maximum key length k_{max}, which is 60 when 30 quadtree levels are used (which is the case in our implementation). In practice, a lower k_{max} is often sufficient. For example, $k_{max} = 44$ allows for indexing cells up to level 22, which corresponds to a precision of less than 4 m (i.e., the distance between a point and a polygon in a false match is at most 4 m). A further advantage of the radix tree is that most queries can be answered using the upper levels of the tree: larger cells use fewer bits and are thus indexed closer to the root node. In the likely event that a query point hits a larger cell, we can complete the tree probe sooner.

We now discuss the design choices of ACT. The fanout f of the radix tree controls space consumption and lookup performance. A fanout of four means that we consume two bits at every tree level. With that configuration, our data structure matches the quadtree scheme (each node has four children, cf. Figure 6 for an example). While this would ease the implementation, it would require up to 30 nodes to be accessed per lookup. With a higher fanout, we can reduce this number. To maximize lookup performance, ACT uses a *default* fanout of 256 (= 8 bits). Thus, each level in ACT corresponds to four levels in the quadtree (each quadtree level is encoded with two bits). Let g be the cell level granularity of ACT (with $f = 256$, $g = 4$). While a fanout of 256 may result in sparsely occupied trie nodes, it allows for efficient lookups as it reduces the height of the trie to k_{max}/g. With $f = 256$, the maximum number of node accesses is $\lceil 60/\log_2(256) \rceil = 8$ for 30 quadtree levels.

Now we exploit a property of the hierarchical cells that we index: We *extend* their cell ids (keys) such that the key length matches the granularity of ACT. This process involves replacing a cell that we want to index with all its descendant cells at the next supported granularity level, and replicating the payload of the original cell to the smaller cells. In other words, if a cell does not match the tree granularity, we recursively split it into smaller cells that cover the same area. The following holds for indexed keys (cells):

$$level(cell) \bmod g = 0$$

Each cell c for which this equation does not hold is decomposed into a set of smaller cells C, with $|C| = 4^{g-(level(c) \bmod g)}$. This is possible since points are represented by cells at the most fine-grained grid level and use the maximum key length. Therefore, for a query point, it does not make a difference whether it matches with the originally inserted cell or with one of its descendant cells. This insight greatly simplifies the memory layout of a tree node and saves many CPU instructions: (i) we do not need to store the level with a cell, since all cells indexed in a tree node will have the same level, and (ii) a lookup in a node (an array) becomes a single offset access. Without this artificial key extension, we would need to perform multiple accesses per node to traverse all cell levels indexed in that node.

Figure 6 illustrates ACT indexing three polygons. While the example shows ACT with a fanout of four, by default we actually use a fanout of 256 to reduce the tree height. Every node thus consists of a fixed-sized array of 256 entries of 8 byte pointers. Entries that neither contain a child pointer nor a value point to a sentinel node indicating a false hit (no hit).

Values (i.e., polygon references) can be found in any level of the tree. This is because the indexed keys (64 bit cell ids in our case) typically use only a small fraction of the 64 bits with the remaining bits all set to zero. Larger cells that use fewer bits are indexed higher up in the tree, possibly even in the root node. In our example, polygon *a* is indexed by a cell in the upper level, while polygons *b* and *c* are indexed by cells in the lower level. Instead of storing values in separate nodes (e.g., adjacent to the tree nodes), we use combined pointer/value slots like in [25]. This design consumes less space and avoids an unnecessary indirection. Here, we exploit another property of the cell ids that we index: Cells in the super covering are disjoint, therefore a tree lookup will return at most one result. Due to this property, we never need to store a pointer and a value in an array entry at the same time. Using *pointer tagging*, we differentiate between pointers and values. We therefore refer to both pointers and values as *tagged entries*.

As stated before, each cell is associated with a set of polygon references. Thus, each value stored in the tree has to identify such a set. The canonical design would be to make each cell point to an entry in a lookup table that stores the references. However, at least in the case of largely disjoint polygons, cells mostly reference only one or two polygons. Therefore, to eliminate additional indirections, when there are no more than two polygon references, we store these references directly in the tree. A tagged entry can thus be:

- An 8 byte pointer to a child or the sentinel node (recall that a pointer to the sentinel node indicates a false hit)
- An inlined polygon reference (a 31 bit value)
- Two inlined polygon references (two 31 bit values)
- An offset (a 31 bit value) into a lookup table indicating that there are at least three polygon references

We use the two least significant bits of the 8 byte pointer to differentiate between these four possibilities. For an inlined polygon reference, we differentiate between a true hit and a candidate hit using the least significant bit of the 31 bit value. Thus, we can effectively only store 30 bit polygon ids (i.e., can index up to 2^{30} polygons).

We have experimented with path compression, but have found that storing common prefixes with inner and leaf nodes only barely reduces the number of nodes. Thus, the additional cache miss to access the prefix does not pay off. We therefore only use a common prefix at the root level.

We have also considered introducing adaptive node sizes, as proposed by the adaptive radix tree (ART) [25]. However, experiments have shown that introducing a second (compressed) node type with four children (Node4 in ART) (i) saves only a negligible amount of space for our workload and (ii) has a significant performance impact (due to the additional instructions and branch misses for dispatching between node types [25]). Also, lookups in compressed node types are more expensive.

Lookup Table. When a cell references more than two polygons, the tree contains an offset into a lookup table. Since cells often reference the same set of polygons, we only store *unique* polygon reference lists. The reference lists are split into two parts, a list with true hits and a list with candidate hits. Both lists contain

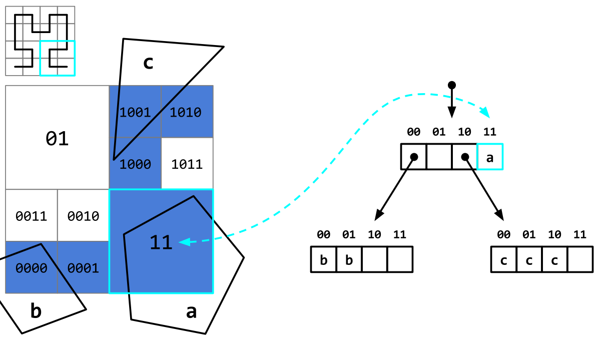

Figure 6: Adaptive Cell Trie indexing three polygons a, b, and c. Here, ACT uses two bits per level. In practice, we use up to eight bits (a fanout of 255) to reduce the tree height. Note that the figure only shows the cell rasterization for the part of the map that corresponds to the radix tree.

```
input:
  root node of ACT rootNode
  the cell id of the query point cellId
output:
  tagged entry taggedEntry
procedure:
  if (common prefix of rootNode does not match)
    return invalid entry
  level = 0
  currNode = rootNode
  bits = getBits(cellId, level++) // extract relevant bits
  // traverse the tree until we either hit the sentinel node or found a
       value
  while (taggedEntry = currNode.getEntry(bits) is a pointer) {
    if (taggedEntry points to the sentinel node)
      return false hit
    currNode = taggedEntry
    bits = getBits(cellId, level++)
  }
```

Listing 2: Probe Adaptive Cell Trie.

polygon ids. The lookup table is encoded as a single 32 bit unsigned integer array. The offsets stored in the tree are simply offsets into that array. Each encoded entry contains the number of true hits followed by the true hits, the number of candidate hits, and the candidate hits.

3.1.3 Index Probing. An ACT lookup returns, at most, one cell mapping to a set of polygon references. Listing 2 shows the probe algorithm. While traversing the radix tree does not involve any key comparison, a comparison is performed to check whether the returned tagged entry contains a payload. For that, we need to differentiate between (i) one polygon reference, (ii) two polygon references, and (iii) an offset. In the first case, we check whether the polygon reference is invalid, which indicates a false hit. Otherwise, we extract the interior flag (the least significant bit of the 31 bit payload) and the polygon id and return the reference. In the second case, we extract and return both references. Only in the third case, we need to access the lookup table to retrieve the polygon references.

3.2 Approximate Join with Precision Bound

The complete point-polygon join algorithm is shown in Listing 3. It is essentially an index nested loop join, using our novel ACT

```
input:
 points points // lat/lng coordinates and cell ids
 polygons polygons // lat/lng coordinates of vertices
 root node rootNode
 lookup table lookupTable
output:
 list of join pairs pairs // point/polygon pairs
procedure:
 for (point in points) {
  taggedEntry = probeAdaptiveCellTrie(rootNode, point.cellId) //
      cf., Listing 2
  if (taggedEntry is invalid)
   continue
  references = getPolygonReferences(lookupTable, taggedEntry) //
      returns a list of polygon references
  for (reference in references) {
   polygonId = reference.polygonId
   polygon = polygons[polygonId]
   if (reference is true hit) {
    add {point, polygon} to pairs
   } else { // candidate hit
#ifdef __APPROX
    // treat candidate hit as true hit
    add {point, polygon} to pairs
#else
    // EXACT: enter refinement phase
    if (polygonCoversPoint(polygon, point)) // PIP test
     add {point, polygon} to pairs
#endif
 }}}
```

Listing 3: The join algorithm.

index that makes the point-cell containment tests very efficient. For a given point, we retrieve the cell that contains it (if such a cell exists) and go over all references of this cell. When approximate results are sufficient, we omit the expensive refinement phase, simply treat all points contained in boundary cells as (approximate) hits, and immediately output the join pairs. In doing so, we introduce false positives. However, the distance of false positives from the polygon is bounded by the diagonal of the largest boundary cell: Any point contained in that cell has at most a distance of $\sqrt{2} * \epsilon$ (with ϵ being the side length of the cell) to the polygon. In order to control this distance, our approximate algorithm exposes a precision bound as a parameter to the user. Based on this bound, we compute the minimum cell level for boundary cells. For example, to guarantee a 4 m precision, the largest boundary cell can at most have a diagonal of 4 m, which corresponds to a minimum cell level of 22 in our implementation (i.e., cell level 21 would be too coarse-grained). We replace all boundary cells in the super covering with their descendant cells at the required level. For each of these descendant cells, we determine whether they intersect, are fully contained in, or do not intersect polygons at all, and update ACT accordingly: We remove the original cell c_o from ACT and insert *only* those descendant cells that intersect or are fully contained in polygons. The new cells may reuse the lookup table entry of c_o or create their own in the event that they only map to a subset of c_o's polygons.

Note that [39] makes use of a similar distance-based precision bound, however, uses a single-resolution grid. When it is not possible to maintain a sufficiently fine-grained index within a certain memory budget, the user can fall back on our accurate approach, in which we train the index with historical data points.

3.3 Accurate Join

When applications require accurate results, or when we cannot build an index that satisfies a user-defined precision without exceeding a memory budget, we use an approach that may enter the expensive refinement phase (cf. Listing 2). To minimize the number of (expensive) PIP tests, we increase the precision of the index by adapting it to the expected point distribution. Since we make use of true hit filtering, a finer-grained index allows us to identify more join partners during the filter phase.

3.3.1 Index Training. To minimize the likelihood of PIP tests, we train the index to adapt to the expected distribution of query points. We train ACT with historical data points (e.g., from a previous year) which has the effect that popular areas that expect more hits are approximated using a more fine-grained grid than less popular areas. This training process replaces *expensive* cells with up to four of their child cells. We define expensive cells as cells that map to polygon reference sets with at least one candidate hit. When we hit such a cell during the join, we need to perform expensive PIP tests.

Specifically, the training works as follows: When a training point hits an expensive cell, for each of its four child cells we check whether they intersect, are fully contained in, or do not intersect the referenced polygons at all, and update ACT accordingly. The cell replacement procedure is the same as for the approximate algorithm (i.e., remove original cell, insert descendant cells, and update lookup table, cf. Section 3.2) with the only difference being that we always replace an expensive cell with its direct children one level below. We do not replace a cell with even smaller cells to be more robust against outliers. In practice, we would stop refining the index once a user-defined memory budget is exhausted. In this work, we focus on training the index in a dedicated training phase. Training the index at runtime would introduce additional concurrency and buffer management issues that we leave for future work. We show the effect of training the index in Section 4.2.

3.4 Implementation Details

Join Predicate. Our current implementation follows the semantics of the ST_Covers join predicate (cf. PostGIS [30]). ST_Covers evaluates whether one geospatial object (e.g., a polygon) covers another (e.g., a point).

Individual Polygon Coverings. We compute the individual polygon coverings using the S2 library. Note that our approach does not depend on S2 and, in fact, works with any other quadtree-based hierarchical grid in which each (implicit) quadtree node [16] corresponds to a geographical area (space partitioning). For our approach to work, each quadtree node needs to be *uniquely identifiable* with a bit sequence that represents the path to the given node starting from the root. Thereby, any (consistent) enumeration scheme (e.g., the Hilbert space-filling curve used by S2 or the Z curve used by Roth [31]) of the four quadrants is valid. To store these encoded node identifiers in a trie, we require the identifiers of child nodes to share a common prefix with their parent node.

Face Nodes. Since our implementation uses S2, which projects points on Earth onto a surrounding cube, we need to maintain up to six radix trees (one for each face). Using the first three bits of the query cell id, we select the appropriate radix tree.

Index Probing. The probe (filter) phase is the performance-critical part of our approach. We therefore parallelize this phase to accelerate lookups in the radix tree. Individual processing threads fetch batches of 16 tuples at a time and synchronize using an atomic counter.

PIP Test. In the refinement phase, we use S2's PIP test, which implements the ray tracing algorithm (cf. [29] for performance numbers).

4 EXPERIMENTAL EVALUATION

In this section, we present a thorough experimental analysis of our point-polygon join algorithms. We use taxi data from NYC, which we join with different polygonal regions of NYC, such as neighborhoods. We also experiment with geo-tagged Twitter data from different cities. Besides these (skewed) real-world point datasets, we experiment with (uniform) synthetic point data. We focus our experiments on the probe phase of the join (probing points against a pre-built polygon index). For completeness, we also report build times.

Our evaluation is structured into three parts: First, we evaluate the performance and space consumption of our approximate algorithm with different data structures, including ACT, a B-tree, and a sorted vector. We demonstrate that for a city like NYC (with its 289 neighborhoods), an approximate index with very high precision (<4 m precision bound) easily fits into the main memory of a single machine and, in the case of ACT, allows for very high probe performance (>50 M points/s per CPU core). We think that this is a good fit with the city-centric model of mobility companies (e.g., Uber, DriveNow [13]). We show that ACT outperforms other physical representations by a large margin, while being more space-efficient in many cases. Second, we evaluate our accurate algorithm and show that it benefits greatly from true hit filtering. We compare it against other filter and refine approaches, including an R-tree on the polygons' MBRs, a geospatial index by Google, and PostgreSQL (PostGIS). We demonstrate that the high precision of our index can be further improved by training it with historical data points. Third, we show that both our algorithms are competitive with state-of-the-art GPU approaches.

Infrastructure. We use a server-class machine that is equipped with two 14-core Intel Xeon E5-2680 v4 CPUs and 256 GiB DDR4 RAM. All CPU-based approaches are implemented in C++ and compiled with GCC version 5.4.0 with `O3` and `march=core-avx2` flags. We conduct the experiments on a single socket to eliminate NUMA effects. For the comparison against the GPU join algorithms, we use these Amazon Web Services (AWS) instances [5]:

c5.4xlarge 16 vCPUs, USD 0.68/hour
g3s.xlarge NVIDIA Tesla M60 GPU, USD 0.75/hour

Datasets and Queries. We use 1.23 B points (pick-up locations) from the NYC yellow taxi dataset (years 2009 to 2016), which is publicly available in CSV format [38]. For each point, we load its lat/lng coordinate and convert it to an `S2Point` [33] (which represents a point on the unit sphere as a 3D vector of doubles) and to an `S2CellId` (an 8 byte value, cf. Section 2) prior to performing any experiments. We maintain one `std::vector` of `S2Points` and another one storing the corresponding cell ids. We join these points against the polygon datasets summarized in Table 1 (top). All three polygon datasets cover approximately the same area. While there are only five boroughs, their polygons are significantly more complex.

In addition, we use geo-tagged tweets collected from Twitter's live public feed over a period of five years. From these, originally over 2.29 B tweets spread across the entire US, we extract four point datasets based on the MBRs of NYC, Boston (BOS), Los Angeles (LA), and San Francisco (SF), consisting of 83.1 M, 13.6 M, 60.6 M, and 9.57 M points, respectively. We join these points against the corresponding neighborhood polygons: NYC (289), BOS (42), LA (160), and SF (117). Since we extract the points using the MBR of the entire polygon dataset and not the individual neighborhood polygons, there are points that do not join with any polygon.

We also generate synthetic point datasets, uniformly distributed within the MBR of the respective polygon dataset.

We focus our experimental evaluation on the probe phase and simply count the number of points per polygon instead of materializing the join result. To avoid any contention in the multi-threaded experiments, we maintain thread-local counters that we aggregate in the last step. Since we are focusing on the case of static polygons, the reported throughput times reflect the time to compute the counts using an *existing* (pre-built) polygon index. We report the time it takes to build the polygon index separately. However, we would like to point out that we did not optimize the build phase.

Polygon Approximations. Our default configuration for computing the individual polygon coverings is as follows: max covering cells = 128, max covering level = 30, max interior cells = 256, and max interior level = 20.

4.1 Approximate Join

We first analyze the performance and space consumption of our approximate algorithm. In all of the following experiments, we first build super coverings (sets of cell/value pairs, cf. Section 3) and then index them with different data structures.

Super Covering Construction. Table 1 shows different metrics of the super coverings for the three polygon datasets with 60 m, 15 m, and 4 m precision. With each cell occupying 64 bits, the largest super covering (census 4 m, 39.8 M cells) amounts to 304 MiB of raw key data and another 304 MiB for the values (64 bit tagged entries, cf. Section 3). Given that most cells reference fewer than three polygons, most polygon references are inlined, which keeps the lookup table small. While the computation of the individual coverings is parallelized over the number of polygons, the construction of the super covering is performed serially.

Data Structures. We essentially need to map cell ids (64 bit integers) to tagged entries (64 bit values). A tagged entry either contains up to two polygon references or an offset into a lookup table. The lookup table is the same among all data structures that we evaluate. The data structure needs to support prefix lookups: given a 64 bit lookup key (the cell id of a query point), find the cell in the super covering (recall that it only contains non-overlapping cells) that shares a common prefix with the lookup key (if such a cell exists). We analyze ACT with three different fanouts: 2, 4, and 8 bits per radix level, which corresponds to 1, 2, and 4 quadtree levels, respectively. Recall that one quadtree level is encoded with two bits. We therefore refer to these three variants as ACT1, ACT2, and ACT4. As competitors we use a B-tree implementation by Google [11] (GBT) and a binary search on a sorted vector implemented with `std::lower_bound` (LB). For GBT, we use a (target) node size of 256 bytes, which turned out to be the most query-efficient configuration. The vector stores pairs of cell ids and tagged entries. We have also experimented with the STX B+-tree [36] but do not include it in this section as its lookup performance is very similar to that of GBT.

The performance of our approximate algorithm is dominated by the costs of the ACT node accesses and the aggregation (count).

Table 1: Metrics of the NYC polygon datasets and of three super coverings with various precisions.

polygons (# polygons / avg. # vertices)	boroughs (5 / 662)			neighborhoods (289 / 29.6)			census (39,184 / 12.5)		
precision [m]	60	15	4	60	15	4	60	15	4
# cells [M]	0.09	1.32	20.9	0.16	0.98	14.0	8.50	8.97	39.8
lookup table [MiB]	0.00	0.00	0.00	0.01	0.01	0.01	1.33	1.33	1.41
build individual coverings [s]	0.11	0.98	16.0	0.07	0.19	1.54	0.96	1.01	3.08
build super covering [s]	0.10	0.94	15.2	0.17	0.81	10.5	11.6	11.8	37.7

Table 2: Metrics of the different data structures (4 m precision).

super cov.	boroughs (20.9 M cells)					neighborhoods (14.0 M cells)					census (39.8 M cells)				
index	ACT1	ACT2	ACT4	GBT	LB	ACT1	ACT2	ACT4	GBT	LB	ACT1	ACT2	ACT4	GBT	LB
size [MiB]	328	198	173	359	319	224	138	143	240	214	624	421	1234	684	608
build [s]	2.11	1.46	1.06	1.39	-	1.36	0.98	0.69	0.85	-	4.00	3.11	2.80	2.85	-

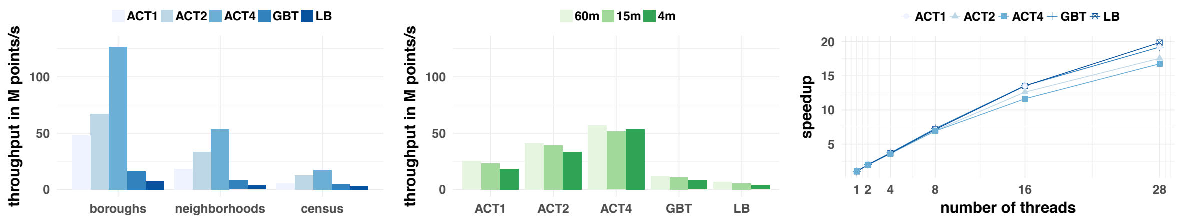

Figure 7: Throughput and scalability of our approximate algorithm (taxi dataset). Left: Single-threaded execution with different data structures (4 m precision). Middle: Single-threaded execution with different precisions and data structures (neighborhood polygons). Right: Multi-threaded execution (neighborhood polygons, 4 m precision).

To better understand the results, we therefore first analyze the space consumption of ACT and compare it with GBT and the sorted vector. Table 2 shows size and build time (single threaded) of the different data structures on the super coverings introduced above (4 m precision only). In many cases, ACT consumes less space than the sorted vector (LB). Due to the high density of the cell ids, ACT is more space-efficient with higher fanouts, except for census where ACT4 consumes the most space: Like for all datasets, ACT4 has fewer (but larger) nodes than ACT1 and ACT2. However, in this case, its nodes are very sparsely populated compared to those of ACT1 and ACT2. The reason is that ACT4's nodes cover too much space for the relatively small census cells. To mitigate the size impact of sparse ACT nodes, one can represent them with a more compact data structure [4]. All 4 m indexes exceed the 35 MiB L3 cache of our evaluation machine. Note that there is no additional build time for LB, since the super covering contains cell id/tagged entry pairs already sorted by cell id.

Single-Threaded Throughput. For this experiment, we compute a super covering with a 4 m precision bound on the three NYC polygon datasets and store it in the different data structures introduced above. We then join the full taxi dataset (all 1.23 B points) against each of these indexes and report the throughput in M points/s (cf. Figure 7 (left)).

ACT clearly dominates the B-tree and the binary search on the sorted vector, especially in its highest fanout configuration (ACT4). A higher fanout means that we consume more bits of the lookup key per tree level and thus require fewer node accesses (i.e., need to traverse fewer levels) to find a key (an indexed cell). With ACT4 for example, we consume 8 bits per tree level and thus need at most 64/8 = 8 node accesses. Since we reduce the tree height further by storing a common prefix at the root level (cf. Section 3), ACT requires even fewer node accesses (e.g., at most five with 4 m precision).

Table 3: Speedups of lookups in smaller (more coarse-grained) over larger (more fine-grained) polygon datasets for different data structures (b = boroughs, n = neighborhoods, c = census).

	b over n	b over c	n over c
ACT1	**2.63×**	**8.63×**	**3.28×**
ACT2	2.00×	5.33×	2.66×
ACT4	2.36×	7.29×	3.08×
GBT	2.05×	3.51×	1.71×
LB	1.83×	2.63×	1.44×

Another insight is that ACT benefits the most from the larger (coarser-grained) cells in the smaller polygon datasets as shown in Table 3. Going from the most fine-grained census dataset (39,184 polygons) to the most coarse-grained boroughs dataset (5 polygons), GBT's lookup performance improves by 3.51×, while ACT1's increases by 8.63×. The reason for ACT's large gain is that larger cells are indexed higher up in the radix tree and are thus found sooner. GBT, in contrast, does not benefit from these larger cells, which might as well be stored in the leaf nodes of the B-tree. GBT's performance gain comes from the smaller number of cells used for indexing the boroughs dataset and the resulting smaller B-tree (i.e., fewer branch and cache misses per point).

Table 4: Distribution of the tree traversal depth (ACT4 with 4 m precision).

points	boroughs	neighborhoods	census
uniform			taxi			

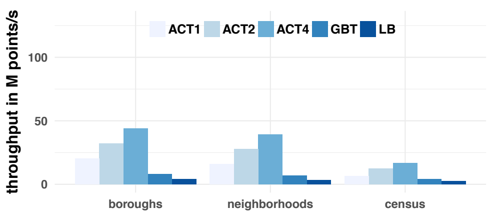

Figure 8: Single-threaded throughput of our approximate algorithm (4 m precision) with uniform point data.

Likewise, the binary search on the sorted vector (LB) is only affected by the number of cells and not their granularity.

Different Precisions. Next, we vary the precision of the indexed super covering. We perform this experiment using the medium size neighborhoods dataset. Figure 7 (middle) shows the throughput numbers for the different data structures. While GBT's and LB's performance decreases by 33.4% and 39.4%, respectively from 60 m to 4 m, ACT4's performance is hardly affected (-5.73%) by the larger number of cells of the more precise super covering. Compared to the 60 m covering, the more precise coverings contain a larger number of small cells (in the boundary areas of the polygons). Query points are unlikely to hit these cells in contrast to the large (more coarse-grained) cells, which are indexed in the upper (cached) ACT nodes (due to their shorter cell ids). ACT1 and ACT2 are more affected by the precision increase (-27.8% and -17.9%, respectively). The reason is that the added small cells have a stronger effect on the depths of these trees. While the average node depth for ACT4 only increases from 2.83 to 2.97 (+4.95%) from 60 m to 4 m respectively, the same metric increases from 10.8 to 14.6 (+35.2%) for ACT1. Although—as already stated above—the new small cells are unlikely to be hit, they still cause a performance hit for lower fanouts.

ACT4's throughput is similar for 15 m and 4 m (-4.15%) because its structure is identical for both precisions. In both cases, it has 70,786 nodes occupying 143 MiB. The only difference is the nodes' structure: Due to the more fine-grained cell approximation, the average node occupancy (measured in terms of occupied slots) of ACT4 at tree level 3 decreases from 88.2% (60 m) to 85.2% (4 m). The occupancies of all other levels are the same. This lower occupancy for 4 m saves some aggregations (for updating the polygon hit counts), causing a slightly higher performance.

In summary, the impact of precision on query performance is less significant for ACT than for the other data structures.

Multi-Threaded Throughput. In this experiment, we study the lookup performance of the different data structures with an increasing number of threads on the neighborhoods dataset with a 4 m precision bound. We use up to 28 threads, which matches the number of hyperthreads of a single NUMA node of our evaluation machine. Figure 7 (right) shows the speedups over single-threaded execution. Up to 8 threads, all index structures scale almost linearly (speedup of around 7× in all cases). This is what we would expect for immutable data structures.

The fact that an oversubscription of cores (hyperthreading) has a positive performance impact suggests that the lookup is bound by memory access latencies (having more threads than physical cores can hide these latencies).

Synthetic Points. To show the general applicability of our approach, we also experiment with synthetic point data. We generate 100 M points uniformly distributed within the MBR of the respective (NYC) polygon dataset. Table 4 shows the probability distribution of the number of search steps during the tree traversal for the synthetic and the taxi point dataset. As expected, the distribution for the uniform data is skewed towards the root. That is because the larger cells (which are more likely to be hit) are indexed closer to the root. The distribution for the taxi data depends on the polygon dataset. For boroughs, most traversals end at tree level 1, while for census, points mostly hit small cells indexed in tree level 3.

Figure 8 shows the single-threaded throughput for the different data structures with the uniform point data. ACT achieves the highest throughput, with ACT4 again being the most query-efficient configuration. The absolute numbers, however, are lower than for the (real-world) taxi data: ACT4's throughput decreases by 65.2%, 26.8%, and 3.11% for boroughs, neighborhoods, and census, respectively.

The reason for this slowdown is simple: The synthetic point data is uniformly distributed, which leads to more branch and cache misses (cf. Table 5 for performance counters on neighborhoods). In contrast, the real-world taxi data is highly clustered with the majority of points located in Manhattan (>90%) and around the airports. For boroughs (not shown in Table 5), ACT4 endures 0.79 and 0.01 branch misses per point for the synthetic and the taxi points, respectively. This is the main cause of the 65.2% performance drop mentioned above.

Twitter Data. Next, we analyze the performance of our approach on the four Twitter datasets and the corresponding neighborhood polygons (cf. Figure 9). The numbers are similar across the different cities, with the highest throughput achieved for BOS with its only 42 neighborhood polygons. Next comes SF followed by LA and NYC, for which the throughput is very close to what we obtained with the taxi data (cf. Figure 7 (left)). In fact, with a 4 m precision, ACT4 achieves a single-threaded throughput of 52.1 M points/s, which is almost the same as the 53.6 M points/s on the taxi data. Similarly to the taxi points, the tweets are clustered, with certain areas having more tweeting activity than others. In contrast, with uniform point data, ACT4 only achieved 39.3 M points/s. This confirms that our approach benefits from the skewed distribution of real-world data. For all four cities, the numbers are (again) hardly affected by the precision.

4.2 Accurate Join

We now evaluate our accurate algorithm, which eliminates false positives in an additional refinement phase. We demonstrate that our index benefits significantly from true hit filtering and that index training with historical data can further improve its effect.

Competitors. We compare against the boost R-tree (1.6.0) [8] on the polygons' MBRs (RT), Google's S2ShapeIndex [34] (SI), and PostgreSQL 9.6.1 (PostGIS 2.3.1) [30] with a GiST index on

Table 5: Performance counters per point (neighborhoods, 4 m precision).

points	uniform					taxi				
index	ACT1	ACT2	ACT4	GBT	LB	ACT1	ACT2	ACT4	GBT	LB
cycles	154	99.8	71.3	415	569	172	93.8	56.4	416	817
instructions	214	121	82.4	486	927	202	121	81.3	393	564
branch misses	1.06	1.04	0.88	5.32	8.38	0.96	0.83	0.48	7.06	10.8
cache misses	0.29	0.23	0.18	0.70	1.89	0.22	0.17	0.15	0.29	0.37

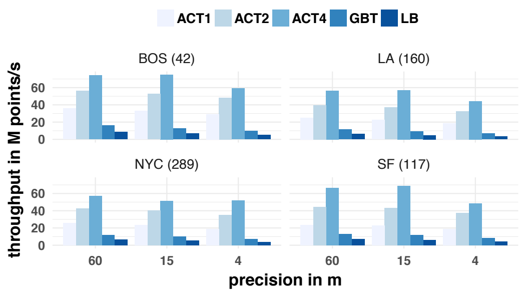

Figure 9: Single-threaded throughput of our approximate algorithm (Twitter datasets, polygon counts in brackets).

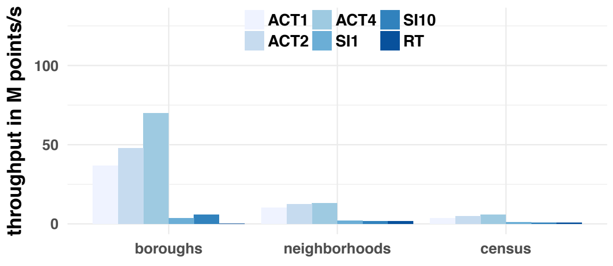

Figure 10: Single-threaded throughput of our accurate algorithm (with different ACT fanouts) compared to S2ShapeIndex (with 1 and 10 edges per cell) and the R-tree.

polygons (PG). Our algorithm and the R-tree both use the same PIP test implementation (cf. Section 3.4). SI also uses that implementation, however, restricts the test to a subset of edges of the polygon in question. This is achieved by using a hierarchical grid approximation of polygons, and internally mapping grid cells (64 bit S2CellIds) to polygon edges using a B-tree. This hierarchical grid approximation is much more coarse-grained than our super covering, given its higher focus on build time than on query performance (compared to our approach). SI allows the maximum number of edges per cell to be configured, essentially controlling the granularity of the employed grid approximation. We evaluate SI with its default configuration of 10 edges (SI10) and 1 edge per cell (SI1). Note that SI1 is the most fine-grained configuration possible. SI also employs true hit filtering (cf. Section 3) to avoid PIP tests, but in a much less effective way than ours (due to its coarser-grained grid). Furthermore, SI does not offer an approximate version. For the R-tree, we use the splitting strategy `rstar` with at most 8 elements per node which performs best in all workloads.

Taxi Data. For this experiment, we compute coarse-grained super coverings that do not guarantee a certain precision, and instead fall back on a refinement phase for candidate hits. Here, the resolution of a super covering is determined by our default configuration for computing individual polygon coverings introduced earlier (cf. Section 4). Thus, these super coverings consist of much fewer cells than those guaranteeing a certain precision. For example, the approximation for the neighborhoods dataset now only consists of 98,687 cells (ACT4 size: 25.9 MiB) compared to the 13.2 M cells (ACT4 size: 143 MiB) needed to guarantee a 4 m precision. For this dataset, SI1, SI10, and RT consume 1.20 MiB, 0.23 MiB, and 27.9 KiB, respectively.

Figure 10 shows the single-threaded throughputs for the accurate join. ACT4 achieves the highest performance for all three datasets. For the medium size neighborhoods dataset, it outperforms SI1 by 6.96×, followed by SI10, which is only 7.41% slower than SI1. For census, ACT4 still outperforms SI1 by 5.79×. RT has the lowest numbers with 0.21, 1.77, and 0.79 M points/s for boroughs, neighborhoods, and census, respectively. The reason for its slow performance for boroughs is as follows: The complexity of each PIP test (ray-tracing algorithm) is linear with the size (number of edges) of the polygon. Since the boroughs are complex polygons with many edges, the PIP tests in the refinement phase are very expensive. Here, our algorithm shines since it can identify most join partners in the filter phase and only enters the refinement phase for 0.1% of the points. As a point of reference, PG achieves 0.39, 1.09, and 0.69 M points/s for boroughs, neighborhoods, and census, respectively (because we use all hyperthreads on our evaluation machine, PG's numbers are not directly comparable and are excluded from the plot). Similar to RT, PG is affected by the complex boroughs polygons.

Index Training. As readers may have noticed, there is a large performance gap between our approximate and our accurate algorithm. For example, ACT4 (accurate) is 75.3% slower than its approximate counterpart (with 4 m precision) on the taxi data/neighborhoods join. The reason is the expensive PIP tests needed to compute an accurate result.

We now show how to narrow this performance gap. The idea is to reduce the likelihood for PIP tests by training the index with historical data points (cf. Section 3.3.1). In other words, we increase the precision of the index by making it more fine-grained in areas where we expect more points. One effect this has is that the size of the area covered by (expensive) boundary cells will decrease. We train the index with taxi points sampled from the year of 2009 and only use the points from 2010 to 2016 for the join. Table 6 shows the performance impact. With 100 K training points, ACT4's performance improves by 1.56× for neighborhoods and increases further to 2.18× with 1 M points (due to a 84.0% reduction in the number of PIP tests). The size of ACT4 only increases from 25.9 MiB (untrained) to 28.0, 34.8, and 44.3 MiB when trained with 100 K, 500 K, and 1 M historical data points, respectively. In absolute terms, ACT4 trained with 1 M points achieves a throughput of 29.1 M points/s for neighborhoods and

Table 6: Speedups of single-threaded lookups when training ACT4 with an increasing number of historical data points (over untrained ACT4).

no. of train. points	boroughs	neighborhoods	census
100 K	1.25×	1.56×	1.16×
500 K	1.40×	2.00×	1.40×
1 M	1.44×	2.18×	1.53×

Table 7: Effect of training the index with 1 M historical data points (STH = solely true hits).

metric	boroughs	neighborhoods	census
STH (%)	99.9 → 99.9	87.2 → 97.7	72.2 → 88.7

thus narrows the performance gap to its approximate counterpart (with 4 m precision) from 75.3% to 45.7% while consuming 68.9% less space. This shows that a trained accurate index is a good alternative to our approximate indexes when main memory is sparse. Table 7 shows the effect of true hit filtering when training the index with 1 M training points. The metric `solely true hits` (STH) indicates the percentage of points that skipped the expensive refinement phase, which is clearly above 70% in all cases (even without training). Training the index significantly improves STH for neighborhoods and census.

4.3 Comparison with GPU Algorithms

Finally, we compare our approximate and accurate (untrained ACT) algorithms against state-of-the-art GPU counterparts [39]. The GPU approaches leverage the graphics rendering pipeline, and in particular the rasterization operation, which converts a polygon into a collection of (equi-sized) pixels. Similar to our approach, the GPU join also comes in two variants: Bounded Raster Join (BRJ), which guarantees a user-defined precision by appropriately scaling the rendering resolution, and Accurate Raster Join (ARJ), which performs PIP tests for points falling on the pixels forming the boundaries of the polygons. To enable a fair comparison, we do not consider any preprocessing times on the polygons (such as triangulation time). Note that the preprocessing time for the GPU join is minimal. In fact, it is designed for computing the join on-the-fly without a priori knowledge of the polygonal regions.

We now compare the throughput of both approaches on two similarly priced AWS machines (cf. Infrastructure in Section 4). Figure 11 shows the results of joining 612 M taxi rides with the NYC polygon datasets. While our approximate algorithm is again hardly affected by the precision (15 m vs. 4 m), BRJ takes a significant performance drop. The reason for BRJ's slowdown is simple: Once the required resolution is higher than what is natively supported by the GPU, it needs to split the scene and perform more rendering passes. This is essentially related to the fact that BRJ relies on a uniform grid. On the contrary, BRJ is barely affected by the polygon datasets, while our approximate algorithm is. The reason is again related to the granularity of the grid: With the more fine-grained census dataset, we need to traverse more tree nodes (as the cells that approximate the polygons are smaller), while the rendering resolution in BRJ depends only on the size of the bounding box of the polygon dataset and the precision. With

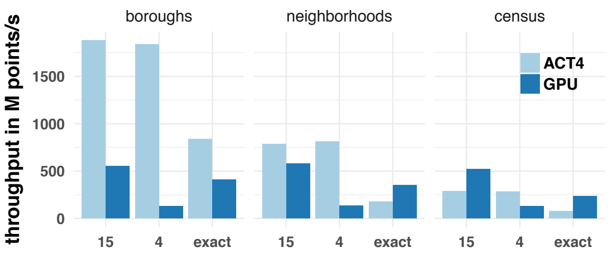

Figure 11: Throughput of ACT4 (16 threads) compared to the two GPU algorithms on AWS (GPU = Bounded Raster Join for 15 m and 4 m and Accurate Raster Join for exact).

exact results, our approach outperforms ARJ for boroughs, while ARJ takes the crown for neighborhoods and census.

5 RELATED WORK

Prior Publications. In [24], we describe a novel approach to reduce control flow divergence on AVX-512 platforms to further increase ACT's lookup performance. Note that [24] is based on an earlier (4-page) version of this work [22].

Spatial Join Techniques. The point-polygon join is one of the core operations in spatial databases, and, a large body of related work on algorithmic techniques [19] is available accordingly.

Naturally, we are not the first to index polygons using raster approximations. Early on, Orenstein [27] proposed decomposing single polygons into multiple cells. Later, Brinkhoff et al. [9] proposed true hit filtering in the form of maximum enclosed rectangles and circles, allowing the refinement phase to be skipped in many cases. Zimbrao et al. [49] followed up on this approach by using raster approximations in the form of uniform grids, thereby improving selectivity. Kothuri et al. [20] recursively divide the MBR of a polygon into four cells until a certain granularity is reached, identify interior cells, and index them in an R-tree to skip refinement checks. The primary goal was to minimize I/O, an important performance factor for disk-based systems. In contrast to these early works on true hit filtering and also to the recent proposal by Tzirita Zacharatou et al. [39], we use a quadtree-based (multi-resolution) grid that can be very coarse-grained in interior and very fine-grained in boundary areas.

Research has, however, also been performed on true hit filtering with quadtree-based rasterizations, including work in Oracle Spatial [21] and Microsoft SQL Server [15]. In both of these works, *individual* polygons are approximated using a set of multi-resolution grid cells. These grid cells are enumerated using one-dimensional cell identifiers and stored in a B-tree. In contrast, we *holistically* approximate and index an entire set of polygons and store these (in our case duplicate-free) cell identifiers in a novel radix tree (ACT), which is more query-efficient than a B-tree. Additionally, these existing approaches neither offer an approximate mode nor allow the accurate index to be trained with historical data points to improve query performance.

To decrease the probability of false matches, [35] improves the precision of MBRs by clipping away empty space that is concentrated around the MBR corners. In contrast to our work, [35] uses the classical filter and refine evaluation strategy.

Related to our approximate algorithm is work by Azevedo et al. [7] that provides precision estimates for approximate polygon-polygon joins using a less space-efficient single-resolution grid. Tzirita Zacharatou et al. [39] propose a similar precision bound to ours but also use a single-resolution grid (cf. Section 4.3 for a comparison).

The PH-tree [47] is another example of a trie data structure that indexes multi-dimensional data. In contrast to ACT, it only indexes points, not higher-level grid cells. Winter et al. [43] propose a query-efficient storage layout for point data that automatically adapts to polygonal queries. Along the same lines, Vorona et al. [42] train a model to approximately answer spatial aggregation queries.

Systems. Several database systems support geospatial joins. PostGIS [30], a geospatial extension to PostgreSQL [1], uses an R-tree implemented on top of GiST [18] for indexing geospatial objects. In recent years, various spatial data management systems based on Hadoop [3, 14] and Spark [26, 37, 44, 46] have emerged. [28] provides a comprehensive analysis of these modern spatial analytics systems by a thorough experimental evaluation. In contrast to our work, most of these systems rely on offline partitioning of the data points.

Modern Hardware. Most work on using modern hardware for geospatial joins focuses on GPU offloading [2, 12, 39, 45, 48] while [10] proposes a GPU-accelerated end-to-end spatial system.

6 CONCLUSIONS

We have presented two point-polygon join algorithms that use a multi-resolution grid indexed in a query-efficient radix tree. We have transformed a traditionally compute-intensive problem into a memory-intensive one. We have shown that it is possible to refine the index up to a user-defined precision and identify all join partners in the filter phase. We have demonstrated that the accurate version of our algorithm can adapt to the expected point distribution. We have also shown that our approach outperforms existing CPU-based joins by up to two orders of magnitude and can compete with dedicated GPU implementations.

ABSTRACT

With the web-scale data volumes and high velocity of generation rates, it has become crucial that the training process for recommender systems be a *continuous* process which is performed on live data, i.e., on *data streams*. In practice, such systems have to address three main requirements including the ability to adapt their trained model with each incoming data element, the ability to handle concept drifts and the ability to scale with the volume of the data. In principle, matrix factorization is one of the popular approaches to train a recommender model. Stochastic Gradient Descent (SGD) has been a successful optimization approach for matrix factorization. Several approaches have been proposed that handle the first and second requirements. For the third requirement, in the realm of data streams, distributed approaches depend on a shared memory architecture. This requires obtaining locks before performing updates.

In general, the success of main-stream big data processing systems is supported by their shared-nothing architecture. In this paper, we propose `DISGD`, a distributed shared-nothing variant of an incremental SGD. The proposal is motivated by an observation that with large volumes of data, the overwrite of updates, lock-free updates, does not affect the result with sparse user-item matrices. Compared to the baseline incremental approach, our evaluation on several datasets shows not only improvement in processing time but also improved recall by 55%.

1 INTRODUCTION

We are living in the era of data abundance whereby good decisions are backed by data-driven approaches. In addition to business-related decisions, we can use data for our personal daily lives. For example, what products to buy, where to have lunch, and best places to spend our vacations are all decisions that we need to make.

Recommender systems [11] have emerged to predict and suggest objects that could be of interest to the user. In general, recommender systems receive input in the form of user-item rating. These ratings are used to update a rating matrix R where the rows represent the users and columns represent items, where usually R is sparse. Collaborative filtering (CF) [5] is a successful technique to guess user preferences based on R. Matrix factorization-based (MF) CF algorithms have shown to be successful. For example, it was able to win the Netflix prize [2]. MF works by decomposing R into two low-dimension vectors of latent factors. Stochastic Gradient Descent (SGD) is used to optimize the weights of these latent factors. In general, SGD is an iterative algorithm that works on a static data set. As data velocity have accelerated, there has become a crucial need to get recommendations with low latency. Therefore, the need to analyze these data and generate new suggestions moved from an offline task on a finite set of data into an online task on a possibly infinite *stream* of data. Thus, a scalable online recommender system has to address three main requirements [3]: 1) The model must be able to produce a result and be updated after each record has been received without passing over all the past data (*latency*). 2)*Concept drifts* [10] ought to be taken care of by adjusting the model with each instance. 3) Online learning from big data must be processed in a distributed streaming environment (*scalability*).

Vinagre et al. [12] have proposed ISGD as an incremental SGD that needs to process each data element once in a streaming fashion. ISGD addresses the first and second requirements above. Yet, it remains a centralized (one worker) solution. Several approaches have introduced parallel (distributed) variants of (I)SGD [1, 4, 6, 7, 13]. However, the common limitation in these approaches is the need to access a shared memory to update the weights among parallel workers. In an online-setting, the overhead to obtain a lock leads to higher latency. An interesting observation by Recht et al. [9] is that with large data, having a lock-free update mechanism, i.e. lost updates, does not affect the overall performance and SGD finally converges. The authors also prove it. Based on this observation, in this paper, we present `DISGD` as a distributed shared-nothing variant of ISGD. By utilizing the shared-nothing architecture, we allow the best *scalability* as each worker is independent. In particular, the main contributions of this paper can be summarized as follows:

- DISGD: A distributed shared-nothing incremental stochastic gradient descent for a distributed online recommender system (Section 2),
- A comparative evaluation with the baseline ISGD on several data sets showing the superiority of our approach not just in the processing speed but also in the improved recall (Section 3).

2 DISGD

ISGD [12] is an incremental matrix factorization algorithm that is based on SGD. ISGD works centrally where training data are streamed element-by-element. For every received element, ISGD updates the model. So this algorithm overcomes the first two challenges we mentioned in Section 1. In this section, we describe our approach towards addressing the third challenge, scalability.

2.1 Background

In order to reach a scalable ISGD, we depend on the observation that usually the ratio of items to users is petite. For instance, Netflix data set has millions of users and only thousands of items. We start from the observation that the rating matrix $R^{n \times m}$ is sparse. So, we decompose the rating matrix into two matrices, the users' matrix $U^{n \times k}$ and the items' matrix $I^{m \times k}$ with low-dimension k, where $k << n$ and $k << m$, latent features that underlie the items' rating by users. So, we can predict the rating of user u to item i in $R^{n \times m}$, by calculating the dot product between their vectors as in Formula 1.

$$\hat{r_{ui}} = U_n . I_m^T = \sum_{k=1}^{k} u_{nk} . i_{mk} \tag{1}$$

The two matrices U and I are initialized with Gaussian random values. Then, iteratively, SGD calculates how different their product is from the rating matrix R and then makes an effort to minimize this difference. ISGD is dealing with positive feedback only so the error can be calculated by $err_{ui} = 1 - \hat{R_{ui}}$ and we are following that in our algorithm. Furthermore, the gradient descent algorithm iterates many times and updates the vectors which are the rows of the matrices U and I with the purpose of finding a local minimum of the difference following the loss function formulated in 2 where λ is the regularization parameter.

$$min_{U.,I.} \sum_{(u,i) \in D} (R_{ui} - U_u . I_i^T)^2 + \lambda(\|U_u\|^2 + \|I_i\|^2) \tag{2}$$

To parallelize ISGD by distributing the workload among n_c processors, the rating matrix R has to be divided into several blocks and the blocks get assigned to different processors. The issue here is that two processors working on different blocks may need to update the same column of U and/or I. The blocks must be distributed in a way that avoids conflicting updates. Our proposal to solve this problem, and thus addressing the scalability challenge, is by utilizing a splitting and replication mechanism of users and items vectors.

2.2 Splitting and Replication Mechanism

Receiving the rating interactions from users formulated as $<u, i, r>$, Algorithm 1 will distribute the received streamed data of tuples by hashing each record where the user vector and item vector reside over the nodes. For each received tuple $< u, i, r>$, ISGD updates the user vector and the item vector according to the two equations below, where η is the gradient step size.

$$U_u = U_u + \eta(err_{ui} . I_i - \lambda U_u) \tag{3}$$

$$I_i = I_i + \eta(err_{ui} . U_u - \lambda I_i) \tag{4}$$

The aim behind our splitting and replication mechanism is to guarantee that the vectors of users and items are divided over the nodes as it would grow larger than the capacity of one node (central solution). It is assumed that the items are known beforehand. Hence, starting by the item matrix, it is divided into n_i splits (partitions) and each split is replicated over n_c/n_i of the nodes -where n_c is number of nodes in the cluster- while each user vector should exist in n_i of the nodes to always guarantee that a tuple $<u, i, r>$ hits one node where its user and item vectors reside. As a requirement, the number of nodes in the cluster n_c should be equal to $n_i^2 + w.n_i$ where $w \in \mathbb{N}_0$. The distribution technique in Algorithm 1 offloads the storage of vectors to around n_i/n_c of the nodes. For example, when $n_i = 2$, the item matrix I is divided into two halves, each half is stored on half of the nodes. The user matrix U is divided over $n_c/2$ of the nodes and each user vector should exist in two nodes, given $n_i = 2$, over the cluster. Hence, any received tuple is always distributed, in such a way that its user and item vectors are always represented in only one node. Thus, the entire rating matrix will not be needed at any point of time for any single processing task.

Algorithm 1: Parallel ISGD algorithm

```
Data: data stream of {< u, i, r >} ∈ D
Input: N, λ, η, n_i, k
Output: Top N recommended list.

2:     $n_c = n_i^2 + w.n_i$
3:     iList ← Map hashing of item id to its $n_c/n_i$ of nodes
4:     uList ← Map hashing of user id to its $n_i$ nodes
5:     key ← Get the common node from uList and iList
6:     outStream < key, u, i, rate >
7: end function
while receiving {< u,i,r >} ∈ D on each node do
    DISTRIBUTINGFN(u,i,n_i)
    if $u \notin Rows(U)$ then
        $U_u$ ← Vector(size : k);
        $U_u \sim \mathcal{N}(0,0.1)$;
    end
    if $i \notin Rows(I)$ then
        $I_i$ ← Vector(size : k));
        $I_i \sim \mathcal{N}(0,0.1)$;
    end
    $err_{ui} \leftarrow 1 - U_u . I_i^T$;
    $U_u \leftarrow U_u + \eta(err_{ui} . I_i - \lambda U_u)$;
    $I_i \leftarrow I_i + \eta(err_{ui} . U_u - \lambda I_i)$
end
```

Algorithm 1 describes how we scale ISGD by means of splitting and replication of the users and items vector. A new top N recommendations list is generated every time a tuple is received. Based on the distributing mechanism shown in Figure 1. This function accords a key to the tuple for maintaining that the pair of user and item vector exists in one node while the single item vector should be in n_c/n_i nodes and the single-user vector should reside in n_i of nodes. This key is produced by hashing the user and item then mapping the hashing output to a predefined list of n_i nodes and n_c/n_i nodes and get the common node number to be the key whereby this key is used for distributing. This node processes the received data and outputs top N recommendations. This particular node only processes $1/n_i$ of the items matrix I that is received in the hashing process described earlier. This does not mean that this particular user will always get his recommendation from this node based on the same items.

It is a random process, based on which $1/n_i$ of the items stored in which node that tuple hits. Moreover, the repetition of the user vector helps offload the storage, making it possible for the algorithm to recommend items for user from different n_i pools of candidates which boosts our recommendation algorithm by giving a wide view for all the items. Algorithm 1 does not need to synchronize between the n_i same user's vectors or n_c/n_i same item's vectors repeatedly stored in the nodes, as Figure 1 shows. It has been proved by Recht et al. [9] that SGD algorithm running over parallel processors with shared memory can converge when the threads overwrite each other and calculate gradient using the outdated current solution which leads to asynchronous machine learning algorithms. Keeping the vectors asynchronous accomplishes two important things, first, it makes DISGD faster and avoids any synchronization or need for lock management.

```

3 EVALUATION

We evaluate DISGD against ISGD as a baseline. The evaluation experiments are done without handling cold start problem as it is not our concern in this paper. We follow prequential evaluation[8] which is suitable and mostly used for streaming algorithms. Prequential evaluation works as follows: for every received instance; it is used first for testing then feed the model with it for training. Specifically, we are following prequential evaluation for streaming recommender systems proposed by Vinagre et al. [12] using the recall evaluation metric which gives indication of how many true positive hits from the user side to the recommendation list by measuring the ratio of relevant items recommended to the total. We compute recall as per Algorithm 2.

The hyperparameter values of equations 3 and 4 used in our experiments are $\lambda = 0.01$, $\mu = 0.05$. We compute the recall with $N = 10$ and set the number of latent features to $k = 10$. DISGD has been implemented on top of Apache Flink version 1.8.1 deployed in a standalone cluster mode with 64 workers. Each worker is a single core running at 2.3 *GHz* with 30 *GB* of main memory. To run the baseline ISGD, we implemented it also as a Flink application and force it to run on a single worker. All the code of our experiments are available for reproducibility [1].

(c) LastFM

Figure 3: Development of recall@10 testing different n_i. The plotted lines relate to a moving average of the recall@10 got for every recommendation with window size w=5000 with different replication factor

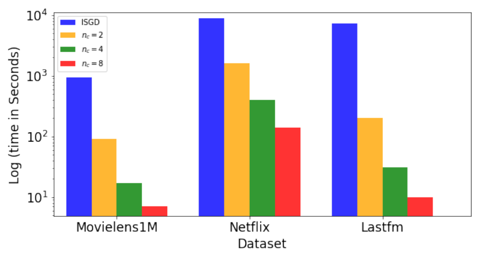

Figure 4: Comparison between the processing time for ISGD and DISGD with different n_i applied on Movielens, Netflix and lastFM datasets.

Movielens and Netflix are notable datasets of rating films and they are sparse. Both the dataset's schema consists of *user*, *item*, *rating* (from 1 to 5) and *time-stamp*. The same preprocessing is done for both datasets. The datasets have been ordered chronologically as indicated by the timestamp for capturing the pattern of how the user interacts with the items consecutively and as our algorithm depends on positive feedback the datasets have been filtered out from any records with a rating under 5. LastFM dataset contains records of listening to music tracks. We extracted the tuples of *<user,trackID>* assuming that the occurrence of the pair as positive feedback and the dataset has been ordered by timestamp.

Experiments and Results. We have run two main experiments. In the first one, we fixed $n_i = 2$; which means that each item vector exists with two versions each on half of the nodes. As per condition in our mechanism, the nodes in the cluster should be n_c=4+2w. We have varied the value of w. The results are reported in Figure 2 showing the results of summing a moving average recall SMA with window size 5000 elements for data sets Movielens 1M and Netflix. We can clearly observe that DISGD achieves significantly a higher recall than the baseline. Obviously, increasing the number of nodes n_c with the same n_i results in higher recall. The recall slightly improves with increasing n_c. The same observation for enhanced recall applies to Netflix.

Regarding the second experiment, DISGD has been tested using different replication factor n_i values with minimum $n_c = n_i^2$. In particular we run our experiments with $n_i \in \{2, 4, 8, 50\}$[5], for `Movielens 1M` dataset and with $n_i \in \{2, 4, 8\}$ for `Netflix`. `LastFM` is tested with $n_i \in \{2, 4, 8, 14\}$[5]. The model has been evaluated using SMA recall at $N = 10$. The results of Figure 3 shows that it is obvious that our approach can scale with different replication factors with enhanced recall in comparison to ISGD.

In general, *processing time* is a major factor in handling streaming data. The x-axis of the graph in Figure 4 shows the three data sets while the log processing time in seconds is on the y-axis. The results show that processing time reduces significantly from ISGD to DISGD and the time decrease dramatically when n_c has risen. It is observed that DISGD is between $6 - 15$ times faster than ISGD with respect to the data sets and the parallelism factor n_c while keeping a significantly higher recall.

[5]The experiment with $n_i = 50$ and $n_i = 14$ have been applied separately on a larger cluster

4 CONCLUSION AND FUTURE WORK

In this paper, we presented `DISGD`, a distributed shared-nothing variant for stochastic gradient descent for streaming data. Our solution allows much lower latency in serving for recommender systems. However, as with other streaming applications, the data distribution change might lead to skewness in the load on workers. Load rebalancing techniques already exist in literature, however, the effect of moving/merging state on the performance of the algorithm is unknown and is an interesting subject for our future work.

ABSTRACT

The problem of team formation in a social network asks for a set of individuals who not only have the required skills to perform a task but who can also communicate effectively with each other. Existing work assumes that all links in a social network are positive, that is, they indicate friendship or collaboration between individuals. However, it is often the case that the network is *signed*, that is, it contains both positive and negative links, corresponding to friend and foe relationships. Building on the concept of structural balance, we provide definitions of compatibility between pairs of users in a signed network, and algorithms for computing it. We then define the team formation problem in signed networks, where we ask for a *compatible* team of individuals that can perform a task with small communication cost. We show that the problem is NP-hard even when there are no communication cost constraints, and we provide heuristic algorithms for solving it. We present experimental results to investigate the properties of the different compatibility definitions, and the effectiveness of our algorithms.

1 INTRODUCTION

Given a task that requires a set of skills, a pool of workers who possess some of the skills and are organized in a social network, team formation refers to finding a subset of the workers that collectively cover the skills and can communicate effectively with each other [9]. The communication cost of the team is measured using the distances between the team members in the network. The idea is that socially well connected users will be more effective in working together.

Since the pioneering work in [9], there has been considerable research activity on the problem [1, 8, 12]. All existing work assumes that the social network contains only positive ties between individuals. That is, the edges denote friendship or successful collaboration between two users. However, very often, we have *signed* networks with both positive and negative ties. A negative edge indicates a contentious relationship and inability of two users to collaborate and thus they should not be in the same team.

In this paper, we study the problem of team formation in signed networks. In addition to the known requirements of the team formation problem, we ask that the team contains users that are all *compatible* with each other. Defining compatibility in a signed network is an interesting problem in itself. Clearly, users connected with a positive edge are compatible, while users connected with a negative edge are incompatible. We infer the compatibility of non-connected pairs of users by using the structure of the graph, and the principle of *structural balance*. Structural balance [4] is based on the premise that "the friend of my friend is my friend", "the enemy of my enemy is my friend", and "the enemy of my friend is my enemy". Using this premise, we determine the compatibility of two users by looking at the paths that connect them. For example, a path of two positive or two negative edges indicates compatibility, while a path of one positive and one negative edge indicates incompatibility. We formalize this idea, and we provide definitions of compatibility of varying strictness. We perform experiments with four real datasets, where we evaluate the different compatibility definitions, and the performance of the algorithms for the team formation problem.

2 PROBLEM DEFINITION

We are given as input a pool of n individuals organized in an *undirected signed* graph $G = (V, E)$. Each node in V corresponds to an individual, and $E = \{(u, v, \ell) : u, v \in V, \ell \in \{+1, -1\}\}$ is a set of edges *labeled* as either positive or negative to indicate that u and v are friends or enemies respectively. We assume that G is connected. We will use a function $sign : E \to \{+1, -1\}$ that returns the label of each edge in E.

We are also given as input a universe S of skills. Each individual u in V possesses a set of skills, $skill(u) \subseteq S$. We define a task as the subset of skills $T \subseteq S$ required for its completion. Given a task, the team formation problem asks for a team X of individuals, $X \subseteq V$, that collectively covers the required skills and whose members can work together *effectively*. The effectiveness of a team is typically quantified by the communication cost, $Cost(X)$, of the team defined as some function of the distances of its members in the graph.

However, when the graph contains both positive and negative edges, we need to take into account that some individuals, although close in the graph, may not be *compatible* with each other. To capture whether two users are compatible, we introduce a relation $Comp \subseteq V \times V$ such that $(u, v) \in Comp$, if and only if, u and v can work together. Two natural requirements for $Comp$ are (1) reflexivity: $(u, u) \in Comp$, and (2) symmetry: if $(u, v) \in Comp$, then $(v, u) \in Comp$. Furthermore, we require that the $Comp$ relation satisfies the following two intuitive properties:

(1) *Positive Edge Compatibility:* For all $(u, v) \in E$, such that $sign(u, v) = +1$, $(u, v) \in Comp$.
(2) *Negative Edge Incompatibility:* For all $(u, v) \in E$, such that $sign(u, v) = -1$, $(u, v) \notin Comp$.

We will provide various definitions of compatibility in Section 3. We now define formally our problem.

Definition 2.1. (Team Formation in Signed Networks (TFSN)) Given a signed graph $G = (V, E)$, a compatibility relation $Comp$, and a task T, find $X \subseteq V$ such that (1) $\bigcup_{u \in X} skill(u) \supseteq T$, (2) for each $u, v \in X$, $(u, v) \in Comp$, and (3) $Cost(X)$ is minimized.

The TFSN problem contains as a special case the original team formation problem which is NP-hard [9], thus TFSN is also NP-hard. Moreover, we have shown that just finding a set of compatible users is NP-hard. Let TFSNC denote the simplified version of the TFSN problem, where we drop the third requirement of minimizing the cost. In particular, we have proven the following theorem.

THEOREM 2.2. *The decision version of* TFSNC *is NP-hard for any compatibility relation that satisfies positive edge compatibility and negative edge incompatibility.*

3 USER COMPATIBILITY

We start with two basic definitions of compatibility.

Definition 3.1. Direct Positive Edge (DPE) compatibility: $Comp_{\text{DPE}} = \{(u,v) \subseteq V \times V : (u,v,+1) \in E\}$.

Definition 3.2. No Negative Edge (NNE) compatibility: $Comp_{\text{NNE}} = \{(u,v) \subseteq V \times V : (u,v,-1) \notin E\}$.

DPE is the strictest form of compatibility, while NNE is the most relaxed one. Specifically, $Comp_{\text{DPE}}$ is the minimal subset of pairs of nodes that satisfies the positive edge compatibility property, while $Comp_{\text{NNE}}$ is the maximal subset of pairs of nodes that satisfies the negative edge incompatibility property.

We will now use the theory of *structural balance* [2, 4, 7] to provide more refined definitions of compatibility. The theory is based on the following socially and psychologically founded premises: (1) the friend of my friend is my friend, (2) the friend of my enemy is my enemy, and (3) the enemy of my enemy is my friend. Let $P = (v_0, \ldots, v_{k+1})$, $(v_i, v_{i+1}) \in E$ denote a path between nodes v_0 and v_{k+1} in a signed graph G. We define the sign of the path as $sign(P) = \prod_{i=0 \ldots k} sign(v_i, v_{i+1})$. We say that path P is positive if $sign(P) = +1$ and negative if $sign(P) = -1$.

CLAIM 1. *A positive path P_{uv} between two nodes u and v indicates compatibility, while a negative one indicates incompatibility.*

The claim follows from the basic principle of structural balance. To see this, let $P_{uv} = (x_0, x_1, ..., x_k, x_{k+1})$, $x_0 = u$, $x_{k+1} = v$ be a path that connects u and v. Let F_u be the set of friends of u and E_u be the set of enemies of u. We start by placing node u in F_u and traverse the path as follows. When we traverse edge (x_i, x_{i+1}), if the edge is positive we place x_{i+1} in the same set as x_i. That is, the friends of my friends are also my friends, and the friends of my enemies are my enemies. If the edge (x_i, x_{i+1}) is negative then we place x_{i+1} in the opposite set of x_i. That is, the enemies of my enemies are my friends, and the enemies of my friends are my enemies. If the path P_{uv} is positive then v will be placed in F_u, while if the path is negative it will be placed in E_u.

We first look at shortest paths. We use SP_{uv} to denote the set of shortest paths between nodes u, v, SP^+_{uv} to denote the positive, and SP^-_{uv} the negative ones.

Definition 3.3. Shortest Path (SP) compatibility relations: – All Shortest Path (SPA) compatibility: $Comp_{\text{SPA}} = \{(u,v) \subseteq V \times V : \forall P_{uv} \in SP_{uv}, sign(P_{uv}) = +1\}$.
– Majority Shortest Path (SPM) compatibility: $Comp_{\text{SPM}} = \{(u,v) \subseteq V \times V : |SP^+_{uv}| \geq |SP^-_{uv}|\}$.
– One Shortest Path (SPO) compatibility: $Comp_{\text{SPO}} = \{(u,v) \subseteq V \times V : \exists P_{uv} \in SP_{uv}, sign(P_{uv}) = +1\}$.

We further relax compatibility by asking for positive paths that are not necessarily the shortest ones. Based on structural balance, certain triangles are more stable. A general signed graph is structurally balanced, if it does not contain any cycle with an odd number of negative edges [7].

Given a path P, let $G_P = (P, E[P])$ be the graph induced by the nodes of P. We say that path P is structurally balanced if the subgraph G_P is structurally balanced. Let BP_{uv} denote the set of all structurally balanced paths between u and v.

Algorithm 1 The SP-compatibility algorithm.

Input: Signed graph G, query node q.
Output: The number of positive and negative shortest paths from q to all other nodes in the graph.

```
1: Initialize $N^+(q) = 1$, $N^-(q) = 0$ $N^+(x) = N^-(x) = 0$, $L(q) = 0$,
   $L(x) = \infty$, empty queue $Q$.
2: $Q$.enqueue($q$)
3: while $Q \neq 0$ do
4:     $u = Q$.dequeue()
5:     for $x$ adjacent to $u$ do
6:         if $L(u) + 1 \leq L(x)$ then
7:             if $x \notin Q$ then
8:                 Q.enqueue($x$)
9:             $L(x) = L(u) + 1$
10:            if $sign(u,x) = +1$ then
11:                $N^+(x)$ += $N^+(u)$; $N^-(x)$ += $N^-(u)$
12:            else if $sign(u,x) = -1$ then
13:                $N^-(x)$ += $N^+(u)$; $N^+(x)$ += $N^-(u)$
14: return ($N^+$, $N^-$, $L$)
```

Definition 3.4. Structurally Balanced Path (SBP) compatibility: $Comp_{\text{SBP}} = \{(u,v) \subseteq V \times V : \exists P_{uv} \in BP_{uv}, sign(P_{uv}) = +1\}$.

The motivation for SBP compatibility is that, in addition to P_{uv} being positive, asking for G_P to be structurally balanced means that the sign of any edge connecting u and v must be positive, otherwise a cycle with an odd number of negative edges will be created. Note that SBP-compatibility does not imply SP-compatibility. Consider the example in Figure 1(a). The (only) shortest path between u and v is (u, x_1, v) which is negative, and thus u, v are not SP-compatible. However, u and v are SBP-compatible, since the path (u, x_2, x_3, x_4, v) is positive and structurally balanced. Note that there is a shorter path (u, x_2, x_1, v) between u and v that is positive, but not structurally balanced, since the shortcut edge (u, x_1) creates the unbalanced triangle (u, x_1, x_2).

It is easy to see that the following holds:

PROPOSITION 3.5. $Comp_{\text{dpe}} \subseteq Comp_{\text{spa}} \subseteq Comp_{\text{spm}} \subseteq Comp_{\text{spo}} \subseteq Comp_{\text{sbp}} \subseteq Comp_{\text{nne}}$.

Algorithms. We now present algorithms for SP and SBP compatibility. Algorithm 1 shows the modified BFS algorithm for counting positive and negative shortest paths. Given the query node q, for each node $x \in V$ in the graph, the algorithm maintains the numbers $N^+(x)$ and $N^-(x)$ of positive and negative shortest paths respectively and the length of the shortest path $L(x)$ from q to x. When reaching node x from node u through a shortest path (line 6), if the edge (u, x) is positive, we increment the number of positive and negative paths of x by $N^+(u)$ and $N^-(u)$ respectively, since all paths retain their sign. If the edge (u, x) is negative, we increment $N^-(x)$ by $N^+(u)$, and $N^+(x)$ by $N^-(u)$, since the sign of the paths change. Each edge is examined only once.

The efficient enumeration of shortest paths is possible due to the prefix property that a shortest path between q and x that goes through node u must use a shortest path from q to u. However, this is not the case for shortest structurally balanced paths. Consider the example in Figure 1(b). The shortest structurally balanced path from u to x_4 is (u, x_3, x_4). However, the shortest structurally balanced path $(u, x_1, x_2, x_4, x_5, v)$ from u to v goes through node x_4 but not through the shortest structurally balanced path from u to x_4, since the path (u, x_3, x_4, x_5, v) is not structurally balanced.

Since the exact algorithm is prohibitively expensive for large graphs, due to the exponential number of paths, we also consider a heuristic alternative for SBP-compatibility that counts only

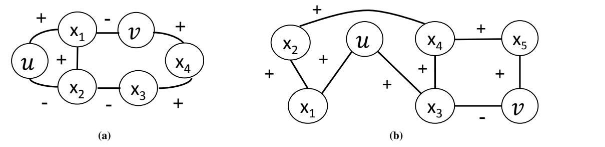

Figure 1: (a) u and v are SBP but not SP compatible. (b) It does not suffice to keep a single path from u to x_4.

Algorithm 2 Team formation algorithm.

```
    Input: Signed graph $G$, task $T$, compatibility relation $Comp$.
    Output: Team $X$.
 1: Initialize $S \leftarrow \emptyset$.   //S: skills covered so far
 2: Initialize $\mathcal{L} \leftarrow \emptyset$.   //$\mathcal{L}$: set of candidate teams
 3: Select skill $s$ from $T$   //skill selection
 4: for each $u$ with skill $s$ do
 5:     $X \leftarrow \{u\}$   // X: candidate team
 6:     $S \leftarrow S \cup (T \cap skills(u))$
 7:     while $S \neq T$ do
 8:         Select skill $s$ from $T - S$   //skill selection
 9:         Select user $v$ with skill $s$   //user selection
10:             s.t. $(v, x) \in Comp$ for all $x$ in $X$
11:         $X \leftarrow X \cup \{v\}$
12:         $S \leftarrow S \cup (T \cap skills(v))$
13:     $\mathcal{L} \leftarrow \mathcal{L} \cup X$
14: return $argmin_{X \in \mathcal{L}}(Cost(X))$
```

paths having the prefix property. We will use SBP to denote the compatibility relation computed by the exact exhaustive algorithm, and $\mathrm{SBP_H}$ the output of the heuristic algorithm.

4 TEAM FORMATION

We now present algorithms for the TFSN problem. Recall that our goal is to find a team of compatible users, that covers all skills, and minimizes the communication cost. The communication cost is defined as the largest distance between any two pairs of users in the team. We define the distance between two users looking at the positive paths connecting them. Specifically, for DPE and SP compatibility, distance is the length of the shortest path, while for SBP the length of the shortest structurally balanced positive path. For NNE compatibility, since there be no positive paths, we define distance as the length of the shortest path ignoring its sign.

Algorithm 2 is a generic algorithm that incrementally builds a solution, each time considering an uncovered skill and adding a compatible user having this skill, until all skills are covered. There are two placeholders in this algorithm. The first is the policy for selecting a skill (lines 3 and 8), and the second the policy for selecting a candidate user (line 9).

We consider two policies for selecting skills: select the rarest skill first (as in [9]), and select the least compatible skill first. We define the compatibility degree $cd(s)$ of skill s based on the compatibility between the users with skill s and the users with all other skills: $cd(s) = \sum_{s_j \in S, s_i \neq s} cd(s, s_j)$, where $cd(s, s_j) = |\{(u_i, u_j) : (u_i, u_j) \in Comp, s \in skills(u_i) \text{ and } s_j \in skills(u_j)\}|$.

Table 1: Dataset Statistics

	Slashdot	*Epinions*	*Wikipedia*
#users	214	28,854	7,066
#edges	304	208,778	100,790
#neg edges	89 (29.2%)	34,941 (16.7%)	21,765 (21.5%)
diameter	9	11	7
#skills	1,024	523	500

We also consider two policies for selecting users: select the user that has the minimum distance, and select the user that is most compatible among the remaining users. The first selection aims at minimizing the cost, while the second at maximizing the chances of finding a group of compatible users. We experimentally evaluate different combinations of these policies in Section 5.

Table 2: Comparison of compatibility relations

	SPA	SPM	SPO	$\mathrm{SBP_H}$	SBP	NNE

5 EXPERIMENTAL EVALUATION

In this section, we compare the different compatibility relations on real datasets and evaluate the team formation algorithm.

Datasets. Table 1 details our real-world datasets. *Slashdot* contains information about users and their posts on Slashdot. We obtained a network of Slashdot users [11], where users have tagged their relationships as friend or foe. Then we used the categories of users' posts as skills. *Epinions* contains information about users and their reviews about products. The dataset is created by combining a signed network of Epinions users [11] with the RED [1] dataset which contains information about the products and product categories the users have reviewed. We used the unique user ids to match users in the two datasets, and we assigned as skills to users the categories of the products they have reviewed. *Wikipedia* [11] is a signed network of editors. The edge sign corresponds to a positive or negative vote in admin elections. Since there was no skill information, we assigned synthetically generated skills to its users. We generated 500 distinct skills with frequencies following a Zipf distribution as in real data. Each skill is assigned to users in the network uniformly at random.

Compatibility Relations. In Table 2, we report the percentage of compatible pairs of users and skills. The DPE is excluded from our analysis, since this corresponds to finding cliques and team formation is too restrictive. Two skills s_1 and s_2 are compatible if they have compatibility degree $cd(s_1, s_2) > 0$, i.e., there is at least one compatible pair of users (u, v) such that u has s_1 and v has s_2 (including self-compatibility, if the same user has both skills).

As expected, the number of compatible user and skill pairs increases as we relax the notion of compatibility. For SPA, less than half of the pairs of nodes are compatible, and as low as 21.98% for the case of *Wikipedia*. Also, in most cases, for a sizeable fraction of pairs of skills there are no compatible users, indicating that for many skill combinations there can be no compatible team. Another interesting observation is that the fraction of compatible pairs for SBP is comparable with that for NNE. This means that, for all pairs that are not directly connected with a negative edge, there exists at least one positive structurally balanced path that connects them.

[1] https://projet.liris.cnrs.fr/red/

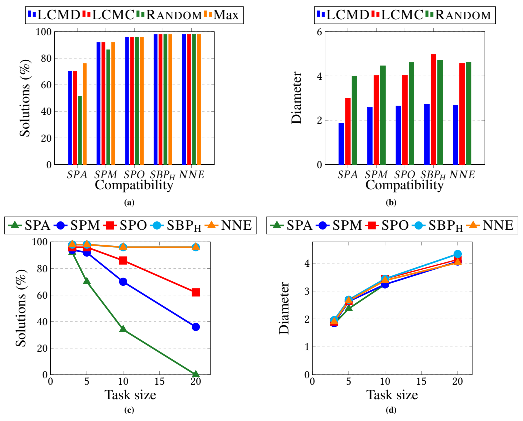

Figure 2: Team formation: comparison of algorithms ((a) and (b)), varying task size (c) and (d).

Distance. In Table 2, we also report the average distance between compatible users. The distance steadily increases as we relax the compatibility definition. The exception is NNE in which we allow negative paths, and thus we are able to discover shorter ones.

Comparison of **SBP** ***and*** **$\mathrm{SBP_H}$.** We also compare the exact (SBP) and heuristic ($\mathrm{SBP_H}$) structurally balanced compatibility for the *Slashdot* dataset, for which we can compute the exact relation. Table 2 shows the difference between SBP and $\mathrm{SBP_H}$ which is only ~2.5%

Team Formation. Due to space limitation, in this set of experiments, we only report results using *Epinions*. Results are similar for the other networks. We generate tasks of different sizes. For a given task of size k, we generated 50 tasks by randomly selecting k skills. First, we compare the four different team formation algorithms obtained by combining the two different skill and user selection policies.We report results for the two algorithms that performed the best which are the algorithms that select the least compatible skill. The LCMD, selects the user with the minimum distance, while the LCMC, the user who is the most compatible with the existing team. We also experiment with a baseline RANDOM that selects a compatible user at random.

In Figure 2(a), we report the percentage of times that each algorithm was able to find a compatible team for $k = 5$. The last bar (MAX) shows the percentage of tasks that contain compatible skills. This is a rough upper bound on the number of compatible teams, since it is based on compatible skills and not the compatibility of users. The two algorithms perform equally well indicating that optimizing for compatibility makes very little difference. Figure 2(b) shows the average cost of the teams produced and indicates that LCMD is the best choice.

In Figures 2(c) and (d), we report results for teams of varying task sizes using LCMD. As expected, more skills means that more people need to co-operate to complete the task, making it harder to form a compatible team, and more likely to include a distant node. The number of solutions drops steeply for more strict compatibility relations, while it remains more or less constant for NNE and $\mathrm{SBP_H}$.

Finally, we compare our approach with previous work on team formation. Since there is no previous work on team formation on signed network, we create two unsigned *Epinions* networks by (1) ignoring the sign of the edges and (2) deleting the negative edges. We run a team formation algorithm [9] on each of these two networks using the same tasks with $k = 5$ skills as in the previous experiments. In Table 3, we report the percentage of the returned teams that satisfy compatibility for the different compatibility relations. As shown, most of the teams returned are incompatible.

6 RELATED WORK

To the best of our knowledge, our work is the first to address team formation in signed networks.

Team Formation. Lappas et al. [9] were the first to formally define the problem of finding a team of experts using the network structure to quantify the quality of the team as a whole. There is considerable amount of work extending their model, (e.g., [1, 8, 12]), but none of these works considers a signed network.

Signed Networks. There is a fair amount of work on signed networks [13]. A problem somehow related to our work is that of link and sign prediction [3, 11]. However, we differentiate, since we are not interested in predicting future links, but rather in evaluating the compatibility between any two individuals in the network. There is also work on detecting communities in signed networks (e.g., see [14]). The notion of the team is somehow related to that of the community, but the objective of team formation is different.

Structural Balance. There is a rich literature in psychology on positive and negative relations among groups of people using structural balance theory, e.g., [2, 4]. Structural balance has been used e.g., for identifying clusters [5] and polarization in networks [10], finding communities [6].

7 CONCLUSIONS

In this paper, we introduced the novel problem of team formation in a signed network. The problem poses the challenge of defining node compatibility in a signed network. To this end, we provided a principled framework by utilizing the theory of structural balance. In the future, we plan to investigate different ways to combine compatibility and communication cost and to exploit compatibility for other tasks, such as link prediction or clustering.

ABSTRACT

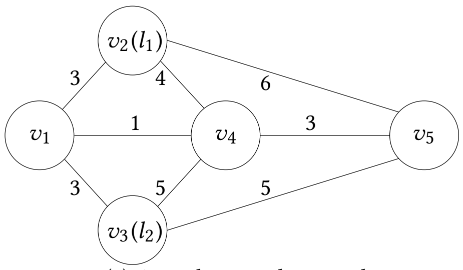
Shortest-path distances on road networks have many applications such as finding nearest *places of interest* (POI) for travel recommendations. To compute a shortest-path distance, traditional approaches traverse the road network to find the shortest path and return the path length. When the distances are needed first (e.g., to rank POIs) while the shortest paths may be computed later (e.g., after a POI is chosen), one may precompute and store the distances, and answer distance queries by simple lookups. This approach, however, falls short in the worst-cast space cost – $O(n^2)$ for n vertices even with various optimizations. To address these limitations, we propose to learn an embedding for every vertex that preserves its distances to the other vertices. We then train a *multi-layer perceptron* (MLP) to predict the distance between two vertices given their embeddings. We thus achieve fast distance predictions without a high space cost. Experimental results on real road networks confirm these advantages. Meanwhile, our approach is up to 97% more accurate than the state-of-the-art approaches for distance predictions.

1 INTRODUCTION

Computing shortest-path distances on road networks with a high efficiency is fundamental for applications such as "finding restaurants within 5 km distance" or "ranking restaurant search results by distance". Real road networks (e.g., Florida road network [8]) may contain millions of vertices, while thousands of users may issue distance queries at the same time (e.g., Google Maps has over a billion active users [1]). Answering distance queries under such settings poses significant challenges in both space and time costs. We aim to address such challenges in this paper.

Problem formulation. We consider a road network graph $G = \langle V, E\rangle$, where V is a set of n vertices (road intersections) and E is a set of m edges (roads). A vertex $v_i \in V$ has a pair of geo-coordinates. An edge $e_{i,j} \in E$ connects two vertices v_i and v_j, and has a *weight* $e_{i,j}.w$, which represents the distance to travel across the edge. Fig. 1a shows an example, where $v_1, v_2, \dots, v_5$ are the vertices, and the numbers on the edges are the weights. For simplicity, in what follows, our discussions assume undirected edges, although our techniques also work for directed edges.

A path $p_{i,j}$ between vertices v_i and v_j consists of a sequence of vertices $v_i \to v_1 \to v_2 \to \dots \to v_x \to v_j$ such that there is an edge between any two adjacent vertices in the sequence. The *length* of $p_{i,j}$, denoted by $|p_{i,j}|$, is the sum of the weights of the edges between adjacent vertices in $p_{i,j}$, i.e., $|p_{i,j}| = e_{i,1}.w + e_{1,2}.w + \dots + e_{x,j}.w$. We are interested in the path $p^*_{i,j}$ between v_i and v_j with the smallest length, i.e., the *shortest path*. Its length is the *(shortest-path) distance* $d(v_i, v_j)$ between v_i and v_j, i.e., $d(v_i, v_j) = |p^*_{i,j}|$. Consider vertices v_1 and v_5 in Fig. 1a. Their



(a) A road network example

(c) Landmark labeling

Figure 1: Shortest-path distance problem

distance $d(v_1, v_5) = 4$ is the length of path $v_1 \to v_4 \to v_5$. We aim to predict $d(v_i, v_j)$ given v_i and v_j with a high accuracy and efficiency, which is defined as the *shortest-path distance query*.

Definition 1.1 (Shortest-path distance query). Given two query vertices v_i and v_j in graph G, *a shortest-path distance query* returns the shortest-path distance between v_i and v_j, i.e., $d(v_i, v_j)$.

For simplicity, we use distance to refer to shortest-path distance hereafter as long as the context is clear.

Related work. A simple solution is to use shortest path algorithms (e.g., Dijkstra's algorithm) to compute the shortest paths and then return the path lengths. In applications such as those mentioned above, the distances are needed first (e.g., to rank restaurants by distance) while the shortest paths may be computed later (e.g., after a restaurant is chosen). Studies (e.g., [3, 7, 12]) thus build data structures to enable fast distance queries without online shortest path computations. *Distance labeling* is commonly used. Its basic idea is to precompute a vector of (distance) values for each vertex as its *distance label*. In an extreme case, the distance label of a vertex contains its distances to all other vertices (cf. Fig. 1b). A distance query is answered by a lookup in $O(1)$ time, but this requires $O(n^2)$ storage space for the distance labels. Techniques (e.g., *2-hop labeling* [7] and *highway labeling* [12]) are proposed to reduce the label size. However, for general graphs, the worst-case space costs are still $O(n^2)$ [11].

To avoid the $O(n^2)$ space cost, approximate techniques are proposed [6, 18, 21], among which *landmark labeling* [10, 16, 20] is a representative approach. This approach uses a subset of k ($k \ll n$) vertices as the *landmarks*. Every vertex v_i stores its distances to these landmarks as its distance label, i.e., a k-dimensional vector $\langle d(v_i, l_1), d(v_i, l_2), \dots, d(v_i, l_k)\rangle$, where $l_1, l_2, \dots, l_k \in L$ represent the landmarks and $d(\cdot)$ represents the distance. At query time, the distance labels of the two query vertices v_i and v_j are scanned, where the distances to the same landmark are summed up. The smallest distance sum, i.e., $\min\{d(v_i, l) + d(v_j, l) | l \in L\}$,

[*]The authors are ordered alphabetically.

is returned. In Fig. 1, v_2 and v_3 are chosen as the landmarks (denoted by l_1 and l_2, respectively), and the distance labels are shown in Fig. 1c. The distance between v_1 and v_5 is computed as $\min\{d(v_1,l_1)+d(v_5,l_1), d(v_1,l_2)+d(v_5,l_2)\} = \min\{3+6, 3+5\} = 8$, which is twice as large as the actual distance between v_1 and v_5 (i.e., 4). Even though landmark labeling reduces the space cost to $O(kn)$, it may not return the exact distance. How the landmarks are chosen plays a critical role in the distance accuracy. Since finding the k optimal landmarks is NP-hard [16], heuristics are proposed [16, 19] such as choosing the vertices that are on more shortest paths as the landmarks. Theoretical results (e.g., [6, 15]) are offered to bound the relationship between the label size and the distance accuracy. On undirected graphs, it is shown [21] that any algorithm with an approximation ratio of $\alpha < 2c+1$ ($c \in \mathbb{N}^+$) must use $\Omega(n^{1+\frac{1}{c}})$ space. A structure is proposed [21] using $O(cn^{1+\frac{1}{c}})$ space and $O(cmn^{\frac{1}{c}})$ time to obtain an approximation ratio of $\alpha = 2c-1$ and an $O(c)$ query time. Chechik [6] improves the space cost to $O(n^{1+\frac{1}{c}})$ and the query time to $O(1)$, with an $O(n^2+mn^{\frac{1}{2}})$ prepossessing time. These studies are mainly of theoretical interest. They do not offer empirical results.

Our contributions. To preserve more information in the distance labels and obtain higher distance accuracy, we propose to learn an *embedding* for every vertex as its distance label. Our idea is motivated by recent advances in graph embeddings [4, 5, 9], which show that vertices can be mapped into a latent space where their *structural similarity* (e.g., the number of common neighboring vertices) can be computed. This motivates us to map the vertices into a latent space to compute their *spatial similarity*, i.e., shortest-path distances. We make the following contributions:

(i) We propose a learning based model *vdist2vec* to predict vertex distances. This model learns vertex embeddings while jointly trains a *multi-layer perceptron* (MLP) to predict vertex distances. It has an $O(k)$ distance prediction time and an $O(kn)$ storage space, where k is a small constant denoting the vertex embedding dimensionality. Our model is highly accurate, since the embeddings are guided by distance predictions directly.

(ii) We further propose two models *vdist2vec-L* and *vdist2vec-S* with an improved loss function and an improved model structure to optimize the embeddings for different types of vertices.

(iii) We perform experiments on real road networks. The results show that, comparing with state-of-the-art approaches, our models reduce the distance prediction errors by up to 97%.

2 PROPOSED MODEL

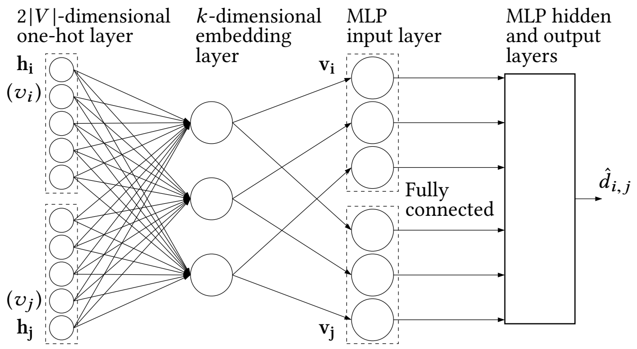

Figure 2: Vdist2vec model structure

Vdist2vec. As Fig. 2 shows, our vdist2vec model takes two vertices v_i and v_j as the input, which are represented as two size-$|V|$ *one-hot vectors* $\mathbf{h_i}$ and $\mathbf{h_j}$. The next layer is an *embedding layer* for representation learning. This layer has k nodes, and its weight matrix is a $|V| \times k$ ($2|V| \times k$ for directed graphs) matrix to be used as the vertex vectors for all vertices, denoted by $\mathbf{V} = [\mathbf{v_1}^T, \mathbf{v_2}^T, ..., \mathbf{v}_{|\mathbf{V}|}{}^T]^T$. Multiplying $\mathbf{h_i}$ ($\mathbf{h_j}$) by $\mathbf{V}$ yields $\mathbf{v_i}$ ($\mathbf{v_j}$):

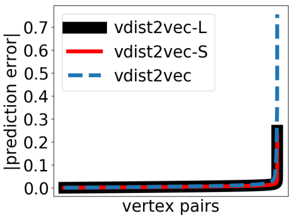
$$\mathbf{v_i} = \mathbf{h_i}\mathbf{V} \tag{1}$$

Vectors $\mathbf{v_i}$ and $\mathbf{v_j}$ are then fed into a distance prediction network (i.e., an MLP) to predict the distance between v_i and v_j. The loss function $\mathcal{L}_d$ is the mean square error on the actual vertex distances $d(v_i, v_j)$ and the predicted distances $\hat{d}_{i,j}$:

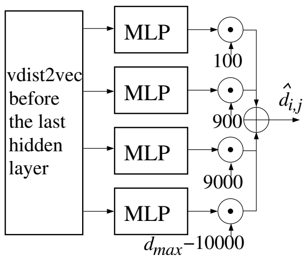
$$\mathcal{L}_d = E_{\mathcal{P}}\left[(d(v_i,v_j) - \hat{d}_{i,j})^2\right] \tag{2}$$

At training, the vertex representation matrix $\mathbf{V}$ is randomly initialized. Vertex pairs are fed into the network in batches to train the MLP. The training loss $\mathcal{L}_d$ will be propagated back to optimize the MLP and the vertex representations in $\mathbf{V}$.

At query time, the query vertex vectors $\mathbf{v_i}$ and $\mathbf{v_j}$ are fetched from $\mathbf{V}$ and fed into the MLP to make a distance prediction.



(a) Error distribution (DG)



(b) vdist2vec-S

Figure 3: Prediction error distribution and vdist2vec-S

Next, we optimize the prediction accuracy further. Our motivation comes from an observation on the distance prediction error distributions. In Fig. 3a, we plot the normalized absolute distance prediction errors of vdist2vec on a real dataset (DG, cf. Section 3). The x-axis represents vertex pairs (sorted by the prediction errors) and the y-axis represents their corresponding prediction errors. We see that a very small portion (e.g., less than 1%) of the vertex pairs have much larger prediction errors (see the spike to the right of the figure) than the other vertex pairs. Such vertex pairs dominate the training error and force the model to focus on them. To optimize the overall prediction accuracy, we need to guide the model to attend more to the other vertex pairs.

Vdist2vec-L. Our first optimization is a novel loss function denoted by $\mathcal{L}_n$ to shrink the larger errors:

$$\mathcal{L}_n = E_{\mathcal{P}}\left[f_\delta(d(v_i,v_j) - \hat{d}_{i,j})\right] \tag{3}$$

$$f_\delta(x) = \begin{cases} \delta|x|, \text{if } |x| \le \delta \\ \frac{1}{2}(x^2+\delta^2), \text{otherwise} \end{cases}$$

Function $f_\delta(\cdot)$ is motivated by the *Huber loss* and is continuously differentiable at $x = \delta$. We set δ as the top 1% largest prediction error after each epoch. If $|x| > \delta$, $\frac{1}{2}(x^2+\delta^2) \le x^2$ which shrinks the error. Replacing $\mathcal{L}_d$ with $\mathcal{L}_n$ results in *vdist2vec-L*.

Vdist2vec-S. Our second optimization is motivated by *ensemble learning*. As Fig. 3b shows, we replace the last hidden layer of vdist2vec with four separate MLPs, each focusing on producing distance predictions in the ranges of (0, 100), (0, 900), (0, 9000), and (0, d_{max}−10000), where d_{max} is the road network diameter. This is done by multiplying ("$\odot$") the sigmoid output of each MLP with 100, 900, 9000, and $d_{max} - 10000$, respectively. The output of the MLPs are summed up to produce the final predictions. We name this model *vdist2vec-S*. Its advantage is in that each MLP can focus on vertex pairs in different distance ranges, making it easier to learn more accurate predictions.

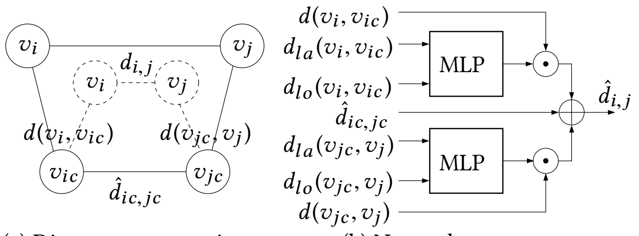
As shown in Fig. 3a, the error distributions of vdist2vec-L and vdist2vec-S are less skewed than that of vdist2vec.

Handling large road networks. Our models compute a $|V| \times k$ embedding matrix. This is cheaper than a $|V|^2$ matrix for all vertex distances. However, we still need to train over $|V|^2$ pairs of vertices. Next, we reduce the number of training pairs.

We cluster (e.g., using *k-means*) the vertices into $|V_c|$ clusters based on their geo-coordinates, where $|V_c|$ is a small constant. The vertex nearest to each cluster center is chosen as a *center vertex.* We train our models over the center vertices. Given query vertices v_i and v_j, their distance $\tilde{d}_{i,j}$ is approximated by their distances to their cluster center vertices v_{ic} and v_{jc} (which are precomputed) plus the predicted distance $\hat{d}_{ic,jc}$ of v_{ic} and v_{jc}:

$$\tilde{d}_{i,j} = \lambda_1 \cdot d(v_i, v_{ic}) + \hat{d}_{ic,jc} + \lambda_2 \cdot d(v_{jc}, v_j) \qquad (4)$$

There are two coefficients λ_1 and λ_2 to weight the contributions of $d(v_i, v_{ic})$ and $d(v_{jc}, v_j)$ based on the relative positions of the vertices (cf. Fig. 4a). To learn λ_1 and λ_2, we build another neural network as shown in Fig. 4b, where $d_{la}(\cdot)$ and $d_{lo}(\cdot)$ return the difference in latitude and longitude between two vertices, respectively. This neural network feeds the coordinate difference between v_i and v_{ic} and the coordinate difference between v_j and v_{jc} into two MLPs to predict λ_1 and λ_2, respectively. The last layer of each MLP uses a *tanh* activation function, which maps λ_1 and λ_2 into the range of $(-1, 1)$. The output of these two MLPs is multiplied ("$\bigodot$") with $d(v_i, v_{ic})$ and $d(v_{jc}, v_j)$, and the products are added ("$\bigoplus$") with $\hat{d}_{ic,jc}$ to produce $\tilde{d}_{i,j}$, which implements Equation 4. For training, we use loss function $\mathcal{L}_d$ but with only a sampled subset of non-center vertices (e.g., $|V_c||V|$ pairs), since the input space (i.e., coordinate difference) is now much smaller.



(a) Distance computation (b) Network structure

Figure 4: Distance prediction for large road networks

Handling updates. Our models can be rebuilt in 13 hours for road networks with over a million vertices (Section 3). This allows us to handle a low update frequency by periodic rebuilds. Our models can also provide distance predictions upon vertex or edge updates without rebuilding, although the accuracy may drop. We leave more robust update handling for future study.

Cost analysis. We consider an MLP to have an O(1) space cost for its parameters and an O(1) time cost for inference. Such costs depend mainly on the model size rather than the input size. Also, the inference can be done by GPUs efficiently. Then, our models can be trained in $O(|V|^2)$ time ($O(|V_c||V|)$ for large road networks). Our models take $O(k|V|)$ space for the embeddings. They take $O(k)$ time to read and feed the query vertex embeddings into the MLP for distance prediction in $O(1)$ time.

3 EXPERIMENTS

We run experiments on a Linux PC with an Intel(R) Xeon(R) E5-2630 V3 CPU (2.40GHZ), a GeForce GTX TITAN X GPU, and 32GB memory. All models are implemented with Python 2.7.12. The neural networks are implemented with Tensorflow 1.13.1.

Datasets. We use six road network datasets as summarized in Table 1, where $\overline{dgr}$ denotes the average degree and d_{max} denotes the diameter. All datasets are undirected except for MB.

Table 1: Datasets

Dataset	$\|V\|$	$\|E\|$	$\overline{dgr}$	d_{max}
Dongguan, China (**DG**) [14]	8K	11K	2.76	96km
Florida, USA (**FL**) [8]	1.07M	1.35M	2.36	1,200km
Melbourne, Australia (**MB**) [2]	3.6K	4.1K	1.14	6km
New York City, USA (**NY**) [8]	264K	366K	2.80	160km
Shanghai, China (**SH**) [14]	74K	100k	2.70	127km
Surat, India (**SU**) [14]	2.5K	3.6K	2.88	50km

Baselines. We compare with five baselines: **landmark-bt** [19]: it uses the top-k vertices passed by the largest numbers of shortest paths between the vertex pairs as the landmarks; **landmark-km**: it uses the k vertices that are the closest to the vertex k-means centroids (computed in Euclidean space) as the landmarks; **ado** [18]: it recursively partitions the vertices into subsets of *well separated vertices* and stores the distance between subsets to approximate the distance between vertices (we tune its approximation parameter ϵ such that it has a similar space cost to ours); **geodnn** [13]: it trains an MLP to predict the distance of two vertices given their geo-coordinates (we use its recommended settings); **node2vec** [17]: it uses node2vec [9] to learn vertex embeddings and trains an MLP to predict vertex distances given the learned embeddings (we use its recommended settings).

Hyperparameters. For our models, the MLP distance prediction component has two hidden layers of 100 and 20 nodes, respectively. We use ReLU as the activation function for the hidden layers and sigmoid for the output layer. We set the batch size to be $|V|$ (we find that a large batch size helps the training efficiency without impacting the prediction accuracy). We initialize the MLP parameters using the truncated normal distribution with 0 as the mean and 0.01 as the standard deviation. The training data is randomly shuffled. We train our model in 20 epochs with early stopping using *AdamOptimizer* and a learning rate of 0.01. Each ensemble MLP of vdist2vec-S has a layer of 20 nodes.

In all approaches except node2vec, we use $k = 2\%|V|$ for DG, MB, and SU, $k = 0.05\%|V|$ for SH, and $k = 0.005\%|V|$ for FL and NY. For node2vec, we use $k = 128$ as suggested by [17].

Evaluation metrics. We predict the distance between every two vertices in each dataset and measure the *mean absolute error* (**MAE**, in meters), *mean relative error* (**MRE**), *precomputation/training time* (**PT**), and *average distance prediction (query) time* (**QT**). The ground truth distances are precomputed using the *contraction hierarchy* algorithm.

Overall results. Table 2 shows the prediction errors. Our models outperform the baseline models across all six datasets and reduce the MAE and MRE by up to 97% and 99% (5 vs. 192 and 0.006 vs. 0.488 for vdist2vec-S and landmark-bt on MB). On NY, landmark-km has a slightly lower MAE than ours, while our MRE is still lower (by more than 50%).

The advantage of our models comes from their capability to learn the vertex distances and preserve them in the embeddings. Landmark-bt and landmark-km rely on the landmarks and may not preserve the distance for all vertices. Ado is designed to control the relative error. It yields the lowest MRE among the baselines on most datasets, but its MAE may be large. Geodnn uses Euclidean distance to approximate shortest-path distance. It suffers on large road networks (e.g., FL and NY) with rivers and large detours. Node2vec focuses on the neighborhood of the vertices. It also suffers on large road networks such as NY (it cannot train on FL in 48 hours which is marked as "OT").

In Table 2, we also show the space required to store the learned embeddings and model parameters on the FL dataset. Geodnn has the smallest space requirement, as it only stores the MLP

parameters. Our models store MLP parameters and center vertex embeddings, which require more space than geodnn but less than landmark-km and ado. Note that, if our models learn vertex embeddings for a full graph, we expect a slightly higher space requirement than landmark-km and ado.

Table 3 shows the preprocesing (training) time PT and distance prediction (query) time QT. In terms of PT, the landmark approaches are much faster on the small road networks DG, MB, and SU. Their precomputation is simpler than the training of the learning based models. On large road networks FL, NY, and SH, our models use the proposed clustering based strategy ($|V_c| = 0.4\%|V|$ and 100,000 random vertex pairs to learn λ_1 and λ_2), which reduces the training time significantly. Ado and node2vec need to run on the full road networks. Their PT grows with the road network size. For geodnn, we randomly sample 100,000 vertex pairs for training on the large road networks. It does not learn vertex embeddings and hence has a lower PT.

In terms of QT, the learning based approaches are highly efficient because their distance prediction is a simple forward propagation, which can be done by GPUs efficiently. Geodnn is the fastest, as its input layer only has four nodes (i.e., two geo-coordinates). The other learning based approaches including ours have very similar MLP structures and input sizes which are larger than that of geodnn. Thus, their QT are similar and are larger than that of geodnn. Ado has the largest QT because it needs to first locate the subsets containing the query vertices.

Among our models, vdist2vec-S yields the smallest distance prediction errors, as it can cope with distances in varying ranges. This advantage comes with a larger PT. In contrast, vdist2vec-L has almost the same PT as vdist2vec but achieves smaller distance prediction errors due to its optimized loss function.

4 CONCLUSIONS

We proposed a representation learning based approach for the shortest-path distance problem. Our approach learns vertex embeddings that preserve the distances between vertices, which only take an $O(kn)$ storage space. At query time, the vertex embeddings are fed into an MLP to predict the distance, which takes a constant time. Experimental results show that our approach is highly efficient. It reduces the distance prediction errors by up to 97% comparing with the state-of-the-art. For future work, we plan to extend our techniques to more types of (and larger) graphs such as social networks. We also plan to study real-time updates for learning based distance prediction models.

ABSTRACT

Despite the increase of memory capacity and CPU computing power, memory performance remains the bottleneck of in-memory DBMS due to ever-increasing data volumes and application demands. Since the scale of data workload has outpaced traditional CPU caches and memory bandwidth, it is essential to optimize data movement from memory to computing units. In this work, we present a near-memory Database Accelerator (DBA) framework that offloads data-intensive database operations via or to a near-memory computation engine. DBA's system architecture includes a DBA software module/driver and memory module with DBA engine. We build a Proof-of-Concept (PoC) of DBA using FPGAs with attached DIMMs, and then conduct an experimental evaluation.

1 INTRODUCTION

Low cost and high capacity of DRAM accelerated the market of in-memory database management systems (IMDBMS). The latest IMDBMS architecture capable of running both Online Transactional Processing (OLTP) and Online Analytical Processing (OLAP) applications in a single system removes the data redundancy and provides higher performance and efficiency with lower total cost ownership (TCO) [9]. However, with ever-increasing data volumes and application demands, memory performance becomes the main performance bottleneck of IMDBMSs. Our study with OLTP/OLAP applications shows that performance can be bound by expensive data-intensive operations like table scan and aggregation of OLAP workloads. These data-intensive operations have very little data reuse for further computation but consume more than 50% of CPU resources and almost all memory bandwidth in many cases. The other mission critical workloads suffer from cache conflicts (or cache thrashing) and memory bandwidth bottleneck. Therefore, it is essential to optimize data movement from memory to computing units.

The best way to optimize this data movement in IMDBMS would be to process these data-intensive operations within memory devices. Instead of transferring the whole data to computing units, forwarding the filtered results to the next processing step could minimize the overhead. Near-storage computing [3, 4] tries to accelerate the data-intensive operations by minimizing the data transfer overhead from storage to processing nodes or CPU. However, this research does not deliver byte addressability and much lower latency necessary for IMDBMS. Previous work to accelerate database operations using FPGA [7, 8, 10] and GPGPU [5, 6] shows an order of magnitude performance gain in compute-intensive operations. However, these approaches show a smaller gain in data-intensive operations because of the data movement overhead [1]. Even Hybrid CPU-FPGA approaches [7, 10] require data movement from host memory to accelerator computing units which has a high memory bandwidth overhead.

Processing-In-Memory (PIM) approaches like UPMEM [2] advance the concept of near-memory computing but are still in early stage. Furthermore, the data needs to be reformatted to utilize the processing units, thus the existing data structure cannot be reused directly.

In this paper, we propose near-memory database accelerator (DBA) to offload data-intensive operations of IMDBMS to memory devices. By placing simple arithmetic units near DRAM within memory devices like DIMMs, we 1) save CPU cycles for data-intensive operations, 2) avoid cache thrashing among threads, and 3) reduce the host memory bottleneck. We implement our proof-of-concept (PoC) system using FPGAs with attached DIMMs. Its DBA kernel is designed to perform parallel comparisons in a SIMD manner fully utilizing internal memory bandwidth. Our evaluation shows that near-memory DBA has more than 2 times performance improvement in OLTP workloads when offloading the data-intensive operations. Finally, we discuss the obstacles to embody the approach in real memory devices.

2 BACKGROUND

2.1 Motivational example

Figure 1 shows the performance degradation of OLTP workload by the interference from the scan workloads on OLAP data in the server having 4 sockets and 72 physical cores. The two workloads managed by two separate processes access the different sets of data but compete with each other for limited hardware resources like CPU, cache and memory bandwidth. As the number of scan threads increases, the CPU resources allocated for OLTP workloads are reduced, thus the throughput of OLTP workloads decreases.

It is quite common to apply SIMD instructions to data-intensive operations like scan within a DBMS [11, 12], as SIMD performs the same operation on multiple data points simultaneously exploiting data level parallelism. We observe that the OLTP workloads show a larger performance degradation, when the scan operation is implemented with SIMD commands like AVX2 or AVX 512 because of much higher memory bandwidth usage. As

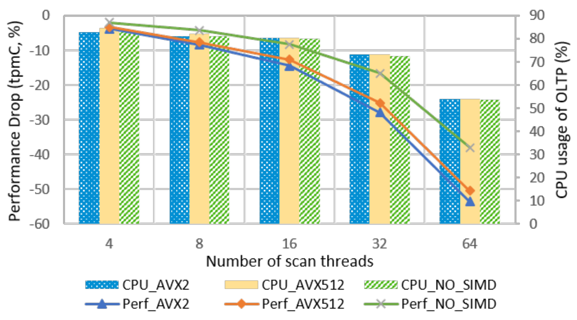

Figure 1: OLTP throughput by number of concurrent scans

Table 1: Memory bandwidth usage (%) by scan workloads

#Threads	AVX2	AVX512	No_SIMD
4	11.3	6.0	0.8
8	21.8	12.3	1.3
16	41.3	23.0	2.8
32	73.8	46.3	5.5
64	94.8	85.3	11.3

shown in Table 1, 64 scan threads consume almost all memory bandwidth of 4 sockets with SIMD, only 12% of memory bandwidth is consumed without SIMD. Interestingly, there is no difference in CPU usage between SIMD and NO-SIMD, but the OLTP throughput shows a larger performance degradation with SIMD. In Figure 1, with 64 scan threads, the CPU usage by OLTP decreased by 30% but the OLTP throughput decreases by about 40% without SIMD and more than 50% with SIMD. This supports our claim that the larger memory bandwidth usage by data-intensive workloads degrades OLTP performance more.

2.2 Scan operation in In-memory DBMS

Recent IMDBMSs are designed to support both OLTP and OLAP workloads and keep the data in the columnar storage for fast read accesses of the tables, storing the majority of data of each column in the read optimized main storage, and maintaining the separate delta storage for optimized writes [9]. The delta storage is periodically merged to the main storage [8]. To reduce the memory footprint (or TCO), the main storage uses dictionary encoding where the distinct values are stored in the dictionary and the individual values are replaced with the corresponding value IDs of the dictionary separately with the bit-packed compression [9]. A scan in IMDBMS reads this value ID array with filter conditions. In this work, the two common scan operations - Range search (having from/to filter conditions) and Inlist search (having a list of filtered values) are offloaded to DBA as they are simple and common data-intensive operations that often consume relatively high CPU usage (5-10% by itself). They include the decompression of value ID (integer) array and return row IDs satisfying the predicates. Offloading only low-level data access operators in the query plans reduces the effort to integrate them with the existing query optimizer.

3 DBA ARCHITECTURE

This section discusses the architecture and design of our proposed near-memory Database Accelerator (DBA). Figure 2 describes the system architecture of DBA. The objective of this work is 1) to demonstrate the offloading feasibility within current ecosystem, 2) to provide a framework to measure the stand-alone DBA engine performance, and more importantly, 3) to study the system impact of our proposal. To remove the unnecessary data movement, database operations are performed by DBA in the device memory where the source data is stored. After DBA completes the operations, the result output is written back to the device memory in FPGA. The host has access to the device memory via memory mapped I/O (MMIO). This eliminates speed and coherency limitations of the PCIe interface from this study and yet leverages the current driver software stack with the OS and the application.

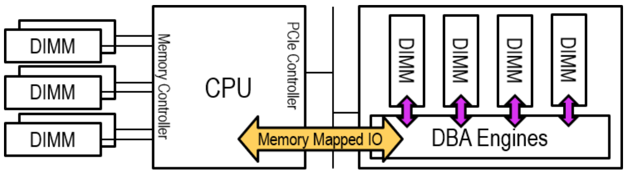

Figure 2: DBA System Architecture

Figure 3 describes the DBA FPGA micro-architecture with functional partitions of host interface, multiple DBA kernels and memory subsystem. The host interface exposes DBA control parameters to the driver that manages offloading from the application API call to the hardware accelerator. Each DBA kernel consists of data prefetcher reading the data, SIMD engine comparing the data with the predicate, and result handler writing the results. The memory subsystem provides the infrastructure to access device memories on the FPGA.

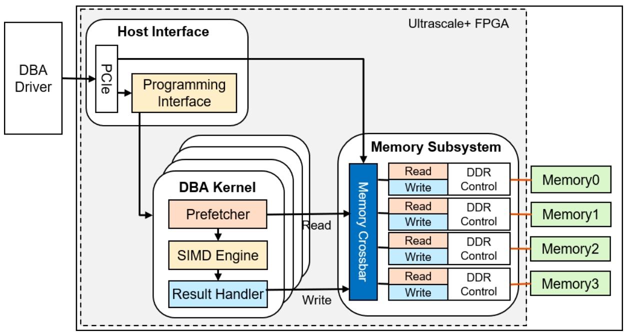

Figure 3: DBA FPGA Micro-Architecture

Internally, DBA kernels read 64B bit-compressed data at a time from the memory. A programmable extractor logic splits the data into multiple values. They are fed into an array of simple processing units and each unit performs a simple comparison independently. The number of parallel units in the array is determined by the number of values in the 64B data so that DBA kernels can keep up with the input data rate. Compared to fixed-length instruction-based processors, each DBA kernel takes the full advantage of parallelism in the data stream due to the flexibility of hardware design. The results are packed into 64B and written back to the device memories. Thus, the data flow is highly optimized for available memory bandwidth.

Figure 4 describes DBA software architecture. Unlike GPU/FPGA accelerators, the DBA engine is located within memory devices. Hence, it allows zero data copy with performance and energy gains. The DBA device driver assigns one DBA engine to a thread of the IMDBMS application per request. Once offloaded, a thread that requested an offloading yields to free CPU for processing. When offloading is done, DBA driver wakes up the requester to resume.

Existing DRAM modules
Memory modules for DBA offloading

Figure 4: DBA Software Architecture

Normally, applications use a virtual address (VA) to access memory in the host system while the DBA engines access memory with a device physical address (DPA). This implies that the DBA driver is responsible to translate all VA parameters of an offloading request into DPA. The DBA driver first obtains the corresponding system physical address (SPA) by referring to a page table. Then, converting DPA to SPA is trivial because the system BIOS has stored the start SPA of device memory in the Base Address Registers (BAR) of the PCI device at boot time.

4 EVALUATION

4.1 Experimental setup

The system consists of the embedded TPCC benchmark in an IMDBMS and a separate micro-benchmark program to generate scan workloads in a single server as shown in Figure 5.

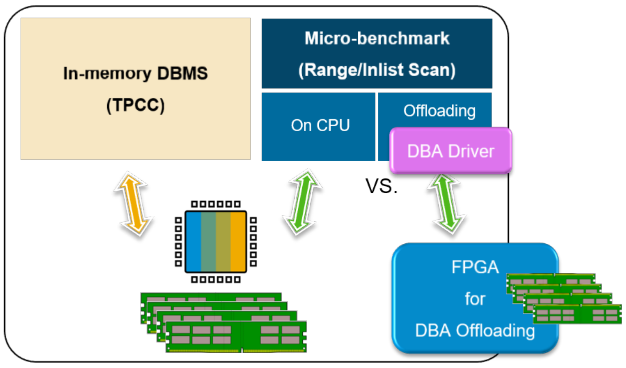

Figure 5: Conceptual diagram

In our experiments, we use the TPCC benchmark for OLTP workload. Its generator is embedded within the IMDBMS engine to remove the communication and session management overhead because the total throughput is usually bound by the session layer, not IMDBMS engine. We want to maximize the throughput (i.e. resource consumption) of the TPCC workload.

The micro-benchmark performs the scan workloads 1) on CPU, or 2) via FPGA. Its data is randomly generated and bit-compressed. The separate data for scans avoids the internal overhead of IMDBMS like locking by two different workloads and enables us to focus on the performance effect by hardware resources. In our experiment, scans read 2 billion bit-compressed integer values and return the row IDs satisfying the filter conditions. When it runs on CPU, the same number of scan threads are bound to each socket to prevent workload skew among the sockets on the 4-socket server (Intel Xeon Gold 6140@2.30GHz, 18 cores and 6 * 64 GB memories per socket). For DBA offloading, we attach one Ultrascale+ FPGA@250MHz per socket and populate 6 scan engines with 4 * 64 GB DDR4 DIMMs @1866MHz per FPGA. The scan data is copied to the memory in each FPGA to emulate that DBA offloading runs within memory devices where the data resides. We compare the performance variation of TPCC workloads and measure the latency and throughput scalability of scan workloads in both options (on CPU vs. on FPGA), while the number of scan threads increases.

4.2 Evaluation results

This section summarizes our DBA PoC evaluation results compared with a state-of-art 4-socket Skylake system having 72 physical cores.

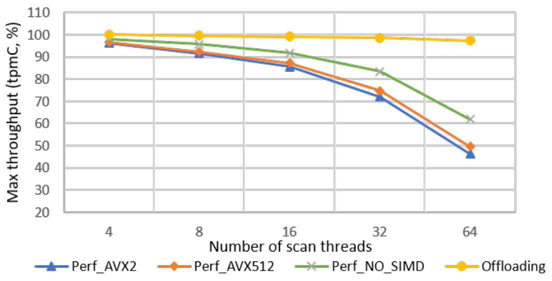

Figure 6: OLTP throughput gain by DBA

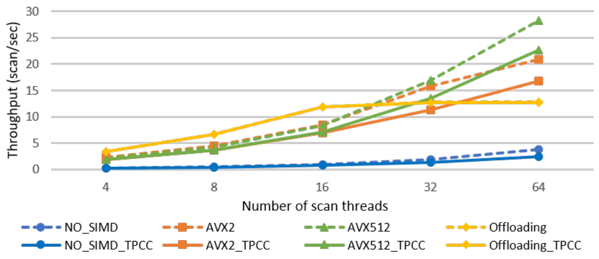

Figure 7: Scan throughputs with/without TPCC

Figure 6 demonstrates the system performance gain of IMDBMS. While TPCC workload runs in the server, the scan micro-benchmark runs on either CPU or DBA with a different number of threads. As a result, DBA offloading shows less performance slowdown as the number of scan threads increases. Therefore, DBA offloading shows 115% better tpmC (transactions per minute) in TPCC workloads when all 64 scan threads are offloaded than when 64 threads use AVX2 on CPU. The results confirm that DBA offloading can alleviate CPU conflict, cache thrashing and memory bandwidth conflict by data-intensive operations.

Table 2: Average latency (sec/scan) of a single scan

Latency of single scan (sec/scan)	On CPU			Offloading
	NO_SIMD	AVX2	AVX512	
	4.16	0.44	0.47	0.29

DBA offloading shows the better performance in scan operation itself, when scans run without OLTP workloads. DBA offloading shows 1.5x better latency (sec/scan) than AVX2 and 14.3x better than NO-SIMD as shown in Table 2.

As for the throughput (scans/sec) scalability, DBA offloading shows quite promising performance as shown in Figure 7. The solid lines represent the throughputs of scans when TPCC workloads are executed concurrently. The dotted lines mean the scan throughputs without TPCC workloads. DBA Offloading shows similar performance regardless of the presence of TPCC workloads, while scan with SIMD/NO-SIMD shows significant performance drop because of the interference from TPCC workloads. DBA offloading outperforms the scan with SIMD/NO-SIMD up to 16 threads and shows similar performance to SIMD scan with 32 threads. With the current implementation, each DBA FPGA has 6 scan engines and 4 DIMM slots. The results show the throughput by DBA offloading is saturated with 16 threads (4 threads per FPGA) because of the limited memory bandwidth of 4 memory channels and resources within the FPGA. Each CPU has 6 DDR channels with 128GB/sec bandwidth while each FPGA has 4 with 60GB/sec. When DBA has the same number of threads, it performs better than CPU running with SIMD. In a SoC (System on Chip) implementation where DBA offloading is embedded in real memory devices, these limitations will be relieved, and the overall performance will be improved further by higher clock frequency or more DBA engines.

In our work, we have the similar performance gain with both range and inlist scans, and similar results regardless of bit-cases used in bit-packed compression [9]. Due to the limited space in this paper, we show only the results of the range scan.

5 DISCUSSION

This research was done using FPGAs with attached DIMMs. The host system accesses the device memory through PCIe MMIO by mapping the device memory in the same address space of the host memory. Even with the slow performance of MMIO in PCIe, the offloading performance is not affected, because our offloading implementation only accesses the local device memory on FPGA once offloading operation starts.

DBA offloading can be implemented on the diverse memory form-factors with their own pros and cons. DIMM-based memory is quite common and very fast, but the memory controller will naturally interleave the data among memory channels. Therefore, even a single value can be crossed on two DIMMs and the DBA driver should handle the data interleaving while processing offloaded operations.

Recently proposed interfaces like CXL(Compute Express Link), Gen-Z and OpenCAPI will enable a new memory pool hosting the columnar main storage in IMDBMS. Although these interfaces introduce a bit higher latency than DIMM, the memory devices are not part of host memory controller pool where data are typically interleaved at 64B granularity. This allows DBA to assume a contiguous data layout in its attached memory and operates without considering data interleaving across memory channels. One more hurdle of DBA offloading would be non-contiguity in the physical address space of the contiguous data in the virtual address space. DBA offloading will provide so-called 'scatter and gather' feature by building a page translation table.

In Clouds, the micro-services of IMDBMS can be spread out among several nodes according to its role. The front-end computing nodes to process the transactions may be easily scaled out, but the storage node cannot be done simply having the same issues on our claim. We believe DBA offloading can contribute to resolving them in Clouds as well.

6 CONCLUSION

We showed that the OLTP-like mission critical workloads can interfere with data-intensive operations like massive scans. We proposed a near-memory database accelerator (DBA) to optimize the data movement and showed that performing the expensive scan operations in the memory devices can alleviate CPU load, cache conflict, host memory bandwidth bottleneck. To confirm its feasibility, we implemented the offloading system using FPGAs with attached DIMMs. Its results show more than 2x performance gain in OLTP workload when offloading the data-intensive operations, and higher or similar throughput scalability with better latency in offloaded scan workloads.

Aggregation is another data-intensive operation in IMDBMS consuming about 20-50% of CPU usage depending on the workloads. While it reads large amounts of data, most of it is rarely referenced again. DBA offloading on aggregation is being investigated as the next target operation.

ACKNOWLEDGMENTS

The authors would like to thank Ismail Oukid for his valuable feedback and contribution in developing our implementation.

ABSTRACT

Applications in several areas, such as privacy, security, and integrity validation, require direct access to database management system (DBMS) storage. However, relational DBMSes are designed for physical data independence, and thus limit internal storage exposure. Consequently, applications either cannot be enabled or access storage with ad-hoc solutions, such as querying the ROWID (thereby exposing physical record location within DBMS storage but not OS storage) or using DBMS "page repair" tools that read and write DBMS data pages directly. These ad-hoc methods are difficult to program, maintain, and port across various DBMSes.

In this paper, we present a specification of programmable access to relational DBMS storage. Open Database Storage Access (`ODSA`) is a simple, DBMS-agnostic, easy-to-program storage interface for DBMSes. We formulate novel operations using `ODSA`, such as comparing page-level metadata. We present three compelling use cases that are enabled by `ODSA` and demonstrate how to implement them with `ODSA`.

1 INTRODUCTION

Relational DBMSes adhere to the principle of physical data independence: DBMSes expose a logical schema of the data while hiding its physical representation. A logical schema consists only of a set of relations (i.e., the data). On the other hand, a physical view consists of several objects, such as pages, records, directory headers, etc. Hiding physical representation is a fundamental design of relational DBMSes: DBMSes transparently control physical data layout and manage auxiliary objects for efficient query execution. However, data independence inhibits several security and performance applications requiring low-level storage access. A small example is provided here, while Section 2 presents more detailed use cases.

Example 1. Consider a bank or a hospital that manages sensitive customer data with a commercial DBMS. For audit purposes, they must sanitize deleted customer data to ensure that it *cannot* be recovered and stolen. Very few DBMSes support explicit sanitization of deleted data (e.g., `secure delete` in SQLite exists but provides no guarantees or feedback to the user)[1]. To programmatically verify the destruction of deleted data, a DBA must inspect *all* storage ever used by a DBMS where such data may reside. This includes DBMS auxiliary objects such as indexes, unallocated fragments in DBMS storage, as well as any DBMS storage released to the OS.

[1]DBMS encryption is similar in not providing any feedback. Furthermore, encrypted values should still be destroyed on deletion.

Comprehensive DBMS storage-level access is an inherent challenge due to DBMS storage management. DBMSes control *allocated* storage objects such as a) physical byte representation of relations, b) metadata to annotate physical storage of relation data, and c) auxiliary objects associated with relations (e.g., indexes, materialized views). Users can manipulate allocated objects exposed by SQL. However, as illustrated in Example 1, the DBA may also need access to *unallocated* storage objects not tracked by a DBMS such as deleted data that lingers in DBMS-controlled files, and DBMS-formatted pages released back to the OS and no longer under DBMS control (e.g., files deleted by the DBMS or OS paging files). These objects are certainly part of the physical view and required for any storage access, but currently not exposed by any DBMS. Vendors such as Oracle incorporate the `DBMS_REPAIR` package [3], enabling users to manually fix or skip corrupt pages, but such tools only access DBMS-controlled storage.

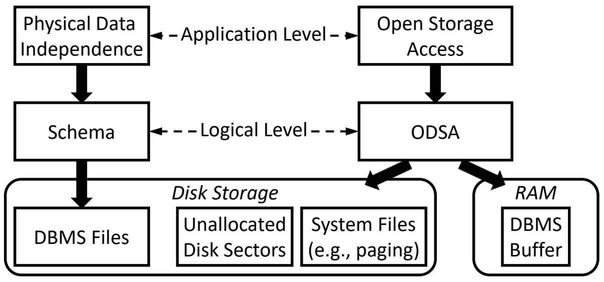

Figure 1: `ODSA` storage access.

In order to enable such security and performance applications, we present Open Data Storage Access (ODSA), an API that provides comprehensive access to all DBMS metadata and data in both (unallocated and allocated) persistent and volatile storage. `ODSA` does not instrument any RDBMS software; it interprets underlying data using database carving methods [8], which we use to expose physical level details. Carving itself is insufficient because the carved data consists of disk-level details making it difficult to program DBMS storage. `ODSA` abstracts low-level disk-level details with a hierarchical view of DBMS storage that is familiar to most DBAs. In particular it organizes them into pages, records, and values, which are resolved to internal, physical addresses. `ODSA` also guarantees the same hierarchy applies to multiple DBMS storage engines, ensuring portability of programmed applications. Figure 1 shows the storage access enabled by `ODSA`.

The rest of the paper is organized as follows. Section 2 presents three representative uses cases that require storage-level access. Section 3 provides an overview of how applications previously had limited access to internal DBMS storage. Section 4 describes the hierarchy exposed by `ODSA` and how it provides a comprehensive view of storage. Section 5 demonstrates implementation and use of `ODSA`. Finally, Section 6 discusses future work for `ODSA`.

2 USE CASES

This section presents three representative use cases that require direct access to different abstractions of storage.

2.1 Intrusion Detection

A bank is investigating mysterious changes to customer data. Unbeknownst to the bank, a disgruntled sysadmin modified the DBMS file bytes at the file system level. This activity bypassed all DBMS access control and logging, and still effectively altered account balances. The sysadmin also disabled file system journaling with `tune2fs` to further hide their activity. The bank cannot determine the cause for inconsistencies with the logs alone. Forensic analysis [7, 9] that detects such malicious activity requires comprehensive storage access to compare volatile storage with allocated and unallocated persistent storage.

2.2 Performance Reproducibility

Alice, an author, wants to share her computation and data based experiments with Bob so he can repeat and verify Alice's work. Out of privacy and access constraints, Alice builds a container consisting of necessary and sufficient data for Bob to reproduce. If the shared data is much smaller than original DBMS file, Bob cannot reproduce any performance-based experiment as the data layout of the smaller data will significantly differ from the original layout. To achieve a consistent ratio between Alice's experiment and Bob's verification, data layout specification at the record and page level must itself be ported. Currently, data layouts as part of a shared DBMS file in a container cannot be communicated [4].

2.3 Evaluating Data Retention

Continuing with Example 1 (Section 1), the bank validates their compliance with data sanitization regulations (e.g,. EU General Data Protection Regulation or GDPR [5]). After deleting data, the bank independently validates data destruction to ensure compliance. No data sanitization validation guidelines for DBMSes exist beyond a complete file overwrite [2]. This guideline is too coarse, especially for DBMS files containing a few deleted records.

Alternatively, consider a compliance officer that has programmatic access to DBMS storage via `ODSA` for validation. The officer can easily access all unallocated storage, and determine the location of deleted data that was not destroyed (e.g., DBMS index or table file, OS paging file).

3 RELATED WORK

We describe built-in tools and interfaces supported by popular DBMSes, which provide physical storage information at different granularities, but no comprehensive views of storage. The ROWID pseudo-column represents a record's physical location within DBMS storage (not disk), and is one of the simplest examples of storage-based metadata available to users most DBMSes. Commercial DBMSes typically provide utilities to inspect and fix page-level corruption. Examples include Oracle's `DBMS_REPAIR`, Oracle's `BBED` (a page editing tool available from Oracle 7 to 10g), and SQL Server's `DBCC CHECKDB`. However, even for accessible metadata such as ROWID, built-in tools do not help interpret its meaning; a DBA must manually make such interpretations. Moreover, no DBMS offers access to unallocated storage. Finally, existing tools only consider persistent storage. `ODSA` offers a universal meaning of DBMS storage (including IBM DB2, Microsoft SQL Server, Oracle, MySQL, PostgreSQL, SQLite, Firebird, and Apache Derby) with support for both persistent and volatile storage.

The term *carving* refers to interpreting data at the byte-level, e.g., reconstructing deleted files without the file system. Wagner et al. previously extended carving to interpret DBMS storage with `DBCarver` [8, 10, 11], retrieving both allocated and unallocated data and metadata without relying on the DBMS. `DBCarver` reads individual files or disk/RAM snapshots and extracts data, including user data and system metadata; it then writes data to a DB3F [12] formatted file. This paper uses `DBCarver` to demonstrate the physical information a DBMS can provide.

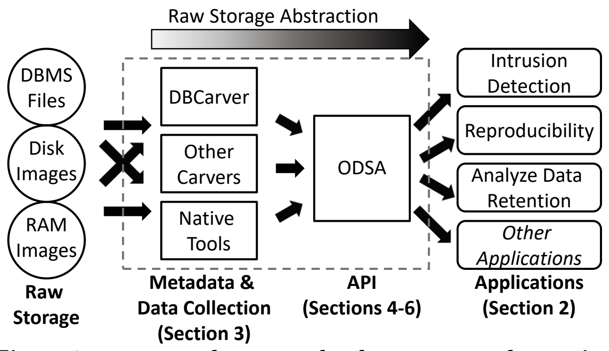

Figure 2: `ODSA` completes raw database storage abstraction in an end-to-end process for storage access.

4 OPEN DATABASE STORAGE ACCESS

Figure 2 shows how `ODSA` relies on carving to access raw storage. `ODSA` abstracts two details from raw storage.

First, it interprets each sequence of raw bytes and classifies it into a physical storage element: **Root**, **DBMS Object**, **Page**, **Record**, or **Value**. Thus, given a collection of interpreted raw storage elements, `ODSA` provides a hierarchical access to these elements by linking them. We provide a brief description of the hierarchy. The root level represents the entry point from all other data to be reached. DBMSes manage their own storage, and a disk partition consisting of both Oracle and PostgreSQL pages, will result in two DBMS roots. The DBMS object level calls return metadata, data, and statistics describing a DBMS object, such as a list of pages or column data types. Pages are uniquely identified by a byte offset in raw storage, rather than the PageID. We also do not rely on the page row directory pointers because deletion may zero out a record's entry.

Second, the `ODSA` hierarchy hides DBMS heterogeneity by accessing physical elements (e.g., pages, records) with physical byte offsets, rather than DBMS-specific pointers.

```
#4.A. Root
class Root:
    def __init__(self, db3f):
        #Initialize
    def get_object_ids(self):
        #Return a list of object ids
    #Calls to Other Instance and Namespace Data
#4.B. Object
class DBMS_Object(Root):
    def __init__(self, parent, object_id):
        #Initialize
    def get_page_offsets(self):
        #Return a list of page offsets
    def get_object_type(self):
        #Return the object type string
    def get_object_schema(self):
        #Return a list of column datatypes
#4.C. Page
class Page(Object):
    def __init__(self, parent, page_offset):
        #Initialize
    def get_record_offsets(self):
        #Return a list of record offsets
    def get_page_id(self):
        #Return a string for page id
    def get_page_type(self):
        #Return a string for page node type
    def get_checksum(self):
        #Return a string for the checksum
    def get_row_directory(self):
        #Return a list of row pointers
#4.D. Record
class Record(Page):
    def __init__(self, parent, record_offset):
        #Initialize
    def get_value_offsets(self):
        #Return a list of value positions
    def get_record_allocation(self):
        #Return Boolean allocation status
    def get_record_row_id(self):
        #Return a string for the row id
    def get_record_pointer(self):
        #Return a string for row pointer
#4.E. Value
class Value(Record):
    def __init__(self, parent, value_offset):
        #Initialize
    def get_value(self):
        #Return string for a data value
```

Figure 3: A sample set of ODSA calls.

Computing a DBMS pointer varies between vendors. For example, Oracle incorporates FileID into index pointer while PostgreSQL does not; index pointers in MySQL differs from both Oracle and PostgreSQL because MySQL relies on index organized tables. Even if all vendors used similar pointer encodings, abstraction is needed in terms of pages since duplicate pages may exist across a storage medium (outside of DBMS-controlled storage, such as paging files). Given Page$_A$ and its physical copy Page$'_A$, ODSA enables application developers to connect an index pointer referencing Page$_A$ along with Page$'_A$.

Implementation. There are multiple ways to implement the hierarchy. The ODSA hierarchy is currently implemented as a pure object hierarchy (Figure 3) and as a relational schema (Figure 4). The pure object hierarchy is stored as a JSON file in the DB3F format [12]. The relational schema is a starting representation – it supports basic applications and is normalized to 3NF requirements. A relational schema is realized since application developers

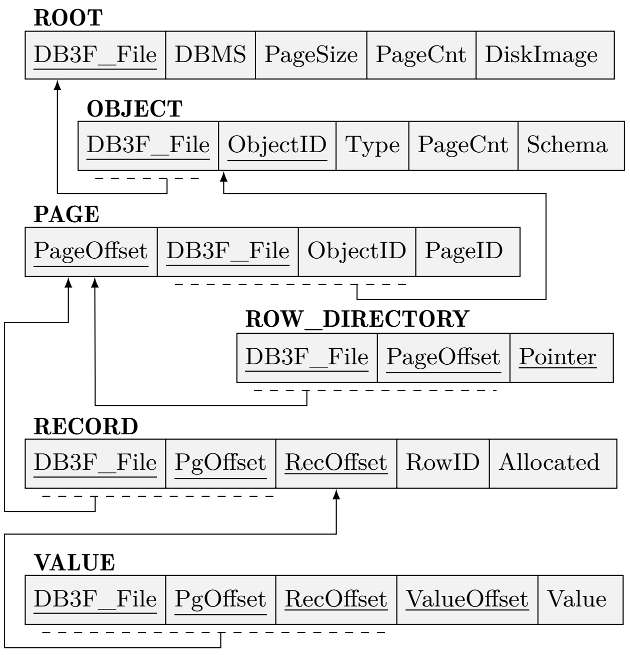

Figure 4: The relational schema used to store ODSA data.

may prefer to access a DBMS storage with SQL rather than calling the ODSA directly. However, as we show in Section 5 the SQL implementation requires several joins and is quite counter-intuitive, despite it being DBMS physical storage.

5 USING ODSA

For use cases in Section 2, two fundamental physical storage access operations are finding unallocated records and matching index pointers to records. ODSA calls enable these operations and show how these operations are achieved in Python and SQL, respectively. The two implementations are shown to contrast programmatic verbosity and maintainability. We focus on ODSA access and do not consider implementation performance.

Example 2: Find Unallocated Records. Use cases 2.1 and 2.3 require a DBA to search and retrieve unallocated records. To retrieve unallocated records, the user must know the carved DBMS file name and the table name (*Customer* table in this example) from which unallocated records are considered. Figure 5 finds and prints all unallocated (e.g., deleted) records from the *Customer* table. All ODSA calls are highlighted.

The implementation in Figure 5 uses ODSA calls to search for unallocated records: Line 3 retrieves page offsets, which uniquely identify pages. Line 5 then iterates through the pages, Line 6 loads each page, and Line 7 retrieves the record offsets for that page. Finally, Line 7 iterates through records using their identifying offsets within a page. Line 11 retrieves the record allocation status to identify and print unallocated records. The same search and retrieval requires an 8-way join in SQL due to the data hierarchy:

```
SELECT PageOffset, RecordOffset, ValueOffset, Value
FROM Object NATURAL JOIN Page
NATURAL JOIN Record NATURAL JOIN Value
WHERE Object.DB_File = 'MyDatabase1.json'
AND Object.ObjectID = 'Customer'
AND Record.Allocated = FALSE;
```

```
DBRoot = odsa.Root('MyDatabase1.json')
CustomerTable = odsa.Object(DBRoot, 'Customer')
PageOffsets = CustomerTable.get_page_offsets()

for PageOffset in PageOffsets:
  CurrPage = odsa.Page(CustomerTable, PageOffset)
  RecordOffsets = CurrPage.get_record_offsets()

  for RecOffset in RecordOffsets:
    CurrRecord = odsa.Record(CurrPage, RecOffset)
    allocated = CurrRecord.get_record_allocation()
    #print unallocated (e.g., deleted) record
    if not allocated:
      print CurrRecord
```

Figure 5: Using ODSA to find deleted records.

```
1  def findIndexEntries(record, Index):
2    RecordPtr = record.get_record_pointer()
3    IndPageOffsets = Index.get_page_offsets()
4
5    for IndPageOffset in IndPageOffsets:
6      IndPage = odsa.Page(Index, IndPageOffset)
7      IndROffsets = IndPage.get_record_offsets()
8
9      for IndROffset in IndROffsets:
10       IndEntry = odsa.Record(IndPage, IndROffset)
11       # IndEntry is a pair (Value, Pointer)
12       IndexPointer = odsa.Value(IndEntry, 1)
13       if IndexPointer == RecordPtr:
14         print IndEntry
```

Figure 6: Using ODSA to find all index entries for one record

Example 3: Match a Record to an Index Pointer(s). To match a record to pointers in a DBMS object such as an index, the user provides as input specific instances of the record and index objects. In Figure 6, Line 5 iterates through all index pages to determine if the input record matches any of the index records. Recall, in an index, records are value-pointer pairs. The code in Figure 6 determines offsets of all index pages (Line 7), and for each index page (Line 9) iterates over all index records in that page. Lines 10 fetches the index entry and Line 12 loads the pointer (offset 1 in value-pair) of the current index entry. Finally, for any index pointer match to the record pointer (Line 13), the index entry is printed.

In this example a brute-force iteration over *all* index pages is necessary, i.e., the program cannot break at the first occurrence of a match in Line 13. In practice, DBMS indexes often contain records of entries that were deleted or updated. For example, consider the record *(42, Jane, 555-1234)* in the *Customer* table where *name* column is indexed. In addition to the expected *(Jane, {PAGEID: 12, ROWID: 37})* entry in the index, the index may also contain *(Jehanne, {PAGEID: 12, ROWID: 37})* if the customer changed their name from Jehanne to Jane (old index entries will only be purged after the index is rebuilt). Moreover, the index might also contain a *(Bob, {PAGEID: 12, ROWID: 37})* entry if another customer named Bob previously deleted their account, free-listing the space for Jane's record at the same location.

As demonstrated in Figure 6, the Python-specific implementation retrieves all records. On the contrary, matching a record to an index in SQL requires a dynamic SQL (shown below) in which after the customary 8-way join to find record values, parameters of each record value must be supplied to match the values. Moreover, this query assumes that there is only one indexed column which is transparently accounted for in the abstraction of the DBMS Object class.

```
SELECT V1.Value
FROM Page NATRUAL JOIN Record
NATURAL JOIN Value V1 NATURAL JOIN Value V2
AND Page.ObjectID = ? --Index name placeholder
AND V1.ValueOffset = 0 --Indexed value at offset 0
AND V2.ValueOffset = 1 --Pointer is at offset 1
AND V2.Value = ( SELECT Record.Pointer FROM Record
     WHERE (DB_File, PageOffset, RecordOffset) =
           (?, ?, ?) /*Record ID placeholders*/);
```

6 CONCLUSION

ODSA was designed based on the principles and challenges described in [1, 6]. In particular, it was designed to be simple and easy-to-use by integrating the terminology used across DBMS documentation. Classes were named based on general concepts giving them an intuitive meaning while abstracting DBMS-specific implementation details. ODSA adheres to single-responsibility principle in that calls focus on single pieces of data and metadata. ODSA supports both 3^{rd} party carving and built-in DBMS mechanisms should vendors choose to expose storage. As a result, ODSA complements physical data independence and enables simple yet powerful implementations of a variety of applications that require access to storage. Additional requirements such as versioning and backward compatibility are future work.

ABSTRACT

Non-obvious relationship detection (NORD) in a knowledge graph is the problem of finding hidden relationships between the entities by exploiting their attributes and connections to each other. Existing solutions either only focus on entity attributes or on certain aspects of the graph structural information but ultimately do not provide sufficient modeling power for NORD. In this paper, we propose KGMatcher– an integrated graph neural network-based system for NORD. KGMatcher characterizes each entity by extracting features from its *attributes*, *local neighborhood*, and *global position* information essential for NORD. It supports arbitrary attribute types by providing a flexible interface to dedicated attribute embedding layers. The neighborhood features are extracted by adopting aggregation-based graph layers, and the position information is obtained from sampling-based position aware graph layers. KGMatcher is trained end-to-end in the form of a Siamese network for producing a symmetric scoring function with the goal of maximizing the effectiveness of NORD. Our experimental evaluation with a real-world data set demonstrates KGMatcher's 6% to 35% improvement in AUC and 3% to 15% improvement in F_1 over the state-of-the-art.

1 INTRODUCTION

Enterprises are equipped with modern computing power, and excel at storing entities of interest and their relationships generated from daily transactions or operations. Making sense of such linked data has gained increasing importance due to its potential of enabling new services. NORD aims at finding relationships between entities in a knowledge graph where the relationships are not explicitly defined in the data.

One of the first NORD systems [2] was designed to detect credit card fraud and later on gained fame for identifying fake identities in casino businesses. The problem of deciding if two entities share a non-obvious relationship such as "fake identity pair" is challenging. First, the attribute information is an important ingredient to characterize entities. However, the attributes are usually expressed in heterogeneous data structures. Extracting useful features and constructing a unified representation from the attributes through manual feature engineering is tedious and ineffective. Second, two related entities may not share similar attribute properties at all. For example, to trick the registration system, the fake identity is often disguised with totally different demographic and contact information. Instead of predicting solely based on the attribute information, a system should also take the surrounding context into consideration. The "neighbors" of the entities of interest in the graph may provide useful information for the detector to tap into the truth of a non-obvious relationship. However, modeling such complex context is a non-trivial task. Third, the entities that share non-obvious relationship usually have a high degree of separation in the graph. It is crucial for a system to be capable of capturing the global position information of the entities in the context of the entire graph so that the distanced separation can be identified later on.

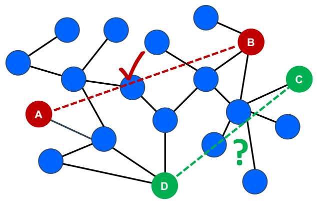

Figure 1: A supervised approach to NORD.

Existing solutions rely on handcrafted features to characterize the entities and domain expert defined rules for the detection. With the rapid growth of the graph size and the increasing complexity of the non-obvious relationships, it is tedious and almost impossible to manually maintain such solutions to achieve high effectiveness. Recently, machine learning approaches designed for similar tasks such as entity resolution [5, 9] and graph link prediction [6] are proposed. However, proven by our experimental results, their approaches are only good at tackling certain aspects of the NORD problem and demonstrate limitations in terms of their overall effectiveness. In this work, we propose KGMatcher– an integrated graph neural network-based system for NORD to address the challenges and overcome the limitations of the existing solutions.

KGMatcher Approach. We approach the problem in a supervised machine learning setting as depicted in Figure 1. That is, in addition to the knowledge graph which contains the entities, their attributes and connections, a set of ground-truth labels indicating the existence of the non-obvious relationships between entities is also available. Our goal is to design a machine learning model that can learn from these pairs and discover new pairs.

In its core, KGMatcher is a neural model that automatically extracts important features from the knowledge graph. The features encode the information regarding their entity *attributes*, *neighborhood* and *position* essential for predicting a non-obvious relationship between two entities. KGMatcher consists of three types of neural layers which are connected and can be trained end-to-end. Attribute features are extracted by the *attribute embedding* layers which support heterogeneous attribute types. The dense representations of the entities generated from these layers as well as the edge information are then fed into two stacks of graph layers. The first type of graph layers called *neighborhood* [1] layer focuses on extracting near-by neighborhood information by aggregating their attribute embeddings to the entity of interest. The second type of graph layers named *position* [8] layer focuses on obtaining global position information of the entities by referring them to a set of sampled anchors. The outputs of the two graph layers are then put together through concatenation to form the final feature vectors of the entities. Finally, KGMatcher's feature extraction network is used in the form of a Siamese network for predicting the existence of a non-obvious relationship between two input entities.

Contributions. It is worthwhile to highlight the following contributions of this work:

(1) We propose a supervised graph neural network-based solution for non-obvious relationship detection called KGMatcher.
(2) We design KGMatcher by adapting and integrating neural architectures for extracting essential NORD features, namely entity *attributes*, *neighborhood* and *position* features.
(3) We demonstrate the effectiveness of KGMatcher using a public dataset. KGMatcher achieves improvement in AUC from 6% to 35% and in F_1 from 3% to 15% over the state-of-the-art.

2 PRELIMINARY

Data Model[1]. Let $G = (V, E)$ denote a knowledge graph where $V = \{v_1, \cdots, v_n\}$ is a set of nodes with each node representing an entity and $E = \{e_1, \cdots, e_m\}$ is a set of edges with each edge $e_k = (v_i, v_j)$ indicating a connection between two entities v_i and v_j. In this work, we assume that the knowledge graph is an undirected graph, i.e., for every $e_k = (v_i, v_j)$, $(v_i, v_j) \equiv (v_j, v_i)$. Let $A = \{a_1, \cdots, a_k\}$ define a set of attributes associated with each entity v_i. An attribute, for example, can be a *date*, an *address*, a *comment*, etc. which means that attributes can be represented in various formats such as numerical, categorical, or text data type. Each entity $v_i = \{x^i_{a_1}, \cdots, x^i_{a_k}\}$ follows the same schema with the attribute types defined by A where $x^i_{a_k}$ denotes the kth attribute value of v_i. In other words, we assume that the entities in the knowledge graph are of the same type, i.e. all the entities share the same attribute types.

Problem Definition. Given two entities v_i and v_j in a knowledge graph G defined above, the goal is to design an algorithm f_G for G that can accurately predict whether or not v_i and v_j share a non-obvious relationship.

In this study, we approach the problem in a supervised learning setting. In addition to the knowledge graph $G = (V, E)$, a ground truth label set $L_G = \{y_1, \cdots, y_r\}$ is also available. A label $y_k = (v_i, v_j)$ where $v_i, v_j \in V$ indicates whether or not there exists a non-obvious relationship between v_i and v_j. Our goal is to design a machine learning model which is able to learn a function f_G from G and L_G that predicts the relationship between two entities presented in G. Following the common practice, the label set is partitioned into train, validation, and test set.

Graph Neural Networks. Graph Neural Networks (GNNs) learn a vector representation of a node from its associated attributes and the graph structure. Modern GNNs [6] adopt a neighborhood aggregation strategy where the representation of a node is learned in an iterative manner by aggregating representations of its neighbors. After k iterations (layers) of aggregation, a node's representation encodes the structural information within its k-hop network neighborhood. Formally, the k-th layer of a GNN is:

$$a^{(k)}_{v_i} = Aggregate^{(k)}\left(\left\{h^{(k-1)}_u | u \in Neighbor(v_i)\right\}\right), \quad (1)$$

$$h^{(k)}_{v_i} = Combine^{(k)}\left(h^{(k-1)}_{v_i}, a^{(k)}_{v_i}\right), \quad (2)$$

[1]The knowledge graph model we adopted in this work can be also seen as a form of the attributed or property graph model referred in the literature.

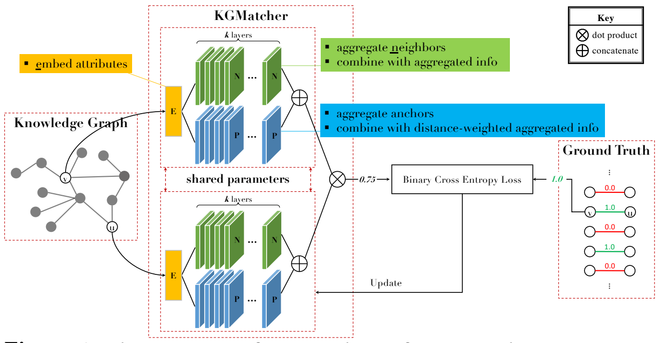

Figure 2: The overview of KGMatcher inference and training.

where $h^{(k)}_{v_i}$ is the vector representation of the node v_i at the k-th iteration. The node's attributes are usually used to initialize $h^{(0)}_{v_i} = Embed(\{x^i_{a_1}, \cdots, x^i_{a_k}\})$ where $Embed(\cdot)$ is an embedding function that obtains a vector representation of the attributes from their raw forms. The exact computation of $Aggregate^{(k)}(\cdot)$ and $Combine^{(k)}(\cdot)$ in GNNs defines their modeling approach. In Section 3.1, we will describe the approaches we introduce to our proposed model and how different models are integrated and trained end-to-end.

3 KGMatcher APPROACH

Overview. We first give an overview of the KGMatcher approach depicted in Figure 2. Each design choice will be discussed in the following sections. The KGMatcher at its core learns a function $f_G(\cdot, \cdot)$ for a knowledge graph G that takes two entities as inputs and produces a score indicating the likelihood of the two entities sharing a non-obvious relationship. KGMatcher characterizes an entity by considering its attributes, its k-hop neighbors' attributes and its position in the knowledge graph. These characterizations are extracted by three types of layers in KGMatcher, namely, **Attribute**, **Neighborhood** and **Position** layer. These layers are connected and trained end-to-end with the goal of producing embeddings of entities which maximize the accuracy of the non-obvious relationship predictions. The function f_G learned by KGMatcher produces a symmetric measure for the input entities which means that $f_G(u, v) \equiv f_G(v, u)$ where $u, v \in V$. The symmetric property is guaranteed by the use of *Siamese network*[4]. The network consists of two identical graph embedding networks which share the same parameters (weight matrices). When measuring two entities, each network takes one of the two inputs and produces the respective embedding. The final score is then computed based on a distance measure between two embeddings.

3.1 Entity Embedding in Knowledge Graph

We introduce the key components in the graph embedding network for entity feature extraction.

Attribute Embedding Layer (E). The attribute information associated with each entity in the knowledge graph provide the central ingredients of the entity. It can be a mixture of structured, semi-structured and/or unstructured data.

By leveraging the existing deep learning based embedding methods, KGMatcher is able to convert arbitrary attributes into a vector representation. First, depending upon the specific type of attribute, one can choose a neural architecture to produce the embedding in an unsupervised or supervised manner. To process "text" type attributes for example, the vector representation can be generated from a pre-trained language model such as XLNet[7]. This unsupervised strategy ensures the generality of the embedding since the pre-trained model is usually obtained from a large general domain corpus. To be able to generate the embeddings that also maximize the accuracy of the entity matching. KGMatcher allows these neural networks to be easily connected to the rest of the KGMatcher's layers and be adjusted through backpropagation from the feedback on the relationship prediction. The connected embedding networks can be either initialized by the pre-trained parameters (weights) and fine tuned onward or randomly initialized and trained from scratch. Second, KGMatcher finally generates the entity attribute embedding by concatenating each of the embeddings of the whole attribute set and feed it to the next layers.

In our experiment, the attributes are of three types, namely numerical, geo-location (in text string) and categorical type. The numerical types are processed by a normalization layer. The geo-location strings are converted into latitude and longitude numbers. For categorical types, we convert them into one-hot-encodings and embed them using multilayer perceptron neural networks.

Neighbors Aggregation Layer (N). An entity in a knowledge graph is usually not isolated by nature. The connectivity among the entities often indicates additional information which may not be explicitly described by their attributes.

To exploit the natural connections among the entities to capture such "surroundings" signal, we adopt a graph neural architecture as part of the KGMatcher embedding network. The GNNs for this purpose broadly follow a recursive neighborhood aggregation scheme. Each node aggregates embedding vectors of its immediate neighbors to compute its new embedding vector. After k iterations of aggregation, a node is represented by its transformed embedding vector, which captures the surrounding information within the node's k-hop distance. Instead of focusing on embedding nodes from a single fixed graph which is assumed by many prior works, we adopt a spectrum of GNNs – *inductive* GNNs, where only the *aggregate* (Equation 5) and *combine* (Equation 6) for a node are learned. The complexity of such GNNs is usually independent to the size of the graph. They are capable of incorporating unseen nodes and easy to scale.

In particular, we implement *GraphSage*[1] layers as our Neighborhood layers. The *Aggregate* function is formulated as:

$$a_{v_i}^{(k)} = \max\left(\left\{\mathrm{ReLU}\left(W_a^N \cdot h_u^{(k-1)}\right) | u \in Neighbor(v_i)\right\}\right), \quad (3)$$

where W_a^N is a learnable matrix and *max* represents an element-wise max-pooling. The *Combine* function is formulated as a concatenation followed by a linear mapping:

$$h_{v_i}^{(k)} = W_c^N \cdot \left[h_{v_i}^{(k-1)}, a_{v_i}^{(k)}\right], \quad (4)$$

where W_c^N is a learnable matrix. The embedding vector of a node is initialized by its attribute embedding vector obtained from the Attribute layer(s).

Position Measuring Layer (P). The GNNs for neighborhood modeling are good at capturing *local* context. One of the limitations of such modeling approach is their lack of emphasis on the position/location of the embedded node within the broader context of the entire graph. To be able to model the high degree of separation between entities, KGMatcher is equipped with P-GNN layers [8] as Position layers to capture the *global* position information for each entity. The intuition of the P-GNN approach is that the absolute position of a node can be defined by its relative positions to a set of reference nodes in the graph.

Specifically, instead of aggregating information from the immediate neighbors, P-GNN aggregates information for an embedded node from a set of "anchor" nodes. Each P-GNN layer samples a set of anchor nodes as references from the graph and then computes the shortest distances from every embedded node to these sampled anchors to encode a distance metric. Each embedding dimension of a node corresponds to the combined of node embedding and the aggregated information from a specific anchor(s) weighted by the distance metric. The weight is inversely proportional to the distance. KGMatcher stacks multiple Position layers to achieve higher expression power. The aggregation for the lth dimension for v_i at time k is formulated as:

$$a_{v_i^l}^{(k)} = \mathrm{mean}\left(\left\{\mathrm{ReLU}\left(W_a^P \cdot (s(v_i,u) \times h_u^{(k-1)}\right) | u \in Anchor^l(v_i)\right\}\right), \quad (5)$$

and the combined embedding of v_i at time k is:

$$h_{v_i}^{(k)} = W_t^P \cdot \left[\cdots, \overbrace{W_c^P \cdot \left[h_{v_i}^{(k-1)}, a_{v_i^l}^{(k)}\right]}^{l\text{th dimension}}, \cdots\right], \quad (6)$$

where $s(v_i, u)$ computes the weight of an anchor node u to the embedded node v_i, $Anchor^l(v_i)$ returns a set of anchors dedicated for computing the embedding value on the lth dimension of the embedded nodes, *mean* represents an element wise mean-pooling and W_a^P, W_t^P and W_c^P are learnable matrices. The weight computed by $s(v_i, u)$ [8] is inversely proportional to the shortest distance between v_i and u in the graph.

Interaction between N and P Layer. To form a single representation that encodes both neighborhood and position information, a few *merging* design choices are made. One can combine the output embeddings immediately after each N and P layer through concatenation or other element-wise operations. The merged node embedding is then fed separately into the next N and P layer. In our work, to clearly separate the contribution of neighborhood and position signal, we allow the information propagation of the two kinds progress in parallel and only merge the two at the very end through concatenation (depicted in Figure 2).

3.2 KGMatcher Inference and Training

Suppose a pair of entities u and v are labeled with a label $y \in L_G$ using a function $d_y(u, v)$. The goal of KGMatcher is to predict such label y for unseen entity pairs. Specifically, KGMatcher solves the problem via learning an embedding function Φ parameterized by θ, where the objective is to maximize the likelihood of the conditional probability $p(y|\Phi_\theta(u), \Phi_\theta(v))$. Formally, we have the learning objective as:

$$\begin{aligned}\min_\theta \; & \mathbb{E}_{(u,v)\sim L_{G_{train}}} \\ & \mathcal{L}(d_z(\Phi_\theta(u), \Phi_\theta(v)) - d_y(u, v)),\end{aligned} \quad (7)$$

where $d_z(\cdot, \cdot)$ is a function that predicts the label based on two entity embeddings. Since the relationship we defined is undirected, d_z should then be a symmetric function. A Siamese neural network, depicted in Figure 2 uses the same weights while working in tandem on two different input vectors to compute comparable output vectors which aligns with the required symmetric property. Therefore, we train KGMatcher's entity embedding layers in the form of Siamese network. In our implementation, d_z computes dot product of the two input vectors.

4 EXPERIMENTAL EVALUATION

Setup & Evaluation Method. We evaluate our proposed system with a publicly available dataset by comparing its performance against other baselines. All methods are implemented in PyTorch and trained on a CentOS server with Intel(R) Xeon(R) Gold 6138 @ 2.00GHz CPUs and NVIDIA Tesla P100 GPUs.

Table 1: Test results of different models. ↑ indicates that the higher the score the better the performance. (·) after each score (average±standard deviation) indicates the ranking of the method (vertical comparison) w.r.t the specific evaluation metric. ⋆ indicates that the baseline is implemented by ourselves. The cut-off thresholds of these reported methods are 0.210, 0.445, 0.620, 0.580, 0.440, 0.375 and 0.530 which produce the maximum F_1 score for each respective method.

Method	AUC ↑	F_1 ↑	Precision ↑	Recall ↑
DeepMatcher [5] ⋆	0.6658±0.0351 (6)	0.6755±0.0108 (6)	0.5255±0.0131 (6)	0.9455±0.0000 (2)
GIN [6]	0.7367±0.0329 (3)	0.7400±0.0311 (3)	**0.7036**±0.0415 (1)	0.7818±0.0000 (6)
GCN [3]	0.7080±0.0333 (5)	0.7210±0.0192 (5)	0.6837±0.0346 (2)	0.7636 ±0.0000 (7)
GraphSAGE [1]	0.7633±0.0320 (2)	0.7442±0.0200 (2)	0.6598±0.0311 (4)	0.8545±0.0000 (5)
PGNN [8]	0.7090±0.0337 (4)	0.7255±0.0199 (4)	0.6108±0.0261 (5)	0.8942±0.0195 (4)
PGNN (w/o attributes) [8]	0.5988±0.0424 (7)	0.6668±0.0023 (7)	0.5003±0.0019 (7)	**0.9994**±0.0040 (1)
KGMatcher ⋆	**0.8079**±0.0343 (1)	**0.7660**±0.0239 (1)	0.6676±0.0331 (3)	0.8998±0.0222 (3)

Since our task is binary classification – predict the existence of the relationship between two input entities, we measure the performance of all methods using *receiver operating characteristic* (ROC), *area under the curve* (AUC), *precision*, *recall* and F_1 typical metrics for the evaluation of a binary classification task. We report the average measurements and the standard deviations of all methods on the test set of 100 repetitions.

Dataset. We use the UDBMS *Person*[2] dataset for our evaluation. The original dataset contains 502,529 unique person entities. Each entity has up to 48 attributes. We use 8 attributes – *relation*, *relative*, *spouse*, *child*, *parent*, *partner*, *predecessor*, *successor*, *opponent* and *rival* to build the edges and select another 25 popular attributes in terms of their presenting rate as entity attributes. We use *subject* information to annotate the non-obvious relationships, i.e. two entities sharing the same *subject* have a non-obvious relationship. We further trim down the dataset by only selecting the entities with reasonable amount of attributes and reasonable level of connectivity. Finally, we have 1,294 person entities, 3,480 edges and 316 relationships. The relationship pairs are split into train, validation and test set as the positive samples. The negative samples are uniformly sampled by fixing one of the entities in the positive sample pairs.

Baseline. We compare KGMatcher against 5 other baselines:

• **DeepMatcher** [5] is a supervised deep learning solution which aims to identity pair of data instances that are referring to the same entity based on their attributes.

• **Graph Convolutional Network** (GCN) [3] is a semi-supervised spectral-based graph neural network. It models the graph topology as well as the node attributes.

• **GraphSAGE** [1] is a spatial-based graph neural network which models the graph topology through neighbors aggregation. The aggregated information is based on the node attributes.

• **Graph Isomorphism Network** (GIN) [6] is a graph neural network that generalizes *Weisfeiler-Lehman* test for maximum discriminative power. It also models the node attributes.

• **Position-aware Graph Neural Network** (PGNN) [8] is a generalized spatial-based graph neural network which aims to identify the node position in the context of the the entire graph through sampled anchors.

Effectiveness. Given two entities on the knowledge graph, all methods produce a score [0-1] which can be interpreted as the level of confidence of predicting a non-obvious relationship. As a data analyst, one has to specify a cut-off threshold for the model to give a firm (binary) answer. To simulate this scenario, we measure the effectiveness using *precision*, *recall* and F_1 where the cut-off thresholds must be provided. Since maximizing either *precision* or *recall* can easily done by varying the threshold, we report these measurements by selecting the thresholds that maximized each method's F_1 score. As shown on Table 1, KGMatcher outperformed all baselines in F_1. Although, GIN and PGNN (w/o attributes) perform well either on *precision* or *recall*, their measurements on the other side (*recall* or *precision*) are poor. The unbalanced performance may not be acceptable to many applications. In particular, the model that only considers attributes (DeepMatcher) or global position information (PGNN w/o attributes) performs worse than the ones that model both attributes and some topology of the graph.

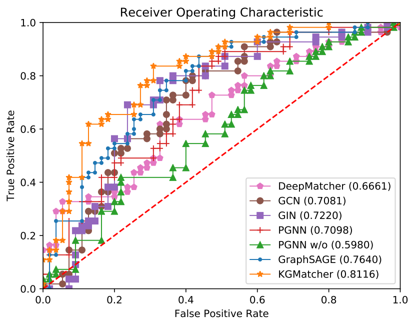

Figure 3: ROC plot of all baselines. (·) after each method in the legend box indicates its corresponding AUC value.

To further evaluate the overall performance of all the methods across different thresholds, we plot the ROC in Figure. 3 and report the AUC value in Table. 1. Our proposed method KGMatcher is significantly better than all the other baselines.

In summary, our experimental evaluation demonstrates KGMatcher's 6% to 35% improvement in AUC and 3% to 15% improvement in F_1 over the other baselines.

ABSTRACT

The increasing ubiquity of multivariate functional data (MFD) requires methods that can properly detect outliers within such data, where a sample corresponds to $p > 1$ parameters observed with respect to (w.r.t) a continuous variable (*e.g.* time). We improve the outlier detection in MFD by adopting a geometric view on the data space while combining the new data representation with state-of-the-art outlier detection algorithms. The geometric representation of MFD as paths in the p-dimensional Euclidean space enables to implicitly take into account the correlation w.r.t the continuous variable between the parameters. We experimentally show that our method is robust to various rates of outliers in the training set when fitting the outlier detection model and can detect outliers which are not detected by standard algorithms.

1 INTRODUCTION

1.1 Functional data context and taxonomy

In many fields (*e.g.* engineering, biology or medicine), detecting atypical behaviors of complex systems enables to better anticipate and understand both undesired and rare situations (*e.g.* engine failure, heart disease). Most of the time, detecting atypical behaviors requires the analysis of p system parameters ($p \geq 1$) measured by high sampling-rate sensors. The raw sensor measurements result in noisy data dependent on a continuous variable (*e.g.* time, wavelength) being discretized by the sampling process of the p sensors. Such data are referred as *univariate* or *multivariate functional* data depending on whether one ($p = 1$) or several parameters ($p > 1$) are analyzed, respectively.

Thus the observation of the parameters along the continuous variable is seen as the realization of an underlying (unknown) function that values in $\mathbb{R}^p$. We emphasize that in the functional data framework, a data set sample is represented as a function rather than a high-dimensional vector of different dimension containing the raw measurements. Dimension refers to the number of measurements which can be different from a sample to another). We refer to [13] for a comprehensive introduction to functional data analysis.

Here we adopt the following notations : the dependent continuous variable is denoted by $t \in \mathcal{T} \subset \mathbb{R}$ where $\mathcal{T}$ is a closed interval of $\mathbb{R}$, the data samples are sub-scripted by $i \in \{1...n\}$, univariate functional data (UFD) samples are denoted by lower case letter $x_i(t) \in \mathbb{R}$ and multivariate functional data (MFD) samples are denoted by capital letter $X_i(t) = (x_{i1}(t), ..., x_{ik}(t), .., x_{ip}(t)) \in \mathbb{R}^p$. Thus a MFD is made up of p UFD which are potentially correlated.

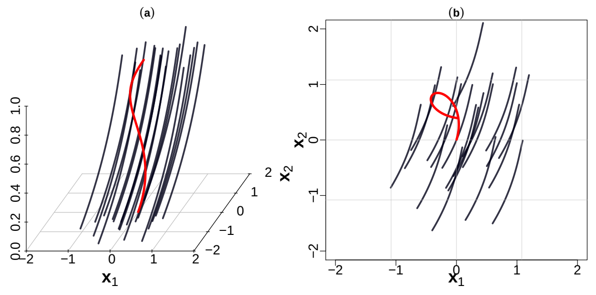

Figure 1: Example of 21 MFD ($p = 2$) with one shape persistent outlier in red. (a) (t, x_{i1}, x_{i2}) representation. (b) (x_{i1}, x_{i2}) representation *i.e.* projection along t-axis.

Detecting atypical behaviors is referred as *outlier* or *anomaly detection*. An outlier is defined as a sample which is rare and very different from the rest of the data set based on some measure [1]. A taxonomy of functional outliers into two classes has been proposed by Hubert *et al.* [8]. First, an *isolated outlier* is defined as a sample which exhibits an extreme behavior for very few points t. For instance a narrow vertical peak in the curve depicted by a parameter x_{ik} w.r.t t is named a *magnitude isolated* outlyingness and a high horizontal translation in the curve is referred as *shift isolated* outlyingness. Second, a *persistent outlier* is a sample which never exhibits extreme behavior but deviates from inliers for many points t, an example of shape persistent outliers is given in Fig.1. Persistent outliers can be divided into other sub-classes, see [8] for detailed examples. Note that an outlier can be of mixed type, *i.e.* a sample entailing several outlier classes. For an instance, one parameter has a shape persistent outlyingness and another one has an isolated outlyingness.

In this paper we focus on a geometric representation for outlier detection in MFD and highlight the situation of outliers of mixed type. The MFD case is more challenging than the UFD one since the potential correlation between the p parameters (*i.e.* how x_{ik} and $x_{ik'}$ are correlated w.r.t t) has to be taken into account additionally to the individual variations of the single parameters w.r.t to t [8]. Indeed contrary to outliers in UFD, where the outlyingness of a sample only consists of an atypical variation w.r.t t of a single parameter, in MFD the outlyingness of sample might be hidden in an atypical variation of the *relationship* between some parameters [8, 11] as well as an atypical variation of one of the p parameters. Note that the representation of MFD we propose can also be used for other tasks than outlier detection (*e.g.* classification) as well as other geometric representations of 2D and 3D shapes which can be applied for the $p = 2$ and $p = 3$ (respectively) MFD cases [16].

1.2 Related work

The outlier detection in MFD is recent and has been addressed by statistical depth functions [18] originally proposed to provide an outward-center ranking score, also named a *depth score* (*e.g.* in the interval $[0, 1]$), of multivariate data which are basically sample points in $\mathbb{R}^d$. In this general multivariate data context, where each sample is regarded as a point in a d-dimensional point cloud, the first ranked samples are the most central ones within such point cloud and are seen as most representative, whereas the last ranked samples are the least central ones and thus they are likely to be outliers. Such ranking is ensured through the monotonicity property of the depth function (see [18] for theoretical understanding of a depth function). Hence, the depth score can be viewed as an outlyingness score which reflects the degree of outlyingness at the sample level.

Some statistical depth functions have been extended first to handle UFD [3] and then MFD [2, 8]. The UFD extension consists in computing a depth function on $x_i(t), \forall i$ at each t and then to compute the integral over $t \in \mathcal{T}$ of the resulting depth scores [3, 6] which in turn provides an average sample depth score for all i. Note that this extension is an aggregation of the depth function applied in a univariate manner since, for a given t, $\{x_i(t)\}_{i\leq n}$ is a point cloud in $\mathbb{R}$. Since $\{X_i(t)\}_{i\leq n}$ forms a point cloud in $\mathbb{R}^p$, the MFD extension relies on the application of a depth function in a multivariate manner and integrates the depth scores as in the UFD case [2]. Such an extension suffers from important issues :

(1) First, it is not sensitive enough to persistent outliers because their point-wise depth scores (*i.e.* for each t) do not differ from those of inliers. One can augment the MFD samples by adding some derivatives functions of the parameters as supplementary (unobserved) parameters but it increases both computations and the complexity of the data analysis.
(2) Second, even if the point-wise depth scores of an isolated outlier are different from those of an inlier, its sample depth score will be mixed with inliers because the integration of the point-wise depth scores acts as an average.
(3) Furthermore, since the capacity of the depth function to capture different types of outlier is fundamental, outliers caused by abnormal correlation between the parameters (*i.e.* outliers of mixed type) are hard to detect. Such an abnormal correlation can result in outliers of mixed type.

To address the first issue (1), and especially to detect shape persistent outliers, several depth functions have been proposed. Khunt and Rehage (*FUNTA*) [9] proposed a depth function based on the intersection angles between a curve sample depicted by x_{ik} and $\{x_{jk}\}_{j\leq n, j\neq i}$ and then average these angles over both their number and the parameters. Such method is not able to detect outliers caused by an abnormal correlation between the parameters and also isolated outliers because their depth function is only focused on shape persistent outliers.

To address the second issue (2) the integral can be replaced by the infimum as the aggregation of the point-wise depth scores, which avoids the masking of outliers having few different point-wise depth scores.

To address the third issue (3), Dai and Genton [4] proposed the *directional outlyingness* (*Dir.out*), a point-wise depth function based on the direction of $X_i(t)$ in $\mathbb{R}^p$ toward the projection-depth [17] of $\{X_i(t)\}_{i\leq n}$. To compute the sample depth score, the point-wise depth scores are aggregated through an integral over $\mathcal{T}$ which is further decomposed into an average component and a variance-like component. Such sample depth score decomposition enables to detect multiple outliers and also to identify their class by analyzing how the two depth components are distributed according the other sample depth scores (*e.g.* samples with high variance-like component value are likely persistent shape outliers and samples with high average component value are likely isolated outliers). However, to detect persistent shape outliers, the direction of $X_i(t)$ is not a sufficient feature and further geometrical representation has to be considered.

1.3 Contribution

In this paper, we propose a different framework than the statistical depth to remedy these issues by treating MFD as trajectories in $\mathbb{R}^p$ from which we extract geometrical features such as the curvature. Such geometrical features are computed by interpretable (from a geometric standpoint) aggregation functions, named *mapping functions* in the sequel, which combine some derived functions (*e.g.* derivatives, integral) from the MFD. We then apply a state-of-the-art algorithm on the geometrical MFD representation to achieve the outlier detection. Considering MFD in a geometric manner enables to implicitly capture the correlation between the p parameters w.r.t t and thus to detect different classes of outliers as well as mixed types. Moreover, such combination results in a more robust outlier detection method *e.g.* when there are more than 5% of outliers in the training set. Thus, we both take benefit from outlier detection algorithm for multivariate data as well as the geometry of the curve (*i.e.* the geometry of X_i in $\mathbb{R}^p$ and the geometry of each parameter x_{ik} w.r.t t).

2 FUNCTIONAL DATA REPRESENTATION

The first step in functional data analysis is to approximate the unknown function, $X_i : \mathcal{T} \to \mathbb{R}^p$, underlying the noisy measurement samples $X_i(t_1), ..., X_i(t_{m_i})$ where m_i is the number of measurements for each parameter of the sample i, by an approximation function $\tilde{X}_i$ defined as X_i. Note that no assumption is made on the distribution of the measurement points $\{t_1...t_{m_i}\} = t_{i\bullet}$, thus the functional data representation can deal with sparse measurements as well as uniform ones.

The functional approximation step aims at removing the noise and thus enables to achieve accurate evaluations of some derived functions that we need for the mapping function computation. This section introduces how $\tilde{X}_i = (\tilde{x}_{i1}, ..., \tilde{x}_{ik}, ..., \tilde{x}_{ip})$ is specified as well as it is inferred from the data.

2.1 Functions as a basis expansion

First, we specify the functional form of the approximation function as a finite linear combination of basis functions, where each basis function depends on $t \in \mathcal{T}$. Suppose we want to approximate x_{ik}. Intuitively, it aims to represent $\tilde{x}_{ik}$ with a small number of "specific functions", each one being able to capture some local features of X_i in hopes to recover it with a small approximation error. Hence, the following form is given for $\tilde{x}_{ik}$ [13],

$$\forall t \in \mathcal{T}, \tilde{x}_{ik}(t) = \sum_{l=1}^{L_{ik}} \alpha_{ikl}\phi_l(t) = \boldsymbol{\alpha}_{ik}^\top \boldsymbol{\phi}(t) \tag{1}$$

where $\boldsymbol{\phi}(t) = \{\phi_l(t)\}_{1\leq l\leq L_{ik}}$ is a vector of orthonormal basis functions at t for some $L_{ik} \in \mathbb{N}^*$ (referred as the basis size) with fewer basis functions than sampled observation points ($L_{ik} \ll m_i$), and $\boldsymbol{\alpha}_{ik}^\top = \{\alpha_{ikl}\}_{1\leq l\leq L_{ik}}$ is the coefficient vector which element α_{ikl} is the importance of the l-th basis function. The choice of the basis of functions is data dependent.

Here we consider that x_{ik} are smooth and so we choose the B-spline basis of functions which are basically piece-wise polynomial functions. If the data were periodic data, one could choose the Fourier basis. We refer to [13] for a discussion on the choice of basis functions. Note that from the functional approximation Eq.1, one can easily compute some derivatives or integral based functional data since by linearity,

$$D^q \tilde{x}_{ik} = \sum_{l=1}^{L_{ik}} \alpha_{ikl} D^q \phi_l(t) \tag{2}$$

where $D^q = \frac{\mathrm{d}^q}{\mathrm{d}t^q}$ is the $q-$th derivative operator, provided that the basis functions ϕ_l are differentiable at the q-th order.

2.2 Inference

Assuming the data were sampled with a white noise ϵ_{ij}, *i.e.* $x_{ik}(t_{ij}) = \tilde{x}_{ik}(t_{ij}) + \epsilon_{ij}$ where ϵ_{ij} is independent from $\tilde{x}_{ik}(t_{ij})$, we can compute the coefficient vector $\boldsymbol{\alpha}_{ik}$ by minimizing the following penalized least-squares criteria:

$$J_{\lambda_k}(\boldsymbol{\alpha}_{ik}) = \|x_{ik}(t_{i\bullet}) - \boldsymbol{\Phi}_{ik}\boldsymbol{\alpha}_{ik}\|^2 + \lambda_k \boldsymbol{\alpha}_{ik}^\top \mathbf{R}_{ik} \boldsymbol{\alpha}_{ik} \tag{3}$$

where $\|\cdot\|$ stands for the l_2-norm, $\boldsymbol{\Phi}_{ik} = \{\phi_l(t_{ij})\}_{1\le j\le m_i, 1\le l\le L_{ik}}$ is the $m_i \times L_{ik}$ matrix containing all the L_{ik} basis functions evaluated at the measurement points $t_{i\bullet}$ and $\mathbf{R}_{ik} = \{\int_{\mathcal{T}} D^q \boldsymbol{\phi}_j(t) D^q \boldsymbol{\phi}_m(t)\mathrm{d}t)\}_{1\le j,m\le L_{ik}}$ is a $L_{ik} \times L_{ik}$ positive semi-definite matrix containing the inner products of the q-th derivative of the basis functions which enforces the approximation function to have a small q-th derivative *i.e.* to vary smoothly; $\lambda_k > 0$ is a hyper-parameter controlling the weight of the penalty and can be set to 0 for no penalization. In practice it is common to choose $q = 1$ or $q = 2$ (i.e to penalize the velocity or the acceleration) and to compute λ_k by cross-validation.

Equaling the gradient of $\boldsymbol{J}_{\lambda_k}$ to $\mathbf{0}$ w.r.t $\boldsymbol{\alpha}_{ik}$ leads to the minimizer in Eq.4 [13] which is a special case of the ridge regression solution:

$$\boldsymbol{\alpha}^*_{ik,\lambda} = (\boldsymbol{\Phi}_{ik}^\top \boldsymbol{\Phi}_{ik} + \lambda_k \mathbf{R}_{ik})^{-1} \boldsymbol{\Phi}_{ik}^\top x_{ik}(t_{i\bullet}) \tag{4}$$

The estimated coefficient vector $\boldsymbol{\alpha}^*_{ik,\lambda}$ can then be plugged in Eq.1 to evaluate $\tilde{x}_{ik}$ over an arbitrary discretization of $\mathcal{T}$.

3 MAPPING FUNCTION

We propose to regard MFD as paths in $\mathbb{R}^p$ to highlight some underlying shape outlyingness features corresponding to a change in the relationship between the parameters. We feature this change with a mapping function that we define as a geometric aggregation of the p parameters. We refer to [15] for an introduction to shape analysis from functional data.

In this section, we present the *curvature* as an example of mapping function. The curvature is a measure of how much bended a curve is, more formally how the curve locally deviates from the tangent line, see Fig.2. It is defined as:

$$\kappa(t) = \frac{\|D^1(\frac{D^1X(t)}{\|D^1X(t)\|})\|}{\|D^1X(t)\|} \tag{5}$$

where $\|\cdot\|$ denotes the Euclidean norm in $\mathbb{R}^p$. One can interpret κ in Eq.(5) as follows: $\frac{D^1X(t)}{\|D^1X(t)\|}$ gives the direction vector (i.e the normalized tangent vector), therefore $D^1 \frac{D^1X(t)}{\|D^1X(t)\|}$ gives the change direction vector and the denominator $\|D^1X(t)\|$ aims to relate the change of direction w.r.t the tangent vector, *i.e.* how the direction vector varies w.r.t a tangent line. Consequently, the

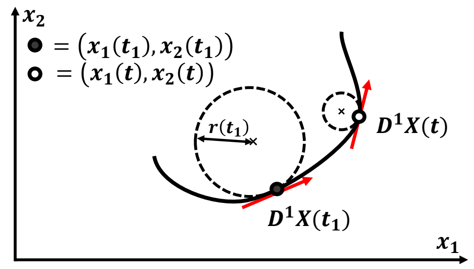

Figure 2: Curvature mapping κ. The curvature measures how large the radius of the tangent circle is. Here, in the neighbourhood of the curve at t_1 (dark-grey dot), the *tangent vector* $D^1X(t_1)$ keeps the same direction, hence the tangent circle has a large radius ($r(t_1) = \frac{1}{\kappa(t_1)}$) resulting in a small curvature. In the neighbourhood of the curve at t (white dot), the tangent vector $D^1X(t)$ quickly changes direction, hence the tangent circle has a lower radius *i.e.* a higher curvature than at t_1.

curvature mapping can highlight functional outliers which curve exhibits a different bended shape than the other samples.

Thus if a curve abnormally changes direction (*i.e.* it deviates from a tangent line) w.r.t most of the data set, then the curvature mapping can highlight outliers. As a result, if the curve X_i depicts a line (*i.e.* the parameters are linearly correlated w.r.t t), then the curvature is constant w.r.t t since the directions do not vary in $\mathbb{R}^p$. Clearly, this is a geometric characterization of MFD.

From the reconstructed samples $\{\tilde{X}_i\}_{i\le n}$, transformed to UFD by the mapping function, we detect the outliers with state-of-the-art algorithms initially proposed to deal with multivariate data (not functional). Here we use Isolation-Forest (*iFor*) [10] and One-class SVM (*OCSVM*) [14] which are both unsupervised.

4 NUMERICAL EXPERIMENTS

We conducted an experimental study on real data. We compare our approach with state-of-the-art depth-based methods, *FUNTA* and *Dir.out* [4, 9] (Sec.1.2) which take the MFD as input.

4.1 Experimental procedure

We experiment our method on a well-known real data set of electrocardiogram (ECG) time series [7] also used in outlier detection in [4]. Such data set correspond to time series of electrical activity and can reveal abnormal heartbeat. The time series are UFD (with number of measurements $m_i = 85, \forall i$) and in order to show the applicability of our approach in the MFD case, we augment the original UFD data to MFD ($p = 2$, bivariate) by adding the square of the initial time series. We did not add some derivatives-based functions as supplementary parameters since it is already considered by our mapping function (see Eq.5).

We evaluate our approach through multiple random splittings. We randomly split the data into a training and a test set. We generate the training set by setting the ratio of outliers (referred as the contamination level c) to 5, 10, 15, 20 and 25%. For each value of c, we repeat the random splitting 50 times, we fit *iFor* and *OCSVM* on the training set and compute the average and standard deviation Area Under (AUC) the Receive Operating Curve (ROC) on the corresponding test set. We present the results in Fig.3 and discuss them in Sec.4.3.

For each sample and each variable $x_{ik} \forall i, k$ we use a B-spline basis of functions (piece-wise polynomial functions, [13]) to achieve the functional approximations and we select the basis sizes L_{ik}

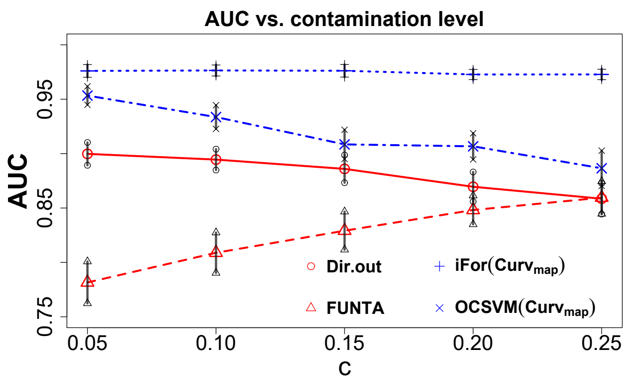

Figure 3: AUC (vertical axis) and standard deviation (vertical segments' length equals one standard deviation) from ECG data set - average results over 50 repetitions considering five contamination levels c (horizontal axis).

trough a leave-one-out cross validation procedure. We evaluate each $\tilde{X}_i$ on the same regular grid of $\mathcal{T}$ with length $m_i = 85$. We compute the mapping function by combining the first and second derivatives, according to Eq.2 and Eq.5, and we apply $iFor$ and $OCSVM$ on the resulting UFD.

4.2 Outlier detection step

We use $iFor$ and $OCSVM$ as outlier detection algorithms on the UFD that our mapping function κ returns (Eq.5). $iFor$ and $OCSVM$ are unsupervised and, like the depth-based methods, output a normalized outlyingness score for each sample. In practice, in outlier detection one has not necessarily access to labeled samples, *i.e.* information depicting whether a sample is an outlier or not, but if he has, the labels can be combined with their corresponding outlyingness scores to learn an outlyingness threshold that can best discriminate outliers from inliers. Such a threshold can be learned from the ROC as well as an imbalanced classification algorithm [5, 12] in a one dimensional manner from the scores. Here, we do not learn any threshold and only consider the label information for empirical demonstration purpose, *i.e.* by computing the AUC on the test set.

4.3 Discussion of the results

From the results in Fig.3, we see that we outperform the two depth-based methods for all the contamination levels in average and perform equally in terms of standard deviation. Since $FUNTA$ is only able to detect persistent shape outliers and $Dir.out$ is expected to detect isolated as well as persistent outliers[1], we can deduce that the abnormal class (*i.e.*outliers) in the ECG data set not only contains persistent shape outliers but also isolated ones or outliers of mixed type which are well discriminated by the curvature mapping function. Thus the curvature mapping enables to detect mixed type outliers.

Moreover, we note that as c increases both $iFor(Curv_{map})$ and $OCSVM(Curv_{map})$ still outperform the baselines. Hence, we show that our combination of outlier detection algorithm with MFD mapped to a geometrical representation is more robust to the presence of outliers in the training set than the baselines. We note that OCSVM degrades as c increases. It is due to the ν hyper-parameter (we tune it on the training set with a 5-fold cross validation) corresponding to an estimate of contamination level in the training set. We observed that such hyper-parameter is hard to tune as c increases and thus could decrease the performance w.r.t c.

[1]Justification can be found in the experiments in [4] which were conducted on several synthetic data sets where each one contains a unique type of outlier.

5 CONCLUSION AND FUTURE WORK

We propose an approach to detect outliers in MFD. It consists in computing a geometrical representation of MFD followed by an outlier detection algorithm. We compare our approach with recent depth-based methods which handle MFD as input.

Through one example of mapping function, we show that the geometrical representation of MFD is well suited to detect outliers of mixed type. However, it is hard to interpret what such mixed type outliers are made up: given a detected outlier, ideally one would like to access to the amount of the different outlyingness classes *e.g.* the amount of shape persistence and shift isolated outlyingness. As future work, a mean to achieve such an interpretability is first to detect some specific outliers with depth functions, second to train outlier detection algorithms (combined with a mapping function) on training sets containing each one a unique class of outlier previously detected and then to average all the models trained to form an ensemble one. As a result, one could know which model(s) in the ensemble most contribute to the outlyingness and deduce the outlyingness composition.

ABSTRACT

A *referring expression* (RE) is a description that identifies a set of instances unambiguously. Mining REs from data finds applications in natural language generation, algorithmic journalism, and data maintenance. Since there may exist multiple REs for a given set of entities, it is common to focus on the most concise and informative (i.e., intuitive) ones. We present REMI, a method to mine intuitive REs on large knowledge bases. Our experimental evaluation shows that REMI finds REs deemed intuitive by users. Moreover we show that REMI is several orders of magnitude faster than an approach based on inductive logic programming.

1 INTRODUCTION

A *referring expression* (RE) is a description that identifies a set of entities unambiguously. For instance, the expression "x is the capital of France" is an RE for Paris, because no other city holds this title. The automatic construction of REs is a central task in natural language generation (NLG). The goal of NLG is to describe concepts in an accurate and compact manner from structured data such as a knowledge base (KB). REs also find applications in automatic data summarization, algorithmic journalism, virtual smart assistants, and KB maintenance, e.g., in query generation. Quality criteria for REs is context-dependent. For instance, NLG and data summarization aim at *intuitive*, i.e., *short* and *informative* descriptions. In this vibe, it may be more intuitive to describe Paris as "the city of the Eiffel Tower" than as "the resting place of Victor Hugo". Indeed, the world-wide prominence of the Eiffel Tower makes the first RE more informative to an average user.

Some approaches can mine intuitive REs from semantic data [1, 4–6]. Conceived at the dawn of the Semantic Web, these methods are not suitable for current KBs for three main reasons. Firstly, they cannot handle current KBs because they were designed to mine REs on scenes[1] for the sake of NLG. Scenes have much fewer predicates and instances than today's KBs. Secondly, most existing approaches are limited to conjunctive expressions on the attributes of the entities, e.g., $is(x, City) \wedge country(x, France)$. However, our experience with today's KBs suggests that this language bias does not encompass all possible intuitive expressions. For instance, to describe Johann J. Müller, we could resort to the fact that he was the supervisor of the supervisor of Albert Einstein, i.e., $supervisor(x, y) \wedge supervisor(y, Einstein)$, which goes beyond the traditional language bias due to the existentially quantified variable y. Thirdly, state-of-the-art RE miners define intuitiveness for REs in terms of number of atoms. In that spirit, the single-atom REs $capitalOf(x, France)$ and $restingPlaceOf(x, V. Hugo)$ are equally concise and desirable as descriptions for Paris, even though the latter may not be informative to users outside France.

[1]The exhaustive description of a place and its objects

The approach in [6] overcomes this limitation to some extent, by allowing users to provide a ranking of preference for the attributes used in the description. Nevertheless, providing such a ranking can be tedious for KBs with thousands of predicates.

We tackle the aforementioned limitations with a solution to mine intuitive REs on large KBs. How to use such REs is beyond the scope of this work, however we provide hints about potential use cases. In summary, our contributions are:

- A scheme based on information theory to quantify the intuitiveness of entity descriptions extracted from a KB.
- REMI, an algorithm to mine intuitive REs on large KBs. REMI extends the state-of-the-art language bias for REs and allows for expressions such as $mayor(x, y) \wedge party(y, Socialist)$. This design choice increases the chances of finding intuitive REs for a set of target entities.
- A user study to assess the intuitiveness of REMI's descriptions.

2 PRELIMINARIES

2.1 RDF Knowledge Bases

This work focuses on mining REs on RDF knowledge bases (KBs). A KB $\mathcal{K}$ is a set of assertions in the form of facts $p(s, o)$ with predicate $p \in \mathcal{P}$, subject $s \in \mathcal{I} \cup \mathcal{B}$, and object $o \in \mathcal{I} \cup \mathcal{L} \cup \mathcal{B}$. In this formulation, $\mathcal{I}$ is a set of entities such as London, $\mathcal{P}$ is a set of predicates, e.g., *cityIn*, $\mathcal{L}$ is a set of literal values such as strings or numbers, and $\mathcal{B}$ is a set of blank nodes, i.e., anonymous entities. An example of an RDF triple is $cityIn(London, UK)$. KBs often include assertions that state the class of an entity, e.g., $is(UK, Country)$.

2.2 Referring Expressions

2.2.1 Atoms. An *atom* $p(X, Y)$ is an expression such that p is a predicate and X, Y are either variables or constants. We say an atom has matches in a KB $\mathcal{K}$ if there exists a function $\sigma \subset \mathcal{V} \times (\mathcal{I} \cup \mathcal{L} \cup \mathcal{B})$ from the variables $\mathcal{V}$ of the atom to constants in the KB such that $\mu_\sigma(p(X, Y)) \in \mathcal{K}$. The operator μ_σ returns a new atom such that the constants in the input atom are untouched, and variables are replaced by their corresponding mappings according to σ. We call $\mu_\sigma(p(X, Y))$ a bound atom and σ a matching assignment. We extend the notion of matching assignment to conjunctions of atoms, i.e., σ is a matching assignment for $\bigwedge_{1 \leq i \leq n} p_i(X_i, Y_i)$ iff $\mu_\sigma(p_i(X_i, Y_i)) \in \mathcal{K}$ for $1 \leq i \leq n$.

2.2.2 Expressions & Language Bias. Atoms are traditionally the building blocks of referring expressions. We say that two atoms are connected if they share at least one variable argument. Most approaches for RE mining define REs as conjunctions of connected atoms with bound objects. We call this language bias, *the state-of-the-art language bias*. We extend this language by allowing atoms with additional existentially quantified variables. For this purpose, we propose subgraph expressions as the new building blocks for REs. A *subgraph expression* $\rho = p_1(x, Y_1) \wedge \bigwedge_{1 < i \leq n} p_i(X_i, Y_i)$, rooted at variable x, is a conjunction of connected atoms such that for $i > 1$, atoms are

1 atom	$p_0(x, I_0)$
Path	$p_0(x, y) \wedge p_1(y, I_1)$
Path + star	$p_0(x, y) \wedge p_1(y, I_1) \wedge p_2(y, I_2)$
2 closed atoms	$p_0(x, y) \wedge p_1(x, y)$
3 closed atoms	$p_0(x, y) \wedge p_1(x, y) \wedge p_2(x, y)$

Table 1: REMI's subgraph expressions.

transitively connected to $p_1(x, Y_1)$ via at least another variable besides x. Examples are: (i) $cityIn(x, France)$, and (ii) $cityIn(x, y) \wedge officialLang(y, z) \wedge langFamily(z, Romance)$. An *expression* $e = \bigwedge_{1 \leq j \leq m} \rho_j$ is a conjunction of subgraph expressions rooted at the same variable x such that they have only x—the root variable—as common variable. Finally, we say e is a *referring expression* (RE) for a set of target entities $T \subseteq \mathcal{I}$ in a KB $\mathcal{K}$ iff:

(1) $\forall t \in T : \exists \sigma : (x \mapsto t) \in \sigma$, i.e., for every target entity t, there exists a matching assignment σ in $\mathcal{K}$ that binds the root variable x to t.
(2) $\nexists \sigma', t' : (x \mapsto t') \in \sigma' \wedge t' \notin T$, in other words, no matching assignment binds the root variable to entities outside the set T of target entities.

For example, consider a complete and accurate KB $\mathcal{K}$ as well as the following conjunction of two subgraph expressions:

$$e = in(x, S.\ America) \wedge officialLang(x, y) \wedge langFamily(y, Germanic)$$

We say that e is an RE for $T = \{Guyana, Suriname\}$ in $\mathcal{K}$ because matching assignments can only bind x to these two countries.

While we do not limit the number of subgraph expressions in REs, we do not allow more than one variable and three atoms in individual subgraph expressions, leading to the expressions in Table 1. This design decision aims at keeping both the search space and the complexity of the REs under control. Indeed, expressions with multiple non-root variables make comprehension and translation to natural language more effortful.

3 REMI

Given an RDF KB $\mathcal{K}$ and a set of target entities T, REMI returns an intuitive RE—a conjunction of subgraph expressions—that describes unambiguously the input entities T in $\mathcal{K}$. Intuitive REs are concise and resort to concepts that users are likely to understand. We first show how to quantify intuitiveness in Section 3.1. We then elaborate on REMI's algorithm in Section 3.2.

3.1 Quantifying intuitiveness

There may be multiple ways to describe a set of entities uniquely. For example, $capitalOf(x, France)$ and $birthPlaceOf(x, Voltaire)$ are both REs for Paris. Our goal is therefore to quantify the *intuitiveness* of such expressions without human intervention. We say that an RE e is more intuitive than an RE e', if $C(e) < C(e')$, where C denotes the Kolmogorov complexity. The Kolmogorov complexity $C(e)$ of a string e (e.g., an expression) is a measure of the absolute amount of information conveyed by e and is defined as the length in bits of e's shortest effective binary description [8]. If e_b denotes such binary description and M is the program that can *decode* e_b into e, $C(e) = l(e_b) + l(M)$ where $l(\cdot)$ denotes length in bits. Due to C's intractability, applications can only *approximate* it via suboptimal encodings and programs $(\hat{e_b}, \hat{M})$, hence $C(e) \approx \hat{C}(e) = l(\hat{e_b}) + l(\hat{M})$ with $C(e) \leq \hat{C}(e)$.

Our proposed encoding builds upon the observation that intuitive expressions resort to prominent concepts. For example, it is natural and informative to describe Paris as the capital of France, because the concept of capital is well understood and France is a very salient entity. In contrast, it would be more complex to describe Paris in terms of less prominent concepts, let us say, its twin cities. In this spirit, we devise a code for concepts as follows: The code for a predicate p (entity I) is the binary representation of its position k in a *ranking by prominence*. This way, prominent concepts can be rewarded with shorter codes. We can now define the estimated Kolmogorov complexity $\hat{C}$ of a single-atom subgraph expression $p(x, I)$ as:

$$\hat{C}(p(x, I)) = l(k(p)) + l(k(I \mid p))$$

In the formula, $l(\cdot) = log_2(\cdot) + 1$, $k(p)$ is p's position in the ranking of predicates of the KB, and $k(I \mid p)$ is I's conditional rank given p, i.e., I's rank among all objects of p. The latter term follows from the chain rule of the Kolmogorov complexity. For instance, if p is the predicate *city mayor*, the chain rule models the fact that once the concept of mayor has been conveyed, the context becomes narrower and the user needs to rank fewer concepts, in this example, only city mayors. The chain rule also applies to subgraph expressions with multiple atoms. For instance, the complexity of $\rho = mayor(x, y) \wedge party(y, Socialist)$ is:

$$\hat{C}(\rho) = l(k(mayor)) + l(k(party(y, z) \mid mayor(x, y))) + \\ l(k(Socialist \mid mayor(x, y) \wedge party(y, z)))$$

The second term in the sum amounts to the code length of the rank of predicate *party* among those predicates that allow for subject-to-object joins with *mayor* in the KB. Likewise, the complexity of the Socialist party in the third term depends on the ranking of parties with mayors among their members, i.e., the bindings for z in $mayor(x, y) \wedge party(y, z)$. If a city can be unambiguously described as $mayor(x, I)$ for a non-prominent mayor I, we may achieve a shorter code length if we replace I by a variable y, an additional predicate, and a well-known party.

In line with other works that quantify prominence for concepts in KBs [7], we rank concepts by frequency (*fr*), and Wikipedia's page rank (*pr*). We denote the resulting complexity measures using these prominence metrics by $\hat{C}_{fr}$ and $\hat{C}_{pr}$ respectively.

Finally, we can estimate the Kolgomorov complexity of an RE $e = \bigwedge_{1 \leq i \leq m} \rho_i$ as the sum of the complexities of its individual subgraph expressions, i.e., $\hat{C}(e) = \sum_{1 \leq i \leq m} \hat{C}(\rho_i)$.

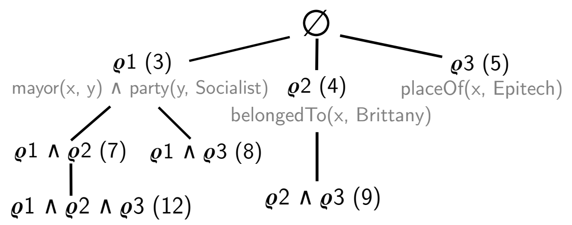

Figure 1: Search space example.

3.2 Algorithm

REMI implements a depth-first search (DFS) on conjunctions of the subgraph expressions common to **all** the target entities. Let us assume the KB knows only three common subgraph expressions ρ_1, ρ_2, and ρ_3 for the entities *Rennes* and *Nantes*, such that $\hat{C}(\rho_1) \leq \hat{C}(\rho_2) \leq \hat{C}(\rho_3)$ as illustrated in Figure 1. Each node in the tree is an expression, i.e., a conjunction of subgraph expressions and its complexity $\hat{C}$ is in parentheses. When visiting a node, DFS must test whether the corresponding expression is an RE, i.e., whether the expression describes exclusively the target entities. If the test fails, the strategy should move to the node's first child. If the test succeeds, DFS must verify whether the expression is less complex than the least complex RE seen so far. If it is the case, this RE should be remembered, and DFS can prune the search space by backtracking. To see why, imagine that $\rho_1 \wedge \rho_2$ in Figure 1 is an RE. In this case, all REs prefixed with this expression (the node's descendants) will also be REs. However, all these REs are more complex. This means that we can stop descending in the tree and prune the node $\rho_1 \wedge \rho_2 \wedge \rho_3$ in Figure 1. We call this step a *pruning by depth*. We can do further pruning if we leverage the order of the entities. In our example, if $\rho_1 \wedge \rho_2$ is an RE, any expression prefixed with $\rho_1 \wedge \rho_i$ for $i > 2$ must be more complex and can be therefore skipped. We call this a *side pruning*. All these ideas are formalized by Algorithm 1 that takes as input a KB $\mathcal{K}$ as well as the entities to describe, and returns an RE of minimal complexity according to $\hat{C}$. For each of the target entities, line 1 calculates (in a BFS fashion) its matching subgraph expressions, and takes those common to all the target entities. The expressions are then sorted by increasing complexity in a priority queue (line 2), which is processed as follows: At each iteration, the least complex subgraph expression ρ is dequeued (line 5) and sent to the subroutine *DFS-REMI* (line 6) with the rest of the queue. This subroutine explores the subtree rooted at ρ and returns the most intuitive RE e' prefixed with ρ. If e' is less complex than the best solution found so far (line 7), we remember it[2]. If *DFS-REMI* returns an empty expression, we can conclude that there is no RE for the target entities T (line 8). To see why, recall that DFS will, in the worst case, combine ρ with all remaining expressions ρ' that are more complex. If none of such combinations is an RE, there is no solution for T in $\mathcal{K}$.

```
Algorithm 1: REMI
  Input: a KB: $\mathcal{K}$, the target entities: $T$
  Output: an RE of minimal complexity: $e$
1 $G := \bigcap_{t \in T}$ subgraphs-expressions($t$)
2 create priority queue from $G$ in ascending order by $\hat{C}$
3 $e := \top$
4 while $|G| > 0$ do
5     $\rho := G.dequeue()$
6     $e' :=$DFS-REMI($\rho, G, T, \mathcal{K}$)
7     if $\hat{C}(e') < \hat{C}(e)$ then $e := e'$
8     if $e = \top$ then return $\top$
9 return $e$
```

We implemented Algorithm 1 in Java 8, including a parallel version called P-REMI (detailed in our technical report [3]).

4 EXPERIMENTAL EVALUATION

We evaluated REMI along two dimensions: output quality, and runtime. The evaluation was conducted on two popular KBs, namely DBpedia and Wikidata[3]. Our technical report [3] offers details about the experimental datasets, as well as a more extensive qualitative evaluation of REMI.

[2]We define $\hat{C}(\top) = \infty$

[3]http://dbpedia.org, http://wikidata.org

metric	#participants	p@1	p@2	p@3
$\hat{C}_{fr}$	44	0.38±0.42	0.66±0.18	0.88±0.09
$\hat{C}_{pr}$	48	0.43±0.42	0.53±0.25	0.72±0.16

Table 2: Average precision@k and standard deviation for $\hat{C}$'s ranking of subgraph expressions in DBpedia

4.1 Qualitative Evaluation

We carried out three user studies in order to evaluate REMI's descriptions on instances of the classes person, settlement, album, film, and organization. The cohort consisted mainly of computer science students, researchers, and university staff. It also included some of their friends and family members.

4.1.1 Evaluation of $\hat{C}$. Subgraph expressions are the building blocks of REs, thus intuitive REs should make use of concise and informative pieces. We measure to which extent the function $\hat{C}$ captures intuitiveness by asking the participants to rank a set of 5 subgraph expressions by simplicity and comparing this ranking with the ranking provided by $\hat{C}$. The expressions come from the common subgraph expressions ranked by Alg. 1 (line 2) using $\hat{C}$, and include the top 3 as well as a baseline defined by (i) the worst ranked, and (ii) a random subgraph expression. We manually translated the subgraph expressions to natural language statements in the shortest possible way using the textual descriptions (predicate *rdfs:label*) of the concepts when available. We show the results of our findings on 24 sets of entities in Table 2 for our two variants of $\hat{C}$. We observe that precision@1 is low. This happens because people usually deem the predicate type the simplest whereas REMI often ranks it second or third (16 times for $\hat{C}_{fr}$). This shows the need of special treatment for the *type* predicate as suggested by [6]. Nevertheless, the high values for the other metrics show a positive correlation between the preferences of the users and the function $\hat{C}$. In 88% of the cases, the three simplest subgraph expressions according to $\hat{C}$ are among the three simplest ones according to users.

4.1.2 Evaluation of REMI's output. A second study requested users to rank by simplicity the answer of REMI and a baseline consisting of 2 to 4 additional REs (solutions encountered during search space traversal). The entities were hand-picked to guarantee the existence of at least two REs sufficiently different from each other. Based on our previous findings, we used *fr* as notion of prominence. We report an average MAP (mean average precision) of 0.64±0.17 for this task on 20 sets of entities with 51 answers each, if we assume REMI's solution as the only relevant answer. We recall that a MAP of 1 denotes full agreement between REMI and the users, while a MAP of 0.5 means that REMI's solution is always among the user's top 2 answers.

4.1.3 User's perceived quality. In order to measure the perceived quality of the reported REs, we requested 86 participants to grade the *interestingness* of 35 Wikidata REs in a scale from 1 to 5, where 5 means the user deems the description interesting based on her personal judgment. Our results exhibit an average score of 2.65±0.71, with 11 descriptions scoring at least 3. During the exchanges with the participants, some of them made explicit their preference for short but at the same time informative REs. The latter dimension is related to the notions of pertinence of concepts and narrative interest. For instance, when asked to select between the REs $country(x, N.\ Zealand) \wedge actor(x, C.Lee)$ and $country(x, N.\ Zealand) \wedge actor(x, y) \wedge religion(x, Buddhism)$ for two movies, 95% of the users preferred the first one. Both REs

Standard	63	97.4k^{8}	10.3k^{1}	576	13.5kx, 2.44x	44	115.5k^{15}	1.06k	76.2	142kx, 4.7x
REMI's	65	508.2k^{68}	66.5k^{8}	28.9k	5218x, 21.4x	44	608.3k^{60}	21.7k	33.8k	6476x, 7.1x

Table 3: REMI's runtime (in seconds) on DBpedia and Wikidata. Speed-ups are provided for P-REMI w.r.t. AMIE and REMI.

had more or less the same length when translated to natural language, but the second one conveys less information and resorts to a domain-unrelated entity (i.e., Buddhism). These observations suggest that prominence captures the notion of simplicity, but it does not always accurately model the dimension of informativeness. While these examples might discourage the use of existential variables in descriptions, we remark that users also liked REs such as $in(x, Brittany) \wedge mayor(x, y) \wedge party(y, Socialist)$ (DBpedia) for Rennes and Nantes, or $actor(x, y) \wedge leader(y, Pisa)$ for the Italian movie "Altri templi" (Wikidata), as they deemed the first one quite pertinent, and the second one narratively interesting. Other interesting REs from DBpedia include "she died of aplastic anemia" for Marie Curie, and "they were both places of the Inca Civil War" for Ecuador and Peru. Finally, we highlight the impact of noise and incompleteness in the quality of the solutions. For instance, REMI cannot describe France as the country with capital Paris, because Paris is also the capital of the former Kingdom of France in DBpedia.

4.2 Runtime Evaluation

4.2.1 Opponent. RE mining can be conceptually formulated as a rule mining task. Hence, we compare the runtime of REMI and a state-of-the-art rule miner designed for large KBs, namely AMIE+ [2]. Given thresholds on support and confidence, AMIE+ mines Horn rules of the form $p(X, Y) \Leftarrow \bigwedge_{1 \leq i \leq n} p_i(X_i, Y_i)$, such as $speaks(x, English) \Leftarrow livesIn(x, UK)$, on RDF KBs . The *support* of a rule is the number of facts correctly predicted by the rule. If we normalize this measure by the total number of predictions made by the rule, we obtain its *confidence*. RE mining for a target entity set T is equivalent to rule mining with AMIE+, if we instruct the system to find rules of the form $\psi(x, True) \Leftarrow \bigwedge_{1 \leq i \leq n} p_i(X_i, Y_i)$, where ψ is a surrogate predicate with facts $\psi(t, True)$ for all $t \in T$. In this case, the right-hand side of the rule becomes our RE. We set thresholds of $|T|$ and 1.0 for support and confidence respectively. This is because an RE should predict the exact set of target entities, neither subsets nor supersets. AMIE+ does not define a complexity score for rules and outputs all REs for the target entities, thus we use $\hat{C}_{fr}$ to rank AMIE's output and return the least complex RE.

4.2.2 Results. We compared the runtimes of REMI and AMIE+ on a server with 48 cores (Intel Xeon E2650 v4), 192GB of RAM[4], and 1.2T of disk space (10K SAS). We tested the systems on 100 sets of DBpedia and Wikidata entities taken from the same classes used in the qualitative evaluation. Small sets of entities are challenging in our setting, so we picked random sets of 1, 2, and 3 entities of the same class in proportions of 50%, 30%, and 20%. We mined REs for those sets of entities according to (i) the standard language bias of conjunctions of bounded atoms, and (ii) REMI's language of conjunctions of subgraph expressions. We show the total runtime among all sets for AMIE+ and REMI in Table 3. The values in red account for the number of timeouts (for a limit of 2 hours), thus cells with red superscripts define runtime lower bounds. We observe that AMIE+ already timed out 23 times with the state-of-the-art language. In particular, AMIE+ is optimized for rules without constant arguments in atoms, such as $livesIn(x, y) \Leftarrow citizenOf(x, y)$, thus its performance is heavily affected when bound variables are allowed in atoms. In contrast REMI and P-REMI are on average 3 and 4 orders of magnitude (up to 142k times) faster than AMIE+ in this language. In the worst case REMI was confronted with a space of 62 subgraph expressions for the state-of-the-art language bias. For REMI's language bias, however, this number increased to 25.2k, which is challenging even for REMI (8 timeouts in total). Despite this boost in complexity, multithreading makes it manageable: P-REMI can be *at least* 4.7x on average faster than REMI for the extended language bias and *at least* 21x faster for the state-of-the-art language, allowing for real-time RE mining. Finally, we observe that the extended language bias slightly increases the chances of finding a solution (column #solutions in Table 3) in DBpedia. This phenomenon is more common among sets with more than one entity.

[4]AMIE assumes the entire KB fits to main memory

5 CONCLUSION AND FUTURE WORK

In this work we have presented REMI, a method to mine intuitive referring expressions on large RDF KBs. REMI builds upon the observation that users prefer prominent entities in descriptions and leverages this fact to quantify the intuitiveness of descriptions in bits. Our results show that (1) real-time RE generation is possible in large KBs and (2) a KB-based frequency ranking can provide intuitive descriptions despite the noise in KBs. This latter factor impedes the fully automatic generation of intuitive REs for NLG purposes, however our descriptions are applicable to scenarios such as computer-aided journalism and query generation. As future work we aim to investigate if external sources—such as search engines or external localized corpora—can yield even more intuitive REs that model users' background more accurately. We also envision to relax the unambiguity constraint to mine REs with exceptions. We provide the source code of REMI as well as the experimental data at https://gitlab.inria.fr/lgalarra/remi.

ABSTRACT

One of the biggest challenges in data management is to retain the high performance of in-memory processing with the ever increasing data volumes. Recent years have shown that the amount of collected data is increasing at a faster pace than DRAM capacities. Many state-of-the-art index data structures are optimized for performance rather than for low space consumption and quickly exceed the limited main-memory capacities when indexing larger data sets. *Succinct data structures* on the other hand allow for space efficient indexing, but compromise performance while still being orders of magnitude faster than disk-based data structures.

In this work, we propose a novel framework that combines state-of-the-art indexes with succinct data structures to form new *hybrid succinct data structures*. These hybrids enable fine-grained trade-offs between space and performance. Frequently accessed parts of an index, e.g. the upper levels of a tree, are thereby maintained in performance-optimized structures whereas less frequently accessed parts have a space-optimized representation. Our evaluation shows that our approach can significantly reduce the amount of used space by up to 50% (resp. 90% for our compressed version) while retaining 93% (resp. 87%) of the performance.

Figure 1: We propose a novel framework that combines state-of-the-art indexes with succinct data structures. It allows indexing even larger data sets entirely in main memory by taking advantage of space-efficient succinct indexes. Furthermore, our hybrid index allows online adaptation to the actual OLAP workload by storing hot nodes in performance-optimized structures.

1 INTRODUCTION

Back in 2006, Jim Gray stated that memory is the new disk and disk is the new tape [7]. This also applies to modern database systems that store the entire data in random access memory (RAM) to allow near real-time analyses for trading companies and finance services. They need to efficiently process large datasets to react within a few milliseconds to new developments or updates.

To achieve the required performance for near real-time data processing, index structures such as B-trees, hash tables, tries, amongst others are used to efficiently find specific elements. In modern database systems, these index structures are also stored in main memory and are most often highly optimized in terms of performance and underlying hardware rather than space efficiency. However, while the main memory capacities tend to double every three years and its costs decrease by a factor of 10 every five years, the data collected by sensors, smartphones, social media platforms, and IoT-devices *increases at an even higher rate* resulting in data overflows [12]. This development requires in-memory data structures to optimize both performance *and* space.

In this paper, we focus on hierarchical indexes comprising nodes and relationships between them, such as trees, tries, and graphs, and distinguish two different types of data structures:

(1) **Pointer Based Data Structures** (PBDS): These state-of-the-art data structures model relationships between elements *explicitly* using `machine addresses`. Traversing to another node directly translates to a pointer resolution.
(2) **Succinct Data Structures** (SDS): These data structures encode relationships in the data *implicitly* using bitmaps and still allow accessing nodes in constant time [13]. While SDS tend to be smaller than PBDS, they are often slower since traversing requires more complex operations [6].

So far, only a few SDS-based approaches, such as succinct range filters [13] and tree-encoded bitmaps [9], have been successfully applied to database systems, as modern PBDS tend to offer much better performance. However, the explicit maintenance of relationships in PBDS also consumes more space. Using 64-bit addresses may introduce significant overheads, since pointers theoretically allow for differentiating between 2^{64} (more than 18 trillion) items, which is not required for most applications. When indexing larger datasets, SDS become more interesting for the case when PBDS do not fit into main memory anymore [6] and would require staging parts of the data structure to disk.

We propose a new, lightweight framework that takes advantage of both types of data structures and allows combining any hierachical PBDS and SDS to a new hybrid index that consumes less space than the PBDS and offers higher performance than the SDS. It also allows online workload adaptation for use cases, in which some elements tend to be more important than others and get accessed more frequently.

The rest of this paper is organized as follows: In Section 2, we present the foundations of succinct index structures as well as the Fast Succinct Trie [13] which is used in our evaluation. We also give a short overview of point-polygon joins, since our evaluation is based on this use case. In Section 3, we present a detailed overview of our approach. We evaluate our framework for the real-world use case of geospatial point-polygon joins in Section 4 and conclude with our next steps and future work in Section 5.

2 BACKGROUND

In this section, we present the foundations of succinct data structures and the Fast Succinct Trie, which is a succinct trie data structure that almost achieves the performance of uncompressed PBDSs [13]. We also discuss a state-of-the-art index for point-polygon joins where we applied and evaluated our framework.

Succinct Data Structures. A data structure is called *succinct* if its space is close to the information-theoretic optimum while most basic operations are still executable in constant time. In the literature, *close* is defined in different ways – we refer to a data structure as succinct if it uses $O(\text{opt})$ bits, with opt being the minimal number of required bits to represent the data and its relationships.

As stated in Section 1, instead of explicitly modeling relationships between elements using machine addresses, this information is encoded *implicitly* in bitmaps. Consider the trie data structure in Figure 2 where each level encodes *two bits* and keys *are not a prefix* of other keys. For a succinct encoding, we store two bitmaps *labels* and *hasChild* that encode for each *node label* (branch) 00_2, 01_2, 10_2, and 11_2 whether it exists and if there is a following child node. E.g., when labels$[4n+2]$ is set, it indicates that the n-th node contains the label 10_2. Then, all encoded nodes are concatenated in *breadth-first ordering* resulting in the above mentioned bitmaps (cf. labels and hasChild in Figure 2). We define $\texttt{rank}(x)$ to count the number of set bits up and including position x, and $\texttt{select}(x)$ to return the index of the x-th set bit:

$$\texttt{rank}(x) = \sum_{i=0}^{i \leq x} \text{hasChild}[i] \tag{1}$$

$$\texttt{select}(x) = i, \text{ with } \texttt{rank}(i) = x \tag{2}$$

Based on rank and select, more complex operations for a node n starting at position p can be defined. E.g., we can calculate the position for the child node at label/branch x (3), and we can find the position of n's parent node (4) (assuming *fixed-sized* nodes comprising w bits) [13]:

$$\texttt{child}(x,p) = \texttt{rank}(x+p) \times w, \text{with hasChild}[x+p] = 1 \tag{3}$$

$$\texttt{parent}(p) = \texttt{select}(\lfloor p/w \rfloor) \tag{4}$$

As one can see in Figure 2, *six bytes* are sufficient to store the trie structure and its relationships (excluding the values). However, while succinct data structures optimize space, they tend to introduce higher latencies than PBDS since resolving a neighboring element involves multiple rank and select statements.

In 2018, Zhang et al. proposed a new data structure called Fast Succinct Trie (FST) [13]. It almost achieves the performance of state-of-the-art trie data structures such as the Adaptive Radix Tree (ART) [10] but needs less space and allows for efficient value compression. It internally uses a hybrid encoding scheme where upper levels are represented similarly to the trie in Figure 2, and lower levels store the data in a more compressed way by only representing branches that actually exist. In Section 3, we apply our framework to this data structure.

Efficient Point-Polygon Joins. We applied and tested our framework for the use case of point-polygon joins according to the approach introduced by Kipf et al. in 2020 [8]. *Dynamic points* get joined with a *static set of polygons* using prefix lookups on *one-dimensional* 64-bit keys. First, a given space (e.g. the minimum bounding rectangle of the polygons, cf. *green cell* in Figure 3) is recursively decomposed into smaller sub-cells. Then, the cells are

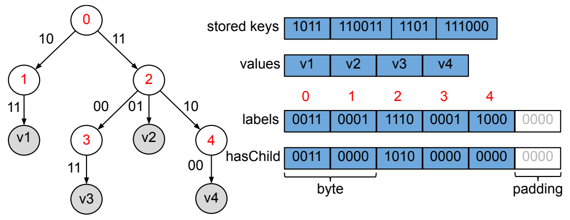

Figure 2: Succinct encoding of a trie with maximum fan-out of four. The relationships between nodes are implicitly encoded in the *labels* and *hasChild* bitmaps in breadth-first order.

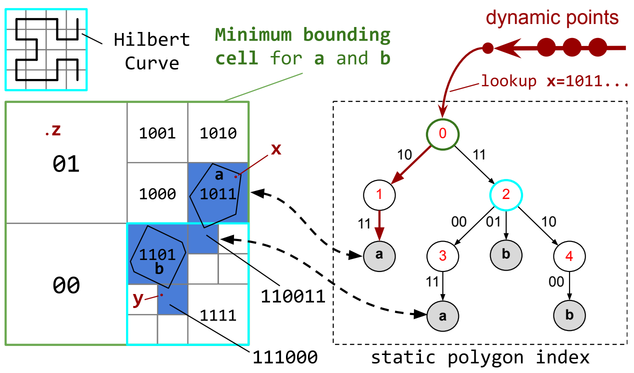

Figure 3: Left: space decomposition into quadtree cells that cover polygons a and b. Right: trie data structure indexing the blue cells level-wise and the exemplary lookup of point x.

enumerated (discretized) by a space-filling curve (e.g. the Hilbert curve) and can be identified by *one-dimensional* keys. Each decomposition divides a given cell into four smaller sub-cells for which reason we store two bits per cell level that uniquely identify one of the four sub-cells. Up to 31 levels can be addressed by a single 64-bit integer where the *least significant set bit* determines the encoded level. Applied to the Earth's surface, we can address every single square centimeter within 64 bits [2].

As a next step, we compute for each polygon p a so-called *covering*, which comprises a set of cells that cover p (cf. blue cells in Figure 3). A specialized pointer-based radix trie with fan-out four, called Adaptive Cell Trie (ACT), indexes the cells of *all combined coverings* (refer to [8] for more details). When joining an incoming point, we first transform the point to the smallest cell level (in this case 31) and then use ACT to find matching polygons using *level-wise prefix checks.* If a cell c_1=0110 is prefix of another cell c_2= $\underline{0110}1101$, then c_2 is fully contained in c_1. E.g., the binary key for point z starts with 01 and we can already detect at ACT's root node *rn* that no polygon encloses the point since the label 01 is not present in *rn*. For point x (1011...), we find the enclosing polygon **a** at level two (cf. exemplary lookup in Figure 3). Point y is an example for a *false positive* match since it is not enclosed by any polygon, but querying ACT indicates that y could be contained by polygon **b**. By this means, this point-polygon join guarantees a precision which corresponds to the diagonal of the largest cell that is not completely enclosed by a polygon.

3 HYBRID SUCCINCT DATA STRUCTURES

We propose a new, lightweight framework that allows combining any hierarchical PBDS and SDS *level-wise* to significantly reduce the memory footprint, while retaining the performance at a large extent. *Online workload adaptation* supports *branch-wise* PBDS refinements for use cases with skewed workloads. Our framework comprises four steps to build a new hybrid index structure for a given dataset:

(1) Build the static, read-only SDS.
(2) Build the PBDS for the upper n levels.
(3) Connect the PBDS nodes at level n to the corresponding child nodes in the SDS (e.g. by using pointer tagging).
(4) Extend the PBDS interface by two operations to allow *branch-wise* online workload adaptation:
    (a) `expand(node)`: Frequently accessed nodes are encoded in the faster PBDS when a specified *threshold* is exceeded.
    (b) `compact(node)`: Colder nodes (under the *threshold*) are compacted, removed from PBDS and indexed in SDS only.

In our approach, we exploit the fact that real-world workloads tend to be *skewed* and therefore, we periodically evaluate the actual queries *at runtime* to determine frequently accessed nodes. For a node n whose accesses exceed a predefined threshold t, we call `expand(n)` to add n to the faster PBDS. In the case that the accesses to n precede t, we simply remove n from the PBDS.

Since *all queries* start at the upper levels of a hierarchical data structure, we encode the frequently queried upper levels l using the performance-optimized PBDS and connect it *level-wise* to the SDS. Furthermore, the upper levels represent only a small fraction of the overall data structure and encoding them as PBDS may not have a noticeable impact on the total size. In contrast to branch-wise refinements, level-wise cutoffs do not introduce additional branch misses since we do *not have to differentiate* between PBDS and SDS references *before* reaching level l.

We deliberately accept that common parts are stored redundantly as it allows the PBDS to become a *dynamic meta index structure* for the static SDS where *lightweight refinements* do affect only the dynamic PBDS. Despite the introduced redundancy, our framework focuses on *minimizing the memory overhead* while our secondary goal is keeping the *read overhead as small as possible*. In accordance with the RUM conjecture by Thanassoulise et al. [5], "there is always a price to pay for every optimization", as our approach does *not* handle updates efficiently so far.

To the best of our knowledge, this is the first approach that applies *tuneable level-wise* cutoffs combined with *branch-wise* workload adaptations to hybrid succinct index structures. In contrast to the proposed framework by Zhang et al. in 2016 [11], we *completely avoid searching redundant parts* of the key space by *directly* pointing from PBDS into SDS using pointer tagging. While Zhang's approach is optimized for OLTP workloads where recently inserted tuples are assumed to be accessed more frequently and therefore are kept in the dynamic structure, we do *not rely* on this assumption but rather adapt to the *actual workload at runtime* using fine-grained branch-wise refinements. Additionally, we connect PBDS and SDS *level-wise*, whereas Zhang et al. completely separate both indexes *tuple-wise*.

Prefix Lookups Based on ACT and FST. In the following, we explain our framework using the Adaptive Cell Trie [8] as PBDS and the Fast Succinct Trie [13] as SDS and apply them to the use case of point-polygon joins as introduced in Section 2.

Given: We start with a set of polygons and its coverings that were calculated according to the aforementioned approach in Section 2. The coverings contain *unique* cell keys where each cell key is represented by a `uint64_t` and for each *key*, the referenced polygon(s) are stored in an `uint64_t`-payload (*value*).

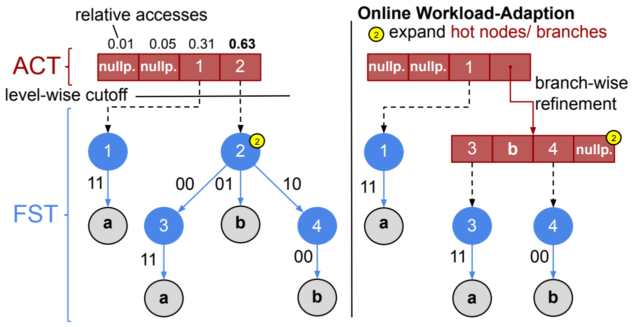

Figure 4: Initial hybrid trie with a threshold of 0.4 and ACT-encoded root node (left). Illustration of hybrid trie after expanding FST node 2 and indexing it in ACT (right).

Step 1: First, we adapted the FST to store *two bits per level* (instead of a *byte*) so that one trie level stores exactly one cell level (cf. Figure 3). The trie indexes the 64-bit cell keys *up to* the cell level while the remaining, unused levels are ignored.

In addition to our framework, we compressed the values using *run-length encoding*. In this use case, neighboring cells are likely to cover the same polygon(s) and thereby share the same polygon reference (value). These values occur directly one after the other in the values vector and offer a high compression potential.

Step 2: As PBDS, we use the Adaptive Cell Trie [8] where one trie level also stores exactly one cell level. Each ACT node comprises an array of four 64-bit *tagged pointers* resulting in an overall size of 256 bits per node. The left trie depicted in Figure 4 stores the cell keys {1011, 110011, 1101, 111000} and shows an ACT encoded root node while the remaining levels are encoded in the FST.

Step 3: We connect ACT and FST by inlining the required information in the ACT pointers. Since pointers do not use the entire 64 bits for memory addressing, we can use the two least significant bits to differentiate whether (i) the pointer stores a memory address for an ACT child node, (ii) a referenced polygon id (value) or (iii) an offset into the FST. In the case a label does not exist in a node, we just store a `nullpointer`.

Step 4: We extended the ACT interface by two functions `expand` and `compact` and stored four access counters for each node (cf. ACT-encoded root node in the left part of Figure 4). During runtime, we periodically determine the number of accesses and after a pre-defined number of lookups, we add those nodes whose access counters exceed a given threshold t to the *candidate set*. Then, we start expanding the candidate nodes and add them to ACT until the candidate list is empty or a given *memory bound* would be exceeded. E.g., node 2 in Figure 4 gets expanded since its relative access counter 0.63 exceeds the threshold of 0.4.

4 EVALUATION

We applied our framework to the use case of point-polygon joins (cf. Section 2). First, we will evaluate the performance of our hybrid trie and compare it against other data structures. Then, we will discuss the impact of workload adaptation on the overall performance and index structure size. Additionally to our approach, we will show a hybrid trie that compresses the values.

We use a real-world data set containing 289 neighborhoods (polygons) in New York City and join them with 1.23 billion publicly available taxi pickup locations (points) for the years 2009 to 2016 [4]. We calculate the cell coverings for the polygons as described in Section 2. Then, we use different index structures

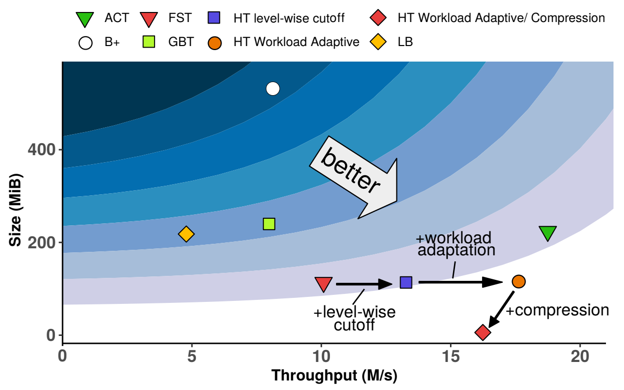

Figure 5: Evaluation of selected index structures considering space and performance. The 'waves' have been added for illustration purposes. Indexes in brighter areas have a better space/performance ratio.

that store the combined covering which contains approximately 14 million cells.

We conduct the experiments on a 14-core Intel Xeon E5-2680 v4 CPUs equipped with 256 GB DDR4 RAM and we compile with GCC 5.4.0 and optimization level 03. Besides ACT and FST, we compare our Hybrid Trie (HT) to the following data structures: the Google B-tree (GBT) [1], the STX B+ Tree (B+) [3], and the `std::lower_bound` algorithm (LB).

Comparing to Other Data Structures. In Figure 5, we show different data structures and their space consumption in MiB for indexing 14 M `uint64_t`-keys on the y-axis. Then, we query 1.23 B keys and denote the performance in M/s on the x-axis.

While LB achieves the lowest throughput (4.78 M/s), the *use-case optimized* ACT allows querying more than 18.75 M entries per second. The most space is used by the B+ tree (535 MiB) and the most space-efficient index structure is the workload-adaptive hybrid trie with enabled *run-length encoding* for the payloads. While GBT uses internal node compression techniques and B+ uses approximately twice the space, they achieve comparable performance (7.98 and 8.10 M/s).

As expected, the performance of the hybrid trie with *level-wise cutoff* (13.27 M/s) is located in between FST (10.09 M/s) and ACT (18.75 M/s), while the required space (113.71 MiB) is increased by a *negligible amount* of 0.007% compared to FST (113.70 MiB, ACT uses 223.65 MiB).

Analyzing Workload Adaptation. In Table 1, we depict the evaluation results for the *workload adaptive* hybrid tries with different level-wise cutoffs and thresholds t. A cutoff level cl means that the upper cl levels are encoded as ACT and the remaining levels are encoded as FST. A node n whose relative accesses *exceed* t gets expanded and added to ACT, whereas n gets removed from ACT if its relative accesses *precede* t. These updates can be performed periodically after a specified amount of time. Entries *without* a given threshold (-) refer to a *non workload-adaptive* hybrid trie. The ACT-encoded part has a *negligible influence* on the total HT size (1.01% for $cl = 11$) and with increasing cutoff levels, the performance impact of the workload adaptation decreases.

For the presented use case, online workload-adaptation works well since taxi pickup locations are skewed (e.g. there are many pickups at the airport and the main train station). The last column of Table 1 shows the percentage of queries that can be answered directly by the refined ACT without entering the FST.

Table 1: Space and performance metrics for the workload-adaptive hybrid tries. With increasing cutoff level and decreasing threshold, the performance increases significantly while the size overhead remains negligible.

Cutoff Level	Refinement Threshold [%]	Size Overhead To FST [%]	TP [M/s] (Perf. of ACT)	ACT-only Lookups [%]
1	-	0.001	10.32 (55%)	0.00
1	1	0.004	14.30 (76%)	31.25
1	0.5	0.008	14.58 (78%)	44.13
6	-	0.007	12.83 (68%)	0.41
6	1	0.009	13.42 (72%)	31.42
6	0.5	0.013	14.65 (78%)	44.30
11	-	1.020	17.28 (92%)	78.13
11	1	1.020	17.27 (92%)	78.13
11	0.5	1.020	17.28 (92%)	78.13

Further Compression Techniques. As discussed in Section 2, most succinct data structures store the payloads in a separate data structure which allows for further compression. We applied *run-length encoding* to the payloads which results in a compression ratio of 19,74 (114856 MiB / 5819 MiB) while the performance of 16.24 M lookups per second is still comparable to ACT. The hybrid trie uses only 2.6% of ACT's space while it retains 86.6% of its performance. By this means, the hybrid trie is *smaller by two orders of magnitude* while it achieves comparable performance to ACT. Note that our approach is not limited to run-length encoding but can of course be combined with any compression technique (e.g. dictionary encoding).

5 CONCLUSIONS AND FUTURE WORK

While our framework achieves good results for the presented use case, it is still an *ongoing work in progress.* As a next step, we will apply the framework to other use cases such as *prefix lookups for strings* and other index structures. We also plan to implement a duplicate-free hybrid trie and apply different compression techniques to the values.

ABSTRACT

The importance of incorporating ethics and legal compliance into machine-assisted decision-making is broadly recognized. Further, several lines of recent work have argued that critical opportunities for improving data quality and representativeness, controlling for bias, and allowing humans to oversee and impact computational processes are missed if we do not consider the lifecycle stages upstream from model training and deployment. Yet, very little has been done to date to provide system-level support to data scientists who wish to develop responsible machine learning methods. We aim to fill this gap and present FairPrep, a design and evaluation framework for fairness-enhancing interventions, which helps data scientists follow best practices in ML experimentation. We identify shortcomings in existing empirical studies for analyzing fairness-enhancing interventions and show how FairPrep can be used to measure their impact. Our results suggest that the high variability of the outcomes of fairness-enhancing interventions observed in previous studies is often an artifact of a lack of hyperparameter tuning, and that the choice of a data cleaning method can impact the effectiveness of fairness-enhancing interventions.

1 INTRODUCTION

While the importance of incorporating responsibility — ethics and legal compliance — into machine-assisted decision-making is broadly recognized, much of current research in fairness, accountability, and transparency focuses on the last mile of data analysis — on model training and deployment. Several lines of recent work argue that critical opportunities for improving data quality and representativeness, controlling for bias, and allowing humans to oversee and influence the process are missed if we do not consider earlier lifecyle stages [5, 9, 10, 15]. Yet, very little has been done to date to provide system-level support for data scientists who wish to develop and evaluate responsible machine learning methods. In this paper we aim to fill this gap.

We build on the efforts of Friedler et al. [4] and Bellamy et al. [1], and develop a generalizable framework for evaluating fairness-enhancing interventions called FairPrep. FairPrep implements a modular data lifecycle, enables the re-use of existing implementations of fairness metrics and interventions, and the integration of custom feature transformations and data cleaning operations from real world use cases. Our framework currently focuses on data cleaning (including different methods for data imputation), and model selection and validation (including hyperparameter tuning), and can be extended to accommodate earlier lifecycle stages, such as data integration and curation.

[*]This work was supported in part by NSF Grants No. 1926250 and 1934464, and by the Moore-Sloan Data Science Environment at New York University.

FairPrep by example. Consider Ann, a data scientist at an online retail company who wishes to develop a classifier for deciding which payment options to offer to customers. Based on her experience, Ann decides to include customer self-reported demographic data together with their purchase histories. Following her company's best practices, Ann will start by splitting her dataset into training, validation, and test sets. Ann will then use pandas, scikit-learn, and the accompanying data transformers to explore the data and implement data preprocessing, model selection, tuning, and validation. She will *identify missing values*, and fill these in using a default interpolation method in scikit-learn, replacing missing values with the most frequent value for that feature. Finally, following the accepted best practices at her company, Ann implements model selection and tuning. She identifies several classifiers appropriate for her task, and then *tunes hyperparameters* of each classifier using k-fold cross-validation. As a result of this step, Ann selects a classifier that shows acceptable accuracy, while also exhibiting sufficiently low variance.

No fairness issues were explicitly surfaced in Ann's workflow up to this point. This changes when Ann considers the accuracy of the classifier more closely, and observes a disparity: the accuracy is lower for middle-aged women, and for female customers who did not specify their age as part of their self-reported demographic profile. Ann goes back to data analysis and observes that the value of the attribute age is missing far more frequently for female users than for male users. Further, she compares age distributions by gender, and notices differences starting from the mid-thirties. Ann hypothesizes that age is an important classification feature, revisits the data cleaning step, and selects a state-of-the-art *data imputation method* such as datawig [2] to fill in age (and other missing values) in customer demographics.

Having adjusted data preprocessing to reduce error rate disparities, Ann is now faced with several related challenges:

- How should the data processing pipeline be extended to *incorporate additional fairness-specific evaluation metrics?*
- How can the *effects of fairness-enhancing interventions be quantified and judiciously validated?* These interventions may range from an improved data cleaning method that helps reduce variance in the outcomes for a demographic group, to a fairness-aware classifier, and they may be incorporated at different pipeline stages.
- How does one continue to follow best practices for ML evaluation when incorporating fairness considerations into these pipelines? For example, how does Ann ensure an appropriate level of isolation of the test set, and how does she tune hyperparameters in light of additional objectives?

To address these challenges, Ann will turn to existing development and evaluation frameworks: that by Friedler et al. [4] and IBM's AIF360 [1]. While these frameworks are certainly a good starting point, they will unfortunately fall short of meeting Ann's needs because they (1) are designed around a small number of academic datasets and use cases, (2) lack the flexibility to integrate additional data preprocessing steps that are a crucial part

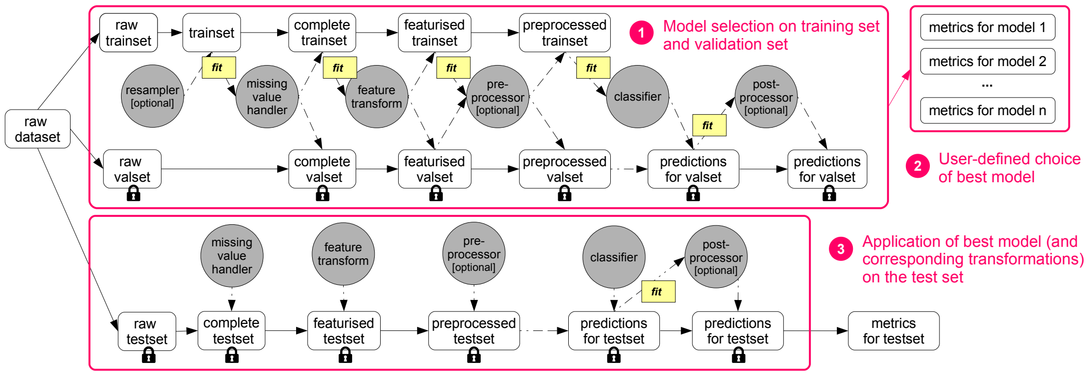

Figure 1: Data life cycle in FairPrep, designed to enforce isolation of test data, and to allow for customization through user-provided implementations of different components. An evaluation run consists of three different phases: (1) Learn different models, and their corresponding data transformations, on the training set; (2) Compute performance / accuracy-related metrics of the model on the validation set, and allow the user to select the 'best' model according to their setup; (3) Compute predictions and metrics for the user-selected best model on the held-out test set.

of existing machine learning pipelines, and (3) are not designed to enforce best practices.

This paper makes the following contributions:

- We discuss shortcomings and violations of sound experimentation practices in existing empirical studies and software for analyzing fairness-enhancing interventions (Section 2).
- We propose FairPrep, a design and evaluation framework that promotes data to a first-class citizen in fairness-related studies (Section 3).
- We demonstrate how FairPrep can be applied to illustrate the impact of violations of best practices of ML experimentation, and how it enables the inclusion of incomplete data into studies, which is not supported by existing frameworks (Section 4).

In what follows, we briefly describe these contributions, see our technical report for additional information [14]. FairPrep is open-sourced at https://github.com/DataResponsibly/FairPrep.

2 SHORTCOMINGS OF PREVIOUS WORK

We inspect the code base of an existing study [4] and of an evaluation framework [1] for fairness-enhancing interventions, and identify a set of shortcomings and violations of best practices that potentially invalidate some the findings of these studies.

Insufficient isolation of held-out test data. A major requirement for the evaluation of ML algorithms is to simulate real world scenarios as closely as possible. In the real world, we train our model (and select its hyperparameters) on observed data from the past. This model is later used to make predictions for unseen target data for which the ground truth is unknown. To emulate this real-world deployment scenario, we evaluate the trained model on a test set that was randomly sampled from observed historical data. It is crucial that this test set be completely isolated from the process of model selection, which, consequently, is only allowed to use the training data (the remaining, disjunct observed historical data). Unfortunately, we encountered violations of the test set isolation requirement in the existing benchmarking framework by Friedler at al. [4], bringing into question the reliability of reported study results. Further, we found that the architecture of the IBM AIF360 toolkit [1] does not support data isolation best practices for feature transformation.

Hyperparameter selection on the test set. Grid search for hyperparameters[1] of fairness-enhancing models and interventions in [4] computes metrics for all hyperparameter candidates on the test set, and returns the candidate that gave the best performance. This strongly violates the isolation requirement. Instead, an evaluation procedure should maintain an additional validation set to select hyperparameters, and only evaluate prediction quality of the resulting single best hyperparameter candidate on the test set, to measure how well the model generalizes on unseen data.

Lack of hyperparameter tuning for baseline algorithms. We additionally found that the study by Friedler et al. [4] did not tune the hyperparameters of the baseline algorithms[2] for which pre-processing and post-processing interventions are applied, even though they tuned the hyperparameters of the fairness interventions. This is problematic because there is no guarantee that the baseline algorithm will converge to a good solution with the default parameters. Friedler et al. [4] found a high variability of the fairness and accuracy outcomes with respect to different train/test splits, which could be an artifact of the described lack of hyperparameter optimisation.

Lack of feature scaling. We observed that both existing frameworks [1, 4] do not normalise the numeric features of the input data, but keep them on their original scale. While some ML models such as decision trees are insensitive to feature scaling, many other algorithm components, such has the L1 and L2 regularizers of linear models, implicitly rely on standardized features.

Removal of records with missing values. Another point of critique is that the study of Friedler et al. [4] ignored records with missing values (by removing them before running experiments), which means that the study's findings do not necessarily generalize to data with quality issues. Thereby, existing frameworks are unable to investigate the effects of fairness enhancing interventions on records with missing values, which could be especially important for cases where a protected group has a higher likelihood of encountering missing values in their data [8].

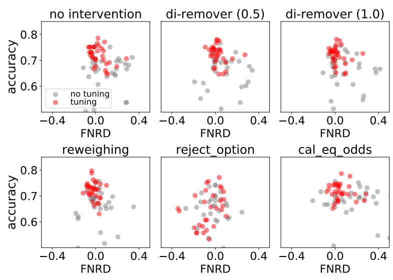
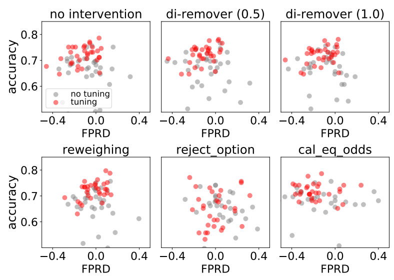
(a) Accuracy / disparate impact.



(b) Accuracy / false negative rate difference.



(c) Accuracy / false positive rate difference.

Figure 2: Impact of hyperparameter tuning on the accuracy and fairness metrics of logistic regression models (in combination with various preprocessing and postprocessing interventions) on the `germancredit` dataset. Hyperparameter tuning (red dots) often results in higher accuracy and reduced variance of the fairness outcome compared to no tuning (gray dots).

3 FRAMEWORK DESIGN

The identified shortcomings motivate us to propose FairPrep, an evaluation and experimentation framework.

Design principles. We implement FairPrep on top of scikit-learn [11] and AIF360 [1], and design it based on two principles: (i) *Data isolation* — to avoid target leakage, user code should only interact with the training set, and never access the held-out test set. User code can train models or fit feature transformers on the training data, which will be applied by the framework to the test set later on. The framework should furthermore especially take care of data with quality problems. For example, it should allow experimenters to quantify the effects of their code on records with missing values by computing metrics and statistics separately for these records. (ii) *Explicit modeling of the data lifecycle* — the evaluation framework defines an explicit, standardized data lifecycle that applies a sequence of data transformations and model training in a particular, predefined order. Users influence and define the lifecycle by configuring and implementing particular components. At the same time, the framework should support users in applying best practices from ML experimentation.

Data lifecycle. Figure 1 illustrates the data lifecycle during the execution of a run of FairPrep: ① *Model selection on the training set and validation set*: we train different models on the training data, where we apply the following consecutive steps: (i) resampling of training data (e.g., bootstrapping or balancing, optional); (ii) treatment of records with missing values (either removal or imputation); (iii) feature transformation (e.g., scaling of numeric values, one-hot encoding of categorical values); (iv) potential application of a preprocessing intervention; (v) model training using grid search; (vi) computation of predictions on the train and validation set; (vii) potential application of postprocessing intervention to predictions from train and validation set. ② *User-defined choice of the best model*: Users can choose between the explored models based on accuracy-related and fairness-related metrics computed on the validation set, trading these off as appropriate in their context. ③ *Application of the best model on the test set*: The user-selected best model (and its corresponding data transformations) are finally applied to the test set, and the resulting accuracy of fairness are reported by FairPrep.

4 EXPERIMENTAL EVALUATION

We now demonstrate how FairPrep can be used to showcase one of the shortcomings from Section 2, and how it enables experimentation on incomplete data. For all experiments, data is randomly split into 70% training, 10% validation, and 20% test.

Impact of hyperparameter tuning on the variability of accuracy and fairness. In the first experiment, we aim to investigate the effect of the lack of hyperparameter tuning of baseline models during experimentation (as discussed in Section 2).

For consistency with Friedler et al. [4], we use the `germancredit` dataset[3], which contains 20 demographic and financial attributes of 1000 individuals, including the sensitive attribute sex. The task is to predict each individual's credit risk. We use two baseline models (logistic regression and decision tree) in two different variants each: (i) without hyperparameter tuning, where we just use the default hyperparameters of the baseline model; (ii) with hyperparameter tuning, where we apply grid search (over 3 regularizers and 4 learning rates for logistic regression; over 2 split criteria, 3 depth params, 4 min samples per leaf params, 3 min samples per split params for the decision tree) and five-fold cross validation on the training data. We apply three different fairness-enhancing interventions that preprocess the data: 'disparate impact remover' ('di-remover' in the plots) [3] with repair levels 0.5 and 1.0, and 'reweighing' [6]. Additionally, we experiment with two fairness-enhancing interventions that post-process the predictions: 'reject option classification' [7] and 'calibrated equal odds' [12]. We use 16 different random seeds and execute 1,344 runs in total. We report metrics computed from predictions on the held-out test set.

Results. We plot the results of this experiment in Figure 2, where we show the resulting accuracy and several fairness related measures[4] between the privileged and unprivileged groups, including disparate impact (DI), the difference in false negative rates (FNRD), and the difference in false positive rates (FPRD). The red dots denote the outcome when we apply hyperparameter tuning to the baseline model, while the gray dots denote the outcome using the default model parameters, without tuning. We observe a large number of cases where the tuned variant results in both a higher accuracy *and* a lower variance in the fairness outcome. Examples are (i) accuracy and disparate impact for the 'di-remover' and 'reweighing' interventions in Figure 2(a), (ii) accuracy and false negative rate difference for 'di-remover' in Figure 2(b); and (iii) accuracy and false positive rate difference for 'di-remover' in Figure 2(c). We obtained similar results for the decision tree model and omit the corresponding plots due to lack of space.

[3]https://archive.ics.uci.edu/ml/support/Statlog+(German+Credit+Data)

[4]We plot these measures regardless of whether the intervention optimizes for them.

Our results indicate that the high variability of the fairness and accuracy outcomes with respect to different train/test splits observed by Friedler et al. [4] may be an artifact of the lack of hyperparameter tuning of the baseline models in these studies.

Enabling the inclusion of incomplete data. Next, we showcase how FairPrep can be used to quantify the effect of including records with missing values into an experimental study. These records are commonly filtered out in other studies and toolkits, as discussed in Section 2.

We use the `adult` dataset[5] for this experiment, with a total of 32,561 instances and 14 attributes, including the sensitive attributes `race` and `sex`, and 2,399 instances with missing values. The task is to predict whether an individual earns more or less than $50, 000 per year. Fairness evaluation is conducted between the privileged group of white individuals (85% of records) and the underprivileged group of non-white individuals (15% of records).

Of the 14 attributes, three have missing values — `workclass`, `occupation`, and `native-country`. Based on our analysis, missing values do not occur at random, as the records with missing values exhibit very different statistics than the complete records. For example, the positive class label (high income) is associated with 24% of the complete records, but with only 14% of the records with missing values. Additionally, married individuals are in the vast majority in the complete records, while the most frequent `marital-status` among the incomplete records is *never-married*. Furthermore, the records with missing values from the privileged group are very different from the records with missing values from the underprivileged group. For example, the attribute `native-country` is missing four times more frequently for non-white individuals than for white individuals. Among the incomplete privileged records, 15% are associated with a high income, the second largest age group consists of 60 to 70 year-olds, and the majority of the individuals is married. For the incomplete records from the underprivileged group, however, only 10.6% have a high income, there are very few individuals over 60, and the majority of the individuals is unmarried.

We use logistic regression as the baseline learner, with hyperparameter tuning analogous to previous experiments. As before, we apply two fairness enhancing interventions that preprocess the data: 'disparate impact remover' [3] and 'reweighing' [7]. We use three strategies to treat missing values: (*i*) complete case analysis, removing incomplete records; (*ii*) retain all records and impute missing values with 'mode imputation'[6] (replace a missing value with the most frequent value for that feature); (*iii*) retain all records and apply model-based imputation with datawig [2]. We execute 530 runs and report metrics computed on the held-out test set.

Results. We investigate the classification accuracy for complete and incomplete records, under imputation with mode and datawig. First, we observe that records with imputed values achieve high accuracy. This is a significant result, since these records could not have been classified at all before imputation! Interestingly, we observe higher accuracy for records with missing values compared to the complete records. Based on our understanding of the data, we attribute this to the higher fraction of (easier to classify) negative examples among the incomplete records. Further, we do not observe a significant difference in accuracy between mode imputation and datawig. We attribute this to the skewed distribution of the attributes to impute — a favorable setting for mode imputation. Because datawig does no worse than mode, and is expected to perform better in general [2], we only present results for datawig-based imputation in the final experiment.

We compute the accuracy and disparate impact of complete case analysis (e.g., the removal of incomplete records) versus the inclusion of incomplete records with datawig imputation. We observe a minimally higher accuracy in the case of including incomplete records, but in general find no significant positive or negative impact on disparate impact. Taken together, the results paint an encouraging picture: Imputation allows us to classify records with missing values, and do so accurately, and it does not degrade performance, either in terms of accuracy or in terms of fairness, for the complete records.

5 CONCLUSION

We identified shortcomings in existing empirical studies on fairness-enhancing interventions. Subsequently, we presented the design of our evaluation framework FairPrep. This framework empowers data scientists to conduct experiments on fairness-enhancing interventions with low effort, and at the same time enforces machine learning best practices. We demonstrated how FairPrep can be used to measure the impact of a lack of hyperparameter tuning, and how it enables the inclusion of incomplete data. We aim to extend FairPrep by integrating additional fairness-enhancing interventions [13], datasets, preprocessing techniques, and feature transformations. Additionally, we intend to extend its scope to scenarios beyond binary classification, and introduce *human-in-the-loop* elements by providing visualisations and allowing end-users to control experiments with low effort.

This paper is supplemented by a technical report [14]. FairPrep is open-sourced at https://github.com/DataResponsibly/FairPrep.

ABSTRACT

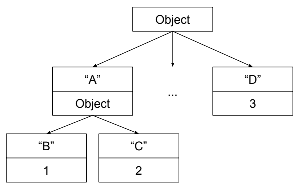
In this paper, we propose delta trees to boost efficiency and reduce storage requirements of iterative data exploration and data wrangling tasks over massive, semi-structured datasets. During such tasks, data is filtered, projected, joined, and converted in multiple successive or independent steps, driven by data scientists or higher-level applications. While the original datasets can often not be disposed, delta trees are necessary to represent only the changes to the original data, instead of creating largely redundant copies. With delta trees, we are able to reduce storage requirements and query execution time for various data manipulation operations, while maintaining acceptable query times for others. We report on a first experimental study over a dataset of Twitter tweets, showing that the expected vast savings of storage consumption can be enjoyed with negligible computational overhead compared to a full data duplication.

1 INTRODUCTION

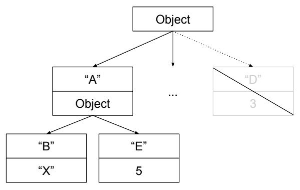
In recent years, the interest in semi-structured file formats steadily increased. Arguably, one of the most visible data formats is JSON, which eliminates the need to force data into relations and is designed to be human-readable. It has been adopted by various platforms and systems, for instance, for data exchange through APIs, to store system access logs, or configuration files. Common operations in semi-structured document processing are adding, removing, and moving values. Consider for instance the case of data scientists working on a large sample of Twitter tweets. While some first extract textual content and geo-coordinates of Canadian tweets written in French they later observe that also the author of the tweet is required, others need to convert the original schema (attribute names) to match their existing data visualization libraries. To execute these operations, systems have to either edit the original document, or perform the operation on a copy. The first option may not always be possible, if the base documents are to be used in future processing steps or by multiple data scientists working in parallel. The second option is undesirable, because it introduces a huge overhead regarding performance and memory usage, for copying the documents. In this paper, we propose a novel way to store changes made to original documents, leading to a vastly reduced memory footprint and an even improved querying performance for some query types, while having a modest performance overhead for others.

1.1 Sketch of the Approach and Related Work

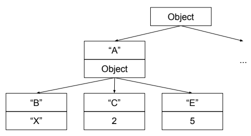
The concept of late materialization [1] is used to push back materializations of (intermediate) results until they are needed. For this to work, the system has to store the queries, or similar information, and the base data. The result is then calculated on demand as soon as it is required.



(a) Base document tree



(b) Delta tree



(c) Combined document

Figure 1: Example of base document with a delta tree

Our approach also aims to reduce the amount of unnecessary transformations of the base data. But instead of storing the operations that lead to the result, we calculate the difference (or delta) of the transformations, compared to the base data and only store this new information, with a reference to the base document. Almeida *et al.* already proposed a map as Conflict-free Replicated Data Type (CRDT) [2], which can be synchronized by sending delta changes of the modification action to replicated instances. This data type can also be nested and JSON documents can be translated to and from nested maps. But the computational overhead required for conflict-free synchronization is too large for our use case. Generally, the concept of extracting or storing deltas from semi-structured documents has been investigated before [3, 6, 7]. It has also been applied in the context of relational database systems to compact historical data [4, 5]. However, in contrast, we store the changes made by incremental data modification operations, in order to improve the memory consumption.

2 DELTA TREES

Figure 1a visualizes the tree representation of one semi-structured document. It consists of (nested) objects containing attributes, with atomic data. Now, a query may transform this base document by deleting the "D" attribute of the root object, changing the atomic data within the "B" attribute, and adding an additional member to the "A" object. Instead of storing the complete transformed document, we only store the changed parts of the tree, as shown in Figure 1b. In this example, the changed "B" member and additional "E" attribute is stored, together with the required parent structure (in this case the root node and "A" object).

Additionally, we keep track of all paths within the tree that have been changed. A path is an ordered list of tokens, identifying all nodes that have to be traversed to arrive at a desired destination. In this example, the changed paths would be "/A/B", "/A/E", and "/D". This information is sufficient to reconstruct the complete transformation result as shown in Figure 1c.

The benefits of this approach may not be immediately evident from the given example. But in real world data sets, documents having hundreds of attributes, distributed over many nested objects, are very common. If a transformation query only modifies a couple of nodes, storing the complete transformation result clearly is unnecessary—and modifying the original data is often prohibited.

2.1 Reconstructing Combined Documents

Given a base tree B and a delta tree D, with the overwritten paths P, we may need to construct the complete result document tree R to return to the user. This is achieved by simultaneously iterating through both trees in a depth-first manner. Starting at the root of the trees, for every unique path p in both trees, there are now five possibilities:

1. $\exists n_B \in B$ and $\exists n_D \in D$ belonging to p
   - (a) $p \in P \Rightarrow$ the path is overwritten in D, hence, we only continue traversing n_D for this sub-tree.
   - (b) $p \notin P \Rightarrow$ the path is shared between B and D, thereby, we continue traversing both n_B and n_D.
2. $\exists n_B \in B$ and $\nexists n_D \in D$ belonging to p
   - (a) $p \in P \Rightarrow$ the path was removed by the transformation and we do not continue traversing this sub-tree.
   - (b) $p \notin P \Rightarrow$ the node is not materialized, but still valid, thus, we continue traversing n_B.
3. $\nexists n_B \in B$ and $\exists n_D \in D$ belonging to p, it must thereby be added by D and we only traverse n_D.

The result is constructed by traversing B and D as above and adding all visited nodes to R.

2.2 Delta Hierarchies

There can be multiple delta trees, which reference the same base tree, in which case the memory savings introduced by delta trees are magnified. Additionally, delta trees may be based on other delta trees. Given $(B, D_1, ..., D_i, ..., D_n)$, where B is the base document, and D_i are delta trees, each based on the previous tree. This is called a *delta hierarchy*. The result document R_1, of B and D_1 may be constructed as shown in Section 2.1. To construct the result document R_i, the same algorithm would then be executed with R_{i-1} as base tree and D_i as delta tree. In case of larger hierarchies, this naïve execution is suboptimal. Instead, we perform the reconstruction algorithm for all trees at the same time, by traversing the whole delta hierarchy simultaneously. For each unique path p in the delta hierarchy, starting at the root: If p exists only in one tree, we follow only this subtree. If p exists in multiple trees, we use the value of the uppermost delta tree, in case of atomic values. In case of objects, whose child attributes are distributed over multiple tree, we continue traversing all affected trees.

3 ARCHITECTURE AND ALGORITHMS

We implemented our approach in our in-house JSON exploration system JODA, written in C++. This system uses the RapidJSON (http://rapidjson.org/) parser, which uses a DOM-tree in-memory representation to store the parsed JSON documents—the extension to XML and YAML is straightforward.

Documents provided to the system are organized in so-called collections, for instance, a collection of Twitter tweets and a collection of blog posts. All documents within a collection are organized into a number of containers. Each container is a self-contained unit, which includes all required information to perform a query upon. After creation, these containers are immutable to make the query execution free of any synchronization overhead.

Queries are simple PIG-style sequences of commands. To begin, a collection can be chosen and data can be imported into the system by the `LOAD` step. This data is then passed to the `CHOOSE` command, which may filter the data depending on a given predicate. The filtered documents may then be transformed in the `AS` step, by using an arbitrary amount of transformation instructions, in the form of (`<destination>:<source>`) tuples, where the destination is a path in the new document, and the source can be any supported function or a path in the base document. The transformed documents are then passed to the `AGG` command for aggregation and may finally stored in a collection or exported into a file with the `STORE` expression.

3.1 Construction

The `AS` instruction also supports the special `*` operator, which copies the whole source document. This operator may be combined with additional transformations to change the source document. If the system detects this combination, delta trees may be used to perform this transformation.

In this case, the system will first create the support structure, by instantiating an empty delta tree with a pointer to the base document, which may also be a delta tree. Each additional transformation is then executed and the result materialized in the newly created delta tree. Additionally, the `<destination>` pointers form the explicitly overwritten paths and are stored with the tree, as described in Section 2. These paths will be the same for all delta trees that are created by a given query. We can therefore store them once in the—previosuly introduced—container class, as it includes all data that may be shared by its documents. Now, a delta hierarchy is given by following the base document pointers from any given delta tree to the bottom.

3.2 Reconstruction

To reconstruct the result document we created a visitor class, which implements the idea described in Section 2.1–2.2. This visitor class simultaneously traverses the delta hierarchy as described. This basic visitor class is then extended to fulfill different needs, like materializing the final result documents or accessing specific subtrees for query evaluation.

Our system preserves the order of members within a JSON object, which is not required by the standard itself. Thereby we have to adapt the traversing algorithm described previously as follows:

Algorithm 1 reconstructs a result document, given a delta hierarchy. Our implementation handles the base document as just another delta tree D_0 which overwrites the whole tree (root path ' '). The algorithm visits a node n, which at the beginning is the root node of D_n. If the given node is shared, i.e., it is an object or array which is distributed over multiple delta trees, then we first search the base document. The base document is the document which has overwritten this node last. Starting from the base, we collect all members of this shared node in all delta trees. The algorithm is then repeated for each of these members.

If the node is not shared, then we retrieve the upper most instance of the node in the delta hierarchy and visit this node.

```
Data: n = root($D_n$); p = ' '; $D_0, ..., D_n$; $P_0, ..., P_n$
if IsShared(n,$P_1, ..., P_n$) then
    Base = GetBaseDeltaTree(n);
    for i = Base to $D_n$ do
        members += GetMembers($D_i$,$P_i$);
    end
    for member in members do
        Recurse(member,p+'/'+member.id,$D_0$,...);
    end
else
    $n_D$ = GetBaseNode(n);
    Visit $n_D$;
end
```

Algorithm 1: Reconstruction algorithm

The visit function belongs to the given visitor, which may, as explained previously, perform different actions for the given node.

3.3 Estimating Memory Usage

The main advantage of delta trees is the reduced memory requirement. We define the memory cost of a tree, as the sum of all costs of its nodes. The cost of a node is given by the byte size of its in-memory representation. Evidently, each delta tree is smaller or equal in size as the result tree, given by combining the base with the delta tree, as all of its nodes are contained in the result, plus potential additional nodes from the base document. Thus, the memory cost of delta trees should always be smaller or equal to materializing the whole result.

In reality, this is often not the case. For instance, the RapidJSON library, that we use to create JSON documents, creates each new object and array with 16 placeholder children. In many cases, this is a sensible decision, as reallocating memory for more children is an expensive operation and objects and arrays often have more than one child. For delta trees that mostly consist of a few nodes, this decision proved to be a disadvantage. Each placeholder child will be added to the cost, which for some queries and documents may be more than materializing the result.

We thereby added a sample step to our system before deciding which execution method, delta trees or complete materialization, to choose. The transformation is performed for $\leq$ 1% of documents with both execution methods. Then the memory requirement of these documents is calculated and the method with the lowest requirement is chosen. This decision is performed on per-container basis in our system, which mostly contain similar documents.

3.4 Accessing values

Queries in our system may use a wide range of functions to evaluate values. The parameters of functions may be nested functions or retrieved directly from the document. Hence, functions have to be able to access all values contained in delta trees. For example, it is not trivial to evaluate the member count of an object, that is distributed over multiple trees. If a function accesses a value, specified by a given path, the system will check top-down for the given delta tree hierarchy if this specific path is shared. If not, the value can be directly passed to the function, without even traversing the whole delta hierarchy. If it is shared, we have to evaluate this function by traversing the delta tree hierarchy as explained in Section 3.2.

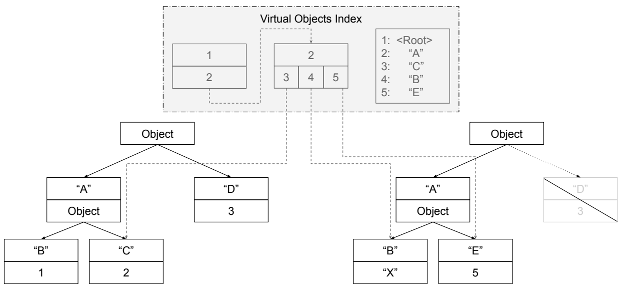


Figure 2: Virtual Object Index

The main cost of accessing values by path is traversing the tree. For each token in the path, the child represented by this token has to be found. For arrays, this is simple, as the token is the index of the child. Objects on the other hand, store their children in order of occurrence in the source document. Here a linear search with string comparisons has to be performed to find the specified child. This operation is the dominating cost factor for finding a value belonging to a path. For delta hierarchies this cost may be amplified, if many trees have to be searched. But if the value is overwritten in one of the higher trees in a delta hierarchy, this cost can be less than for one materialized result document.

4 PARTIAL MATERIALIZATION AND OBJECT INDICES

It may happen, that multiple queries repeatedly require the same value, which may be an object or array distributed over multiple delta trees. In these cases it can be beneficial to materialize the given object or array at the cost of increased memory usage. This is achieved by traversing only this sub-tree in the delta hierarchy, as described previously, and copying the whole sub-tree into the highest delta tree. We call this *partial materialization* of the result. By strategically materializing parts of the result we can still massively reduce the memory footprint while preventing the performance drawbacks of simultaneously traversing multiple trees.

To prevent the materialization of objects, we created an *virtual object index*. This index tries to combine the powers of delta trees with the read performance of materialization. A virtual object, is a list of tuples, containing an attribute id and a pointer to a value or nested virtual object, as shown in Figure 2. The attribute id is a numerical value, retrieved by mapping a string attribute name to a numerical value using a hash map. This has two advantages. (1) Having a numerical value reduces the cost of comparisons needed for the linear search of children. (2) The string dictionary is stored in the container and shared by many documents, thereby reducing the required memory of this index. We create these virtual objects, as soon as an object, that is distributed over multiple trees in the delta hierarchy, is traversed for the first time. During traversal, we map the attribute names of the children to the attribute id and add it to the virtual object, together with the pointer of the actually traversed value. Each value may reside in a different tree within the delta hierarchy. The traversed object is then replaced by the virtual object in the highest delta tree of the hierarchy. Future accesses of the object can then use the created index without traversing multiple trees.

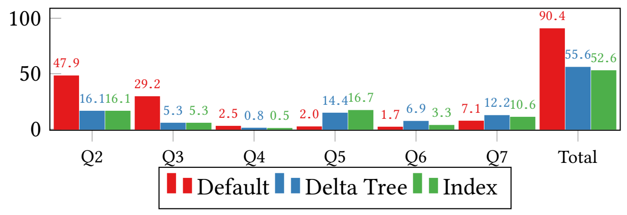

Figure 3: Runtime [s] of different execution methods

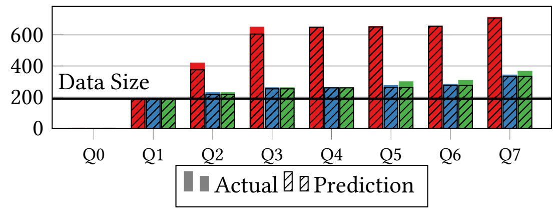

Figure 4: Memory consumption [GB] of different execution methods

5 EVALUATION

In this section, we will evaluate the performance and memory footprint of our delta tree implementation. The data set used is a 109 GB selection of the Twitter JSON stream[1]. It consists of 29,634,708 JSON documents, where each document has between 7 and 348 attributes, containing every JSON type. The documents are split into two major groups. Around 23.5 million (79.33%) documents are normal tweets, while around 6.1 (20.67%) million documents are deletion instructions. The tweets have a varying number of attributes, depending on their status, e.g., retweets and favorites, while the deletion documents consist of seven attributes.

The tests are executed on a machine with 4 Xeon E7-4830 CPUs, each having 12 cores—and 24 threads—with 2.1 GHz. Furthermore, 33 RAM-Kits, each having 32 GB of memory at 2400 MHz, are included, providing the server with around 1 TB of RAM. The data is stored on one HGST Ultrastar 7K4000 HDD, with 7200 RPM. Ubuntu 16.04.3 LTS is used as the underlying operation system.

The first query in Listing 1 loads the Twitter data set. Then a collection is created which adds one member to the user object of the previous data set. Derived from this collection, another attribute is added to the user object. In the following query, only the data added in Q2 is used in an aggregation. Then the member count of the user object is queried in the next two queries. The last query copies the shared user object into a new collection.

```
Q1: LOAD t1 FROM FILES "/data/twitter";
Q2: LOAD t1 CHOOSE EXISTS('/user')
    AS *,('/user/v1':1) STORE t2;
Q3: LOAD t2 AS *,('/user/v2':2) STORE t3;
Q4: LOAD t3 AGG ('':SUM('/user/v1')) STORE a;
Q5: LOAD t3 AS ('':MEMCOUNT('/user')) STORE c1;
Q6: LOAD t3 AS ('':MEMCOUNT('/user')+1) STORE c2;
Q7: LOAD t3 AS ('':'/user') STORE user;
```

Listing 1: Queries iteratively changing an object and reading it

We compare our introduced approaches against the default execution method, which copies and modifies the full JSON documents. The delta tree approach is based on our implementation within the system, as explained in Section 3. The index approach uses the same implementation, but with enabled virtual object indexing, as described in Section 4. The query time plot in Figure 3 is omitting the first data import query, as it is unaffected by the execution method and requires the same time for all of them.

As we can see, for queries Q2 and Q3, the delta tree approaches have a strong advantage over the default execution method. While the default execution copies the whole Twitter data set, the delta tree approaches only require one reference to the base document and the `/user/v<x>` values, with the supporting tree structure. This results in an increase of maximum 37.24GB and 31.89GB to the previous query for Q2 and Q3 respectively, as can be seen in Figure 4. The default approach on the other hand increases its memory consumption by 228GB and 230GB. As copy operations are the dominating cost for these queries, the execution times of the delta tree methods is also significantly lower.

In Q4 the value written in Q2 is read. This is fast and memory unintensive for all approaches, but the delta tree approaches are faster, as the value can be read very fast in one of the delta trees without traversal. In Q5 and Q6 the user object, which is distributed between three delta trees is used. For the default execution method this is fast and requires nearly no memory. For the normal delta tree method, this operation is slow, as the whole delta hierarchy has to be traversed. The index introduces additional overhead, as it creates the virtual object indices. This results in vastly improved query times, but increased memory consumption in Q6, which brings it closer to the default implementation, while the delta tree execution is much slower. In Q7 the modified user object is materialized to a new document. This is relatively fast for the default execution method, but once again slow for the delta tree. The indexed method can use the virtual objects to improve its query time. All in all are the delta tree implementations faster and very similar for this query set. But if it would contain additional read queries this situation could quickly change.

6 CONCLUSION

In this paper, we introduced the concept of delta trees, for materializing only the differences of a transformation, to reduce the memory footprint of exploration systems. We explained the basic idea and specific implementation details, based on our in-house JSON exploration tool JODA. Additionally, we introduced improvements to the systems to mitigate the performance bottlenecks introduced by the approach. As we have seen, delta trees enable systems to perform the same set of queries, with a fraction of the required memory.

Towards Fine-Grained Data Access Control Through Active Peer Probing

ABSTRACT

Data is routinely being shared online by peers, for instance in business transactions, social activities and others. This data, in turn, is often transferred, processed and combined through complex querying and analytics. This raises questions such as the following: who owns the derived data? With whom and for what purpose may it be published? If consent is required for its dissemination, whose consent should be obtained?

The related topics of data sharing, privacy and access control have been extensively studied, but uniquely our focus here is not on data management with known policies but rather on the active probing of peers to ask for their consent. Active probing has the potential to allow finer-grained access control, where it is unreasonable to expect data owners to publish their full policies, defined for all possible sharing scenarios. They may not even have a clear view of their own policies, before asked whether they are willing to share data with a specific third party.

This short paper informally introduces and motivates this new problem. It further identifies interesting connections to two distinct areas: data provenance, which captures the way output data are derived from inputs, and Boolean evaluation, which focuses on effective strategies to probe hidden Boolean values for evaluating a formula. As we shall demonstrate, the composition of these two areas in the context of this problem yields intriguing avenues for further research.

1 INTRODUCTION

When peers share data – on social networks, for event planning or in business collaborations – access control is often a concern. Data may be re-shared and used in analysis that combines input from multiple sources, thereby making it difficult to correctly decide access permissions. For example, the data of Alice's recruitment agency may consist of personal data of job seekers, confidential data on companies and internal information on collaborators. Now assume Alice wants to re-share parts of this data with a collaborating agency. In common data sharing platforms, peers that have originally contributed data to Alice either have no control over the re-sharing of their data, or give a broad consent to re-sharing within some group (e.g., for non-commercial purposes), or disallow re-sharing altogether [1]. However, a finer-grained approach may allow re-sharing more data without compromising the preferences of data owners. For instance, Bob, a collaborating agent, may not have agreed that his data is shared with every third party; but if Alice actively asks for his permission to share data with Carol, a specific mutual collaborator, he may agree. Next, Alice may compute statistics based on combining and analyzing the data provided from many sources. May she share the derived data (analysis results) with a third party? Who should be probed for permissions in this case?

The related topics of data sharing, privacy and access control have been extensively studied (see a brief discussion below), but uniquely our focus here is not on data management with known policies but rather on the *active probing of peers* to ask for their consent, to achieve fine-grained access control. The peer answers may either be given manually (by one of Bob's employees), or (semi)-automatically (by Bob's servers). In either case, probing requires resources and reveals parts of Bob's proprietary policy, and therefore should be minimized. As we shall demonstrate, this active setting, coupled with reasoning performed over the data, leads to novel computational problems. Informally, we introduce the following high-level problem:

We are given a database whose tuples have been contributed by multiple peers, and a query (in some language) over the database. Access control policies with respect to the input *tuples are (completely or partially) unknown, but we may* probe *data owners to ask about them. Our goal is to decide whether* the query output *(or a subset thereof) may be shared with a third party, while minimizing the number of probes (or otherwise optimizing with respect to a related target).*

To continue our above example, assume that an agency owned by Carol seeks information on companies in Pennsylvania in which positions were successfully found for graduates of environmental studies. The agency of Alice, a collaborator of Carol, may have such data at hand, and the information needs of Carol may be captured by an SPJU query on this data – but may the query results be shared? For instance, an output value "PennSolar-Experts Inc." may be the result of joining several tuples involving data on (1) the PennSolarExperts company; (2) three environmental studies graduates who found positions in this company, and (3) the agency owned by Bob who collaborated with Alice in finding positions for some of the candidates (and then projecting on the company name). In this case, to share the query result with Carol, Alice may need the consent of the company, at least one of the assigned workers, and Bob. Importantly, Alice may not know in advance whether the company, workers or Bob agree that computation results based on their data are shared with Carol; they could have shared their data with Alice without giving her permissions to share it with a third party. In this case, Alice would need to actively probe the peers, but what is her best "strategy" for probing (i.e. who should she probe and in what order)?

In this short paper we introduce and motivate this new problem in a high-level manner, through an example. We further outline a promising approach for a solution, based on two seemingly disjoint areas of research: Data Provenance and Boolean Evaluation. We believe that the problem, and our line of attack, are worthy of in-depth investigation.

Related Work. We conclude this Introduction with an overview of related work. The theory and practice of Access control have been extensively studied in different contexts, including social

networks (e.g., [1–7]), distributed systems (e.g., [8, 9]) cloud services (e.g., [10–12]), Web applications (e.g., [13, 14]) , databases (e.g., [15–17]), and many other areas. With respect to these works, our novelty is in focusing on a setting where access policies may be unknown or undetermined in advance, which requires active probing of involved peers to obtain permissions. Fine-grained access control policies may be too large or complex to be specified by a client, if, e.g., the permission for every peer and action must be specified. To assist clients in specifying policies, previous work has considered (semi-)automatic computation of access control policies. This includes the computation of policies based on example permissions [18]; evaluating the credibility of peers [5]; mining or interactively defining user roles [19, 20]; using semantically-rich languages to compactly capture real-life factors on policy definition [21]; and using game-theoretic considerations in defining policies with respect to risk minimization [22]. These works are complementary to ours, in the sense that we probe peers as a "black box": peer answers may be obtained manually or predefined using methods such as above.

2 MODEL, VIA AN EXAMPLE

We next outline a preliminary model for the problem, illustrated informally via an example.

We are given a Relational Database[1] where each tuple is annotated with a label which we refer to as *concept*, taken from a set of concepts C. Each concept "belongs" to a single owner out of a set of peers $\mathcal{P}$. We will refer to such annotated database as a *shared database*.

Example 2.1. Table 1 outlines a simple DB for the recruitment agency example described above, consisting of details of companies and job vacancies in these companies, with the type of position and the number of open positions; job seekers with their name, education and agency to which they have applied; and the assignment of seekers to vacancies, including the status of the assignment and the agency responsible for matching. The annotations here can be set to reflect the row (table+key) and the owner of the data. In this case, we assume for simplicity that company and vacancy data is owned by the company, and job seeker and vacancy data is owned by the relevant agency as the seekers' representatives. The annotation for the first row in Companies could for instance be `Companies11PennSolar` and the first row of Assignment could be `Assignment1-111Bob`.

The premise is that there is a hidden truth value to whether or not we are allowed to share each concept with a specific third party (or publish it in public, etc.); this truth value is known only to the concept owner.

[1]For brevity, we demonstrate the problem and our approach in a relational setting and for tuple-level access control; it applies similarly, with some extensions, to semi-structured data and value-level access control.

Example 2.2. Recall the database in Table 1, and assume that Alice wishes to share the **JobSeekers** table with Carol. In this case, Alice's agency is the owner of the third tuple, and thus can check whether she can share the data - e.g., if Frank agreed in his contract with the agency to share data with third parties. The yes/no answer would translate to a valuation of true/false respectively to the Boolean variable captured by the annotation `JobSeekers3Alice`. The other tuples correspond to job seekers recruited by Bob's agency, hence we assume that when asked by Alice, Bob's agency can answer yes/no to the sharing request, again translated to a Boolean valuation.

Some concepts may be associated with a semantic interpretation, in which case the hidden truth values are constrained. For instance, in the database from Figure 1, we can assume that access permission to a row in **Vacancies** implies access permission to the relevant company's row in **Companies**. To capture such constraints, we use taxonomies.

Next, instead of sharing the data as-is, we consider a *query* executed on the database to perform some analytics and the sharing of its results. We consider "query" as a broad term here, and variants of the problem will focus on different query languages (e.g., relational SPJU, Datalog, etc.).

```
SELECT DISTINCT c.name
FROM   Companies c,
       JobSeekers j,
       Vacancies v,
       Assignments a
WHERE  c.cid = v.cid AND
       v.vid = a.vid AND
       a.status = `hired' AND
       a.sid = s.sid AND
       s.education = `Env. studies'
```

Figure 1: Query over the example database

Example 2.3. Recall our running example and now assume that Alice wishes to share with Carol the names of companies where environmental studies graduates have successfully found jobs. To this end, she runs the query in Figure 1 on the database in Table 1. In this simplified example the answer is the single company in the database - "PennSolarExperts Ltd.", where David, Ellen and Georgia have been hired.

The question is then: given an (annotated) database and a query, are we allowed to share the result?

Example 2.4. Sharing the single result value returned by the example query, "PennSolarExperts Ltd.", requires the company's consent, as the owner of the relevant tuple. Furthermore, sharing the result may reveal information about other tuples participating in the derivation. For instance, if there are few environmental studies graduates who work in PennSolarExperts, sharing the result with Carol would reveal personal information about them, including that at least one of them was recruited by Alice's agency or her collaborators (and in turn, that this person belongs to the type of job applications at which Alice and her collaborators specialize, e.g., interns, part-time positions, etc.). Beyond our example, peers can ask queries, e.g. Boolean, whose result does not contain any tuple cell, and yet may reveal the existence of other tuples. We shall therefore consider to *which* tuples used in the derivation permissions are needed. In our case, intuitively, it is sufficient to have permissions to the data involved in *one* relevant job assignment, since the existence of additional assignments does not change the result. To share e.g., Georgia's assignment details, Alice needs permission to share all the tuples jointly involved in it in addition to the company's tuple – tuple 4 in **JobSeekers**, vacancy 112 and the relevant assignment. To obtain these permissions, Alice needs to probe Bob Bob, the owner of the relevant **JobSeekers** tuple, and PennSolarExperts for the **Companies** and **Vacancies** tuples. The owner of the assignment itself is Alice's agency, which means she has the information of whether this tuple can be shared or not. If only one of the four aforementioned tuples cannot be shared, Georgia's assignment cannot be shared.

Since access control policies with respect to the individual concepts are "hidden", namely known only to owners, the tool that we have for deciding whether or not a result may be shared is to pose questions or *probes* to the owners of relevant data items. The goal is then to optimally select probes in order to discover whether sharing is permitted.

Example 2.5. In our running example, 9 tuples contributed in some way (to be formalized below through the notion of provenance) to the result of the example query. If the only tuple owned by Alice (the assignment of job seeker 4) can be shared, we are left with 8 tuples. If we ask PennSolarExperts whether their company's details can be shared and get a negative answer, we know that the data cannot be shared and there is no need to ask further questions. As another example, recall that we assumed that vacancies data can only be shared if the company's data can be shared. Then assume we get PennSolarSystem's permission to share data about vacancy 112 (and hence also the company details) and Bob's permissions to share Georgia's details – we obtain that the query result can be shared having used only 2 probes.

Naturally, the number of questions that will be asked in practice depends on the answers received, which are unknown in advance. The goal is to design a strategy for choosing which questions to pose and in what order, where multiple variants of the problem could be of interest. These variants may be based on axes such as the query language expressiveness (e.g. Conjunctive Queries, Datalog, etc.); the optimization goal (e.g. minimizing the number of questions or maximizing the number of shareable results for a given "budget" of questions); optimizing for the worst or expected case (with respect to the peer answers); selecting probes in advance or incrementally; and restricting the per-peer probes or optimizing the overall number of probes.

3 TOWARDS A SOLUTION

Having informally introduced the problem, we next outline a preliminary approach for a solution, combining multiple areas of previous work.

Provenance. We are interested in whether or not we may share *derived* data, whereas (hidden) access control policies are defined with respect to the original, *atomic* data items. The propagation of meta-data from atomic data items to the query results related to them has been studied under the prism of *provenance* [15, 16, 23] (and previously, c-tables [24]). In our case, we may use provenance to compute expressions capturing the access control of derived data, in terms of the concepts annotating the input.

Example 3.1. Recall the query in our running example from Figure 1. Using c-tables [24] (or alternatively Boolean provenance [15, 23]), we can compute a Boolean expression reflecting the dependencies of access control credentials to the output on permissions to view relevant input tuples.

$$\begin{aligned}&\mathtt{Companies11PennSolar}\wedge\\&(\mathtt{Vacancies111PennSolar}\wedge((\mathtt{Assignment1\text{-}111Bob}\wedge\mathtt{JobSeekers1Bob})\\&\qquad\qquad\vee(\mathtt{Assignment2\text{-}111Bob}\wedge\mathtt{JobSeekers2Bob}))\\&\vee(\mathtt{Vacancies112PennSolar}\wedge\mathtt{Assignment4\text{-}112Alice}\wedge\mathtt{JobSeekers4Bob}))\end{aligned}$$

The formula uses the access control concepts of the relevant tuples as variables. Indeed, it matches the intuition of Example 2.5 on how probe answers may affect the final decision: if PennSolarExperts refuse sharing their company details with Carol, `Companies11PennSolar` will be evaluated to false, and the truth value of the entire formula will be false. Alternatively, if we know that `Vacancies112PennSolar`, `Companies11PennSolar`, `Assignment4-112Alice` and `JobSeekers4Bob` evaluate to true, the entire expression evaluates to true.

(Boolean) provenance constructions such as the one exemplified above have been developed for different query languages and formalisms, and the shape of the resulting Boolean expression depends on the formalism for which provenance is tracked, which in turn may affect the probe selection process. For instance, if we restrict attention to Union of Conjunctive Queries, then provenance of each output tuple may be represented in Disjunctive Normal Form of polynomial size with respect to the input database size [24]; negation is needed for queries with relational difference [25]; for Datalog, a polynomial size representation is possible in the worst case only if we resort to Boolean circuits [26]; etc.

(Incremental) Boolean Evaluation. Given Boolean provenance formulas over data items, had we known whether they are authorized for publication, we could simply assign true/false to the corresponding variables in the formulas and decide whether the derived data could be shared. However, policies of peers may be unknown or undetermined, therefore we probe peers to obtain them. We now consider the optimization problem of selecting the best variables to observe next.

To illustrate, we next outline our preliminary solution for the following setting:

- Relational SPJUD queries (select-project-join-union-difference),
- Minimizing the number of questions
- Optimizing the expected case
- Selecting questions incrementally
- Considering either the number of questions overall or per peer
- Assuming an equal cost for all the questions/peers and given answer prior probabilities.

In this case, as explained above, output tuples would be annotated by Boolean expressions (computed via [24]). We then explore results on Boolean evaluation for such expression, and may leverage them to show that the problem is NP-hard, via [27, 28]. In contrast, previous work has studied optimal solutions for restricted cases, heuristics and approximations (see, e.g., [27, 29] for a survey). In particular, in [30] we have adapted and extended an approximate solution by [31], as we next briefly outline.

Denote the set of output tuple annotations by $\mathbf{E}$. For each Boolean formula $e_i \in \mathbf{E}$ we define two *utility* functions $g_0^i, g_1^i : \{1, 0, *\}^{|C|} \to \mathbb{R}^+$, where C is the set of variables in the Boolean expressions and each entry represents either a value assignment to a variable or no assignment ($*$). $g_0^i(\vec{c})$ and $g_1^i(\vec{c})$ are respectively the number of terms (conjunctions) set to 0 in the DNF form of e_i, and the number of clauses (disjunctions) set to 1 in the CNF form of e_i by the partial assignment $\vec{c}$. Denote by m_i and l_i the number of terms and clauses in e_i respectively. The utility function $g^i(\vec{c}) = m_i l_i - (m_i - g_0^i(\vec{c}))(l_i - g_1^i(\vec{c}))$ reaches its maximum, $m_i l_i$, when $g_0^i(\vec{c}) = m_i$ or $g_1^i(\vec{c}) = l_i$, i.e., e_i is evaluated.

To minimize the *overall* number of questions a greedy algorithm is then used. The algorithm repeatedly selects the unknown variable c_j whose probe maximizes the expected value (over the possible answers) of g^i. Some properties of g^i (monotonicity, submodularity) guarantee that the expected number of questions is within a factor of $\ln(m_i l_i) + 1$ from the optimum.

Next, we need to simultaneously evaluate all the formulas in **E**, which may be done by defining $g(\vec{c}) = \sum_{e_i \in E} g^i(\vec{c})$. g is a function that reaches its maximum, $\sum_{e_i \in \mathbf{E}} m_i l_i$, when all the expressions are evaluated. By similar analysis to that of g^i, we get that the solution is a $\ln(\sum_{e_i \in \mathbf{E}} m_i l_i) + 1$ approximation of the optimum.

The above adaptation is an example of a rather direct combination of results from the provenance and Boolean evaluation literature; our setting suggest further novel algorithmic developments. For instance, in [30] we have extended the solution to compute batches of probes rather than single probes and to account for constraints imposed by a taxonomy over the items (i.e., implication constraints between access rights), showing that we still achieve the same approximation bound. We also study an incremental setting where the client is allowed to terminate the process at any point and share partial results via "safe views" – views of the results that are known to be safe for sharing.

Another example for a variant that is not accounted for by previous results is one that targets the minimization of the probes *per peer*, in this case, minimizing. For that, we keep track of the number of probes per peer $p \in \mathcal{P}$ (denoted by probes(p)). At each step, let C^* be the set of variables still unknown. When selecting the next probe, we consider only variables in $\{c \in C^* \mid \text{probes}(\text{owns}(c)) = \min_{p' \in \mathcal{P}^*} \text{probes}(p') \land \mathrm{E}[g(\vec{c})] > 0\}$, i.e., that are owned by least-probed peers and whose utility is non-zero.

Our preliminary results are encouraging and suggest that the combination of provenance constructions and Boolean evaluation methods is a promising direction towards studying our problem complexity and designing efficient algorithms. There are still many challenges to be overcome in this space, both theoretical and practical: for instance, can we achieve better guarantees by restricting the query language? What guarantees can we obtain for more expressive languages? For instance, what if we have aggregates, or recursion and then Boolean circuits rather than formulas? What if we have a "budget" for the number of probes to be used? How can we estimate the probe answer probabilities, in light of constraints defined by the taxonomy, peer trust, and accumulated probe answers? The interplay between the choice of query language/provenance model, optimization goal and constraints leads to many intriguing computational questions which will be central to research on this problem.

4 CONCLUSION

This paper has advocated the study of access control management in a setting where peers are actively probed to ask for their permissions. Our main insight is that the problem may be addressed by computing Boolean provenance for query results, and treating the Boolean expression as input to active Boolean evaluation algorithms. We believe that this high-level approach paves the way to exciting research possibilities at the intersection of these two seemingly unrelated areas.

ABSTRACT

We present the ML-Index, a memory-efficient Multidimensional Learned (ML) structure for processing point, KNN and range queries. Using data-dependent reference points, the ML-Index partitions the data and transforms it into one-dimensional values relative to the distance to their closest reference point. Once scaled, the ML-Index utilizes a learned model to efficiently approximate the order of the scaled values. We propose a novel offset scaling method, which provides a function which is more easily learnable compared to the existing scaling method of the iDistance approach. We validate the feasibility and show the supremacy of our approach through a thorough experimental performance comparison using two real-world data sets.

1 INTRODUCTION

Processing queries on multidimensional data is a classical and thoroughly investigated problem. A plethora of index structures provides mechanisms for compactly storing and querying multidimensional datasets, applied in countless application scenarios. A recent idea proposed by Kraska et al. [4], suggests improvement and replacement of traditional index structures with machine learning and deep-learning models. They in particular successfully replace the B-Tree with a recursive learned model that maps a key to an estimated position of a record within a sorted array. With the use of the proposed learned models, they are able to utilize the patterns in the data distribution, resulting in an improvement of both the memory consumption and the execution time over the traditional index.

To provide a generalization of the B-Tree for multiple dimensions, the data needs to be sorted in an order which can be easily learned by supervised learning models. The ordering needs to be done in such a manner that the correctness guarantees are fulfilled when answering range and KNN queries. In practice, techniques, such as the Morton and the Peano-Hilbert order, can be exploited for sorting multidimensional data. However, directly mapping the multidimensional data points within the aforementioned orders cannot be easily learned by deep learning models. Kraska et al. [3] propose an approach for learning an order based on successively sorting and partitioning points along several dimensions into equally-sized partitions. However, choosing only a subset of dimensions may lead to performance degradation when the number of dimensions increases and the deduction of the partition neighbors may not be a time-efficient task.

Therefore, we create a novel Multidimensional Learned (ML) index which generalizes the idea of the famous iDistance scaling method [2] and uses the scaled ordering in combination with a two-layer learned index, to answer multidimensional queries. Unlike existing indexes, it captures the data distribution in two manners, by efficiently partitioning and scaling the data with respect to distribution-aware reference points and by learning the distribution of the sorted scaled values. Harnessing the power of the deep-learning models, the ML-Index is the first complete learned index, able to answer point, range and KNN queries efficiently while having a low memory consumption.

2 RELATED WORK

Until recently, limited research was present in improving data indices by interweaving them with machine learning. One of the first distribution aware indices [1] focuses on the combination of R-Trees with a self-organizing map. Another exact KNN algorithm [9] employs k-means clustering and triangle inequality pruning for efficient query execution.

Recently, Kraska et al. [4] draw the focus on a novel idea of substituting indices with deep learning models. Lead by the assumption that each index is a model, they draw a parallel between the indices and their respective analogue in the machine learning world. For instance, B-Tree Index and Hash-Index can be seen as models that map a key to a position within a sorted and unsorted array accordingly and can be easily replaced with neural network models. A learned database system called SageDB [3], extends the concepts to multidimensional data, by successively partitioning points along a sequence of dimensions into equal-sized cells and ordering them by the cell that they occupy. Although the order produces a layout noted as learnable, the complexity of directly learning the projection of n-dimensional points to an order position increases with the increase of dimensionality. Even though limiting the number of dimensions for partitioning avoids the added complexity, it results in slower execution of range queries including the missing dimensions.

Providing an inexpensive representation of multidimensional points which can be meaningfully sorted has been already widely explored, such as presorting the data by their Z-order [6], Hilbert order [5], or the respective distance to reference points [2]. A learned Z-order Model [8] focuses on combining the Z-order scaling with a staged learned model, for efficiently answering spatial queries. Although applicable for smaller dimensions, both the Z-order model and the UB-Tree are limited when dealing with a larger number of dimensions, which will be analyzed upon the experiments and the direct comparison.

3 THE ML-INDEX

The ML-Index is a compound of two main components, as illustrated in Figure 1. Its creation is carried out in two stages, guided and generalized by the idea of previously existent iDistance index [2]. The upper part consists of a set of reference points, responsible for scaling the multidimensional data to one-dimensional values, which can be easily sorted. The lower part is a Learned Model used for learning the distribution of the scaled values and a sorted array used for searching and storing the data.

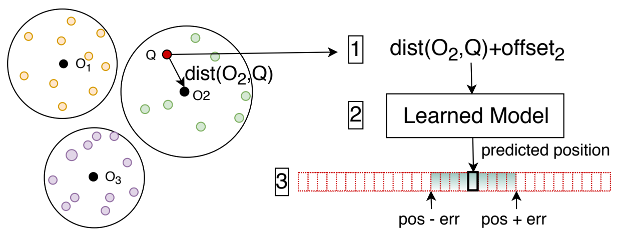

Figure 1: The ML-Index Approach

3.1 Scaling Methods

Consider a set of data points $d_l \in D$, where $d_l = (d_0, d_1, ..., d_n)$ is in an n dimensional metric space. The first stage, responsible for creating the upper part, maps the data points from a n into a one-dimensional data space. The scaling method aims to group points that are similar to each other and project them in one-dimension, such that the similarity is preserved by the proximity of the one-dimensional values. To efficiently do the scaling, m reference points O_i are chosen, each representing an identification or a centroid of the data in partition P_i. The partition P_i is formed from the points whose closest reference point is O_i. This means that the minimal distance of a point d_l to the reference points determines the appropriate partition.

Irrespective of the way to find reference points, we elaborate on the usage of different scaling methods and we discuss their advantages and disadvantages. The straightforward case is scaling d_l with respect to a single reference point, by mapping it to a one-dimensional value $key = dist(O_i, d_l)$. Although applicable for smaller datasets, the method creates a considerably large amount of false positives, produced by mapping multidimensional points that are far from each other to the same value.

The second scaling method is the iDistance method described by Jagadish et al. [2]. This method maps a data point d_l into a one-dimensional value key, based on $key = i * c + dist(O_i, d_l)$, where i is the index of the closest reference point O_i. The constant c serves to partition the points into predefined ranges and based on its value it stretches the ranges differently. Using the constant, the points belonging to a partition P_i will be mapped to a range $[i * c, (i+1) * c]$. Although it provides well-scaled values and drastically reduces the number of false positives, it is highly dependent on the parameter c. A smaller value for c may create an overlap between the partitions, causing multidimensional points from different partitions to be mapped to the same scaled value. Hence, upon search, the number of unnecessarily examined points will be increased. On the other hand, having a larger c directly affects the creation of the second stage of the ML-Index which we thoroughly discuss in Subsection 3.2.

Finding the right value for the constant c, which will cause no overlap and have perfectly ordered partitions, with no gaps between them, is impossible. This comes as no surprise since reference points correspond to partitions of different sizes. Prompted by the previous, we propose a novel scaling approach that provides a perfect ordering between the ranges of different partitions and overcomes the problem of overlapping. The new method termed *offset method*, given a point d_l and its closest reference point O_i, calculates the scaling value as $key = offset_i + dist(O_i, d_l)$, where $offset_i$ is different for every partition P_i. Given an arbitrary ordering of the reference points $O_1, O_2, ..., O_m$ and their adequate partitions $P_1, P_2, ..., P_m$, the offset is calculated as the sum of the radii of their previous partitions:

$$offset_i = \sum_{j<i} r(j)$$

where r is the maximal distance from O_j to the points in partition P_j. This method assures no overlap and it reduces the gap between the partitions, which is crucial regarding the performance of the second stage of the ML-Index. Additionally, it omits the problem of tuning the parameter c, for a suitable range creation. The downside in comparison to iDistance is an unnoticeable memory increase, caused by storing the offsets. Following the scaling of the original data, each data point d_l is associated with a value key. Multiple points can have the same scaled value. Before the execution of the second stage of the ML-Index, we sort the points according to the value key. The resulting order is used as a starting point for creating a learned model, which efficiently predicts the position of a given key within a sorted array.

3.2 Learning the Order

The second stage of the ML-Index represents a *Recursive Learned Index*, similar to the one described by Kraska et al. [4]. The index, mimics the behavior of a traditional B-Tree, by mapping a given lookup key within a sorted array with the guarantee that the key is within proximity of the predicted position $[pos - err, pos + err]$. As observed [4], a model, which performs this task, effectively approximates the cumulative distribution function (CDF), modelled as $p = F(key) * N$, where N is the number of keys and $F(key)$ is the estimated CDF that estimates the likelihood to predict a key smaller or equal than the lookup key. The learned index is built in a top-down manner where a model in each stage provides a prediction used to choose the model in the next stage, or the position of the key when the final stage is reached. For model $f(x)$ from models M_l at stage l, with input x, the loss is calculated:

$$L_l = \sum_{x,y} (f_l^{\lfloor M_l f_{l-1}(x)/N \rfloor}(x) - y)^2 \quad [4]$$

Although Kraska et al. [4] suggest using multiple stages of the learned index, we use only two. The incentive behind this decision is that if the second stage index produces a larger than expected error, the increase in the number of models in the second stage is sufficient to reduce the error. Additionally, unlike their proposed learned index, the second stage of learned models in the ML-Index is constructed solely by using a regression, with the purpose of balancing the construction time and the performance of the learned index. By using a simpler model, the number of multiplications and additions upon search is reduced, leading to lower search time. The final prediction of the learned model is a predicted position within the sorted array where the key, in our case the scaled value is stored. Because a position is predicted with a certain error, one must also search within the error bounds around the prediction for the correct position.

As mentioned, the different scaling methods impact the second stage of the ML-Index. Since the naive scaling method is infeasible, we elaborate only on the impact of the iDistance and the offset scaling method. Both methods result in different functions that need to be estimated by the learned index. When considering the iDistance we distinguish two scenarios, one with overlap between the partitions and one without. When c is smaller than the maximum radius of all the partitions, then an overlap between the ranges of the partitions is inevitable. However, sorting the data with a smaller c creates a function which can be easily learned. This is a result of the overlapping that leads to a larger density of the scaled values which results in a fairly continuous function. The second case is having a larger c, that avoids overlaps, but creates large gaps within the function. Therefore, the neural network will learn the data present in the different ranges. However, upon search time it is possible to search for a point that is not present within these ranges, but it is located within the gaps of the function. Vast research has been proposed for filling the missing values in a function to be learned, however, this leads to a pre-processing step which can be easily avoided by using the offset method. The offset method circumvents the gaps created by the different maximal sizes of the partitions and provides a better "learnable" function in which the missing values may only appear due to sparsity in the clusters and not the scaling method.

4 QUERY PROCESSING

Point Query: The point query identifies the existence of a multidimensional point within the index and it is executed in three steps as shown in Figure 1. The first step includes searching for the closest reference point O_i to the query q and calculating the scaled value $key = offset_i + dist(ClosestO_i, q)$, where $offset_i$ is calculated as $i * c$ for the iDistance scaling and appropriately for the offset method. Once calculated the key is used to predict the position of the point q, within the sorted array of points. The predicted value is the position pos of the key within the sorted array, and it is used in its exponential search with bounds $[pos - err, pos + err]$. The complexity of the first step, for m reference points and d dimensions, is $O(m * d)$. The learned model complexity depends on the architecture of the neural network. A neural network with a single hidden layer with width h and input size N will have $O(hN)$ multiplications and additions.

KNN Query: Given a query q and a parameter k, the KNN query finds the closest k points S_k, to the query such that $\forall d_i \in S_k,\ \forall d_j \in D \setminus S_k,\ dist(q, d_j) \geq dist(q, d_i)$. Since the iDistance was initially created for executing KNN queries, we adapt the algorithm for the ML-Index. The algorithm creates several one-dimensional range queries, whose selectivity expands until the result is complete. The major modification is locating the start of the range. For this purpose, the Algorithm 1 is used, that exploits the learned model to predict the position of a given key within a sorted array. However, since a key which is not present within the array can be provided, we need to search for the key with the smallest difference to the initial key. Nonetheless, searching for the closest key to the initial key is not only dependent on the bounds provided by the error of the learned model but also the bounds of the ranges occupied by the reference points. Therefore, we modify the binary search to also include the $offset_i$ and $offset_{i+1}$, which further reduces the search space. The method *closest* returns the position of the value closest to the key in the range $[offset_i, offset_{i+1}]$. To describe the need for the second bounds, we consider having two reference points and their respective ranges within the array $[1, 5][6, 10]$. Let's further take the assumption that the first range has the keys $[1, 3, 5]$ and the second $[7.5, 8, 10]$. Upon search, we want to find the closest key to $key = 6$ for the reference point O_2. If we do not consider that the reference point O_2 has a lower bound 6 we would retrieve the key 5 as closest which does not belong to the region 2 and thus, in reality, may not be even close to the query point.

Range Query: Widely applicable for smaller dimensions, the range query $q = q_1, q_2, ..., q_n$, where $q_j = [bound_{min}, bound_{max}]$, defines bounds of a dimension j, retrives the data points $d_i \in D$

Algorithm 1 Predict Closest Position

```
Require: scaled value $key$ (if outside of range, set to $offs_i$ or $offs_{i+1}$),
    range for $O_i$ $[offs_i, offs_{i+1}]$
 1: $mid = predict(key),\ s = mid - err,\ t = mid + err$
 2: while $s \leq t$ do
 3:     $mid = \lceil (s + t)/2 \rceil$
 4:     if $data_{mid} == key$ then
 5:         return $mid$
 6:     $withinRange = True$
 7:     if $data_{mid}$ outside $[offs_i, offs_{i+1}]$ then
 8:         $withinRange = False$, set $s$ or $t$ to $mid$
 9:     if $withinRange$ or $|s - t| \leq 1$ then
10:         if $key < data_{mid}$ then
11:             if $key \geq data_{mid-1}$ then
12:                 return $closest(data, key, mid - 1, mid, offs_i)$
13:             $t = mid - 1$
14:         else
15:             if $key \leq data_{mid+1}$ then
16:                 return $closest(data, key, mid, mid+1, offs_{i+1})$
17:             $s = mid + 1$
```

where $\forall j \in n,\ d_{ij} \geq q_{j0}$ and $d_{ij} \leq q_{j1}$. For the execution of the range query within the ML-Index, we adapt the Data-Based Method for range approximating suggested by Schuh et al. [7]. The algorithm iterates over the reference points and for each reference point calculates the closest and the furthest point from the given range q. For the computed furthest and closest point, the algorithm issues a range query of the form $[dist(O_i, point_{closest}) + offset_i,\ dist(O_i, point_{furthest}) + offset_i]$. Since the closest and furthest points can also have keys which are not present within the sorted array, the method described in Algorithm 1 is used.

5 EXPERIMENTS

For evaluation, all indices are in main memory and implemented in Java. The learned model is implemented with TensorFlow and it is extracted to omit the overhead. Its width is set according to the dataset. The reference points selection is done using the KMeans algorithm, due to better results for the real-world data. GMeans was not considered, since the branching factor of the M-Tree is set to k, for a fair comparison. We compare the following structures: the ML-Index, the iDistance index [2] with keys computed by our offset method, the M-Tree, and the index based on learning a Z-order, ZM-Index [8]. Two real-world datasets were used, Color Histogram (dim: 32, points: 68040, size: 19.5 MB) and Forest Cover Type (dim: 10, points: 581012, size: 68.7 MB).

Scaling Methods Comparison: Figure 2a shows the absolute error of learning the order produced by the different scaling methods, by varying the width of a single layer neural network. For the iDistance, c is once set to produce 10% and once 0% range overlap between the different reference points. The data is directly learned in several epochs, without preprocessing. The error produced by the offset scaling method is much lower from the error by the iDistance method when no overlap occurs. Differently, due to the density of the values, the approach with an overlap performs slightly better. However, an overlap between the ranges will result in slower query execution, therefore, the offset method performs the best when considering both aspects.

Memory: Figure 2b (Note the log scale 2) shows the memory consumption of the M-Tree, the iDistance and the ML-Index for both datasets. As observed, the ML-Index has a drastic reduction in memory and has only small storage required for the learned model and the offset distances. Increasing the number of clusters

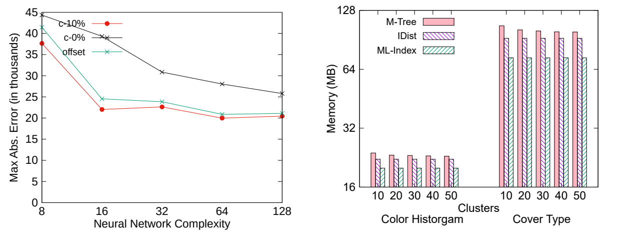

Figure 2: Scaling methods comparison (left) and memory consumption when varying datasets and clusters (right)

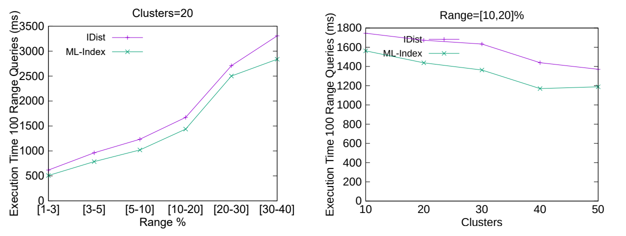

Figure 3: Range search when varying range selectivity (left) and clusters (right) for Forest Cover Type dataset

results in an unnoticeably small increase in memory due to the number of offset values.

Query Execution: Since the M-Tree is drastically slower, we show only the comparison between iDistance and ML-Index. Figure 3 shows the execution time of 100 range queries by varying the query selectivity, representing the fraction of points within the query range from the total number of points, and the number of clusters used for choosing the reference points. Figure 4 shows the execution time of 1000 KNN queries by varying k and the number of clusters. The ML-Index is always faster than the iDistance, which is a result of the superiority of the search with the learned model over the search with B+Tree. This is especially visible for larger ranges and k values where the result may belong to more clusters, requiring multiple predictions from the learned model, causing a more visible difference in the execution time. Upon an increase of clusters, the difference between the search time of the ML-Index and iDistance is smaller. Assuming we search for the closest point, we need to first find the closest cluster among m clusters, which is performed the same for the iDistance and ML-Index. Hence, when m is large, the execution will be impacted more by the cluster iteration than the prediction.

Comparison with learned ZM-Index: For comparison with ZM-Index, we extract 2, 4, and 6 dimensions from the Forest Cover dataset, we scale the values to reduce the number of bits and the large gaps between successive Z-values, which produce a slower execution time. We always use our learned model, since having the number of neurons mentioned in [8], results in incomparably large execution time. ZM-Index outperforms ML-Index when searching for a two-dimensional point, as seen in Figure 5a. This is intuitive since a search through multiple clusters requires more time than a bit shifting operation, which is not the case for larger dimensions and a smaller number of clusters. When considering the range query comparison in Figure 5b, the ZM-Index performs far worse. Upon searching for a next Z-value which is within the range, we exchange every bit accordingly, resulting in a longer

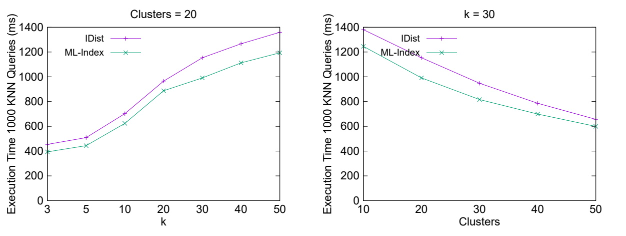

Figure 4: KNN search when varying k (left) and clusters (right) for Forest Cover Type dataset

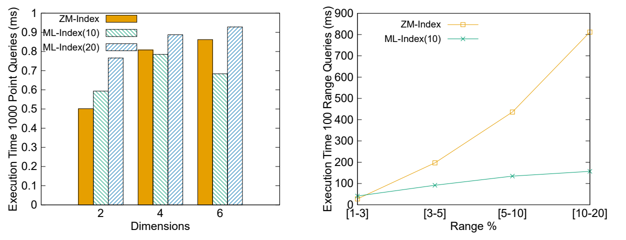

Figure 5: Point search (left) and range search (right) comparison with ZM-Index for Forest Cover Type dataset

execution when dealing with both large numbers and dimensions. More importantly, in each step, the next Z-value within range is calculated, which may correspond to a value not present within the dataset and thus it will lead to unnecessary access.

6 CONCLUSION

We addressed the problem of replacing multidimensional indices with a learned, distribution-aware ML-Index. The ML-Index entails two core tasks: representing the dataset by one-dimensional values based on reference points chosen with respect to the data distribution, and a learned model capable of accurately learning the order of the values. Experimental results demonstrated the feasibility of the approach and its superior performance compared to state-of-the-art competitors. Future work includes rendering the index resilient to updates by observing degenerated performance and triggering retraining only when necessary.

ABSTRACT

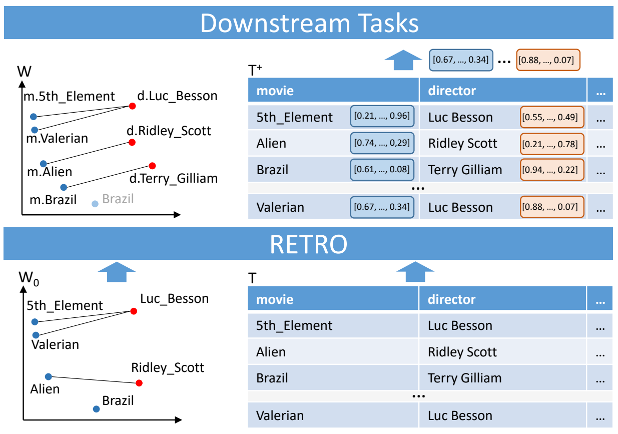
There are massive amounts of textual data residing in databases, valuable for many machine learning (ML) tasks. Since ML techniques depend on numerical input representations, word embeddings are increasingly utilized to convert symbolic representations such as text into meaningful numbers. However, a naïve one-to-one mapping of each word in a database to a word embedding vector is not sufficient since it would miss to incorporate rich context information given by the database schema, e.g. which words appear in the same column or are related to each other. Additionally, many text values in databases are very specific and would not have any counterpart within the word embedding. In this paper, we therefore, propose RETRO (RElational reTROfitting), a novel approach to learn numerical representations of text values in databases, capturing the information encoded by general-purpose word embeddings and the database-specific information encoded by the tabular relations. We formulate *relation retrofitting* as a learning problem and present an efficient algorithm solving it. We investigate the impact of various hyperparameters on the learning problem. Our evaluation shows that embedding generated for database text values using RETRO are ready-to-use for many ML tasks and even outperform state-of-the-art techniques.

1 INTRODUCTION

Due too their appealing properties, word embeddings techniques such as Word2Vec [7], GloVe [8] or fastText [3] have become conventional wisdom in many research fields such as machine learning, NLP or information retrieval. Typically, these embeddings are used to convert text values in a meaningful numerical representations presenting the input for ML tasks. However, a naïve application of a word embedding model is not sufficient to represent the meaning of text values in a database which is often more specific than the general semantic encoded in the raw text embedding.

Thus, we argue to incorporate information given by the disposition of the text values in the database schema into the embedding, e.g. which words appear in the same column or are related. Therefore, we develop a relational retrofitting approach called RETRO which is able to automatically derive high-quality numerical representations of textual data residing in databases without any manual effort.

Relational Retrofitting. Figure 1 provides a small example sketching the main principles of the relational retrofitting process. RETRO expects a database and a word embedding as input, e.g. a movie table T that should be retrofitted into a pre-trained



T^+

Figure 1: Relational Retrofitting: basis word embedding W^0 and relation T (left), retrofitted word embedding W and augmented relation T^+

word embedding W_0. To provide vector representations for textual information in databases one could simply reuse the vectors of pre-trained embeddings, e.g. map each term from T to a term-vector pair in W_0. However, often there will be a semantic mismatch between word embeddings and textual information in databases:
1) Given the movie table, it is known that all entities within the movie column must be movies, although some of the titles, such as “Brazil" or “Alien", may be interpreted differently by the word embedding model.
2) T provides a specific amount of relation types like the movie-director, whereas in the word embedding representation W_0 large amounts of implicit relations are modeled, e.g. if the director of a movie is also the producer or one of the actors this might be represented in the word embedding although not explicitly visible.
3) Terms in T which occurring infrequent in the general domain can not be modeled accurately by word embedding models. For instance Word2Vec has a limited vocabulary according to a frequency threshold. Many terms appearing in a database will therefore have no counter-part within the embedding.
We present RETRO[1], a novel relational retrofitting approach addressing all these challenges. RETRO augments all terms in database tables by dense vector representations encoding the semantics given by the relation T and the word embedding W_0. In the context of our movie example, RETRO would generate a new embedding for “Terry Gilliam" which should be close to other directors and their respective vectors. Furthermore, RETRO would create vectors for all other textual values in the movie table that encode the semantic given of the pre-trained word embeddings and the database. On the one hand, this ensures that vectors

[1] https://github.com/guenthermi/postgres-retrofit

appearing in the same column, such as movies or directors, are close to each other. On the other hand, this ensures that the difference vectors between movie-director pairs are similar. These vectors are ready-to-use for a wide range of ML, retrieval and data cleaning tasks such as classification, regression, null value imputation, entity resolution and many more.

Outline. In Section 2, we give an overview of the problem and a briefly introduce the original retrofitting problem. We then present our novel *relation retrofitting* and formulate the underlying learning problem in Section 3. In Section 4, we show the feasibility of Retro in automatically creating vector representations by defining different classification task and conclude in Section 5.

2 RETROFITTING AND PROBLEM SCOPE

We aim at leveraging powerful word embedding models to generate good vector representations for text values residing within relational databases. We therefore extend the notion of retrofitting which was initially proposed by Faruqui et al. [5]. Retrofitting is performed as a post-processing step and allows to inject additional information into word embeddings. The approach of Faruqui et al. took a matrix $W^0 = (\boldsymbol{v_1'}, \dots, \boldsymbol{v_n'})$ of word embeddings and a graph $G = (Q, E_F)$ representing a lexicon as input. The retrofitting problem was formulated as a dual objective optimization function: The embeddings of the matrix W^0 are adapted to $W = (\boldsymbol{v_1}, \dots, \boldsymbol{v_n})$ by placing similar words connected in the graph G closely together, while at the same time the neighborhood of the words from the original matrix W^0 should be preserved. Hereby, $Q = \{q_1, \dots, q_n\}$ is a set of nodes where each node q_i corresponds to a word vector $\boldsymbol{v_i} \in W$ and $E_F \subset \{(i,j)|i,j \in \{1,\dots,n\}\}$ is a set of edges. The graph is undirected, thus $(i,j) \in E_F \Leftrightarrow (j,i) \in E_F$. The authors specified the retrofitting problem as a minimization problem of the following loss function:

$$\Psi_F(W) = \sum_{i=1}^{n} \left[\alpha_i ||\boldsymbol{v_i} - \boldsymbol{v_i'}||^2 + \sum_{j:(i,j)\in E_F} \beta_i ||\boldsymbol{v_i} - \boldsymbol{v_j}||^2 \right] \quad (1)$$

The constants α_i and β_i are hyperparameters. $\Psi_F(W)$ is convex for positive values of α_i and β_i. Thus, the optimization problem can be solved by an algorithm, which iterates over every node in Q and updates the respective vector in W.

However, while retrofitting is typically used to improve the vector quality of general-purpose word embeddings by using lexical knowledge graphs, we aim at learning vector representations for text entries in database tables. Here the objective is to 1) reflect the semantics of the text value specifically referred to in the database and 2) to fit into the vector space of the given basis word embedding model.

3 RELATIONAL RETROFITTING

In this paper, we extend idea proposed in [5] and formulate the *relational retrofitting* approach that learns a matrix of vector representations $W = (\boldsymbol{v_1}, \dots \boldsymbol{v_n})$ corresponding to text values $T = (\boldsymbol{t_1}, \dots \boldsymbol{t_n})$ where each $\boldsymbol{v_i} \in \mathbb{R}^D$ represents a unique text value in a specific column of the database. To find an initial vector representation for every text value, we tokenize the text values based on the vocabulary of the basis word embedding model and build centroid vectors which is a convenient way to obtain a representation of text values consisting of multiple tokens [1, 11]. These vectors are stored in a matrix $W^0 = (\boldsymbol{v_1'}, \dots \boldsymbol{v_n'})$ forming the basis for the retrofitting process. Besides, *columnar and relational connections* are extracted from the database (see Section 3.1). This encompasses semantic relations between text values, which are derived from the relational schema. Those connections are used to create a representation capturing the context of the text value in the database (e.g. “Brazil” in the column “movie.title” is considered as a movie) and thus helps to preserve their semantics more accurately compared to a plain word embedding representation. The core procedure of the relational retrofitting is the adaption of the basis vectors W^0. This is performed by solving an optimization problem detailed further in Section 3.2.

3.1 Extracting Relational Information

One can derive different structural relations from the alignment of text values in the relational schema.

Columnar Connections: Text values with the same attribute, i.e. appearing in the same column, usually form hyponyms of a common hypernym (similar to subclass superclass relations). Thus, they share a lot of common properties which typically leads to similarity. We capture this information and assign each text value t_i to its column $C(i)$.

Relational Connections: Relations exhibit from the co-occurrence of text values in the same row as well as from foreign key relations. Those relations are important to characterize the semantics of text value in the database. We define a set of relation types R for each specific pair of related text value columns. Those columns are related because they are either part of the same table or there exists a foreign key relationship between their tables. For every relation type $r \in R$ there is a set E_r containing the tuples of related text value ids. Relation types are directed. Accordingly, there is an inverted counterpart $\bar{r}$ for each relation r with $E_{\bar{r}} = \{(j,i)|(i,j) \in E_r\}$.

3.2 Optimization Problem

Retro considers relational and columnar connections (see Section 3.1) to retrofit an initial embedding. Accordingly, we define a loss function Ψ adapting embeddings to be similar to their basis word embedding representation W^0, the embeddings appearing in the same column, and related embeddings.

$$\Psi(W) = \sum_{i=1}^{n} \left[\alpha_i ||\boldsymbol{v_i} - \boldsymbol{v_i'}||^2 + \beta_i \Psi_C(\boldsymbol{v_i}, W) + \Psi_R(\boldsymbol{v_i}, W) \right] \quad (2)$$

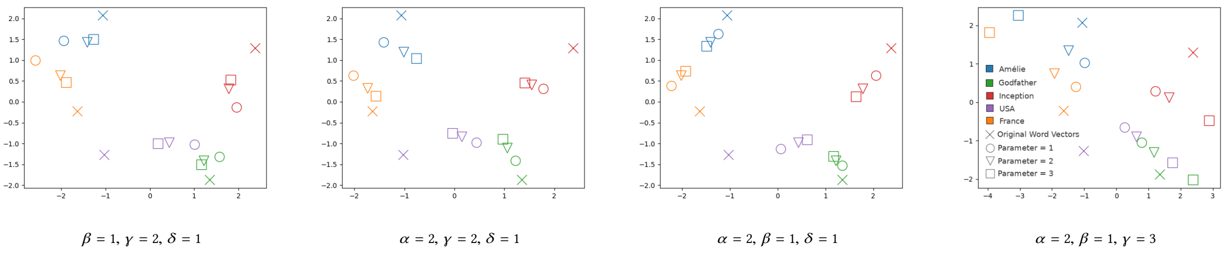
The columnal loss is defined by Ψ_C and treats every embedding $\boldsymbol{v_i}$ to be similar to the constant centroid $\boldsymbol{c_i}$ of the basis embeddings of text values in the same column $C(i)$.

$$\Psi_C(\boldsymbol{v_i}, W) = ||\boldsymbol{v_i} - \boldsymbol{c_i}||^2 \quad \boldsymbol{c_i} = \frac{\sum_{j\in C(i)} \boldsymbol{v_j'}}{|C(i)|} \quad (3)$$

The relational loss Ψ_R treats embeddings v_i and v_j to be similar if there exists a relation between them and dissimilar otherwise. E_r is the set of tuples where a relation $r \in R$ exists. $\widetilde{E_r}$ is the set of all tuples $(i,j) \notin E_r$ where i and j are part of relation r. Thus, each of both indices has to occur at least in one tuple of E_r.

$$\Psi_R(\boldsymbol{v_i}, W) = \sum_{r\in R} \left[\sum_{\substack{j:(i,j)\\ \in E_r}} \gamma_i^r ||\boldsymbol{v_i} - \boldsymbol{v_j}||^2 - \sum_{\substack{k:(i,k)\\ \in \widetilde{E_r}}} \delta_i^r ||\boldsymbol{v_i} - \boldsymbol{v_k}||^2 \right] \quad (4)$$

α_i, β_i, γ_i and δ_i are hyperparameters. Ψ should be a convex function. In [6] we proved the convexity of Ψ for hyperparameter



(a) Influence of $\alpha = 1, 2, 3$ **(b) Influence of $\beta = 1, 2, 3$** **(c) Influence of $\gamma = 1, 2, 3$** **(d) Influence of $\delta = 0, 1, 2$**

Figure 2: Examples for Different Hyperparameter Settings

configurations fulfilling the following inequation:

$$\forall r \in R, i \in \{1, \dots, n\} \quad (\alpha_i \geq 0, \quad \beta_i \geq 0, \quad \gamma_i^r \geq 0) \qquad (5)$$
$$\forall \boldsymbol{v_i} \in W \quad \Big(4\alpha_i - \sum_{r\in R} \sum_{j:(i,j)\in\widetilde{E_r}} \delta_i^r \geq 0\Big)$$

In practice, however, other parameter configurations that do not comply might work as well. The impact of the hyperparameter values on the retrofitting result is shown in Section 4.1. The retrofitting algorithm iteratively executes for all $\boldsymbol{v_i} \in V$ the following equation, which is derived from the root of the partial derivative $\frac{\partial \Psi(W)}{\partial \boldsymbol{v_i}}$.

$$\boldsymbol{v_i} = \frac{\alpha_i \boldsymbol{v_i'} + \beta_i \boldsymbol{c_i} + \sum_{r\in R}\Big[\sum\limits_{\substack{j:(i,j)\\ \in E_r}} (\gamma_i^r + \gamma_j^{\bar{r}})\boldsymbol{v_j} - \sum\limits_{\substack{k:(i,k)\\ \in \widetilde{E_r}}} (\delta_i^r + \delta_k^{\bar{r}})\boldsymbol{v_k}\Big]}{\alpha_i + \beta_i + \sum_{r\in R}\Big[\sum\limits_{\substack{j:(i,j)\\ \in E_r}} (\gamma_i^r + \gamma_j^{\bar{r}}) - \sum\limits_{\substack{k:(i,k)\\ \in \widetilde{E_r}}} (\delta_i^r + \delta_k^{\bar{r}})\Big]} \qquad (6)$$

Given the property of convexity, such an iterative algorithm can be used to minimize Ψ illustrated in more details in the next section.

3.3 Retrofitting Algorithm

The retrofitting algorithm can be expressed as a set of matrix operations that can be solved with linear time complexity according to the number of text values in W. We update all vectors at once using a recursive matrix equation. $\Psi(W)$ can be minimized by iteratively calculating W^k according to (7).

$$W_R = \sum_{r\in R} \Big[((\gamma_{ij}^r) + (\gamma_{ij}^{\bar{r}})^T) - ((\delta_{ij}^r) + (\delta_{ij}^{\bar{r}})^T)\Big] W^k$$
$$W' = \alpha W^0 + \beta \boldsymbol{c} + W_R$$
$$D = diag\Big(\alpha + \beta + \sum_{r\in R}\Big[\sum_{\substack{j:(i,j)\\ \in E_r}} (\gamma_i^r + \gamma_j^{\bar{r}}) - \sum_{\substack{k:(i,k)\\ \in \widetilde{E_r}}} (\delta_i^r + \delta_k^{\bar{r}})\Big]\Big)$$
$$W^{k+1} = D^{-1} W'$$
$$\boldsymbol{c} = (\boldsymbol{c_1}, \dots, \boldsymbol{c_n}) \quad \alpha = (\alpha_1, \dots, \alpha_n) \quad \beta = (\beta_1, \dots, \beta_n) \qquad (7)$$

More details are outlined in [6].

4 EVALUATION

Retro is a fully functional system built on top of PostgreSQL. Given an initial configuration including the connection information for a database and the hyperparameter configuration, Retro fully automatically learns the retrofitted embeddings and adds them to the given database. We created two databases based on the Movie Database[2] (TMDB) and the Google Play Store Apps dataset[3] (GPSA). TMDB consists of 15 tables containing 493,751 unique text values, whereas the GPSA database has 7 tables and 27,571 unique text values (details are outlined here[45]). Both of them are available as CSV files and are imported in our Retro PostgreSQL database system.
One baseline we compare our retrofitted embeddings to, are plain word vectors (PV) that have no notion of the relational schema. The counterpart to this would be embeddings that just rely on the the structural information given by the database. Here we use the node embedding technique DeepWalk [9] (DW) that is learned based on a graph representation of the database relations. Moreover, we applied the original retrofitting approach [5] leading to another baseline embedding dataset (MF).

4.1 Hyperparameter Analysis

The influence of the hyperparameters is visualized in Figure 2: We learned 2-dimensional embeddings for a small example dataset containing three movies and the country where those movies have been produced. Accordingly, there are two columnar (movie and country) and one relational connection (see Section 3.1). "Amélie" was produced in "France", the other movies in the "USA". Usually the hyperparameters for each vector are derived from four global hyperparameters α, β, γ, and δ as detailed in [6]. We set the hyperparameters α, β, γ, and δ to different values and performed the relational retrofitting.
As shown in Figure 2a, the learned embeddings stay closer to their original embeddings when the α values increasing. Higher values of β make it easier to cluster the categories from each other, e.g. reduce the distances between the movie vectors of "Inception" (red), "Godfather" (green), and "Amélie" (blue). The γ value controls the influence of relational connections. This brings the representations of text values which share a relation closer together. The δ factor causes vectors with different relations to separate and thus prevent concentrated hubs of vectors with different semantic. One can see in Figure 2d how $\delta = 0$ causes all vectors to concentrate around the origin of the coordinate system. If δ is set to a high value like $\delta = \alpha = 2$, the algorithm places the vectors far from the origin of the coordinate system. However, related text values still get assigned to similar representations. In the example, the retrofitting algorithm is still converging for this configuration. Our analysis shows, that the exposed hyperparameters allow to steer the relational retrofitting

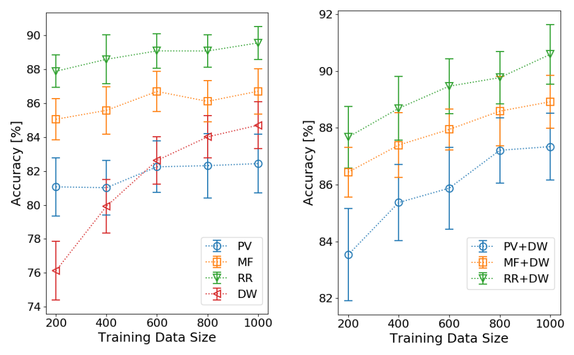

Figure 3: Classification of Birth Places of US-American Directors with Increasing Sample Size

process into different directions in a fine-grained manner, i.e. to adapt to different downstream tasks.

4.2 Machine Learning Tasks

Binary Classification. We implemented a binary classifier to label a set of directors of the TMDB dataset according to there citizenship. The classifier should decide between US-American and non-US-American directors. Since this information is not available from the TMDB dataset, we extract the citizenship from Wikidata [10] by using the SPARQL query service. We trained a feed-forward neural network (one hidden layer with 600 neurons; applying dropout and L2 regularization; Nadam optimizer [4]) on the different 300-dimensional embedding representations of the director names (full names). We used for the training 200 to 1,000 samples and validate the accuracy with 1,000 test samples. We compared the accuracies achieved when using plain word embeddings (PV), node embeddings (DW), simple retrofitted (MF) and relational retrofitted embeddings (RR). We ran the training and testing on the ANNs 20 times for each configuration with different sample sets.

The accuracy values and their standard deviation achieved by the classifiers are shown on the left in Figure 3. The best results are achieved with our relational retrofitting approach (RR) utilizing word embedding features of the directors name but indirectly also word embedding features of related text values like the movie titles directed by them. The influence of the training sample size is at lowest for the plain word embeddings (PV). DeepWalk (DW) needs a larger amount of training data to achieve comparable results. The right side of Figure 3 shows the accuracies achieved by running the same experiment but combining the previous embeddings with node embeddings by concatination. This leads to better results for all methods. Notably, the accuracies of the retrofitting methods are much better compared to methods where node embeddings (DW) and plain word embeddings (PV) are just concatenated.

Missing Value Imputation. Further, we built classifiers to predict app categories within GPSA database which can be used to impute missing values. Here,a feed-forward neural network (two hidden layer with 600 and 300 neurons; applying dropout and L2 regularization; Nadam optimizer [4]) is applied on the embeddings of the application names. The network was trained 10 times on 400 random samples to predict the one out of 33 categories. The category information and the genre information (which is often redundant) are omitted for the retrofitting. We trained the network on all embedding types and compared it to

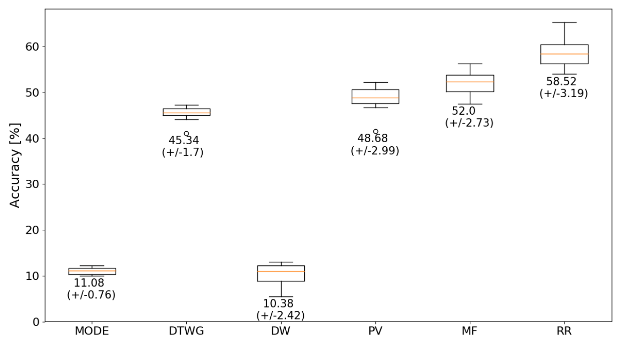

Figure 4: Imputation of Categories of Android Apps

MODE imputation, choosing always the most frequent category in the training data, and Datawig [2]. Figure 4 shows that best accuracy is achieved by relational retrofitting (RR).

5 CONCLUSION

In this paper, we presented Retro, a system that augments all terms in database tables by dense vector representations. Therefore, we employed the notion of retrofitting to modify word embedding representations to specialize for given relational schemas. We validated Retro experimentally by building standard feed-forward neural networks for different classification tasks. Our evaluation showed that the generated relational embeddings are ready-to-use for different ML tasks and even outperform state-of-the-art techniques such as the approach of Faruqui et al. or DeepWalk [9].

ABSTRACT

Database cracking (DBC) provides an adaptive data storage environment that meets the needs of modern applications in business and science, reorganizing data on demand and adapting indexes on the fly, automatically, and collaterally to query processing. Despite intensive research on cracking and other adaptive indexing variants, their theoretical side has scarcely been investigated. Yet, quite surprisingly, as we show, an antecedent of database cracking in a pure, no-frills form had been developed in the theory community 24 years ahead of its time by the name of *deferred data structuring* (DDS). While lacking system implementations, DDS corresponds to what we would call, by the terminology used in the database community, *materialization-based data-driven center* cracking for point lookup queries, as well as a stochastic variant thereof. Further, DDS has gone beyond regular cracking proposals by suggesting a policy that reorganizes index ranges along the median of a *sample* set, i.e., a *mediocre* element.

In this paper, we reanalyze state-of-the-art database cracking algorithms with the benefit of hindsight provided by deferred data structuring, and propose new alternatives that use a mediocre element as cracking pivot instead of a random or a median one. In a thorough experimental study, we determine that a logarithmic or linear sample size yields best performance on a standard benchmark across the board of cracking algorithms.

1 INTRODUCTION

Database Cracking (DBC) [1–3] addresses the needs of dynamic environments where workload knowledge and idle time are scarce, queries follow an exploratory path, and new data arrive continuously [1]; as a form of adaptive indexing [6], it paves the way to self-organizing database management systems, eschewing the need for human administration in physical database design. Cracking builds and refines index data structures for a column-oriented database incrementally, in response to queries and arriving data, without a need for human intervention; its core operation, applied within the select operator, reorganizes a column into pieces [5], handles updates [4] and invites security features [8]. A *stochastic* alternative [1] improves performance by refraining from *blindly* following queries; it also creates *random cracks* on its own, and thereby avoids the deterioration of performance that skewed workloads may cause.

Surprisingly, while database cracking has been studied over the last decade, an antecedent thereof had been investigated from a theory perspective two decades in advance by the name of **Deferred Data Structuring** (DDS) [7]. Specifically, DDS suggested that, instead of processing a data set in advance, we may instead process it while responding to queries. Traditionally, to answer the query *"is integer x in list ℓ?"*, we would scan ℓ in $O(n)$. If the number of queries is high, it pays off to sort $O(n \log n)$ in a pre-processing step and then perform binary search in $O(\log n)$ for each query. By DDS, we create a data structure that represents the list *while* processing queries, achieving better performance in all cases. While DDS was proposed for lookup queries on a static data set only, we will argue that its main logic uncannily resembles that of database cracking.

In this paper, we observe the resemblance between DBC and DDS and bring both concepts under the same roof. We conduct a thorough theoretical study of state-of-the-art DBC algorithms under the light of DDS methods. We implement existing DDS and DBC proposals and propose new intermediary, mediocre-based solutions, that inherit both the theoretical elegance of DDS and the practical applicability of DBC.

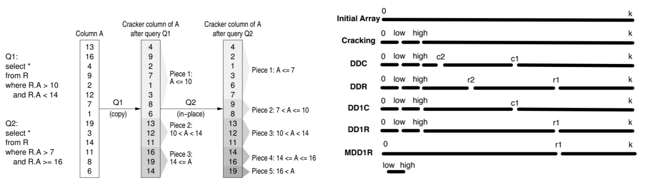
2 RELATED WORK

We discuss related works in two fields: database cracking and defferred data structuring.

2.1 Database Cracking

Database Cracking [2, 3] reorganizes and indexes columns in an adaptive manner triggered by user queries, within the SELECT operator. In the general case, a query requests all values within a range, [*low*, *high*]; when responding to that query, the a cracking system finds one or more *pieces* of the current index where the requested data resides, reorganizes (i.e., cracks) the column so as to bring the result values between query bounds *low* and *high* in a contiguous space, and updates the index accordingly. Figure 1a provides an example.



(a) Reorganizing a column. **(b) Cracking algorithms at work.**

Figure 1: Database cracking illustration [1].

Stochastic Cracking [1] maintains performance when faced with pathological workloads; in addition to cracking using query bounds as pivots, it creates additional cracks while traversing the index towards query bounds. Figure 1b indicates how several stochastic cracking algorithms work. We discuss the six main alternatives: DDC, DDR, DD1C, DD1R, MDD1R, and PMDD1R.

The *Data-Driven Center* (**DDC**) algorithm divides (i.e., cracks) each value range it encounters while traversing the index along the *middle* (i.e., median) of its value domain *recursively*, as in an ideal case of pivot selection by quicksort. This recursive splitting process terminates when pieces become smaller than a size threshold. Thereafter, DDC cracks on query bounds as usual. Algorithm 1 illustrates the process. On the other hand, the *Data-Driven Random* (**DDR**) algorithm avoids the median-finding overhead: it uses a random element instead of the median as pivot when cracking each value range in Line 6 of Algorithm 1.

Both DDC and DDR incur an overhead on the first few queries, as they *recursively* introduce many cracks on the way to query bounds. Two lightweight alternatives, **DD1C** and **DD1R**, eschew the recursion, i.e., crack only *once* at a median or random pivot, respectively, in addition to cracking at query bounds, by turning the *while* loop in Line 5 of Algorithm 1 to an *if* statement.

ALGORITHM 1: DDC [1]

```
   Result: Cracks at center of each relevant piece and bounds
1  int DDCCrack(C:array, v:value)
2      Find the piece Piece that contains value $v$;
3      $pLow$ = $Piece$.firstPosition();
4      $pHigh$ = $Piece$.lastPosition();
5      while ($pHigh - pLow >$ CRACK-THRESHOLD)
6          $pMiddle = (pHigh + pLow)/2$;
7          Introduce crack at $pMiddle$;
8          if ($v < C[pMiddle]$)
9              $pHigh = pMiddle$
10         else
11             $pLow = pMiddle$
12     $position$ = crack($C[pLow, pHigh]$, $v$);
13     return $position$;
   /* Main Body : DDC                                   */
   /* Crack array C on bounds a and b                   */
14 $positionLow$ = DDCCrack($C$, $a$);
15 $positionLow$ = DDCCrack($C$, $b$);
16 result = createView($C$, $positionLow$, $positionHigh$);
```

Still, the hitherto presented algorithms create cracks at each query's bounds, which may hurt performance without bringing a benefit in the long run. **MDD1R**, a variation of DD1R, dispels the cracking at query bounds as well, and simply *materializes* query results while creating exactly *one* random crack per query. Algorithm 2 shows the corresponding pseudocode.

ALGORITHM 2: MDD1R [1]

```
   Result: Cracks at a random point in one relevant piece and bounds
1  array split-and-materialize(Piece, a, b)
2      $L = Piece$.firstPosition;
3      $R = Piece$.lastPosition;
4      $result$ = newArray;
5      $X = C[L + rand()\%(R - L + 1)]$;
6      while ($L \leq R$)
7          while ($L \leq Q$ and $C[L] < X$)
8              if ($a \leq C[L]$ and $C[L] < b$)
9                  $result.Add(C[L])$
10             $L = L + 1$;
11         while ($L \leq R$ and $C[R] \geq X$)
12             if ($a \leq C[R]$ and $C[R] < b$)
13                 $result.Add(C[L])$
14             $R = R - 1$;
15         if ($L < R$)
16             swap($C[L]$, $C[R]$)
17     Add crack on $X$ at position $L$;
18     return $result$;
   /* Main Body: MDD1R                                  */
   /* Crack array C on bound a, b                       */
19 Find the piece $P1$ that contains value $a$;
20 Find the piece $P2$ that contains value $b$;
21 if ($P1 == P2$)
22     $result$ = split-and-materialize($P1$, $a$, $b$)
23 else
24     $res1$ = split-and-materialize($P1$, $a$, $b$);
25     $res2$ = split-and-materialize($P2$, $a$, $b$);
26     $view$ = createView($C$, $P1.lastPosition + 1$, $P2.firstPosition - 1$);
27     $result$ = concat($res1$, $view$, $res2$);
```

In more detail, the algorithm first finds the pieces where the two bounds are. If they are in the same piece, it partitions that piece with respect to a random pivot, while collecting the query results in an array. Should they be in different pieces, it partitions the pieces where each bound belongs and then concatenates the query results, as well as all pieces in between to produce the response to the query. Note that MDD1R maintains a data-driven character: even though not cracking at query bounds, it introduces random cracks in the pieces where those bounds are.

Even with MDD1R, the initial queries of a workload need to reorganize almost all the the data. **PMDD1R** is a *progressive* instantiation of MDD1R that takes the incremental nature of cracking one step further. MDD1R performs a reorganization task on a given piece in smaller units, performed with each query touching that piece. A percentage p determines how much of the pending reorganisation task is done with each relevant query, while materializing and returning the query result.

2.2 Deferred Data Structuring

Deferred Data Structures [7] are tree-like structures built in response to queries. Their objective and rationale resembles database cracking, even though they were introduced two decades earlier with a focused theoretical intent and no accompanying system implementation. Consider a list $\ell = \{x_1, x_2, x_3, \ldots, x_n\}$ and *existence* queries thereupon, $q = \{q_1, q_2, q_3, \ldots, q_r\}$. A conventional approach would sort the list and answer each query by binary search. DDS performs sorting through query answering: it answers each query in $O(n)$ time, and partition the list as well while doing so. Algorithm 3 illustrates DDS. By the terms of Section 2.1, Algorithm 3 corresponds to a **DDC** variant of database cracking specialized on point lookup queries, without a size threshold: it cracks recursively on the median, like DDC does, and reports the existence or absence of the lookup query value; were there a size threshold, it would correspond to an **MDDC** variant, yet without such a threshold **MDDC** degenerates to **DDC**.

ALGORITHM 3: DDS via recursive median finding [7]

```
   Result: Create a tree structure representation of list l while responding to queries
1  boolean SEARCH(v:node, q:query)
2      if(v is not labeled)
3          $EXPAND(v)$;
4      if(label(v) == q)
5          return true;
6      if(v is a leaf node)
7          return false;
8      if(q < label(v))
9          return $SEARCH(left\_child(v), q)$;
10     if(q > label(v))
11         return $SEARCH(right\_child(v), q)$;
12 void EXPAND(v:node)
13     $S \leftarrow set(v)$;
14     $m \leftarrow MEDIAN - FIND(S)$;
15     $label(v) \leftarrow m$;
16     if($\|S\|$ == 1)
17         return ;
18     $S_l \leftarrow [x \mid x \text{ in } S \text{ and } x < m]$;
19     $S_r \leftarrow [x \mid x \text{ in } S \text{ and } x > m]$;
20     $set(left\_child(v)) \leftarrow S_l$;
21     $set(right\_child(v)) \leftarrow S_r$;
   /* Main Body                                         */
22 initialize the tree $T_X$ with the n data keys at the root;
23 Get a query $q$;
24 Result $\leftarrow SEARCH(root, q)$;
25 Output the result;
26 Goto Line 23;
```

Further, DDS [7] comes along with a *randomized* proposal, which replaces the exact median-finding operation with a *mediocre* function, i.e., the median of small sampled set of values, whose computed rank passes a sanity test, instead of the whole set, as Algorithm 4 shows; this choice improves the cost per query while it still creates a well-balanced tree structure in the long term. Once again, the rationale is reminiscent of what we would call **MDDR** in database cracking terms. In particular, a randomized DDS where the size of the sampled set is one element corresponds to an MDDR cracking algorithm specialized on point lookup queries and without a size threshold.

ALGORITHM 4: Mediocre finding function [7]

```
   Result: Finds mediocre of set $T$
1  int mediocreFind(T:set of values)
2      $t \leftarrow size(T)$;
3      Pick a random of sample $S$ of size $2 * \lceil t^{5/6} \rceil + 1$ from T;
4      $m \leftarrow MEDIAN - FIND(S)$;
5      Compute rank(m) by comparing with each element of $T - S$;
6      If rank(m) is not in the range $(t/2) \pm t^{2/3}$;
7      return $m$;
```

3 THEORETICAL ANALYSIS

Here, we analyze state-of-the-art database cracking algorithms by the tools of deferred data structuring, assuming a cracking size threshold of zero and point lookup queries. We also propose, study, and build upon an alternative stochastic cracking algorithm, **DDM**, which uses a *mediocre* element as cracking pivot, as in Algorithm 4, instead of a random one, as DDR algorithms do, or a median one, as DDC algorithms do.

Theorem 3.1. *DDC: The number of operations needed to process r queries on a list of n points is no more than $\lambda(n, r)$:*

$$\lambda(n,r) = \begin{cases} 3n\log r + r\log n, & \text{if } r \le n \\ (3n+r)\log n, & \text{if } r > n \end{cases}$$

Proof. In case $r \le n$, at any level of the tree, at most r nodes are expanded. For the top $\log r$ levels, the total cost is less than $3n\log r$, since all nodes have to be expanded. The creation of a crack includes finding the median, which requires $3|set(node)|$. The cost of node expansion at level i of the tree for $i > \log r$, is $O(rn/2^i)$, since the expansion of a node at this level costs at most $3n/2^i$. Summing over all but the first $\log r$ levels, we get an $O(n)$ cost, which is dominated by $3n\log r$. Searching for each query costs $O(\log n)$, since the tree is balanced, hence the $r\log n$ term. When $r > n$, expansion will complete the tree, with a cost of $3n\log n$, while search follows the same principles. □

Theorem 3.2. *DDR: The number of operations needed to process r queries on a list of n points is no more than $\lambda(n, r)$:*

$$\lambda(n,r) = n^2 + rn$$

and is expected to be no more than $\lambda(n, r)$ operations:

$$\lambda(n,r) = \begin{cases} 1.39n\log r + r\log n, & \text{if } r \le n \\ (1.39n+r)\log n, & \text{if } r > n \end{cases}$$

Proof. As there is no guarantee that the created tree will be balanced, in the worst case, the random numbers chosen to create cracks yield a completely unbalanced tree. A query may cause the entire tree to be created in $O(n^2)$. Due to the lack of balance, search can take up to n operations, producing the rn term. In the average case, we expect performance similar to quicksort [9], with 1.39 in place of 3 in Theorem 3.1. □

Theorem 3.3. *DDM: The number of operations needed for processing r queries in a list of n points is no more than $\lambda(n, r)$:*

$$\lambda(n,r) = \begin{cases} (1+\alpha)(n\log r + r\log n), & \text{if } r \le n \\ (1+\alpha)(n+r)\log n, & \text{if } r > n \end{cases}$$

with probability greater than $1 - \frac{\log r}{\beta n}$, where $\alpha \ll 1$ and β depends on the value of α.

Proof sketch. The proof follows from [7]. The height of the tree created only differs from $\log n$ by a constant, so the search operations are $r\log n$. Then, the probability of the first sample chosen rendering a median that passes the test is higher than $(1 - \frac{1}{4|set(node)|})$, which leads to the conclusion that the total cost of testing for mediocrity is at most $(1+\alpha)n\log r$ with probability higher than $1 - \frac{\log r}{k^2 n}$, where α and k are small constants, and β depends on α. The total cost of finding the medians for the first $\log r$ levels is $O(n^{\frac{5}{6}} r^{\frac{1}{6}})$ with probability higher than $1 - \frac{\log r}{\beta n}$, from which the complexity for $r \le n$ follows. If $r > n$ the tree will be complete with some extra costs, as in the DDR case. □

Theorem 3.4. *DD1C: The number of operations needed to process r queries in a list of n points is no more than $\lambda(n, r)$:*

$$\lambda(n,r) = \begin{cases} 14n + r\log n, & \text{if } r \le n \\ (3n+r)\log n, & \text{if } r > n \end{cases}$$

Proof. As the first query, q_1 is made to a list of length n, the median should be found in $3n$. Then, one of the two crack pieces is chosen and another crack is made, with regards to the query. The process of partitioning takes at most $\frac{n}{2}$ comparisons. For the second query, up to two comparisons are made based on the crack created in the first query, to choose a chunk of size at most $n/2$, find its median, and crack one of the resulting pieces, yielding $\frac{3n}{2} + \frac{n}{4}$. Following the same pattern until the rth query, we get a cost of:

$$\sum_{i=1}^{i=r} \frac{3n}{2^{i-1}} + \sum_{i=1}^{i=r} \frac{n}{2^i} = 7n \sum_{i=1}^{i=r} \frac{1}{2^i} < 14n$$

while the search component costs $r\log n$. When the number of queries reaches n, the tree will be complete, and the cost is as in the proof of Theorem 3.1. □

Theorem 3.5. *DD1R :The number of operations needed to process r queries in a list of n points is no more than $\lambda(n, r)$:*

$$\lambda(n,r) = \begin{cases} 3rn + r, & \text{if } r \le n \\ n^2 + rn, & \text{if } r > n \end{cases}$$

and is expected to be no more than $\lambda(n, r)$ operations:

$$\lambda(n,r) = \begin{cases} 7.56n + r\log n, & \text{if } r \le n \\ (1.39n+r)\log n, & \text{if } r > n \end{cases}$$

Proof. In the worst case in terms of random pivot choices, for query q_1 we pick a random point and partition based on it, in at most n operations. The pieces may be of size 1 and $n-1$. One of those two is partitioned based on the query in $n-1$ comparisons. The second query will partition a piece of size as large as $n-2$ for the random crack and one as large as $n-3$ for the query bound, and so on, in $[n-2(i-1)] + [n-(2i-1)]$ operations for the i^{th} query. Going all the way to q_r, we have

$$\sum_{i=0}^{i=2r-1} (n-i) = 2rn - 2r^2 + r$$

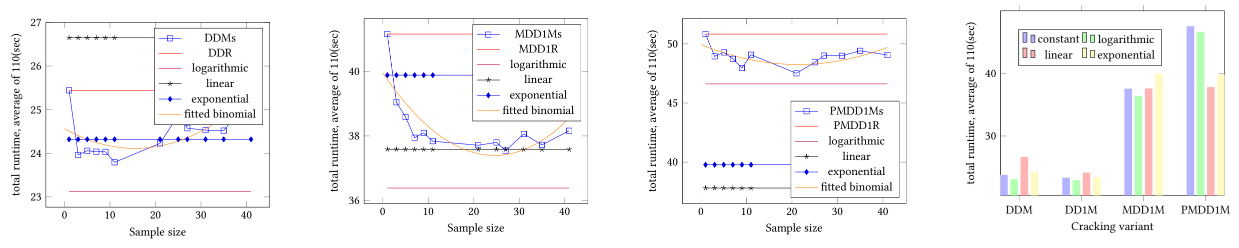
operations for expansion and rn operations for search. Should the number of queries exceed n, the tree is completed, hence n^2 operations. In the expected case, the tree resembles a balanced tree and results follow Theorem 3.4, with the quicksort complexity factor $1.39n$ replacing $3n$ in calculations, as in Theorem 3.2. □

Theorem 3.6. *DD1M: The number of operations needed to process r queries in a list of n points is no more than $\lambda(n, r)$:*

$$\lambda(n,r) = \begin{cases} (1+\alpha)(n\log r + r\log n), & \text{if } r \le n \\ (1+\alpha)(n+r)\log n, & \text{if } r > n \end{cases}$$

with probability greater than $1 - \frac{\log r}{\beta n}$.

Proof. By Lemma 3 in [7], with high probability we only need to compute a median over a sample once, as the first attempt passes the mediocrity test. For the first r queries, we compute the medians of nodes that will overall lead to $O(n^{\frac{5}{6}} r^{\frac{1}{6}})$ (Lemma 5 in [7]). The cost testing for mediocrity at level i, denoted by c_i, is proven to be less than $(1+\alpha)n\log r$. After cracking at the



(a) **Recursive crack** (b) **Crack with materialization** (c) **Progressive materialization** (d) **All variants, constant** $m = 21$

Figure 2: Total runtime, 160K queries; linear: $m = \frac{size}{1000}$**, logarithmic:** $m = log(size)$**, exponential:** $m = size^{\frac{5}{6}}$**.**

mediocre, we scan the list to find the query point and create another crack there, in at most s_i (Lemma 1 in [7]), yielding:

$$n^{\frac{5}{6}} r^{\frac{1}{6}} + \sum_{i=1}^{i=r} c_i + 1.5 s_{i+1} \leq$$

$$n^{\frac{5}{6}} r^{\frac{1}{6}} + (1+\alpha) n \log r + 2n(1-(0.5)^r) + 20 n^{\frac{2}{3}} \frac{1-2^{\frac{2r}{3}}}{1-2^{\frac{2}{3}}}$$

The cost of search remains similar to that of DDM. □

Overall, materialization-based algorithms have similar complexities as their default counterparts due to their common bases.

4 EXPERIMENTAL STUDY

We assess the performance of mediocre-based variants database cracking algorithms [1] inspired from our study of deferred data structures [7]. We conduct experiments on a Ubuntu Linux server release 18.04 machine with a 10-core 3.1GHz Intel E5-2687W processor and 377GB of RAM. All methods are implemented in C++ upon the code[1] of [1]; our code is also available[2] online. We use the 4TB SkyServer[3] data and workload [1], derived from an astronomy project mapping the universe. We filter selection predicates from 160K chronologically ordered queries using the right ascension attribute of the Photoobjall table, which contains 500 million tuples. Query patterns are complex, as users tend to focus in a specific area of the sky before moving on.

4.1 Compared Algorithms

We compare the state-of-the-art stochastic cracking algorithms presented in Section 2, namely DDR, DD1R, MDD1R, and PMDD1R with $p = 0.1$ and $CRACK\_THRESHOLD = 128$ to their median-based counterparts and to counterparts that use a mediocre cracking pivot, i.e., the median of a random *sample* set of a cracked piece, rather than a median or random one: DDM, DD1M, MDD1M, and PMDD1M, respectively.

The median-based counterparts of DDR, DD1R and MDD1R are DDC, DD1C and MDD1C respectively; we included those three in our study, but they proved to be too expensive. We do not include a median-based counterpart of PMDD1R, since median-finding operations are hard to render progressive. The mediocre-based policy is reduced to the median-based one for m equal to piece size, and to the randomized one for $m = 1$.

4.2 Results

We apply each algorithm on the same 160K-query workload and measure the total runtime, juxtaposing mediocre-based variants to their randomized and median-based counterparts, where such exist. Figure 2 shows the results when varying the sample set size m from 1 to 41, and as a linear, logarithmic, or exponential function of piece size, with the mediocre-based policy, averaging over 110 runs and foregoing the mediocrity check [7]. The case of single crack without materialization is very similar to that of single crack with materialization in Figure 2b, hence we omit a separate figure for that case.

In the case of a constant sample size, the cost of calculating the median of a small sample set is initially a worthwhile price to pay for the benefits it brings, yet the cost to benefit ratio deteriorates as m grows; binomial fit curves visualize the trends in Figure 2a, 2b, and 2c. However, cases where sample size is a simple function of piece size achieve the best performance in all variants. The logarithmic function is the best performer with recursive and simple crack with and without materialization. In the variant with progressive materialization, a linear function, $m = \frac{size}{1000}$, performs best.

5 CONCLUSION

We revisited the theory and practice of *database cracking*, which has been intensively studied in practice, yet scantily examined in theory. We provided the first thorough study of the complexity of the all state-of-the-art stochastic cracking algorithms, drawing from an overlooked 32-year-old study that introduced analogous concepts under the name of *deferred data structuring*. Inspired from deferred data structuring, we introduced a refined stochastic cracking policy that uses a sample-based *mediocre* pivot, rather than an arbitrary random or median one, for data-driven cracking. We showed that variants of state-of-the-art stochastic cracking algorithms using the mediocre-based policy have lower complexity than their median-based and randomized counterparts with high probability, and demonstrated experimentally that they stand out in terms of cumulative time efficiency.

Boosting Blocking Performance in Entity Resolution Pipelines: Comparison Cleaning using Bloom Filters

Leonardo Gazzarri

ABSTRACT

Entity Resolution (ER) allows to identify different virtual representations of entities that refer to the same real world entity. When applied to highly heterogeneous data, ER relies on schema-agnostic blocking techniques to improve efficiency while yielding good effectiveness. A drawback of schema-agnostic blocking is the potentially high number of redundant pairwise comparisons. This has led to the introduction of additional efficiency layers beyond blocking in the overall ER pipeline, which all aim at pruning comparisons to reduce the unnecessary time overhead.

This paper proposes a novel technique based on Bloom filters that integrates in such an efficiency layer. In addition to avoiding redundant comparisons, it further prunes superfluous comparisons that are unlikely to result in matches when actually compared. Experiments on benchmark datasets show that our approach improves existing approaches in space and time efficiency, with insignificant changes in effectiveness.

1 INTRODUCTION

Entity resolution (ER) is the problem of identifying or *matching* different digital representations of the same real-world entity (e.g., the same person, manufactured part). It represents a fundamental task in data integration and data cleaning. While ER has mostly been studied for homogeneously structured data (to which we refer to as *structured ER*) [6], recent work has been extended to *unstructured ER*, i.e., ER when it is not possible or useful to transform heterogeneous entities to match a common schema [5, 10]. This for instance applies when considering ER for the Web of Data or for data stored in data lakes.

For large datasets, handling the inherently quadratic complexity of ER generally becomes computationally prohibitive. Therefore, ER solutions commonly adopt blocking techniques [6, 12] that reduce the total number of pairwise comparisons by performing comparisons only between entity representations placed in the same block according to some criteria. This typically prunes a significant number of comparisons between entity descriptions that do not match anyway, to which we refer to as *superfluous* comparisons. In structured ER, blocking techniques (and ER in general) heavily rely on a fixed schema among all entity representations. As this assumption does not hold in unstructured ER, schema-agnostic blocking techniques have recently been proposed for unstructured ER [5, 8, 10].

Figure 1 depicts a general pipeline for unstructured ER [12]. It comprises three layers enabling efficient and effective ER. *Block building* places entity representations, each denoted as e_i, into blocks. One problem of schema-agnostic blocking is that the

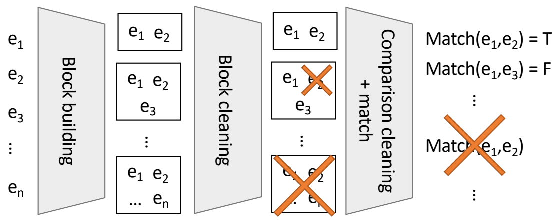

Figure 1: Unstructured ER pipeline.

resulting blocks may significantly overlap and thus yield *redundant* comparisons and the distribution of entity descriptions over blocks may still yield too many pairwise comparisons. These two problems have resulted in two further techniques for unstructured ER. *Block cleaning* acts at a block level and either prunes entire blocks (e.g., too large and thus most likely resulting in mostly superfluous comparisons) or entity descriptions within blocks (e.g., descriptions appearing in too many blocks are removed from the least important blocks). Finally, *comparison cleaning* considers pairs of entity descriptions resulting from the cleaned block collection. It prunes pairs if they are identified as either redundant or superfluous. Otherwise, pairs of entity descriptions are compared using a *match* function to determine whether they represent the same entity or not. Examples of comparison cleaning techniques are *comparison propagation* [9] and *meta-blocking* approaches [4, 11, 14].

Contribution. This paper presents a novel comparison cleaning approach that prunes both redundant and superfluous comparisons. It relies on (i) a favorable order of blocks being processed, for which we validate a heuristic that works in practice, and (ii) false positives that are, in our context, a useful feature of *Bloom filters (BFs).* Indeed, while false positives are typically undesired, we shall see that we can turn them to our advantage when coupled with a favorable order. As Bloom filters are static data structures that need to be correctly set up upfront, we further extend our method to use *scalable Bloom filters (SBFs).* Our experimental validation on several real-world benchmark datasets shows that comparison cleaning using SBFs is robust to different block collection characteristics and provides a good trade off between efficiency and effectiveness of comparison cleaning that improves on baseline and state-of-the-art solutions.

Structure. Section 2 introduces our novel approach based on Bloom filters and its extensions. Section 3 presents our experimental evaluation. We conclude in Section 4.

2 BLOOM FILTER ENHANCED BLOCKING

BFs have been previously used in ER, for example, to obscure sensitive data [15] or to summarize the blocking structure of a dataset [7]. In our work, we employ BFs for comparison cleaning. In this section, we describe our algorithm leveraging BFs (Section 2.1), the block ordering heuristic allowing to turn false positives inherent to BFs to our advantage (Section 2.2), and details on extending our algorithm with SBFs (Section 2.3).

Algorithm 1: Comparison cleaning using a Bloom filter

```
Input: $p_{max}$, $s$, $B$
1 initialize($BF$, $p_{max}$, $s$);
2 while $B$ has further pairs to process do
3     $p_{i,j}$ ← next pair according to order defined by $P$;
4     if !lookup($BF$, key($i$, $j$)) then
5         insert($BF$, $key(i, j)$);
6         submit(match($p_{i,j}$));
```

2.1 General BF based comparison cleaning

To discuss our algorithm that uses BFs, we first provide relevant background on BFs. We refer readers to [2, 3] for further details.

A BF is a space-efficient probabilistic data structure that offers two operations: *insert(k)* inserts the key k in the filter and *lookup(k)* answers if the key k has been inserted with some probability, or definitely if it has not been inserted. False positive probability (the probability of a lookup returning true even though k has not been inserted) can be computed and it increases with insertions of unique keys. A Bloom filter BF is initialized by providing a maximum acceptable false positive probability p_{max} and the number of expected keys to be inserted, denoted s.

In our context, a key $k_{i,j}$ uniquely identifies a pair $p_{i,j} = (e_i, e_j)$. We assume that e_i and e_j are unique identifiers of entity descriptions. We generate $k_{i,j}$ using a function $key : Integer \times Integer \longrightarrow Integer$. The pairs to be sequentially inserted into the BF (by inserting their integer key) are pairs produced from a block collection $B = [b_1, \ldots, b_n]$ that comprises n blocks of various sizes. The maximum number of keys possibly being inserted is bounded by $O(|b_1|^2 + |b_2|^2 + \ldots + |b_n|^2)$. Given that the false positive probability increases with the number of keys that have been inserted into a BF, we assume that we can iterate over pairs resulting from B in a specific order. That is, our algorithm uses an iterator to retrieve pairs in the order given by

$$P = \left[(e_i^k, e_j^k)\,\middle|\, e_i^k e_j^k \in b_k, 1 \leq k \leq n, 1 \leq i < |b_k|, i < j \leq |b_k|\right]$$

where the three ranges specified for k, i, and j are to be interpreted as three nested loops with k being the outer and j the most inner loop. How to sort B in a good order for efficient and effective comparison cleaning is further discussed in Section 2.2.

Using the above assumptions and notation, Algorithm 1 summarizes how we leverage BFs to perform comparison cleaning. It first initializes a Bloom filter BF, given p_{max} and s. While p_{max} is generally user defined (we will see how to best set it in practice in Section 3), s can also be computed as the upper bound of comparisons based on B (which we do in all experiments). The algorithm then iterates over pairs retrieved from B in the order given by P, retrieving each pair $p_{i,j}$ one at a time. In line 4, we check if $p_{i,j}$ has already been inserted in BF. To this end, a unique key $k_{i,j}$ is generated for pair $p_{i,j}$. If looking up $k_{i,j}$ in BF returns false, we know that the pair has not been compared before. So we insert the key into BF, perform the pairwise comparison of the actual pair of entity descriptions using a *match* function, and propagate the result (could be e.g., a boolean, a similarity score, or a match probability) for further processing via a submit method.

Time analysis. Time to insert or search a key in a BF is $O(|H|)$, with $|H|$ the number of hash functions used to fingerprint the key in the BF [3]. Defining $\bar{c}$ the average cost for comparing two entities, the desiderata is that $O(|H|) \ll \bar{c}$. This typically holds in practice because hashing a pair of integers is less expensive than fetching and matching two entity representations.

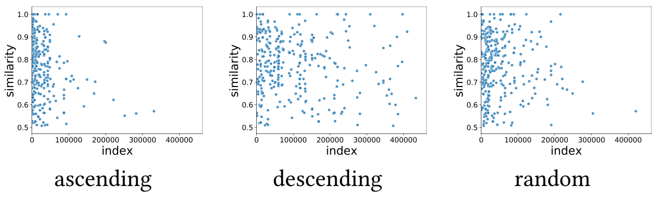

Figure 2: Distribution of pairwise similarities per iteration for different order heuristics

Space analysis. The minimum bits size m of the filter is determined by $m \geq 1.44s \cdot log_2(1/p_{max})$ [3]. For instance, assuming $p_{max} = 0.1$, we have $m \approx 4.78s$ bits.

In our algorithm, we can easily replace the BF by any other dictionary data structure implementing an $insert(\cdot)$ and a $lookup(\cdot)$ method. We opt for BFs for two reasons. First, a BF is a well known space efficient data structure and we validate experimentally that in comparison to other dictionary data structures, it exhibits better performance for comparison cleaning (see Section 3). Second, a BF allows us to additionally prune superfluous comparisons. This slightly more hidden benefit is rooted in both p_{max} inherent to Bloom filters and the order of entity pairs determined by P. This interplay is further discussed next.

2.2 Block ordering heuristic

The false positive probability inherent to a BF results in three possible cases when a pair $p_{i,j}$ is processed by Algorithm 1:

True negative (*tn*) $lookup(BF, p_{i,j})$ returns false, so $p_{i,j}$ is not redundant

True positive (*tp*) $lookup(BF, p_{i,j})$ returns true and the pair is indeed redundant

False positive (*fp*) $lookup(BF, p_{i,j})$ returns true even though $p_{i,j}$ has not yet been inserted

While *tn* and *tp* are desired cases, *fp* may be problematic for the effectiveness of ER as it may reduce the recall of ER if a wrongly pruned $p_{i,j}$ had, if compared, resulted in a match. We refer to this case as *miss-match*. On the other hand, if $p_{i,j}$ would have resulted in a non-match upon comparison, the comparison was a superfluous one, i.e., a comparison we actually want to prune.

When the number of keys inserted in the BF increases, the false positive rate of the BF increases up to p_{max}. The basic idea of our Bloom filter based comparison cleaning is to put this "effect" of BFs to good use by determining an order of pairs for P that has a high probability of processing true matches early (to minimize the negative effect of miss-match cases) and using the increasing false positive probability coming with later processing to prune superfluous comparisons. Such behavior is intuitively obtained when finding an order of pairs where the match probability decreases with increasing number of iterations. Clearly, the performance of our approach relies on both identifying a suited order that mimics the behavior described above, and on the parameter p_{max}. Given a block collection, [12] postulated that similar entity descriptions are more likely to be found in small blocks rather than in big blocks. We experimentally validate this heuristic on several real-world datasets (see Table 1). Figure 2 shows representative results for three order heuristics resulting from sorting blocks in ascending, descending, and random order of the number of entities they contain on the CDDB dataset. The plots show the first occurrence of a pair $p_{i,j}$ at position (x, sim) when it is the x-th pair to be processed and the similarity computation yields a similarity sim. We cut off similarities below 0.5 for better readability. As is common in ER, we assume that the match

Dataset	Size(D1)	Size(D2)	Duplicates	Brute-force
AG Products	1354	3039	1104	4.11e06
CdDb	9763	//	299	4.77e07
Movies	27615	23182	22813	6.40e08

Table 1: Dataset characteristics (same as in [1]).

	Dataset	Redundancy	Comparisons	Recall
E1	AG Products	79%	1.9e7	1.0
E2	Movies	15%	6.5e7	0.98
E3	Movies	7%	9.7e6	0.96
E4	CdDb	36%	2.2e7	0.99
E5	CdDb	7%	4.6e5	0.99

Table 2: Experiment settings.

function determines $p_{i,j}$ to match if its similarity is above a similarity threshold. So the higher the similarity, the more likely it is we determine a match. Clearly, the ascending order of block sizes best mimics the desired behavior for our order heuristic. This experimentally validates the claim that in practice, sorting the block collection B in ascending order of its block sizes is suited to approximate the desired behavior on match probability.

2.3 Extension using scalable Bloom filters

We have seen in Section 2.1 that initializing BF requires setting both p_{max} and s, which are key in optimally setting the number of bits allocated to the Bloom filter. While s is in the order of sum of squares of individual block sizes, this is in practice a very loose upper bound for the expected number of *unique* keys to be inserted, especially when a high degree of redundancy can be expected. To avoid allocating unnecessary space to a BF and be less sensitive to variations of both the redundancy and match distribution in P, we explore how to extend our comparison cleaning algorithm with scalable Bloom filters. We provide relevant background on SBFs and refer readers to [2] for details.

A SBF is a list of Bloom filters $BF_0, \ldots, BF_n$. Initially, the list includes a single BF, denoted BF_0, with an associated initial capacity s_0 and maximum false positive probability p_0. More generally, each BF_i has an associated capacity s_i and a false positive probability p_i. Given BF_i the last BF in the list, a new key is inserted into BF_i. When BF_i becomes full (i.e., new keys cannot be inserted without exceeding p_i), a new BF_{i+1} is inserted in the list. Given a tightening ratio θ with $0 < \theta < 1$ and a growth ratio $\sigma \geq 1$, BF_{i+1} is set with $p_{i+1} = p_0\theta^i$ and $s_{i+1} = s_i\sigma$. Overall, the capacity of the SBF gradually increases as needed while the compound false positive probability p_{fp} is bounded by $p_{fp} \leq p_0 \frac{1}{1-\theta}$. This means that we do no longer have to set s upfront, assuming the worst case in Algorithm 1. We can choose a more conservative initial capacity $s_0 << s$ to improve space efficiency and extend it if needed. The additional parameters of SBF can be fixed to $\theta = 0.9$ and $\sigma = 2$, following the recommendation of [2].

3 EVALUATION

We experimentally validate the comparison cleaning approaches presented in this paper. We both perform a parameter sensitivity study and a comparative evaluation to baseline and state-of-the-art methods. Performance metrics are runtime (time), memory footprint (space), and quality (recall over the set of executable comparisons considering a ground truth file).

All algorithms were implemented in Java 1.8 as extensions of the JedAI library [13] that supports numerous state-of-the-art unstructured ER solutions. We ran experiments on an OpenStack virtualized server (16 processors at 2.30GHz, 50GB RAM).

Our experiments use data from three benchmark datasets commonly used to evaluate unstructured ER (e.g., in [8, 11]). Their characteristics are summarized in Table 1. They are publicly available at the JedAI webpage together with ground truth files.

Our evaluation relies on different experiment settings. Each setting varies in the block collection B input to the evaluated comparison cleaning techniques, obtained by varying datasets and steps preceding comparison cleaning. Table 2 summarizes the characteristics of five settings E_1 through E_5. Here, "Redundancy" reports the fraction of redundant pairs produced by B. "Comparisons" is the total number of pairs resulting from B, i.e., $|P|$. "Recall" reports the maximum possible recall that can be obtained based on B.

3.1 Parameter sensitivity

We study the effect of parameter variations on performance by varying the parameters for both BF and SBF as follows:

BF Capacity $s = |P|$ (see Comparison column in Table 2), $p_{max} \in \{0.1, 0.5, 0.8\}$

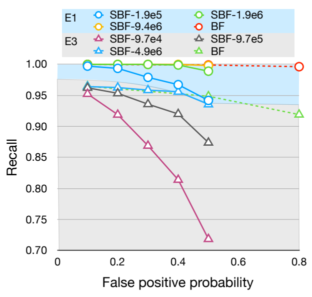
SBF Initial capacity $s_0 \in \{0.01|P|, 0.1|P|, 0.5|P|\}$ and $p_0 \in \{0.1, 0.2, 0.3, 0.4, 0.5\}$

For all considered parameter settings, we studied their effect on time, space, and recall. Due to space constraints, we only report representative results on settings E_1 and E_3, two extreme cases with high and low redundancy. The remaining results are analogous and in line with our discussion.

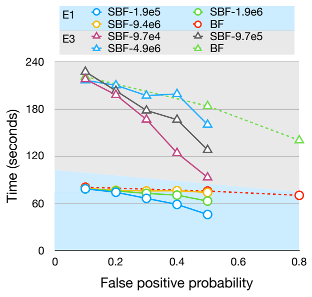
Figure 3(a) studies recall when varying the false positive probability for different configurations of the capacity in both E_1 and E_3. For setting E_1, we observe that recall is stable across all tested configurations. The reason is that E_1 has high redundancy, so even the most aggressive configuration setting for a SBF (low initial capacity, high initial false positive probability) has an acceptable low loss in recall because typically, it only prunes comparisons that are indeed unnecessary. In E_3, where we have low redundancy, an aggressive solution based on SBFs with a very small capacity and high false positive probability loses much more in effectiveness (25% total loss in recall) compared to a solution using an higher capacity and same false positive probability or a solution that uses a smaller false positive probability. This is due to the fact that a SBF with such aggressive configuration converges faster to the maximum compound false probability than the other solutions, resulting in more miss-matches.

Figure 3(b) shows runtime for the same configurations as the previous experiment. In E_1, the aggressive configuration mentioned before using SBF with very low initial capacity and high false positive probability is particularly efficient because it starts to remove non-redundant pairs earlier than the other solutions but in a point where the match probability is already very low. This positive effect on runtime decreases as the initial capacity of a SBF increases, until it eventually converges to the behavior of a BF. In E_3 and similarly in other settings with low to moderate redundancy, the behavior is similar, yet the slopes are more evident. This is due to the fact that in such settings, higher false positive probabilities prune more pairs that are not redundant (and thus pruned by any configuration).

Considering space (no graphs shown for conciseness), all configurations require less than 25MB of memory, making both SBFs and BFs space efficient data structures. Considering BFs, as expected by the formula in Section 2, the space decreases with



(a) E1-E3 recall



(b) E1-E3 time

Figure 3: Recall and runtime for parameter configurations

increasing p_{max}. Considering SBFs, we observe that required space is lower than for BFs only when the degree of redundancy is sufficiently high.

From our parameter sensitivity analysis, we observe that good performance across all settings is obtained when SBF capacity is set between 0.1 and 0.5 times $|P|$ (the size of a BF) coupled with a high/moderate false positive probability (0.3 to 0.5). As BFs do not suffer from efficiency or space degradation caused by SBF extensions, their false positive probability can be set to even higher values (as these high values kick in late in the process where typically, most matches have already been processed), for which we recommend the range between 0.5 and 0.8.

3.2 Comparative evaluation

Given our above conclusion, we now select two good configurations: BF* with $s = |P|$, $p_{max} = 0.5$ and SBF* with $s_0 = |P| * 0.5$, $p_0 = 0.5$). We compare them to two other comparison cleaning approaches. The first baseline uses a hash set (HS) instead of a BF. The second approach applies comparison propagation (CP) [9]. CP uses inverted indexes to avoid redundant comparisons. The inverted index is basically a hash-map where the keys are entity identifiers and the list of values associated to the key identifies the block indexes where the entity appears. Given a processing order of the blocks $b_1, b_2, ..., b_n$, two entities are compared in a block b_i only if the lowest common index of their associated block indexes is i. We again evaluate time, space, and recall. We do not consider meta-blocking [11] as a competitor because it is not integrable in Algorithm 1, which interleaves pairwise similarity computation with comparison cleaning.

Quality comparison. Both HS and CP yield the maximum possible recall (see Table 2) as they exclusively prune redundant comparisons. The possibly lower recall of our Bloom filter based solutions is attributed to miss-matches caused by false positives (see Section 2). Throughout all settings E_1 through E_5, the recall of BF* (SBF*) does not reduce by more than 4%.

Time comparison. Table 3a shows the runtime for the compared approaches in all setings. We further report on the runtime of ER without any comparison cleaning in the "Nothing" column. When high redundancy occurs like in E1, all the comparison cleaning solutions outperform the approach that compares all redundant pairs (Nothing). Also, we observe that HS and CS consistently have comparable runtimes. In scenarios with low redundancy, HS and CS are worse than (or comparable to) Nothing, as their overhead time to find redundant pairs is higher than the time avoided by not comparing them (see E_3 and E_4). Both BF* and SBF* outperform the baseline approaches thoughout all settings, improving runtime between 7% and 31% over the best competitor.

	BF*	SBF*	CP	HS	Nothing
E1	75	74	95	81	540
E2	1235	1161	1557	1566	2038
E3	183	160	255	218	221
E4	77	71	103	112	120
E5	4	4	5	5	4

(a) Time (in seconds)

	BF*	SBF*	CP	HS	Dataset
E1	6	3	4	223	3
E2	23	38	55	5063	40
E3	3	5	39	785	40
E4	7	13	12	1281	6
E5	<1	<1	5	39	6

(b) Space (in MB)

Table 3: Results for time and space

Space comparison. Table 3b shows space required by the compared comparison cleaning approaches. Unsurprisingly, HS performs worst. CP performs better because the size of its inverted index depends on the number of entity descriptions of the datasets, the number of blocks in B, and the level of redundancy of entities in multiple blocks. We observe that the space used by BF* and SBF* further usually improves on CP (up to 90%) while, at the same time, improving efficiency and maintaining high quality.

4 CONCLUSIONS

We proposed a novel approach comparison cleaning approach in entity resolution based on Bloom filters that removes both redundant and superfluous comparisons to improve efficiency. The technique relies on a validated heuristic that pairs a decreasing match probability with an increasing false positive probability. We further present an extension to our approach, using scalable bloom filters. Our experimental validation demonstrates that our approach outperforms state-of-the art algorithms in space and time, while maintaining high effectiveness.

ABSTRACT

Many business applications benefit from fast analysis of online data streams. Modern stream processing engines (SPEs) provide complex window types and user-defined aggregation functions to analyze streams. While SPEs run in central data centers, wireless sensors networks (WSNs) perform distributed aggregations close to the data sources, which is beneficial especially in modern IoT setups. However, WSNs support only basic aggregations and windows. To bridge the gap between complex central aggregations and simple distributed analysis, we propose Disco, a distributed complex window aggregation approach. Disco processes complex window types on multiple independent nodes while efficiently aggregating incoming data streams. Our evaluation shows that Disco's throughput scales linearly with the number of nodes and that Disco already outperforms a centralized solution in a two-node setup. Furthermore, Disco reduces the network cost significantly compared to the centralized approach. Disco's tree-like topology handles thousands of nodes per level and scales to support future data-intensive streaming applications.

1 INTRODUCTION

Modern business use-cases often require the analysis of high-volume data streams. To efficiently process such large amounts of data, stream processing engines (SPEs) provide complex windows and aggregations. But to perform these complex aggregations, state-of-the-art SPEs such as Apache Flink [2], Apache Spark Streaming [16], and Apache Storm [12] require the data to be collected in a single data center. Current research approaches to improve the performance of window aggregation, such as Scotty [13, 14], Cutty [3], and Pairs [7] also require data to be centrally available. However, efficiently analyzing an ever-increasing data volume requires streams to be processed on multiple nodes as the central collection of data quickly becomes a limiting factor in processing latency and network cost [17]. While SPEs require data to be available centrally, wireless sensor networks (WSN) perform aggregations on multiple nodes close to the data sources. WSNs drastically reduce the network costs by actively leveraging the distribution of incoming data streams. However, previous work on WSNs, such as TAG [10] or Cougar [15], provides only simple aggregation operations on basic window types.

To bridge the gap between complex central aggregation in SPEs and distributed basic aggregation in WSNs, we propose Disco, a distributed complex window aggregation approach. While SPEs processes incoming data in one central stream, Disco leverages the distribution of incoming data streams to perform distributed window creation and aggregations closer to the sources. We propose multiple strategies to efficiently merge distributed windows and their respective aggregates. With this approach, we benefit from both the reduced network cost of WSNs and the complex analysis of SPEs.

In this paper, we make the following contributions: 1.) We propose Disco, an approach for distributed complex window aggregation that does not require raw data collection on single nodes. 2.) We introduce window merging strategies to distribute the processing of common window types while maintaining correct aggregation semantics. 3.) We evaluate Disco and show that the throughput of our approach scales linearly with the number of nodes as well reduces the network cost drastically compared to state-of-the-art central window aggregation techniques.

The rest of the paper is structured as follows. In Section 2, we present the foundations of window aggregation that Disco is built upon. In Section 3, we present our distributed aggregation approach for arbitrary window types and aggregation functions. Before concluding, we present our evaluation of these distributed aggregation concepts implemented in our prototype in Section 4.

2 BACKGROUND

In this section, we present the background of distributed window aggregation. We first present the two window types on which we build, as well as two classes of aggregation functions. We then introduce stream slicing for efficient window aggregations.

Window Types. For this work, we distinguish between two types of windows, *context-free* and *context-aware* windows [9, 14]. In this case, context refers to the state that is required to calculate the start- and end-bounds of all the windows up to time t.

Context-free (CF) windows do not require any state and their bounds can be computed statically. For a time t, all window bounds can be computed without processing a single event. Examples of CF windows are tumbling and sliding windows [1, 9].

Context-aware (CA) windows require some kind of state to determine the window bounds, i.e., the windowing function needs to see either previous or future events to know when a window ends. An example of a CA window is a session window [1]. The windowing function needs to see future events after t in order to know that a session has terminated at t.

Aggregation Functions. For distributed aggregation, we distinguish between two classes of aggregation functions, *decomposable* and *holistic* (or *non-decomposable*) [4, 5]. Decomposable functions are aggregations for which the aggregation can be performed on subsets of the data and merged afterwards, e.g., $\texttt{sum}\{1, 2, 3, 4\} = \texttt{sum}\{1, 2\} + \texttt{sum}\{3, 4\}$. We call the aggregation values on subsets of the data *partial aggregates*. Other examples of decomposable functions are `avg`, `count`, and `max`.

Holistic functions are all functions that are not decomposable, i.e., they require all values to perform the correct aggregation. There is no partial aggregation state for these functions. Examples of holistic functions are `median` and `quantiles`.

Stream Slicing. In Disco, we apply general stream slicing [14] to efficiently aggregate windows. Stream slicing divides windows into non-overlapping slices. The slices then store either *i)* a running, partial aggregate or *ii)* the individual events, depending on the aggregation function. The final aggregation result is computed from the individual slices that fall in the window's range. For commutative, decomposable aggregations only partial aggregates are needed, leading to a large memory reduction [14].

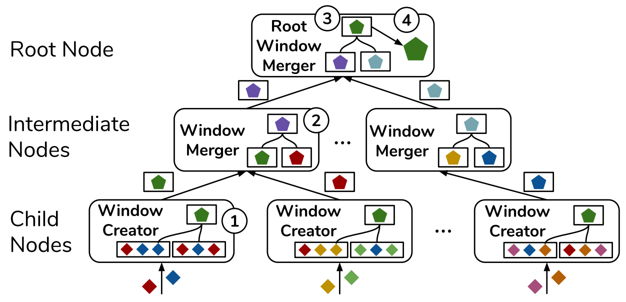

Figure 1: Disco's Architecture.

Each event belongs to exactly one slice, thus avoiding redundant storage and computation compared to other windowing techniques such as *Buckets* [9]. Also, slices represent logical event groups that can be transferred between nodes more efficiently than individual events. We refer to previous work [8, 14] for a detailed description of stream slicing and its advantages.

3 THE DISCO APPROACH

Efficiently aggregating windowed streaming data is a core task for modern SPEs. State-of-the-art window aggregation techniques require data to be available centrally on a single node. We introduce Disco, an approach for distributed window aggregation, which overcomes the central collection of raw events. Disco processes the incoming streams independently of each other and creates independent windows and aggregations on multiple nodes. These windowed aggregations are then merged to produce the final aggregation result. Disco's components communicate in a tree-like structure, in which leaf nodes (called *child nodes* in Disco) create independent windows and inner nodes (called *intermediate nodes*) merge them. This independence allows Disco to scale by adding new child nodes to process more events and by adding intermediate nodes to process more child nodes.

In the remainder of this section, we provide an architecture overview of Disco (Section 3.1) followed by a detailed description of Disco's window merging strategies (Section 3.2) and its distributed computation of aggregation functions (Section 3.3).

3.1 Architecture

We show Disco's architecture in Figure 1. Disco consists of three main components, the *root node*, the *intermediate nodes*, and the *child nodes*. These individual components communicate in a tree-like structure, where each node, except the root, communicates with exactly one parent node and each node can have many children, limited only by its network and processing power. Each event stream connects to one child node, which in turn receives the raw events. The *Window Creator* on each child node creates slices and windows according to user-specified queries ①. The child nodes then pass on partial aggregates for each window to their parent. On the intermediate nodes, a *Window Merger* then merges incoming windows according to the strategies presented in Section 3.2 ②. On the root node, the *Root Window Merger* finally merges all partial windows ③ and performs the final aggregation to retrieve the result for a given window ④. As the nodes process events and windows independently, there can be an arbitrary number of child nodes and intermediate levels, depending on the scale that the system requires.

Our implementation relies on the Scotty library[1] [14] for the window and slice creation step ①. Because Scotty requires data to be available centrally, we extend its windowing concepts to support distributed windows.

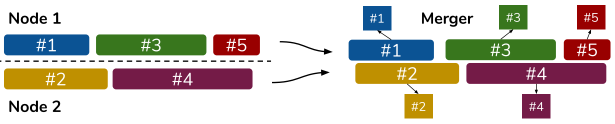

Figure 2: No merging for unique windows.

3.2 Distributed Window Merging

Depending on the window characteristics (i.e., type and measure), Disco selects the appropriate window creation and merging strategy. In particular, Disco differentiates between the two window types: *context-free* and *context-aware* (as described in Section 2). Disco processes incoming event streams and resulting windows independently on child nodes. In order to create the correct *global* window result over all streams, Disco merges the individual windows. To this end, Disco has to determine which partial windows belong to the same global window. We present three merging strategies for distributed window aggregation in Disco, *i)* unique window merging, *ii)* context-free merging, and *iii)* context-aware merging. For our explanation, we assume there are k independent child nodes producing windows and one *Root Window Merger* that merges the windows to produce a global result.

Window Merging Operations. In order to perform distributed aggregations, we use the three operations: *lift*, *combine*, and *lower* to model our aggregation functions [11]. *lift* converts a single input value x to an aggregation into a partial aggregate, e.g., $x = 5 \longrightarrow \langle \text{sum: } 5, \text{count: } 1\rangle$ for avg. *combine* merges two partial aggregates into a new partial aggregate, e.g., $\langle 5, 1\rangle \oplus \langle 7, 2\rangle \longrightarrow \langle 12, 3\rangle$. *lower* converts the partial aggregate to the final result, e.g., $\langle 12, 3\rangle \longrightarrow 12/3 = 4$.

To merge multiple windows, we extend the *slice-merge* operation [14] for windows. The *window-merge* operation $\uplus$ takes two windows w_1 and w_2 and creates a new window w with a merged aggregate state ($w.state = \texttt{combine}(w_1.state, w_2.state)$), as well as the according bounds ($w.start = min(w_1.start, w_2.start)) \land w.end = max(w_1.end, w_2.end)$).

Unique Window Merging. The first merging strategy that Disco uses is based on *unique* windows. A unique window is a window for which data is present in only one stream. With no matching data, there are no further windows to merge the unique window with. This strategy is applicable to queries where there are no overlapping keys on different nodes and the query is defined on individual keys only. We show this in Figure 2. A Window Merger that receives a unique window w, emits w unchanged and the Root Window Merger calls $\texttt{lower}(w.state)$ to retrieve the final aggregation result. For unique windows, we benefit from a distributed aggregation compared to central processing, as we do not need to transfer raw data to the root node and we distribute the aggregation cost across all child nodes. An example for a unique window is a smart home setting in which we calculate the average temperature per house.

Context-Free Window Merging. Disco determines to which global window a partial context-free window belongs by its start and end bounds. As the bounds are statically computed and require no context, they are identical on all nodes. Thus, equivalent partial windows have equal start and end bounds. We show this for a sliding window on two nodes in Figure 3. For each global window w with $w.start = x$ and $w.end = y$, we collect the k matching partial windows out of all windows W, $\{w_i \in W \mid w_i.start = x \land w_i.end = y\}$ and merge them into a

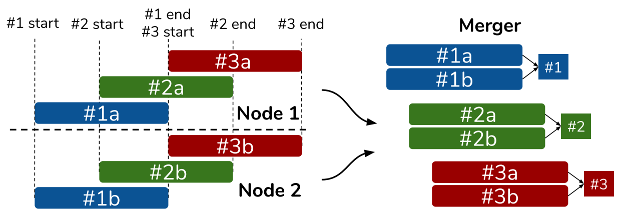

Figure 3: Merging distributed context-free windows.

new global result window $w = w_1 \uplus w_2 \uplus \ldots \uplus w_k$. The global result is then calculated by calling lower($w.state$) in the *Root Window Merger*. An example of a context-free window is a smart home setting in which we calculate the average temperature of all houses for the last hour.

Context-Aware Window Merging. Unlike context-free windows, the creation of context-aware windows cannot generally be distributed. As CA windows require some form of context, Disco cannot make assumptions about whether this context needs to be viewed centrally or can be viewed independently. If the window requires a global view of the context, we cannot create windows independently on multiple nodes. An example of such a global view is a count-based window, which uses a global event count to compute the window bounds.

However, certain CA windows, such as session windows, can benefit from a distributed aggregation. Session windows terminate if the event stream contains a period of inactivity (gap). In Disco, we define a period of inactivity across all distributed streams as a *global window gap*. A timestamp t is *active* in the set of all windows W if $\exists w \in W \;:\; w.start < t \land w.end > t$. A timestamp t is thus *inactive* if it is not active, i.e., there are no windows spanning across t. A period of inactivity is bound by two timestamps t_{start} and t_{end} between which there are no active timestamps. Disco leverages this knowledge to merge session windows in a distributed manner. Session windows are created independently on child nodes and the *Window Merger* then checks if there is an overlap between received windows. If an incoming window w_{in} overlaps with an existing window w_{ex}, it is merged to produce a new window $w_{new} = w_{ex} \cup w_{in}$ in their place. Two windows overlap if, and only if $w_{old}.start \leq w_{new}.end + gap \land w_{new}.start \leq w_{old}.end + gap$. For session windows, an overlap between two windows needs to take the session gap into account as events within the gap would cause the session to continue in a global stream. An arriving window can merge multiple windows, e.g., if it is a very long window or it closes the gap between two currently non-overlapping windows. We show this in Figure 4, where window #1b combines the windows #1a and #1c because it overlaps with both of them. An example for a context-aware window is a smart home setting in which we calculate the average temperature of certain houses as long as they are actively heating.

3.3 Distributed Window Aggregation

While the window type generally decides whether a window is computed centrally or distributed, the class of aggregation function determines which data needs to be transferred between nodes. For decomposable functions (e.g., `sum`, `avg`, `count`), Disco transfers partial aggregate values. The partial aggregates are then merged by the window merger.

As holistic functions require all data for a correct aggregation, Disco needs to transfer all events to the root. However, Disco does not send individual events but *slices*. For holistic functions, the slices contain the raw events and Disco uses these slices to send logical event groups between nodes. As each slice is immutable and uniquely identifiable, Disco sends it only once, regardless of how many windows it appears in. As all holistic functions require central processing, the root node is the only node that needs to store slices to performs aggregations on the events. Intermediate nodes do not process the data in the slices and thus, do not need to store the slices. Intermediate nodes only keep track of which slices they have sent to avoid duplicate transmission.

In summary, local and context-free windows can generally be distributed, while context-aware windows require certain data characteristics for distribution. If a window or aggregation function requires a global ordering of events (e.g., count-based windows), Disco cannot distribute the window creation across multiple nodes but requires central processing. For holistic aggregations, Disco transfers slices between nodes and for decomposable functions, it sends only partial aggregate values.

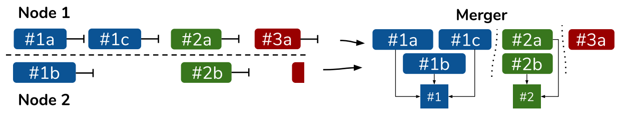

Figure 4: Merging distributed context-aware windows.

4 EVALUATION

In this section, we experimentally evaluate Disco's scalability (Section 4.1) and its network efficiency (Section 4.2). We choose `avg` and `median` as representative decomposable respectively holistic aggregation functions, as they show similar characteristics to other functions of the same group. We execute our experiments on a cluster consisting of 20 nodes. Each node has an AMD Opteron 6128 @ 2.0 GHz with 16 physical cores and 32 GB of RAM. All nodes are running Ubuntu 18.04.3 LTS, OpenJDK 12.0.2 64 bit, and are connected via Gigabit LAN. Furthermore, Disco and our experiments are available on GitHub[2].

4.1 Scalability

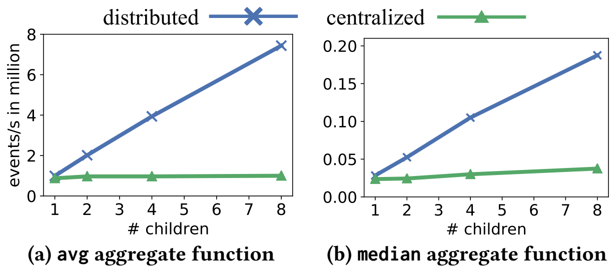
In this experiment, we compare the scalability of Disco's distributed window aggregations to a centralized implementation.

Workload. We evaluate the throughput of a one-second tumbling window query for a decomposable as well as a holistic aggregate function. We define throughput as sustainable if the system can handle incoming events without an ever-increasing backlog at the sender [6]. In the centralized implementation, the child nodes forward the raw events without processing.

Results. In Figure 5, we observe that Disco scales nearly linearly with the number of child nodes for both aggregation types. For decomposable aggregation functions (e.g., `avg` in Figure 5a), each child node can process around one million events per second. In the centralized approach, the root node becomes the bottleneck, as it processes all raw data centrally. As a consequence, it is limited by the single node performance (~1 million events/s). In contrast, Disco's root node receives only one partial window per second per child node instead of all raw events. Thus, Disco allows for linear scaling as the majority of the window aggregations is processed independently across all child nodes.

Furthermore, Disco provides scalability for holistic window aggregation functions (e.g., `median` in Figure 5b). Overall, the `median` aggregation performs significantly worse than the `avg` aggregation as it requires the centralized accumulation of all

[2]https://github.com/hpides/disco



(a) avg aggregate function (b) median aggregate function

Figure 5: Scalability of different aggregations in Disco.

events at the root node. As a consequence, the centralized approach is limited to a throughput of 0.025 million events/s. In contrast, Disco also performs window creation and merging of holistic states on multiple nodes in parallel. Thus, the root node only receives up to eight windows per second in this experiment. Consequently, Disco is able to scale nearly linearly for the holistic `median` function as the final `median` calculation on the root does not become a bottleneck for Disco.

Further scalability experiments show that the root node can process thousands of holistic and tens of thousands of decomposable windows per second before it becomes a bottleneck. Thus, Disco scales to support thousands of child nodes.

Summary. In this experiment, we showed that Disco scales linearly with the number of nodes for both decomposable as well as holistic aggregation functions. Even for functions that require central aggregation but can be windowed independently, Disco outperform centralized approaches significantly.

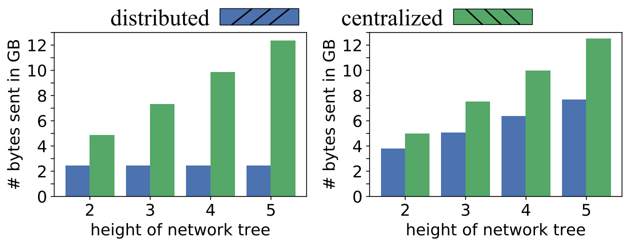
4.2 Network Cost

In this experiment, we evaluate the overall network costs of distributed and centralized aggregations.

Workload. We scale the height of the network topology to evaluate the network impact of the number of hops between child nodes and the root. We measure the total bytes sent for a one-second tumbling window query on 100 million events.

Results. Overall, we observe in Figure 6 that Disco has a significantly lower network footprint compared to a centralized approach. For decomposable distributed aggregations, the network consumption of the central approach scales linearly with the height of the network tree (see Figure 6a). In contrast, the network consumption of Disco stays nearly constant. Disco is independent of the height of the network topology, as all raw events are sent exactly once from a sensor to a child node. Beyond that, the intermediate nodes only exchange one partial aggregate and some window metadata per second. This causes an additional network traffic of only 1 MB per node level. As a consequence, a network height of five levels causes up to 6x less network traffic (2GB) compared to the centralized approach (12GB).

For holistic aggregations (see Figure 6b), Disco needs to send all raw events to the root node. Already for a tree of height two, we observe that Disco sends fifty percent more data than for decomposable aggregations. However, by sending events as groups of slices instead of individually, we avoid the additional TCP overhead of a purely centralized approach. While all single events are sent at each level for a centralized approach, slices become the smallest message unit in the distributed approach. In this scenario, we can save 50% per level compared to the centralized approach, which has a large effect once the tree becomes significantly deep. For five levels, we send only 7.5 GB of distributed slice data compared to 12.4 GB centralized single events.



(a) avg aggregate function (b) median aggregate function

Figure 6: Network cost for different aggregations in Disco.

Summary. Sending raw events is the dominant factor of the network cost. In Disco, we avoid sending individual events between nodes, which results in a high reduction of network traffic. For decomposable functions, Disco completely avoids sending individual events, which drastically reduces the network load. Even for holistic functions, we reduce TCP overhead by combining and sending events in slices.

5 CONCLUSION

In this paper, we present Disco, a distributed complex window aggregation approach. Disco combines the distributed data aggregation concepts from wireless sensor networks with the complex windowing and aggregation semantics from modern stream processing engines. This allows us to reduce network traffic while providing efficient aggregations on arbitrary windows. Our evaluation shows that Disco's throughput scales linearly and that Disco significantly reduces network costs compared to a centralized approach. With the ever increasing number of sensors in the IoT, Disco lays a foundation for efficient, application transparent, distributed stream processing.

ABSTRACT

We propose in this paper a novel approach for explaining query non-answers in Natural Language within the context of Natural Language Interfaces to Databases (NLIDBs). Such interfaces allow non-expert users to pose queries over an underlying database; our goal is to further allow users to ask why some results that they have expected to see, are missing from the output. In a nutshell, our approach is to "marry" NLIDBs with an existing model for explaining missing query results by pinpointing the last query operator that is "responsible" for the missing result. We observe that one can often trace the parts of the original NL question that correspond to these operators. This paves the way for intuitive explanations of the non-answers, that are based on highlighting the relevant parts of the question. Our architecture is generic and is not coupled with a specific NLIDB, and our solution yields clear explanations in interactive speed.

1 INTRODUCTION

Natural Language (NL) interfaces to database systems are often used as easy-to-understand gateways for accessing complex databases [1, 8, 13]. The rise of NL interfaces allows non-experts to access and query complex databases, without writing formal queries or understanding execution plans.

Yet often, the answers returned by such queries do not quite match the expectations of the users who formed them. Users are then faced with the problem of understanding the gap between their expectations and the result. Previous work has dealt with presenting the users the reason for the presence of a certain tuple in the result set in a manner that does not require technical proficiency [5, 6]. When users ask about a *missing* tuple, however, a different form of explanation is required. Explaining missing tuples, or non-answers, is termed why-not provenance and has been the focus of multiple previous works [2, 3, 10]. Such information is crucial for understanding the result, debug and improve the query and/or the input database. However, all of these works have provided this information in the form of *internal representation*, not suitable for non-experts.

Figure 1: MAS database instance

Example 1.1. Assume the NL question depicted in Figure 2a which was correctly translated by an NL interface to a formal query (shown as SQL in Figure 2b) and executed on the database instance depicted in Figure 1. The user is presented with a result set, but is surprised to see that Marge is missing. A why-not explanation for this missing tuple could be the predicate `pub.pyear > 2005` filtering Marge out, or a modified formal query without this predicate. However, understanding such explanations requires, at the very least, SQL knowledge.

In this paper, we aim to provide explanations for non-answers through natural language. The setting is unique in the sense that the query is given in NL and the user is not familiar with the technical details of the query execution, and the explanation should be tailored to bridge this knowledge gap. We rely on the frontier picky model [3] to provide explanations to non-expert users. Our main observation is that, if we use this model, when the original query was given in NL, we can in many cases trace back the responsible query operator to the part of the NL query that corresponds to it.

Example 1.2. For the NL query in Figure 2a, the SQL in Figure 2b, and the why-not query "why not Marge?". If we employ the mapping from the words in the NL query to the SQL one we can find that the words "after 2005" are connected to the operator `pub.pyear > 2005`, and reveal that these words in the NL query caused the removal of the result Marge.

To the best of our knowledge, presenting why-not provenance to non-experts was not previously studied. This form of explanations is fundamentally different from existing models that show SQL operators or other technical representations, as it allows users without technical knowledge to understand the gap between their expected result and the one they received. We claim that such explanations are of even greater importance in the context of NLIDBs, because of the cumulative errors that arise in such systems. In this setting, users have to specify their intent in a form of an NL sentence; a failure to specify certain conditions or a too specific sentence might result in tuple loss, simply because the user performed an error in the NL formulation. Since the user has no means of viewing or understanding the SQL query, this error may go unnoticed.

The solution is based on word highlighting in the original sentence form: we highlight the reason for the missing tuples, manifested as one or more words in the original NL query.

Example 1.3. In our running example, an operator-based why-not model would return the selection operator filtering tuples before 2005 as the explanation, i.e. `pub.pyear > 2005`. Using our system, the user will be shown her original NL query, with an emphasis on “after 2005" as the relevant words that caused this absence (see Figure 2c). This enables the user to better understand the query, validate the translation process and the credibility of the database, and reformulate her NL query accordingly.

We have implemented our solution and demonstrated it [7]. We now provide an experimental evaluation, showing multiple use-cases where the system provides useful explanations and showing that generating such explanations does not incur substantial time cost compared to the other steps in the computation.

Related Work: NLIDBs are aimed at bridging the gap between database systems that use formal query languages such as SQL for interaction, and users who are not experts in forming formal queries, yet posses domain knowledge [1, 8, 13, 16]. These interfaces allow users to form questions in English, and be presented with a set of results which satisfy the query. The whole process of converting the NL question to a formal SQL query can be treated by the users as a black box. Explaining query results that were returned in NL has been the focus of previous work [4].

There are multiple approaches and models for explaining why a certain piece of information that is expected to be returned from a query was actually discarded. We can broadly divide the approaches by their type.

(1) *Operator-based explanation* models (e.g. [2, 3]) aim to provide one or more query operators that are responsible for omitting a tuple in the query execution process.
(2) *Query modification* models (e.g. [9, 17]) try to broaden the given query to include the missing tuple. Depending on the model and the query, the change to the query may be as minor as replacing a constant, or even modifying the query completely by joining other tables etc.
(3) *Tuple modification / generation* models (e.g. [10, 11]) create or modify factoids in a way that will ensure that the required tuple will be returned from the query evaluation.

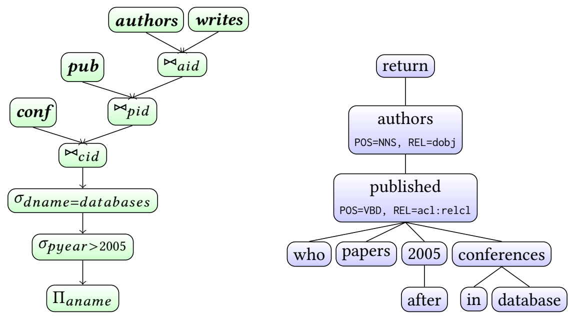
We focus here on explaining non-answers using the frontier picky model showing the “last” responsible operator [3]. To the best of our knowledge, no previous work in this field has dealt with the challenge of explaining missing tuples to non-expert users.

2 MODEL

In this section we review necessary notions in Natural Language Processing, formal queries and relevant provenance models.

From Natural Language to Formal Queries: This work relies on an NL interface named `NaLIR` [13] for translating English questions to SQL queries. The translation utilizes a data structure called *query dependency tree*, designed for conveying the relations between words in a sentence and their syntactic roles. A dependency tree $T = (V, E, L)$ is a node-labeled tree where labels consist of two components, as follows: (1) Part of Speech (*POS*): the syntactic role of the word [12] ; (2) Relationship (*REL*): the grammatical relationship between the word and its parent in the dependency tree [14].

After the translation phase, an SQL query Q is being generated along with a *query plan*. The query plan is a directed tree $T_Q = (V_Q, E_Q)$, where V_Q is the set of query operators in Q and the database table names which Q takes as input, and E_Q is a set of directed pairs (u, v). Table names form the leaves of T_Q and an edge (u, v) indicates that during the evaluation of Q over the database, all tuples outputted by the operator u are inputted to the operator v. Finally, the output implied by T_Q is the output of Q. Importantly, `NaLIR` maps the words in the NL query to their respective operators in the generated query plan. Reversing this mapping and augmenting it allows us to map why-not provenance back to NL.



(a) Query Plan **(b) NL query dependency tree**

Figure 3: Query plan and dependency tree

Definition 2.1. Given an NLIDB, a dependency tree $T_d = (V_d, E_d, L_d)$ and a query plan $T_Q = (V_Q, E_Q)$, a *operator-to-word mapping* is a partial function $M_{ops} : V_Q \rightarrow V_d$, where M_{ops} is the reverse of the mapping created by the NLIDB during the mapping from NL query to SQL.

Example 2.2. Consider the MAS database instance in Figure 1, and the NL query in Figure 2a. `NaLIR` parses this sentence to create the dependency tree shown in Figure 3b and returns the SQL query shown in Figure 2b; its query evaluation plan depicted in Figure 3a. The operator-to-word mapping, M_{ops}, includes the mappings: $M_{ops}[\sigma_{pyear>2005}]$ = “2005”, $M_{ops}[\sigma_{dname=databases}]$ = “*database*”, and $M_{ops}[\Pi_{aname}]$ = “*authors*”.

Why-not provenance: We start by defining a *why-not question WNQ*. Intuitively each hypothetical output tuple of Q that matches the criteria of WNQ is a tuple whose non-existence in the answer we wish to explain.

Definition 2.3. Given an database instance D and an SQL query Q, a why-not question WNQ is an SQL query such that (1) Q and WNQ have the same result schema, and (2) $Q(D) \cap WNQ(D) = \emptyset$.

The why-not question might be more complex than the initial query, as long as the query it represents has the same result schema. This allows the user to pose constraints on other attributes as well.

Example 2.4. Reconsider the database instance in Figure 1 and the SQL query in Figure 2b. Assume the user expects to see the author Marge in the result set, and surprised when she is not a part of the answer. The user may form a why-not question, “Why not Marge?", which would be translated by `NaLIR` to the query:

```
SELECT DISTINCT author.aname FROM author
WHERE author.aname = 'Marge'
```

The query is over the projected attribute of the original query (author names), and that the author Marge is returned by WNQ.

Some why-not provenance models allow users to define questions over attributes not in the result schema. We focus here on the subset of queries over the projected attributes, as we think that it is the most natural approach for posing why-not questions.

We will focus on *frontier picky* model [3]. This model for why-not provenance focuses on explaining non-answers using a single query operator. Intuitively, the last operator to contain in its input a tuple matching the why-not predicate. The motivation for explaining tuple loss with the frontier picky operator is that the answer is compact, easy-to-understand and provides a real value in the sense that it is necessary to modify the returned operator in order to include the tuple in the result list.

Definition 2.5 (adapted from [3]). Given a database D, a query Q with its query plan $T_Q = (V_Q, E_Q)$, a WNQ, and a tuple $t \in WNQ(D)$, a *picky operator* w.r.t. t is a node $v \in V_Q$ that gets t (or a predecessor of t in the evaluation process) through one of its incoming edges, as its input, and does not output it through its outgoing edge. An operator $v \in V_Q$ is *frontier picky* if:

(1) v is a picky operator for at least one tuple in $WNQ(D)$.
(2) There is no tuple $t \in WNQ(D)$ in the input of any operator $u \in V_Q$ such that u is a successor of v in T_Q.

According to this model, the answer to a why-not question is the frontier picky operator. Notice that the frontier picky operator might be different even if for the same query, evaluated with different query plans, as it depends on the structure of the query plan, i.e., the ordering of the operators in the plan.

Example 2.6. Consider the SQL query in Figure 2b and its query plan in Figure 3a, with the WNQ from Example 2.4. If Marge has not published papers after 2005, the operator node $\sigma_{pyear>2005}$ is picky w.r.t. the tuple that contains *Marge*. As all successors of this operator do not contain a tuple with $aname = Marge$, the node $\sigma_{pyear>2005}$ is the frontier picky operator w.r.t. this tuple.

3 HIGHLIGHT ALGORITHM

Our approach is composed of two stages: find the frontier picky operator for every removed tuple, and, given a why-not questions, find the relevant words that correspond to the frontier picky operator of the tuple in question.

Provenance-Aware Query Evaluation: As a first step, we evaluate the query while storing why-not provenance. We start by translating the NL query to a formal one, via NaLIR [13] augmented so that we keep track of which word in the original NL query has been mapped to which operator of the formal query, as done in [4]. The reverse of this mapping is stored in the data structure M_{ops}. Then, the query is evaluated. During evaluation, whenever a tuple is removed (due to a selection operator or as part of a filtering join), we update the mapping M_{filter}, which maintains the relation between the query operators and the tuples that were removed by them.

Example 3.1. Reconsider the NL query translated by NaLIR to the query in Figure 2b. First, we store the operator-to-word mapping between the query operators and their respective words in the original NL query, shown in Example 2.6. During evaluation, M_{filter} includes intermediate tuples such as (Marge, Paper x, 2001) and its respective picky operators $\sigma_{pyear>2005}$ (additional attributes, such as *pid*, are omitted for brevity).

Finding Relevant Words to Answer Why-Not: After viewing the evaluation results, the user now formulates a why-not query in NL. Algorithm 1 gets as input the results of the evaluation, i.e., the result, $Q(D)$, the mapping M_{filter}, the mapping M_{ops}, the why-not query formulated in NL Q_{WN}, the dependency tree of the NL query T_d, and the database D. Its output is the set of word indices that correspond to the reason for excluding the tuple of interest. Algorithm 1 operates as follows. It uses a sub-mechanism of NaLIR to convert the NL why-not query Q_{WN} into a formal why-not selection query WNQ (line 1). In lines 2–3 it checks whether WNQ is valid, i.e. if there are indeed no output tuples satisfying both the why-not query and the original query (this is a sort of sanity check). If this is not the case, it finds the frontier picky operator (line 4) for each of the tuples satisfying the formal why-not query in WNQ and returns the last of them which is the frontier picky operator w.r.t WNQ. We may get NULL as the operator in the case where there is no match to WNQ in the input; in this case we consider the last projection operation that took place to be the "reason" (lines 5–6). For instance, if someone asked about "why not Krusty?", who is not an author in the example database, the reason would be Π_{aname} which is mapped to the *author* table.

We then use the mapping outputted by the evaluation process to trace back the words corresponding to the operator. The *map*() function exploits the data structure M_{ops}, and gets as input variable names, values or table names that can be mapped back into words in the original query. Lines 13-18 are used to help link back the join operators which could not be directly mapped to words. The main idea is to exploit the typical scenario where unmapped joins are used as means for the query generation engine to link two other relations, which are directly referenced in the NL query. The algorithm traverses the ancestor and successor join operations of the given join operator (by repeatedly calling *GetJoinedRelations*()), until two operators, one ancestor and one successor of the join, which can be mapped into words $(left, right)$, are found. The returned indices are not of these two words, but rather of the words between $left$ and $right$ in T_d (by calling *GetPath*()), corresponding to the intuition that the answer to the why-not query is an unmapped operator between the two mapped operators.

Example 3.2. Consider the NL query in Figure 2a, its SQL query plan in Figure 3a, and the database in Figure 1. The author Bart exists in the *author* table, but has no published papers. Therefore, the frontier picky operator for the NL why-not query "why not Bart?" is the join operator $\bowtie_{aid}$ (see Figure 3a), connecting the *author* table with the *writes* table, which is a join table, containing author ids and publication ids. Algorithm 1 will first convert Q_{WN} to its SQL form and check that Bart is indeed not in the result set of Q in Figure 2b (lines 1–3). It will then get the frontier picky operator $\bowtie_{aid}$, depicted in Figure 3a, which took the tuple (4, *Bart*, 1) as input and did not output it (line 4). Since the output of this line is not NULL, it will continue to line 9. The *writes* table cannot be mapped into a word in the NL query in Figure 2a because the word *writes* does not even appear in it. The reason for the join operation being included is that NaLIR has used this table as a link between the authors table and the papers table. Lines 13-18 are then used to trace back the joined relations. Left and right would be "authors" and "papers" respectively, and the returned path would include only the word "published" as this is the word connecting "authors" and "papers" as seen in the dependency tree of the NL query in Figure 3b, thus our word highlight answer is "return authors who **published** papers in database conferences after 2005".

Algorithm 1: Highlight

```
    input  : $Q(D)$, $M_{filter}$, $M_{ops}$, $Q_{WN}$, $T_d$, and $D$
    output : Word highlight set
 1  $WNQ = NLToFormal(Q_{WN})$;
 2  if $Q(D) \cap WNQ(D) \neq \emptyset$ then
 3      return $\emptyset$;
 4  $op \leftarrow FrontierPicky(M_{filter}.find(WNQ(D)))$;
 5  if $op = NULL$ then
 6      $op \leftarrow GetProjectionOperator(M_{filter})$;
 7  if $op$ is $\sigma_{A=x}$ then
 8      return $map(A, M_{ops}) \cup map(x, M_{ops})$;
 9  if $op$ is $T \bowtie R$ where $R$ is a new input table then
10      if $map(R, M_{ops}) \neq \emptyset$ then
11          return $map(R, M_{ops})$;
12      else
13          $(left, right) \leftarrow GetJoinedRelations(R)$;
14          while $map(left, M_{ops}) = \emptyset$ do
15              $(left, \_) \leftarrow GetJoinedRelations(left)$;
16          while $map(right, M_{ops}) = \emptyset$ do
17              $(\_, right) \leftarrow GetJoinedRelations(right)$;
18          return $GetPath(left, right, T_d)$;
```

4 IMPLEMENTATION AND EXPERIMENTS

We describe various use cases and our scalability evaluation.
Use cases:

Table 1: Sample of Natural Language queries along with Why-Not questions and "Why-Not answers"

ID	NL Query With Highlight Explanation	Why-Not Question
	Selection Frontier Picky Operator	
1	Return authors who published in database conferences after **2015**	Catriel Beeri
2	Return authors who published in **database** conferences after 2015	Yishay Mansour
3	Return authors from **"Tel Aviv University"** who published in VLDB	Benny Kimelfeld
4	Return authors from "Tel Aviv University" who published in **VLDB**	Yishay Mansour
5	Return organizations of authors who wrote in **database** journals	AI University (org. without DB authors)
6	Return papers of authors in **"Artificial Intelligence"** after 2005 and before 2007	Active Views for Electronic Commerce
7	Return papers of authors in "Artificial Intelligence" after **2005** and before 2007	Stochastic Link and Group Detection
8	Return authors from **"North America"** who presented in VLDB in 2000	Tova Milo
9	Return authors from "North America" who presented in **VLDB** in 2000	Geoffrey E. Hinton
10	Return authors from "North America" who presented in VLDB in **2000**	Christopher Ré
11	Return publications about **graphics** after 2005	Overflow Controled SIMD Arithmetic
	Join Frontier Picky Operator	
12	Return organizations of **authors** who wrote in database journals	MadeUp College (org. without authors)
13	Return authors who **published** in database conferences	John Doe (author without publications)

Table 1 depicts representative examples of NL queries along with relevant why-not questions that were executed on the MAS database [15]. The first 11 examples demonstrate cases in which the reason for the tuple absence was a selection operator. Queries 12 and 13 demonstrate the operation of Algorithm 1 when the frontier picky operator is a join operation, this is often an indication of missing tuples in the dataset. Overall we can see that for the vast majority of NL queries and why-not questions the explanations supply valuable information that justify in concise manner the absence of the tuples in question.

Scalability: Here again we have used the MAS database whose total size is 4.7 GB, and queries 1–11 from Table 1, running the algorithm to generate word highlight and NL explanation. The computation steps execution times, for each query, are depicted in Figure 4. The computation times are given in nanoseconds and the y axis is log-scaled. As evident from the graph, most of the time is spent on NL to SQL conversion, query evaluation and identifying the relevant tuples for the why-not queries. Generating the why-not explanations incurs a negligible performance cost (less than a millisecond on average for selection frontier picky operators), and thus provides an interactive experience for the user.

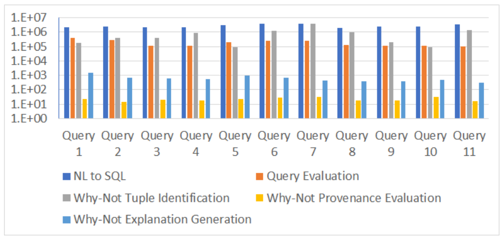


Figure 4: Average computation time by step (log scale, values in nanoseconds)

ABSTRACT

In recent years, the amount of available data keeps growing at fast rate, and it is therefore crucial to be able to process them in an efficient way. The level of parallelism in tools such as Hadoop or Spark is determined, among other things, by the partitioning applied to the dataset. A common method is to split the data into chunks considering the number of bytes. While this approach may work well for text-based batch processing, there are a number of cases where the dataset contains structured information, such as the time or the spatial coordinates, and one may be interested in exploiting such a structure to improve the partitioning. This could have an impact on the processing time and increase the overall resource usage efficiency.

This paper explores an approach based on the notion of context, such as temporal or spatial information, for partitioning the data. We design a context-based multi-dimensional partitioning technique that divides an $n-$dimensional space into splits by considering the distribution of the each contextual dimension in the dataset. We tested our approach on a dataset from a touristic scenario, and our experiments show that we are able to improve the efficiency of the resource usage.

KEYWORDS

Big Data, Partitioning, Contextual dimensions

1 INTRODUCTION

A dataset analyzed using parallel data processing systems, such as Hadoop or Spark, is usually divided into chunks, or *splits*. The basic partitioning approach uses the amount of bytes (e.g., 64 or 128 MB) as splitting technique, without considering the content of the data. In case of batch processing, where the dataset is always analyzed entirely, this solution is reasonable. Nevertheless, if the dataset is analyzed using selective queries based on some attributes of the data, like time intervals or spatial regions [6, 11], such an approach may not be efficient, since the partitioning does not exploit the correlations in the data.

Consider for instance a dataset that collects the visits of tourists at different Points of Interests (PoIs). The tourists have a city pass which they swipe at the entrance of a PoI. Each swipe contains the identifier of the city pass, the name and location (coordinates) of the visited PoI, together with an entrance timestamp. One may analyze such a dataset considering the timestamp (How many tourists have been there in a specific day?), or the space (How many times has a specific PoI been visited?), or PoI type (Are modern-art museums preferred to science museums?). One may also combine different dimensions (How many tourists visited a specific PoI in a specific hour?).

As a general approach, we consider *context-aware* partitioning techniques. Assuming that a dataset can be analyzed w.r.t. several dimensions, the idea is to group in the same split records that are context-related [7]. For instance, if the context is defined by the space and time dimensions, a context-aware partitioning will include in the same split records that are nearby to each other from both a spatial and temporal point of view.

Previous works proposed partitioning approaches mainly based on spatial [9, 12] and spatio-temporal [1, 2] characteristics. In case of spatial partitioning, one may partition based on space (grid and Quad-tree), based on data (STR, STR+, K-d tree), or based on space filling curves (Z-curve, Hilbert curve) [8]. The selection of the partitioning technique is usually left to the user, and only few works automatically select the best partitioning technique based on the dataset distribution [5].

When two or more dimensions need to be combined, there are two possible approaches. The first one considers each dimension independently and builds a *multi-level partitioning*. This approach produces a list of n grids (one for each level) that are used for performing the partitioning, and it imposes an order between them. The chosen order can have a great impact on the nature and balancing of the resulting splits. For instance, ST-Hadoop [1] firstly divide the dataset based on temporal granularity, and then splits each portion based on spatial proximity. A query focused on spatial properties (e.g., Has PoI x been visited more than PoI y?) requires the analysis of all, temporally organized, splits.

The second approach considers all the dimensions together and builds a *multi-dimensional partition*, i.e., a n-dimensional grid. An example is HadoopTrajectory [2], in which partitions are 3D cubes where the three dimensions are space (planar coordinates) and time. Given a query focused on one dimension, this approach allows the exact selection of the splits that could be useful in answering the query. The challenge imposed by the multi-dimensional partitioning is to find the best size of the grid cells in each dimension, so that the amount of data in each cell is balanced. This can be a non trivial task, especially in the general case where data are not uniformly distributed [3, 5].

In this paper, we consider a context-based multi-dimensional partitioning approach, which takes as input a dataset D and the set of n contextual dimensions relevant to analyse D. We design a solution that automatically produces the most appropriate division of the $n-$dimensional space, considering the distribution of each contextual dimension inside D. The proposed technique could be adopted in case of recurrent queries, to drive the partitioning of the dataset that is stored permanently (e.g., HDFS), or it can be used in a dynamic scenario, where the dataset is kept in-memory (e.g., Spark), and it can be repartitioned based on the current set of queries.

We evaluate our solution on a real-world dataset containing the swipes of a city pass – with the characteristics previously described. The results show that we are able exploit the partitioning to efficiently process a set of representative queries.

2 PROBLEM FORMULATION

This section formalizes the context-aware partitioning problem.

Definition 2.1 (Dataset). A *dataset schema* $S = \langle a_1, \ldots, a_m \rangle$ is a list of attributes, each one belonging to a particular domain, denoted as $\Delta(a_i)$. A *dataset* $D = \{r_1, \ldots, r_n\}$ over a schema S is a collections of records $r_i = \langle v_1, \ldots, v_m \rangle$, where $\forall i \in \{1, \ldots, m\}\ v_i \in \Delta(a_i)$.

Definition 2.2 (Context). Given a dataset D over a schema $S = \langle a_1, \ldots, a_m \rangle$, the context is a subset of the attributes in S:

$$C = \{c_1, \ldots, c_k\} \subseteq \{a_1, \ldots, a_m\} \tag{1}$$

Definition 2.3 (Partitioning). Given a dataset $D = \{r_1, \ldots, r_n\}$, a partitioning P is a collection of subsets of D:

$$P = \{p_1, \ldots, p_h\} \text{ such that } \forall p_i \in P\,(p_i \subseteq D) \text{ and } D = \cup_i p_i \tag{2}$$

Definition 2.4 (Balanced partitioning). A partitioning $P = \{p_1, \ldots, p_h\}$ for a dataset D is said to be balanced if and only if:

$$\forall p_i, p_j \in P : \; abs(|p_i| - |p_j|) \leq \varepsilon \tag{3}$$

where $|p_i|$ denotes the cardinality of the partition p_i.

Definition 2.5 (Context-aware partitioning). A partitioning P_C for a dataset D is the minimal one for the context C and a context-based query q if and only if:

(1) it is a balanced partitioning, i.e. it is able to produce balanced partitions,
(2) it minimizes the number of splits to consider for answering the query q. Notice that a partition might contain also more than one split.

3 CONTEXT-BASED PARTITIONING

In order to partition a dataset D considering a context C with several dimensions of analysis, different approaches can be applied. For instance, in the multi-dimensional partitioning the subdivision of the elements in D is performed by defining an n-dimensional grid where $n = |C|$. Conversely, a multi-level partitioning could also be applied by using n grids, each one representing a level and corresponding to a dimension in C.

Notice that given a dataset D, a context C and a query q, it is possible to have multiple minimal partitionings. Indeed, the quality of the resulting set of partitions can highly depend on the distribution in D of the values of the dimensions belonging to C and those used in q. When our partitioning technique is not applied on-line before executing each query q, the minimality of a partitioning can be evaluated by considering the average number of splits used for a reference set of context-based queries.

Given a context C for a dataset D, the identification of the most appropriate partitioning requires an easy and efficient way for evaluating the skewness in D of each context dimension. Based on this evaluation, the right shape of each n-dimensional cell inside the n-dimensional grid can be determined.

The aim of this paper is to propose a partitioning technique able to capture the distribution of the dataset w.r.t. each context dimension and based on this to build the right set of partitions even for skewed datasets. For this purpose, we extend the idea originally proposed in [5] for the spatial domain to the management of a generic number n of context dimensions. For this reason, we present below the definition of the box-counting function $BC_r^q(D, a)$ for a given dataset D and a context dimension a, that is the fundamental notion for the skewness evaluation.

Definition 3.1 (Box-counting function for a dimension a). Given a dataset D, containing an attribute a belonging to a domain $\Delta(a)$, and a scale r representing the cell size of a mono-dimensional grid covering the range of values of $\Delta(a)$ appearing in D, the box-counting function $BC_r^q(D, a)$ is defined as:

$$BC_r^q(D, a) = \sum_i \delta_i(D, a)^q \quad \text{with } q \neq 1 \tag{4}$$

where $\delta_i(D, a)$ is the number of records in D whose value for a is contained in the cell i. The case $q = 1$ is excluded, since it does not depend on r and it equals the number of records in D. □

Intuitively, given a grid with cells of side r, the box-counting function with $q = 0$ counts the number of cells that contains at least one record of D. When q is greater than 1, the box-counting becomes the sum of the number of records that a cell contains, raised to q. This function can be used to detect the skewness of a dataset by computing it for $q = 0$ and $q = 2$, while varying the value of r. More specifically, the level of skewness of a dataset depends on how this value changes while increasing r.

Definition 3.2 (Box-counting plot). Given a dataset D, containing an attribute a belonging to a domain $\Delta(a)$, the box-counting plot is the plot of $BC_r^q(D, a)$ versus r in logarithmic scale.

On datasets representing fractals, since it can be derived from theory, and on real datasets, as shown in [5, 10], the following observation can be considered valid.

Observation 1. *For finite datasets representing fractals and real datasets the box counting plot reveals a trend of the box counting function that, in a large interval of scale values r, behaves as power law:*

$$BC_r^q(D, a) = \alpha \cdot r^{E_q} \tag{5}$$

where α is a constant of proportionality and E_q is a fixed exponent that characterizes the power law.

The power law exponent E_q for a given dataset D and an attribute a can be computed by starting from the box-counting plot, since it becomes the slope of the strait line that approximates $BC_r^q(D, a)$ in a range of scale (r_1, r_2), thus it can be computed by a linear regression procedure.

We can observe that E_0 and E_2 could be chosen as reference descriptors about the distribution of the values of the attribute a in the dataset D. Indeed, E_0 can be an indicator of the cases where the dataset leaves empty some areas of the range of values of a covered by D, while E_2 can also be affected by the concentration of the values in some areas with respect to other ones, i.e. the situations where there are no empty areas, but different data concentrations in different areas.

In order to optimize the computation of E_0 and E_2 for a big dataset D_{big} the following approach can be applied. First, we consider a sample of D_{big} (usually 10% of the records) for the computation of the n-dimensional histogram: it is composed of a n-dimensional cube counting the number of records falling in each cell (only the non-empty cells are represented). Second, the projection of the n-dimensional cube on each dimension produces n one-dimensional histograms to be used for the computation of E_0 and E_2 for each dimension. Third, considering the heuristics presented in [5], accordingly to E_0 and E_2 the suitable partitioning technique for each dimension is chosen (possible techniques are: regular grid, space-based partitioning, record-based partitioning). Finally, D_{big} is scanned and partitioned using the n-cube produced by intersecting the list of splitting planes obtained by applying the chosen techniques. Notice that for each dimension a different technique might have been chosen.

4 CASE STUDY EVALUATION

The proposed technique has been applied to a real-world dataset containing the swipes of a city pass, called *VeronaCard*, which is provided by the tourist office of Verona, a municipality in Northern Italy. The dataset contains about 1,200,000 records concerning 4 years. Each record reports beside to the identifier of the city pass and the name of the visited PoI: the location (coordinates) of the PoI, the entrance timestamp and the age of the tourist holding the card.

Fig. 1 shows the spatial distribution of the records: the size of the circle surrounding the PoI name represents the number of records regarding that location: bigger cycles represent PoIs with the higher number of visits. As you can notice, the records are not uniformely distributed w.r.t. space, since there are some PoIs, such as *Arena* and *Casa di Giulietta*, which have much more visits w.r.t. others, like *San Fermo*.

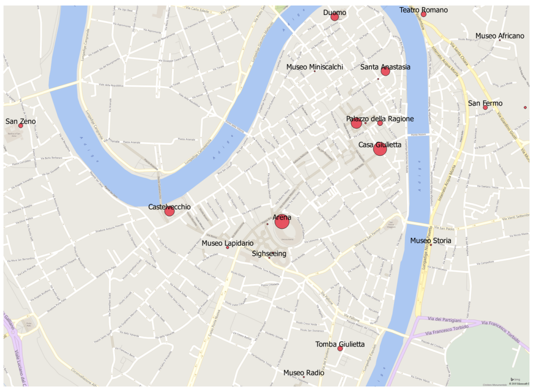

Figure 1: Spatial distribution of the swipes: bigger circlers represent an higher number of visits in that PoI (records).

A sample about the distribution of the records w.r.t. the time is represented in Fig. 2 by means of histograms. In particular, we show the distribution of three PoIs aggregated by the day of the week. Even in this case the distribution is not uniform, since there are some days in which a PoI is mostly visited than others (es. weekend days vs week days). Moreover, some PoI can have a closing day in which there are no visits at all.

Finally, the age distribution is reported in Fig. 3 by means of a Pie chart. Even in this case the distribution is not uniform: some ages more frequent than others, reflecting the fact that there are PoIs more suitable for some kinds of tourists than others.

These different distributions are recognized also by the exponents E_0 and E_2 of their box counting plot, as reported in Tab. 1 together with the chosen partitioning technique.

Tab. 2 illustrates some statistics about the partitions produced by the four considered partitioning techniques: *Rand* is the default partitioning technique traditionally supported by a MapReduce environment, it simply subdivides the dataset into parts with homogeneous size in bytes. MD_{grid} is a multi-dimensional uniform grid partitioning technique which essentially subdivides the dataset by using uniform d-dimensional cells for data aggregation, while ML_{grid} is a multi-level uniform grid partitioning

Figure 2: Number of swipes for 3 PoIs by day of the week.

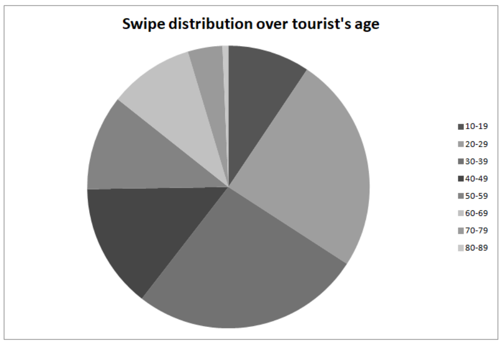

Figure 3: Number of swipes for each age value.

Table 1: Exponents E_0 and E_2 and technique choice.

Context attribute	$-E_0$	E_2	Index
time	1.041	0.963	Regular Grid
x	0.041	0.001	Space-based partitioning
y	0.054	0.154	Space-based partitioning
age	0.506	0.474	Record-based partitioning

which considers only a dimension at each phase during the uniform subdivision. Finally, *CBP* is the context-based partitioning technique proposed in this paper which uses the computation of the box counting plot and the corresponding exponents E_0 and E_2, in order to produce the most appropriate d-dimensional grid in order to accomodate also non uniform data.

Table 2: Experimental results: RAND is the random partitioning, %RSD is the relative standard deviation with respect to the dimension analysis.

Index	#parts	#splits	%RSD	%RSD	%RSD	%RSD	%RSD
			#size	time	x	y	age
Rand	69	69	1%	57%	33%	35%	58%
MD_{grid}	64	109	64%	25%	4%	17%	24%
ML_{grid}	73	117	71%	26%	4%	14%	23%
CBP	88	88	26%	20%	2%	3%	19%

The first consideration we can done is that while *Rand* is able to produce the minimum number of splits with respect to the dataset dimension and the split size (#parts = #splits), the other techniques can produce a greater number of splits which is equal to: $\lceil \sqrt[d]{ds/sp} \rceil$ where d is the number of dimensions, ds is the dataset size in bytes and sp is the split size in bytes. Notice that since the dataset is not uniformly distributed: (1) some cells could be empty, so they are not produced (i.e., MD_{grid} has 64 partitions and ML_{grid} has 73 partitions). (2) Some cells could be overpopulated, so they have to be split in order to comply with the split size prescription, i.e., at the and MD_{grid} has 109 splits, while ML_{grid} has 117 splits. Conversely, *Rand* and *CBP* has a number of splits equal to the number computed of partitions. *CBP* produces more partitions than *Rand* due to the additional subdivision of the n-dimensional space in case of clustered data.

The non uniformity of the dataset distribution has a direct effect also on the split size variability. In order to evaluate the variability of a given feature, we use the %RSD, which is the relative standard deviation, namely it is a statistical measurement describing the spread of data with respect to the mean and the result is expressed as a percentage. Clearly, the *Rand* technique is able to produce very balanced splits, since the partitioning is guided only by this parameter. Conversely, MD_{grid} and ML_{grid} produce very unbalanced splits due to the data skeweness. With *CBP*, we obtain quite good results in terms of balancing.

The second aspect to consider is the variability of each dimension values inside the splits. Columns 5-8 in Tab. 2 reports the average %RSD for each considered dimension. As you can notice, all the last three techniques generally improve the performances of the *Rand* technique. In particular, as regards to the temporal dimension, since it is quite uniformly distributed and also it is the first considered dimension by the ML_{grid}, its average spread is the same for MD_{grid} and ML_{grid}, while for the other dimensions the spread is less for MD_{grid} since it considers all dimensions at the same level for producing the partitioning. *CBP* produces splits with less variability in each dimension w.r.t. all the other techniques.

Given the partitions induced by the four considered partitioning techniques, we have performed some representative range queries in order to evaluate their performances. The performances are evaluated as the number of splits that have to be processed in order to produce the desired result, namely in the filtering capabilities induced by each partitioning technique.

We consider 4 queries, the first one has a condition on all the context dimensions, while the other ones contain conditions on less dimensions. The results are reported in Tab. 3.

Q_1: *find all visits performed around the Arena during spring 2015 by young tourists.* The spatial location is defined by a buffer around the Arena, while the period *spring 2015* is defined by a temporal interval, and the *young tourists* are identified by an age range. Since the condition regards all the four dimensions, the performance of MD_{grid} and ML_{grid} are quite similar.

Q_2: *find all visits performed by teenager in 2016 everywhere in Verona.* In this case the spatial dimensions are not considered in the filter, while a pruning is performed on the temporal dimension. Since this represents the first level for ML_{grid}, it sightly outperforms MD_{grid}.

Q_3: *find all visits around Arena performed by senior tourists.* In this case the temporal dimension is not considered, while the spatial and age dimensions are considered. Differently to the previous case, the advantage of ML_{grid} is loss, since no filtering can be performed at the first level.

Q_4: *find all the visits performed by adult tourists.* As you can notice here the filter is applied only on the 4th dimension, so

Table 3: Experimental results. Numbers represents #splits.

Query	*Rand*	MD_{grid}	ML_{grid}	*CBP*
Q1	69	3	3	2
Q2	69	32	30	14
Q3	69	6	6	5
Q4	69	85	94	80

ML_{grid} performs worst than MD_{grid}, because it has to scan all the levels before applying a filter.

5 CONCLUSION

In MapReduce frameworks the partitioning of a dataset into independent splits is a critical operation, since the degree of parallelism and the overall performances directly depend from the initial partitioning technique. This is particularly true in case of context-based applications, where data present correlations and consequently data could be aggregated and filtered in order to reduce the amount of work to be done during the analysis. Moreover, beside the need for a context-based partitioning technique, in order to produce balanced splits, it is necessary to consider the distribution of the dataset w.r.t. the analysis dimensions. This paper proposes a context-based partitioning technique which takes care of the dimension distributions to produce the best partitioning for the dataset at hand. We also apply it to a real-world dataset and compare its performances w.r.t. existing partitioning techniques for highlighting its differences and benefits. The obtained preliminary results confirm the goodness of the approach and encourage further research in this direction, for instance as regards to the managament of multi-accuracy data [4].

ABSTRACT

Aggregate window computations lie at the core of online analytics in both academic and industrial applications. To efficiently compute sliding windows, the state-of-the-art algorithms utilize incremental processing that avoids the recomputation of window results from scratch. In this paper, we propose a novel algorithm, called SlideSide, that extends `TwoStacks` for multiple concurrent aggregate queries over the same data stream. Our approach uses different yet similar processing schemes for invertible and non-invertible functions and exhibits up to 2× better throughput compared to the state-of-the-art incremental techniques in a multi-query environment.

1 INTRODUCTION

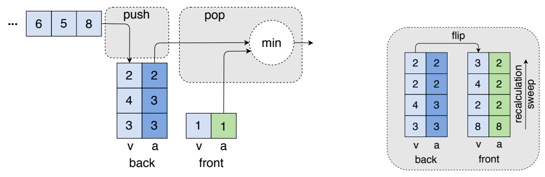
An ever-growing amount of data needs to be analyzed in real-time. Applications ranging from credit card fraud detection to clickstream analytics are not supported by "classic" relational systems and algorithms. Consequently, streaming applications have become increasingly important. One of the key operators in stream processing is window aggregation [1], i.e., the calculation of running aggregates over the continuous data stream.

Since data streams are conceptually infinite, they are partitioned into finite subsets of elements, called *windows.* A window has a *definition*, which maps each input tuple to a window *instance.* Upon aggregation, each window instance yields a result. Windows can be distinguished by whether their instances are disjoint ("tumbling windows") or not ("sliding windows"). Tumbling (a.k.a. fixed) windows slice up the input stream into segments with a fixed size temporal length (static *window size*). Sliding (a.k.a. hopping) windows generalize tumbling windows by specifying a *slide* parameter in addition to the size that specifies the distance between the start of two windows.

While tumbling windows are amenable to classic "relational" queries implementation techniques, the performance of sliding windows is more challenging to compute efficiently. Incremental algorithms introduce inherent control dependencies in the CPU instruction stream, as intermediate results from previous window instances have to be used to compute efficiently the next result. This is amplified in the case of multiple-queries applying computations over the same data stream, which has not been explored comprehensively. An example of the latter scenario is a live-visualization dashboard that plots line charts of aggregates on time-series data at different zoom levels [9].

Our contributions are the following:

- We study the performance of the best-performing incremental algorithms, as reported in recent literature [4, 6]. We determine sections of the problem space in which different approaches perform best (focusing specifically on multi-query processing).



(a) Pushing and Popping (b) Flipping

Figure 1: The TwoStacks algorithm

- We propose a novel approach for incremental processing in multi-queries scenarios, called SlideSide. Our solution extends the logic of `TwoStacks` [4] based on the insight that the algorithm maintains a running `preffix-`/`suffix-scan` over the input stream. SlideSide optimizes its performance for associative aggregation functions and can serve as a drop-in replacement for the aggregation operator in a streaming system.
- Finally, we demonstrate that SlideSide is competitive with highly optimized single-query algorithms, while it yields up to 2× better throughput and comparable latency in the multi-query scenario.

The remainder of the paper is organized as follows: in Section 2 we survey the state-of-the-art in incremental window computation. Section 3 introduces our novel incremental algorithm. The paper finishes with evaluation results (Section 4), and conclusions (Section 5).

2 BACKGROUND

In this section, we provide background on the underlying concepts of incremental processing. We also review current approaches and provide in Table 1 a summary of their complexities.

Algebraic Properties. In this work, we focus on associative algebraic aggregations [3] and consider the following properties:

- Invertibility: $(x \oplus y) \ominus y = x, \forall x, y$. This property can be exploited by introducing the following function: `inverse(a: Agg, b: Agg): Agg`, which removes the oldest partial aggregate from the window result with an incremental operation.
- Commutativity: $x \oplus y = y \oplus x, \forall x, y$

Partial Aggregates are smaller units of computation that compose the aggregate functions. Partial aggregation allow us to buffer and apply inexpensive aggregation and trivially parallelize the computation (e.g., using SIMD instructions [8]), when there are no data dependencies. This idea is applied in the form of *window slicing* [9] over a stream of data, where a slice is defined as the largest sequence of tuples that offer no sharing potential.

Incremental Aggregation Techniques. After the computation of partial results, the final aggregation step has to be applied to generate the query results. For that, streaming systems utilize the incremental aggregation techniques we describe next and summarize in Table 1.

Subtract-on-Evict (SoE) [4] is the best-performing approach in the case of invertible functions, i.e., AGG_{sum}. With SoE, the result of the previous window instance is re-used to compute the next

Algorithm		Time				Space	
		Single Query		Multi-Queries		Single-Query	Multi-Queries
		Amort	Worst	Amort	Worst		
SoE [4]	Inv	2	2	q	q	n	qn
	Non-Inv	n	n	qn	qn	n	qn
FlatFAT [7]		$log(n)$	$log(n)$	$qlog(n)$	$qlog(n)$	$2n$	$2n$
TwoStacks [4]		3	n	q	qn	$2n$	$2qn$
SlickDeque [6]	Inv	2	2	$2q$	$2q$	n	$q+n$
	Non-Inv	<2	n	q	qn	2 to $2n$	2 to $2n$
SlideSide	Inv	3	n	q	q	3n	$3n$
	Non-Inv	3	n	q	qn	$2n$	$2n$

Table 1: Algorithmic Complexities (partial aggregates: n, queries: q)

in constant time, by removing the expired elements and merging in the new data. However, SoE cannot efficiently compute non-invertible functions (e.g., AGG_{min}), as the whole window needs to be rescanned in the worst-case scenario.

TwoStacks [4] can be used for non-invertible functions. Figure 1 illustrates an example of the TwoStacks algorithm, which maintains a *back* and a *front* stack to store the input values and the aggregates required to produce the window results. When a new input value v arrives, its aggregate is computed based on the value of the back stack's top element and it is **push**ed onto the back stack. For every **pop** operation, the top from the front stack is removed and a result is produced by aggregating its value with the top of the back stack. Whenever the front stack is empty, the algorithm **flip**s the back onto the front stack, reversing the order of the values and recalculating the aggregates. However, as this happens infrequently, it exhibits $O(1)$ amortized complexity.

Multi-Query Algorithms. The previous algorithms are not designed to efficiently share intermediate results between multiple window definitions over the same stream, in contrary to approaches such as FlatFAT [7] and SlickDeque [6]. FlatFAT uses a pointer-less binary tree structure to store the partials, which results in $O(logn)$ complexity for a single query. SlickDeque proposes a different solution for invertible and non-invertible functions. For invertible functions, SlickDeque generalises SoE to answer multiple queries, by maintaining multiple instances of the original algorithm with partials that share the same memory space. In the case of non-invertible functions, instead of using a queue implemented by two stacks, SlickDeque uses a deque structure for insertions/removals of aggregates and answering queries with $O(1)$ amortized complexity. The time and space complexities of the non-invertible functions (see Table 1) depend on the input, with the worst-case scenario being a stream that is ordered in the opposite way of the aggregate operator order (i.e., if AGG_{max} the input is ordered descendingly).

3 SLIDESIDE

Let us now, describe SlideSide, our novel algorithm for accelerating incremental aggregation in a multi-query environment. It aggressively reuses intermediate results with data structures that have a sequential memory layout. Fundamentally, SlideSide is an extension of the TwoStacks algorithm. However, it uses different processing schemes for invertible and non-invertible functions.

Regarding the algebraic properties of the aggregate functions, SlideSide has the same requirements as the state-of-the-art algorithms described in Section 2 (associative aggregate functions). SlideSide can be applied to FIFO windows (in-order data).

3.1 Invertible Aggregates

The simpler case are invertible combiners, such as AGG_{sum}. The natural approach of evaluating multiple simultaneous windows would be to run multiple loop-fused instances of SoE. However, we found that the TwoStacks algorithm can be extended to support this case as well, yielding a more cache efficient approach. Somewhat surprisingly, this can be implemented using only two stacks (illustrated in Figure 2). Like the single query case, the elements of the back and front stacks share the same memory space and their aggregates are kept separately. Next, we will explain the algorithm and provide an example with two queries.

Algorithm 1: SlideSide (Inv) Pseudocode

```
Input: A set of aggregate queries Q, a combiner operation ⊕, an inverse operation ⊖
Output: The results of the window queries in Q
1 windowSize = Q.getMaxWindowSize()
2 backStack [windowSize+1] = {neutralVal} // used for prefix-scan
3 frontStack [windowSize+1] = {neutralVal} // used for suffix-scan
4 elements [windowSize] = {neutralVal} // used for input stream
5 curPos = 0
6 foreach val: stream do
7     insert(backStack, frontStack, elements, curPos, windowSize, val)
8     emitResults(backStack, frontStack, curPos, windowSize, Q)
```

Algorithm 2: Algorithm for insert(...)

```
1 // compute the suffix-scan
2 if (curPos==0) then
3     for i=0,1,..., windowSize do
4         frontStack[i+1] = frontStack[i] ⊕ partials[windowSize-i-1]
5 elements[curPos] = val
6 backStack[curPos+1] = elements[curPos] ⊕ backStack[curPos]
7 curPos = (curPos+1) % windowSize // wrap around the circular buffer
```

During the initialization phase of Algorithm 1, the *back* stack (blue row), the *front* stack (green row) and a circular buffer of *elements* (light-blue row) are allocated with size equal to the largest window from a given set of queries, Q, and initialized with the neutral element of the aggregate function (lines 1-4). For every input value *val* from the stream, we call the *insert* function and then compute the results for every query in Q with *emitResults* in line 6-8.

Upon the arrival of a new element, using the *insert* function (Algorithm 2), its *val* is stored in the next available slot in the circular buffer, defined by the *curPos* variable in line 5. The back stack is used for maintaining the prefix-scan of the input with every insert (line 6). If we reach the end of the elements buffer, we wrap around to the beginning and compute a suffix-scan over the input (lines 2-4) before applying the new insertion. Note that, as in TwoStacks, the computation of the suffix-scan occurs infrequently and the algorithm has $O(1)$ amortized complexity.

Algorithm 3: Algorithm for emitResults(...)

```
1 foreach query q : Q do
2     curWindowSize = q.getSize();
3     hasWrapped = false;
4     endPtr = curPos;
5     if (endPtr == 0) then
6         endPtr = windowSize
7     startPtr = endPtr - curWindowSize;
8     if (startPtr < 0) then
9         hasWrapped = true // the window wraps around the circular buffer;
10        startPtr + = windowSize;
11    if (!hasWrapped && startPtr == 0) then
12        res = backStack[endPtr] // use the result from prefix-scan;
13    else if (hasWrapped) then
14        res = backStack[endPtr] ⊕ frontStack[windowSize - startPtr];
15    else
16        res = backStack[endPtr] ⊖ backStack[startPtr];
17    forward answer res to query q;
```

After the insertion, the *emitResults* function (Algorithm 3) is called for computing the results for each query with the set

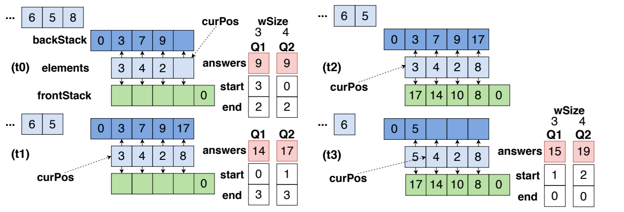


Figure 2: SlideSide (Inv)

Q. Based on the values of *curPos* and the window size of each query, this algorithm first computes the `start` and `end` pointers (lines 2-10) that are used for "bookkeeping". Next, we distinguish three different cases based on the value of these pointers: ***a)*** if the start pointer is 0, the result is already computed by the `prefix-scan` and returned in line 12; ***b)*** if the start pointer is greater than 0 and the end pointer does not wrap around the beginning of the elements buffer, the result value is computed by applying the *inverse* aggregate function on the values from the back stack in the positions of start and end pointers (line 16); ***c)*** if the end pointer has wrapped, the result is computed by combining `backStack[endPtr]` and `frontStack[winSize-startPtr]` in line 14.

In Figure 2, we present an example of SlideSide for two windows of size 3 ($Q1$) and 4 ($Q2$) and slide 1. The red boxes represent the result for the queries on each phase. The white boxes hold the values of the start and end pointers we discussed above. At our initial phase $t0$, the values 3, 4 and 2 have been already inserted in the *elements* buffer (from left to right) and their `prefix-scan` is computed in the back stack above (3, 7, 9). In the next phase $t1$, we have an insertion in the last slot of the *elements* buffer, which triggers the computation of the `prefix-scan` again for `backStack[4]` by combining the values 9 (previous result) and 8.

After the insertion, the algorithm is ready to emit results for both queries. For $Q2$, the result contains all the elements and the window starts from position 0 (case ***a)*** from above). Thus the result is already computed by the `prefix-scan` and can be obtained by accessing the value of `backStack[3]` which is 17. For $Q1$, the result contains only the latest three elements and the window points at positions 1 and 3 (case ***c)***). Thus, the result is computed by applying the *inverse* aggregate function on the elements from the back stack placed at that positions (17-3=14).

When we reach the end of the elements buffer ($t2$), we wrap around to the beginning and we compute a `suffix-scan` over the input using the front stack. In phase $t3$, we have the first eviction, where the latest input value 5 replaces value 3 and `backStack[1]` becomes equal to 5. Now, both query windows have wrapped (case ***b)***). This operation is going to return the `suffix-scan` of the remaining elements after evictions using the front stack and the current running aggregate from the back stack, which results in 15 and 19 respectively for queries $Q1$ and $Q2$.

3.2 Non-Invertible Aggregates

Processing multiple non-invertible functions can be performed with the Algorithm 1, but the `suffix-scans` have to be triggered more frequently. The algorithm is omitted to conserve space, but the logic is similar. The intuition behind this approach is that, while each of the queries maintains and operates on its own pair of stacks, these can be overlayed and start at the same memory address. In effect, the smallest stack is stored in the same memory region as the bottom part of the next larger, and so forth. To preserve correctness among the results, the computation of the `suffix-scan` is triggered every time the query with the smallest window size starts to evict.

In addition to the previous observations, we can apply optimizations proposed for single-query evaluation in Hammer-Slide [8], such as maintaining only the top value of the back stack. During the `suffix-scan` computation we can also stop propagating the changes from the current position until the end of the stack, if our computations do not alter the aggregate values, which reduces greatly the overhead of multiple flip phases and result in constant amortized complexity (see Table 1).

4 EVALUATION

In this section, we evaluate SlideSide for both invertible and non-invertible functions to show the benefits of our incremental strategy. To evaluate the efficiency of different aggregation algorithms, we run our experiments as a standalone prototype. We compare SlideSide to `SlickDeque` (for non-invertible functions we tradeoff performance with memory by using a fixed size deque), `TwoStacks` (using optimizations from [8]), `SoE` and `FlatFAT` when it's applicable (e.g., `SoE` is evaluated only for invertible functions). Each prototype maintains sliding windows with slide 1 by performing an eviction, an insertion and producing a result. We start our evaluation with the case we focus on: multi-queries and we demonstrate that SlideSide achieves higher performance. After that, we study the performance in the single query case, in which our solution exhibits only small performance loss.

4.1 Experimental setup and workloads

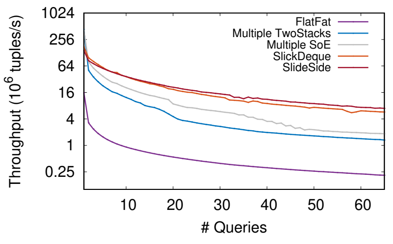
Hardware. All experiments are performed on a server with 2 Intel Xeon E5-2640 v3 2.60 GHz CPUs, a 20MB LLC cache and 64 GB of memory. We used Ubuntu 18.04 with 4.15.0-50-generic Linux kernel and compiled all experiments with clang++ version 9.0.0 and optimization level `-O3`.

Workload. Our workload emulates an anomaly detection scenario using the energy consumption trace from a smart electricity grid. This trace contains smart meter data from electrical devices in households [5] (32 bytes tuple size). We use two queries to perform analysis over the stream and detect outliers: SG_1, an aggregation that computes a sliding global AGG_{sum} and SG_2, which computes a sliding global AGG_{min} over the meter load.

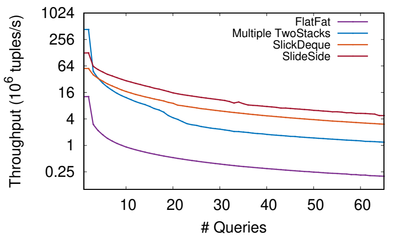
4.2 Multi-Query Evaluation

In the multi-query experiments, we generate queries of uniformly random window sizes (within the range [1, 32768] of tuples), while maintaining a constant window slide of 1 tuple for all of them. In this setup, we created workloads that contain from 1 up to 65 concurrent queries. `TwoStacks` and `SoE` can not be used to evaluate multiple queries, so we replicate their data-structures for every single window definition, as illustrated in Table 1.

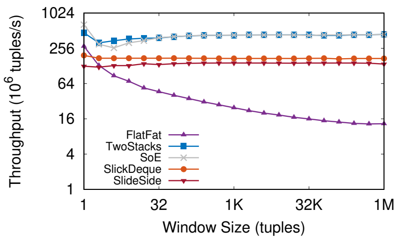
Invertible Functions. For invertible functions, we are computing query SG_1 over different window definitions. Figure 3a demonstrates that `SoE` is the fastest algorithm and outperforms the multi-query solutions by up to 2.5× for a single query. However, as the number of queries increases, the overhead of maintaining multiple data-structure replicates becomes noticeable. Thus, we observe that the multi-query algorithms perform nearly 4×. Comparing SlideSide with `SlickDeque` reveals a small performance benefit that reaches up to 40% with the increase of query concurrency. Our approach allows the compiler to generate more efficient code, because of the simpler CPU instruction stream, while providing more predictable memory access.



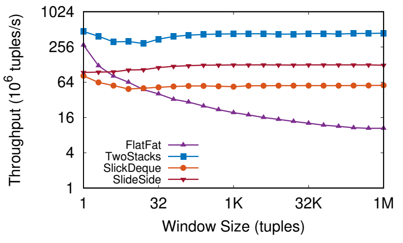
(a) Throughput of multi-queries (AGG$_{\mathrm{sum}}$)



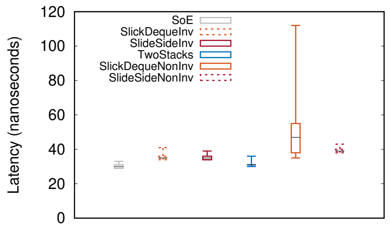
(b) Throughput of multi-queries (AGG$_{\mathrm{min}}$)



(c) Throughput of single-query (AGG$_{\mathrm{sum}}$)



(d) Throughput of single-query (AGG$_{\mathrm{min}}$)



(e) Latency in nanoseconds

Figure 3: Comparison of incremental techniques

Non-Invertible Functions. For the non-invertible functions we are computing the AGG$_{\mathrm{min}}$ over the generated windows. In Figure 3b, we observe that the multiple instances of TwoStacks outperform both SlideSide and SlickDeque for the first two and three workloads respectively. After that point, SlideSide is from 70% up to 2.2× faster compared to SlickDeque and more than 4× compared to the other two techniques. This illustrates that even though SlideSide requires more memory compared to SlickDeque, its CPU-cache-friendly data layout scales better with the number of queries in comparison to the deque data structure.

4.3 Performance Overhead for Single-Query

In this section, we present the efficiency of SlideSide for single-query workloads. We use queries SG$_{1\text{-}2}$ to measure throughput and latency of the aforementioned approaches.

Throughput. For this experiment, we use SG$_1$ and SG$_2$ over windows with window sizes that vary between 1 and 1048576 tuples. Figure 3c illustrates the throughput penalty introduced by our algorithm for invertible functions in a single query scenario. SlideSide exhibits throughput nearly 3× worse than SoE and TwoStacks. In Figure 3d, we observe that TwoStacks is the best-performing non-invertible algorithm for different window sizes (440 million tuples/sec). In contrary, SlideSide is 3× worse but exhibits better performance than SlickDeque, because of its underlying data structure with sequential memory layout.

Latency. To measure the latency of all the previous approaches, we use a fixed window size of 32K tuple and window slide of 1. In Figure 3e, we omit the latency of FlatFAT, as it consistently is an order of magnitude higher than the other algorithms. We show that SlideSide exhibits latency that is comparable to the best-performing solutions for both invertible and non-invertible functions (minimal overhead) and better compared to the other multi-query solution, SlickDeque.

Overall, we observe that for single query evaluation SlideSide ends up exhibiting nearly 3× worse performance in throughput and similar latency compared to the best-performing approaches. This is the result of the memory pressure from maintaining extra dependencies (not needed by a single-query) along with a more complex CPU instruction stream that hinders optimizations.

5 CONCLUSION

In this paper, we presented a novel algorithm for highly efficient evaluation of multiple aggregate queries by maintaining a prefix- and a suffix-scan over the input. Our algorithm can be used as a drop-in replacement for any associative aggregation operator in a commercial streaming system, such as Flink [2] (e.g., as an aggregate store for Scotty[9]). SlideSide outperforms the state-of-the-art algorithms in multi-query scenarios by up to 2× in throughput, while exhibiting better latency. However, our study reveals that current window aggregation techniques do not exhibit robust performance across different types of aggregation functions and concurrency levels. Thus, a streaming engine will either perform poorly for different points within this design space or have to maintain multiple algorithms with a cost model.

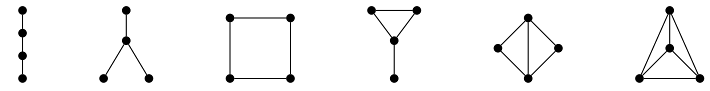

Figure 1: Four node graphlets: a 3-path, a 3-star, a rectangle or 4-cycle, a tailed-triangle, a diamond, and a 4-clique.

ABSTRACT

Graphlet enumeration is known to be a challenging task in graph analysis. This is because the cost is exponential in the order of the graphlet. Triangle is a graphlet of order three that has received special attention because it is relatively small but non-trivial, and can still be enumerated quite fast even for massive graphs of millions of nodes and edges. In this paper, we propose an efficient algorithm for enumerating four node graphlets, such as 4-cycles, 4-cliques, diamonds, etc by leveraging the most efficient algorithm for triangle enumeration. We show that despite the belief that any such enumeration algorithm cannot terminate in reasonable time, our method can handle large graphs containing trillions of such graphlets, using a single commodity machine, within a reasonable amount of time.

1 INTRODUCTION

It is commonly thought that graphlets, beyond three nodes, are difficult to enumerate. This is because the number of possible instances grows as $O(n^k)$, where k is the order of the graphlet and n is the order of the graph. Thus, for massive graphs, it was believed that an enumeration algorithm, which has to touch each graphlet, cannot terminate in a reasonable time [11]. Indeed, previous methods, such as Fanmod [18] and Rage [8], do not scale well and take a very long time to run on million scale graphs. Other proposed solutions, such as Arabesque [17] and PGD [1] use distributed platforms. However, our focus is to explore the limits of what can be achieved using single-machine algorithms.

There are several algorithms proposed in the literature to count the number of the graphlets. They are either estimates using approximation methods, such as Graft [13], or exact counting without full enumeration, notably Orca [6] and Escape [11]. However, what if we need to find each of the graphlet instances? Knowing where the graphlets are is useful in analysing the local structures of the graph. For example, enumerating graphlets is important in detecting cancer through differential graphlet communities [19]. Also, enumeration can yield graphlet degree counts which are useful for uncovering biological network functions [9].

It is worth noting that there have been plenty of studies on triangle enumeration. It was found that triangles can be enumerated quite efficiently using the compact forward edge-iterator algorithm [7]. In general, graphlets of order k can be enumerated using an algorithm with runtime $O(nd^{k-1})$ where d is the maximum degree [15]. However, in [14] it was shown that through careful preprocessing, triangle enumeration using edge-iterator can be significantly faster than $O(nd^2)$ time. Can we achieve a better runtime than $O(nd^{k-1})$, for higher order graphlets?

In this paper we show that efficient enumeration for triangles can be leveraged to enumerate higher order graphlets, in particular four node graphlets. Our algorithm achieves a significantly improved runtime, which depends on the number of three-node graphlets and is able to handle large graphs efficiently on a single machine. Moreover, unlike most in the literature, our solution yields the counts of *all* four node graphlets in a *single* run.

Our contributions are as follows:

(1) We propose a new algorithm to enumerate *all* types of four node graphlets of an undirected graph on a single run. Enumeration is done carefully so that no graphlet is listed more than once.
(2) We provide detailed analyses on the algorithm correctness and time complexity. We refine the time upper-bound of enumeration to depend on the number of three-node graphlets and thus be significantly better than $O(nd^3)$ for real-world networks.
(3) We create an efficient implementation of the algorithm for a single machine. Our algorithm is able to run on graphs of millions nodes and edges, which contain trillions of graphlets, within reasonable time.

2 RELATED WORK

Chiba and Nishizeki published several subgraph listing algorithms [5] which can be considered as a pioneering work on graphlet enumeration. Milo et al. [10] analysed frequent subgraph patterns, and called them network motifs. Since then, there have been many studies on how to find and count small subgraphs within a graph or network, including those we already discussed in the Introduction. Also, Silvestri [16] provided another complexity analysis on subgraph enumeration. To the best of our knowledge, there has not been a solution using the method that we propose here, to simultaneously, and fully, enumerate all the graphlets (of order four) through triangles and wedges, and that can scale to large graphs using a single machine.

3 PRELIMINARIES

In this paper we solely work on simple undirected graphs. We denote a graph by $G(V, E)$ where V is the set of nodes and E is the set of edges. Let $n = |V|$ and $m = |E|$. The degree of a node is the number of edges incident on it. For simple graphs, there is no self-loop and the degree is equal to the number of neighbours. We

Algorithm 1 Triangle Enumeration

```
Input: An undirected graph $G(V, E)$ in an adjacency list representation
1: for all vertex $u \in V(G)$ do
2:     for all vertex $v \in N(u)$ do
3:         if $v > u$ then
4:             for all $w \in N(u) \cap N(v)$ do
5:                 if $w > v$ then
6:                     EnumerateTriangle $(u, v, w)$
```

denote the set of neighbours of node u by $N(u)$, and the degree of u by $d(u) = |N(u)|$. A *subgraph* of $G(V(G), E(G))$ is a graph $H(V(H), E(H))$ such that $V(H) \subseteq V(G)$ and $E(H) \subseteq E(G)$. We use the notation $H \subseteq G$ to say that H is a subgraph of G. A subgraph $H \subseteq G$ is an *induced* subgraph if any edge (u, v) (which $= (v, u)$ for undirected graphs), with $u, v \in V(H)$, is in $E(H)$ if and only if (u, v) is in $E(G)$. A subgraph is *connected* if every pair of nodes in it is connected by a path of edges. We assume the following definition: A *graphlet* is an induced connected subgraph.

There are two kinds of graphlets of three nodes: wedge (Henceforth labeled as g_1) and triangle (g_2). Note that for induced subgraphs, wedges and triangles cannot be on top of each other (i.e., a wedge and a triangle cannot have the same set of three nodes within the same graph.). For four nodes, we have six types of graphlets, depicted in Figure 1. These are 3-path (or four-node-path) (g_3), 3-star (g_4), 4-cycle or rectangle (g_5), tailed-triangle (g_6), diamond (g_7), and 4-clique (g_8). The labels that we use here follow the common labelling used by some papers in the literature [2, 12].

Notice that g_6, g_7 and g_8 contain triangle(s). A g_6 contains one triangle, a g_7 contains two triangles, and a g_8 contains four triangles. This fact suggests that we can find them through the triangles in the graph. Whenever we find a triangle, we can check if this triangle is a part of any g_6, g_7 and/or g_8. Similarly, g_3, g_4 and g_5 contain two, three and four wedges, respectively. Therefore, we can find them through wedges.

We list graphlets by their nodes. Thus, for example, $(u, v, w, z)_8$ is a g_8 with nodes u, v, w and z. In enumeration, some care is needed to avoid multiple listing. Without lost of generality, we can use label 1, 2, 3, 4 to represent the nodes in a graphlet. Clearly, $1 < 2 < 3 < 4$, so 1 represents the smallest node.

There are $3! = 6$ permutations of three nodes. Therefore, for **wedges**, we have $(1, 2, 3)_1$, $(1, 3, 2)_1$, $(2, 1, 3)_1$, $(2, 3, 1)_1$, $(3, 1, 2)_1$ and $(3, 2, 1)_1$. However, $(1, 2, 3)_1$ is the same wedge as $(3, 2, 1)_1$, $(1, 3, 2)_1$ is the same as $(2, 3, 1)_1$, and $(2, 1, 3)_1$ is the same as $(3, 1, 2)_1$. Thus, we have only three possible wedges, only one can be present (for induced case). Our convention is to list with the smaller leg first, i.e. $(1, 2, 3)_1$, $(1, 3, 2)_1$, and $(2, 1, 3)_1$. We can divide these into two types: those with the smallest node at the center of the wedge (type 1), i.e., $(2, 1, 3)_1$, and those with the smallest node at one of the legs (type 2), i.e., $(1, 2, 3)_1$ and $(1, 3, 2)_1$. We will see that they require separate treatment. For **triangles**, all six permutations are isomorphic. Therefore, we only need one to list. We choose the one with the nodes ordered ascendingly: $(1, 2, 3)_2$.

Now for four nodes, there are $4! = 24$ permutations. For **3-paths**, by symmetry we only need half (i.e. twelve) of them. For **3-stars**, we have four distinct ones depending on which one is the centre. For **4-cycles**, the cyclic symmetry gives us a factor of four, while the clockwise counter-clockwise symmetry gives

Algorithm 2 Graph-Prep

```
Input: An undirected graph $G(V, E)$
1: Sort $V$ based on the degrees, in ascending order.
2: Relabel the vertices according to their new order.
3: Build adjacency list of the sorted and relabeled vertices.
4: Cut out the smaller neighbours from each neighbour list.
```

us a factor of two. Therefore, we have only $24/8 = 3$ distinct permutations. For **tailed-triangles**, the distinguishing nodes are the end node and the centre node, giving us $\binom{4}{2}$ or twelve distinct configurations. For **diamonds**, we have a pair of triangles. Let us call the two end nodes of the shared edge as the connecting nodes, and the other two nodes as the opposing nodes. There are symmetries between the two opposing nodes, and between the two connecting nodes, giving us $24/2/2 = 6$ distinct configurations. For **4-cliques**, we can exchange any pair of nodes and get the same clique. Thus there is only one unique configuration, and we choose to list the nodes in order: $(1, 2, 3, 4)_8$.

4 THE ALGORITHMS

The algorithm that we use for triangle enumeration is an edge iterator algorithm (Algorithm 1) combined with nodes ordering. This combination is similar to the Compact-Forward algorithm [7] but with the ordering done in a pre-processing before the enumeration (Algorithm 2).

Algorithm 3 Triangle and Wedge Enumeration

```
Input: An undirected graph $G(V, E)$ in an adjacency list representation
1: for all vertex $u \in V(G)$ do
2:     for all vertex $v \in N(u)$ do
3:         if $u < v$ then
4:             for all $u' \in N(u)$ and $v' \in N(v)$ do
5:                 if $(u' > u) \wedge (v' > u)$ then
6:                     if $u' = v' > v$ then
7:                         EnumerateTriangle $(u, v, u')$
8:                     if $(u' < v') \wedge (u' > v)$ then
9:                         EnumerateWedgeType1 $(v, u, u')$
10:                    if $u' > v'$ then
11:                        EnumerateWedgeType2 $(u, v, v')$
```

The graph preprocessing is based on the following observations: (i) Because of lines 3 and 5 of Algorithm 1 we need to consider only bigger neighbours of every vertex, i.e., $N^{>}(u) = \{v \in N(u) | v > u\}$. (ii) The triangle count in a graph will not change if we relabel the vertices.

Algorithm 1 can be modified to enumerate the wedges as well. This is shown in Algorithm 3. Notice that by condition on line 3 we assure that u is always smaller than v. To avoid multiple listing, when we iterate neighbours of v we consider only those that are bigger than u (line 5). However, we need to include smaller neighbours of v (i.e. those between u and v) to catch all of the wedges.

We extend each of the EnumerateTriangle and EnumerateWedge functions above to search for four-node graphlets. Whenever we find a triangle, $(u, v, w)_2$, we call the ExploreTriangle function (Algorithm 4), which checks for the intersections among the neighbour sets of the three triangle nodes, $N(u)$, $N(v)$ and $N(w)$. If we find a $z \in N(u) \cap N(v) \cap N(w)$, then (u, v, w, z)

Algorithm 4 Explore Triangle

```
Input: Given triangle $(u, v, w)_2$, $u < v < w$: $N(u)$, $N(v)$, $N(w)$.
1: Compute intersections among the three neighbour sets.
2: for all $z \in N(u) \cap N(v) \cap N(w)$ with $z > w$ do
3:     EnumerateCLIQUE $(u, v, w, z)_8$
4: for all $z$ in two sets and $z >$ opposite node do
5:     EnumerateDiamond $(.)_7$
6: for all $z$ in one set only do
7:     EnumerateTailedTriangle $(.)_6$
```

is a four-clique (i.e. g_8). A node z that is in two of the three neighbour sets gives us a diamond (i.e. g_7), while a z that is in only one of the three neighbour sets gives us a tailed triangle (i.e. g_6). For 4-cliques, we can use the sets of larger neighbours. For diamonds, we can use the sets of neighbours larger than u. For the tailed triangles, however, we need to include all of the neighbours. Due to this last case we lost some of the advantage of the graph preprocessing. As a result, the runtime might be much longer compared to the triangle enumeration time, depending on the maximum degree.

Algorithm 5 Explore Wedge Type-1

```
Input: Given wedge $(v, u, w)_1$, $u < v < w$: $N^{>u}(u)$, $N^{>u}(v)$, $N^{>u}(w)$.
1: Compute intersections among the three neighbour sets.
2: for all $z \in N^{>u}(v) \cap N^{>u}(w)$ with $z \notin N^{>u}(u)$ do
3:     EnumerateRectangle $(u, v, z, w)_5$
4: for all $z \in N^{>u}(u)$ only do
5:     if $z > w$ then
6:         Enumerate3Star $(u, v, w, z)_4$
7: for all $z \in N^{>u}(v)$ only do
8:     Enumerate3Path $(w, u, v, z)_3$
9: for all $z \in N^{>u}(w)$ only do
10:    Enumerate3Path $(v, u, w, z)_3$
```

For the wedges, we call two different functions depending on the type of the wedge, either Algorithm 5 or 6. In this two functions we only need sets of neighbours that are larger than u, but this is not done in a pre-processing. Notice that in Algorithm 6 w can be smaller than v, which is the center of the wedge.

Algorithm 6 Explore Wedge Type-2

```
Input: Given wedge $(u, v, w)_1$, $u < v$, $u < w$: $N^{>u}(u)$, $N^{>u}(v)$, $N^{>u}(w)$.
1: Compute intersections among the three neighbour sets.
2: for all $z \in N^{>u}(v)$ only do
3:     if $z > w$ then
4:         Enumerate3Star $(v, u, w, z)_4$
5: for all $z \in N^{>u}(w)$ only do
6:     if $z \neq v$ then
7:         Enumerate3Path $(u, v, w, z)_3$
```

5 ANALYSIS

Theorem 1. *Algorithm 3 correctly enumerates wedges and triangles in an undirected graph.*

Proof. Each edge (u, v), with $u < v$, is iterated once and only once. For each, we enumerate all the intersecting neighbours (i.e., triangles), and non-intersecting neighbours (i.e., wedges). Thus, all wedges and triangles in the graph would be found. For triangles, we avoid multiple listing by imposing condition $u' = v' > v$. For type-1 wedges we impose condition $u' > v$. For type-2 wedges, since $u < v'$ there will be no double counting. □

Theorem 2. *Algorithms 4, 5 and 6, combined with algorithm 3, correctly enumerate all four node graphlets in an undirected graph.*

Proof. As proven above, all triangles and wedges are enumerated once. For each triangle, the three neighbour sets are checked. Each node that is in only one of the sets yields a tailed-triangle. All tails would be found in the sets. A node that is in the intersection of two sets yields a diamond. By asserting that this node is larger than the opposite node in the diamond we assure that any diamond would be listed just once. A node that is in the intersection of all three sets yields a 4-clique. We assert that this node is larger than any node in the triangle to assure that the clique has not been listed in any previous iteration. For wedges, similarly, all four node graphlets attached to each wedge would be found. Multiple listing is avoided by considering only 3-paths, 3-stars and 4-cycles, and by careful conditions on the node ordering. For the 3-paths we make sure that the smallest node is always in the first half of the path. For the 3-stars we make sure that the fourth node is greater than the third node. The center node does not need to be the smallest. For 4-cycles we make sure that the fourth node is opposite to the first node. □

Theorem 3. *The runtime of the four node graphlet enumeration is bounded by $O((N_\Delta + N_\angle)\, d_{\max} + T_{3g})$, where N_Δ ($N_\angle$) is the number of triangles (wedges), and T_{3g} is the time to enumerate triangles and wedges.*

Proof. For each triangle and wedge the algorithm runs through the neighbor sets to check the intersections with cost $\leq (d(u) + d(v) + d(w))$. □

Note that in general $(N_\Delta + N_\angle) \lesssim nd^2_{\max}$, with the upper value is satisfied by a regular graph. However, for all real world networks, we have $(N_\Delta + N_\angle) \ll nd^2_{\max}$. Also, $T_{3g} \ll nd^2_{\max}$ using efficient enumeration. Therefore, in practice, our runtime is much less than worst case bound of $O(nd^3_{\max})$.

6 EXPERIMENTS

The networks that we study are listed in Table 2. All of the datasets were downloaded from the Laboratory for Web Algorithmics [3, 4], http://law.di.unimi.it/datasets.php. We symmetrized them and got rid of any loops to get simple undirected graphs. We implemented our code in Java with parallel streams, and use Webgraph library [4]. We used a Linux machine with dual Xeon E5-2620 processors of 24 threads and 128 GB of RAM. We notice, however, that the memory usage is < 1 GB throughout the experiment.

The graphlet counts are listed in Table 1. We can check that for all of these graphs, $N_\Delta + N_\angle \ll nd^2_{\max}$ using their $d_{\max}$ values from Table 2. For example, for **amazon**, $N_\Delta + N_\angle \approx$ 42M and $nd^2_{\max} \approx$ 853B, a four order of magnitude difference. For all of the graphs that we consider here the difference is from three to five orders of magnitude.

The runtimes are shown in Table 3. We include the triangle enumeration time, T_Δ, for comparison. As wedges cannot take full advantage of the pre-processing, they take longer time for enumeration, hence T_{3g} is larger than T_Δ. Notice that the preprocessing time, T_{Prep}, is just about the same magnitude as T_Δ.

Table 1: Counts of the graphlets. The dewiki dataset needs longer than our time limit to terminate.

Graph	g_1	g_2	g_3	g_4	g_5	g_6	g_7	g_8

Note that T_{4g}, the time required to enumerate all 3 and 4-node graphlets, does not strongly depend on the size of the graph, but rather on the degrees and the numbers of triangles and wedges, validating our analysis. For example, comparing **ljournal** with **amazon**, the ratio of their $(N_\angle + N_\Delta)\, d_{\max}$ values is about four thousand, while the ratio of their T_{4g} values is about six thousand, i.e. approximately the same order. This observation experimentally validates the statement of Theorem 3 relating the runtime to the $(N_\angle + N_\Delta)\, d_{\max}$ value.

Interestingly, **cnr** requires longer runtime than **ljournal**. Even though it is smaller by an order of magnitude it has more graphlets. The **amazon** dataset, which has relatively small maximum degree can be processed in merely 14 seconds. The **dewiki** dataset has enormous number of wedges and large maximum degree and the algorithm did not terminate even after running for four days.

7 CONCLUSIONS

In this study we have shown that it is possible to enumerate all types of four node graphlets simultaneously with runtime $O((N_\Delta + N_\angle)\, d_{\max} + T_{3g})$. Wedges and triangles can be enumerated relatively fast (in a pre-run) and the result can be used to estimate the time needed to enumerate the four node graphlets. We found that the runtime upper bound depends more on the maximum degree than on the size of the graph. Our algorithm can finish the enumeration in seconds when the maximum degree is around 1K. Moreover, it does not require large memory space, and it would run for even larger graphs (provided that we allow enough time). Notably, we were able to process massive graphs of millions of nodes and edges and enumerate about 40 trillions graphlets in a single run, within a reasonable amount of time.

ABSTRACT

Interval data are found in a wide range of applications (e.g., validity intervals in temporal databases, ranges of uncertain values in probabilistic databases, etc.) We study the efficient (parallel) evaluation of *band joins* for interval data. Specifically, given two collections R and S of intervals, the objective is to find all pairs (r, s), such that $r \in R$, $s \in S$, and the *difference gap* between r and s is at most equal to a given threshold ϵ. We first show how this problem can be solved by directly applying the state-of-the-art domain-based partitioning approach for interval joins, after extending the intervals by ϵ. Then, we propose a novel partitioning strategy for the original intervals, which defines the partitions using the threshold ϵ and achieves much better performance, on most datasets, for reasonably large values of ϵ.

1 INTRODUCTION

The evaluation of joins with non-equality predicates finds many applications, especially in data domains where values are approximate by nature (e.g., temporal data). For example, one application is finding pairs of events whose time difference is not greater than a given threshold ϵ. This bounded-difference join is also called *band join* [6], since for each value v in one join input, the objective is to find the values in the other input, which are inside an $[-\epsilon, \epsilon]$ band around v.

Although the evaluation of band joins has already been studied for offline (disk-resident) [6, 10] and streaming data [1, 7], previous work focuses on joins between collections of values (not intervals). In addition, the possibilities of parallel evaluation using modern hardware are not fully explored. In this paper, we study the evaluation of band joins between two collections of intervals. Specifically, given two collections R and S of intervals and a band constraint ϵ, our objective is to find all pairs (r, s) of intervals, such that $r \in R$, $s \in S$, and the *difference gap* between r and s is at most ϵ. More precisely, for two intervals $r = [r.start, r.end]$ and $s = [s.start, s.end]$ to qualify the join, it should be $s.start \leq r.end + \epsilon$ and $r.start \leq s.end + \epsilon$.

To our knowledge, this problem has not been studied before, although it has important applications. For example, the user of a temporal database [9] may often be interested in finding pairs of intervals that qualify some overlap or distance constraints (e.g., find pairs of flights which do not have a difference gap larger than 2 hours). Band joins can also be useful for *coalescing* pairs of intervals that overlap or they are close to each other [2]. Another application is in probabilistic databases, where uncertain values are often approximated by confidence intervals [5, 11]. Finding pairs of values that differ less than a threshold ϵ can be modeled and solved as a band interval join problem. XML queries can be modeled as joins between intervals that capture the positions and ancestor-descendant relationships scope of nodes in XML trees [4]. Queries over data streams [1] also constrain the time differences between events, which could be instantaneous or with a temporal duration (i.e., intervals); hence, streaming data analytics could benefit from fast band join evaluation algorithms.

In our previous work [3], we studied the parallel evaluation of *interval overlap joins*, where the objective is to find the pairs of intervals from two collections that *overlap* (i.e., share at least one value). This is a special case of the problem that we study here for $\epsilon = 0$. We proposed a *domain-based partitioning* approach, which divides the data from the two collections into partitions and processes the partitions independently and in parallel, while avoiding duplicate results.

In this work, we extend our framework to evaluate interval band joins. An intuitive and straightforward approach in this direction is to *expand* the intervals in both collections by ϵ (e.g., by adding ϵ to endpoint $x.end$ of each interval x). The interval overlap join between the two collections of expanded intervals is equivalent to the interval band join on the original data inputs and, hence, we can directly apply the original approach of [3]. On the other hand, expanding the intervals increases data replication, which could slow down the evaluation of the join.

This motivated us to design an alternative approach that partitions the original intervals, as in an overlap join, but sets the width of each partition to ϵ. Our new algorithm joins each partition R_i from R with exactly two partitions from S, S_i and S_{i+1} (and vice versa), corresponding to the same and the next ϵ-wide stripes of the domain. As we show, the $R_i \bowtie S_i$ band join reduces to a cross-product, while the $R_i \bowtie S_{i+1}$ band join can be processed very efficiently, after further dividing the intervals in each partition into classes, based on the way they intersect the corresponding stripe.

We evaluate the proposed algorithm on four real datasets and varying ϵ thresholds and confirm that the ϵ-wide stripes approach is superior to the baseline adaptation of [3] on most datasets, for reasonably large values of ϵ.

2 BACKGROUND

In this section, we review the domain-based partitioning approach of [3] for interval overlap joins, which is necessary for understanding our solutions to the band interval join problem.

In order to process the join efficiently and in parallel, this approach first divides the data domain into disjoint regions (stripes),

No need to evaluate: they would generate duplicates

Figure 2: Breakdown of $R_i \bowtie S_i$ into mini-joins

the union of which covers the entire domain. For each of the two input collections R and S, we then define one partition per stripe and assign each interval to all stripes that the interval overlaps. Hence, an interval may span multiple partitions. After this *partitioning phase*, partition R_i (respectively, S_i) includes all intervals from R (respectively, S) which overlap the i-th stripe. During the *join phase*, each partition R_i only has to be joined with the corresponding partition S_i. Moreover, each of the $R_i \bowtie S_i$ partition-to-partition joins can be evaluated independently from the others and the joins can be processed in parallel. Figure 1(a) illustrates an exemplary domain partitioning to four stripes and two intervals; $r \in R$ is assigned to partitions R_1, R_2, and R_3 and $s \in S$ is assigned to partitions S_1 and S_2.

However, a brute-force implementation of the *join phase* may produce *duplicate results*. For example, in Figure 1(a), join pair (r, s) would be reported by both $R_1 \bowtie S_1$ and $R_2 \bowtie S_2$. Duplicates can be avoided by reporting a pair (r, s) in a partition-to-partition join $R_i \bowtie S_i$ only if at least one of r or s starts inside the i-th stripe. Otherwise, the pair would also be detected in the join of a previous stripe. Hence, in our example, pair (r, s) is reported by $R_1 \bowtie S_1$, but the pair is *pruned*, after being detected by $R_2 \bowtie S_2$.

Instead of eliminating duplicates this way, the approach of [3] goes one step further, by avoiding the generation of such duplicates overall. The idea is to further divide each partition R_i into three *mini-partitions* R_i^A, R_i^B, and R_i^C; R_i^A takes all intervals in R_i which start in stripe i, R_i^B takes all intervals in R_i which start before stripe i and end inside stripe i, and R_i^C takes all intervals that start before stipe i and end after stripe i. Figure 1(b) shows examples of three intervals from R_2 that go to different mini-partitions. Now, each $R_i \bowtie S_i$ can be computed by performing 5 *mini-joins* between the mini-partitions, as shown in Figure 2:

- $R_i^A \bowtie S_i^A$ is computed as a typical interval overlap join;
- $R_i^A \bowtie S_i^B$ and $R_i^B \bowtie S_i^A$ are computed as a special case of an interval join, where the start point of every interval in S_i^B (resp. R_i^B) precedes all start points of all intervals in R_i^A (resp. S_i^A) [3].
- $R_i^A \bowtie S_i^C$ and $R_i^C \bowtie S_i^A$ are cross products, hence their computation requires no comparisons;
- $R_i^B \bowtie S_i^B$, $R_i^B \bowtie S_i^C$, $R_i^C \bowtie S_i^B$, and $R_i^C \bowtie S_i^C$ *do not have to be computed* because they would produce duplicate join results (guaranteed to be found in previous stripes).

Mini-joins are evaluated by an optimized version of a *forward scan* algorithm based on plane-sweep (also proposed in [3]).

3 EVALUATING BAND JOINS

3.1 Evaluation based on interval overlap joins

As discussed in the Introduction, a baseline evaluation algorithm for interval *band* joins transforms the problem to an interval *overlap* join. For this purpose, it expands the intervals from both input collections by ϵ. Without loss of generality, each interval $r \in R$ and $s \in R$ becomes $r' = [r.start, r.end + \epsilon]$ and $s' = [s.start, s.end + \epsilon]$, respectively. We can easily show that if r' overlaps s' then $s.start \leq r.end + \epsilon$ and $r.start \leq s.end + \epsilon$ hold, i.e., pair (r, s) satisfies the band join predicate.

This baseline can be straightforwardly implemented using the approach of [3]. The expansion of the input intervals takes place before they are assigned to the partitions, while the mini-joins breakdown operates exactly as discussed in the previous section.

3.2 Evaluation on ϵ-wide partitions

Despite its simplicity, the baseline exhibits two shortcomings. First, due to expanding intervals by ϵ,data replication increases (compared to the replication in the overlap interval join problem). This increases the cost of the partition-to-partition joins. The second drawback is that the domain-based partitioning is agnostic to the input parameter ϵ. For instance, a pair of intervals located at the two different ends of a stripe may not qualify the band join predicate; nevertheless, they need to be checked.

To address these issues, we next propose our second solution for band joins. The key idea of the method is to split the domain into disjoint ranges (stripes), such that the width of each stripe is ϵ (in case the domain cannot be divided exactly by ϵ, the last stripe is narrower). The input intervals from R (resp. S) are not expanded, but directly assigned to every partition R_i (resp. S_i) they intersect, as described in Section 2.

Since the width of each stripe i is (at most) ϵ, it is guaranteed that every pair of interval (r, s) with $r \in R_i, s \in S_i$ forms a result of the band join. In other words, $r.end + \epsilon < s.start$ or $s.end + \epsilon < r.start$ cannot hold; otherwise, r and s would not have been assigned to the same partition. Hence, we can directly report all pairs (r, s) with $r \in R_i, s \in S_i$ as results. However, the same pair of intervals could co-exist in other stripes as well (e.g., the $(i-1)$-th and/or the $(i+1)$-th). Therefore, as in the interval overlap join case, we should only report a pair if it is not a join result in a previous stripe, i.e., if at least one of r or s start inside stripe i. To avoid this test, we can divide each partition R_i (and S_i) again into three mini-partitions R_i^A, R_i^B, R_i^C (and S_i^A, S_i^B, S_i^C), as explained in Section 2 and then evaluate *all* $R_i^A \bowtie S_i^A$, $R_i^A \bowtie S_i^B$, $R_i^B \bowtie S_i^A$, $R_i^A \bowtie S_i^C$, and $R_i^C \bowtie S_i^A$ mini-joins as *cross-products*.

However, we are not done yet. There could also be band join results (r, s), such that r *ends* in stripe i, s *starts* in stripe $i + 1$ and $r.end + \epsilon \leq s.start$ (and the symmetric case). The current decomposition has no explicit partition for all intervals that end in stripe i, i.e., the mini-partition R_i^A does not distinguish between the intervals $r \in R$ that end in stripe i from those that end after stripe i. To this end, we define an *additional* mini-partition R_i^{A1}, which contains the intervals $r \in R_i$ that both *start* and *end* inside stripe i. Mini-partition R_i^{A1} is a subset of R_i^A, but their contents are sorted differently to enhance the join evaluation, as we discuss in the next paragraph. Figure 3 shows examples of four intervals

which are assigned to R_2^A, R_2^B, R_2^C, and R_2^{A1}. Observe that intervals which are assigned to R_2^{A1} are also assigned to R_2^A.

In Figure 4, we illustrate the set of mini-joins that have to be evaluated by the new algorithm. Besides the 5 cross-products between mini-partitions in the same stripe, we have to perform four mini-joins $R_i^{A1} \bowtie S_{i+1}^A$, $R_i^B \bowtie S_{i+1}^A$, $S_i^{A1} \bowtie R_{i+1}^A$, $S_i^B \bowtie R_{i+1}^A$, at every pair i and $i+1$ of neighboring partitions. All these mini-joins can be evaluated efficiently in a similar manner as mini-join $R_i^B \bowtie S_i^A$ of the interval overlap join problem (illustrated in Figure 2). Specifically, the intervals in mini-partitions R_i^{A1}, R_i^B, S_i^{A1}, S_i^B are sorted by $r.end$ or $s.end$ and the intervals in mini-partitions R_i^A and S_i^A are sorted by $r.start$ and $s.start$, respectively. Then, at each of the four mini-joins, we can compute the result by *concurrently scanning* the join inputs only once.

Consider, for instance, the mini-join between R_i^{A1} (sorted by $r.end$) and S_{i+1}^A (sorted by $r.start$). We first check whether $r.end + \epsilon \geq s.start$ holds for the first r in R_i^{A1} and the first s in S_{i+1}^A. If so, (r, s) is a band join result. At the same time, we can conclude that for all intervals r' that follow r in R_i^{A1}, (r', s) is also a band join result, since $r'.end \geq r.end$ holds (due to sorting). Note that all these join results are generated without any comparisons. Afterwards, we advance to the next interval $s \in S_i^A$ and repeat the test $r.end + \epsilon \geq s.start$. If the test is negative, we advance to the next interval $r \in R_i^{A1}$ and repeat the test, etc. As soon as either r or s is out of bounds, i.e., the input mini-partitions are fully scanned, the join algorithm terminates.

For example, in Figure 5, we first consider intervals r_1 and s_1. As $r_1.end + \epsilon \geq s_1.start$ holds, all intervals in R_i^{A1} form band join pairs with s_1. Next, we examine s_2 and repeat the test to find again that $r_1.end + \epsilon \geq s_2.start$. Hence, we also report all intervals in R_i^{A1} paired with s_2 as band join results. However, when we advance to s_3, we observe that $r_1.end + \epsilon < s_3.start$, so (r_1, s_3) is not a join result. At this point, we consider the next intervals r from R_i^{A1} while $r.end + \epsilon < s.start$ holds and stop at r_3, where we have $r_3.end + \epsilon \geq s_3.start$. Again, we report join pairs (r_3, s_3) and (r_4, s_3) and advance to s_4. Since $r_3.end + \epsilon < s_4.start$, we finally advance to r_4; since, $r_4.end + \epsilon \geq s_4.start$ holds, we report join pair (r_4, s_4). At this point, both mini-partitions are completely scanned and the algorithm terminates.

The number of comparisons conducted by the above algorithm (applied for all mini-joins which are not cross products) equals

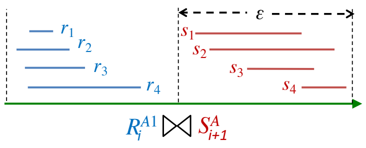

Figure 5: Mini-join between neighboring partitions

Table 1: Statistics of datasets

	INFECTIOUS	BOOKS	TAXIS	WEBKIT
Cardinality	415,912	2,312,602	14,212,261	2,347,346
Domain duration (secs)	6,946,360	31,507,200	2,592,000	461,829,284
Distinct domain points	81,514	5,330	2,229,932	174,471
Shortest interval (secs)	20	1	1	1
Avg. interval dur. (secs)	20	2,201,320	685	33,206,300
Longest interval (secs)	20	31,406,400	1,816,164	461,815,512

the total number of intervals in its two inputs (e.g., $|R_i^{A1}| + |S_{i+1}^A|$), which means that mini-joins are evaluated very efficiently.

Parallel evaluation. As shown in [3], the best approach to parallelize interval joins based on domain-based partitioning is to treat every mini-join as an independent task. Each task is scheduled to one of the available CPU threads. To maximize load balancing, the tasks are greedily assigned to threads in decreasing order of their expected costs (based on the size of the involved partitions).

4 EXPERIMENTAL EVALUATION

Our evaluation was conducted on a machine with 384 GBs of RAM and a dual Intel(R) Xeon(R) CPU E5-2630 v4 clocked at 2.20GHz. All methods were implemented in C++, compiled using `gcc` (v4.8.5) with flags `-O3`, `-mavx` and `-march=native`. We activated hyper-threading, allowing us to run up to 40 threads and used OpenMP for multi-threaded processing. Every interval contains two 64-bit domain point attributes (i.e., `start` and end) while the workload accumulates the number of result pairs. All data reside in main memory.

Methods. We compare our ϵ-wide partitioning join (denoted by ϵ-WIDE) to the baseline (denoted by BSL). In addition, we include a version of BSL (denoted by ϵ-BSL), which uses ϵ-wide domain partitions, but it conducts an overlap join using the extended intervals, instead of the method described in Section 3.2. Both variants of the baseline use our optimized forward scan based plane sweep method from [3] and all our optimizations to improve load balancing in domain-based partitioning.

Datasets. Table 1 details our 4 real-world experimental datasets. INFECTIOUS [8] stores contact intervals between visitors at an exhibition at the Science Gallery in Dublin from 2009/05 to 2009/07. BOOKS [3] includes periods of book lent outs at Aarhus public libraries in 2013 (https://www.odaa.dk). TAXIS (https://www1.nyc.gov/site/tlc/index.page) stores durations of taxi trips in NYC, in Jan 2013. WEBKIT [3] records durations of file versions in the git repository of the Webkit project from 2001 to 2016 (https://webkit.org).

Tests. To assess the performance of the methods, we measure their response time while varying (i) threshold ϵ as a fraction of the domain duration inside $\{0.001, 0.005, 0.01, 0.05, 0.1\}$ and (ii) the number of available CPU threads inside $\{5, 10, 15, 20, 25, 30, 35, 40\}$. We also experimented with uniformly sampled subsets of the dataset as R and set the entire dataset as S; for this purpose, we varied the $|R|/|S|$ ratio inside $\{0.25, 0.5, 0.75, 1\}$.

Results. Figures 6-8 summarize our experimental results. When varying ϵ, we observe the following. First, ϵ-WIDE is consistently faster than ϵ-BSL. This shows that applying the mini-joins

described in Section 3.2 on the original intervals is faster than applying the mini-joins of [3] on the ϵ-extended intervals. However, the number of ϵ-wide partitions can become extremely large for small values of ϵ, which renders these approaches slower compared to BSL. Note that BSL chooses the number of partitions, according to the number of threads that can run in parallel as suggested in [3]. On WEBKIT, TAXIS and INFECTIOUS, ϵ-WIDE is up to a few time faster compared to BSL and ϵ-BSL for a wide range of ϵ/domain ratios. On the other hand, on dataset BOOKS, ϵ-WIDE is faster than the competition for ϵ/domain ratios larger than 2%. When varying the number of threads, we observe that all methods scale well until when the number of threads becomes 20, after which hyper threading comes into effect. The join on INFECTIOUS is already very cheap and does not benefit from increasing parallelism. Last, as expected all methods are affected by increasing $|R|/|S|$; their execution time rises.

5 CONCLUSION

In this short paper, we studied the evaluation of band joins between two collections of intervals. We extended our framework for interval overlap joins [3] in two directions; a baseline approach that expands all intervals by ϵ and then evaluates an overlap join and a novel approach that uses ϵ to define the partitions and then conducts cheaper joins between partitions. Our experimental findings show that the second approach is more efficient, unless ϵ is very small compared to the domain size.

ABSTRACT

Graphs are everywhere. Personalized Page Rank (PPR) is a particularly important task to support search and exploration within such datasets. PPR computes the proximity between query nodes and other nodes in the graph. This is used, among others, for entity exploration, query expansion, and product recommendation. Graph databases are used for storing knowledge graphs. Unfortunately, the exact computation of PPR is computationally expensive. While different solutions have been proposed to compute PPR values with high precision, these are extremely complex to implement, and in some cases require heavy preprocessing. In this work, we sustain that a better approach exists: *particle filtering*. Particle filtering methods produce ranks with sufficient precision while exploiting what graph databases architectures are already optimized for: navigating local connections. We present the implementation of such an approach in a popular commercial database and show how this outperforms the already implemented functionality. With this, we aim to motivate future research to optimize and improve upon this research direction.

1 INTRODUCTION

Graphs are everywhere [20], in particular, Knowledge Graphs (KG) [17] gained increasing attention thanks to their ability to represent entities and their relationships in many domains. Knowledge graphs model entities as nodes and the relationships among them as labelled edges. They are used to store the relationships about products, customers, events, locations, and more.

Personalized Page Rank [4, 5, 9, 12] (PPR) is a particularly important task to support search and exploration within graphs. At a high level, PPR extends the well known Page Rank [18] by computing a *local* popularity (or *proximity*) instead of a global importance score for nodes. In practice, given a small set of query entities, PPR returns a ranked list of other relevant entities based on a computed *random-walk proximity* to the query nodes. Famous examples of the application of PPR are the Twitter *Who To Follow* [8] that suggest to users other users to follow and the Pinterest related pins suggestions [14]. In other contexts, it can suggest related scientific articles, related entities, or suggest products to buy.

When it comes to PPR applications to KGs, a number of aspects become important, namely: the possibility to use a small set of nodes as query (e.g., for product recommendation or query expansion), the ability to include edge weights in the computation (given that in a KG different edges have different semantics), and fast response times for top-k queries (since in practical cases only a small set of high ranked nodes are required in contrast to computing such values for all nodes in the graph).

Currently, graph data management systems (GDBMS) [13] are the de-facto solution for managing knowledge graphs in transactional settings, thus, they need to support PPR queries. Unfortunately, the exact calculation of PPR is computationally expensive. In the literature many solutions have been proposed to provide fast computation of PPR values [2, 6, 7, 10, 11, 15, 19, 22–25]. Yet, they have been designed with the needs of social networks in mind, i.e., they focus on single source queries, unlabeled edges, and high-precision PPR value computations (required for community detection [26]). In many cases, they require pre-computation of indexes and other data-structures. In short, most existing methods are not designed to focus on the real needs for KG search, neither they take into account the requirements for being implemented in real-world Graph DBMS.

In this work, we study PPR computation solutions designed around the needs of Knowledge Graph search and the strengths of graph databases. We proposed a much simpler approach for computing Personalized Page Rank queries with multiple sources and heterogeneous edge weights. To achieve a significant performance in computing the top-k PPR, we extend the *damping function* template [4] with the *particle filtering procedure* [12], extended to correctly take into account the *teleportation probability* and account for the non-uniform edge importance typical of KGs. Currently, the only implementation of a similar approach has been proposed for an in-memory research prototype [16]. In our work, instead, we show how real word commercial graph databases can support this functionality.

Our experiments, on real large graphs, demonstrate the superiority of this approach (which we have made available as open-source[1]) against the currently implemented version in a major commercial GDBMS (Neo4j[2]). Furthermore, this direction is open to interesting challenges and can foster the development of new techniques to improve real-world graph databases.

2 RELATED WORKS

Personalized Page Rank [9] has been initially proposed as an alternative to global Page Rank since it computes local proximity to query nodes based on random-walks. Since that seminal work, many different approaches and implementations have followed. In general, they follow three alternative strategies, namely (1) matrix computation, (2) Monte-Carlo simulations, or (3) local search. For matrix computation, the graph is represented as its adjacency matrix, as in the original formulation, and different matrix multiplications are performed to compute the final values. These approaches [7, 10, 11, 22] are typically computationally expensive, hence they tend to be optimized through heavy pre-computations and large scale indexing. Matrix computation approaches are impractical for real-world graph databases, since GDBMS do not usually represent a graph as an adjacency matrix, and would require to maintain the pre-computed results.

[1]https://github.com/DenisGallo/Neo4j-ParticleFiltering
[2]https://neo4j.com/docs/graph-algorithms/

Monte-Carlo approaches, on the other hand, simulate a number of random traversals of the graph in order to compute the final PPR values. Employing this strategy offers few guarantees on the final output and on the actual response time. In general, a large number of random traversals are required to obtain reliable results. Hence, also in this case, precomputed values and indexes are employed [23, 24], suffering though from the same shortcomings discussed earlier.

Local search approaches, start, instead, from the query nodes and spread a rank value following the local neighborhoods until some stopping condition verifies. Usually, once this condition is encountered, they employ some additional Monte-Carlo traversals to refine the obtained approximate results and ensure higher precision [2, 5, 6, 15, 19, 24, 25]. Yet, most of these approaches have focused on either source-target queries, i.e., compute the PPR value of a target node given a source node, or single source queries with focus on computing high precision PPR values for very large portions of nodes in the graph. Both these directions, while useful in cases like social networks, impose an unnecessary burden on the system (since they focus on the actual PPR value instead of just computing a ranking of nodes) and neither address other important required features, like the necessity to differentiate edge types, the possibility to have multiple source nodes in the query, or the requirement of returning a ranked list of nodes of usually small size (i.e., top-k queries).

Contrary to most recent literature, following promising preliminary results from knowledge graph exploration [16], we study a method to enable multi-source, edge-weighted, top-k Personalized Page Rank queries within a Graph DBMS. We explicitly focus on the now prevalent need of Knowledge Graph search and on fully exploiting the ability of graph databases to efficiently query the local neighborhood of nodes [13]. Our method extends the *damping function template* [4], yet it implements an approach similar to *particle filtering procedure* [12] with two main differences: it has been extended to correctly take into account the *teleportation probability* that was not accounted for there, and it provides the ability to include edge relevance in the calculation, a feature that has been largely neglected in the literature. This solution has the advantage that it does not require any internal ad-hoc data-structure (our solution is a stored procedure of about two hundreds lines of code) and obtains both fast response time and high-quality results in practice.

3 APPROXIMATE PERSONALIZED PAGE RANK COMPUTATION

Given a graph $G : \langle V, E\rangle$ with V nodes and E edges, the result of a Personalized Page Rank (PPR) [9] given a set of query nodes $Q \subset V$ computes a proximity value of every node in V to the nodes in Q. Formally, the result of the computation is represented as a vector $\mathbf{v}$, with size $|V|$ representing the stationary distribution of the Markov chain [9] with state transition given by the equation

$$(1-c)A\mathbf{v} + c\mathbf{p} \tag{1}$$

Given the column normalized transition probability matrix A, the teleportation probability c, and the preference vector $\mathbf{p}$. The matrix A (of size $|V| \times |V|$) contains values between 0 and 1 according to the probability that an edge is traversed (hence the column normalization), where a value of 0 corresponds to non-existing edges. In general, a KG is a graph with edges of different types (an edge-labelled graph) and in many cases, different edge types are assigned different relevance scores (i.e., a weight in [0,1]). Furthermore, $\mathbf{p}$ is an $|V| \times 1$ column vector, which serves

Algorithm 1 PPR by Particle Filtering

```
Require: Graph $G$; Query nodes $\mathbf{Q}$
Require: Restart probability $c \in [0,1]$; Threshold $\tau \in [0,1]$
Require: Query value $k$
Ensure: Ranked Top-K nodes
 1: $\mathbf{p} \leftarrow \{\}$
 2: for each $q_i \in \mathbf{Q}$ do
 3:     $\mathbf{p}[q_i] \leftarrow 1/\tau$                          ▹ Initialize Particles
 4: while $\exists\ n_i \in \mathbf{p} \mid \mathbf{p}[n_i] \neq 0$ do
 5:     temp $\leftarrow \{\}$
 6:     for each $n_i \in \mathbf{p} \mid \mathbf{p}[n_i] \neq 0$ do
 7:         $particles \leftarrow \mathbf{p}[n_i] \times (1-c)$
 8:         for each $e : (n_i \rightarrow n_j) \in G$ do    ▹ Sorted by Weight
 9:             if $particles \leq \tau$ then
10:                 break
11:             $passing \leftarrow$MAX($particles \times e$.weight(),$\tau$)
12:             $\mathbf{temp}[n_j] \leftarrow \mathbf{temp}[n_j] + passing$
13:             $particles \leftarrow particles - passing$
14:     $\mathbf{p} \leftarrow \mathbf{temp}$
15:     for each $n_i \in \mathbf{p}$ do
16:         $\mathbf{v}[n_i] \leftarrow \mathbf{v}[n_i] + \mathbf{p}[n_i] \times c$         ▹ Update score
17: return top-k($\mathbf{v}$)
```

as the normalized preference vector, for which $\mathbf{p}[n]{\neq}0$ and in particular $0{<}\mathbf{p}[n]{\leq}1$ *iff* $n{\in}Q$. Finally, the *teleportation* probability $c \in (0, 1)$ is typically ≈ 0.15 in the literature [18].

In practice, the goal of the PPR value is to rank nodes, hence *the exact value of the PPR is not necessary as far as the ranking is preserved.* We propose an approximation of this process [4] and apply an approach similar to the *weighted particle filtering procedure* [12] to consider the non-uniform edge weights.

The approach simulates a set of $1/\tau$ floating particles (lines 2-3, Algorithm 1) starting from each node in the query set Q. At each iteration (lines 5-16), the particles distribute among the neighbors of the current node (minus the number of particles that *restart*, line 7). An important optimization is to prevent particles to split to arbitrarily small sizes, limiting them to a minimum of τ (lines 9-11). When distributing the particles among the neighbors, the algorithm gives preference to the edges with higher weights (line 8). Since the weight is normalized on the edges of each node, this operation matches the damping function framework [4]. The restart probability c will dissipate part of the particles at every iteration (line 8), and the algorithm will stop when no more particles can be distributed. During the process, a vector $\mathbf{v}$ accumulates the total amount of particles visiting each node (lines 15-16). Hence, the final list of top-k nodes is based on $\mathbf{v}$.

Here, we argue that for the case of Knowledge Graphs, the Particle Filtering approach for PPR computation is the best-suited approach to extend GDBMS functionalities for retrieving Top-K nodes.

The benefits of this approach are that (1) it does not require any complex preprocessing nor any additional persistent data structure, (2) it is directly implementable within any graph databases by direct use of core operations that are already optimized (namely local node neighbor traversal [13]), (3) it returns a ranking that strictly correlates with the actual ranking, (4) it can account for heterogeneous edge types and importance, (5) it does not require to traverse the entire graph and its exploration rate (and hence running time) can be fine-tuned through the τ and c parameters.

4 EXPERIMENTS

We investigated the performance and the quality of the ranking of Particle Filtering (PF) compared to the current exact implementation of Personalized Page Rank (PPR) in a commercial database. In particular, we implemented particle filtering (**PF** – Algorithm 1) as a Java stored procedure in Neo4j[3] v3.5.5, and compared it against the current implemented exact solution (**PPR** - Graph Algorithms v3.5.2)[4]. Experiments have been executed on a server with 12 cores and 128GB RAM.

Datasets: We compared the two alternatives on 4 different KGs from different domains and different sizes, widely used in the literature (Table 1). These KGs have been obtained from a dataset of movies, including also information about actors, directors, and genres[5] (*Movies*); from an established benchmark for triplestores [1] representing an heterogenous product catalog (*WatDiv*); an open domain knowledge graph (*DBpedia* [3]); and finally a knowledge base about drugs, their composition, and their interactions (*DrugBank* [21]). Of these, Movies, DBpedia, and DrugBank are real-world datasets, while WatDiv is synthetic.

Queries, Parameters, and Evaluation Metrics: For each dataset, we extracted 5 sets of 20 queries. Each set contains 20 queries of the same size (i.e., number of source nodes). We generated through sampling queries of size 1, 5, 10, 20, and 100 nodes, for a total of 100 queries. For each query, we recorded the execution time (average of 3 runs), and for the queries executed with PF, we recorded NDCG score at top-5, 50, 100, and 500. We executed queries both with the weighted (i.e., assigning weights based on label informativeness [16]) and unweighted (i.e., uniform weights) version of the algorithm. We tested the PF with three values of τ: 0.1, 0.05, and 0.01.

Results: Due to space constraints, we report here only results for the two largest graphs, namely WatDiv and DBpedia, for the labelled case. The full set of experimental results can be found in the extended version of this document[6]. Nonetheless, we also comment on some of the findings of the excluded experiments.

Quality of Ranking: Over all the datasets, the NDCG score for PF with $\tau = 0.01$ has the best quality, and often close to the perfect ranking (i.e., between 0.8 and 1.0) with queries containing up to 10 nodes. In most cases, also PF with $\tau = 0.05$ obtains a good quality ranking (NDCG>0.65). With more than 10 query nodes, the quality of ranking is subject to high variability, especially depending on the dataset. On DBpedia and WatDiv, still, we obtain NDCG scores above 0.65 for both τ=0.05 and 0.01 with 20 nodes in input at top-500, while for 100 nodes, we need τ=0.01 on DBpedia. This confirms the suitability for KG exploration cases.

Running Time: Compared to the running time of exact PPR, the PF algorithm provides a speedup between 1 and 4 orders of magnitudes, i.e., returning on average in 1-30 seconds while the exact solution requires 3-6 minutes (on DBpedia). In general, the speedup is proportional to the value of τ, i.e., τ=0.01 is between 10 and 100 times slower than τ=0.1. Yet, for 100 query nodes on DBpedia, we report that τ=0.01 rarely achieves sensible improvements due to the high number of particles generated.

Effect of Weights: when considering weights particle transitions are skewed towards more relevant nodes (through more informative edges). This has a noticeable effect on the running time because for high degree edges only the most informative edges are traversed (given the fact that they are prioritized), and many less relevant edges are skipped. For a similar reason, we notice that the NDCG score when weighted edges are considered is higher because for nodes with very high degrees, there are not enough particles to visit all the neighbors, hence in the weighted case the PF prioritization is consistent with the importance of the node, while in the unweighted case all of them should be visited.

	Movies	WatDiv	DBpedia	DrugBank
#Nodes	63K	5.2M	11.6M	391K
#Edges	106K	95.8M	216.7M	1M

Avg In-degree	9.18	20.3	20.1	2.8
Median In-degree	8	1	2	1

Table 1: Size and characteristics of the datasets

Open Challenges: In our experiments, we noticed that when starting nodes are hubs (i.e., nodes with high degree) or are near hubs, the weighted traversal is the bottleneck. The reason is that current GDBMS can very quickly retrieve all the neighbors of a node, but then we require to sort them by weight. Hence, we identify the opportunity in GDBMS for implementing *sorted edge iterators for weighted edges* to speed up this step and other similar cases. Moreover, automatic tuning of the τ threshold depending on the query is an open research challenge.

5 CONCLUSIONS

In this paper, we argue that, when computing the Personalized Page Rank value in a knowledge graph, the approximate computation framework offered by the Particle Filtering approach, provides substantial advantages in terms of running time and ease of implementation, while ensuring good ranking quality. Our implementation can provide an efficient solution for extending existing graph databases since it exploits the strengths of these systems. While this approach is simple and effective for queries with few input nodes and limited to the first few hundreds nodes (typical of on-line exploration settings), we believe that the algorithm can be further expanded to assure high-quality ranking also for nodes in the long tail and larger queries.

Towards Planning of Regular Queries with Memory

Thomas Mulder, Nikolay Yakovets, George Fletcher
Technische Universiteit Eindhoven

ABSTRACT

We investigate efficient evaluation of regular path queries with memory (RQM), which are an extension of regular path queries (RPQ) with additional constraints on data encountered along a path in a graph. We show how *Waveguide*, a state of the art system capable of planning RPQs, can be extended to facilitate RQM planning. Furthermore, we show that RQM planning is not as trivial as finding a conventional optimal join order and adding-on data constraints. Rather, we showcase that efficient evaluation of RQMs poses a number of non-trivial novel challenges.

1 INTRODUCTION

Regular path queries with memory (RQM) are subgraph-matching queries that allow the definition of constraints on both *topology* and *data* in graphs [3]. RQMs extend the expressive power of regular path queries (RPQ) [1] in many useful ways while maintaining an acceptable PSPACE-complete combined complexity.

An example of a query that is expressible as an RQM but not as an RPQ is to find all pairs of people (x, y) such that x directly or indirectly knows y and all people along the chain of acquaintance have the same age.

The initial study of RQMs [3], provides an extension of regular expressions called regular expressions with memory (REM) that are used to write RQMs, along with a procedure for constructing a *k-register data path automaton* that can be used for the evaluation of an RQM. While k-register data path automata are an excellent tool for the investigation of the expressive power and complexities of RQMs, they do not represent effective query plans, and do not provide opportunities for query optimisation.

We aim to develop the first practical evaluation engine for RQMs [4]. Here we take first steps towards this goal by (1) studying the shortcomings of the proposed automata from a query planning- and evaluation perspective, (2) addressing these shortcomings by proposing a more expressive type of automata that can be used to represent query plans and (3) showing that optimising such plans for *topological*- and *data* constraints are *orthogonal* problems. That is, a query plan that is optimal for evaluating only the topological constraints of a query on a particular graph, and another query plan that is optimal for evaluating the topological- *and* data constraints of the same query on the same graph, need not consider the topology of the query in the same order.

We extend Waveguide [5], a cost-based optimizer for property paths which builds query plans called *waveplans* that guide query evaluation. Waveplans are based on automata, which allows us to combine concepts from waveplans and k-register data path automata to obtain k-register waveplans.

2 REGULAR QUERIES WITH MEMORY

Data graphs are defined over a finite alphabet Σ and a countably infinite set of data values $\mathcal{D}$ as a triple $G = \langle V, E, \rho \rangle$, where:

- V is a finite set of nodes;
- $E \subseteq V \times \Sigma \times V$ is a set of labelled edges; and
- $\rho : V \to \mathcal{D}$ is a function that assigns a data value to each node in V.

To write regular expressions that can specify paths in data graphs, regular expressions with memory (REMs) over a finite alphabet Σ and set of variables $x_1, \ldots, x_k$ are introduced and defined by the grammar

$$e := \epsilon \mid a \mid e + e \mid e \cdot e \mid e^+ \mid e[c] \mid \downarrow \bar{x}.e \mid (e), \tag{1}$$

where $a \in \Sigma$, c is a condition and $\bar{x}$ a tuple of variables from $x_1, \ldots, x_n$. A condition, in turn, is defined by the grammar

$$c := x_i^= \mid x_i^{\neq} \mid z^= \mid z^{\neq} \mid c \wedge c \mid c \vee c \mid \neg c \mid (c),\ 1 \leq i \leq k, \tag{2}$$

where z is a data value in $\mathcal{D}$, also referred to as a constant.

As an example, consider the following REM:

$$(\mathtt{owns} \cdot \downarrow x_1.\mathtt{isLocatedIn})^+ \cdot \mathtt{hasCapital}[x_1^=] \tag{3}$$

This REM specifies paths where we encounter at least one sequence of two edges labelled `owns` and `isLocatedIn`, followed by an edge labelled `hasCapital`. Additionally, the data value associated with the source of an edge labelled `isLocatedIn` is stored in the first register, which is subsequently compared to the data value associated with the target of an edge labelled `hasCapital`.

A regular query with memory is defined as an expression of the form $Q := x \xrightarrow{e} y$ where e is an REM, and x and y are variables that are mapped to nodes in a data graph. Hence, the evaluation of Q amounts to finding pairs $(u, v) \in V \times V$ such that there exists a path from u to v that adheres to e. See Section 3.3 of [3] for the formal semantics of REMs and RQMs.

3 QUERY PLANNING

Query planning in the most general sense, is the process of finding an ordering of operations that, when executed, produce the solution to the given query. In the context of regular queries with memory, this means finding an ordering of *edge labels*, *assignments*, *conditions* and *projections*.

3.1 Automata as Query Plans

Query plans for relational database systems are often represented as trees. Due to the recursive nature of RQMs introduced by the Kleene plus ($^+$) operator, it is more convenient to represent query plans for RQMs as *automata* instead.

Regular Data Path Automata (RDPA) [3] have been proposed as a representation of RQMs. These RDPAs, however, capture the operations necessary for the evaluation of an RQM $Q = x \xrightarrow{e} y$ only in the order corresponding to the left-deep parsing of e. Hence, RDPAs are not a suitable formalism for representing query plans for RQMs.

Instead, we will consider *Waveguide* [5], a state of the art query optimiser for RPQs. It represents query plans as *waveplans*, a automaton-based formalism that allows for a rich variety of query plans, due to its *inverse transitions* and *transitions over views*. Conceptually, a waveplan consists of one or more *wavefronts*, which are automata that are used to compute (part of) the solution to a query. We extend wavefronts with assignments, conditions and projection over data values and registers.

Inverse- and view transitions. Let Σ be a finite alphabet, and L a finite set of state labels disjoint from Σ. We define $\Sigma^* = \bigcup_{a \in \Sigma \cup L} \{/a, a/\}$ as a set of labels. A transition with label $/a \in \Sigma^*$ is said to *append* edges labelled a to an intermediate result, whereas a transition labelled $a/ \in \Sigma^*$ is said to *prepend* edges labelled a to an intermediate result. The latter is referred to as an *inverse* transition. Inverse transitions allow our plans to represent many different orders of edge labels, such as a right-deep order.

A transition with label $/2 \in \Sigma^*$ appends paths computed by the state with label 2 to an intermediate result. Such a transition is called a *transition over a view*. Transitions over views further extend the orders of edge labels our plans can express by including *bushy* plans.

Projection. *Data paths* are defined as a sequence of interleaving nodes and edge labels that always start and end with a node [3]. Consider the REM e from (3) and a data path:

$$\pi = v_1 \, \texttt{owns} \, v_2 \, \texttt{isLocatedIn} \, v_3 \, \texttt{hasCapital} \, v_4$$

Checking whether or not π is accepted by e in a right-deep order means first finding edges labelled `hasCapital`, then amongst those finding edges that are preceded by edges labelled `isLocatedIn`, etc. This is a valid order of evaluating the edge labels and may be more efficient than a left-deep order, depending on the input graph. This order provides a problem with respect to the assignment- and condition in this REM. Namely, we would like to check that $\rho(v_4) = x_1$ where x_1 is the value in the first register. We can only do so once the first register has been assigned the value $\rho(v_2)$. Hence, to make this ordering of the edge labels work, $\rho(v_4)$ will have to be stored until the assignment has been made. To indicate which data- and register values must be stored at which point during query evaluation, we associate with each state in our automata finite sets $P_{\mathfrak{D}} \subset \mathbb{N}$ and $P_r \subset \mathbb{N}$ that contain the positions of nodes in a path and the indices of registers that must be kept, respectively. For instance, to indicate that $\rho(v_4)$ and x_1 (i.e. the value of the first register) must be kept, we would set $P_{\mathfrak{D}} = \{4\}$ and $P_r = \{1\}$.

3.2 k-Register Waveplans

We will refer to the extension of waveplans and wavefronts with assignments, conditions and projections as *k-register waveplans* and *k-register wavefronts*, respectively.

Let Σ^* be a finite labelling alphabet, k a natural number and C a finite set of conditions. Formally, a *k-register wavefront* is a tuple $w_l = \langle l, S, Q, q_0, \Pi_{\mathfrak{D}}, \Pi_r, \delta, F, \tau_0 \rangle$, where

- l is a wavefront label,
- S is a seed,
- Q is a set of states,
- q_0 is the starting state $q_0 \in Q$,
- $\Pi_{\mathfrak{D}} : Q \longrightarrow 2^{\mathbb{N}}$ is a function assigning a projection $P_{\mathfrak{D}}$ of path positions corresponding to data values to each state,
- $\Pi_r : Q \longrightarrow 2^{\mathbb{N}}$ is a function assigning a projection P_r of register indices to each state,

Figure 1: A k-register waveplan for (3)

- δ is a transition relation $\delta : Q \times \Sigma^* \times 2^{[k]} \times C \times Q$,
- $F \subseteq Q$ is a set of accepting states, and
- $\tau_0 \in \mathfrak{D}_{\perp}^{k}$ is the initial configuration of the registers.

A tuple $d = (q_1, a, K, c, q_2) \in \delta$ consists of source- and target states q_1 and q_2, label a, a set $K \subseteq \{1, ..., k\}$ indicating which registers are to be assigned a value during this transition and a condition c which is to be checked during this transition.

A *k-register waveplan* p is an ordered set of wavefronts. Consider any pair of wavefronts $w, w' \in p$ such that
$w = \langle l, S, Q, q_0, \Pi_{\mathfrak{D}}, \Pi_r, \delta, F, \tau_0 \rangle$ and
$w' = \langle l', S', Q', q_0', \Pi_{\mathfrak{D}}', \Pi_r', \delta', F', \tau_0 \rangle$. Then p defines an order $<_p$ on wavefronts as follows:

$$\forall w, w' \in p \mid w <_p w' \; : \; l' \notin S \wedge l' \notin L$$

Given this order, lower wavefronts cannot use labels of higher wavefronts in their seeds or transitions.

The role of *seeds* in Waveguide is quite complex. Here it suffices to say that seeds are necessary to ensure semantically correct plans when dealing with multiple wavefronts in a waveplan, or single wavefronts implementing a closure over an expression.

Figure 1 shows a k-register waveplan for the REM from (3). It consists of two wavefronts. The first wavefront computes the result to the expression $e' = (\texttt{owns/}{\downarrow}\; x_1.\texttt{isLocatedIn})^+$ in a right-deep order. It assigns a value to the first register (i.e. x_1 is set to the data value at the source of an edge labelled `isLocatedIn`). The second wavefront computes the result to (3) by first computing $e'' = \texttt{hasCapital}$, storing the data value at the target of edges labelled `hasCapital` in state 5. The result of state 2 is prepended to the result of state 5, and x_1 is checked for equality against the data value at the end of the resulting paths (i.e. at the target of an edge labelled `hasCapital`).

3.3 Topological Order

Let e be a regular expression with memory. We will refer to t_e as the topology of e which is a regular expression obtained by recursively replacing

- every sub-expression $e_1[c]$ of e by e_1, and
- every sub-expression $\downarrow \overline{x}.e_1$ of e by e_1

such that t_e no longer contains assignments and conditions.

We can now define the order in which a k-register waveplan p considers the topology of a query as follows. Consider a wavefront $w \in p$. We define the *topological order* λ_w of w as a sequence $\langle t_0, ..., t_n \rangle$ where t_i is the sub-expression of t_e for which the state with label i in p returns an intermediate result. We

ignore all states that are part of a cycle in w, except for accepting states, when constructing any sequence λ_w. We define the topological order λ_p of a k-register waveplan p as a sequence of sequences $\langle\langle t_0, ..., t_l\rangle, ..., \langle t_m, ..., t_n\rangle\rangle$, where each inner sequence corresponds to the topological order of the wavefronts that make up p, in the order defined by $<_p$. Consider the waveplan in Figure 1. Its topological order is
$\langle\langle \epsilon, \texttt{isLocatedIn}, (\texttt{owns/isLocatedIn})^+\rangle,$
$\langle \epsilon, \texttt{hasCapital}, (\texttt{owns/isLocatedIn})^+\texttt{/hasCapital}\rangle\rangle$.

3.4 Query Evaluation

As per [5], query evaluation is done using a procedure based on breadth-first search in which a waveplan guides the search (i.e. determines which edges are to be explored based on their label and possibly the satisfaction of conditions) until a fix-point is reached.

Edge walks. The metric by which we will judge the performance of a plan on the query evaluation task is that of the total number of *edge walks*. Every distinct tuple that is added to the queue during the search is considered one edge walk. Notice that a tuple that is added to the queue is an n-tuple with $n \geq 3$. A tuple contains at least a pair of nodes representing the end-points of a path and the state of the waveplan that produced this pair. Additionally, for a query $Q := x \xrightarrow{e} y$, a tuple can also contain up to k register values and up to l data values, where l is bounded by the number of sub-expressions of e of the shape $e_1[c]$. Hence $n \leq k + l + 3$.

Optimality of query plans. - Consider a pair of RQMs $Q := x \xrightarrow{e} y$ and $Q' := x \xrightarrow{t_e} y$. These queries are topologically equivalent (since t_e is the topology of e), but Q may contain assignments and conditions. Let P_Q and $P_{Q'}$ be sets of k-register waveplans for Q and Q', respectively. For every plan $p \in P_Q$ there exists a plan $q \in P_{Q'}$ such that $\lambda_p = \lambda_q$ because Q and Q' are topologically equivalent. Hence, we can construct a relation $R \subset P_Q \times \mathbb{N} \times P_{Q'} \times \mathbb{N}$ where $(p, n, q, m) \in R$ if and only if $\lambda_p = \lambda_q$ and be assured that there exists a tuple $r \in R$ for every $p \in P_Q$ such that p is part of r. The values n and m denote the total number of edge walks produced by p and q, respectively.

We can define sets $OPT_Q \subseteq P_Q$ and $OPT_{Q'} \subseteq P_{Q'}$ as

$$OPT_Q = \{\, p \mid \exists (p, n, q, m) \in R \wedge \forall (p', n', q', m') \in R : n \leq n' \,\} \tag{4}$$

$$OPT_{Q'} = \{\, q \mid \exists (p, n, q, m) \in R \wedge \forall (p', n', q', m') \in R : m \leq m' \,\} \tag{5}$$

That is, OPT_Q and $OPT_{Q'}$ are the sets of plans for Q and Q' that produce a minimal number of edge walks. We say that any $q \in OPT_{Q'}$ is *optimal with respect to topology*, and any $p \in OPT_Q$ is *optimal with respect to topology and data.*

We define a *simple* query Q as a query where

$$\forall (p, n, q, m) \in R \mid q \in OPT_{Q'} \Rightarrow p \in OPT_Q$$

which states that a simple query is one where optimality with respect to topology guarantees optimality with respect to topology and data.

We investigate the performance difference between a plan $p_2 \in OPT_Q$ and a plan $p_1 \notin OPT_Q$ for which there exists $(p_1, n_1, q_1, m_1) \in R$ such that $q_1 \in OPT_{Q'}$. Such an investigation will yield insights into the performance improvements that are neglected when query plan- and graph topology are assumed to be the determining factors in query performance.

To this end, we define a performance ratio between the edge walks produced by such plans p_1 and p_2. Formally, φ is defined over Q (from which R, OPT_Q and $OPT_{Q'}$ are derived) as

$$\varphi(Q) \begin{cases} \frac{n_1}{n_2}, & \text{if } \exists (p_1, n_1, q_1, m_1), (p_2, n_2, q_2, m_2) \in R \mid \\ & \quad q_1 \in OPT_{Q'} \wedge p_1 \notin OPT_Q \wedge p_2 \in OPT_Q \\ 1, & \text{otherwise} \end{cases} \tag{6}$$

Notice that $\varphi(Q) = 1$ if and only if Q is simple.

4 EXPERIMENTAL SETUP

In order to show that optimising k-register waveplans with respect to the topology of a query is orthogonal to optimising these plans with respect to the query's data constraints, we will construct a workload $\mathcal{W}$ consisting of pairs (Q, G) where Q is a regular path query with memory, and G is a data graph. We will count the number of pairs (Q, G) such that Q is *simple* on G, and investigate the average- and worst-case improvements in performance that are neglected when the topology of a query plan and graph are assumed to be the determining factors in query performance.

4.1 Query Pattern

The queries in $\mathcal{W}$ will be based on instances of the pattern:

$$((a\cdot \downarrow x_1.b)^+) \cdot c[x_1^=] \tag{7}$$

The motivation for the choice of this particular pattern is threefold:

(1) it contains interactions with data through a register (i.e. an assignment and condition) *inside* of a closure,
(2) it is simple in terms of the number of edge labels it contains and registers it uses, and
(3) its interactions with data apply to nodes that are neither:
  - part of the pairs in the result of the query evaluation problem, or
  - guaranteed to have the same data value associated with them

The first point is important because any pattern that does not interact with data at all, or does so only outside of closures can be modelled as a (C)RPQ [1], and is therefore not an example of the increased expressive power of RQMs. The second point is more practical in that it is possible to find many different instances of a pattern which contains few edge labels and uses few registers in real graph data. Thirdly, a pattern such as $(\downarrow x_1.a\cdot b\cdot c[x_1^=])^+$ would also satisfy the first two points. However, since all its interactions with data pertain to the data values in nodes that are either part of the pairs in the result of the query evaluation problem, or pertain to nodes that have the same data value associated with them (i.e. the nodes with an incoming edge labelled c and an outgoing edge labelled a in the closure), such queries are too selective in practice.

Seventeen concrete combinations of edge labels for a, b and c are obtained from the semantic knowledge graph Yago2s [2]. Example instances are:

- $(\texttt{isLocatedIn}\cdot \downarrow x_1.\texttt{dealsWith})^+ \cdot \texttt{hasCapital}[x_1^=]$
- $(\texttt{owns}\cdot \downarrow x_1.\texttt{isLocatedIn})^+ \cdot \texttt{hasCapital}[x_1^=]$
- $(\texttt{isLocatedIn}\cdot \downarrow x_1.\texttt{owns})^+ \cdot \texttt{isConnectedTo}[x_1^=]$

4.2 Data Graphs

A data graph $G = \langle V, E, \rho \rangle$ is extracted from the semantic knowledge base Yago2s. Yago2s consists of RDF-triples, derived from Wikipedia, WordNet and GeoNames [2].

Let U denote the set of all distinct subjects and objects in Yago2s' RDF-triples. Similarly, let Σ denote the set of all distinct predicates in Yago2s' RDF-triples. We identified $P \subset \Sigma$ as a set of 13 predicates such that for all triples (s, p, o) with $p \in P$ it holds that o is a numerical value. No other predicates in the Yago2s data set could be identified that co-occur with edge labels for (7) and have numerical values. The range of values over all objects o was categorized into three equally sized categories. Thus, the data domain for each $p \in P$ is set to $\{0, 1, 2\}$ where we interpret the data values 0, 1 and 2 as low, medium and high, respectively. Consider an RDF-triple (s, p, o) where $p \in P$. Let $\gamma(o) \in \{0, 1, 2\}$ denote the category that o was assigned to.

Since $|P| = 13$ but the data graph model only allows a single data value per node, we can construct multiple data graphs G_i from Yago2s. Note that the query pattern from (7) requires data values at the source of edges labelled b and at the target of edges labelled c. Hence, for all 13^2 pairs from $P \times P$ we construct a data graph G_i.

Let (q_1, q_2) be an arbitrary pair from $P \times P$. To construct G_i we:

- add a node v to V for every $u \in U$. Let $\eta(u) = v$ denote the node in G that corresponds to u;
- for every triple (s, p, o) with $p \in \Sigma - P$ we add $(\eta(s), p, \eta(o))$ to E;
- for every pair of triples $(s, p, o), (s, b, o')$ where $p \in P$ and b in some instance of (7) we set $\rho(\eta(s)) = \gamma(o)$;
- for every pair of triples $(s, p, o), (s', c, s)$ where $p \in P$ and c in some instance of (7) we set $\rho(\eta(s)) = \gamma(o)$;
- for every $v \in V$ where v is not yet in the domain of ρ we set $\rho(v) = 3$.

Thus the labelling alphabet of each G_i is $\Sigma - P$ and the set of data values $\mathcal{D}$ is $\{0, 1, 2, 3\}$. When checking equality for two data values $d_1, d_2 \in \mathcal{D}$, we will maintain that $d_1 = 3 \lor d_2 = 3 \Rightarrow d_1 \neq d_2$. That is, if neither of the data values were obtained from Yago2s we consider them unknown and therefore unequal.

4.3 Query Workload

The combination of 17 instances of query pattern (7) and the $13^2 = 169$ data graphs allows for a maximum workload size of $17 * 169 = 2873$. However, many of these combinations will yield empty result sets on the query evaluation problem because there existed no RDF-triples in Yago2s that produce data values from $\{0, 1, 2\}$ for the source- or target nodes of edges labelled b or c, respectively. Instead, the workload $\mathcal{W}$ consists of 579 distinct pairs of RQMs and data graphs where the combination of edge labels for a, b and c from $\Sigma - P$ and properties q_1 and q_2 from P resulted in at least one $v \in V$ where $\rho(v) \in \{0, 1, 2\}$.

5 RESULTS

Out of the 579 pairs of regular queries with memory and data graphs (Q, G) only 87 queries Q are simple on G (as shown in Table 1). Because a large majority of the queries is not simple we conclude that, for the given query pattern and data set, the topology of a data graph and RQM are not, by themselves, determining factors in the performance of query plans.

On average, k-register waveplans that are optimal with respect to topology (but not necessarily optimal with respect to data) produce close to 2.5 times the number of edge walks to evaluate a query as do those k-register waveplans that are optimal with respect to topology and data.

	simple	non-simple	total
# of queries	87	492	579
% of queries	15.03%	84.97%	100%

Table 1: The number- and percentage of simple and non-simple queries

	min	max	mean	std
$\varphi(Q)$	1.0	29.08	2.42	5.30

Table 2: A breakdown of the values for $\varphi(Q)$ over $\mathcal{W}$

Moreover, for the worst-case ratio $\varphi(Q)$ observed in $\mathcal{W}$, a plan that is optimal with respect to topology performed just over 29 times more edge walks than a plan for the same query, on the same graph, that is optimal with respect to topology and data. A breakdown of the minimum, maximum, mean and standard deviation of $\varphi(Q)$ over $\mathcal{W}$ is presented in Table 2.

A caveat to the results obtained in this way is the following; the evaluation procedure employs a time-out mechanism whereby a query plan that has produced more edge walks than the best performing (i.e. fewest edge walks producing) plan thus far for the same query is terminated, even if it has not yet completed its evaluation. Hence, the observed ratios are a lower-bound on the actual performance ratios.

We have presented evidence of the orthogonality that exists between optimising query plans for RQMs with respect to topology and data, showing that such optimization involves novel- and non-trivial challenges that go beyond finding an optimal join order for edge labels. Ignoring this orthogonality leads to significant decreases in performance, both on average and in worst-case scenarios.

6 CONCLUDING REMARKS

In our experimental study we found that (1) a large majority of queries is not simple, from which we can conclude that optimising for topology and data are orthogonal problems; (2) on average, plans that are optimal w.r.t. topology (but not necessarily w.r.t. data) perform 2.5 times worse than plans that are optimal overall; and, (3) plans that are optimal w.r.t.topology only can perform up to 29 times worse than plans that are optimal overall

Looking ahead, a main direction of future work is to continue our study of RQM query optimization in the context of a fully-fledged property graph query engine.

ABSTRACT

Demand forecasting, which aims to predict future product sales, is one of the most important tasks in retail markets. With the help of time series prediction models, the literature works either perform the prediction of each individual product item separately, or adopt a multivariate time series forecasting approach. However, none of them leveraged the structural information of product items, such as product brands and multi-level categories. Moreover, various product items have significantly different temporal characteristics, such as periodicity. In this short paper, we propose a deep learning-based prediction model to find inherent inter-dependencies and temporal characteristics among product items for more accurate prediction. Evaluation on two real-world datasets validates that our model can achieve much higher accuracy compared with state-of-the-art methods.

1 INTRODUCTION

Demand forecasting, which aims to predict future product sales, is one of the most important tasks in retail markets. The accurate prediction is important to avoid either insufficient or excess inventory in product warehouses for a typical retail market which typically sells at least thousands of product items.

Traditional works adopt either univariate time series models or multivariate time series model. The univariate time series models, such as the autoregressive integrated moving average (ARIMA) [1], autoregression (AR) [1], moving average (MA) [1] and autoregressive moving average (ARMA) [1], treat different product items separately. ARIMA is rather time consuming especially when there are thousands of products or more. In addition, ARIMA assumes that the current value of time series is a linear combination of historical observations of itself and a random noise. It is hard for ARIMA to capture non-linear relationships and inter-dependencies of different product items. Some machine learning models can also be applied to demand forecasting problems, such as linear regression [11] and linear support vector regression (SVR) [2]. Nonetheless, these machine learning models suffer from the similar weaknesses as ARIMA [15].

Multivariate time series models instead take into account the inter-dependencies among product items. For example, as an extension of ARIMA, vector autoregression (VAR) [9] can handle multivariate time series. However, the model capacity of VAR grows linearly over temporal window size and quadratically over the number of variables, making it hard to model thousands of product items with a long history. More recently, deep learning models have demonstrated outstanding performance in time series forecasting problems. There are basic recurrent neural network (RNN) [5] and its variants including long short-term memory (LSTM) network [10] and gated recurrent unit (GRU) [4]. On this basis, a recent work LSTNet [7] combines convolutional neural network (CNN) [8] and GRU to perform multivariate time series forecasting. The LSTNet model uses a special recurrent-skip component to capture very long-term periodic patterns. However, it assumes that all variables in the multivariate time series have same periodicity, which is invalid for most real datasets.

Other than the aforementioned weaknesses, the existing prediction methods ignore that product items have inherent structural information, e.g., the relations between product items and brands, and the relations among various product items (which may share the same multi-level categories). Our work is motivated by a clustering algorithm [3] to segment product items with help of a so-called *product tree*. This tree structure takes product categories as internal nodes and product items as leaf nodes. Beyond that, we extend the product tree by incorporating product brands and then construct a *product graph* structure. This structure explicitly represents the structural information of product items. Figure 1 illustrates an example of the graph structure of four product items. We can easily find that the brand *Master Kong* has three products, which belong to two different subcategories. Consider that a customer prefers the brand *Master Kong* and recently bought a product item *Master Kong Jasmine Tea*. It is reasonable to infer that he will try another product item *Master Kong Black Tea*, especially when *Master Kong Black Tea* involves a sale promotion campaign.

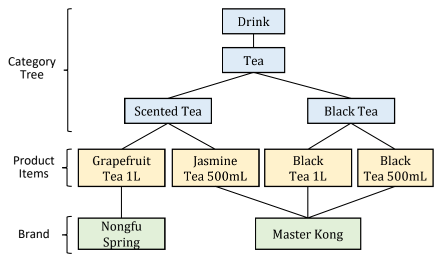

Figure 1: An example of Product Graph Structure involving Categories, Items and Brands.

Without the product graph structure as prior, previous methods either treat all product items equally or have to implicitly infer the inherent relationship but at the cost of accuracy loss. To overcome the issues, with help of the graph structure, we propose a new deep learning model to precisely predict product demands in a multivariate time series forecasting manner, called Structural Temporal Attention Network (STANet). This network incorporates both the product graph structure (see Figure 1) and temporal characteristics of product items. In particular, we note that the inter-dependencies of products and temporal dependencies (e.g., temporal periodicity) may change over time. Thus, we leverage attention mechanism [12] to deal with these variations. In this way, STANet assigns various weights with respect to different inputs involving the variations. Based on graph attention network (GAT) [13], GRU, and a special temporal attention, STANet performs better than existing methods. As a summary, we make the following contributions.

- We give adequate analysis on two real datasets to validate the motivation of our model, including the product structural inter-dependencies and temporal dependencies.
- The proposed STANet leverages GAT to capture the product structural inter-dependencies and GRU to capture temporal patterns. Moreover, a temporal attention mechanism is adopted on the hidden states of GRU to deal with diverse temporal characteristics of product items. Thus, the two attention mechanisms, i.e., GAT and temporal attention, work together to comfortably learn the product structural inter-dependencies and temporal dependencies.
- Evaluations on two real-world sales datasets show that STANet achieves the best results compared with several state-of-the-art methods.

The rest of this paper is organized as follows. Section 2 gives the problem formulation, and Section3 describes the proposed approach STANet. Then, Section 4 reports evaluation results on two real-world datasets. Finally, Section 5 concludes the paper.

2 PROBLEM FORMULATION

We consider a data set of transaction records in a market. Each transaction record contains 3 fields: the transaction timestamp, item ID, and amount of sold items. Moreover, via the item ID, we can find a list of product categories (in our dataset, each product item is with a list of 4-level categories) and an associated product brand. In this way, we augment each transaction record by totally 8 (=3+4+1) fields. Given a certain time horizon (e.g., one day or one week), we pre-process the transaction records into a multivariate time series of the volumes of sold product items. In addition, for a certain category (or brand), we sum the volumes of all product items belonging to the category (or brand). In this way, we have the multivariate time series of the volumes of product items, categories, and brands. Meanwhile, the product graph structure is stored in an adjacency matrix, where an element 1 indicates an edge between two nodes (such as a product item and its brand), otherwise 0.

Formally, we denote the number of product items by N_p and the total number of items, brands and categories as N. Given the augmented multivariate time series $X = \{\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_T\}$, $\boldsymbol{x}_t \in \mathbb{R}^{N\times 1}$, $t = 1, 2, \ldots, T$ and adjacency matrix $M \in \mathbb{R}^{N\times N}$, we aim to predict future product sale volume $\boldsymbol{x}_{T+h}$ where h is the desirable horizon ahead of the current time stamp. More specifically, to train a model using historical data, we use a time window of size τ to split existing data into fixed length inputs, where each input is expressed as $\{\boldsymbol{x}_t, \ldots, \boldsymbol{x}_{t+\tau-1}\}$ and $\boldsymbol{x}_{t+\tau-1+h}$ is the label. The adjacency matrix M is fixed. In this way, the demand forecasting problem is equivalent to learning a function $f_M : \mathbb{R}^{N\times\tau} \to \mathbb{R}^{N\times 1}$. On the testing stage, we only need to calculate evaluation metric for the N_p real product items.

3 FRAMEWORK

In this section, we present the detail of the proposed model STANet. Figure 2 gives the framework of STANet.

3.1 Graph Attention Component

For multivariate time series forecasting, one of the most crucial tasks is to capture the inter-dependencies between different variables. What's more, as shown in Section 4.1, the inter-dependencies may change over time. To explore inter-dependencies

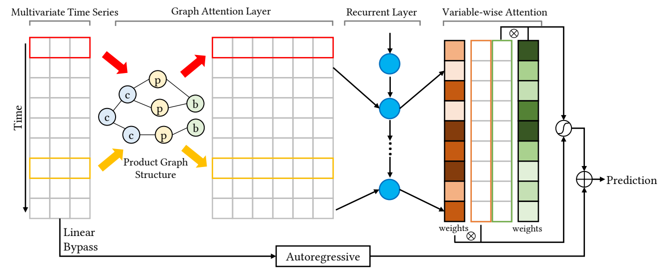

Figure 2: The framework of STANet.

from product graph structure, we need graph neural network. Furthermore, to handle dynamic inter-dependencies, we choose attention mechanism because it can assign various weights with respect to different inputs. As a result, the first layer of STANet is a graph attention layer [13]. Given the input time series $X \in \mathbb{R}^{N\times\tau}$ and adjacency matrix $M \in \mathbb{R}^{N\times N}$, we use a multi-head graph attention layer to process X time step by time step. Formally, this operation at time step t is given by

$$\boldsymbol{h}_t^i = \sigma\left(\frac{1}{K}\sum_{k=1}^{K}\sum_{j\in\mathcal{N}_i}\alpha_{ij}^k W^k x_t^j\right), \tag{1}$$

where x_t^j is the sale of variable (product, or brand, or category) j at time step t, W^k is a linear transformation to obtain sufficient expressive power, $\mathcal{N}_i$ refers to all the adjacent nodes of variable i given by M, K is the number of multi-head attention and σ is an activation function. α_{ij}^k is the coefficient of attention mechanism computed by

$$\alpha_{ij}^k = \frac{exp\left(LeakyReLU\left(f_a\left(W^k x_t^i, W^k x_t^j\right)\right)\right)}{\sum_{\ell\in\mathcal{N}_i} exp\left(LeakyReLU\left(f_a\left(W^k x_t^i, W^k x_t^\ell\right)\right)\right)}, \tag{2}$$

where f_a is a scoring function to evaluate relevance, and in our model it is a single-layer feedforward neural network.

Suppose $W^k \in \mathbb{R}^{F\times 1}$, with aforementioned X and M, the output of the graph attention component is $X_G \in \mathbb{R}^{FN\times\tau}$.

3.2 Recurrent Component

When the variable-to-variable relationships have been processed, X_G is fed into the recurrent component to capture temporal patterns. Here we use gated recurrent unit (GRU) [4] as the recurrent layer. Compared with vanilla recurrent neural networks (RNN) [5], GRU is more capable to capture long-term patterns. Suppose the hidden size of GRU is d_r, then the output of recurrent component is $X_R \in \mathbb{R}^{d_r\times\tau}$.

3.3 Variable-Wise Temporal Attention

After the graph attention component and recurrent component, the model has successfully captured inter-dependencies and basic temporal patterns. Nonetheless, temporal patterns could also be dynamic. Therefore, as a commonly used technique in RNN, temporal attention can be added to the model as

$$\boldsymbol{\alpha}_{t+\tau-1} = f_a\left(H_{t+\tau-1}, \boldsymbol{h}_{t+\tau-1}\right), \tag{3}$$

where $\boldsymbol{\alpha}_{t+\tau-1} \in \mathbb{R}^{\tau\times 1}$, f_a is a scoring function and $\boldsymbol{h}_{t+\tau-1}$ is the last hidden state of RNN, $H_{t+\tau-1} = [\boldsymbol{h}_t, \ldots, \boldsymbol{h}_{t+\tau-1}]$ is a matrix stacking the hidden states of RNN.

However, we will show in Section 4.1 that various products may have rather different temporal characteristics such as periodicity. Instead of using the same attention mechanism for all product items, we propose a variable-wise temporal attention

Table 1: Datasets statistics, where T is length of time step, P is the time interval, N_p, N_b, N_c are numbers of products, brands, categories respectively, $N = N_p + N_b + N_c$, and sparsity means proportion of zero value in the data.

Datasets	T	P	N_p	N_b	N_c	N	Sparsity
Dataset-1	572	1 day	1878	433	612	2923	53%
Dataset-2	833	1 day	1925	289	771	2985	39%

mechanism to compute the attention for each variable independently as

$$\alpha^i_{t+\tau-1} = f_a\left(H^i_{t+\tau-1}, h^i_{t+\tau-1}\right). \tag{4}$$

Equation (4) is similar to Equation (3), except a superscript $i = 1, 2, \ldots, d_r$, indicating that the attention mechanism is calculated for a particular GRU hidden variable. In this way, our model could deal with different temporal characteristics such as periodicity for different variables. With the coefficients $\boldsymbol{\alpha}^i_{t+\tau-1}$, the weighted context vector of i^{th} hidden variable is calculated as

$$c^i_{t+\tau-1} = H^i_{t+\tau-1}\alpha^i_{t+\tau-1}, \tag{5}$$

where $H^i_{t+\tau-1} \in \mathbb{R}^{1\times\tau}$ and $\boldsymbol{\alpha}^i_{t+\tau-1} \in \mathbb{R}^{\tau\times 1}$. Let $\boldsymbol{c}_{t+\tau-1}$ be context vector of all hidden variables, then we can calculate the final output for horizon h as

$$\boldsymbol{y}_{t+\tau-1+h} = W\left[\boldsymbol{c}_{t+\tau-1}; \boldsymbol{h}_{t+\tau-1}\right] + b, \tag{6}$$

here $W \in \mathbb{R}^{N\times 2d_r}$ and $b \in \mathbb{R}^{1\times 1}$ are parameters of a fully connected layer.

3.4 Autoregressive Component

Similar to LSTNet [7], we add an autoregressive component to capture the local trend of product demands. This component is a linear bypass that predicts future demands directly from the input data to address the scale problem. This linear bypass will fit all products' historical data with a single linear layer.

The final prediction of STANet is then obtained by integrating the outputs of the neural network part and the autoregressive component using an automatically learned weight.

4 EXPERIMENTS AND EVALUATIONS

We first analyze two used real-world datasets to motivate STANet and then compare STANet against 6 counterparts.

4.1 Datasets and Analysis

We use two real-world datasets collected from two medium size stores of a chain retail in Shandong Province, China. Table 1 summarizes the statistics. As shown in this table, the sparsity of dataset-1 is greater than 50%, which makes the forecasting task rather challenging. Both datasets are split into training set (70%), validation set (15%) and testing set (15%) in chronological order. To explore the inter-dependencies and temporal characteristics of datasets, we give following analysis.

We consider two variables have inter-dependencies if the history of one variable can help forecasting another. Assuming two univariate time series $\boldsymbol{x} = x_1, x_2, \ldots, x_T$, $\boldsymbol{y} = y_1, y_2, \ldots, y_T$ and a specific time lag m, we model $\boldsymbol{y}$ as a regression of itself and $\boldsymbol{x}$:

$$y_t = a_0 + a_1 y_{t-1} + \ldots + a_m y_{t-m} + b_1 x_{t-1} + \ldots + b_m x_{t-m}. \tag{7}$$

If $\boldsymbol{y}$ gets the best fitting when all $b_i = 0$ for $i = 1, \ldots, m$, we believe that $\boldsymbol{x}$ cannot help forecasting $\boldsymbol{y}$. To test whether $\boldsymbol{x}$ can help forecast $\boldsymbol{y}$, we use the Granger causality test [6], and for each lag m the result maybe differ. We use

$$GR_{\boldsymbol{x},\boldsymbol{y}} = \frac{number\ of\ m\ where\ \boldsymbol{x}\ helps\ forecast\ \boldsymbol{y}}{total\ number\ of\ m} \tag{8}$$

to represent importance of $\boldsymbol{x}$ to $\boldsymbol{y}$, $GR_{\boldsymbol{x},\boldsymbol{y}} \in [0, 1]$. We select one category and two concrete products to verify the inter-dependencies in Figure 3.

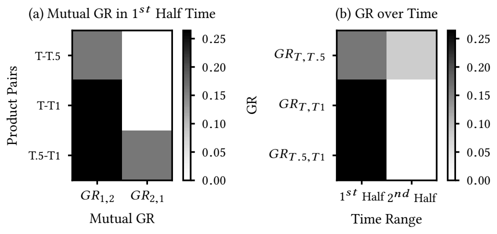

Figure 3: GR among three variables, where $T.5$ is the product item "Black Tea 500mL", $T1$ is the item "Black Tea 1L" and T is the category "black tea". Time range is split into two parts. (a) Mutual GR of three pairs. (b) Change of dependencies over time.

From Figure 3(a), we can find that $GR_{T,T.5}$ and $GR_{T,T1}$ are quite darker while $GR_{T.5,T}$ and $GR_{T1,T}$ are almost white. This figure means that the historical data of the category "black tea" helps forecasting the demand of its children and instead the children's history data is trivial to the forecast of their parent category. $GR_{T.5,T1}$ and $GR_{T1,T.5}$ involve the different degree of darkness. It means that $GR_{T.5,T1}$ can improve the forecast of $GR_{T1,T.5}$ and vice versa. However, the improvement degree is not identical. Figure 3(b) shows that the inter-dependencies is dynamically changing over time.

To verify that various variables have different temporal characteristics, we use Fast Fourier Transform (FFT) to plot the periodogram [14] for the category "black tea" and its two children product items in Figure 4. We can easily find that they have rather different periodicity at the rectangles. Thus, we cannot simply apply the same attention onto all variables.

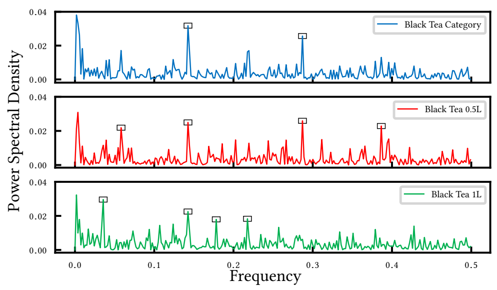

Figure 4: Periodogram of one category and two products. The rectangles highlight points for periodicity candidates.

4.2 Methods and Metric

We compare our model with five other methods, and their variants. For AR, Ridge and LSVR, we train models for each product separately, while neural network models take multivariate data as input directly.

- AR [1]: A classic univariate time series modeling method.
- Ridge [11]: Linear regression with $\ell 2$ regularization.
- LSVR [2]: Linear SVR, another machine leaning method for regression.

Table 2: RSE of six methods and their variants on two datasets: boldface indicates the best result on each dataset.

Methods	Dataset-1	Dataset-2
AR [1]	0.8016	0.5313
Ridge [11]	0.7981	0.5628
LSVR [2]	3.2446	7.8246
GRU [4]	0.8535	0.9067
LSTNet [7]	0.7907	0.7570
LSTNet-IAttn	0.8230	0.5399
STANet	**0.7783**	**0.5233**
STANet-oStructure	0.8907	0.6179
STANet-oCategory	0.8256	0.5569
STANet-oBrand	0.8640	0.5471
STANet-oAR	0.8327	0.8850

- GRU [4]: Recurrent neural network using GRU cell.
- LSTNet [7]: A state-of-the-art model composed of CNN, GRU and highway network.
- LSTNet-IAttn: LSTNet improved by the variable-wise temporal attention.
- STANet-oStructure: STANet without structural information.
- STANet-oCategory: STANet without category information.
- STANet-oBrand: STANet without brand information.
- STANet-oAR: STANet without autoregressive component.

We measure the forecasting performance by root relative squared error (RSE).

$$RSE = \frac{\sqrt{\sum_{i=1}^{N}\sum_{t=t_0}^{t_1}\left(y_{i,t} - \hat{y}_{i,t}\right)^2}}{\sqrt{\sum_{i=1}^{N}\sum_{t=t_0}^{t_1}\left(y_{i,t} - mean(Y)\right)^2}}, \tag{9}$$

where y and $\hat{y}$ are ground truth and predicted value respectively, t_0 and t_1 are start and end time of testing set, and $Y \in \mathbb{R}^{N\times(t_1-t_0)}$ represents the matrix of all labels y in testing set. RSE can be regarded as RMSE divided by standard deviation of testing set, so scale differences between different datasets can be ignored. Lower RSE generally means better forecasting performance.

4.3 Results of Different Methods

Table 2 provides the RSE of aforementioned methods on two datasets for horizon = 1. Our proposed model STANet outperforms others on both datasets. It is because STANet leverages the attention mechanism and inherent product structural information to precisely capture structural and temporal dependencies. LSVR performs worst on both datasets. Vanilla GRU suffers from worse performance than univariate models, because not every product has inter-dependency with each other and simply adding irrelevant data would harm the forecasting task. LSTNet can achieve lower errors than AR and Ridge on dataset-1, but not on dataset-2. It is mainly because the product items in dataset-1 exhibit much stronger structural inter-dependencies than those in dataset-2. For most methods except LSVR and GRU, the RSE on dataset-2 is much lower than that on dataset-1. It is due to the fact that dataset-1 contains much sparser data than dataset-2.

In terms of the ablation experiments of STANet, we can find that the structural information and the AR component play the major contribution in the forecasting task. For example, the result of STANet-oStructure indicates that the removal of structural information could greatly harm the forecasting accuracy. Incorporating the brand and category information will benefit the forecast and their corresponding contribution heavily depends upon the datasets. Both parts work together to the best performance. Also the results of STANet-oAR without the AR component indicate that its RSE is much higher than the original STANet especially on dataset-2. This is because the AR component can more comfortably capture the local trend in dataset-2 with a lower sparsity than the one in dataset-1. Finally, by comparing the results of LSTNet and LSTNet-IAttn, we find that LSTNet-IAttn by incorporating the variable-wise attention mechanism can greatly improve the forecast performance on dataset-2.

5 CONCLUSIONS

In this paper, we propose a novel deep learning-based forecasting model STANet in a multivariate time series manner. The model integrates the four components of GAT, GRU, variable-wise attention mechanism and auto-regression to precisely capture the inherent product structural information and temporal periodicity for more accurate prediction. Our analytic result on two real datasets demonstrates that the two real datasets exhibit strong product structural information and temporal periodicity. The evaluation result on the two datasets validates that STANet outperforms 6 counterparts and 4 variants of STANet. As the future work, we plan to further improve STANet and provide more experimental results on both online and offline transaction data.

ABSTRACT

We present a dimension indexing based algorithm for skyline computation. We first show that the dominance tests required to determine a skyline tuple can be sufficiently bounded to a subset of the current skyline, and then propose the algorithm SDI, of which the time complexity is better than the best known algorithm in high-dimensionality domains with reasonably low cardinality. Our performance evaluation on synthetic and real datasets shows that SDI outperforms the state-of-the-art skyline algorithm in both low-dimensionality and high-dimensionality domains.

1 INTRODUCTION

The *skyline computation problem* aims at retrieving the complete set of dominating tuples from multidimensional data, with respect to a monotonic *preference order* on all dimensions. Over several past decades, many algorithms have been developed, which can be categorized into sorting based [1, 4, 6, 7, 14] and partitioning based [2–4, 8–13, 15]. Most the existing skyline algorithms have been designed for low-dimensionality domains because of the quadratic issue raised by the worst case time complexity.

In this paper, we present a dimension indexing based skyline algorithm SDI (Scalable Dimension Indexing) that is efficient in high-dimensionality domains as well as in low-dimensionality domains. We show that by indexing all dimensions, it is sufficient to test a tuple only with the existing skyline tuples on an arbitrary dimension instead of with the complete set of skyline tuples. We also show that any skyline tuple can be used as a *stop line* that traverses the indexed dimensions to stop the computation, which is much performant than the calculation of *stop point* mentioned in SaLSa [1]. Furthermore, SDI adopts the *weak incomparability checking* to take the incomparability between tuples into account, which is the most important feature of the state-of-the-art skyline algorithm BSkyTree [10]. Our analysis shows that the worst time complexity of SDI is better than the best known one [13] in high-dimensionality domains with reasonably low cardinality, and our performance evaluation shows that SDI outperforms BSkyTree on both low and high dimensional data, but less efficient than BSkyTree on medium dimensional data.

The rest of this paper is organized as follows. Section 2 presents the SDI algorithm with preliminary definitions. We show our theoretical analysis of the computational complexity of SDI in Section 3. Section 4 reports the performance evaluation of SDI on both synthetic and real datasets. We conclude in Section 5.

2 THE SDI APPROACH

Let t be a d-dimensional tuple, we denote $t[i]$ the *dimension value* of t on the dimension i, where $1 \leq i \leq d$. We define the *preference order*, denoted by $\prec$, as a total order that covers each dimension such that given two tuples t and u, $t[i]$ is *better than* $u[i]$ if $t[i] \prec u[i]$; $t[i]$ is *equal to* $u[i]$ if $t[i] = u[i]$; $u[i]$ is *not worse* than $t[i]$ if $(t[i] \prec u[i]) \vee (t[i] = u[i])$ holds, denoted by $t[i] \preceq u[i]$. We say that a tuple t *dominates* a tuple u, denoted by $t \prec u$, if and only if for each dimension i, we have $t[i] \preceq u[i]$, and for at least one dimension k we have $t[k] \prec u[k]$. We denote $t \not\prec u$ that t does not dominate u, and $t \nsim u$ that t and u are *incomparable*, that is, $(t \not\prec u) \wedge (u \not\prec t)$. Considering a d-dimensional database $\mathcal{D}$ and a preference order $\prec$ on $\mathcal{D}$, a tuple $t \in \mathcal{D}$ is a *skyline tuple* if and only if $\nexists u \in \mathcal{D}$ such that $u \prec t$. The *skyline* of $\mathcal{D}$ is the complete set $\mathcal{S}$ of skyline tuples such that $\mathcal{S} = \{t \in \mathcal{D} \mid \nexists u \in \mathcal{D}, u \prec t\}$. We have $s \nsim t$ for any two skyline tuples s and t.

Given a database, the *dimension index*, denoted $\mathcal{I}$, is the set of d ordered lists on a preference order $\prec$, in which each list $I_i \in \mathcal{I}$ is a *dimensional subindex* that contains all dimension values sorted with respect to $\prec$.

(a) (h) (i) (e) (g)
■ Skyline □ Non skyline

Figure 1: A dimension index example.

Let us consider the 5 tuples $\{a, e, g, h, i\}$ presented in Figure 1 that shows a dimension index example consisting of 10 tuples and 6 subindexes, where the dashed lines link the tuple among the subindexes. Obviously, a is a skyline tuple, which can be independently concluded from I_1, I_2, and I_6 because no tuple can dominate a; if we regard only I_4, h is immediately a skyline tuple and in order to determine whether i, the second tuple in this subindex, is a skyline tuple, it is enough to compare i with h because any tuple x located after the position of i in I_4 cannot dominate i since we have $i[4] \prec x[4]$ in I_4. Nevertheless, if we focus on I_3, we see that $h \prec i$ and $i \prec h$ must be first tested in order to decide whether h or/and i shall be skyline tuple(s) since $h[3] = i[3]$ (indeed we have $h \prec i$ and $i \not\prec h$). That is also the case in I_6, where 3 tuples contain the same dimension value 0.15, so all these 3 tuples must be first locally compared in order to filter the potential skyline tuples (in our example, e). We call such tuples as h in I_3 and e in I_6 the *local skyline tuple*. It is easy to see that any tuple is a local skyline tuple on a given dimension if there are no identical dimension values.

Theorem 1. *Let $\mathcal{I}$ be the dimension index of a database $\mathcal{D}$ and $I_i \in \mathcal{I}$ be an arbitrary subindex of the dimension i. Then, a local* *skyline tuple t is a skyline tuple if and only if (1) there is no tuple u such that $u[i] \prec t[i]$, or (2) for any skyline tuple s such that $s[i] \prec t[i]$, we have $s \not\prec t$.*

Proof. Let t be a local skyline tuple. If t is the first tuple in I_i, then t is a skyline tuple because no tuple is better than t. Otherwise, let s be a skyline tuple such that $s[i] \prec t[i]$, then if $s \prec t$, t cannot be a skyline tuple since s dominates t; if $s \not\prec t$, then there exists at least on dimension $k \neq i$ such that $t[k] \prec s[k]$ so no tuple dominated by s dominates t. Hence, for each skyline tuple s such that $s[i] \prec t[i]$, if we have $s \not\prec t$, then no tuple in the database dominates t, thus, t is a skyline tuple. If $t[i] \prec s[i]$, then $s \not\prec t$ so it is meaningless to compare t with s. □

Theorem 1 allows to determine whether a tuple is a skyline tuple only with a subset of the existing skyline. Furthermore, once the dimension index has been constructed, Theorem 1 allows to switch among subindexes so that the best one containing the least of known skyline tuples can always be selected. Indeed, let p be a skyline tuple, then any tuple t such that $p \prec t$ can be pruned from the database in order to reduce the computation time. In this paper, we propose the notion of stop line based on the dimension index of which the effectiveness can be guaranteed.

Theorem 2. *Let $\mathcal{I}$ be a dimension index of a d-dimensional database $\mathcal{D}$ and $p \in \mathcal{D}$ be an arbitrary skyline tuple. Let $o_i(p)$ denote the largest offset of any tuple x such that $x[i] = p[i]$ in the dimensional subindex $I_i \in \mathcal{I}$, if all offsets $o_i(p)$, $1 \leq i \leq d$, have been reached by following a top-down traversal on all dimensions, then the complete set of skyline tuples has been identified and the computation can be terminated.*

Proof. Let p and $t \in \mathcal{D} \backslash p$ be two skyline tuples in $\mathcal{D}$, we have: (1) $t \nsim p$; or (2) t and p have identical values on all dimensions. We denote $L_p = \bigcup_{1 \leq i \leq d} o_i(p)$ the set of all offsets $o_i(p)$. In the first case, $t \nsim p \Rightarrow \exists k$ such that $p[k] \prec t[k]$, i.e. $o_k(p) < o_k(t)$, hence, if the index traversal reaches all offsets in L_p, t must have been identified at least in the dimension k. In the second case, we have $p[i] = t[i]$ on any dimension i. In both cases, if all offsets in L_p have been reached, all skyline tuples have been identified. □

We call the set $L_p = \bigcup_{1 \leq i \leq d} o_i(p)$ a *stop line* that can safely terminate the skyline computation of SDI. In theoretical, any skyline tuple can be selected as a stop line, however, different stop lines behave differently in pruning irrelevant tuples. We propose therefore a function min_{stop} to find the best stop line L_p^*, defined as:

$$L_p^* = min_{stop}(p) = \arg\min_p (max\{o_i(p)\}, \sum_{i=1}^{d} o_i(p)),$$

where d is the dimensionality of the data. The function min_{stop} sorts first by the maximum offset, then by the sum of offsets in all dimensions, so the skyline tuple having the minimized value is the best stop line. The best stop line L_p can be dynamically maintained by keeping $min_{stop}(p) < min_{stop}(t)$ for any two skyline tuples p and t.

The *incomparability checking* is taken into account while a dominance test is proceeding. In our approach, we consider that a d-dimensional dominance test runs in $O(d)$ time, so any tuple comparison better than $O(d)$ time shall improve the efficiency of SDI. Indeed, to efficiently determine $s \nsim t$ in stead of testing $s \prec t$ in the case of $s \not\prec t$ is an essential time-costly task while comparing t with all existing skyline tuples in a dimensional subindex. In this paper, we propose a *weak* checking mechanism of the incomparability between a skyline tuple s and a testing tuple t in a dimensional subindex I_i as following.

Theorem 3. *Let $\mathcal{I}$ be a dimension index and s be a skyline tuple present in a dimensional subindex $I_i \in \mathcal{I}$. Given a tuple t such that $s[i] \prec t[i]$, we sufficiently have $s \nsim t$ if $max(s) > max(t)$, or $min(s) > min(t)$, or $sum(s) > sum(t)$.*

Proof. The sets L_s and L_p (see the proof of Theorem 2 for the definition) can be considered as the coordinates of two curves in a two-dimensional space. In Euclidean geometry, $max(s) > max(t)$, or $min(s) > min(t)$, or $sum(s) > sum(t)$ are sufficient conditions for the existence of at least one intersection of the curves formed by s and t since we have $s[i] \prec t[i]$, i.e. $o_i(s) < o_i(t)$, that is, according to the definition of dominance, $s \nsim t$. □

Note that the maximal value, the minimal value, and the sum of a tuple can be pre-calculated while constructing the dimension index, so Theorem 3 can efficiently determine $s \nsim t$. However, Theorem 3 shows in fact 3 sufficient conditions for $s \nsim t$, hence a dominance test is necessary to determine $s \nsim t$ in the cases that are not covered by Theorem 3, for which we call Theorem 3 a weak incomparability checking. The sketch of SDI is listed in Algorithm 1.

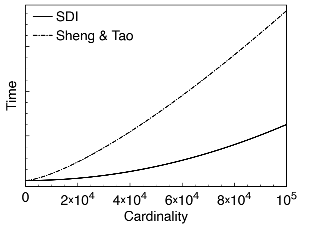
Algorithm 1: SDI

```
   Input: Dimension index $\mathcal{I}$
   Output: Skyline $\mathcal{S}$
1  while true do
2      $I_{best} \leftarrow BestSubindex(\mathcal{I})$
3      while $T \leftarrow NextLocalSkyline(I_{best})$ do
4          if $T = null$ then
5              return $\mathcal{S}$
6          foreach $t \in T$ and $t \notin \mathcal{S}$ do
7              if $\mathcal{S}_{best} \not\prec t$ then
8                  $\mathcal{S}_{best} \leftarrow \mathcal{S}_{best} \cup t$
9                  $\mathcal{S} \leftarrow \mathcal{S} \cup t$
10         if Found new skyline tuples then
11             Update StopLine
12             break
13     if StopLine is reached then
14         return $\mathcal{S}$
```

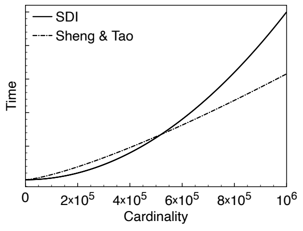
Extensions. (1) SDI computes the skyline in the categorical domains as long as the preference order $\prec$ can be defined; (2) SDI can be immediately adapted to subspace skyline computation by skipping unrelated dimensions; (3) SDI can be extended to the skyline maintenance by dynamically constructing the dimension index; (4) SDI can handle the top-k skyline query by finding the skyline tuples having the best positions in the dimension index.

3 THEORETICAL ANALYSIS

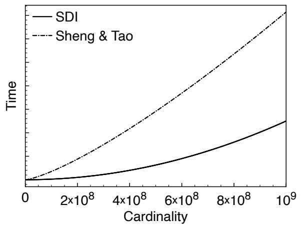
We denote d the dimensionality and N the cardinality of the data, and M the size of the skyline. We discuss without duplicate values on any dimension, but if K duplicate values are present in a dimensional subindex, $O(dK^2)$ shall be considered in assuming that BNL is applied to compute local skylines. Note that we consider $O(d)$ time for a d-dimensional dominance test, which implies the tests of $s \prec t$ and $t \prec s$, hence, the dominance test



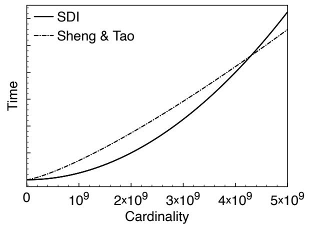
(a) $d = 6, N = 1 \times 10^5$.



(b) $d = 6, N = 1 \times 10^6$.



(c) $d = 8, N = 1 \times 10^9$.



(d) $d = 8, N = 5 \times 10^9$.

Figure 2: Numerical simulation for complexity study in the worst case.

within SDI is considered in $O(d/2)$ time since $s < t$ is sufficient. We also note that the construction of dimension index requires $O(dN \log N)$ time with respect to general $O(N \log N)$ sorting algorithms on d dimensions, and we do not consider the two heuristics of stop line and incomparability checking.

The average time complexity of SDI is measured on M skyline tuples uniformly distributed in d dimensional subindexes.

Theorem 4. *Considering M skyline tuples, SDI computes the skyline of a d-dimensional database with the cardinality N in*

$$O(dN \log N + \frac{M(2N - M - d)}{4}).$$

Proof. With M skyline tuples uniformly distributed on each dimension, $(N - M)/d$ non skyline tuples must be compared with M/d skyline tuples. For each dimension, in the worst case, $(M/d)(M/d - 1)/2$ dominance tests are required by skyline tuples, $((N - M)/d)(M/d)$ dominance tests are required by non skyline tuples, and each dominance test cost $O(d/2)$ time. Therefore, the average time complexity of SDI is $O(((M/d)(M/d - 1)/2 + ((N - M)/d)(M/d))(d/2)d)$, that is the result shown in Theorem 4. □

Theorem 5. *In the worst case, all N tuples in a d-dimensional database are skyline tuples. SDI computes the skyline in*

$$O(dN \log N + \frac{N^2 - dN}{4}).$$

Proof. The proof is immediate if we replace M in Theorem 4 by N. □

Comparing with the best known worst-case time complexity $O(N \log^{max(1,d-2)} N)$ proposed by Sheng and Tao [13], given $d > 2$, the following equation must be resolved:

$$N \log^{d-2} N > dN \log N + \frac{N^2 - dN}{4}.$$

The above equation belongs to transcendental equations that have no closed-form solutions. Our numerical simulation results presented in Figure 2 shows that while $d = 6$, SDI is better than the approach of Sheng and Tao for $N < 5 \times 10^5$; and while $d = 8$, the compared approach beats SDI only if $N > 4 \times 10^9$. SDI performs better in high-dimensionality domains with respect to a reasonable data cardinality.

4 PERFORMANCE EVALUATION

We evaluate the performance of SDI in comparison with BSkyTree implemented in SkyBench[1] [5] on both synthetic datasets and real world datasets. The synthetic datasets are generated by Skyline Benchmark Data Generator[2], including uniform independent (UI), correlated (CO), and anti-correlate (AC) data; the real world datasets include NBA, HOUSE, and WEATHER [5]. We implemented SDI[3] in C++ standard and all executables are compiled by LLVM Clang with -O3 option. All experiments have been conducted on an Intel Core i5 2.8 GHz processor with 16GB 1600 MHz DDR3 RAM, running macOS 10.15.1 operating system. We note that all results reported are the average performance over 5 iterations.

First, the effects of **(1) dimensionality** and **(2) cardinality** of data have been evaluated. For (1), the cardinality is fixed to 100K and for (2), the dimensionality of data is fixed to 24. Due to the space limitation, only overall elapsed time, that is, the sum of data loading time, data structure construction time, and query time, has been reported in this paper. Indeed, we consider that for single-round skyline queries, to focus on total processing time is much important than to focus only on the query time without looking at data structure building time.

Dataset	$d = 2$	$d = 4$	$d = 6$	$d = 8$	$d = 10$	$d = 12$
UI	7	259	2,597	9,960	25,737	46,301
CO	1	5	31	120	449	790
AC	50	4,100	26,713	56,118	75,668	87,857
Dataset	$d = 14$	$d = 16$	$d = 18$	$d = 20$	$d = 22$	$d = 24$
UI	67,676	82,286	92,011	96,832	99,059	99,662
CO	1,439	2,941	5,471	8,936	14,498	16,948
AC	94,053	96,956	98,413	99,205	99,570	99,760

Table 1: Skyline size of synthetic datasets (N = 100K).

Table 1 lists the skyline size of synthetic datasets with the cardinality of 100K. We see that the higher the dimensionality of data, the closer to the worst case is likely to be. For instance, the skyline consists of 92% of tuples in UI data while $d = 18$, however while $d = 14$ of AC data, the skyline rate reaches already 94%. Figure 3 shows the effect of dimensionality on SDI where the cardinality N = 100K is reasonable in the most of use cases. SDI outperforms BSkyTree in both low-dimensionality and high-dimensionality domains on UI ($d \leq 10$ or $d > 20$) and AC data ($d \leq 4$ or $d > 20$), but is less efficient than BSkyTree in other dimensionalities. In fact, we note that the stop line takes no advantage in AC data because of the *anti-correlated* characteristics of data, however SDI systematically outperforms BSkyTree on the CO data because the stop line can efficiently determined with respect to the strong *correlation* in data. Figure 4 shows the effect of cardinality on SDI with the highest dimensionality in our experiments. In high-dimensionality domains, SDI outperforms BSkyTree in most cases except in AC data. Again, we confirm that the stop line does not show any advantage in high-dimensionality

and high-cardinality AC data. Table 2 lists the pruned tuples by the stop line in different synthetic datasets while $N = 100$K, that are relevant to our experimental results.

Dataset	$d = 2$	$d = 4$	$d = 6$	$d = 8$	$d = 10$	$d = 12$
UI	99,849	88,011	63,260	30,576	12,381	8,110
CO	99,997	97,773	98,832	97,656	96,526	92,066
AC	36,731	5,022	2,227	240	30	27
Dataset	$d = 14$	$d = 16$	$d = 18$	$d = 20$	$d = 22$	$d = 24$
UI	3,794	297	933	35	3	8
CO	87,901	80,587	73,837	51,347	39,742	48,239
AC	13	25	0	10	0	0

Table 2: Pruned tuples by the stop line (N = 100K).

Table 3 shows the performance comparaison between SDI and BSkyTree on real datasets. SDI outperforms BSkyTree on NBA and HOUSE datasets but is much slower than BSkyTree on the WEATHER dataset because the huge number of duplicate dimension values in WEATHER makes $O(dK^2)$ (discussed in Section 3) an important factor.

Dataset	d	N	$\|\mathcal{S}\|$	SDI	BSkyTree
HOUSE	6	127,931	5,774	306 ms	839 ms
NBA	8	17,264	1,796	45 ms	155 ms
WEATHER	15	566,268	26,713	18,680 ms	11,641 ms

Table 3: Performance evaluation on real datasets.

5 CONCLUSION

In this paper, we presented an efficient Skyline computation algorithm. We proved that in multidimensional databases, skyline computation can be conducted on an arbitrary dimensional index which is constructed with respect to a predefined total order that determines the skyline. We further showed that any skyline tuple can be used to stop the computation process by outputting the complete skyline. Our experimental evaluation shows that SDI outperforms the state-of-the-art skyline algorithm in both low-dimensionality and high-dimensionality domains.

ABSTRACT

Transformer architectures have proven to be very effective and provide state-of-the-art results in many natural language tasks. The attention-based architecture in combination with pre-training on large amounts of text lead to the recent breakthrough and a variety of slightly different implementations.

In this paper we analyze how well four of the most recent attention-based transformer architectures (BERT[6], XLNet[33], RoBERTa[17] and DistilBERT [23]) perform on the task of entity matching - a crucial part of data integration. Entity matching (EM) is the task of finding data instances that refer to the same real-world entity. It is a challenging task if the data instances consist of long textual data or if the data instances are "dirty" due to misplaced values.

To evaluate the capability of transformer architectures and transfer-learning on the task of EM, we empirically compare the four approaches on inherently difficult data sets. We show that transformer architectures outperform classical deep learning methods in EM[7, 20] by an average margin of 27.5%.

1 INTRODUCTION

Entity Matching (EM) is the task of determining if two data instances refer to the same real-world object. As a simple example consider the entries in Table 1 and Table 2. We need to match two entities based on attributes like names, addresses or product information while dealing with various formats and differing, missing or wrong values. Given this uncertainty, the challenge of entity matching is to identify which existing entity pairs have the highest probability of being a match.

The task of entity matching is crucial especially for the process of data integration and data cleaning [4]. Due to the large amount of data produced every day, the challenge of data integration and therefore entity matching becomes more urgent than ever for corporations and large institutions with data stemming from multiple sources [27].

While early solutions often relied on rule-based approaches and hand-crafted heuristics, entity matching by now is mainly based on machine learning (ML) approaches. Large projects like *Magellan*[14] provide tools and libraries for the whole EM-pipeline with good results on structured and semi-structured data.

However, what if the data consists of large textual instances, such as product descriptions, posts on Reddit, Quora, Stackoverflow, or company descriptions? What if the data has structure, but attributes are dirty, e.g. the attribute "name" consists of a given name and a last name, while "given name" is empty? In those cases, traditional EM approaches provide only mediocre results or require large efforts in hand-crafted features [2, 13]. Therefore and due to the recent advances of deep learning in natural language processing (NLP), several papers suggest end-to-end deep learning architectures [7, 20, 34] for EM.

Table 1: Database A - structured product information, with *description* being a text-blob.

Title	Brand	Description	Price
iPhone XS	Apple	The brand new iPhone now available in white, red and silver.	899.99
ZenFone 4 Pro	Asus	Thin and light, yet incredibly strong, the ZenFone 4 Pro (ZS551KL) features an expansive 5.5-inch, Full HD AMOLED display	530.00

Table 2: Database B - textual product information.

Product description
Apple's new iPhone XS - a masterpiece of design. Available now with 64 or 128GB storage and in three colors: white, silver and red
A smart device for a decent price - Nokia's Pure View 9, powered by a pure android, is the gift you need for Christmas. With it's incredible robust design and a battery duration of two days under heavy load, you will love it from day one.

The above-mentioned deep learning architectures for EM apply different modern NLP techniques: [7] is based on a bi-directional LSTM and word embeddings, [20] uses an attention mechanism on top of an LSTM and [34] introduces the power of pre-trained models.

While these deep learning approaches already lead to massive performance improvements on difficult data sets [20], none of them use modern transformer architectures for EM. Transformer architectures, largely based on the influential "Attention is All You Need" [30] paper, have proven to be effective on a large variety of NLP tasks. Especially in combination with pre-training on large text corpora, they almost always beat earlier deep learning approaches based on recurrent neural networks (RNNs) on popular NLP benchmarks [6].

The contributions of our paper are as follows:

- To the best of our knowledge, we are the first to compare four of the most recent transformer architectures, namely BERT[6], XLNet[33], DistilBERT[23] and RoBERTa[17] on the task of entity matching. We run experiments with all of them on five different EM data sets. Since the authors

of [20] have shown that most of the traditional, structured EM data sets are not challenging for advanced deep learning architectures anymore, we focus on "dirty" data sets and data sets with large textual data instances.
- We compare the results of modern transformer architectures with more traditional deep learning architectures [7, 20, 34]. Our experiments demonstrate that all transformer architectures clearly outperform classical deep learning methods in EM. On challenging datasets, the best transformer outperforms DeepMatcher[20] by an average margin of 27.5%.
- Finally, we analyze how much training is required to achieve good results on the EM tasks with heavily pre-trained transformers. To elaborate on this, we compare the results before fine tuning on the data set (zero-shot learning) and after each epoch. The results indicate that transformers reach already good results after only one epoch of training, while after 2-3 epochs they converge towards their optimum solution.

The paper is organized as follows. Section 2 reviews the related work on entity matching and gives a brief overview on transformer technologies that appear to be a valid technology for entity matching. Section 3 provides the background knowledge on attention-learning and the transformer architecture. Section 4 describes the four architectures and their pre-training algorithms in detail and explains the intuition behind each approach. In Section 5 we compare the four architectures based on their results on five selected EM data sets. Finally, we present our conclusion and future work in Section 6.

2 RELATED WORK

We can divide the work related to this paper roughly in two categories, namely *entity matching* and *transformer architectures*. We will discuss each of them in more detail.

2.1 Entity Matching

The entity matching process as a whole has been tackled over the years by many works [4, 7, 13, 14, 20], with [4] providing an excellent overview over the major challenges of entity matching. Recent projects like *Magellan*[14] focus not only on research, but provide a set of practical tools to solve entity matching in data integration processes. For a long time the field of entity matching focused on rather structured data records [8], with each attribute of the data records containing only relatively short amounts of text.

To calculate the similarity of such textual attributes, a variety of similarity functions has been developed [4]. Many of them focus on specific data structures as e.g. the *Jaro-Winkler* distance [11], known to work well on person names. The similarity values of such functions where then used as features in a binary classification problem (*match*/*no match*)[4].

With the emergence of deep learning in NLP, several papers [7, 20] started to apply new techniques such as *word embeddings* and *attention* to the task of entity matching. The advantages of such deep learning models is that they remove the need for handcrafted features. While recent work [34] introduced the power of *pre-training* for entity matching, we are to our knowledge the first paper approaching entity matching with modern *transformer architectures*.

2.2 Transformer Architectures

Based on the well-known paper "Attention is all you need"[30], transformers - a special type of neural networks - started by mid 2017 to become one of the most interesting techniques for NLP. BERT [6], combining the transformer architecture with massive unsupervised pre-training was the first paper to achieve state-of-the-art results in a large number of NLP tasks. Succeeding works by [16, 17, 33] achieved even higher results on said NLP benchmarks.

While transformers undeniably are one of the largest achievements in the 2018/2019 NLP landscape, they also started a controversy about the *more data/larger models/more computational power* mentality. Therefore, in addition to increasing model sizes like the authors of [26] did, research started also to develop more lean transformer models, which can be used on mobile devices or non-GPU servers at inference time [23].

Transformers have traditionally been used for NLP-tasks. However, we will apply this technology for entity matching - an important aspect of data integration.

3 ATTENTION AND TRANSFORMERS

In this section we provide detailed background information on a special type of neural networks called transformers. We will use this technology later on for entity matching.

The field of NLP has been dominated for a long time by architectures using recurrent neural networks (RNNs) at its core. The most popular approaches for machine translations were so-called *seq2seq*[29] or *encoder/decoder*[3] architectures, which basically consist of two RNNs, one for the encoder, and one for the decoder. Incrementally improved versions of these architectures are used in most translation software packages. For instance, Google Translate started using such models in late 2016. Even though the RNN architecture seems to be well-suited for building representations of sequential text data, several issues were discovered:

- The so-called *bottleneck problem*[1] makes it hard to transfer knowledge about the source sentence to the target sentence. The bottleneck is the context vector, which is basically all the decoder network gets as an input. By conditioning only on this single vector, the decoder then has to produce an output sequence of length N. It is intuitive to understand that the longer the sequence, the harder it is to get all necessary information of the source sentence in one single vector.
- An RNN is, due to its sequential nature, harder to parallelize and therefore takes longer to train than a simple feed forward network.
- Long range dependencies are hard to learn with RNNs, even though LSTMs and GRU (gate recurrent unit) architectures theoretically allow it. The authors of [30] describe this effect by the path length between two tokens (e.g. two words in a sentence), which is the number of steps the signal has to flow through the network. The longer the path, the harder to learn a dependency.

3.1 Attention

To overcome the bottleneck problem, [1] and [18] came up with a new technique called *attention*. Let us first elaborate on the idea of *self-attention*, to describe the intuition: A word can be represented as a weighted combination of its neighborhood. As an example, take the word *"it"* in Figure 1. For the human reader it is intuitive that the word *it* in this sentence can be represented by the words *The* and *animal*. By applying an attention mechanism, we can train a language model to pay attention to relevant words in its neighborhood in a similar way.

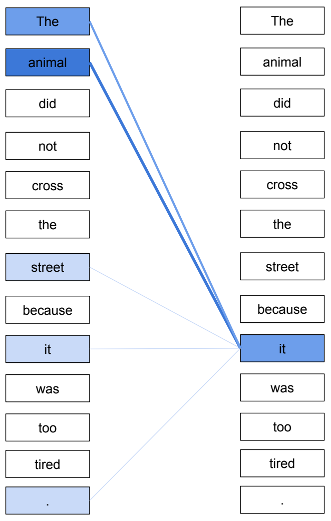

Figure 1: Self-Attention: The token "it" (see right side) can refer to the tokens "The", "animal", "street" etc. (see left side).

A sightly different version of attention was used by the first seq2seq model with attention mechanism[1]. This approach applied attention between the target sentence and the source sentence. So instead of only transferring knowledge between encoder and decoder via one context vector at the end of the encoding, the decoder has access to all the hidden states of the encoder.

Assume that we want to translate the English sentence *"The cat is sleeping"* to the German counterpart *"Die Katze schläft"*, as in Figure 2. It is helpful for the decoder to only consider information of the encoder's hidden state for *is* and *sleeping*, when the decoder is trying to produce the word *schläft*. By applying attention, the decoder will learn to focus on the important hidden states of the encoder at each given time step.

3.2 The Transformer

In 2018, Vaswani et al. published a paper with a more radical approach [30]: an architecture that completely relinquishes RNNs with the idea to build a model with attention only. The core of this paper, the so-called transformer, can be found in Figure 3. While the transformer still retains the classical encoder/decoder structure, it replaced the RNN by a so-called Multi-Head-Attention sub-layer. There are three of those attention sub-layers in each of the *N* stacked layers. The first two Multi-Head Attention sub-layers implement the self-attention mechanism. During the training, they will independently learn dependencies in the source and target sentence respectively, as previously shown in Figure 1. It is important to understand that in the decoder, the self-attention mechanism will only have access to all the words produced by the decoder so far, while all the words that still need to be processed are masked. Masking words with high negative values will basically "hide" them from the learning algorithm.

While the encoder contains only one Multi-Head Attention sub-layer per layer, the decoder contains a second one. This sub-layer performs attention over the output of the encoder stack.

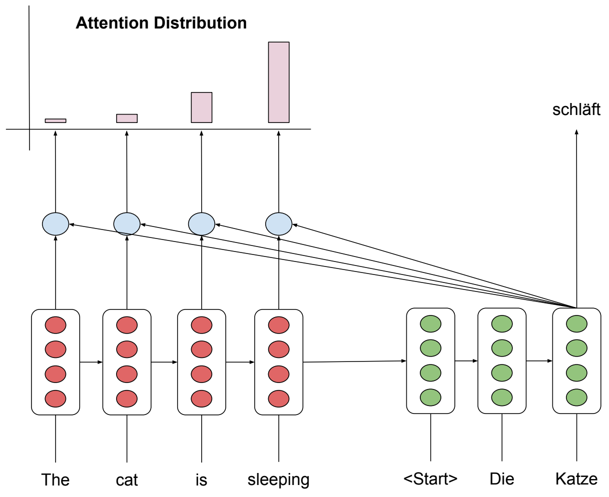

Figure 2: Sequence-to-sequence model with attention. The decoder (green) has access to all hidden states of the encoder (red) and learns how much attention to pay to each hidden state. To predict the word *schläft*, the decoder pays most attention to the hidden state of *is* and *sleeping*.

From a conceptual point of view, this sub-layer performs a similar task to the attention mechanism of classical seq2seq architectures (see previously discussed Figure 2). As a consequence, the Multi-Head Attention sub-layer allows the decoder to pay attention only to the relevant words of the source sentence.

Since a transformer model does not contain any recurrence, the authors had to introduce the idea of ordered, sequential inputs in a different way. They do this by using so-called *positional encoding* for each input word. This allows the model to make use of both the position of a word and the relative distance between two words. The authors of [30] use a combination of the functions sine and cosine with different frequencies to implement positional encodings.

A last detail to mention is the *residual connection* [9] around each sub-layer. The residual connection will, on the one hand, improve training performance, but even more importantly, it allows the positional encoding to flow untouched up to the higher layers.

4 BERT AND FRIENDS

The transformer architecture appearing first in 2017 triggered a wave of new papers based on this idea. With BERT [6] being the most popular one and setting a new state-of-the-art for many NLP tasks in 2018, other papers followed quickly and further improved performance on many tasks. In this section we will have a look at the four approaches used in our experiments: BERT, XLNet, RoBERTa and DistilBERT. The order of the subsections corresponds to the publication date of the papers.

4.1 BERT

BERT is a universal language model, pre-trained on large amounts of text data with the intention of fine-tuning it on downstream tasks (e.g. entity matching) in a supervised manner with relatively little data.

The abbreviation BERT stands for *Bidirectional Encoder Representations from Transformers*, with the emphasis on *bidirectional*.

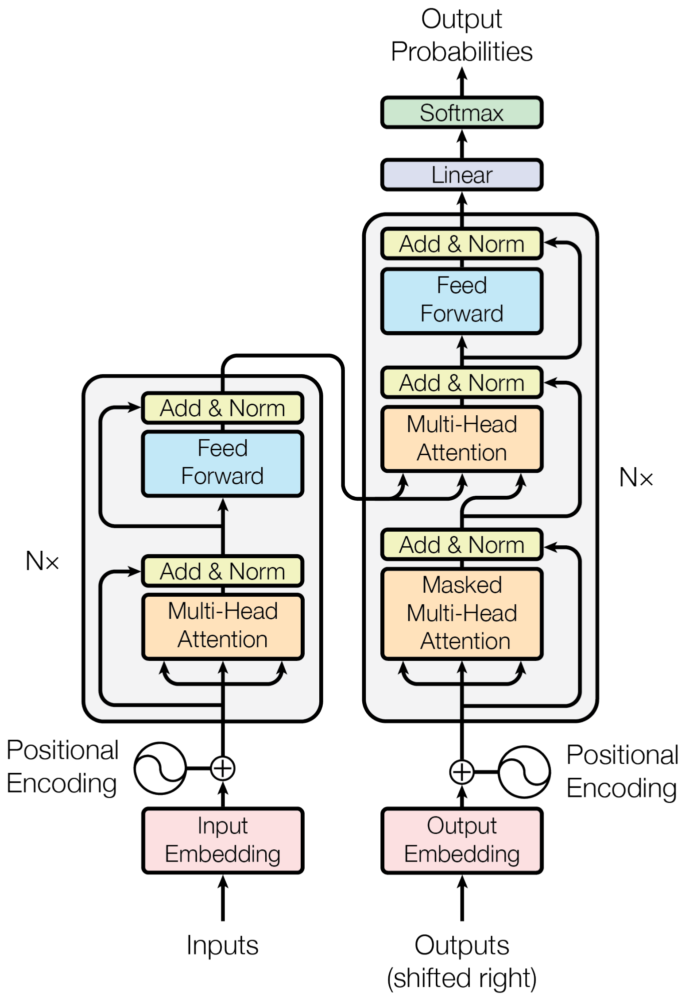

Figure 3: The original transformer architecture by Vaswani et al. as shown in the paper[30].

It is in its core a transformer language model as designed by [30], but contrary to other language models (e.g. OpenAI's GPT[21]) it is jointly conditioning on both the left- and right context of the query token during pre-training. This is somehow counter intuitive, as the most common training task of language models is to simply predict the next token (word).

Let us consider the following fraction of a sentence "[..] problems turning into banking crisis as [..]" (see Figure 4). Let us further assume that we want to predict the query token *"into"* by its left context, which is all the input to the left of the query token. With this training task one can by definition only use the left or the right context. By using both contexts together, the task would become trivial since you already know the next token.

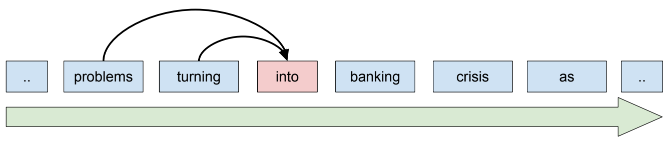

Figure 4: Left-to-right: Using the left context to predict the query token *into*.

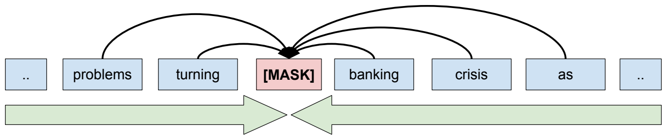

Figure 5: Bidirectional: Using both the left- and right context to predict a masked token.

To be able to condition on both the left and right context, BERT had to change the training task. Instead of predicting the next word, it tries to predict masked tokens as seen in Figure 5 by using both the left and right context. By predicting masked tokens, the BERT model is classified as an auto encoder. It learns to reconstruct the original data by restoring corrupted input, i.e. the masked tokens.

In a second training task, BERT performs *Next Sentence Prediction* (NSP). Here, the model receives two sentences as input, and has to predict if the first sentence is followed by the second one. This pre-training is necessary for all tasks which are based on the relationship between sentences. Typical examples of these tasks are *Question Answering*, *Natural Language Inference* or *Entity Matching*. It is important to understand that both training tasks are unsupervised tasks and do not require labels, but only large amounts of text data. Labeled data are only required for task-specific fine-tuning.

The ablation studies of the BERT paper demonstrate that using both the left and right context is the most important contribution of the paper. As a second contribution the BERT-team shows, that massive unsupervised pre-training on large data (BooksCorpus and Wikipedia) improves performance on a large number of tasks without the need for task-specific architectures. The BERT architecture further demonstrates to be very flexible as it allows simple fine-tuning on a range of downstream tasks such as *Question/Answering*, *Named Entity Recognition* or *Classification*.

4.2 XLNet and Transformer-XL

As seen in Section 4.1, BERT's most important contribution is its bidirectional representation. To achieve it, an auto encoder approach is necessary, with the training task to predict **[MASK]** tokens instead of predicting the next word. The XLNet [33] paper demonstrates the downsides of this approach and proposes a new architecture to solve it. According to XLNet there are two major downsides of the BERT approach:

- Predicting **[MASK]** tokens is what BERT learns during its pre-training phase. But those artificial symbols never occur in downstream tasks, which creates a pretrain-finetune discrepancy.
- BERT reconstructs all **[MASK]** tokens in parallel and independent of each other. This independence assumption is not justified as a simple example in Figure 6 demonstrates.

To overcome these flaws, XLNet returns to the more classical architecture of an autoregressive (AR) language model. In contrast to BERT's autoencoder approach, an AR model does not suffer from the downsides described above, as it does not introduce any artificial symbols and simply learns to predict the next token.

However, as we discussed in Section 4.1, an AR pre-training cannot use forward and backward contexts at the same time. To be able to capture a bidirectional context (as in BERT) and still

I went to [MASK] [MASK] and saw the [MASK] [MASK] [MASK].

I went to ***New York*** *and saw the* ***Empire State building.*** ✓

I went to ***San Francisco*** *and saw the* ***Golden Gate bridge.*** ✓

I went to ***San Francisco*** *and saw the* ***Empire State building.*** ✗

Figure 6: The independence assumption between the masked tokens is not justified.

have the advantages of an AR model, XLNet proposes a new *generalized autoregressive pre-training method*.

The core of this method is a new pre-train objective, which is called *permutation language modeling*. Instead of approaching a sequence of tokens only in a forward or backward manner, permutation language modeling takes into account all possible factorization orders of a sequence.

Assume that we have the following sentence "New York is a city". Further assume that we have already received the tokens "New" and "York". Next, we want to predict the token "is". Figure 7 shows how the model tries to predict the third token *"is"* with different factorization orders.

Let us discuss the three permutations in more detail:

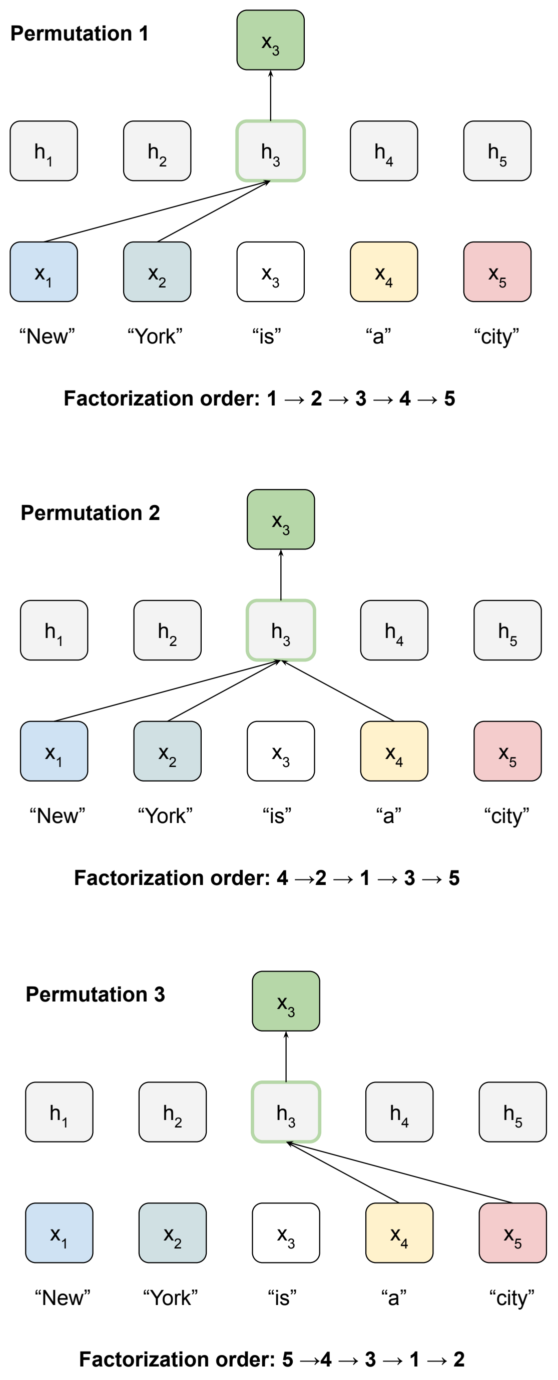
- *Permutation 1* is the classical autoregressive left-to-right order. The model has access to the left side context (x_1, x_2) and tries to predict the query token x_3.
- In *Permutation 2* one can grasp the advantage of the permutation method: due to its order, the model now has access to the context x_4, x_2, x_1 to predict x_3. Be aware that in this sequence order, token x_5 is not accessible, as it appears to the right of token x_3.
- In *Permutation 3* the model has access to the tokens x_4 and x_5, as those appear to the left of token x_3 in the factorization order. By looking at this example it becomes intuitive that the token x_3 (that has to be predicted) has seen every other tokens in the sequence and will therefore, similar to an autoencoder model, capture the bidirectional context.

In addition to its core contribution, the *permutation language modeling*, XLNet includes two major improvements originally proposed in the Transformer-XL paper [5]. The Transformer-XL architecture is based on the original transformer [30], but with several improvements. The most important one, which is also implemented in XLNet, is the ability to learn dependencies beyond a fixed length without disrupting temporal coherence. This is possible due to a segment-level recurrence mechanism and a novel positional encoding scheme.

XLNet outperforms BERT on 20 tasks and achieves state-of-the-art results on 18 tasks including question answering, natural language inference, sentiment analysis, and document ranking [33].

4.3 RoBERTa

RoBERTa [17], a paper released at the end of July 2019, differs from other all the other papers as it does not come up with a new transformer approach, but new insights on BERT. The authors claim that BERT, without any major changes, can match or exceed every published model after it by just using the right hyperparameters and enough training data.



Permutation 1
x3
h1 h2 h3 h4 h5
x1 x2 x3 x4 x5
"New" "York" "is" "a" "city"
Factorization order: 1 → 2 → 3 → 4 → 5
Permutation 2
x3
h1 h2 h3 h4 h5
x1 x2 x3 x4 x5
"New" "York" "is" "a" "city"
Factorization order: 4 →2 → 1 → 3 → 5
Permutation 3
x3
h1 h2 h3 h4 h5
x1 x2 x3 x4 x5
"New" "York" "is" "a" "city"
Factorization order: 5 →4 → 3 → 1 → 2

Figure 7: Permutation language modeling: predicting x_3 given the same input sequence but with different factorization orders.

The authors find that BERT was significantly undertrained and propose the following modifications for maximal performance:

- **More training data.** The original BERT was trained on the BookCorpus and English Wikipedia, covering around 16 GB of text. Many of the subsequent papers used much larger data sets, some of them publicly available, others not. RoBERTa uses five English-language corpora with a total size of over 160 GB of text.

- **Longer training.** RoBERTa evaluates three training durations with 100K, 300K and 500K steps. They show that maximal training duration, together with the additional data, results in best performance.
- **Larger batch size.** While the original mini-batch size of BERT is 256, RoBERTa further evaluates batch sizes of 2,000 and 8,000 samples per mini-batch. The experiments on several downstream tasks indicate that a batch size of 2,000 is the best choice, given the learning rate is increased appropriately.
- **Get rid of the next sentence prediction (NSP) objective.** In contrast to [6], the authors of RoBERTa show that by removing the NSP loss, they achieve slightly better downstream task performance. They also show though that it is crucial to use the full attention span (the model input size, max. 512 tokens) during pre-training in order for BERT to learn long-range dependencies.
- **Change the masking pattern of training data dynamically.** While BERT uses a relatively static masking procedure applied during preprocessing, RoBERTa suggests dynamically masking of each sample during training before feeding it to the model.

With all these modifications, RoBERTa's performance is evaluated on the GLUE, SQuAD and RACE benchmarks. RoBERTa achieves state-of-the-art results on all three challenges, with slightly better results than XLNet (its closest competitor) on most challenges and clearly better than the original BERT [17].

4.4 DistilBERT - Smaller, Faster, Cheaper

While all three models discussed so far focused on improving the state-of-the-art, the authors of DistilBERT [23] pursue another objective. Instead of better results, DistilBERT aims for a smaller and faster models which can be used in real-world projects. Indeed, the size of recent transformer models is impressive:

- A BERT-Large model uses 340M parameters.
- RoBERTa works with 355M parameters while using 160 GB data for pre-training.
- NVIDIA trained a transformer language model called *MegatronLM*[26], using 8300M parameters.

The authors of DistilBERT see the challenge of modern transformer models mainly at inference time, when a model should be small and fast, so it can work on mobile devices or non-GPU servers.

There are several approaches to reduce model size while approximating performance, namely *quantization*, *weights pruning* and *distillation*. The authors of DistilBERT focus on knowledge distillation.

4.4.1 *Knowledge Distillation.*

The core idea of knowledge distillation is to train a smaller model (the *student*) which learns from the original model (the *teacher*). The method has been generalized by [10] and is sometimes also referred to as *teacher-student learning*.

The challenge of knowledge distillation is to learn the so-called *dark knowledge* of a model. Let us assume the example in Figure 8, where a language model predicts the last token in a sentence. While one or two predictions usually have a high probability, there will almost always be a long tail of tokens with low probability. This knowledge, even though the probabilities might be low, is crucial for a model to generalize. The challenge of knowledge distillation is therefore not only to learn the one prediction with high probability, but also the near-zero probabilities on other classes. In terms of distillation loss function, this near-zero probabilities are called *soft targets*.

Input:

'I', 'think', 'this', 'is', 'the', 'beginning', 'of', 'a', 'beautiful', **[MASK]**

Predicted token (top 16):

#1 token: 'day'	**p:** 0.213		**#9** *token:* 'summer'	**p:** 0.016
#2 *token:* 'life'	**p:** 0.183		**#10** *token:* 'adventure'	**p:** 0.013
#3 *token:* 'future'	**p:** 0.062		**#11** *token:* 'dream'	**p:** 0.012
#4 *token:* 'story'	**p:** 0.058		**#12** *token:* 'moment'	**p:** 0.012
#5 *token:* 'world'	**p:** 0.049		**#13** *token:* 'night'	**p:** 0.011
#6 *token:* 'era'	**p:** 0.045		**#14** *token:* 'beginning'	**p:** 0.010
#7 *token:* 'time'	**p:** 0.032		**#15** *token:* 'season'	**p:** 0.009
#8 *token:* 'year'	**p:** 0.017		**#16** *token:* 'journey'	**p:** 0.006

Figure 8: Predicting a masked token with BERT: The first two tokens show a high probability, followed by a long tail of near-zero possibilities.

4.4.2 *Loss Objective.*

To motivate a model to learn both high and near-zero probabilities, DistillBERT suggests a composite loss function as follows:

- **Distillation Loss** The student learns the probabilities of the teacher (*soft targets*) with $L = \sum_i t_i * \log(s_i)$ where t_i is a probability estimated by the teacher and s_i the probability estimated by the student. To control the smoothness of the output distribution, a further technique from [10] called *softmax-temperature* is used.
- **Masked Language Modeling (MLM) Loss [6]** As the teacher model used in DistilBERT is the original BERT model, the second loss function is the original MLM, with the goal to predict the masked tokens.
- **Cosine Embedding Loss** A rather technical loss to align the directions of the student and teacher hidden states vectors.

4.4.3 *Student Model Architecture.*

While using the original BERT architecture as teacher model, the student model architecture is a purged version of the BERT model. *Token-type embeddings* and the *pooler* have been removed and the number of layers have been reduced by factor 2. This reduces the overall size of the model by 40% [23].

Note that the distillation process happens on the general-purpose model, before applying fine-tuning on downstream tasks. This in contrast to task-specific distillation, which distills the model after already being fine-tuned on a specific task.

4.4.4 *Performance.*

To compare DistilBERTs performance, it has been fine-tuned on two of the usual benchmarks (GLUE, SQuAD). DistilBERT retains 97% of the original BERT model while reducing the model size by 40% and being 60% faster [23].

5 EVALUATION

In this section, we present and discuss the results of the experiments conducted with the transformer architectures described in Section 4. In particular, we will address the following research questions with respect to entity matching:

- How well do transformer architectures perform compared to traditional, non-deep-learning ML approaches?
- How well do transformer architectures perform compared to recent deep learning approaches?
- Which transformer architecture performs best on the task of entity matching?
- Transformer architectures are complex deep neural networks. How much training is necessary to fine-tune them on the entity matching task? Is the amount of training data in a traditional EM dataset sufficient to fine-tune a transformer?

5.1 Datasets

The authors of *DeepMatching*[20] demonstrated that modern deep learning methods do not perform better in entity matching tasks on structured data than traditional approaches. Traditional ML approaches such as e.g. *Magellan*[14] perform even slightly better and training time is magnitudes shorter than for deep learning methods. In addition, the scores of *Magellan* on structured data are high - it performs on those 11 datasets with an average F1-score of 86% - without the rather textual dataset *Amazon-Google* the F1-score is even 90%. The authors of DeepER[7], a second approach using deep learning for entity matching, confirm these results with F1-scores between 88% and 100% on these structured datasets.

We therefore focus our experiments on challenging datasets where other approaches showed relatively low performance. To evaluate our transformer approaches we use both *textual* and so-called *dirty* datasets provided by the Magellan team [20]. We use all publicly available datasets except the textual dataset *Company*, as this contains text blobs with lengths between 2000-3000 tokens, which exceeds the maximal attention spans of 512 tokens for transformer architectures. There have been recent approaches to extend this attention span to 8000+ tokens by [28]. However, we leave these challenges for future work.

For our entity matching experiments, we use the following five datasets to evaluate the transformer architectures (see Table 3): *(1) Abt-Buy*: Product data from Abt.com and Buy.com. The core attribute is *description*, which is a long text blob describing the product. We use no informative attribute (e.g. the *title*), but only the noisy *description* attribute, similar to [20]. *(2) iTunes-Amazon (Dirty):* music data from iTunes and Amazon. The data has been modified to simulate dirty data as done by [20]. They suggest for each attribute other than "title" to randomly move each value to the attribute "title" in the same tuple with a probability of $p = 0.5$. *(3) DBLP-ACM (Dirty):* Bibliographic data from DBLP and ACM. The data has been modified to simulate dirty data. *(4) DBLP-Scholar (Dirty):* Bibliographic data from DBLP and Google Scholar. The data has been modified to simulate dirty data. *(5) Walmart-Amazon (Dirty):* Product data from Walmart and Amazon. The data has been modified to simulate dirty data.

To evaluate our transformer architectures, we split all five datasets into into three parts with a ratio of 3:1:1. We use the 60% split of the data for training, and the two 20% splits for validation and test. All reported numbers in this paper show results on the test split.

Table 3: Datasets used in our experiments.

Dataset	Domain	Size	# Matches	# Attr.
Abt-Buy	Products	9,575	1,028	3
iTunes-Amazon	Music	539	132	8
Walmart-Amazon	Products	10,242	962	5
DBLP-ACM	Citation	12,363	2,220	4
DBLP-Scholar	Citation	28,707	5,347	4

5.2 Setup & Methods

In this section we will describe the hardware we used for our experiments as well as the implementation of the transformers along with the hyperparameters and pre-trained models.

5.2.1 Hardware. All experiments were executed on a single Nvidia TITAN Xp GPU (12GB Memory) with Intel(R) Xeon(R) CPU E5-2650 v4 (4 cores) and 8GB memory. The experiments are implemented using PyTorch and the transformer implementations are based on [32].

5.2.2 Methods. Figure 9 shows how an entity pair consisting of `Entity A` and `Entity B` is fed into a transformer architecture. This approach is used at both training and inference time. The data feeding approach looks similar in all four transformer architectures, while having minor differences in the use of separator tokens, position embeddings and the classification representation (`CLS`) in the last layer. The detailed description of the following section refers to BERT/RoBERTa and DistilBERT, while being very similar in XLNet.

We will now describe how we use the transformer for entity matching in detail. `Entity A` and `Entity B` contain a single text blob each. In case of textual data (*Abt-Buy*), the text blob consists of the single attribute *description.* For "dirty" datasets, all attributes of a data instance are concatenated, for instance `[name + brand + description + price]`. Next, the single text blob is tokenized. For each token, the corresponding embedding is looked up (for details on tokenizing and embedding see Section 5.2.3).

Each token embedding is then summed up with a positional embedding and a segment embedding. The segment embedding is used to distinguish between tokens of `Entity A` and `Entity B`. The sum of all three embeddings is then fed into the transformer. The maximum length of the input ($A_1 - A_N$ plus $B_1 - B_M$ plus the two artificial tokens *classification* and *separator*) has been empirically defined based on the longest data rows in the training data. It lies between 128 and 265 tokens, depending on the data set.

In one pass, a pair of two entities (all tokens of `Entity A` and `Entity B`) is processed by the transformer model. This leads to major performance improvements compared to classical deep learning models based on RNNs[20], where each token is depending on the tokens appearing earlier in the sequence. The output of a pass is then represented in the hidden state at position 0, the purple `CLS` symbol in Figure 9. This hidden state (a vector of size 768) is then passed into a single classification layer (*Classifier* in Figure 9).

Keep in mind that transformer models are universal language models, capable of performing different downstream tasks (e.g. classification, seq2seq, question/answering, NER, etc.). Hence, to feed the classification output of the transformer model via a

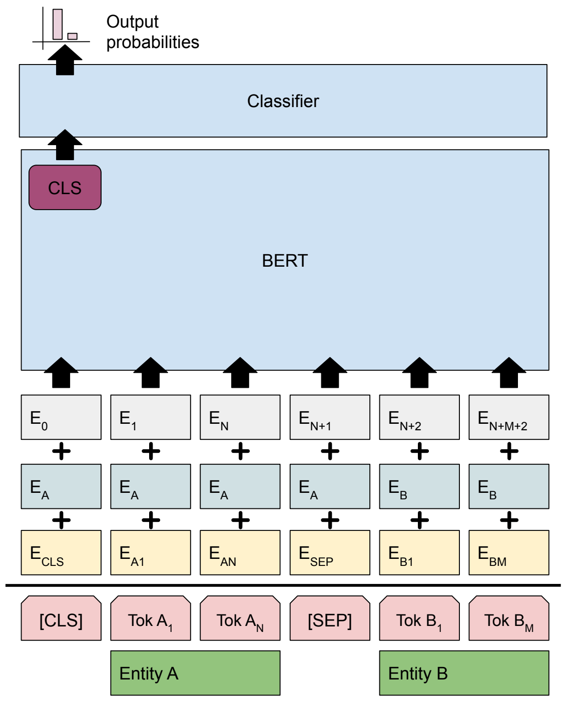


Figure 9: Transformer feeding approach. Entity A and Entity B are tokenized (e.g. `Tok A`$_1$`,red`). The embedding of each token (`E`$_{A1}$`,yellow`) is fed into the transformer together with positional- and segment embeddings (`E`$_0$`,gray/E`$_A$`,blue`). Special symbols are used to feed the output into the classification layer (`[CLS]`) and to separate the two entities (`[SEP]`)

designated representation symbol (CLS) into a specific classification layer, is an architectural decision of [6] to keep the model flexible. When using the model for other tasks, e.g. for NER, the ouput layer looks differently.

The classification layer is - in contrast to the rest of the model - not pre-trained and contains a fully connected layer with 768 neurons plus two output neurons. These two output neurons finally represent the two classes of an entity matching problem: *"Entity A and B match"* or *"Entity A and B do not match"*.

We use Adam [12] for optimization in combination with a linear learning rate. The choice of optimizer, learning rate and other hyperparameters are based on best practices for similar classification tasks, e.g. the GLUE-QQP benchmark [6, 17, 23, 31, 33].

With the implementation described above, we evaluate all four transformer architectures described in Section 4: BERT, XLNet, RoBERTa and DistilBERT. To reproduce the experiments, we provide source code and hyperparameters on GitHub[1].

5.2.3 Tokenization and Embeddings. Before feeding a pair of `Entity A` and `Entity B` into the transformer, tokenizing the input and a lookup of embeddings is necessary. Transformers like almost all modern language models work with embeddings as input values. Using embeddings increases performance over simple one-hot encoded vectors massively, as demonstrated by the influential *word2vec* paper [19].

We use the following tokenization/embedding techniques:

[1]https://github.com/brunnurs/entity-matching-transformer.

Table 4: Pre-trained models used in our experiments.

Transformer	Details
BERT	12-layer, 768-hidden, 12-heads, 110M parameters. BERT-base model. Trained on lower-cased English text.
XLNet	12-layer, 768-hidden, 12-heads, 110M parameters. XLNet English model
RoBERTa	12-layer, 768-hidden, 12-heads, 125M parameters. RoBERTa is using the BERT-base architecture.
DistilBERT	6-layer, 768-hidden, 12-heads, 66M parameters. The DistilBERT model is distilled from the BERT-base model.

- **BERT/DistilBERT:** We first split the whole input textblob into single tokens by simple white space- and punctuation splitting rules. In a second step, we create Wordpiece embeddings by applying the original algorithm from[24].
- **RoBERTa:** We split the whole input into tokens by using white spaces, punctuation and special abbreviations (`'s|'t|'re|'ve|'m|'ll|'d`). We then apply Byte-level Byte-Pair-Encoding [25].
- **XLNet:** In contrast to the other approaches, we do not pre-tokenize the input into word sequences, but directly input the raw text blob into a SentecePiece[15] subword tokenizer.

5.2.4 Pre-Trained Models. Due to their model sizes, all four transformer architectures require very resource-intensive pre-training on large amounts of data. As an example, the BERT$_{LARGE}$ model was trained on 64 TPU chips for 4 days while RoBERTa uses 1024 V100 GPUs for approximately one day [6, 17]. The transformers performance is therefore heavily dependent on the pre-trained model. In Table 4 we list all pre-trained models used in the experiments. We use the pre-trained models provided by the original papers [32] and gathered by Hugging Face[2]. Note that due to hardware constrains, we always used the smallest available pre-trained model. We expect larger pre-trained models to perform as good or even better.

5.3 Comparison with Classical Models

Table 5: F1-scores of the best performing Transformer model in comparison with Magellan (MG) and DeepMatcher (DeepM).

Dataset	MG	DeepM	T$_{BEST}$	ΔF_1
Abt-Buy	33.0	55.0	90.9	35.9
iTunes-Amazon$_{Dirty}$	46.8	79.4	94.2	14.8
Walmart-Amazon$_{Dirty}$	37.4	53.8	85.5	31.7
DBLP-ACM$_{Dirty}$	91.9	98.1	98.9	0.8
DBLP-Scholar$_{Dirty}$	82.5	93.8	95.6	1.8

Table 5 shows the performance of transformer models in comparison with Magellan and DeepMatcher. The results are measured, similar to other papers in the field [7, 20], by an F1 score where recall is the ratio of true matches predicted vs. all true

[2]https://github.com/huggingface/transformers

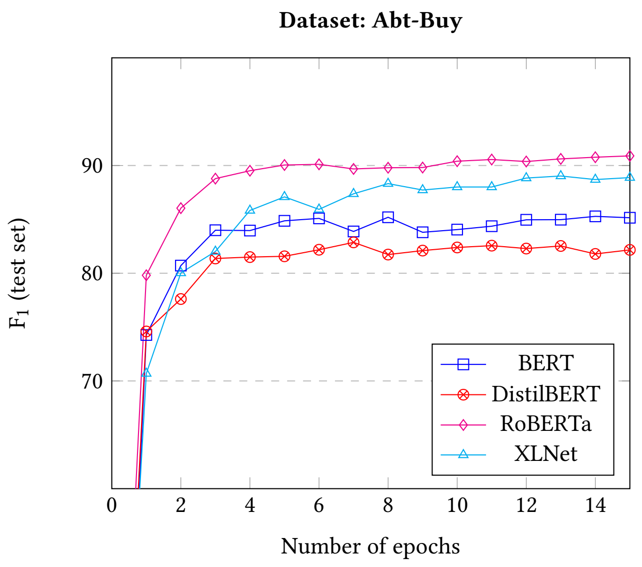

Figure 10: Performance of transformers on the Abt-Buy dataset, averaged over five runs. We only visualize F_1 scores in range 60 - 100% to emphasize the difference.

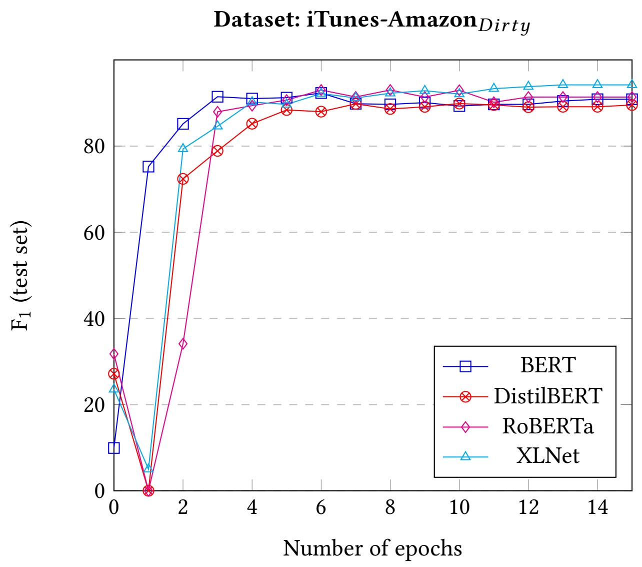

Figure 11: Performance of transformers on the iTunes-Amazon$_{Dirty}$ dataset, averaged over five runs. The effect of little training data is visible at epoch 1.

matches. For each dataset we report the best performing of the four DeepMatcher DL models, the result of Magellan and the best performing transformer. The transformer result is an average over five runs. **We see that transformer architectures outperforms both DeepMatcher and Magellan by a large margin on the challenging datasets *Abt-Buy* (35.9%), *iTunes-Amazon* (14.8%) and *Walmart-Amazon* (31.7%).**

We are also interested in how transformer architectures perform on datasets where DeepMatcher and Magellan perform very well, like on *DBLP-ACM* (DeepMatcher: 98.1%, Magellan: 91.9%) and *DBLP-Scholar* (DeepMatcher: 93.8%, Magellan: 82.5%). As expected, the transformers perform better than existing methods also on these datasets with a ΔF_1 of 0.8% and 1.8%, respectively. In comparison to the challenging datasets though, the improvements are relatively small. Since the results of DeepMatcher on these datasets are already very high (F1-score: 98.1% and 93.8%) we assume that better language models only slightly improve the performance on those tasks.

5.4 Transformers Architectures Head-to-Head

The performance of transformer architectures has been compared many times in recent papers [6, 17, 33], usually on large NLP benchmarks (e.g. GLUE, SQuAD [22, 31]). However, we are not aware of any related work where transformers were used for entity matching.

Figures 10 - 14 show the performance of the different transformer architectures on the datasets defined in Section 5.1. The results have been averaged over five runs. The main findings of our systematic, experimental evaluation are as follows:

- **All transformer architectures perform remarkably well on the task of entity matching.** Even the least performing transformer, *DistilBERT*, performs clearly better than classical approaches (see Section 5.3).
- After only **one epoch of training**, most experiments range within a 5% interval of their peak performance. After 3-5 epochs, almost all experiments converge to their peak performance. The effort to fine-tune a transformer on an entity matching task is therefore manageable, especially considering the training time per epoch in Section 5.5.
- Overall, *RoBERTa* performs best, also reaching high results already after only a few epochs. We conclude that the massive pre-training effort on a huge amount of data (compared to the other three approaches) gives RoBERTa a slight advantage in the task of entity matching.

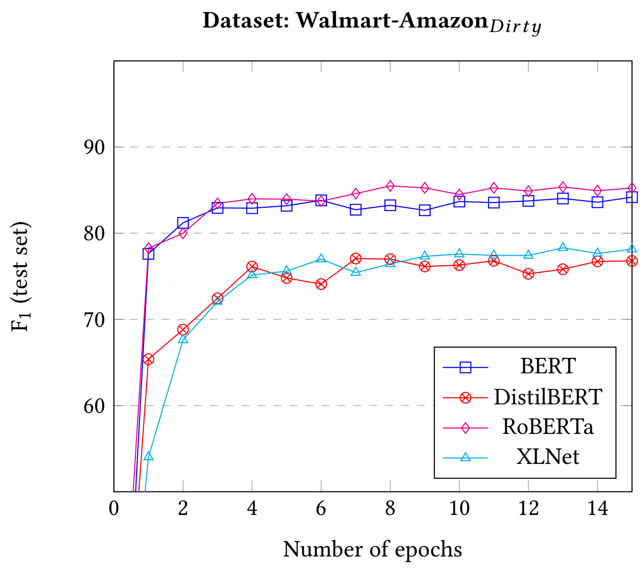

Figure 12: Performance of transformers on the Walmart-Amazon$_{Dirty}$ dataset, averaged over five runs. We only visualize F_1 scores in range 50 - 100% to emphasize the difference.

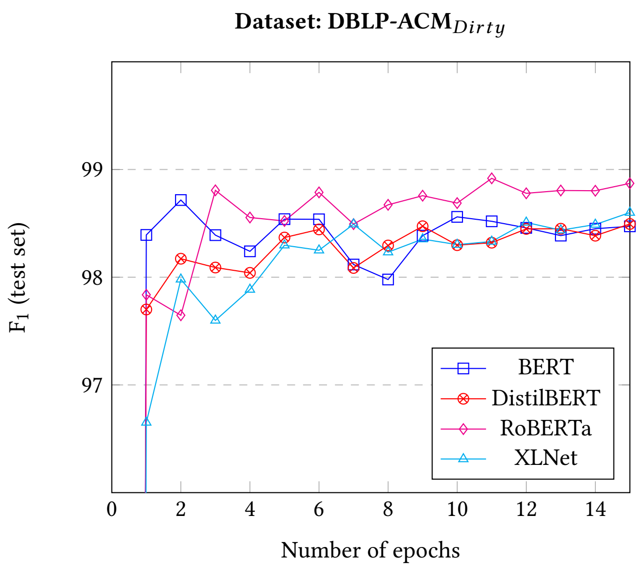

Figure 13: Performance of transformers on the DBLP-ACM$_{Dirty}$ dataset, averaged over five runs. We only visualize F_1 scores in range 96 - 100% to emphasize the difference.

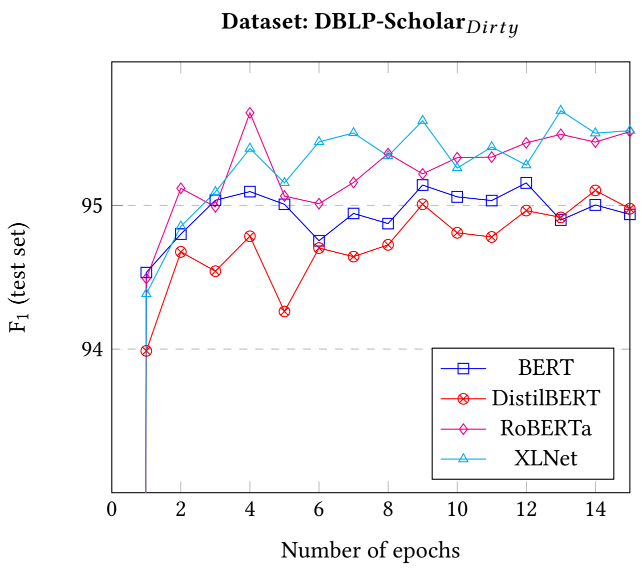

Figure 14: Performance of transformers on the DBLP-Scholar$_{Dirty}$ dataset, averaged over five runs. We only visualize F_1 scores in range 93 - 96% to emphasize the difference.

- *DistilBERT* performs worst, averaged on all tasks. This is explainable due to the comparably small model of DistilBERT. Still though the results of DistilBERT are close to its "big brothers" and higher than classical approaches (see Section 5.3).
- *XLNET* requires, on average, longer training times to reach peak results. We conclude the *permutation language modeling* eventually results in high performance (XLNet performs often almost equally well as RoBERTa), but due to the large amount of permutations, it requires more training time.

Table 6: Training time per epoch on each data set.

Dataset	BERT	XLNet	RoB.a	D.BERT
Abt-Buy	2m 42s	6m 15s	2m 43s	1m 22s
iTunes-Amazon$_{Dirty}$	7s	12s	7s	3.5s
Walmart-Amazon$_{Dirty}$	1m 41s	2m 29s	1m 41s	52s
DBLP-ACM$_{Dirty}$	2m 24s	4m 9s	2m 24s	1m 13s
DBLP-Scholar$_{Dirty}$	4m 5s	5m 57s	4m 13s	2m 6s

- The iTunes-Amazon$_{Dirty}$ dataset is extremely small containing only 132 matching records . As we see in Figure 11, this is influencing the training process. After epoch 1 almost all experiments have an F1-score of 0%, in comparison to the other datasets where after epoch 1 the results are already close to peak performance. We see, though, that even with this small amount of training data, the fine-tuning converges after 4-6 epochs of training.

5.5 Training Time

Transformer models are known to be resource-intensive architectures with millions of parameters. For instance, DistilBERT$_{SMALL}$ consists of 66 million parameters and RoBERTa$_{LARGE}$ has even 355 million parameters. As we have seen in Section 4, training a transformer is split in two tasks: *(1)* unsupervised *pre-training* on large amounts of unspecific data and *(2)* supervised *fine-tuning* on downstream tasks (e.g. entity matching) with task-specific data. While pre-training is doing a major part of finding these parameters (see Section 5.2.4), it is still a large model to fine-tune on a specific downstream task like entity matching.

Table 6 shows the training time for fine-tuning each transformer on the given datasets. The times reported are per epoch on the training set (which is roughly 60% of the total dataset).

As fine-tuning usually converges to maximum performance after 1-3 epochs (see Section 5.4), total training takes between **10s** (DistilBERT on iTunes-Amazon$_{Dirty}$, 3 epochs) and **11m 55s** (XLNet on DBLP-Scholar$_{Dirty}$, 2 epochs). It is important to note that the experiments ran on low budget hardware (see Section 5.2.1) without any parallelization. With state-of-the-art-hardware, these times can be reduced by an order of magnitude.

If we compare these training times to the reported results of DeepMatcher [20], we can draw two important conclusions:

(1) Compared to conventional, non-deep learning EM models as e.g. *Magellan*, fine-tuning a transformer is still relatively slow.
(2) Compared to training a deep learning model as proposed in DeepMatcher, fine-tuning a transformer is fast. DeepMatcher reports training times from **10min** to **11h**, depending on the dataset and solution. This is 1-2 magnitudes slower than fine-tuning a transformer as we propose, especially as DeepMatcher uses faster hardware than we do.

The reason fine-tuning a transformer is faster than training a comparably light-weighted deep learning model[20] is clearly the resource-intensive pre-training, which improves convergence on the downstream task (entity matching) enormously.

6 CONCLUSIONS

In this work, we show for the first time the strong impact of transformer architectures and pre-training for entity matching on datasets with large textual- or "dirty" data. We show that all transformers described can be used for EM out of the box, without the need for a task-specific architecture. Our experiments on five datasets show a significant improvement of F1-scores of up to 35.9% of transformers on challenging datasets compared to state-of-the-art approaches. In addition, we demonstrate that on relatively small and clean datasets, transformers still perform slightly better than earlier deep learning approaches.

We demonstrate that fine tuning a transformer on an EM task takes relatively little time and requires no particularly capable hardware, which might be contrary to expectations due to the large size of transformer models. Regarding the question on which of the four transformer models performs best on the EM task, experiments show that all of them deliver relatively similar results. In comparison with average results, RoBERTa shows slightly better and DistilBERT slightly worse performance, which is in line with the theoretical background of these approaches.

We consider transformer approaches as a valuable technology for entity matching. Using standard transformer architectures instead of designing EM-specific architecture does not only benefit from simplicity, but profits also directly from further advances in the NLP field of pre-training and transformers.

ABSTRACT

Machine learning is critical to the success of many products across application domains. At Uber, we have a variety of machine learning applications including matching, pricing, recommendation, and personalization. As a result, we have a large number of machine learning models to manage in production. Generally, building machine learning models is an iterative process and machine learning models span across a set of stages of a lifecycle. In this paper, we describe Gallery, a machine learning model lifecycle management system to save and serve models and metrics and automatically orchestrate the flow of models across different stages in the lifecycle. We then use the Uber Marketplace Forecasting and Simulation platforms as examples to show how Uber uses Gallery in production and the benefits we get by using Gallery.

1 INTRODUCTION

Machine learning is critical to the success of many products across application domains. Companies employ machine learning for recommendation, targeting, and personalization. Uber uses machine learning across product features including matching, pricing, personalization, ETA estimation, and Uber Eats recommendations. Recently, there have been various systems and frameworks [1, 12, 22, 26] designed and built to make machine learning easy-to-use and scalable in production systems. However, as the interaction of models with systems have become more complex, a growing technology need exists to manage machine learning models through their lifecycle to accelerate the process of getting a model from exploration to production and improve the model iteration velocity.

Building machine learning models is an iterative process [7]. Given a problem to solve, the common lifecycle of a model, as shown in Figure 1, starts with model exploration, during which we design and explore multiple models. When we find a model that beats a benchmark, we build the model into a production system. Getting a model into production starts at the model training, where we generate model instances. We refer to the trained models as the instances of a model. We evaluate the performance of trained model instances and deploy instances when the performance is above certain thresholds. Otherwise, we continue to improve the models. When models are deployed in production, monitoring performance is critical. If a performance degradation is detected or we have a new model, we will need to re-train the appropriate model, deprecate the old model instances, and deploy the new model instances.

Managing a handful of models is feasible for a production system. However, operational scale quickly becomes untenable

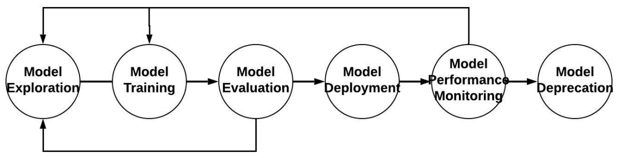

Figure 1: Machine Learning Model Lifecycle

with multiple machine learning problems, and more so when each problem has hundreds of model instances to manage. For example, when doing Marketplace-level forecasting at Uber, we forecast supply, demand, and other quantities in real time for hundreds of cities across the globe. We shard the problem spatially by city, training a model instance for each city-quantity combination because Uber is operating in many cities across the world, and different cities may pose different geospatial characteristics. Besides, the Uber business might be at different growth stages for different cities.

Though there are variances across applications and projects, many interesting questions about how to manage a large number of machine learning models in production are common. In this section, we list a sample of the questions which are raised between use cases: Where do we save and serve the models generated during model exploration or trained in production? How do we efficiently search for models and their experiment results? How can we confidently deploy a large-scale number of models and avoid regressions? How and when do we trigger model retraining due to model performance deterioration? In a complex system like the Uber Marketplace, the result of applying one model could be the input to another model. How can we manage the dependencies between multiple models?

How to address the above model management questions often depends on the experiences of machine learning engineers who work on these problems. Even within one company like Uber, different machine learning applications may use different approaches to solve these problems. For example, prior to Gallery there were over seven different storage solutions (e.g., MySQL, HDFS, Cassandra and Git repo) engineers used to save machine learning models. As a result, similar functionalities to manage machine learning models are scattered across a variety of production systems. This results in increased overhead to build and maintain individual systems, and causes a loss of visibility into the machine learning models across a production system. With the increasing number of machine learning solutions being built to solve business problems at Uber, we built Gallery, a model lifecycle management system to systematically and uniformly address these common questions to improve machine learning model velocity and productivity across Uber.

Gallery was started as a system to solve Uber Marketplace Forecasting model management problems and was later integrated as part of Michelangelo [6], Uber's ML Platform. It is a system designed to manage machine learning models by providing functions for model saving, searching, serving, performance monitoring, and orchestration across different stages of the model development lifecycle.

Overall, the major contributions in this paper are as follows:

- A comprehensive analysis of the problems we addressed at Uber in order to manage machine learning models in a large-scale, distributed, microservices-based system.
- We describe Gallery, a model lifecycle management system used in production at Uber.
- We use Uber Marketplace Forecasting and Simulation case studies to demonstrate how we utilize Gallery to manage machine learning models and the benefits we have gained with Gallery.

2 THE MODEL MANAGEMENT PROBLEM

We first share some machine learning model management context at Uber before we define the problem. At Uber, we employ numerous machine learning applications, such as request dispatching, pricing, user growth, and recommendations. Overall, the Uber platform is microservice-based. Application teams build their own services and have different requirements for cadence and latency, implying different patterns of running the models. For example, long-term forecasting predicts hourly trips for a city for weeks in the future, while real-time forecasting predicts sub-hour demand. As a result, different applications might use different languages, modeling techniques, and frameworks for building and serving models.

In addition to the variety of applications and models, Uber is operating in markets across the world that have unique conditions in terms of population, city layout, climate, and population density. As a result, it is common to see machine learning models trained separately for different markets. We also need to frequently retrain the models when we detect model performance degradation due to the changing market conditions, and we need to independently trigger the retraining of the models for a city. Often it is not efficient to blindly re-train the models for all the cities, e.g., the training data for real-time demand forecasts can easily go up as much as terabytes for one city. Instead, we would like to retrain the models periodically if performance evaluation shows the need.

To solve the model management issue across heterogenous use cases, a system to manage a variety of machine learning models across different frameworks, languages, and usage patterns, from model exploration to models deployed in production, is necessary. To be clear, we refer to a machine learning model as an abstract data transformation which we can use to solve a particular problem or business use case. A model contains the specification of the input, output, and transformation, e.g., linear regression or random forest classification and all the corresponding hyperparameters. A model instance consists of a set of coefficients that is a learned representation of a given model on a particular training data set. The terms "model" and "model instance" are commonly used interchangeably when there is no ambiguity. Accordingly, we define the model management problem as: how to consistently and scalably manage a large number of complex models and model instances across stages of a model lifecycle.

3 THE GALLERY SYSTEM

In the section, we describe Gallery, a model lifecycle management system, built at Uber to solve the aforementioned model management problems. We first introduce the principles that guide our design. Then, we discuss the overall system architecture, followed by the description of each major system component.

3.1 Design Principles

Immutable. Any machine learning model and model instance generated and managed in our system is immutable. Any update of a model or model instance will result in a new version in production. This is critical to guarantee no unexpected behavior in production, and ensures that all decisions can be traced back to a specific model version. This builds the foundation for model performance observability and debuggability.

Model Neutral. Each model is treated as a black box and the model management system does not interpret the models. In this way, we can have one system to provide management for the varying models built for each application, e.g., a deep learning model using TensorFlow or PyTorch, or linear regression models using scikit-learn. Users are not blocked from leveraging the model management system because of their modeling technology choices.

Framework Agnostic. Any framework for model training, evaluation, deployment and serving, e.g., model exploration with Python code manually on a local server or scheduled pipelines to train models in production, could be seamlessly integrated with the model management system. With this flexibility, we can manage models from all different machine learning projects at different development stages. This lowers the on-boarding cost for new users and provides model management support for a wide array of use cases.

Automation. With a large number of machine learning models and model instances, automatically moving models across different stages in the lifecycle is the key to high scalability and velocity. Achieving automation requires the management system to have an integrated holistic view of the model workflow including training, evaluation and deployment.

3.2 Overall Architecture

We show the overall view of the Gallery architecture in Figure 2. Advanced model management is a core component of a machine learning system as it orchestrates the flow of a model across different stages of a lifecycle. For the sake of completeness, we include a generic machine learning system that encompass the basic stages of a machine learning lifecycle and the data infrastructure we leverage in Gallery for the storage in the architecture. We describe the major components of the Gallery system separately in the rest of this section.

3.3 Data Model

To manage the lifecycle of a machine learning model, Gallery collects data of *models*, *model instances*, and *model performance*, and the corresponding metadata information. We present a simplified version of the basic Gallery data model in Figure 3.

3.3.1 Model. A machine learning model is generally a representation of a transformation from a given input to a given output. We use model metadata to store the basic model information including the model owner, model description (e.g., linear

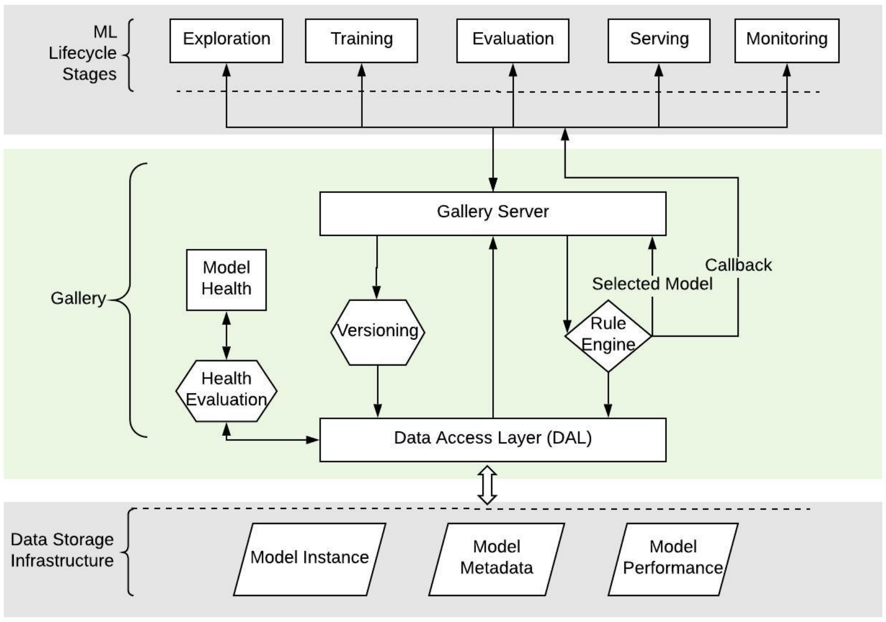

Figure 2: Gallery Overall Architecture

regression formula or neural network structure), features, hyperparameters, and also the information on how the model can be trained and served.

Building machine learning models is always an iterative process through which we generally start with a simple baseline model and subsequently improve the model performance by optimizing the model structure, tuning the hyperparameters, or updating the model features. Therefore, we keep track of the evolution of a model through next and previous pointers in the model record. In a complex production system, we often have one model depending on the output of other models. To get a holistic view of the application of machine learning models in such a system, we also keep track of the model dependency via upstream and downstream pointers.

3.3.2 Model Instance. A model instance is a realization of a model given a set of training data. It consists of the model parameters learnt from the training data and it is used to construct the model in serving for prediction. To achieve model neutrality, we treat model instances as uninterpreted binary blob data and any updates to the blob will be versioned as a new instance in Gallery. As a result, Gallery can not interpret any model and treats all the models the same. Depending on the types of models, the model instance sizes vary from a few KBs to 10s GBs. Model blob storage is abstracted from the users, and the blob is saved via Gallery in distributed data storage systems, e.g., S3 or HDFS.

We decouple the storage of the model instance blob with other model information. Each model instance has a field to record the model instance blob location, which could be a HDFS or S3 path.

For a model instance, we use metadata to keep track of the training data, training framework, and other configurations (e.g., seed for random number generator, number of epochs for training a deep learning model) we have set for the training to generate the model instance. Storing all the information about the models and model instances allow users of Gallery to closely reproduce their model instances on demand. Note that it is not always possible to generate exactly the same model instance due to the randomness introduced in training the models.

3.3.3 Model Performance. We track the performance of every model instance for offline model evaluation and online performance monitoring. When users measure their models either offline or online, they can write blobs of evaluation metrics that pertain to a specific mode instance. Each metric also has its own set of metadata to describe the nature of the evaluation. We store metrics as blobs in order to remain model neutral and framework agnostic. For different model evaluations, we can have different metrics, e.g., precision, recall, AUC for classification models and MSE (Mean Squared Error), MAPE (Mean Absolute Percentage Error) for regressions models. There are also a lot of customized metrics defined for application-specific evaluations. Gallery treats all the metrics the same and the metrics take the form of a structured blob with the basic format of "<metric>: <value>" pairs.

3.3.4 Metadata. As shown in the Figure 3, for Gallery models, model instances, and model performance, we keep a comprehensive set of metadata to identify model ownership, associate each model with its serving context, and link models to their training datasets. With metadata, we can improve the discoverability of models and instances by enabling search over key metadata fields. We record all necessary configurations, e.g., training code pointer, hyperparameters, and training data location and version, to make model instances reproducible. We provide a standard set of metadata fields and naming conventions to unify the characteristics of a model over a production system.

Note that none of the metadata about a model or a model instance is generated in Gallery. Users of Gallery need to save the information to Gallery via APIs within the Gallery server. An example of the usage of the Gallery APIs is presented in Section 4.1. Gallery simply manages the information and indexes the data

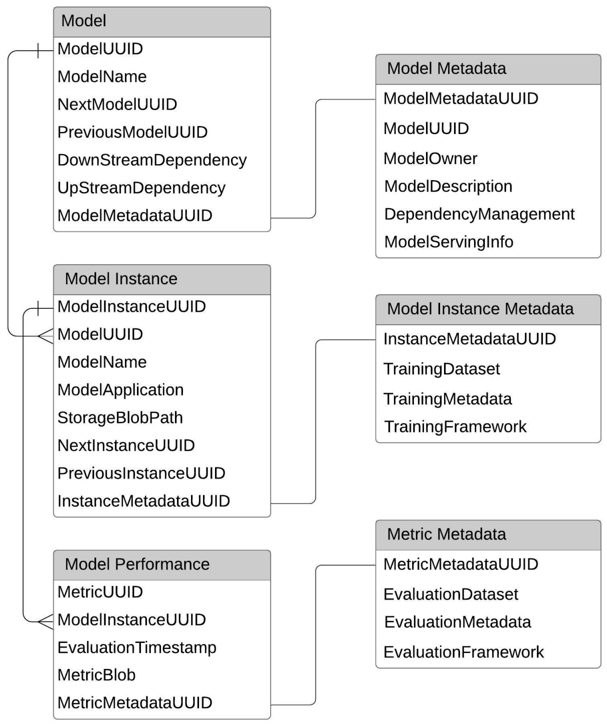

Figure 3: Gallery Basic Data Model

for querying. As a result, Gallery is model neutral and agnostic to any modeling framework.

3.4 Model Versioning

Model versioning is an approach to uniquely identify a model or model instance. It is the foundation for model immutability. With versioning, we never override an existing model or model instance. Any update to a model or model instance will introduce a new version. We keep track of the update history as the lineage of the model or model instance.

Versioning of code or artifacts is a basic requirement for any production system. While it is standard to use Git for code version control, there is no such standard for versioning models or model instances. As a result, many users derive their own versioning schemas, like Semantic Versioning [8] and timestamps, which lead to high maintenance costs due to lack of standandarization across users users and applications. Gallery abstracts model versioning away from users, analogous to what Git provides to code, and provides APIs for users to trace model lineages.

3.4.1 Model Instance Versioning. Each model can have one or multiple model instances. We not only version models, but also model instances. This is because both models and model instances have their own notions of change that need to be tracked. An update to a model represents some change to the underlying data transform such as feature and hyperparameter changes. Typically, these changes happen in response to new approaches for solving a problem and are usually less frequent than model instance updates. Model instance versions represent updates against an existing model with new training data. In production, periodic retraining is expected as new training data becomes available, and information about retraining is captured in the model instance versioning.

The versioning approach we took before Gallery is based on semantic versioning using the format of "<major>.<minor>.<patch>". A version example for a demand forecasting model instance is "1.3.10". We adhere to the following basic version updating rules: 1) update major versions when model architectures change, e.g., from linear regression to neural network; 2) update minor versions when features or hyper-parameters change, e.g., adding a new feature, and 3) update patch versions when the model instance is retrained. This approach works well when we have one simple forecasting model for a handful of cities. However, it is not manageable when we build and launch multiple forecasting model for hundreds of cities. As different models might perform better or worse for different cities and the forecasting model performance might degrade gradually due to the changes in the Uber business, we expect retraining models to improve model performance. However we do not want to retrain models for all the cities if one city performs poorly since that needlessly wastes computing resources. As a result, we very quickly end up with multiple model versions for different cites in the production system which becomes impossible to manually manage. The basic semantic versioning schema also loses meaning because cities are no longer aligned against the same versions.

In Gallery, instead of incorporating model semantics into the versions, we adopted a Git style versioning approach and assign a UUID for each model instance. We associate metadata to capture the model semantics and make it easy to search for. To be specific, when users create a new model, they declare a base version id for the model. The base version id is the top-level identifier that is linked to all its descendent model instances. Typically, a base version id represents some approach to solving a particular problem (e.g., demand forecasting). Each time a model instance is trained, a unique identifier is assigned to the trained model and its metadata tracks which base version id the instance was trained from. In this way, users can query for specific model instances, or traverse the evolution of their model by following all instances linked to a given base version id.

Figure 4 shows one example of a model and model instance. There are two base model version ids "demand_conversion" and "supply_cancellation" which represent models for the corresponding business problems. For example, "supply_cancellation" has evolved over four iterations with different model instances which are identified by four different UUIDs. The model instances are sorted by time and linked to the base model they were trained from.

3.4.2 Dependency Management With Versioning. Besides model and instance identification, versioning is at the core of model dependency tracking and management. As collaboration grows within a production system and models become more advanced, there are scenarios where models become dependent on one another. For example, the output of one demand forecasting model could be used as a feature for a pricing model. As systems become more complex, these types of relationships become very difficult to track. Tracking these relationships is an important prerequisite for understanding how a model impacts the entire production environment with a holistic view. Users need to be aware of the consequences of changes in their models, or need to be aware that changes in their model's behavior could be due to upstream dependencies. For example, the performance of Model A could improve even though the only change is on its upstream Model

Figure 4: Model and Model Instance Versioning

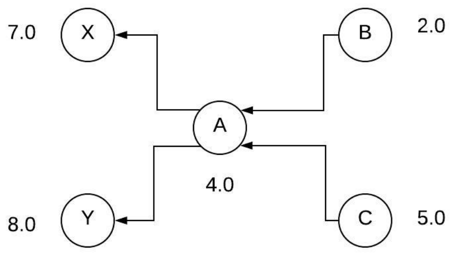

Figure 5: Model Dependency Graph

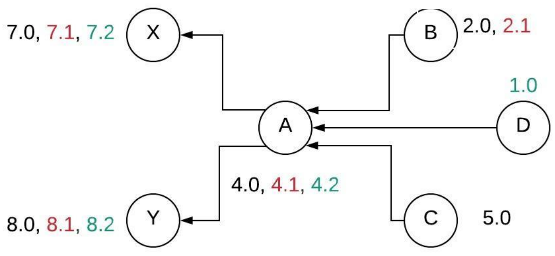

Figure 7: Adding New Model Dependency

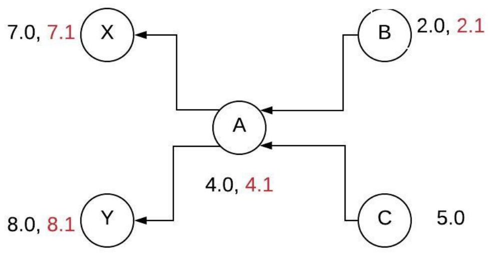

Figure 6: Model Dependency Update

B. Without tracking this dependency relationship, we would lose track of Model B's impact on the production system.

Here, we present one example to show how dependencies of 5 models are managed by Gallery. In Figure 5, we show a dependency graph of five models. Both Model X and Y depend on Model A and Model A depends on Model B and C. For readability, we use numbers instead of UUIDs to represent the model instance versions in this example. In Figure 6, we show the case of a model dependency update. When we update instance of Model B from version 2.0 to 2.1, this triggers the version updates for all Model B's downstream models including A, X and Y. Considering that there is no real change of Model A, X or Y, we automatically update the model instance version by adding a new model version to Gallery without changing the production versions. The owner of Model A can choose to upgrade to the new model version, if they want to include the updated Model B. But, models are not automatically updated because we would like users to be aware that their model dependencies have changed before their production environment is updated.

Figure 7 shows a use case when we add a new model dependency for an existing model. By adding the Model D as the dependency of Model A, we will automatically update model A's instance version to 4.2. Accordingly, the downstream Models X and Y will also be updated to instance version 7.2 and 8.2 separately.

Dependencies between models are established by the user when models are first registered in Gallery. When adding models, Gallery provides operations for the user to add dependent models by their uuids. There are also operations exposed for updating or removing dependencies. Once the dependencies are established, Gallery provides users with APIs to query their model's upstream or downstream dependencies and will track model updates across dependencies.

3.5 Model Storage

The Gallery model storage layer defines the interface through which model blobs, metadata, and metrics are stored and retrieved. We have the following model storage requirements: *searchability*, *agnostic*, *high availability*, and *low-latency*.

To satisfy these requirements, we build the Gallery model storage using a hybrid approach. Considering that model metadata and metrics are commonly structured data, we use a relational database, e.g., MySQL, for storing metadata and providing support of flexible queries. The MySQL service is supported by the Uber infrastructure team to guarantee high availability and deployed cross data centers. Considering the enormity of models and model instances, we would not be able to scale up to handle thousands of models and instances if we need to interpret each model. As a result, we treat each model equally and store each model blob as binary data. We leverage Uber's large data storage service built on top of S3 and HDFS to store the model blobs to achieve model neutral and framework agnostic design principles. We expect Gallery users to provide their models as serialized binaries, which are in turn stored in Uber's large data storage service. The storage locations are subsequently stored as part of the model metadata so that they can be retrieved at serving time. Another benefit of taking this approach to save model blobs is that it does not have data size constraints, which can be an issue for large deep learning models. To handle cases of inconsistent data due to system failures, e.g., MySQL or HDFS write fails, we always write model blobs first and only write the model metadata after the model blobs are successfully stored. If the model blob of a model instance is saved but the metadata fails to save, then the model instance will not be available in the system.

Model metadata searchability is critical for users managing a high volume of models. Users conducting experiments or managing production environments need the ability to easily search and query models based on key metadata like training dates, model type, and features. Model searchability allows easy tracking of all models in the wild and more efficient analysis and experimentation over the various models.

Briefly, model storage is accessed via a unified DAL (data access layer). The model performance metrics are saved and read from MySQL to support flexible queries for analysis and monitoring. When models instance blobs are queried, the request first goes to MySQL to get the location of the model blob, and then the model is directly accessed via the storage location. The cache is updated with the requested blob and then is subsequently returned to the user.

3.6 Model Performance and Health

When building and maintaining production-grade software systems, it is standard to define SLAs with consumers to establish accountability and trust. Typical SLAs for software systems include availability, latency, and throughput. For machine learning systems, we also would like to have SLAs on performance. We define model health as a set of metrics and standards for users to adhere to in order to guarantee some level of accountability of models in Gallery.

More specifically, we define two categories of metrics to measure the model health. One category of the metrics is on the completeness of model information, which consists of metadata for model reproducibility and model performance. Production models should contain enough metadata to reproduce the model and annotate the behavior leading to a decision. Different models may have different performance metrics. In Gallery, we ensure that the performance of each model is evaluated and stored for monitoring and analysis.

The second category of model health metrics provides a holistic view of model performance across model lifecycle stages including training, validation and production. All model performance is agnostic to the system and provided by the applications. Model training performance is generally available as a by-product of model training. Model validation performance is produced by validation processes or backtesting and is used to check for model overfitting or as a gauge of whether to deploy a model to production. Model production performance is measured against served predictions and reflects the online performance of a model. The evaluation criteria for each performance metric is entirely up to the user and is configurable, since different models and applications optimize for varying outcomes. We store an object of metrics in Gallery and define the above metrics as guidelines for users.

With model performance metrics, we can derive various insights about the models in Gallery. The insights can give model owners a signal on how their model behaves over time, information about their serving environment, and establishes a level of trust between model owners and model consumers. Here are two examples of insights that Gallery can provide: model drift and production skew.

Model Drift . Model drift refers to the case when the statistical properties of the target variable, which the model is trying to predict, change over time in unpredictable ways. With real-time platforms, data changes. Accordingly, if the data we use in production gradually evolve to have different patterns from the data we use in the training, we may see the model performance degrade over time. Considering Uber's rapid growth in many markets, this drift can occur and once detected, triggers model re-training via Gallery rule engine using the new training data.

Production Skew. Production skew is the difference between performance at training time and serving time. Multiple factors can result in production skew, such as bugs in training or serving implementation, or discrepancies between training data and data feeding to model serving. The ability to detect production skew is critical for model performance monitoring.

3.7 Orchestration Rule Engine

As the number of models and model instances grow in a production system, it becomes increasingly difficult to manually manage their various states. Therefore, we designed and built a rule engine in Gallery to orchestrate the model workflows. Based on the model metadata, such as deployment configuration and various model performance metrics in Gallery, users can define conditions and actions in rules to automatically move the models across the stages of the lifecycle, such as model deployment and serving, monitoring and retraining, and deprecation.

In the following section, we first show the basic automations we need in the model lifecycle stages where the rule engine can help. Then, we describe our design of the rule engine system and illustrate how it works with examples.

Model Deployment and Serving Automation. When we generate model instances through training, we decide whether to deploy a model instance to production and replace the existing instance. It is common to have multiple models and instances deployed in production and use rules to select the best performer for serving, based on performance metrics generated by evaluation systems. Normally, different applications will have their own evaluation systems to measure the performance of the models. For example, in real-time forecasting, we have a heuristic model which uses the mean value of last 5 minutes as the forecasts. The heuristic model is stable and consistent, but may not always produce the best performance. We also have complex forecasting models that take in more features, like historical data, into the prediction, which are generally better performing but may not perform well when there are unanticipated events not specifically considered in the modeling. We have a real-time system to evaluate the performance of the models. Therefore, we can combine the benefits of different models to achieve the overall best performance by using the model metrics in Gallery to make decisions. With a rule engine, we can define the model candidates to consider and the selection criteria for choosing a champion. At serving time, users will query Gallery for the champion model to serve based on the user-defined rules.

Model Monitoring and Retraining. After we train models and deploy model instances into production, we need to keep monitoring the performance and alert in cases like model drift, as discussed in the previous section. At the same time, model performance can degrade because the training data we used to fit the model no longer best represents the production data. Therefore, we can re-train the model with the latest training data. With a rule engine, we can set rules to automatically detect model drift, send out alerts, and trigger model training.

Model Deprecation. Models are not used forever, we may not always improve the performance of a model by retraining, and we keep experimenting with new models. When a model consistently performs worse than other models, we should deprecate it to save computational resources. Users can utilize the rule engine to define the deprecation criteria based on sustained underperformance, and training and serving costs, e.g., training takes too long or requires a large amount of computational resources. This precaution allows users to ensure that their production systems are not being negatively impacted by poorly performing models. When a model or model instance is deprecated, we would not delete them from the system, but rather flag them as deprecated. With the flag, we can skip them during model fetching or searching. Any application depending on these deprecated models or model instances can still use them until the application finishes migration to new models.

3.7.1 Rule Engine Design. To satisfy the needs of orchestrating models across lifecycle stages in production, we identify three requirements to design the rule engine: rules being *easy to understand*, *reliable*, and *agnostic to supporting services.*

Making rules easy to understand and safe to update is the first principle. We use the rules to control the production systems for model deployment and serving. We need to make sure Gallery users understand the rules and have confidence updating the rules to avoid outages due to unexpected rule usage or changes. At the same time, we need to make sure the system reliably applies the rules within a reasonable response time (SLA) when the rule is triggered. The rule engine needs also to be framework-agnostic so that any model training, monitoring, or serving components can leverage and integrate with the Gallery.

Based on frequent use cases, Gallery leverages two type of rules: *model selection rules* and *action rules.* Applying a model selection rule will return a model based on some selection criteria, e.g., returning the model that maximize AUC (area under curve). Applying an action rule will trigger some event, e.g., deploying a model instance. To make the rule engine agnostic to different frameworks within the machine learning workflow, we expect users to define callback functions that will be triggered by the rule engine. For example, to deploy a real-time forecasting model, we have one action that automatically makes a configuration change, via http request, that updates the version of the model served to consumers. There are also a default set of common actions that users can leverage or extend, like sending an email or alerting.

We use the classical *Given/When/Then* model to define rules. More concretely, for "Then" we define two templates: model selection and callback action. For example, the following rule is designed for the selection of a forecasting model.

Listing 1: Model Selection Rule Example

```
{
  "team": "forecasting",
  "uuid": "316b3ab4-2509-4ea7-8025-ca879dac61",
  "rule": {
      "GIVEN": modelName ==
        "linear_regression"
        AND model_domain == "UberX",
      "WHEN":  "metrics["mae"] <= 5",
      "ENVIRONMENT": "production",
      "MODEL_SELECTION":
      "a.created_time > b.created_time"
    }
}
```

With this rule, we select the latest trained linear regression model if the model performance is good, i.e., mae (mean absolute error) is less than 5. This rule allows the user to automatically fetch the freshest models and have confidence that the returned models are within their accepted error threshold.

The following is an example of an action rule which specifies: when we have a new model instance, and if the model performance is within a threshold, e.g., forecasting bias less than 0.1 and greater than -0.1, we can deploy the model in production.

Listing 2: Action Rule Example

```
{
  "team": "forecasting",
  "uuid": "43057544-92b0-4421-a1b0-d7d87f77a",
  "rule": {
      "GIVEN": "model_domain == "UberX"
           AND model_name == "Random Forest",
      "WHEN": "metrics.bias <= 0.1
           AND metrics.bias > -0.1",
      "CALLBACK_ACTIONS": [
        {
            "action":"forecasting_deployment"
        }
       ],
   "ENVIRONMENT": "production"
   }
}
```

3.7.2 Rule Engine Implementation. We show the overall architecture of the Gallery rule engine in Figure 8. For rule storage, we use a Git repository. To add or update a rule, users need to check it into Git within their allocated directory. The advantage of using Git is that we automatically have version control for the rules, which is critical for a production environment and enables us to set up a test framework to validate each rule before it can impact production. With Git, we can also easily enforce the peer review process for the rules to avoid production outages due to accidental updates of rules. We use Java Expression Language (JEXL) [2] to implement the rules.

The rule evaluation implementation is event based and we currently have two kinds of events to trigger the evaluation of a

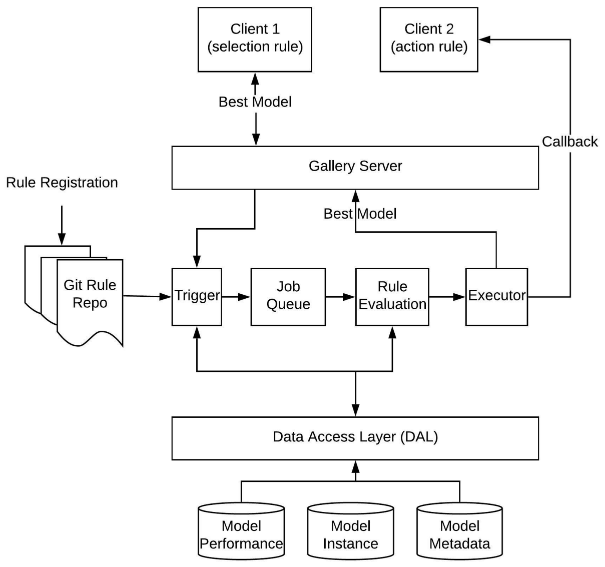

Figure 8: Gallery Rule Engine

rule: 1) directly sending a request to the rule trigger or 2) updating any metadata or metrics specific in a registered rule. Since we focus on two types of customized rules, we implement the rule evaluation ourselves instead of using other rule engines. In Figure 8, we demonstrate the workflow of the rules with two application clients. Client 1 has a model selection rule and sends the rule directly to the rule engine trigger via Gallery service. The rule is first placed in the job queue and goes through the evaluation during which the performance metrics of the related models are queried from the storage. Then the best model instance is fetched and returned to Client 1 via a Gallery service based on the condition in the rule.

Client 2 has an action rule registered in the Git rule repo. Whenever there is an update of the corresponding metadata or metric specified in the rule via a Gallery service, the evaluation of the rule will start and the job is put into evaluation job queue. If there are any action triggers, then the callback specified in the rule is executed, e.g., "when a model instance performance metric mae is less than 0.2, we deploy the model in production."

4 GALLERY IMPLEMENTATION AND USAGE CASE STUDIES

Gallery was built by the Uber Marketplace team for managing forecasting models to improve the Uber plaftform. We leverage the Uber storage infrastructure for saving the model related information and we built Gallery as a stateless microservice that includes versioning, dependency management and rule engine in Java. Gallery was designed and built to be horizontally scalable across different data centers.

Before Gallery, there was a lot of manual cost and overhead to manage our forecasting models. For about 100 models, engineers and data scientists spent 1-2 hours a day manipulating files on HDFS and Git, measuring performance and triggering model retraining. Now, Gallery has been in production for two years and is supported as part of Uber's Michelangelo ML platform. Under Michelangelo, Gallery is managing more than 1 million model instances for many machine learning applications, and engineers or data scientists no longer spend time managing files and training scripts, but instead are able to spend their energy on model iteration and experiments.

4.1 Gallery Interface

Gallery users interact with Gallery via a standard set of Thrift APIs with language-specific clients. By using Thrift, users can access the functionality of Gallery in their own modeling environment and language of their choice (e.g., Jupyter notebook, Spark application, services build in Java). With the APIs, Gallery users can manage their models cross the stages of a model lifecycle. In the following example, we use a Python application example to show one typical Gallery user workflow using the basic Gallery APIs.

```
'''
Train a ML model using SparkML and upload the
    model blob to Gallery with model instance
    metadata information.
'''
# Using a SparlML pipeline to fit a model
model_object = pipeline.fit(train_df)
# Model is serialized to a binary blob
model_content = serialize(model_object)

# Create and upload the trained model instance
    with metadata to Gallery.
model = createGalleryModel(project='example-
    project', base_version_id='supply_rejection'
    )

# Add model instance information
modelInstance = createModelInstance(model)
modelInstance.content = model_content
modelInstance.modelName = 'Random Forest'
modelInstance.city = 'New York City'
modelInstance.modelType = 'SparkML'
modelInstance.trainingDataSet = '...'
modelInstance.trainingDataMetadata = '...'
...

# Update model instance to Gallery
modelInstanceId = uploadModel(project='example-
    project', base_version_id='supply_rejection'
    , modelInstanceRecord=modelInstance
  )
```

Listing 3: Create and Save Gallery Model

The sample code in Listing 3 shows that we use SparkML to train a machine learning model and serialize the model into a binary blob. Then we add the related model instance metadata information and save the model instance to Gallery.

```
# Upload a model instance performance metric
modelPerformanceRecord = ModelEvaluationMetric(
  metricName='bias',
  scope='Validation',
  value=0.05
  )
insertModelInstanceMetric(project='example-
    project', modelInstanceId=modelInstanceId,
    modelPerformanceRecord=
    modelPerformanceRecord
  )
```

Listing 4: Save Model Performance Metric

With the model instance we have trained previously, we keep track of the model evaluation performance by saving the performance metrics in Gallery as shown in the sample code in Listing 4. At the same time, if we have one rule similar to what is shown in Listing 2 registered in the rule Git repository, then the corresponding model deployment process might be triggered based on a rule condition. How to automatically deploy model in production is different for different serving systems and we leave this part to Gallery users to define their own callback functions. For example, a realtime forecasting model is deployed in Uber by updating some configuration which is continuously monitored by the forecasting serving system in production.

```
# Model query with a given performance criteria
searchConstraint = [
    {'field':'projectId',   'operator':equal,
         'value':'example-project'},
    {'field':'modelName',   'operator':equal,
         'value':'random_forest'},
    {'field':'metricName',  'operator':equal,
         'value':'bias'},
    {'field':'metricValue', 'operator':
    smaller_than, 'value':0.25}
]
modelInstance = modelQuery(searchConstraint)
```

Listing 5: Model Search

We save the related metadata and performance metrics of the models and model instances in Gallery. Then, we could fetch the models we want with the conditions as shown in Listing 5.

4.2 Case 1: Marketplace Forecasting

At Uber, the Marketplace Forecasting team generates real-time and long-term forecasts for multiple applications, including driver suggestions and pricing [4]. Multiple supply and demand models have evolved through different model classes ranging from simple time series models, linear regression models, and now deep learning models. Each model class is trained and deployed per city Uber operates in. Each city faces different market dynamics, and classes of models perform differently based on certain spatial or temporal characteristics of the city. Therefore, the team needs a mechanism to track and train each model's performance on a per city basis, and a systematic way to determine which model class to serve at a given time. As a result, the Marketplace Forecasting team alone has thousands of model instances to maintain and decisions to make each minute about which model to serve. Gallery's model management solution with storage and automation via rule engine has reduced model deployment from two hours of engineering work per model to 0.

Another use case is dynamic model switching for forecasts when there are events e.g., holidays. Via action rules, Gallery is able to inform forecasting serving system about the performance of models that include holiday/event features versus those that do not, and subsequently switch to serve the appropriate models for the duration of the event. This improves the accuracy of the served predictions by more than 10% MAPE (Mean Absolute Percent Error) compared to a static served model. Furthermore, Model Health alerts continue to monitor the performance of such models and can alert engineers regarding issues with prediction accuracy. These alerts have proven useful in the case of unplanned events (e.g., public transit outages) that cause unexpected spikes in demand, and gives engineers or ops an opportunity to intervene and mitigate the performance degradation.

4.3 Case 2: Marketplace Simulation Platform

The Marketplace Simulation platform [5] hosts a simulated world with driver-partners and riders, mimicking scenarios in the real world. Leveraging an agent-based discrete event simulator, the platform allows Uber Marketplace engineers and data scientists to rapidly prototype and test new features and hypotheses in a risk-free environment.

Priori to leveraging Gallery, one issue the simulation platform had is model reusability. ML developers implemented models directly in the simulator and trained them on the fly as the simulator ran. As a result, the complexity of the system and the wide array of models being simulated degraded the performance of the platform.

Gallery became part of the solution by providing the simulation platform with metadata and model binary storage, which enabled the platform to decouple model training and serving. Offline processes can store reusable model instances into Gallery, and the simulation backend service can instantiate such models as they're needed. This decoupling allows model developers to iterate and evolve their models, independently of the simulator's backend, whereas before they need to wait for the entire end-to-end process each time they trained/updated a model. Once a model developer is satisfied with their model, they can store their model in Gallery, which will signal to the backend service the presence of a new model. Furthermore, decoupling model training workloads from the simulator, allowed the Simulation team to simplify the complexity of the simulator reduce maintenance costs, conserve hardware resources while improving system efficiency. The Gallery system has saved the simulation platform an estimated 8GB memory and one hour CPU time per simulation.

5 RELATED WORK

With the proliferation of Big Data and large-scale computing (e.g., MapReduce [16], Apache Spark[31]), several scalable machine learning platforms [32] have emerged in recent years with the focus of machine learning training on a large amount of data. Apache Spark is a general data processing framework. MLlib [20, 23], the machine learning library added to Apache Spark, makes Apache Spark broadly used for some simple large-scale machine learning model training. However, for complex machine learning tasks, especially deep learning [17], which requires state updates and iteration, parameter server architecture is used for enabling in-place updates for very large parameters, e.g., Parameter Server [18], PMLS [30], Google DistBelief [15]. TensorFlow [11] and MXNet [24] are advanced machine learning frameworks focusing more on the deep learning problem and can fully utilize different devices like CPU and GPU.

Managing a large number of machine learning models in production is challenging. There is an ever-increasing interest in the problem and several academic and industry efforts have been published. ModelDB [28] is an open source model management system which provides APIs for saving models and associated metadata, measuring performance, and querying models. It has a web-frontend for easy visualization and summary of the model information. ModelDB also provides clients with the ability to integrate its model management features with Apache Spark ML and scikit-learn [25]. However, there is no orchestration of model training, serving and deployment in ModelDB.

A lightweight system is proposed in [27] to extract, store, and manage machine learning model metadata. It tracks the provenance information of datasets, models, predictions, evaluations

Table 1: Model Management System Comparison (Y: Yes, N: No)

Systems	Saving	Loading	Metadata	Searching	Serving	Metrics	Orchestration
ModelDB [28]	Y	Y	Y	Y	N	Y	N
ModelHUB [21]	Y	Y	Y	Y	N	Y	N
Metadata Tracking [27]	N	N	Y	Y	N	Y	N
Velox [13]	Y	Y	Y	N	Y	Y	Y
Clipper [14]	Y	Y	N	N	Y	Y	Y
MLFlow [22]	Y	Y	Y	Y	Y	Y	N
TFX [12]	Y	Y	Y	N	Y	Y	Y
Azure ML [1]	Y	Y	N	N	Y	N	Y
SageMaker [26]	Y	Y	N	N	Y	N	Y
Gallery	Y	Y	Y	Y	N	Y	Y

and training runs in machine learning experiments. With model metadata and provenance, the system provides a basis for comparability and repeatability of machine learning experiments. Similar to ModelDB, there is no orchestration of machine learning stages in this system. This system is focusing on the metadata associated with model experiments instead of managing the machine learning models.

ModelHUB [21] was built to manage the lifecycle of deep learning models. Considering the huge space of potential deep learning models by tweaking neural network architectures and hyperparameters, ModelHUB compactly stores a large number of models and snapshots with fast query performance. It also keeps track of the model metadata including the model accuracy score. ModelHUB focuses on deep learning models and is not framework agnostic.

Velox [13] is a low-latency and large-scale model serving system. It focuses on making the model serving efficient by caching computation and scaling out model prediction. Velox leverages a cluster computation framework and incremental model updates to scale out the model training process. Velox also manages the model lifecycle by detecting model performance degradation to trigger model rollback or re-training. However, the project was deprecated [29].

Clipper [14], the follow-up project of Velox, is a general-purpose low-latency prediction serving system. It can incorporate multiple machine learning frameworks including TensorFlow [11], Apache Spark [31] and scikit-learn [25]. Similar to Velox, it uses caching, as well as batch and adaptive model selection to improve model prediction latency and performance. Clipper focuses on serving models with low latency across different frameworks.

MLflow [22] is an open source platform under active development for managing the machine learning lifecycle. There are three major components in MLflow: MLflow Tracking, which tracks the experiments results and parameters; MLflow Project, which packages the ML code to be easily reproducible; and MLFlow Model, which provides a standard format for packaging ML models across different libraries or framework. The same model could be packed with different flavors such that a model could be applied in different frameworks, e.g., a TensorFlow model can be used with TensorFlow flavor or python function flavor. With this MLflow Model format, the models can be used in a variety of downstream tools, e.g., real-time serving through a REST API or batch inference on Apache Spark. MLFlow also provides CLI to run the MLflow models for model deployment. However, there is no orchestration to coordinate the moving of models across different stages in a model lifecycle.

TFX [12] is a production-scale machine learning platform for TensorFlow and it consists of multiple components for machine learning, including data transformation, model training, model evaluation, and model serving. With the TensorFlow serving component [9], TensorFlow models can be deployed and served in production. However, TensorFlow serving is a not generic component for managing a variety of machine learning models using different frameworks. Kubeflow [3] is a project to make deploying ML workflows on Kubernetes simple, portable, and scalable. It started as an open source project from Google that highlighted how the company ran Tensorflow internally based on TFX. Now, Kubeflow has extended to be a multi-architecture, multi-cloud framework for running entire ML pipelines.

Azure ML [1] is a machine learning platform where we can process data, build models and publish and stage a predictive model as an Azure-based service. Similar to Azure ML [1], AWS SageMaker [26] also provides the functionality to build models, train models, and deploy models in production. Both Azure ML and AWS SageMaker are closed systems making single component integrations challenging. The model management in Azure ML and AWS SageMaker is really focused on training a model and deploying a model in its own system. They are not model neutral and framework agnostic. Kepler [19] and Taverna [10] are popular scientific workflow systems which manage complex data analytics pipelines including data access, data analysis and mining steps, and many other steps including computationally intensive jobs on high-performance cluster computers.

We present a feature comparison of different model management systems in Table 1.

6 LESSONS LEARNT IN BUILDING GALLERY

6.1 Common ML Tools

Machine learning is becoming the essential component of many Uber product features. Accordingly, more and more teams at Uber are using machine learning or beginning to use machine learning. Different teams might be at different maturity stages of applying machine learning depending on the team's experience, but all of them will go through solving the common issues of managing the models in a machine learning application. Without shared common ML infrastructure tools, each team might waste a lot of resources to "reinvent the wheel." When we built Gallery, many teams express the similar needs of Gallery to manage their models. As a result, we made Gallery part of Uber's standard ML infrastructure as part of Michelangelo so that it could benefit all the teams at Uber. It also shows the importance of building common ML tools so that all the product teams can boost their productivity by focusing on their own business problems and model iterations without worrying about how to train, manage and serve their models.

6.2 Model Reproducibility

Shortly after onboarding the first group of users of Gallery, we observed and learned that one of the more desired features was model reproducibility. Reproducibility was not one of the original use cases we had in mind when we built Gallery. Instead, we had focused directly on performance tracking and alerting. However, it became clear that a user's natural follow-up to an alert is to attempt to reproduce the problem, and it was apparent a model management system needs to support this functionality. The original Gallery data model did not include many of the metadata components included today that led to model reproducibility (e.g., training data information, training frameworks and features), but an important lesson learned is that reproducibility is central to supporting the ML model lifecycle. Users need the ability to recreate models or replay history in order to understand their production flows and debug performance. Gallery has proven to be a valuable tool for model builders at Uber in simplifying the model debugging process.

6.3 Tiered Service Offering

Another lesson we have learned during the development of Gallery is how to make user adoption of such tools easy. As discussed before, there is a wide variety of ML tooling being used at Uber and teams across the company are working against their own deadlines with different features in their tech stacks. Therefore, there would be no single opportunity to ask users to migrate their workflows and no central mechanism by which we could directly onboard them to Gallery. Instead, we opted to provide a tiered set of features and solutions that teams could leverage as they had the bandwidth and discovered the need. We wanted our features to be modular in that users at any point in their maturity could leverage the system, with the opportunity to add more complex functionalities in the future.

Gallery features are broken up into four groups that are built on top of one another: 1) model storage and retrieval; 2) metadata storage and search; 3) metric storage and search; and 4) rule engine automation. As teams start to use Gallery in their systems, they sequence their onboarding based on the features and complexity that they need to unlock. For teams exploring new modeling techniques or building a system from scratch, it is often the case that they only need feature set 1), and optionally 2). Teams doing experimentation have not yet thought about automation and only need a place to dump models to rapidly do more testing. However, once teams have built out a model and are trying to scale to meet business requirements, they then see the need for feature sets 3) and 4). By using the base functionality of data storage and retrieval in their experimentation, there is only an incremental additional effort required to unlock more complex Gallery features that help to automate entire workflows. This approach helped Gallery gain quick adoption among five teams with in its first six months.

7 CONCLUSIONS

In this paper, we describe the machine learning model management problem across the different stages of a model's lifecycle for a large number of models and model instances in production environments at Uber. We describe the model lifecycle management system, Gallery, a solution used in production to manage machine learning models across different services at Uber.

Design for system automation up front is critical to manage thousands of machine learning models in production. Developing and applying machine learning models involves multiple stages across a model's lifecycle. Manually managing the models and model instances in production is not scalable and is error-prone. Building generic systems to be able collect and keep track of model and instance information, as well as dependencies is critical for maintaining accurate production systems. On top of the raw information, we can produce intelligence. With the help of rules, we can orchestrate the whole modeling workflow, which dramatically boosts data scientists and engineers' productivity and also makes the machine learning systems more reliable and scalable.

Building an agnostic model management system is critical for adoption and user on-boarding. At Uber, there are a large number of existing machine learning applications, which often leverage different languages and frameworks for model development and serving. Building Gallery to be agnostic to machine learning frameworks has allowed the system to be adopted by many teams at Uber and has helped the company to align on a common infrastructure for the machine learning model management.

8 ACKNOWLEDGMENTS

We would like to sincerely recognize and acknowledge the following contributors who played a significant role in the design, development, and productionization of Gallery at Uber: Anne Holler, Yifan Ma, Luke Duncan, Mani Bhushan, Aparna Dhinakaran, and Zhenghui Wang. Additional contributors to the project that we would like to thank also include Andrii Iasynetskyi, Rashmi Venugopal, and Steven Wright. We would also like to thank Haoyang Chen, from the Simulation Platform, for being the first to adopt Gallery and providing extensive feedback to improve the design of the system.

Diverse User Selection for Opinion Procurement

ABSTRACT

Many applications maintain a repository of user profiles with semantically rich information on each user. Such repositories have a potential of allowing active *opinion procurement*: reaching out to users to ask for their opinions on different topics. An important desideratum of the procurement process is that it targets a *diverse* set of users.

To realize this potential, we present `Podium`: a first framework, to our knowledge, that supports the selection of diverse representatives in presence of high-dimensional, semantically rich user profiles. We demonstrate that data dimensionality is a challenge for both defining and achieving diversification. We address these challenges by proposing a lightweight, flexible notion of diversity that in turn allows explanations and customization of diversification results. We show that the problem of finding an optimally diverse user subset is intractable, and provide a greedy algorithm that computes an approximate solution. We have implemented our solution in a system prototype and tested it on real-world crowdsourcing platform data. Our experimental results show that `Podium` is effective in selecting users with diverse properties, and in turn that the opinions of these users are diverse according to multiple metrics.

1 INTRODUCTION

Multiple applications involve active procurement of opinions from users. Consider, for example, a traveler planning a trip and looking for specific "tips" on some destination; an owner of a new restaurant wishing to perform a preliminary customer survey; or a website manager seeking usability feedback. A recurring desideratum in such applications is that procured opinions are *diverse*: the restaurant owner may seek users with diverse culinary preferences who live in a certain region, whereas the website manager may seek feedback from users with diverse activity history. Notably, diversity considerations may greatly differ between scenarios, even if users are selected from the same set.

Platforms such as Yelp[1] that have a large user base and high-dimensional, rich data on each user, provide an opportunity for procuring opinions from a diverse set of users. Yet, to our knowledge, there is no generic solution for selecting diverse representative users accounting for high-dimensional user profiles. In particular, users chosen for opinion procurement should ideally reflect the full range of user properties as observed in the source population – e.g., the full range of opinions on different topics, from positive to negative; the full range of user skills or activity levels, from low to high; etc. Hence, existing diversification solutions that target the overall accuracy of user answers/relevance of items and therefore operate by optimizing properties across multiple axes (e.g., selecting users' highest skills or activity levels) are inapplicable in this context, as explained in Section 2.

[1]Yelp website: https://www.yelp.com

To this end, we introduce `Podium`: a novel tool for the procurement of diverse opinions, utilizing multidimensional user profiles. We next overview our main contributions.

Model. Our model captures user profiles including both personal details provided by the users and their past interactions with the platform. These properties may be associated with a numeric score (reflecting, e.g., rating) and form high-dimensional data. We then provide a formal definition of the diverse user selection problem that is *coverage-based* [1–4]: i.e., the goal is selecting a user subset that in some sense represents or "covers" many of the different, possibly overlapping *groups* within a source population. This class of diversity notions fits typical scenarios of opinion procurement (e.g., surveys, market research), in contrast with *distance-based diversity*, which focuses on maximizing the differences between the members of the selected group [4–7]. As observable from Table 1, our diversity notion fulfills a unique combination of desiderata that arise at an opinion procurement scenario. We overview the desiderata and the compared solutions in Sections 2 and 9. We further propose an operative method for computing user groups from a repository of profiles, along with weight functions to prioritize the coverage of these groups, where the coverage of every group is impossible.

Analysis of the Basic Problem. Based on our model, we develop a solution to the diverse user selection problem. First, we show by a reduction from Set Cover that the decision problem corresponding to user selection in our context is NP-complete, and that finding a user subset of size approximately minimal that covers all the possible groups is also computationally hard. Moreover, in a high-dimensional setting, full coverage would typically require an unrealistically large number of procured opinions. Thus, instead of targeting full coverage and optimizing the subset size, we bound the size according to some budget and aim to select a user subset of that size that maximizes the *total coverage score*, to be defined in Section 3. Fortunately, a user subset whose coverage score is within a constant factor of the optimal can be found in PTIME. We show a simple greedy algorithm that achieves this bound, explain its data structures and optimizations, analyze its time complexity and demonstrate its operation on a sample user repository.

Customization and explanations. The required notion of diversity may vary based on the concrete application and depending on the multiple dimensions of user data, as exemplified above with respect to the different needs of a traveler versus restaurant owner versus website manager. We thus adopt a lightweight solution that facilitates interpretation of the results and in turn allows the clients to interact with the system to customize and fine-tune user selection. This is achieved through a formal definition of *explanations* for how the selected subset covers the population groups and the contribution of each selected user. We then formally define the semantics of a *user feedback* that allows an informed control over the user groups/data dimensions whose coverage is targeted. We extend our problem definition and analysis accordingly.

System	Type		Range	High-Dimension	Explanations	Customizable
Podium	Coverage-based	Intrinsic	✓	✓	✓	✓
Cohen & Yashinski [2]	Coverage-based	Intrinsic	✓*			✓
Stratified sampling (e.g., [8])	Coverage-based	Intrinsic			✓	✓
T-Model [4]	Coverage-based	Predicted	✓*

Yu et Al. [7]	Distance-based	Intrinsic		✓	**	
S-Model [4], DiRec [5]	Distance-based	Intrinsic	✓***	✓***		
DivRSci [6]	Distance-based	Predicted	✓***	✓***		

Table 1: Comparison of selected diversification solutions, according to the aspects discussed in Section 2. A diversity notion fulfills **Range** if it can diversify along a range of values (low to high) rather than just among categories, and **High-Dimension** if every candidate may be associated with a high number of properties. See Section 9 for more details on these solutions. Remarks: * Can support range coverage on a single dimension/property. ** Explanation for item relevance rather than subset diversity. *** Depends on the choice of distance function.

Implementation and experiments. We have implemented our solution in `Podium`, a prototype system including back-end implementation of our diverse user selection algorithm and a front-end that provides visualizations for our notions of explanations and user-friendly means of providing customization feedback (see Figure 1 for its architecture). We use this prototype to examine our approach over data from large-scale real-life user repositories. We first study the performance of our approximation algorithm, showing that it is effective in achieving diversity in terms of the selected user profiles according to the target function it approximates as well as multiple other diversity metrics. Next, we simulate opinion procurement using our algorithms (using ground truth user opinions), and test the diversity of procured opinions according to different metrics. Finally, scalability tests support the practicality of our algorithm for real-world data.

Paper Outline. In Section 2 we describe and motivate the desiderata from a diversification system in our context. Section 3 presents our model and basic problem definition, without customization, and in Section 4 we develop and analyze our solution for this basic problem. Next, we extend the basic solution to support the explanation and customization of the selection results in Sections 5 and 6 respectively. We describe our implementation of `Podium` in Section 7 and the experimental study conducted over it in Section 8. Section 9 discusses related work and we conclude in Section 10.

2 DESIDERATA

Diversification has been extensively studied in multiple contexts; we claim that diversification in the concrete context of opinion procurement has a *unique combination of traits*, which are not accounted for by previous work. We compare several representative previous solutions under the prism of these traits in Table 1. Next, we explain these features as well as the desiderata of diversification that follow; further detailed comparison with related work is given in Section 9.

Coverage vs. distance-based. A prominent approach for diversification is to quantify the (dis)similarity between items, and to then aim at finding items that optimize some aggregate function over the similarity scores, for instance, maximizing the minimal pairwise distance (e.g., [4–7]). Such an approach is valid in our setting, yet its sensitivity to skews in group sizes may yield less meaningful results for real-life datasets, as observed in our experimental results for the Yelp dataset in Section 8.

When it comes to gathering user opinions, a natural desideratum is that opinions are collected from users that in some sense faithfully represent the characteristics of the full population. Such representativeness is targeted by *coverage-based* approaches in different selection contexts – e.g., retrieving documents that cover the topics in a repository, or users that represent predefined groups within a source population (e.g., [1–4]). In contrast with distance-based approaches, coverage-based approaches can in particular be agnostic of the similarities within the selected subset.

We next define the *proportionate-allocation* user subset.

Definition 2.1. Let $\mathcal{G} \subseteq P(\mathcal{U})$ be a set of user groups. A user subset $U \subseteq \mathcal{U}$ is a *proportionate allocation* of $\mathcal{G}$ if for every $g \in \mathcal{G}$, it holds that

$$\frac{|g \cap U|}{|U|} = \frac{|g|}{|\mathcal{U}|}$$

A user subset for which this definition holds faithfully represents the source population in the sense that it has a number of selected representatives from each group that is proportionate to their number in the population. This trait is used by surveyors in *stratified sampling* to guarantee that certain inferences from the survey are statistically sound (e.g., [8, 9]). For that, surveyors and domain experts carefully define a small set of non-overlapping population groups to be represented (in particular, $|U| \geq |\mathcal{G}|$). See further discussion on surveys in Section 9.

However, in this work we consider user repositories that often form a huge number of highly overlapping user groups, *making proportionate allocation infeasible.* A user subset of size $|U| << |\mathcal{G}|$ with every group even roughly proportionally represented is unlikely to exist. We therefore develop, in the following sections, solutions for a relaxed problem formulation, in particular, aiming to avoid under-representation of groups but allowing over-representation and prioritizing the coverage of certain groups over others.

Intrinsic vs. predicted. Intrinsic diversity is computed based only on known properties (e.g., [2, 4, 5, 7]), whereas *predicted* diversity utilizes a function predicting unknown values for each selected item (e.g., a probabilistic distribution of the answer to some question) [1, 3, 4, 6]. Thus, predicted diversity notions typically optimize an expected target function (e.g., the expected number of different answers to be obtained).

In opinion procurement scenarios, the intrinsic approach, i.e., relying on user profiles rather than prediction of their opinions, is often preferable. First, the representation of different groups in the population may be the main client need, regardless of what their opinions are (e.g., having representatives for as many genders, age groups, nationalities, etc. as possible). Second, obtaining a reliable prediction of user opinions may be impractical – at least as hard as the original opinion procurement task. When this is the case, users with diverse profiles may provide a good alternative, since they are likely to provide relatively diverse opinions (as demonstrated in our experimental results in Section 7 and in [4]).

Diversification along a range of opinions. Diversification for opinion procurement is characterized by the need to diversify *along ranges of property values* – for example, one has to represent the full range of user opinions, from negative to positive; the full range of user activity or expertise levels, from low to high; users of all ages; etc. In contrast, diversification solutions that target the maximization of user skill or item relevance in diverse categories (as in, e.g., [1, 3]) are not applicable for capturing the full range of (skill/relevance) values in each category.

Support of high data dimensionality. In large-scale user repositories, each profile may consist of hundreds to thousands of properties (e.g., up to 2189 properties per user in the TripAdvisor dataset used in Section 8). Using such properties along with ranges of values associated with them (e.g., frequencies of some activity from lowest to highest), allows defining a huge number of meaningful population groups, larger by orders of magnitude from the number of selected representatives. A practical diversification solution should address this dimensionality problem either by significantly reducing the number of considered groups and/or by adopting a diversity notion and implementation that scale with the problem dimension.

Explanations and customization. Last, we have already noted (in the Introduction) that there is no one-size-fits-all solution for diversification and that different clients may have different diversification needs. To be able to fine-tune the diversification results, the clients must first be able to understand them - via some notion of *explanations* – and then have user-friendly *customization* mechanisms of modifying them according to their needs. The use of intricate optimization problems and/or interdependencies between selected items, which often makes sense the context of diversification, as well as the high scale and dimension make this desideratum nontrivial to achieve. Here, we address this challenge by adopting a simple diversification notion based on profile properties, which in turn are human-understandable, and then explanations and customization pertain to (modifying) how these properties are represented by the selected subset. (See Sections 5-6.)

In the following sections we describe our model and algorithmic solutions, achieving these desiderata.

3 MODEL

We next describe how user profiles are modeled in our framework. We then formally define the problem of diverse user selection with respect to this model.

Property	**Alice**	**Bob**	**Carol**	**David**	**Eve**
livesIn	Tokyo$^{(2)}$	NYC$^{(1)}$	Bali$^{(1)}$	Tokyo	Paris$^{(1)}$
ageGroup	50-64$^{(2)}$	–	50-64	–	–
avgRating Mexican	0.95$^{(3)}$	0.3$^{(1)}$	–	0.75	0.8
visitFreq Mexican	0.8$^{(1)}$	0.25$^{(1)}$	–	0.6$^{(2)}$	0.45
avgRating CheapEats	0.1$^{(1)}$	0.9$^{(1)}$	0.45$^{(2)}$	–	0.6
visitFreq CheapEats	0.6$^{(1)}$	0.85$^{(1)}$	0.2$^{(2)}$	–	0.3

Table 2: Example user profiles

3.1 User Profiles

Let $\mathcal{U}$ be a population of users and $\mathcal{P}$ be some domain of property labels. Following [10], we define the profile of a user $u \in \mathcal{U}$ as a tuple $D_u = \langle P_u, S_u \rangle$ where $P_u \subseteq \mathcal{P}$ includes all the properties known for u and $S_u : P_u \to [0, 1]$ maps each property to a score (normalized to $[0, 1]$). We use the notation $|p| = |\{u \in \mathcal{U} \mid p \in P_u\}|$, where $\mathcal{U}$ is assumed to be clear from the context. Property scores may have different interpretations depending on the type of property, e.g., true/false, user rating, and so on, and may be provided directly by u or automatically derived from u's activity in the website.

Example 3.1. Table 2 shows a few profiles from a travel website (for now, ignore the numbers in superscript). In the first two rows, `livesIn <city>` and `ageGroup <X-Y>` are true/false properties for relevant cities and age ranges. E.g., `livesIn Tokyo` is a property with score 1 (i.e., true) in Alice's profile. The third and fifth rows show scores that reflect the user average ratings for different types of restaurants, normalized to $[0, 1]$. Not every property is recorded for every user, e.g., Carol has never rated Mexican food. The fourth and sixth rows show scores reflecting the relative frequency that each of the users visits different types of restaurants.

In practice, user profiles may contain many properties – e.g., we have constructed from TripAdvisor[2] a user repository with up to 665 properties per user (Section 7). This is due to various activities of a user in the system (e.g., providing opinions about many destinations, each with many different features), due to various types of analysis performed over the data (e.g., one can compute the average rating, maximum rating...) and so on.

Using taxonomies to enrich profiles. To allow for an informed selection of users based on their profiles, these profiles should be as complete as possible. To this end, we perform a preprocessing step and apply *inference rules* on Boolean properties or on the raw data from which properties are derived. Such inference rules can be pre-specified as in RDF languages [11, 12] or derived via rule mining techniques [13]. A particularly useful type of inference rules is *generalization rules*, as exemplified next.

Example 3.2. The property `avgRating Mexican` in Table 2 is derived by averaging over the ratings given by each user to restaurants labelled as "Mexican Cuisine". On this raw data, we can apply a generalization rule if we know, e.g., by a cuisine taxonomy, that Mexican cuisine is a particular type of Latin cuisine. This will enable us to derive properties such as `avgRating Latin` for existing user profiles.

As another example, if `livesIn` is known to be a function, i.e., each person can only have one residence location in our repository, we can infer the falsehood of residence locations other

[2]TripAdvisor website: https://www.tripadvisor.com

than the one specified. Thus, by $S_{\text{Alice}}(\texttt{livesIn Tokyo}) = 1$ we can infer that $S_{\text{Alice}}(\texttt{livesIn X}) = 0$ for every X≠Tokyo.

Having inferred all possible properties, we consider all other properties by the *open world assumption*: missing properties may be either false or true. For instance, if no frequency of visiting Mexican restaurants is known for Carol, this does not mean she has not been to such restaurants.

3.2 Weight-based Diversification

We next define a generic, weight-based approach to coverage-based diversification. We exemplify different choices of weights and show their usefulness for capturing user selection strategies.

Definition 3.3. A *diversification instance* is a tuple $(\mathcal{G}, \text{wei}, \text{cov})$ where $\mathcal{G} \subseteq 2^{\mathcal{U}}$ is a set of (possibly overlapping) user groups of interest, $\text{wei} : \mathcal{G} \rightarrow \mathbb{R}^+$ captures the weight of each group, and $\text{cov} : \mathcal{G} \rightarrow \mathbb{N}$ captures the number of users required so that a group is said to be covered.

Given a diversification instance and a selected user set $U \subseteq \mathcal{U}$, we define the score of U as $\text{score}_{\mathcal{G}}(U) = \sum_{G \in \mathcal{G}} \text{wei}(G) \cdot \min\{|U \cap G|, \text{cov}(G)\}$.

Finally, given a diversification instance and a budget $B \in \mathbb{N}$, we define BASE-DIVERSITY as the problem of finding a subset $U \subseteq \mathcal{U}$ such that $|U| \leq B$ and $\text{score}_{\mathcal{G}}(U)$ is maximized.

Note that if groups in $\mathcal{G}$ are overlapping, each user may contribute multiple group weights to the total score. This definition accounts for diverse subset selection in the sense that the score increases as more groups in $\mathcal{G}$ have (more) representatives in U. *Excessive* representation ($|U \cap G| > \text{cov}(G)$) is not rewarded but also not penalized.

The problem is defined in a generic way with the diversification instance given as input. We next discuss and exemplify the three parts of this instance.

Groups. Our diversification solution can support any set of groups input by the client, including manually crafted groups as typically defined by surveyors [8, 9].

To support large-scale, high-dimensional user repositories we develop here a concrete group definition that is efficiently computable for such repositories on the one hand, and effective in identifying meaningful groups for diversification on the other hand. Recall that user profiles comprise of properties from $\mathcal{P}$ with scores in $[0, 1]$.

Definition 3.4. Let $p \in \mathcal{P}$ be a property and $b \subseteq [0, 1]$ be a (continuous) range of scores. A *simple user group* is the subset of users whose score for p falls in b, formally,

$$G_{p,b} := \{u \in \mathcal{U} \mid D_u = \langle P_u, S_u \rangle \wedge p \in P_u \wedge S_u(p) \in b\}$$

For the ranges of scores, we split the range of scores of each property $p \in \mathcal{P}$ into a set of *non-overlapping buckets* $\beta(p)$. The rationale is, e.g., to group Mexican food lovers and dislikers separately. The computation of $\beta(p)$ is done by partitioning the 1-d data into intervals (clusters). There are several methods for 1-d interval splitting that are more effective than general clustering since the data is ordered (e.g., Jenks optimization [14], K-means, Expectation Maximization and by kernel density).

Simple user groups can be used to define more complex ones as the intersection or union of a few simple groups.

We note that the simplicity of our group definition is key for allowing explanations (see Section 5). There are more complex alternatives to splitting ranges into groups, such as multidimensional clustering (in our case, over multiple properties); however, these generally do not facilitate explainability. For instance, multidimensional clusters have no intuitive "label" or meaning.

Example 3.5. Reconsider Table 2. Let p be the property `livesIn Tokyo` and $b = [1, 1]$; then $G_{p,b} = \{\texttt{Alice}, \texttt{David}\}$ (group of "Tokyo residents"). Let p' be the property `avgRating Mexican` and $b' = (0.65, 1]$; then $G_{p',b'} = \{\text{Alice, David, Eve}\}$ (group of "Mexican food lovers"). One can also define, e.g., $G_{p,b} \cap G_{p',b'} = \{\texttt{Alice}, \texttt{David}\}$ ("Tokyo Residents who are also Mexican food lovers").

Our default definition of $\mathcal{G}$ consists only of simple groups, and we examine its effectiveness in Section 8. In particular, we empirically show that this approach also implicitly accounts for more complex groups in the population (such as 'Tokyo Residents who are also Mexican food lovers" from the example above).

Group functions. Similarly to group definition, the group weights (wei) and cover sizes (cov) functions can in principle be manually tailored for a specific domain and diversification context. As a more practical alternative, we next propose a few general-purpose choices, which can be fine-tuned by clients via our customization mechanism (see Section 6).

Definition 3.6. Weights are used to prioritize groups. The following are three examples of $\text{wei}(G)$:

- *Identical Group Importance (Iden):* $\text{wei}(G) := 1$ (constant function).
- *Group Importance Linearly By Size (LBS):* $\text{wei}(G) := |G|$.
- *Group Importance Enforced By Size (EBS):* define $\text{ord}(\cdot)$ as an ordering of the groups from smallest to largest, [3] then define $\text{wei}(G) := (|U| + 1)^{\text{ord}(G)}$

Iden is the most "diverse" choice in the sense that it does not distinguish between groups, which by our problem definition will maximize the number of groups that are covered. However, in cases where only a small fraction of the groups can be represented/covered, one may choose to prioritize certain groups – e.g., large groups. Using LBS, the group importance is linear with its size, thus, e.g., the total weight of two groups of size X equals the weight of one group of size $2X$. This roughly corresponds to maximizing the number of groups represented *per user.* In EBS group importance by size is enforced, meaning that representing larger groups is always preferred over smaller ones. The latter requirement may apply to some diversification contexts, e.g., political surveys may aim to have at least one representative for each of the largest population groups.

Definition 3.7. The coverage function $\text{cov}(G)$ is used to guide how many users will be selected from each group. Examples include

- *Single Representative (Single):* $\text{cov}(G) := 1$ (constant function).
- *Proportional Representation (Prop):* $\text{cov}(G) := \max\{\lfloor |U| \cdot |G| / |\mathcal{U}| \rfloor, 1\}$ where $|U|$ is the size of the subset to be selected.

Here, Single is the most "diverse" definition in the sense that it requires only one representative from a group to consider it covered. In contrast, Prop rewards a representation that is proportional to the group size in the population.

We next exemplify the effect of using different functions on the resulting user choices.

Example 3.8. Reconsider the user profiles in Table 2 and assume that we define, for each property, three groups of users:

[3]Ties, i.e., groups of equal size, are broken arbitrarily.

those with scores in $[0.65, 1]$ ("high"), in $[0.4, 0.65)$ ("medium") and in $[0, 0.4)$ ("low"). The numbers in superscript at the table show the weights according to LBS – i.e., number of users – on the first user of each group. E.g., the only group with 3 users is `avgRating Mexican high`. The diverse user subset of size 2 that would be selected is {Alice, Eve} with total score 17. Single and Prop behave similarly here, and EBS would yield the same result with different scores. If instead we use Iden, then {Alice, Bob} will be selected with total score 11 (number of represented groups). This exemplifies the tendency of Iden to select more eccentric users, in this case Bob who is the only member of his groups, where LBS and EBS prioritize representatives of larger groups, in this case leading to a larger overlap (Alice and Eve are both Mexican food lovers).

Having defined our model, we next address the computational problem of BASE-DIVERSITY.

4 SOLVING BASE-DIVERSITY

We next consider the computation of a diverse subset of users according to Def. 3.3 of the BASE-DIVERSITY problem. We start by analyzing the complexity of the problem.

Unsurprisingly, we show that achieving an optimal solution is intractable in the subset size B unless P = NP, even for simple weight functions and even without customization. The decision problem DEC-DIVERSITY corresponding to BASE-DIVERSITY is that of the existence of a subset U with $|U| \leq B$ such that the sum of (customized) weights of covered groups exceeds a threshold T. We can then show:

PROPOSITION 4.1. DEC-DIVERSITY *is* NP*-complete in B.*

PROOF. Membership is immediate, since computing the total weight of a given user subset is in PTIME.

Hardness is proved by a reduction from Set Cover: Given a universe $\{1 \ldots N\}$, a set of subsets $\{S_1, \ldots, S_m\}$ and an integer k, we define $B = k$, $\mathcal{G} = \{G_1, \ldots, G_N\}$ and $\mathcal{U} = \{u_1, \ldots, u_m\}$, such that iff $i \in S_j$, then $u_j \in G_i$. Finally, we set $T = \sum_{G \in \mathcal{G}} \text{wei}(G) \cdot \min\{\text{cov}(G), B\}$, where wei$(G)$ can be any legal function and we set cov(G) as the constant function 1 (Single, as we need only one set to cover each element). Since T is the maximum total score achievable, by covering every group in $\mathcal{G}$, it will be achieved by and only by a user subset that corresponds to a Set Cover. □

Approximate solution. The reduction from Set Cover implies not only the intractability of an exact solution but also of a constant-factor approximation in terms of the size of the *covering group.* To formalize this, given an instance of BASE-DIVERSITY and a threshold score T, let opt(T) be the minimal size of a subset $U \subseteq \mathcal{U}$ whose score exceeds T. We then have, based on [15] inapproximability result for set cover:

PROPOSITION 4.2. *Assuming $P \neq NP$, there is no PTIME algorithm for* BASE-DIVERSITY *that given a threshold score T, finds a user subset U of size* $(1-O(1)) \cdot ln(|\mathcal{G}|) \cdot \text{opt}(T)$ *with* $\text{score}_{\mathcal{G}}(U) \geq T$.

Fortunately, this does not exclude the possibility of approximation in the second axis, namely achieving a near-optimal score while conforming to the given budget. Indeed, a simple greedy algorithm achieves a constant approximation ratio in this sense.

Algorithm 1 outlines this greedy selection. Its input is a repository of users, a bound B on the number of users and a diversification instance (groups, weight function and coverage function). The algorithm starts by initializing an empty U (line 1) and computing, for each user the value $\text{marg}_{u,U}$, which stands for the

Algorithm 1: Greedy User Selection

```
Input: $\mathcal{U}$, $B$, $\mathcal{G}$, $wei$, $cov$
Output: $U$ (a set of $\leq B$ users)
1  $U \leftarrow \emptyset$;
2  foreach $u \in \mathcal{U}$ do $\text{marg}_{u,U} \leftarrow \sum_{G \in \mathcal{G} | u \in G} \text{wei}(G)$ ;
3  for $i \in 1..B$ do
4      if $\mathcal{U}$ is empty then break;
5      maxUser $\leftarrow \arg\max_{u \in \mathcal{U}} \text{marg}_{u,U}$;
6      $U \leftarrow U \cup \{\text{maxUser}\}$, $\mathcal{U} \leftarrow \mathcal{U} - \{\text{maxUser}\}$;
7      foreach Group $G$ such that maxUser $\in G$ and $\text{cov}(G) > 0$
        do
8          $\text{cov}(G) \leftarrow \text{cov}(G) - 1$;
9          if $\text{cov}(G) = 0$ then
10             foreach $u \in G$ do $\text{marg}_{u,U} \leftarrow \text{marg}_{u,U} - \text{wei}(G)$;
11 return $U$
```

potential marginal contribution of u to the total score if added to U (line 2). The algorithm then iteratively selects B users. Unless $\mathcal{U}$ is empty (line 4), the user maxUser with the greatest marginal contribution is selected (line 5) and moved from $\mathcal{U}$ to U (line 6). For each group G covered by maxUser, its required coverage cov(G) decreases by 1 (line 8), and if no more representatives are required to cover G (cov$(G) = 0$) then G should have no effect on the selection of the following users. We thus, subtract wei(G) from the marginal contribution of its other members (line 10). After B iterations (or earlier, if $|\mathcal{U}| < B$) the algorithm returns U.

Data Structures. For efficiency, we represent both the groups and the users as lists, each group $G \in \mathcal{G}$ with its current wei(G) and cov(G) values, and each user $u \in \mathcal{U}$ with $\text{marg}_{u,U}$. We further keep links in both directions between the lists, from groups to their members and vice versa. Whenever we (re)compute $\text{marg}_{u,U}$ we can remove the links from the user to groups with weight 0 or coverage size 0, which are not (or no longer) relevant for the user selection, to improve the performance of subsequent computations.

Example 4.3. We next exemplify the execution of Algorithm 1 for the user selection scenario in Example 3.8, using LBS and Single. After executing line 2 the marginal contributions of Alice, Bob, Carol, David and Eve, namely, the sum of weights of their properties, are 10, 5, 7, 6 and 10 respectively. Assume that at the first iteration of the external loop Alice is chosen and removed from $\mathcal{U}$ to U (ties are arbitrarily broken; in this example, selecting Eve happens to lead to the same output). Then the coverage of each of Alice's groups is set to 0. For each such update, the marginal contribution of other members of the groups is reduced: first, the contribution of David is reduced by 2 due to the `livesIn Tokyo` group; next, the contributions of David and Eve are reduced by 3 due to the `avgRating Mexican high` group; and so on. At the end of the first iteration, the contributions of Carol, David and Eve are updated to 5, 2 and 7 respectively. Thus, Eve is chosen at the next iteration, and {Alice, Eve} would be the output, which in this case is also the optimal solution.

PROPOSITION 4.4. *Algorithm 1 computes a* $(1-1/e)$*-approximation of* BASE-DIVERSITY*, i.e. achieves a score that within a multiplicative factor of at least* $\geq (1 - 1/e)$ *of the optimal for the given budget, in time* $O(B \cdot \max_{G \in \mathcal{G}} |G| \cdot \max_{u \in \mathcal{U}} |\{G' \in \mathcal{G} \mid u \in G'\}|)$.

PROOF. The complexity of Algorithm 1 is $O(B \cdot |\mathcal{U}| \cdot |\mathcal{G}|)$ due to the updates of the marginal user contributions (line 10). This line is nested within three loops. The loop line 3 repeats O(B) times, the loop at line 7 repeats O($\max_{u \in \mathcal{U}} |\{G' \in \mathcal{G} \mid u \in G'\}|$) times, namely, bounded by the maximal number of groups per user, and the innermost loop (line 10) repeats at most O($\max_{G \in \mathcal{G}} |G|$) times, namely, bounded by the size of the largest group. We assume constant complexity for arithmetic computations and for getting the next group of a given user/next user of a given group (as links in both directions are maintained).

As for the approximation ratio, observe that the score function satisfy the following properties *regardless of the choice of wei, cov*:

- *Submodularity.* For any $U \subseteq U' \subseteq \mathcal{U}$ and $u \in \mathcal{U}$ we have $\text{score}_{\mathcal{G}}(U \cup \{u\}) - \text{score}_{\mathcal{G}}(U) \geq \text{score}_{\mathcal{G}}(U' \cup \{u\}) - \text{score}_{\mathcal{G}}(U')$.
- *Non-negativity.* $\text{score}_{\mathcal{G}}(\cdot) > 0$ since wei(G) and cov(G) are positive.
- *Monotonicity.* If $U \subseteq U'$ then $\text{score}_{\mathcal{G}}(U) \leq \text{score}_{\mathcal{G}}(U')$.
- *Bounded input.* The size of a selected subset is bounded by B.

For such functions, a greedy algorithm that iteratively adds one user u to the selected subset U so as to maximize $\text{score}_{\mathcal{G}}(U \cup \{u\})$ is known to guarantee the stated approximation ratio [16]. □

Clearly, $\max_{G \in \mathcal{G}} |G| = \text{O}(|\mathcal{U}|)$ and $\max_{u \in \mathcal{U}} |\{G' \in \mathcal{G} \mid u \in G'\}| = \text{O}(|\mathcal{G}|)$. If we use only simple groups, the complexity bound of Prop. 4.4 may be simply written as $\text{O}(B \cdot \max_{G \in \mathcal{G}} |G| \cdot \max_{u \in \mathcal{U}} |P_u|)$.

5 EXPLANATIONS

We have proposed a simple generic framework for diverse user selection. We next consider notions of *explanations* of the diversification results, allowing clients to understand why certain users were selected and how certain groups were covered. This, in turn will enable the clients to use customization (see the next section) to refine these results.

Recall first that we have defined user profiles based on support values with respect to properties. We will use the set of property names in $\mathcal{P}$ to define *labels*; in practice, this entails that we will keep them in a human-readable form, and their combination will be used in presented explanations.

We further introduce labeling to simple groups, as follows. Each bucket is given a label, e.g. "low scores", "medium scores" and "high scores". Then, the *label* $G_{p,b}$ of each group can be constructed from the property name p and the label corresponding to the bucket b, e.g., "high scores for Mexican cuisine (average rating)".

We then define the notion of explanation to be presented to the client alongside the computed user subsets. Such explanations may be practically shown to users by visual means (see Section 7).

Definition 5.1. We introduce three types of explanations.

- *Group explanations.* Let $G \in \mathcal{G}$ be a group labeled l_G, we define its explanation as $\text{expl}(g) = \langle l_G, \text{wei}(G), \text{cov}(G) \rangle$, namely the property and bucket that defines it, along with its weight and required coverage.
- *User explanation.* The explanation of a selected user $u \in U \subseteq \mathcal{U}$ is defined as $\text{expl}(u) = \{G \in \mathcal{G} \mid u \in G\}$, namely, the groups which u represents.
- *Subset-group explanation.* Let $U \subseteq \mathcal{U}$ and $G \in \mathcal{G}$ be a selected user subset and a group. The explanation of how U covers G is the pair $\langle \text{cov}(G), |U \cap G| \rangle$, which represents the required versus actual coverage.

These explanations are complementary in the sense that they provide intuition about different aspects of the diverse selection: respectively, of the group meaning and importance; of why a given user was selected; and on how the selected user subset, as a whole, covers a certain group.

Example 5.2. Reconsider the selection of {Alice, Eve} in Example 3.8 in our running example. Assume that each property is given a human readable label, and we are further given labels for the buckets of Boolean properties and properties with a score. Group explanations may then be ⟨"high average rating for Mexican Cuisine", 3, 1⟩, since the weight of this group reflects its size, 3, and we use Single – one user to cover each group. "High" is the label of the bucket in range $(0, 65, 1]$. Similarly, we may have ⟨"lives in Tokyo", 2, 1⟩, where the label of the bucket $[1, 1]$ is empty for Boolean properties, and "lives in Tokyo" is the property label. Next, an explanation for Alice would be the groups she represents, "high average rating for Mexican Cuisine", "lives in Tokyo" and so on. The explanation for {Alice, Eve} with respect to the former group would be ⟨1, 2⟩, meaning both selected users belong to this group, exceeding the required coverage.

6 CUSTOMIZATION

Given the user selection results and their explanations, clients may fine-tune the algorithms if the results do not fit their needs. Specifically, we introduce customization at the level of individual groups (which, in a sense, correspond to the granularity of explanations that are shown). This customization is applied "on top" of the high-level decisions of how weights are assigned, which would typically not be made at the group level.

Definition 6.1. A *customization feedback* of the user is composed of four subsets of $\mathcal{G}$.

- $\mathcal{G}_+$: "must have" groups, each selected user must belong to all of them.
- $\mathcal{G}_-$: "must not" groups, each selected user must belong to none of them.
- $\mathcal{G}_d$: "priority coverage" groups, whose coverage is prioritized over others.
- $\mathcal{G}_{d?}$: "standard coverage" groups, whose coverage is of a lower priority with respect to the priority coverage groups.

Intuitively, the first two types of feedback serve to filter the repository of users. To avoid contradictions, if $\mathcal{G}_+$ contains more than one bucket of some property p, users need only belong to one of them. By default, $\mathcal{G}_+ = \mathcal{G}_- = \emptyset$. The priority and standard coverage group definitions allow to prioritize the coverage of certain groups, or completely ignore them in terms of coverage (groups in $\mathcal{G} - (\mathcal{G}_d \cup \mathcal{G}_{d?})$). By default, $\mathcal{G}_d = \emptyset$ and $\mathcal{G}_{d?} = \mathcal{G}$.

Example 6.2. Assume that for a particular application, the client prefers users from diverse locations and who are familiar with Mexican food. This may be captured by the following customization feedback:

- The "must have" groups consists of the three buckets of `AvgRating Mexican`, thereby requiring that the selected users have provided some rating for some Mexican restaurant.
- The "priority coverage" groups $\mathcal{G}_d$ consists of the multiple `livesIn <city>` properties.
- Finally, $\mathcal{G}_- = \emptyset$ and $\mathcal{G}_{d?} = \mathcal{G} - \mathcal{G}_d$.

We will demonstrate below how these choices guide user selection.

The effect of a customization feedback on the chosen groups is formalized as follows.

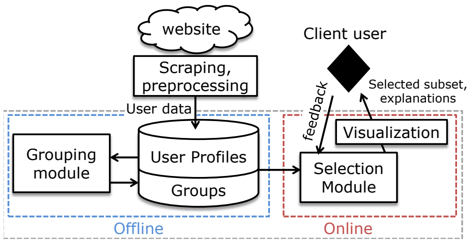

Figure 1: System Architecture

Definition 6.3. Given a customization feedback $\mathcal{G}_+, \mathcal{G}_-, \mathcal{G}_d$ and $\mathcal{G}_{d?}$, define the refined set of users as

$$\begin{aligned}\mathcal{U}' =& \{u \in \mathcal{U} \mid \forall G_{p,b} \in \mathcal{G}_+,\ \exists b' \in \beta(p):\ u \in G_{p,b'} \wedge G_{p,b'} \in \mathcal{G}_+\} \\ & \cap \{u \in \mathcal{U} \mid \forall G_{p,b} \in \mathcal{G}_-:\ u \notin G_{p,b}\}\end{aligned}$$

The customized diversity problem CUSTOM-DIVERSITY is then to select new subset $U \subseteq \mathcal{U}'$, of size $\leq B$, that maximizes $\text{score}_{\mathcal{G}_d}(U)$, namely, the sum of weights over covered groups from $\mathcal{G}_d$, breaking ties by $\text{score}_{\mathcal{G}_{d?}}(U)$.

Example 6.4. Reconsider the problem of selecting a user subset of size 2 from Example 3.8. We now incorporate the customization feedback of Example 6.2. The refined user set will exclude Carol who did not rate Mexican food. The best user subsets using Single and LBS functions is still {Alice, Eve}: first, it maximizes the sum of weights over `livesIn <city>` properties (to 3). Among other subsets that achieve this maximum (e.g., {Alice, Bob}), the selected subset further maximizes the sum of weights over other properties (to 14). Note that a different customization feedback would yield a different result; e.g., if we set $\mathcal{G}_{d?} = \emptyset$ then any subset maximizing the sum of weights over `livesIn <city>` properties may be selected.

Results revisited. CUSTOM-DIVERSITY is NP-complete, as an easy consequence of the NP-completeness of BASE-DIVERSITY. Further, the counterpart of Proposition 4.4 holds:

Proposition 6.5. CUSTOM-DIVERSITY *may be approximated within a multiplicative factor of at least* $(1 - 1/e)$ *in time* $O(B \cdot \max_{G \in \mathcal{G}} |G| \cdot \max_{u \in \mathcal{U}'} |\{G' \in \mathcal{G} \mid u \in G'\}|)$

Proof. The approximation algorithm is an adaptation of Algorithm 1 to account for customization feedback, as follows.

We first change the weights of the total score function to simulate a primary order by "priority coverage" groups and secondary order by "standard coverage" groups. The $\widetilde{\text{score}}(U) = \text{score}_{\mathcal{G}_d}(U) \cdot \text{MAX-SCORE} + \text{score}_{\mathcal{G}_{d?}}(U)$ where MAX-SCORE is a value greater than the maximum value of $\text{score}_{\mathcal{G}_{d?}}(U)$.

It now holds that:

Lemma 6.6. *The* $\widetilde{\text{score}}(U)$ *function is submodular, non-negative and monotone.*

We further refine the user repository to be $\mathcal{U}'$ of Definition 6.3, by filtering out user profiles that do not satisfy the conditions.

Last, we change Algorithm 1 so that instead of greedily selecting from $\mathcal{U}$ based on $\text{score}_{\mathcal{G}}(U)$, it selects from $\mathcal{U}'$ based on $\widetilde{\text{score}}(U)$. Following Lemma 6.6, the refined algorithm satisfies the approximation guarantees.

Figure 2: Screenshot of Podium UI: selection explanation

Explanations. The explanations defined in Section 5 can also be used for explaining customized results. The set of users and weights of groups may be different; in particular priority coverage groups will have a higher weight indicating a higher priority. Clients may not be able to interpret the values of weights, but they will be able to compare weights between groups to understand their relative importance.

7 IMPLEMENTATION

We developed Podium as a prototype system, implemented in Python using Flask[4]. Its architecture is depicted in Figure 1. The input to Podium is a set of user profiles, as explained in Section 3.1, in JSON format. Given a set of user profiles, the *Grouping Module* computes the bucketing of properties and the weights of groups in an offline process. Podium also allows an administrator to feed in an *initial set of diversification configurations* with associated textual descriptions.

The Graphical User Interface of Podium was created using AngularJS 1.6.4[5]. Given a user selection request, the *Selection Module* executes the user selection algorithm and returns the selected subset and its explanations to the client via the *Visualization* module. Figure 2 shows the explanation page for the initial configuration titled "Summer Pavilion", which only considers properties related to a restaurant in that name. The labels of the groups in this page are taken from the group explanations of Def. 5.1. The left pane displays the names of selected users, along with the top-weight groups that were covered by each (corresponding to user explanations of Def. 5.1). The middle pane uses the subset-group explanations of Def. 5.1 to show the percentage of top-weight relevant groups covered by the selected subset (in this case, 97%). The list of groups, ordered by decreasing weight, is displayed below with covered groups in green and the others in red.[6] When clicking any group, the right pane displays a graph comparing the score distribution for the relevant property between the entire population and the selected subset (in Figure 2 the distributions are almost identical). Users can browse the different groups and refine the selection by adding groups to $\mathcal{G}_+$ and $\mathcal{G}_-$ ("Selected users must / not have this property"); and to $\mathcal{G}_d$ and $\mathcal{G}_{d?}$ ("Do not / diversify on this property").

8 EXPERIMENTAL STUDY

We have examined the performance of our system, first, by evaluating the intrinsic diversity of the selected subset, i.e., how well it represents the source population (as explained in Section 2, proportional allocation is generally impossible in our setting). While an intrinsically diverse subset is sufficient in some user selection scenarios, in others one cares also for the eventual diversity of procured opinions. In order to examine this aspect, we

[4]Flask. http://flask.pocoo.org
[5]AngularJS. https://angularjs.org
[6]For space constraints, some group names in Figure 2 are truncated.

have selected datasets *with known ground truth*, i.e., where user opinions are already recorded. We have used these to simulate opinion procurement from the selected user subset and evaluate the diversity of collected opinions.

8.1 Datasets

The datasets used in our experimental study are real-world user repositories, focusing on the domain of restaurant reviews. The raw data is pre-processed to obtain aggregated scores for different categories based on user activity, as explained below.

The first dataset that we use consists of a sample of TripAdvisor [17] restaurant reviews data. This dataset contains data from 4475 users reviewing a total of 50K restaurants, and 11749 different groups. The raw data contains both user submitted data (e.g. age, residence) and user activity data (e.g. visited destinations), pre-processed and enriched as explained in Section 3.1, to generalize, e.g., Mexican cuisine to Latin cuisine.

The second dataset is the Yelp Open Dataset [18], which contains businesses, reviews, and user data for use in academic purposes. In our experiments we have used a subset of the data: for compatibility with the TripAdvisor dataset we used only restaurant-related data and took the 60K users with most reviews – reviewing a total of 52K restaurants and forming 8491 different groups. This limit was used in our *qualitative* experiments (see Section 8.4) due to memory limitations of some of the other baselines – recall that each user belongs to many groups. In comparison with the TripAdvisor dataset, the Yelp dataset has more users, but less groups due to its simpler semantics.

The datasets include two types of properties: ones that appeared explicitly in the original data, such as age and address; and ones that we have derived based on aggregation of user activities, as follows.

- *Average Rating.* The average rating given by a user to restaurants of a certain category (e.g. French cuisine), normalized by the overall average rating of that user.
- *Visit Frequency.* The fraction, among all the restaurants visited by a user, of restaurants from a certain category.
- *Enthusiasm Level.* A combination of rating and visit frequency, computed as the fraction of rating points given by the user to restaurants of a certain category.

8.2 Metrics

We next introduce metrics for algorithm performance, in three categories. *Intrinsic diversity metrics* are computed from the known properties of the selected user subset. *Opinion diversity metrics* are computed from opinions of the user subset, which are unknown to the user selection algorithms as explained in the beginning of this section. Finally, we evaluate the *scalability* of the algorithms.

Intrinsic diversity metrics. We consider a few complementary metrics, including our definition of total score – since our algorithm only approximates its optimal value – but also metrics of coverage that are not targeted directly by `Podium`.

- *Selection total Score.* According to Def. 3.3. We focus on the LBS weights and Single coverage functions, which our algorithm aims to approximate. This score can give us an intuition about alternative algorithms, since it reflects the number of groups and users within them that are represented by the subset.
- *Top-k groups coverage.* There are thousands of groups within the source population, which cannot be covered even by one representative in a small selected subset. We consider whether the top-k largest groups have selected representatives. In our experiments we have set $k = 200$.
- *Intersected-Property Coverage.* This metric is similar to the previous one, but now we consider intersections of simple groups that are at least as large as the k-th largest simple group.
- *Distribution Similarity.* This metric examines the similarity of user distribution between the source population and the selected subset, according to Def. 8.1 below.

The last metric aims at testing whether the number of representatives selected for groups is proportional to their number in the population, even if the coverage size is Single. Intuitively, our algorithm is likely to choose more representatives for larger groups without targeting it explicitly. However, standard distribution similarity metrics (such as Kolmogorov-Smirnov goodness of fit test) are not adequate for this purpose: to enhance coverage, small groups *must be over-represented.* We therefore define a distribution similarity metric that only taxes the selected user subset for under-representation of groups.

Definition 8.1. Let $B = b_1, \ldots, b_k$ be a discrete set of values. Let $f_{\text{subset}}, f_{\text{all}} : B \to [0, 1]$ be two functions over B, intuitively applied to the entire population and the selected subset respectively. We define the *coverage-oriented distribution similarity* (CD-sim, for short), as cd-sim$(f_{\text{subset}}, f_{\text{all}})$ =

$$1 - \frac{1}{k} \sum_{f_{\text{subset}}(b_i) < f_{\text{all}}(b_i)} \frac{(f_{\text{all}}(b_i) - f_{\text{subset}}(b_i))}{f_{\text{all}}(b_i)}$$

Note that this definition sums only over values of the domain for which the subset (f_{subset}) returns a lower result than the full population (f_{all}), corresponding to under-representation. Normalizing by the size of the full population guarantees that under-representations of larger groups are preferred, since the relative tax each missing user incurs is smaller.

For the group bucket distribution similarity, for a given property $p \in \mathcal{P}$, we set $B = \beta(p)$ (i.e., the set of buckets computed for p) and for $b \in \beta(p)$, we define $f_{\text{all}}(b) \mapsto \frac{\text{wei}(G_{p,b})}{\sum_{b' \in \beta(p)} \text{wei}\left(G_{p,b'}\right)}$ (the fraction of the weight that falls in the b bucket, which corresponds to the fraction of the users that belongs to this group). Similarly, we define $f_{\text{subset}}(b) \mapsto \frac{\text{wei}(G_{p,b} \cap U)}{\sum_{b' \in \beta(p)} \text{wei}\left(G_{p,b'} \cap U\right)}$ for a selected subset $U \subseteq \mathcal{U}$. For the overall distribution score, we average CD-sim for the top-20 largest groups.

Example 8.2. An example user distribution for the property "Mexican Food Average Rating" could be [0.23,0.4,0.37], meaning 23% of the population rate Mexican food poorly, etc. A selection distribution of [0.4,0.5,0.1] would receive a CD-sim score of 0.76, reflecting a penalty solely for the under-representation of the third sub-group, and not for the over-representation of the others.

Diverse opinion metrics. Thus far, the diversity metrics we considered were defined over user profiles. We next introduce metrics that consider the diversity of procured opinions. For that, we split the data into profiles used for selection, and data that simulates the procured opinions. For instance, we can select users from TripAdvisor based on their profiles excluding the data related to some destination, then evaluate diversity of the selected subset reviews on the excluded destination.

To measure diversity of opinions we have used complementary metrics that relate to the rating provided by the selected subset and their reviews' contents. Importantly, user opinions range not only over sentiment (positive or negative), but also over the facets that interest them with respect to the object in review.

- *Topic+Sentiment Coverage.* We measure content coverage using a list of prevalent topics extracted by TripAdvisor from each destination's reviews. We measure the fraction of topics that appear in the selected subset reviews. We also consider the review sentiment, such that 100% coverage means every topic appears in both a positive and a negative review.
- *Usefulness.* Available only for Yelp dataset, based on user feedback to reviews. A review is more useful when it is well-written, but also when a larger group of users agree or can relate to its contents. In this sense, the review is more likely to represent the opinions of large population groups, which is what we target in coverage-based diversity. We compute this metric by summing over individual reviews usefulness levels.
- *Rating Distribution Similarity.* Reusing our distribution similarity metric CD-sim, we measure the similarity in *rating distribution* between the selected subset and the entire population. For a given destination we set $B = \{1, \dots, k\}$ (i.e., the set of possible rating values) and for $i \in \{1, \dots, k\}$, let $R_i \subseteq \mathcal{U}$ be the set of users that gave this destination a rating of i. We define $f_{\text{all}}(i) \mapsto \frac{|R_i|}{\sum_{j=1}^{k} |R_j|}$. Similarly, for a selected subset $U \subseteq \mathcal{U}$ we define $f_{\text{subset}}(i) \mapsto \frac{|R_i \cap U|}{\sum_{j=1}^{k} |R_j \cap U|}$
- *Rating variance.* Variance of the rating given by the selected subset to a given destination.

All of the above metrics are defined per destination, to obtain an overall score we average over all destinations.

Scalability. We have tested the system execution times and scalability with respect to the number of users and profile size.

8.3 Baselines

We consider the following alternatives algorithms for diverse user selection.

- `Podium`. Our implementation as described above. By default, we use no customization feedback, LBS weights (Def. 3.6), the Single coverage function (Def. 3.7) and a budget $B = 8$, which also applies to the other baselines.
- *Random Selection.* An algorithm that selects a subset of the users uniformly at random. This method is a common practice in user selection for opinion procurement in the context of e.g. surveys, and under certain conditions there are reasons to assume the selected set of users is likely to be diverse. However, it has already been observed that explicitly managing diversity is often helpful in improving the results [4], which we will demonstrate in our setting.
- *Clustering.* Splitting the entire user repository into clusters, and choosing one representative from each – assuming each cluster represents a community. This approach has an inherent drawback as the clusters may have no intuitive explanation or customization; yet here we compare its performance to ours on other metrics. There are many options for clustering algorithms and representative choice. We have tested several options and show here one generally practical choice: computing B clusters using k-means (Scikit-Learn implementation[7]), then taking the near-mean user as the representative per cluster. k-means is particularly suitable to our settings: large, high-dimensional normally-distributed data, easy parametrization and is known to achieve comparatively high quality and low execution times (see, e.g., a comparison of clustering solutions in [19]).
- *Distance-based diversity.* While the distance-based approach for diversification has a different goal than coverage-based diversity (as explained in Section 2), it is still interesting to compare its performance to ours. As a representative distance-based baseline we use the S-Model of [4] via a greedy algorithm that maximizes the pairwise Jaccard distances between the properties of the selected subset.
- *Optimal Selection.* Naïve iteration over all user subsets of size B to obtain the optimal total score. This baseline is naturally applicable only for small values of B, and used to examine how good is the approximation achieved by our algorithm in practice, compared to the theoretical bound.

[7]Scikit-Learn. http://scikit-learn.org

8.4 Qualitative Results

We next describe our experimental results regarding the achieved diversity. All experiments have been conducted on a Windows 10 machine powered by an Intel Core i7 7500U processor with a 16 GB of DDR4 memory.

Intrinsic diversity results. We depict the intrinsic diversity comparison between baselines for the TripAdvisor and Yelp datasets in Figures 3a and 3c, respectively. For showing different metrics on a similar scale, all scores are *normalized relative to the leading algorithm's score*; the value of the leading score is denoted on the relevant bar. Our main findings are summarized as follows.

- `Podium` outperforms its alternatives in every tested diversity metric.
- Yelp is a more difficult dataset than TripAdvisor, since the former has less properties and less "room for maneuver"; for this dataset our results are better than the baselines by a significantly larger gap.
- Results for top-200 coverage and intersected property coverage indicate that our algorithm implicitly accounts for representing a high percentage of the largest groups, including complex ones – suggesting that selection based on simple groups may be sufficient for coverage purposes.
- The distance-based baseline performs poorly in covering complex groups, since it explicitly avoids intersections with overlapping properties between users.
- Surprisingly, our algorithm achieves a high similarity to the group distribution in the source population, although we do not optimize this directly.
- Our algorithm achieves the best total selection score by a large gap - this is expected, since our algorithm approximates the optimal value for this function.
- We were only able to test the optimal selection algorithm on a restricted source population and very small subset sizes due to the exponential runtime, hence it is omitted from the graphs. Generally, the total score achieved by `Podium` greatly exceeded the approximation bound and was near-optimal in all of our experiments. E.g., for selecting 5 out of 40 users `Podium` provided a .998 approximation ratio of the optimal.
- Since each user belongs to many groups, we can achieve high coverage even with a small B. As B increases, all the

quality metric improve and the gaps between the baselines slightly decrease, but the general trends are preserved.

These results indicate that it is able to select good representatives of the sources population in different respects, covering most large groups and leaving few under-represented groups. Regarding the competitors, we observe that clustering is inferior in almost every metric; this indicates that the splitting of population into cluster is probably unable to identify meaningful groups, and is outperformed even by random sampling.

The results also indicate that distance-based selection is less able to represent groups not explicitly defined in the dataset. Generally, the main difference between the distance-based approach and ours is the pairwise intersection in user properties – e.g., 2 versus tens on average that we get for the Yelp dataset. Consequently, when there are a few prevalent categories that are shared by many users, the distance-based approach tends to seek the few users that do not have these categories, which comes at the expense of coverage and distribution similarity.

Opinion diversity results. We now consider whether indeed the selected user subset, by Podium and its alternatives, provides diverse opinions, according to the metrics defined in Section 8.2. Naturally, the considered groups in $\mathcal{G}$ may affect the opinion diversity for algorithms that rely on groups. In these experiments, we have chosen to consider groups that are defined from properties related to cuisine and location, as a client seeking opinions about a restaurant might have chosen.

For the TripAdvisor dataset (Figure 3b) we have examined 50 destinations with an average of 90 reviews per destination.

For the Yelp experiment (Figure 3d) we have considered 130 destinations with an average of 1730 reviews per destination.

Concluding both experiments, our main findings are:

- Podium achieves the best results in any tested metric for each dataset, with the exception of rating variance.
- Distance-based is the strongest competitor of Podium in this set of experiments; however, in the Yelp dataset we still see a significant gap w.r.t. Podium in topic coverage and usefulness.
- Podium achieves a good balance in the tradeoff between attaining dissimilar ratings/sentiments (as reflected in rating variance and distribution similarity) – which tends to the selection of "eccentric" users – and attaining representative opinions that cover prominent topics (as reflected in topic coverage, usefulness) – which tends to the selection of "mainstream" users.
- Random achieves a comparatively better performance in "dissimilarity" metrics (rating variance and distribution similarity), although still inferior to Podium and distance-based, and inferior results in "representativeness" metrics (topic-sentiment, usefulness), as expected.
- Clustering shows the opposite trends to those of Random, probably due to selection of near-mean users as representatives, which reduces the randomness of their selection but increases their representativeness.

These results reconfirm the assumption, proposed in previous work, that diverse users provide diverse opinions [4]. We have been able, by selecting a small user subset, to capture prominent topics and the ratings of the source population – even though Podium is not explicitly calibrated to predict opinions.

The effect of customization. We next consider the effect of customization on the selected user subset, with respect to the intrinsic quality metrics of the selected subset. We focus on the effect of "priority coverage" feedback from Def. 6.1. For that, we have selected from the Yelp dataset with 30K users, uniformly at random, four subsets $\mathcal{G}_{20} \subseteq \mathcal{G}_{40} \subseteq \mathcal{G}_{60} \subseteq \mathcal{G}_{80} \subseteq \mathcal{G}$ such that $|\mathcal{G}_i| = i$. Each subset was, in turn, fed into Podium as the set of priority coverage groups $\mathcal{G}_d$. Then, we have selected a user subset of size 8 in the customized setting. We have repeated this process 20 times and recorded the average for each metric.

The results are detailed in Figure 4, along with the intrinsic diversity metrics for the setting without customization, for comparison. Notably, all the quality metrics slightly decrease with

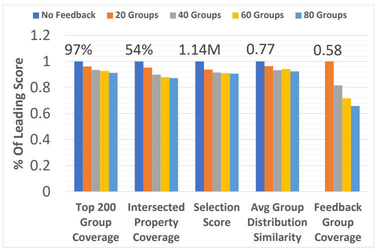

Figure 4: Yelp intrinsic diversity with customization

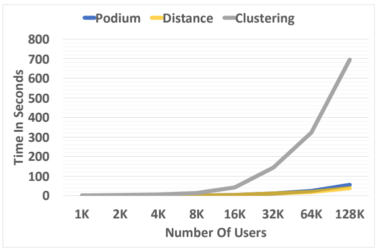

Figure 5: The effect of $|\mathcal{U}|$ on execution time.

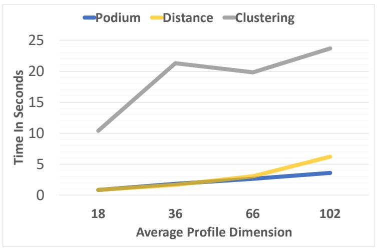

Figure 6: The effect of profile size on execution time.

every increase of the subset size, indicating that covering the priority groups restricts Podium's ability to cover standard priority groups – surprisingly, not by a significant gap. The newly-added *Feedback Group Coverage* metric measures the percentage of priority groups that were covered. Note that the groups are randomly selected with equal probability and are thus likely to be small and non-overlapping. Hence, there may not be 8 users who cover all of them. As expected, we can observe that the more priority groups are defined their coverage significantly decreases.

8.5 Scalability Results

We have examined the scalability of our algorithm w.r.t. the number of users and size of user profiles, which affect the number of groups. Here we only compare results with the clustering and distance-based baselines (random is immediate).

Scalability in number of users. In these experiments we have used user profiles with up to 200 properties. Following the complexity analysis in Section 4 we expect to witness a linear growth in the running time of the algorithm with accordance to the change in population size.

Scalability in profile size. The number of users has been set at 8K, and we varied the properties assembling the user profiles thus affecting their size. Again, we expect the running time to be linear to the average profile size.

Figures 5 and 6 depict the running times achieved by the algorithms. Our main findings are:

- Podium and distance-basedare ∼9 times faster than the clustering alternative.
- Execution time for Podium scales linearly in the size of the population as well as the number of properties.
- The Optimal baseline, due to its exponential complexity, demonstrated poor scalability. E.g., for $|\mathcal{U}| = 40$ and B=5 its execution time was 443 seconds, and for $|\mathcal{U}| = 100$ we have terminated its execution after an hour. It is therefore omitted from the graphs.

9 RELATED WORK

A comparison between diversification approaches is given in Table 1. We now elaborate more on these solutions and others.

Diversity in crowdsourcing. A few studies (e.g., [2–4]) have considered the selection of diverse users in the context of crowdsourcing, namely performing tasks with the collaborative help of Web users/workers. The work of [4] is the most relevant to ours since it also studies diverse opinion procurement. They present two approaches for diversification: S-Model is distance-based, where pairwise distance is assumed to be known; and T-Model is coverage-based on predicted data, i.e., targets the selection of a user subset with a certain opinion distribution, but only in a single category. Other studies consider the selection of diverse crowd workers in order to improve the overall accuracy. In [3] the authors study the selection of diverse users by modeling the dependence of error rates within access paths (corresponding to non-overlapping user groups), and optimizing the information gain by the selected subset. This, however, does not apply to opinion procurement where there are no errors and every opinion should be accounted for. The recent [2] resembles ours in considering coverage-based diversity and supporting customization. However, they consider only a single group per worker.

Diverse search results. Search results diversification has been extensively studied in the field of information retrieval (e.g., [1, 6, 20, 21]). Apart from solving query ambiguity, diversification is used to avoid over-personalization of search results [22]. The classification of diversity definitions as coverage-based versus distance-based is also considered in this context [23, 24]. In contrast with our approach, IR solutions generally target relevance and therefore are inadequate for diversifying along different axes and accounting for positive and negative opinions.

Diversity in recommender systems. Diversification has also been studied in the context of recommender systems. Diversity can be computed based on item properties [6] or collaborative filtering, namely, the ratings of similar users to similar items [5, 7]. Specifically, in [7] a notion of explanation-based diversity is presented, but is different than ours – certain item properties are identified as recommendation-relevant and these are used for diversification. In contrast, we do not assume that relevant properties are predefined but rather derive explanations from the actual diversification results. Moreover, to our knowledge, coverage-based approaches have not been considered in the context of recommender systems.

User sampling in survey research. The selection of people representing some population has been vastly studied in the context of surveys. While also concerned with opinion procurement, the focus of this research field is different. Specifically, as explained in Section 2, the dimensionality of user profiles in surveys is typically, by design, much lower than ours. This is because the goal of surveys is to ensure the statistical soundness of specific inferences from the participants' answers to larger populations [8, 9]. Statistical soundness may require the selected participants to be *proportionally allocated* (Def. 2.1), which, as explained in Section 2, is impossible in our high-dimensional setting due to the presence of many overlapping groups. Our approach involves a different problem formulation suitable for the high-dimensional setting. Also in contrast to surveys, which require a careful design and thereby a heavy load of manual curation, our solution applies to a given user repository as-is and may be easily executed multiple times, e.g., to incorporate data updates.

User selection. Various studies have considered the selection or filtering of users who undertake a task in crowdsourcing platforms or social networks. This includes assessment of crowd worker skill and filtering of low-skill workers [25]; filtering of low trust or spammer users [26]; filtering of slow or inefficient users [27]; expert finding [28–30]; and general-purpose declarative crowd selection [10, 31–33]. In general, these works are orthogonal to ours, since we can view the scores they derive as additional user properties that can be used for diversification.

A particular line of work considers *team formation* (or group formation), namely the selection of a set of workers that in some sense function as a team, by having e.g. complementary skills, similar properties, and/or better collaboration means [2, 34–37]. Among these, [2] is the most relevant to ours in targeting worker diversification, as discussed above. [37] uses coverage and diversity notions that our quite different than ours and thus render the problem and solution techniques quite different: diversity is considered between formed groups and is distance-based; and coverage is considered with respect to items rather than groups and does not support dimensionality.

10 CONCLUSION AND FUTURE WORK

In this work, we presented a framework for the selection of diverse user subsets for opinion procurement. We define a generic diversity notion that, while simple, satisfies a unique combination of desiderata that arise in presence of high-dimensional user profiles. In particular, as we showed, this notion admits efficient near-optimal computation and allows explanations and customization by the client. Our experimental study, on real user data, examines different metrics for diverse selection and shows that our algorithm outperforms a variety of baselines.

In future work, we plan to investigate further enhancement of the usability of our system, by methods of proposing relevant refinements for the user and by additional visualizations of the selection results. Another direction involves foundational study of the statistical properties of our algorithm: we have empirically shown that it performs well with respect to various measures other than our total score, e.g., distribution similarity and coverage of complex groups; the next step is formulating the guarantees for the algorithm performance in these metrics. The framework we have proposed is deterministic in choosing the (near-)optimal user subset by our definition, and is shown to outperform a fully random algorithm. Our implementation adds some randomness in randomly breaking ties, and we plan to further incorporation of randomness in our solution, e.g., adding noise to group weights, and its effect on the output diversity.

ABSTRACT

Cloud infrastructures allow to dynamically adapt to workload changes by provisioning additional resources or deprovisioning resources to reduce costs. This offers also opportunities for scalable distributed data management. However, elastic scaling in databases requires to migrate or even repartition data. In this work, we present an approach implemented in Actian's MPP solution VectorH that speeds up the elastic resizing process by minimizing partition reassignments while still achieving load balancing. Moreover, we describe a buffer matching and pre-filling technique to further increase performance after the resize step. The experimental evaluation shows that our solution significantly outperforms the non-elastic way of scaling using a system restart by a factor of 2 up to 4 and reduces downtimes during resizing to less than one minute.

1 INTRODUCTION

Cloud computing gained extraordinary importance over the past several years with the advent of enabling technologies like distributed systems, virtualization or fast network. While consumers moved their business applications to the cloud environment, important technology companies like Amazon, Google or Microsoft directed their focus towards cloud technologies, competing with each other for the leadership position in this promising new market. One of the decisive properties for the success of cloud computing is elasticity, providing users with flexibility to meet requirement changes in the fast moving technology world we live in. In the context of the cloud environment, elasticity describes a system's ability to adapt to changes in user demands and can be achieved in every system layer, e.g. storage, network or computing power. Therefore, developing software that is optimized for the cloud environment requires the software to support elastic changes in the underlying environment.

Actian Avalanche is the Software as a Service version of Actian VectorH [4], a massively parallel processing (MPP) solution for data analytics. The software is deployed in public cloud environments like Amazon web services (AWS) or Microsoft Azure, which both offer an elastic environment. As the VectorH MPP solution was originally designed to run on a static cluster, it does not exploit the opportunities provided by those environments. Furthermore, the currently implemented partition management is not designed to cope with non-static clusters and needs to be overhauled.

As the cloud environment offers elasticity, the main goal is to make VectorH able to utilize the provided elasticity of computing and storage resources. For this purpose, we focus on three major goals:

- **Develop an elastic resize feature:** Nodes need to be **efficiently** added or removed from a VectorH cluster during the system uptime, avoiding the drawbacks of a full restart. This is the key feature to enable elastic scaling.
- **Provide a partition strategy applicable for the cloud environment:** Partitioning is the key concept of VectorH to distribute work among nodes. As scaling the system becomes a frequent operation in the elastic environment, the partition strategy has to support elastic scaling by minimizing partition reassignments to nodes while providing load balancing.
- **Smoothen the performance after a cluster resize:** Although the partition strategy in intended to minimize partition reassignments, each cluster resize operation involves changes in data responsibilities. These changes should be transparent to the user by providing the full system performance once the scaling process finished.

The remainder of this paper is organized as follows. We give an overview over related work in Section 2, including a discussion of commercial products available on the market and how they provide elasticity. Section 3 provides an overview over the basic concepts of VectorH, before describing the design of the elastic scaling feature in Section 4. We compare different approaches for partition management and present the implemented approach in Section 5. Based on experiments, we describe the design of the buffer matching and filling mechanism in Section 6, which is an optimization on top of elastic scaling. Finally, we evaluate our solution in several experiments in Section 7, before concluding and giving an outlook in Section 8.

2 RELATED WORK

Achieving elasticity for cloud database systems is solved in different ways in the research community. ElasTraS [6] as an example is explicitly designed for the cloud environment and supports elasticity by the separation of storage and compute resources. The system distinguishes between high level transaction managers (HTM) and owning transaction managers (OTM). While HTMs handle user connections and execute queries using their local caches, OTMs are responsible for the actual data access. Depending on the current load, both HTM and OTM can be scaled independently and tasks are distributed among all running managers. As a different approach, Albatross [7] uses virtualization and live migration of databases to provide elasticity. The system aims at multi-tenant databases, which often face the problem of efficiently migrating single tenants instead of the whole system. To accelerate migration performance Albatross creates a database snapshot, which is placed in a network storage, and only migrates caches and active transaction states to a newly provisioned system. Afterwards, the system is switched using an atomic handover operation. In addition to elasticity, the system ensures serializability and correctness in failure cases. The experiments show that this approach does not abort any active transactions, harms query latency only in a negligible way and makes the database unavailable only for a small time window of about 300ms. A similar concept is used by ShuttleDB [1]. In contrast to Albatross, ShuttleDB can be seen as a middleware to make an arbitrary database management system elastic. It uses virtualization techniques to be transparent from the actual database instance and therefore works with common database systems without changes in their engine. On top of the live migration concept for single tenants, ShuttleDB offers automated elasticity. The system monitors query latencies of database tenants, automatically chooses tenants to scale and migrates them to another instance after deciding for a suitable migration strategy.

While ElasTraS, Albatross and ShuttleDB are mainly evolved from a cloud provider point of view, meaning maximizing utilization while fulfilling user demands, the Kingfisher system presented in [14] deals with elasticity from a customer point of view. Exploiting cloud pricing models, Kingfisher dynamically provisions virtual server capacity while being cost-aware. Using monitoring and forecasting of the query workload in combination with solving a linear optimization problem, the system minimizes infrastructure costs (e.g. cores, servers) and transition costs (time and costs to change environment).

In the field of commercial systems, Snowflake [5] was build from scratch for the cloud environment. It uses so called micro-partitions of several MB size to automatically partition and cluster data. Based on that, work distribution among nodes is realized using consistent hashing. In combination with work stealing, this approach automatically handles node failures as well as elastic scaling, while also minimizing the reassignment of micro-partitions as a property of the consistent hashing algorithm. As a second example, Amazon Redshift [9] divides compute nodes into the abstract concept of slices and assigns data to these slices. For scaling, the system offers two possibilities. While the "classic resize" deploys a new cluster in the background and sets the system in a read-only mode for several hours, the "elastic resize" reduces the downtime by saving a snapshot to the cloud file system, adding/removing nodes and reassigning work by reshuffling the abstract slices between nodes. This way, the downtime for the scaling process is reduced to several minutes. Nevertheless, user queries are on hold during the scaling. Third, Googles BigQuery relies on the concept of overpartitioning to avoid repartitioning in the elastic environment. In the case of scaling, tasks in the Dremel execution engine [13] are resized and data is read again from the storage layer, trusting in the speed of Google's Jupiter network technology and the Colossus storage system.

3 VECTORH OVERVIEW

Actian VectorH [4] is the scale-out version of the Vectorwise/X100 system [3] running on Hadoop clusters. It offers high and scalable query performance by exploiting opportunities of modern CPUs (e.g. SIMD, caching) with its vectorized execution engine. As a key for parallel processing of data the system uses hash partitioning and exploits co-located foreign-key joins for efficient node-local join processing, while partitions are assigned to nodes using a round-robin assignment. Furthermore, it reduces I/O costs by advanced compression methods and data skipping.

The Hadoop distributed file system (HDFS) is used as the storage layer and provides fault tolerance and scalability. Although HDFS is append-only, VectorH offers efficient updates by using Positional Delta Trees [11]. In order to efficiently read data from HDFS, the system is aware of data locality and replication. Nevertheless, processing data that is already in memory is another key to high query performance. Therefore, VectorH allocates a configurable bufferpool on system startup and maintains buffered blocks over different buffer policies [15].

For data exchange among cluster nodes, VectorH uses the Message Passing Interface (MPI) for implementing exchange operators described in the Volcano model [8]. The MPI library offers point-to-point communication as well as collective communication and is based on the concept of groups. Nodes within a group are identified using a rank starting at 0 and they are able to communicate with each other using a so called intra-communicator related to this group. In addition to that, so called inter-communicators allow communication among groups.

In order to scale a VectorH installation, the cluster configuration has to be changed and the system has to perform a restart, which has two major drawbacks. During the start process the system replays the write-ahead log, which might be a long-running operation depending on the log size. In addition to that, allocated memory is freed during the system shutdown. As a result, buffers are empty after a restart and data needs to be read again from storage, which impacts the performance of the first queries. Therefore, we need a solution to scale a running MPI application without performing a full restart. In addition to that, we want to avoid a performance degradation after the scaling operation by adapting the buffer management using the buffer matching and filling mechanism presented in Section 6 and by being aware of this issue when assigning work to nodes in a scaled environment.

Scaling can be invoked by the user to achieve one of the following goals. Either performance should be increased while keeping the data size fixed, or the system should be enabled to handle larger data sizes (while keeping performance constant). While the first goal refers to Amdahl's law, the second one is the use case for Gustafson's law (both in [10]). For VectorH, work distribution among cluster nodes is realized using partitioning, where the optimal number of partitions per table is approximately the total number of parallel threads the cluster offers. Assuming a homogeneous cluster, this is equal to the number of nodes multiplied with the number of physical cores per node. In order to support both mentioned scaling cases while avoiding an expensive repartitioning, we use the concept of overpartitioning, initially splitting tables into more partitions than necessary for the initial cluster configuration. The chosen number of partitions is crucial in terms of performance and the ability to scale the cluster size. Figure 1 shows the runtime of the TPC-H [2] query set on scale factor 1000 GB as a function of the number of partitions. The experiments were made on a cluster of 4 to 6 nodes with 24 cores each, providing a parallelism of 96 to 144 threads. First, the results show that increasing the cluster size while keeping the data size constant can lead to a performance benefit. Second, one can observe that increasing the number of partitions above the optimal partitioning of one partition per thread comes with an increasing performance penalty, which is caused by the introduction of an Union operator on top of table scans. Furthermore, increasing the number of partitions heavily impacts update performance, as update operations have to be performed on more fine-grained partitions. As a consequence, the number of partitions should not be chosen too large. Third, one can observe that VectorH is able to handle underpartitioning to a certain degree by performing node-local splits during table scans, achieving the assignment of one partition per thread. However, this resplitting harms node-local join processing and is therefore not a desired behaviour.

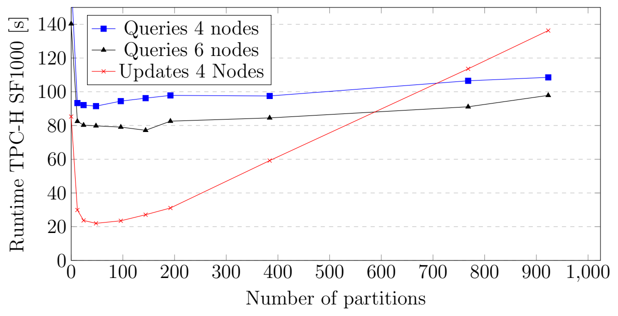

Figure 1: Dependency of Partitioning on TPC-H SF1000 runtime

4 ELASTIC SCALING

This section presents the design and implementation a dynamic cluster resize functionality for VectorH. With this feature we want to face the problem of scaling VectorH and solve the first goal stated in Section 1. Two new functions, *add_nodes* and *remove_nodes*, were implemented using the VectorH syscall functionality, allowing to issue commands against the system without forming SQL queries.

The new cluster resize functionality exploits the opportunities of the MPI group and communicator management. The basic approach of adding nodes using MPI routines is illustrated in Figure 2. Starting from an existing group of current nodes with an intra-communicator (A), a new group of processes is spawned by starting the application on the newly provisioned cluster nodes using the MPI_COMM_SPAWN routine. All nodes of the new process group are able to communicate with each other using their own intra-communicator (B) and with the old group of nodes using the inter-communicator (C) returned by the MPI routine. In order to abstract from these different types of communication in a second step, both groups form a new intra-communicator (D) using the MPI_INTERCOMM_MERGE routine and replace group communicators (A), (B) and (C). After new nodes are added in the *add_nodes* call, the master node has to broadcast the current partition mappings as described in Section 5 in order to provide the new nodes with the correct initial partition assignments. Afterwards the current nodes have to follow the new nodes' startup, as there are various synchronization points within the startup procedure. To simulate a collective start of all servers, the current servers have to perform all of these synchronizations to make the added servers finish their initialization, before performing the buffer matching mechanism described in Section 6. The cluster resize functionality has to be compatible with the following optimization made in VectorH. In order to reduce memory consumption, the creation of storage objects and minmax indexes is skipped for partitions a node is not responsible for. After adding nodes, this responsibility assignment changes as some partitions of the current nodes get assigned to the newly added ones. As a result, current nodes hold structures for partitions they are not responsible for anymore. Each node checks for these kind of unused structures by iterating over all tables in their catalogs, dropping information and freeing memory whenever possible. This could also be done in a lazy way by checking for unused information within a partition responsibility check during query execution. But as these checks are very frequent operations and are called multiple times within each query, the decision was made to cleanup the unused structures directly as part of the *add_nodes* operation.

Removing nodes reverses the presented mechanism. In the first step the nodes are divided into two distinct groups S and R with corresponding intra-communicators using a MPI_COMM_SPLIT routine. While nodes of group S perform a collective shutdown as a second step, the nodes of group R form the new cluster. Passing a list of hostnames to the function call, each node checks whether it is included in S and should terminate or not. It is currently not allowed to terminate the master node, so *remove_nodes* returns an error in this case. The remaining nodes (group R) now update their partition mappings as described in Section 5. Removing nodes assigns more partitions to the remaining nodes, and, as the nodes were not responsible for these partitions before, the creation of storage structures and minmax indexes was skipped. In order to reconstruct the missing information, an adapted replay of the write ahead log is performed. Within this replay, all log actions are skipped except those related to storage and minmax indexes for tables the node is now responsible for and was not responsible for before. This information is provided by the partition manager.

With the design of the elastic cluster resize feature we achieved the possibility to scale the VectorH cluster without restarting the existing nodes. We therefore ensured that the scaled system state is similar to the state before the scaling in terms of communication, metadata and catalog state. Furthermore, we automatically achieve support for updates that are resident in in-memory PDT structures

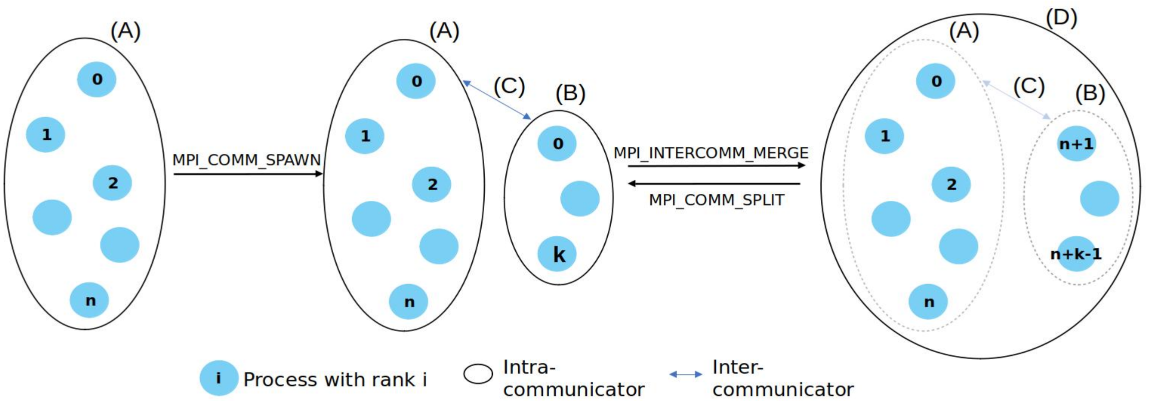

Figure 2: Schematic overview of cluster resize

mentioned in Section 3, as the log replay that is included in both *add_nodes* and *remove_nodes* also covers PDT log actions. As a result, the process reconstructs the update information needed to ensure data consistency.

Our implementation relies on the following assumption. For the *add_nodes* functionality binaries, configuration files and user data are accessible from the new nodes in the same way (especially using the same directory paths) as for the already running nodes. Triggering the operation over a front-end, e.g., a web-based management tool, would invoke starting the new nodes (dependent on the cloud service provider) and synchronizing necessary data before the *add_nodes* operation is started. A functionality for synchronizing the VectorH installation directory already exists and is used for cluster deployment, so this assumption is no restriction.

Besides assumptions the presented implementation comes with some limitations. First, the resize functionality must be issued in a separate session with no concurrent sessions. The system is able to block/hold incoming session requests when a scaling request is made. Second, the hosts to be removed are restricted to be the ones with the highest ranks. As all nodes except the master node are treated equally and the user does not call this function directly but through a frontend only providing the cluster size he wants to reach, the frontend can choose the nodes to remove as the ones that where added most recently. This ensures that only the highest ranks are selected. In case this is considered as too restrictive, one could extend the algorithm such that it first rearranges the nodes before the resize operation and assigns ranks in a way that fulfills the restriction. Third, it is currently not allowed to remove the master node as worker nodes are not able to replace a missing master node (which also holds for master node failure).

5 PARTITION MANAGEMENT

In this section, we present a partition management approach that is suitable for the elastic cloud environment, which corresponds to the second goal stated in Section 1.

5.1 Partition assignment approaches

We start by comparing basic approaches for partition assignment. The comparison is based on the following requirements, prioritized from most important to least important:

(1) **Load balancing:** Assigning an equal number of partitions to each node is crucial to achieve an optimal query performance. As partitions are already built using the partitioning method, the assignment strategy can only affect the number of partitions per node, not the size of each partition.
(2) **Lookup time:** The mapping *partition* $\rightarrow$ *node* is evaluated numerous times within each query and should therefore be an efficient operation.
(3) **Update time:** As resizing the cluster changes partition assignments, the structures of the partition assignment should be updatable in an efficient way.

Besides these main objectives, the partition assignment strategies must fulfill the following side conditions for performance reasons:

- Keep co-locality of foreign-key related tables
- Minimize the number of reassigned partitions on cluster resize

Keeping the co-locality of related tables is a key for achieving optimal query performance by exploiting node-local joins and is therefore an important demand. Reassigning partitions has several effects and should therefore be minimized. First, it leads to storage access for reading the partition, as the data is not present in the node's buffer. Second, nodes have to update their catalog information when becoming responsible or loosing the responsibility for a new partition, as described in Section 4.

We can state a lower bound for the minimum number of partitions that have to be reassigned on cluster resize. Let d be the total number of partitions for an arbitrary table and we assume that partition assignment is balanced before a resize operation. When adding n nodes to an existing cluster of n_{old} nodes with $n_{new} = n_{old} + n$, it is clear that every node has to be responsible for $\frac{d}{n_{new}}$ partitions after resizing to achieve load balancing. We assume that n_{new} is a divider of d and if not, every node gets one additional partition until the remaining partitions are assigned. As every new node get's $\frac{d}{n_{new}}$ partitions, the minimum total number of reassigned partitions is $\frac{d}{n_{new}} \cdot n$. For removing n nodes from an existing cluster of n_{old} nodes it can be easily seen that $\frac{d}{n_{old}} \cdot n$ partitions have to be reassigned, as every node was responsible for $\frac{d}{n_{old}}$ partitions before resizing. Overall we can state the lower bound of

$$reassigned\_partitions \geq \frac{d}{n_{max}} \cdot n$$

with $n_{max} = max\{n_{new}, n_{old}\}$ for adding/removing n nodes.

Round-robin assignment: Round-robin assignment is the currently used assignment strategy in VectorH. It is clear that this strategy provides load balancing and as it can be evaluated using an arithmetic operation, has a very fast lookup time while not needing additional data structures. Nevertheless, with respect to the additional cluster resize functionality, round-robin is one of the worst choices as it reassigns nearly all partitions when not resizing the cluster with a factor that is a power of two, as shown in Figure 3. Doubling the number of nodes leads to a reassignment of half of the partitions, which is basically the minimum for achieving load balancing. But increasing the number of nodes by a factor being an arbitrary number and not being a power of two leads to a reassignment of nearly all partitions. Therefore, this strategy is not applicable for the cloud environment.

Figure 3: Round-robin partition assignment on cluster resize

Consistent hashing: The requirement of minimizing the number of reassignments on cluster resize directly leads to the method of consistent hashing, which places elements and buckets on a logical ring representing the set of hash values produced by the hash function. In order to improve load balancing, buckets can be replicated on the logical ring. It is shown that removing/adding one hash bucket leads to a reassignment of $\frac{k}{n}$ keys, with k being the total number of keys and n being the number of hash buckets [12]. With keys being partitions and hash buckets being nodes, this is the lower bound of reassigned partitions we stated before. If a node is removed, only the partitions assigned to the removed node have to be reassigned and adding a node leads to a reassignment of all partitions between the added node and its last predecessor on the logical ring. Consistent hashing can be implemented by holding a sorted array or list of nodes, so a lookup operation to find a node responsible for a partition takes time $O(\log(n \cdot r))$ with r being the replication factor and using binary search on that list. Updating the number of nodes leads to resorting the list with a complexity of $O(n \cdot \log(n))$, for example using insertion sort for adding a few nodes or merge sort for adding a sorted list of nodes. Holding the list consumes memory in the size of $O(n \cdot r)$, which is independent from the number of partitions.

Explicitly storing and maintaining the assignment mapping: This approach tries to provide a minimal lookup time and a best possible load balancing by explicitly maintaining and storing the mapping $[d] \rightarrow [n]$ from the set of partitions to the set of nodes for each possible partitioning using a partition manager structure. The mapping can be stored as an array with the size d, providing lookup time $O(1)$. Tables with equal number of partitions d_i build an equivalence class $i \in Eq$, so as a side effect, this guarantees co-location of foreign-key related tables when assuming them to have equal partition numbers (otherwise node-local joins would not be possible anyway). Maintaining the mapping explicitly ensures that the best possible load balancing is achieved. As a drawback, this approach has a quite high memory consumption of $O(\sum_{i \in Eq} d_i)$, which is especially not independent from the number of partitions and increases with the number of distinct numbers of partitions. Nevertheless, the number of different partitionings and therefore the number of equivalent classes is typically small in user scenarios.

Comparison: Table 1 compares the approaches of consistent hashing and partition manager. The partition manager approach outperforms consistent hashing in the most important categories load balancing and lookup time, while also minimizing partition reassignment. Assuming that the number of different partitionings is quite small and hence the number of equivalence classes is small, the time for updating the structure and the memory consumption is justifiable. As an example, a database consisting of 1000 tables sharing the same partitioning schema of 1000 partitions would lead to a memory consumption of around 5KB for 1000 4-byte-integer values and 1000 boolean values regarding the partition manager design shown in Section 5.2. Even for 1000 different partitioning schemas with a maximum of 2000 partitions each we would get a few MB of memory consumption. Therefore, the decision has been made towards the partition manager approach.

5.2 Partition manager design

The partition manager structure, illustrated in Figure 4 maintains *partition mapping* objects for each equivalent class, which consist of the number of *partitions*, a *mapping* array and an *is_moved* array, both of the size of the specific number of partitions. Each position i in *mapping* holds the node ID of the node responsible for partition i. The mappings are adapted during each cluster resize operation to maintain load balancing. In addition to that, the boolean *is_moved* value at position i indicates, whether the partition was moved during the last cluster resize operation, which is important to determine partitions to replay from the log when removing nodes or to delete the storage objects from when adding nodes. On top of the *partition mapping* objects, the partition manager maintains a hash table of *partition mapping* pointers to efficiently find the mapping for a given number of partitions.

For implementing a partition assignment, two assumptions are stated. First, it is assumed that co-local partitions have the same partition ID. This assumption is fulfilled by the hash partitioning method, as tuples with same keys

	Consistent hashing	**Partition manager**
Load balancing	Good, not guaranteed	Best possible
Partition reassignment	Minimized	Minimized
Lookup time	$O(\log(\mathit{nodes} \cdot \mathit{replication}))$	$O(1)$
Update	Re-sort array	Adapt every mapping $O(\mathit{equi\_classes} \cdot \mathit{partitions})$
Memory consumption	$O(\mathit{nodes} \cdot \mathit{replication})$	$O(\mathit{equi\_classes} \cdot \mathit{partitions})$

Table 1: Comparison of partition assignment strategies

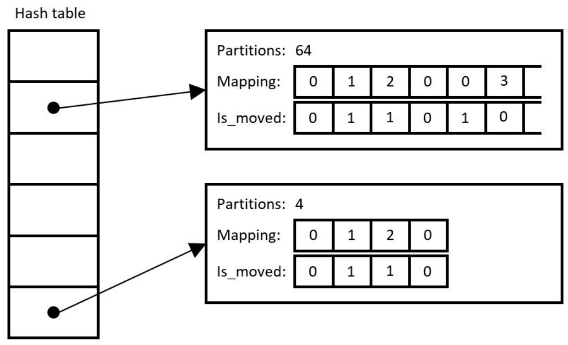

Figure 4: Partition manager overview

(either primary or foreign keys) are mapped to the same hash value, which is used as partition ID. Second, it is assumed that tables with a foreign key relationship have the same number of partitions specified. Having an unequal number of partitions while using the currently implemented hash partitioning violates the requirement of co-locality. Especially, it is not ensured by the current hash function that having a table T with k times the number of partitions than it's join partner S results in a partitioning that maps one partition of S to exactly k partitions of table T.

Initialization: During server startup, the partition manager structure is initialized to a global variable by creating an empty hash table. When the partition manager gets queried for a partition mapping that is not present in its hash table, a partition mapping object for the queried number of partitions is created and inserted into the hash table using the number of partitions d as key. The *mapping* is initialized using a round-robin strategy, so for partition ID i we get $\mathit{mapping}[i] = i \bmod d$. The choice of this initial strategy is arbitrary and could be replaced by any other strategy that provides a balanced assignment for n nodes. The *is_moved* array is initialized with *FALSE* at every position. The described process has time complexity $O(d)$ to initialize a single partition mapping.

Lookup: Knowing the structure of the partition manager, the lookup implementation is straight forward by a single hash table access and a single array access. Due to the design, the lookup operation has complexity $O(1)$.

Update: Whenever adding or removing nodes, all partition mappings have to be adapted. Therefore, we iterate over all entries in the partition manager's hash table and adapt every mapping using an algorithm divided into the following steps:

(1) Compute the optimal load balancing for the new cluster state by computing *partitions_per_node* and a *remainder* if the number of nodes is not a divider of the number of partitions.
(2) Compute a *diffs* array, with *diffs*[i] indicating wether node i has to get additional partitions (positive entry) or get partitions removed (negative entry) to achieve the computed load balancing. The sum over all entries in the *diffs* array is 0, as the total number of partitions does not change.
(3) Adapt the actual partition mapping by iterating over the *mapping* array. If we find a partition whose responsible node has a negative *diffs* entry, we move the partition to a node with a positive *diffs* entry.

With step three being the dominant step in terms of runtime, the algorithm runs in $O(d)$. As we adapt the mapping of every equivalence class, the update operation has a total runtime of $O(\sum_{i \in Eq} d_i)$.

Exchange: After new nodes are added to the system, they check during startup whether they are added to an existing cluster and if so, they prepare to receive the current partition assignments. The current nodes trigger this exchange functionality within the execution of the *add_nodes* query. The exchange operation is implemented using MPI_BCAST (broadcast), so it has to be performed collectively. After broadcasting the number of mappings, the number of partitions and the *mapping* array are broadcasted for each partition mapping. This way it is ensured that all nodes call the broadcast the same number of times.

As a result, the chosen approach minimizes the reassignment of partitions in the case of scaling while providing load balancing and efficient lookup and update functions.

6 BUFFER MATCHING AND FILLING

We now motivate the problem of decreased performance after a cluster resize operation and present the design and the implementation of the buffer matching and filling mechanism, solving the performance problem and therefore being a solution to the third goal stated in Section 1.

For a brief intermediate evaluation of the cluster resize functionality and the partition manager described in Sections 4 and 5, the TPC-H benchmark was run on scale factor 300 using 8 of the 16 cluster nodes described in Section 7. Afterwards, the remaining 8 nodes were added and the benchmark was run again. Overall, it was observed that queries are slower after adding nodes than before. As an example, we pick query 1 of the benchmark, which is a selection and aggregation query on the lineitem table. The runtimes are shown in Figure 5. The query was run on 8 nodes with filled buffers (run 1) before adding 8 additional nodes and running the query several times again (runs 2, 3, and 4). Doubling the number of resources, we would expect a speedup up to factor 2, but the results clearly show an increase in runtime for the first run after the resize operation. However, the performance increases as expected with more consecutive query runs.

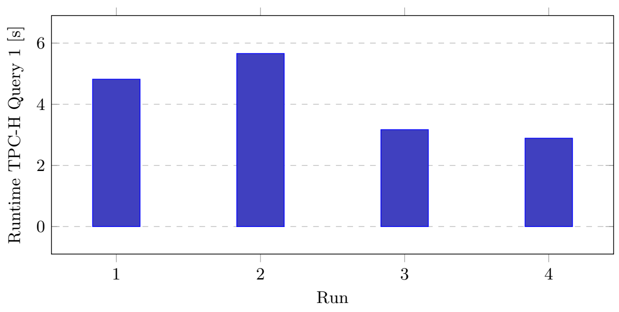

Figure 5: Runtime of TPC-H SF300 Query 1 in consecutive runs with run 1 on 8 nodes and runs 2,3 and 4 on 16 nodes after a cluster resize

From a user perspective, this behavior is not satisfactory, as he pays for extra resources without getting any immediate benefit. The observed performance is a direct consequence of the buffer management. Figure 6 shows the qualitative performance (runtime and output cardinality) of the scan operation of TPC-H query 1 for all threads on all nodes. The right half of the plot, which covers the 8 nodes added by the cluster resize, shows a runtime that is up to 5 times slower with respect to the left half of the plot, which covers the 8 nodes that were already running before the cluster resize. This is caused by filled buffers of the old nodes, while the added nodes start with empty buffers. In order to smoothen this runtime, we present the buffer matching mechanism to fill the buffers of added nodes during the cluster resize step. Doing so, we move the overhead of filling the buffer from user queries to the cluster resize operation, which is more justifiable to the user, as the elapsed time between the user toggling a cluster resize until finishing the resize also involves demanding new cluster nodes from the cloud service provider, which is also a potentially long-running operation and dependent on the actual provider. General approaches for buffer pre-filling must answer the following questions:

- Which data should be chosen to fill into the buffers?
- How is data brought to the buffers?

Especially the second question is important for the cloud setup. As cloud storage systems offer lower bandwidth and higher latencies than node-local storages, sending buffered data between nodes is also worth considering next to reading data from storage.

The chosen solution for this problem is our buffer matching mechanism. In order to discuss the mechanism from an abstract point of view, we identify a sender side and a receiver side, dividing the set of nodes into two distinct sets. Nodes of the sender side are characterized by losing the responsibility of partitions and having blocks in their buffer they are not responsible for anymore, while nodes of the receiver side become responsible for new partitions and do not have any buffered data for them. Note that because of our partition manager design in Section 5, a node is either a sender or a receiver. During data exchange, each node of the sender side can possibly have a connection to each node of the receiver side.

Block selection: The first step of buffer matching is to identify for each node the set of blocks that needs to be sent to other nodes, as well as each block's specific destination. First we get a list of all blocks currently resident in the buffer memory sorted by importance. The importance of a block is determined by the actually used buffer replacement policy. In addition to that, we identify the destination of the blocks by querying the partition manager described in Section 5 to get the responsible node. Blocks that belong to a partition for which the node remains responsible are not sent and therefore dropped from the list. All other blocks are appended to a list of blocks per receiver, so as the result of the block selection step, each sender node holds a (potentially empty) list of blocks for each receiver node. One special case needs to be handled. Due to data distribution or due to buffering blocks of only a few partitions caused by selection predicates, it might occur that receiver nodes are intended to receive more blocks than they can actually fit into their buffers. The calculated cardinality difference is balanced between all senders to this receiver node and each sender is informed about the number of blocks to send before starting to send data. As the block lists are sorted by importance, the sender just drops the end of the list in this case.

Data exchange: We now want to answer the question how buffer data is brought to nodes. As reading data from cloud storage might be slow compared to usual local disks or network transfer, the decision was made towards explicitly sending data to nodes over the network. The implemented data exchange mechanism follows three basic steps:

(1) Exchange the number of blocks to transfer between each sender and receiver node.
(2) Exchange block metadata.
(3) Exchange buffer content.

The first step is important to establish synchronization between senders and receivers. Each node of the receiver side has to know about the number of blocks to receive from each node of the sender side. After the block selection step, each sender node holds a list of blocks per receiver. The length of these lists is shared with the respective receivers using MPI_GATHER routines, called within a loop over all added nodes. A receiver node with rank i becomes the receiver of the MPI_GATHER call in exactly one loop iteration. In this round, all other nodes send the length of their list i, indicating the number of blocks to send to node rank i. As a result, node i has the complete information about the number of blocks to receive after success of loop iteration i. In the second step, we transfer the blocks metadata (e.g., used bytes, columnID or the ID of the commit creating the block) to the receiver nodes. It is important to note that metadata and actual data of a block cannot be transferred all-in-one using a single MPI call by default, as metadata and actual data are not placed in consecutive memory areas due to the VectorH buffer management, which preallocates the whole buffer memory during startup. Constructing an additional structure holding both metadata and buffer data would lead to copying major parts of the buffer, which is not desirable. Sending

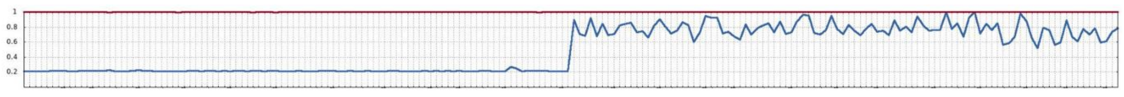

Figure 6: Qualitative TPC-H scan performance of query 1 for run 2

the metadata is important for two reasons. First, the respective block can be searched in the receiver's catalog. VectorH uses a replicated catalog, so a each block is already created on the receiver side. Second, the metadata contain information about the buffer content, like the actual data size or a flag to indicate wether data has been changed. This information is created during data load, so it needs to be sent as we do not load data from storage. Sending the metadata arrays is realized using non-blocking MPI point-to-point communication. This eliminates the need for explicit synchronization in this step. After receiving the metadata, each receiver performs catalog lookups to get pointers to the block structures and demands memory in the buffer memory for each block, before the blocks are inserted into the buffer replacement policy. In the third step, we transfer the actual buffer data. As the data for blocks is not placed in consecutive memory areas, they have to be sent one-by-one. Using non-blocking MPI communication like in the second step would therefore lead to k communication calls per sender and receiver with k being the number of blocks to transfer between sender and receiver, making it difficult to handle for the MPI environment when scaling the problem up. Therefore, we use synchronous, blocking communication for this step. To avoid deadlocks and reduce waiting time, we handle the communication in a multi-threaded way. For each point-to-point connection between a sender and a receiver node, having a non-zero number of blocks to transfer, both sender and receiver node open a separate thread running their side of the communication, resulting in a communication network. Each thread blocks until the respective counterpart of the communication is called. Upon receiving buffer data for one block, the data is copied to the buffer memory of the receiver node.

Fault tolerance: The buffer matching mechanism is an addition to the cluster resize functionality. The success of the buffer matching step is not indispensable for the success of the whole cluster resize operation, but should not lead to a undefined state on the occurrence of errors. Therefore, the mechanism is designed to be fault tolerant. We distinguish between different times of error occurrence. If an error is detected before the block metadata in the catalog of a receiver is changed, we can simply perform a collective abort, as no durable changes were done yet. This is realized using a synchronization point between the second and the third step. If an error occurs during data exchange within third step, we have to ensure that the system handles the block's buffer content in the right way. After receiving a single block's data and copying it to the buffer memory, we verify the correctness of the data using an already existing magic number in the block's data. This magic number is a fixed constant which is used to discover transmission failures. This mechanism could be further improved using a checksum. If the verification succeeds, the block is flagged to be in memory. If the verification fails or an error occurs during communication, the current block is flagged as "LOAD", leading the system to not use the buffer content before an IO-thread loads the data from storage (and adjusts the metadata again). Furthermore, all pending blocks that have not been transferred yet are also flagged as "LOAD". All other communication threads are not affected and may succeed.

Integration: The described mechanism is integrated into the *add_nodes* and the *remove_nodes* call. For adding nodes, the sender side is formed by the current nodes, as they lose responsibilities for partitions and may have buffered data for them, while all newly added nodes form the receiver side. During the system startup of the added nodes, buffer matching is integrated after the partition mapping exchange and the log replay, but before the server is able to handle user connections. This way the server already has the full catalog information. The current nodes perform buffer matching after following the server startup communication of the new nodes. For scaling the cluster size down, the removed nodes form the sender side of the buffer matching mechanism, while the remaining nodes form the receiver side. In order to enable removed nodes to determine the target of their buffered blocks, they update their partition mappings according to Section 5. Afterwards, they perform buffer matching while the remaining nodes perform it during execution of the *remove_nodes* call. In order to isolate the buffer matching communication from all other communication, a separate MPI communicator is build, being only valid during the buffer matching step. Finishing the buffer matching step, this communicator is destroyed. To provide the user the possibility to toggle the buffer matching mechanism on/off, an additional parameter is introduced into the VectorH configuration API.

Optimizations: After describing the basic ideas behind the buffer matching mechanism, we want to introduce two additional optimizations to the concept: the deletion of unused blocks at the sender side and the use of an alternative data exchange implementation. The strategies of the buffer policies are designed to keep the most important elements in the buffer by using priority queues. After performing buffer matching, blocks a sender node is not responsible for anymore may remain in its buffer queues. Due to the behavior of the strategies, these blocks are displaced at some time in the future. Nevertheless, a block may remain a long time in the queues once it is categorized as very important, depending on the actual displacement strategy. As a consequence, this buffer page is useless for a long time, blocking possibly important blocks from finding their way into the buffer. Therefore, we explicitly drop sent blocks from the buffer replacement policy on the sender side. The third step of the buffer matching mechanism uses blocking MPI calls to send the block's data one-by-one, as the buffered data of multiple blocks are not placed in consecutive memory areas (in this case, one call pointing to the start of the memory area would suffice). The MPI environment can be configured to use several communication protocols and uses the Transmission Control Protocol (TCP) in the VectorH integration. Therefore, each call to send/receive a data block invokes communication setup, as well as the common TCP slow start phase, which is unnecessary overhead. As an optimization, we introduce a second, socket-based data exchange implementation. Similar to the described mechanism in the third step of the data exchange step, each sender-receiver pair with non-zero number of blocks to be transferred opens a thread on each side. Instead of starting MPI communication, the nodes establish a TCP stream socket connection. The receiver node creates a socket, sends the socket address information to the sender node using MPI and listens for an incoming connection. The sender node connects to the socket and sends data over the socket. As this single connection keeps alive until all data is sent, the overhead of communication establishment and slow start phase is reduced compared to the MPI implementation. In order to provide the same level of fault tolerance, each side of the socket checks the socket status using *select* before sending/receiving data. Furthermore, data blocks can be send in chunks, and only after a full block is received, the receiver verifies the block. Similarly to the fault tolerant behavior, blocks are flagged on connection or communication errors.

7 EVALUATION

During the evaluation, we want to prove the superiority of the implemented cluster resize feature over the inelastic way of scaling. Furthermore, we want to show that the usage of the buffer matching and filling mechanism improves query performance after a cluster resize operation and is, therefore, a useful extension. Due to expenditure reasons, the evaluation was done on a private cluster of 16 nodes, each with the following configuration:

- AMD Opteron Processor 3380 @2600MHz with 4 modules of 2 cores each
- 32 GB DDR3 RAM
- 3.5 TB disk space, distributed among 4 HDDs
- CentOS-7 64 Bit

The nodes are connected over a 1GBit/s ethernet connection and Hadoop 2.7.1 is installed on the cluster. Comparing the hardware to resources available on Amazon Web Services (AWS), this setup should be slower than all available EC2 instances. Therefore, the measured runtimes in the experiments can be seen as an upper bound and we expect our implementation to perform better on any AWS clusters with equal number of nodes. In addition, the TPC-H benchmark [2] on scale factor 1000 GB provided test data and test queries. This benchmark covers a well-understood synthetical workload in order to evaluate and compare data warehouse solutions with a dataset inspired by real world applications. The large tables of the benchmark are partitioned into 192 partitions, which is an overpartitioning for the cluster of 16 nodes with 8 cores each.

Scaling performance: The first experiment evaluates the performance of the implemented cluster resize feature. For the investigation of the upscaling process we start with a cluster of 4 nodes with filled buffers and vary the number of added nodes, while we start with 16 nodes and vary the number of removed nodes for the downscaling process. For these experiments, we keep the size of the bufferpool at 10 GB and the block size at 1 MB. Figure 7 illustrates the results of the experiment. One can observe that the runtime for adding nodes without using buffer matching increases in a linear way with the number of added nodes. The main reason for this behavior is the collective startup of the nodes. Starting more nodes at the same time increases the impact of the various synchronization points within the startup process. The buffer matching mechanism adds a nearly constant overhead to the measured *add_nodes* runtime. In a more detailed consideration one can observe that the buffer matching mechanism shows its minimum runtime when adding 8 nodes. Adding more nodes also increases the buffer matching data exchange parallelism (the number of receiver nodes per sender node), so the minimum runtime is expected to be at the number of physical cores, which is 8 in the used hardware setup. The downscaling runtime shows a slight increase when removing more nodes, which is caused by the adapted log replay the remaining nodes have to perform. Within this step, removing more nodes leads to more log entries that have to be replayed in the remaining nodes. The buffer matching mechanism was not applied for the downscaling process, as buffers where totally filled before scaling, so there was no buffer space left in the remaining nodes to receive blocks from removed nodes. Overall we can state that downscaling takes significantly less time than upscaling, because the synchronization effort for downscaling is lower. Once the nodes are split into two groups within the *remove_nodes* process, the group of removed nodes can simply perform a shutdown.

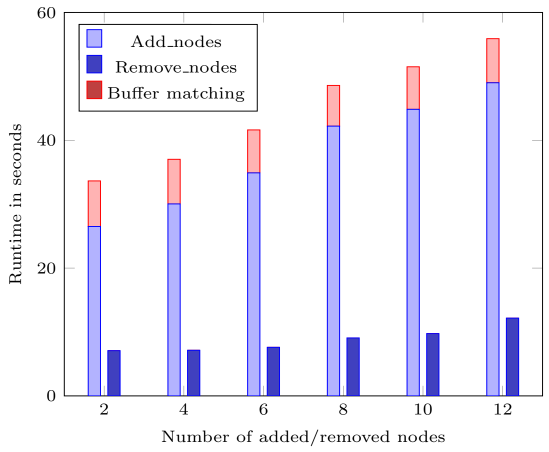

Figure 7: Scaling performance for adding and removing nodes

Scaled query performance: This experiment investigates the impact of the cluster resize operations on query performance. For this we repeatedly run a query while changing the cluster size between runs. As the main impact is expected to be within the scan operators, we use a query scanning two columns of the lineitem table. In order to fit the data into the buffer of the smallest cluster configuration, we limit the number of tuples to 500 million using a selection predicate, while setting the buffer memory to 20 GB per node. This way we avoid I/O access that would create an unintended bias in the measurements. Moreover we minimize the network traffic by applying an aggregation on each column, which is executed locally on each partition and results in a single tuple that needs to be send to the master node. Figures 8 and 9 show the measured query runtimes. Regarding the case of upscaling, we can observe that adding nodes accelerates the query runtime as expected. However, the behavior varies between different buffer matching configurations. With activated buffer matching, query runtime drops and stays on the same level for the respective query runs after cluster resize, because the buffers already contain the needed data. On the contrary, not using buffer matching leads to significantly slower queries, especially for the first run after a cluster resize. The reason for this behavior is that added nodes have to read data from storage. In the following runs the query performance improves as buffers of added nodes fill. For the case of downscaling, we have to distinguish between two use cases. On the one hand, the reason a user triggers a downscale operation can be that the system is in an overprovisioning state, so the system underutilizes the provided hardware. In this case, removing server capacity should not have an impact on the systems performance. For VectorH we neglect this case as we aim to have more partitions than nodes at every point in time. If this condition is violated, a repartition operation is triggered by the system. On the other hand, the user could invoke the downscaling to save costs while accepting slower system performance, e.g., when the expected load becomes less during specific times of a day. This case is expressed by Figure 9. When scaling down the cluster, we can observe a performance degradation, again varying between buffer matching configurations. Similar to the upscaling case, the runtime of the first query run after cluster resize is significantly slower when not using buffer matching, as remaining nodes become responsible for data of removed nodes and have to read it from storage. With activated buffer matching, data is sent to the remaining nodes, leading to an immediately fast runtime after resize. Overall, this experiment proves that using the buffer matching mechanism during cluster resize perceptibly increases query performance after resizing.

Buffer matching performance: In this experiment, we want to evaluate the buffer matching performance for both implemented data exchange mechanisms, using MPI and using data streams over sockets. The two main parameters that have an impact on the buffer matching performance are buffer size and block size. While the buffer size affects the amount of data that is shipped during the buffer matching data exchange, the block size affects the granularity of shipped blocks and as a result also the communication overhead. Trying to touch as much data as possible, we use query 9 of the TPC-H benchmark for this experiment, as it touches five of the 8 tables in the benchmark and scans about seven billion tuples for the used scale factor of 1000 GB.

The plot in Figure 10 shows the runtime of the buffer matching mechanism as a function of the buffer size per node for both data exchange implementations, using a constant block size of 1 MB. For these measurements, we used the up-scale step from 8 to 16 nodes. First of all, the results show that the data exchange takes the major part (about

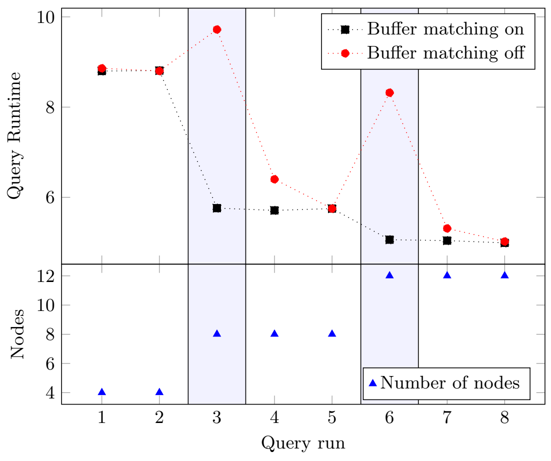

Figure 8: Scaled query performance after adding nodes (buffer matching impact highlighted)

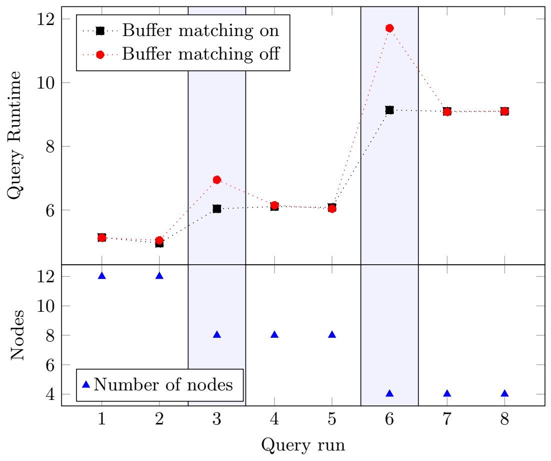

Figure 9: Scaled query performance after removing nodes (buffer matching impact highlighted)

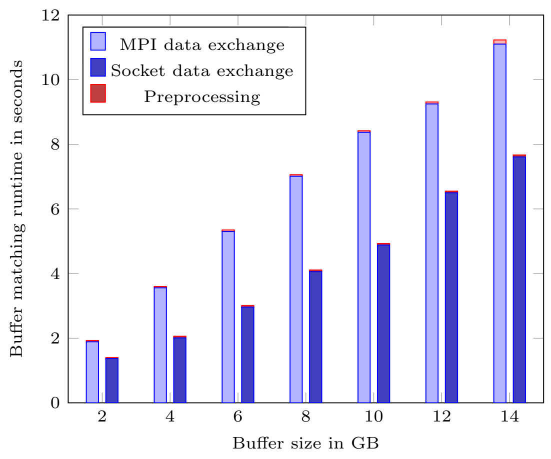

Figure 10: Buffer matching runtime for preprocessing and actual data exchange as a function of the buffer size for upscaling from 8 to 16 nodes with a constant block size of 1 MB

98%) of the whole buffer matching step. Furthermore, the plot illustrates the expected runtime increase when increasing the buffer size and shows that they correlate in a linear way. Comparing both data exchange implementations, we can observe that the socket implementation is faster in terms of runtime and also shows a smaller grow in runtime when increasing the buffer size. As discussed in Section 6, this behavior is presumably caused by the fact that the MPI implementation has to re-initiate the communication for each block, as the blocks may be randomly placed within the buffer memory space. The socket implementation on the other hand initiates the communication once before sending a data stream and therefore reduces the communication overhead.

In a further experiment we evaluate the impact of varying block sizes on the buffer matching mechanism. For this we keep the buffer size constant at 10 GB and we only consider the pure data exchange runtime, as we have seen in Figure 10 that preprocessing only takes a minor part of the overall runtime. Increasing the block size implies an increase of the necessary memory to allocate blocks. Therefore, we had to switch to scale factor 300 GB for this experiment as the overall available memory did not suffice for the largest tested block size of 8 MB and scale factor 1000 GB. Figure 11 shows the results of this experiment. For both implementations we can observe a slight increase in runtime when increasing the block size. This is caused by increased data volume that has to be exchanged, as larger block sizes come along with larger unused space or padding. Besides that, the socket implementation is not heavily impacted by varying block sizes, as data is simply written to stream sockets not considering any block boundaries. On the contrary, the MPI implementation profits from larger block sizes, as the communication overhead shrinks with the decreasing number of blocks to be sent. As a result, the difference in runtime between both implementations also shrinks with larger block sizes. Nevertheless, the choice of the block size also impacts other parts of the system, so this choice is usually fixed around a value of 1MB and can not be changed after database creation. For these block sizes, the socket implementation is surely the better choice compared to the MPI implementation.

Cluster resize usability: In the last experiment, we compare the implemented cluster resize functionality with the "inelastic" scaling, which involves the following steps:

(1) Shutdown of the system
(2) Adjustment of a list that holds the VectorH node names
(3) Restart of the system
(4) Run a query

These step are encapsulated in a script to reliably measure the runtime. We define the start state of the experiment as a running VectorH system with filled buffers. Furthermore, we define the end state as the moment we get a query result from a scaled VectorH instance. The runtime between start and end state is measured for the cluster resize feature with and without activated buffer matching, as well as for the inelastic scaling process. As query workload we choose query 1 and query 9 of the TPC-H benchmark. The buffer size is set to 10 GB per node and we investigate the cases of scaling from 8 to 16 nodes and vice versa.

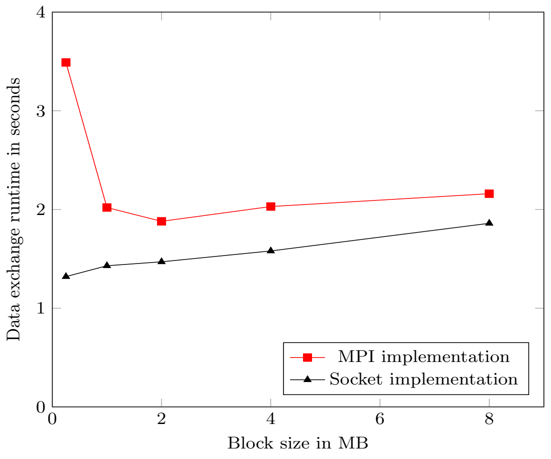

Figure 11: Buffer matching data exchange runtime as a function of the block size with constant buffer size of 10GB when upscaling from 8 to 16 nodes

	add_nodes		remove_nodes	
	Q1	Q9	Q1	Q9
BM on	57.74 s	77.55 s	32.02 s	51.06 s
BM off	58.70 s	87.95 s	32.56 s	52.04 s
Inelastic	167.68 s	223.30 s	123.20 s	147.94 s

Table 2: Runtime for scaling the system using the inelastic scaling process or the cluster resize feature with and without buffer matching (BM)

Table 2 shows the measured runtime results of the experiment. For all cases, the implemented cluster resize feature outperforms the inelastic scaling up to a factor 4. In addition to that, activated buffer matching shows a benefit in runtime for the cases of scaling the system up, caused by the buffer pre-filling. The amount of benefit is dependent on the actual query for this experiment, so query 9 shows a better speedup than query 1 using buffer matching. For the case of removing nodes, buffer matching has a negligible impact, as buffers of the remaining nodes are already filled. Therefore, a buffer merging strategy could be a possible optimization in the future. Moreover, we can state that adding nodes to the system is slower than removing nodes, both for inelastic scaling and the cluster resize feature. The reason for this is that started servers perform a collective startup with several synchronization points and do a full log replay. Increasing the number of servers, this startup time also increases, leading also the inelastic scale-up to be slower than the scale-down. In the contrary, removed nodes can shutdown independently after the remaining servers form a new communicator (see Section 4), not influencing the further query processing. This experiment is highly dependent on the cluster configuration (e.g. network speed) as well as the size of the write-ahead log that has to be replayed. Therefore, this experiment should not be used for a quantitative comparison, but is intended to show a qualitative difference between the scaling methods.

Overall the evaluation proves that the implemented cluster resize feature outperforms the "inelastic" scaling method using a restart up to a factor of 4. The buffer matching mechanism shows to add a minor runtime overhead to the scaling step, but proves to have a major impact on the query performance. The first queries after scaling show a significant performance gain when using buffer matching, which is caused by the pre-filling of buffers. As a result, the user gets an immediate performance boost when deciding to scale the VectorH installation up, which is the behavior he expects when increasing his service cost. Furthermore, the experiments prove that the socket implementation improves the buffer matching data exchange step compared to the MPI implementation, which was the expectation this optimization was based on. As we evaluated our implementation using a private cluster, the time for acquiring resources from a cloud service provider is not included in our results.

8 CONCLUSION

In this paper, we presented our approach to adapt Actian VectorH for the elastic cloud environment. As the first goal, we implemented an elastic cluster resize feature for VectorH, enabling adding and removing nodes during system uptime and therefore avoiding the drawbacks of a full system restart, e.g. full log replay and empty buffers. For the implementation of the feature we utilized group and communicator management offered by the Message Passing Interface (MPI), which is used for node-to-node communication within VectorH. As a second contribution, we designed a partition manager that is suitable for the cloud environment. By using overpartitioning and explicitly managing partition-to-node mappings for equivalence classes of partitionings, the implemented solution minimizes partition reassignments, keeps partition co-locations, balances load on partition level and provides efficient lookup and update functions. The partition manager replaces the round-robin partition assignment in VectorH, which showed to be not suitable for the elastic cloud environment. While evaluating the cluster resize feature in combination with the implemented partition manager, queries did not show the expected speedup immediately after the resize, which was caused by empty buffers. As an optimization, we introduced the buffer matching and filling mechanism into the cluster resize feature. After changing partition mappings, nodes scan their buffers and send buffered data to other nodes in order to pre-fill their buffers, leading to immediate speedup after cluster resize. For the buffer matching data exchange, we implemented two different approaches using MPI communication and using data streams over sockets and evaluated them against each other.

The experiments showed that the elastic cluster resize feature significantly outperforms the inelastic scaling process using a system restart. Activating the buffer matching mechanism further increases the performance after the cluster resize, enabling the user to immediately profit from additional resources. Evaluating both buffer matching data exchange mechanisms, the socket implementation showed to be the better choice for all tested cases.

Future work includes the investigation on online scaling allowing concurrent read and/or write transactions during the scaling process, as well as query driven scaling, optimizing a query for a given goal (e.g., cost, runtime) by scaling the system automatically. In addition to that, further data exchange mechanisms, such as RDMA (remote direct memory access) based data exchange, will be evaluated to accelerate the buffer matching data exchange step. The buffer matching mechanism could also be further extended with a predictive buffer filling strategy for adding nodes or a buffer merging strategy for removing nodes.

ABSTRACT

Online job marketplaces are becoming very popular. Either jobs or people are ranked by algorithms. For example, Google and Facebook job search return a ranked list of jobs given a search query. TaskRabbit and Fiverr, on the other hand, produce rankings of workers for a given query. Qapa, an online marketplace, can be used to rank both workers and jobs. In this paper, we develop a unified framework for fairness to study ranking workers and jobs. We case study two particular sites: Google job search and TaskRabbit. Our framework addresses group fairness where groups are obtained with any combination of protected attributes. We define a measure for unfairness for a given group, query and location. We also define two generic fairness problems that we address in our framework: *quantification*, such as finding the k groups (resp., queries, locations) for which the site is most or least unfair, and *comparison*, such as finding the locations at which fairness between two groups differs from all locations, or finding the queries for which fairness at two locations differ from all queries. Since the number of groups, queries and locations can be arbitrarily large, we adapt Fagin top-k algorithms to address our fairness problems. To evaluate our framework, we run extensive experiments on two datasets crawled from TaskRabbit and Google job search.

1 INTRODUCTION

Online job search is gaining popularity as it allows to find people to hire for jobs or to find jobs to apply for. Many online job search sites exist nowadays such as Facebook job search[1] and Google job search[2]. On those sites, users can find jobs that match their skills in nearby businesses. On the other hand, freelancing platforms such as TaskRabbit[3] and Fiverr[4] are examples of online job marketplaces that provide access to a pool of temporary employees in the physical world (e.g., looking for a plumber), or employees to complete virtual "micro-gigs" such as designing a logo.

[1]https://www.facebook.com/jobs/
[2]https://jobs.google.com/about/
[3]https://www.taskrabbit.com/
[4]https://www.fiverr.com/

In online job search, either jobs are ranked for people or people are ranked for jobs. For instance, on Google and Facebook job search, a potential employee sees a ranked list of jobs while on TaskRabbit, an employer sees a ranked list of potential employees. This ranking of jobs or individuals naturally poses the question of fairness. For instance, consider two different users searching for a software development job in San Francisco using Google job search. If the users are shown different jobs based on their search and browsing history, which could correlate with their demographics such as race or gender, this may be considered unfair. Similarly, a ranking of job seekers in NYC might be unfair if it is biased towards certain groups of people, say where White Males are consistently ranked above Black Males or White Females. This can commonly happen since such rankings might depend on the ratings of individuals and the number of jobs they completed, both of which can perpetuate bias against certain groups of individuals.

In this paper, we propose to quantify unfairness in ranking when looking for jobs online. We develop a unified framework to address group unfairness, which is defined as the unequal treatment of individuals based on their protected attributes such as gender, race, ethnicity, neighborhood, income, etc. [11]. To quantify unfairness for a group, we measure the difference in rankings between that group and its *comparable* groups, i.e., those groups which share at least one protected attribute value with the given group. For instance, consider the group “Black Females”, comparable groups would be “*Black* Males”, “White *Females*” and “Asian *Females*”.

The difference in ranking naturally depends on what is being ranked, jobs or people, and we formalize various measures of unfairness on different types of sites (job search sites and online job marketplaces). Figures 1 and 2 illustrate examples of job ranking on Google job search and people ranking on TaskRabbit, respectively. For a given query on Google job search, “Home Cleaning" in location "San Francisco” in Figure 1, we quantify unfairness in ranking for a given demographic group, “Black Females”, using Kendall Tau (we also use Jaccard Coefficient in our data model), between the search results of black females and all other users in comparable groups, as is done in [12]. To quantify unfairness for “Black Females” on TaskRabbit for the query "Cleaning Services" in location "New York City", we compute the average Earth Mover’s Distance [20] between the distribution of rankings of Black Females and all comparable groups, as in [11]. In our framework, we also compute the difference of exposure of workers from this demographic group and their relevance in contrast to comparable groups and then use this as a measure of unfairness for this group, as in [2, 22].

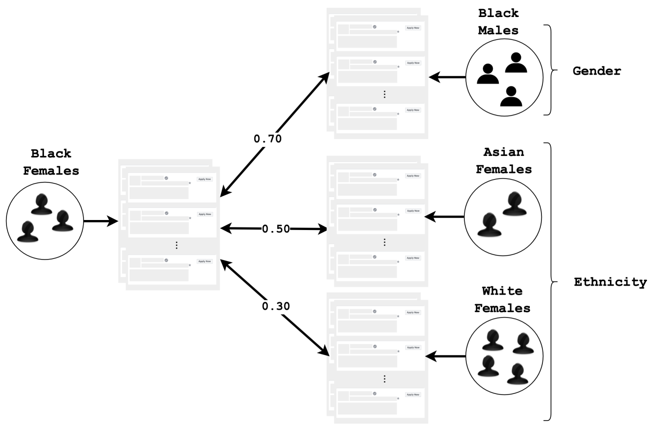

Figure 1: The unfairness for "Black Females" for the Google job search query "Home Cleaning" in location "San Francisco" using Kendall Tau between the search results of Black Females and all other users in comparable groups is $\frac{0.70+0.50+0.30}{3} = 0.50$.

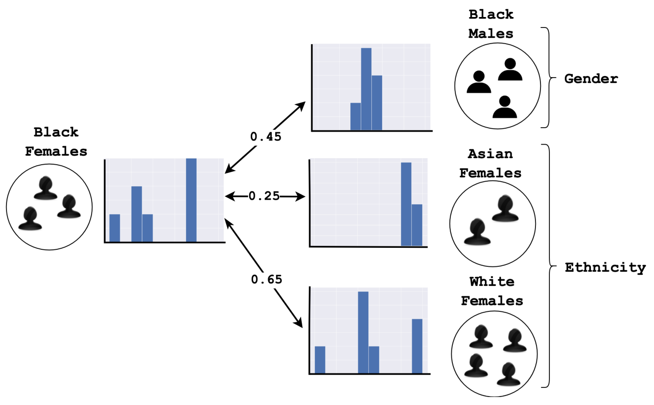

Figure 2: The unfairness for "Black Females" for the query "Cleaning Services" in location "New York City" on TaskRabbit using Earth Mover's Distance between ranking distributions of Black Females and its comparable groups is $\frac{0.45+0.25+0.65}{3} = 0.45$.

Various fairness questions can be formulated either to quantify how well a site treats groups for different jobs and at different locations, or to compare groups, queries or locations. Our framework allows us to define two generic fairness problems: *quantification*, such as finding the k groups (resp., queries, locations) for which the site is most or least unfair, and *comparison*, such as finding the locations at which fairness between two groups differs from all locations, or finding the queries for which fairness at two locations differ from all queries. Examples of *quantification* questions are: *what are the five groups for which Google job search is most unfair? what are the five fairest queries for women?* and *at which locations do Asians have the highest chance to be hired for a given job?*. Examples of *comparison* questions are: *how differently does TaskRabbit treat men and women and for which queries is the treatment different? at which locations is it easiest to be hired as a house cleaner than as a gardener?* and *which jobs are the most likely to accept hiring asian females over black females?*.

We develop efficient Fagin top-k algorithms to solve our problems. Our algorithms make use of three types of indices: *group-based*, *query-based*, and *location-based*, that pre-compute unfairness values for combinations of groups, queries and locations, for faster processing.

To evaluate our framework, we run extensive experiments on two datasets crawled from Google job search and TaskRabbit. The choice of these two platforms is justified by our goal to show the applicability of our framework to two different treatments of online employment, namely ranking jobs and ranking workers. We ran 5,361 queries on TaskRabbit and extracted for each query, the rank of each tasker, their profile pictures, and demographics, where the number of taskers returned per query was limited to 50. We processed the results and recorded unfairness values. We then derived user groups of interest and equivalent Google search terms from data crawled from TaskRabbit. This resulted in 20 queries (the top 10 and bottom 10 frequently searched queries) and their corresponding locations from data crawled in TaskRabbit. We setup 60 user studies on Prolific Academic[5] and recruited participants, who belong to chosen groups. To control for noise in search, we asked those participants to use a Google Chrome extension we developed that automatically executes on Google the search queries in 10 locations. We processed the results and recorded unfairness values.

Our results are organized into the two problems we solve: fairness quantification and fairness comparison. On TaskRabbit, we found that *Asian Females and Asian Males are the ones most discriminated against.* We also found that *Handyman and Yard Work are the most unfair jobs and that Furniture Assembly and Delivery, are the fairest* and that *Birmingham, UK and Oklahoma City, OK are the least fair while Chicago and San Francisco are the fairest locations across all jobs.* We also quantified the fairest/unfairest locations for some jobs and the fairest/unfairest jobs for some locations. Our TaskRabbit results demonstratethe flexibility and expressiveness of fairness quantification, and provided the ability to generate *hypotheses to be tested on Google job search.*

On Google job search, we found that *Washington, DC is deemed the fairest.* On the other hand, *London, UK is deemed the unfairest location.* For queries, we found that *Yard Work jobs are deemed the most unfair whereas Furniture Assembly jobs are deemed the most fair.*

While fairness quantification resulted in largely known results, our fairness comparison experiment on both platforms revealed new results. For instance, *on TaskRabbit, in Chicago, Nashville and San Francisco, Females are treated more fairly than Males, which differs from the overall comparison.* Most results are consistent between EMD and Exposure. Similarly for Google job search, most results are consistent between Jaccard and Kendall Tau. This is quite encouraging and and merits further investigation in future work.

The paper is organized as follows. We review related work in Section 2. In Section 3, we present our data model. In Section 4 we describe our unfairness problems and the algorithms we use to solve these problems. Section 5 describes our case study on two sites, Google job search and TaskRabbit. Finally, we conclude and present future work in Section 6.

2 RELATED WORK

To the best of our knowledge, our work is the first to formalize group-fairness, query-fairness, location-fairness, and fairness comparisons, and conduct an extensive evaluation of job search on a virtual marketplace and a job search site. Further statistical and manual investigations are necessary for causality and explainability. Our goal is to reduce initial manual effort by providing necessary tools to assess fairness.

Fairness has been trending in research for the last few years as we increasingly rely on algorithms for decision making. Bias has been identified as a major risk in algorithmic decision making [4, 11, 16, 23, 27]. One algorithmic solution is based on the formalization in [16] to quantify unfairness. To detect unfairness in algorithms, a framework [24] for "unwarranted associations" was designed to identify associations between a protected attribute, such as a person's race, and the algorithmic output using the FairTest tool. In [11], the notion of unfairness was defined as a disparity in treatment between different groups of people based on their protected attributes (i.e., what is commonly referred to as *group unfairness*). In this context, to assess unfairness mathematically, one needs to compare distributions of decisions across different groups of people. In our work, we adapt the definition of unfairness in [11]. However, rather than trying to fix it, the goal of our work is to just *reveal* any unfairness by the ranking process, which in some cases might be *positive* discrimination [19] where certain disadvantaged individuals are favored based on their protected attributes.

There is a wealth of work on addressing fairness of ranking in general (for example [6, 16, 22, 24–26]). Unlike our work, the majority of these works that focus on group fairness either assume the presence of pre-defined groups based on protected attributes of users, or the presence of ranking constraints that bound the number of users per protected attribute value in the top-k ranking. On the other hand, the work in [2] focuses on addressing amortized individual fairness in a series of rankings. In [15], the authors introduce *subgroup fairness* and formalize the problem of auditing and learning classifiers for a rich class of subgroups. Our work differs in many ways: we are interested in ranking individuals and not classifying them, as well as ranking jobs and we seek to quantify the fairness of jobs, locations and groups and compare fairness across different dimensions.

In [1], the authors develop a system that helps users inspect how assigning different weights to ranking criteria affects ranking. Each ranking function can be expressed as a point in a multidimensional space. For a broad range of fairness criteria, including proportionality, they show how to efficiently identify groups (defined as a combination of multiple protected attributes). Their system tells users whether their proposed ranking function satisfies the desired fairness criteria and, if it does not, suggests the smallest modification that does.

In [9], the authors studied fairness of ranking in online job marketplaces. To do this, they defined an optimization problem to find a partitioning of the individuals being ranked based on their protected attributes that exhibits the highest unfairness by a given scoring function. They used the Earth Mover's Distance between score distributions as a measure of unfairness. Unlike other related work, we did not assume a pre-defined partitioning of individuals and instead developed two different fairness problems, one aiming at quantifying fairness and the other at comparing it.

There is a wealth of work that empirically assessed fairness in online markets such as crowdsourcing or freelancing platforms [8, 13, 17, 17, 21]. For instance, the authors in [17] analyze ten categories of design and policy choices through which platforms may make themselves more or less conducive to discrimination by users. In [13], the authors found evidence of bias in two prominent online freelance marketplace, TaskRabbit and Fiverr. Precisely, in both marketplaces, they found that gender and race are significantly correlated with worker evaluations, which could harm the employment opportunities afforded to the workers on these platforms. The work in [21] studies the Uber platform to explore how bias may creep into evaluations of drivers through consumer-sourced rating systems. They concluded that while companies like Uber are legally prohibited from making employment decisions based on protected characteristics of workers, their reliance on potentially biased consumer ratings to make material determinations may nonetheless lead to a disparate impact in employment outcomes. Finally, discrimination in Airbnb was studied in [8] and high evidence of discrimination against African American guests was reported.

In [7], the authors study ethics in crowd work in general. They analyze recent crowdsourcing literature and extract ethical issues by following the PAPA (privacy, accuracy, property, accessibility of information) concept, a well-established approach in information systems. The review focuses on the individual perspective of crowd workers, which addresses their working conditions and benefits.

Several discrimination scenarios in task qualification and algorithmic task assignment were defined in [3]. That includes only accounting for requester preferences without quantifying how that affects workers, and vice versa. Another discriminatory scenario in [3] is related to worker's compensation since a requester can reject work and not pay the worker or a worker can be under-payed. Discrimination in crowdsourcing can be defined for different processes.

In [18], the authors study how to reduce unfairness in virtual marketplaces. Two principles must be adapted: 1) platforms should track the composition of their population to shed light on groups being discriminated against; and 2) platforms should experiment on their algorithms and data-sets in a timely manner to check for discrimination. In this same paper, the authors define four design strategies to help reduce discrimination, a platform manager should first answer these questions: 1) are we providing too much information? 2) can we automate the transaction process further? 3) can we remind the user of discriminatory consequences when they are making a decision? 4) should the algorithm be discrimination-aware? In question 1), they address the issue of transparency. Discrimination and transparency might be highly correlated but their correlation has yet to be studied profoundly. In [3], transparency plug-ins are reviewed. Those plug-ins disclose computed information, from worker's performance to requester's ratings such as TurkBench [14], and Crowd-Workers [5]. Such plug-ins might be helpful in a more detailed study of the effect of transparency on fairness.

3 FRAMEWORK

3.1 Unfairness Model

On any given site, we consider a set of groups $\mathcal{G}$, a set of job-related queries $\mathcal{Q}$, and a set of locations $\mathcal{L}$. We associate to each group g a label $label(g)$ in the form of a conjunction of predicates $a = val$. We use $A(g)$ to refer to all attributes used in $label(g)$. For example, if *label*(g) is *(gender = male)* ∧ *(ethnicity = black)*, we have: $A(g)$ is *{gender, ethnicity}*. We define $variants(g, a)$ where $a \in A(g)$ as all groups whose label differs from g on the value of a. For instance, $variants(g, gender)$ contains a single group whose label is *(gender = female)* ∧ *(ethnicity = black)*, $variants(g, ethnicity)$ contains two groups whose labels are *(gender = male)* ∧ *(ethnicity = asian)* and *(gender = male)* ∧ *(ethnicity = white)*, respectively.

We define the set of *comparable* groups for a group g as $\{g' \in \cup_{a \in A(g)} variants(g, a)\}$. In our example, it is $variants(g, gender) \cup variants(g, ethnicity)$. This notion of comparable groups can be more easily leveraged for explanations. To consider other notions, we believe we would need to extend only our fairness model, and not the full framework.

Each query $q \in Q$ contains a set of *keywords* such as "Home Cleaning" or "Logo Design". The same query can be asked at different geographic locations $l \in \mathcal{L}$. In some applications such as TaskRabbit, a query will be used to refer to a set of jobs in the same category such as Handyman, Furniture Assembly and Delivery services.

We denote by $d_{<g,q,l>}$ the unfairness value of the triple $< g, q, l >$. We discuss next how this unfairness value is computed for different types of sites.

3.2 Unfairness Measure for Search Engines

In a search engine such as Google Search, each user $u \in g$ is associated with a ranked list of search results $E^l_q(u)$. We compute unfairness of g as:

$$d_{<g,q,l>} = \text{avg}_{g'}\ DIST(g, g')\ \forall g' \in \cup_{a \in A(g)} variants(g, a) \quad (1)$$

A common way to compare search results is to use measures such as Jaccard Index or Kendall Tau [12]. Hence, we define $DIST(g, g')$ as one of the following two:

- $\underset{u,u'}{\text{avg}}\ \tau(E^l_q(u), E^l_q(u')), \forall u \in g, \forall u' \in g'$, where $\tau(E^l_q(g), E^l_q(g'))$ is the Kendall Tau between the ranked lists $E^l_q(u)$ and $E^l_q(u')$.
- $\underset{u,u'}{\text{avg}}\ JACCARD(E^l_q(u), E^l_q(u'))$, $\forall u \in g, \forall u' \in g'$, where $JACCARD(E^l_q(u), E^l_q(u'))$ is the Jaccard Index between the ranked lists $E^l_q(u)$ and $E^l_q(u')$.

In Table 1, we display a toy example of the top-3 results for 10 users on a search engine for the query "Home Cleaning" in location "San Francisco". Figure 3 shows how the unfairness value for the group "Black Females" is computed using Jaccard index. In the figure, the Jaccard index between every Black Female user and Asian Female user is computed and then average of the Jaccard index is used to measure unfairness value between the two groups "Black Females" and "Asian Females". To compute the overall unfairness value for the group "Black Females", the same computation must be done between Black Females and all other comparable groups, namely "Black Males" and "White Females" and then the average of the individual unfairness values between groups is taken.

3.3 Unfairness Measure for Online Job Marketplaces

In online marketplaces such as TaskRabbit, we are given a set of workers $\mathcal{W}$, and a scoring function $f^l_q : \mathcal{W} \rightarrow [0, 1]$. Each worker $w \in \mathcal{W}$ is ranked based on her score $f^l_q(w)$. To measure $d_{<g,q,l>}$, we can use one of two methods: *Earth Mover's Distance (EMD) [20] and Exposure [2, 22].*

Table 1: Top-3 results for 10 users for the query "Home Cleaning" in location "San Francisco" on a search engine.

Worker	Top-3
w1	b, d, e
w2	d, b, e
w3	a, b, c
w4	b, a, c
w5	a, b, c
w6	d, a, b
w7	a, b, d
w8	d, a, b
w9	a, b, c
w10	a, b, c

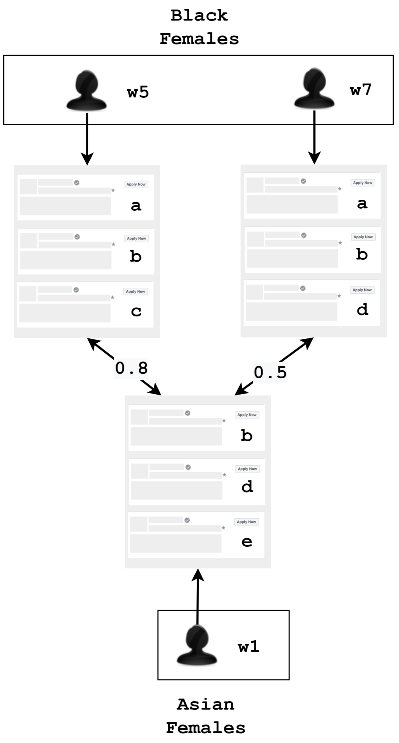

Figure 3: The partial unfairness in a search engine for "Black Females" in Table 2 with respect to one of its comparable groups, "Asian Females", using Jaccard Index is $\frac{0.8+0.5}{2} = 0.65$.

3.3.1 EMD Unfairness. In the EMD notion of unfairness, the unfairness for a group g for query q at location l is computed as the distance between the score distributions of workers in group g and all its comparable groups $g' \in \cup_{a \in A(g)} variants(g, a)$ as follows:

$$d_{<g,q,l>} = \text{avg}_{g'}\ DIST(g, g')\ \forall g' \in \cup_{a \in A(g)} variants(g, a) \quad (2)$$

where

$$DIST(g, g') = EMD(h(g, f^l_q), h(g', f^l_q))$$

where $h(g, f^l_q)$ is a histogram of the scores of workers in g using f^l_q.

In Table 2, we show a toy example consisting of 10 workers looking for a "Home Cleaning" job in San Francisco and their protected attributes. The ranking of these workers is shown in Table 3. Figure 4 illustrates how the EMD unfairness of Black Females, g, is calculated. Since $A(g)$ is *Gender* and *Ethnicity*, the comparable groups in the toy example are *Black* Males, Asian *Females* and White *Females.*

Table 2: Example of 10 workers looking for a "Home Cleaning" job in San Francisco and their protected attributes

Worker	Gender	Nationality	Ethnicity
w1*	Female	America	Asian
w2	Male	America	White
w3*	Female	America	White
w4	Male	Other	Asian
w5	**Female**	**Other**	**Black**
w6*	Male	America	Black
w7	**Female**	**America**	**Black**
w8*	Male	Other	Black
w9	Male	Other	White
w10*	Female	America	White

Table 3: Ranking of the 10 workers for the query "Home Cleaning" in San Francisco on an online job marketplace

Ranking	Worker	$f_q^l(w)$
1	w3	0.9
2	w8	0.8
3	w6	0.7
4	w2	0.6
5	w1	0.5
6	w4	0.4
7	w7	0.3
8	w5	0.2
9	w9	0.1
10	w10	0

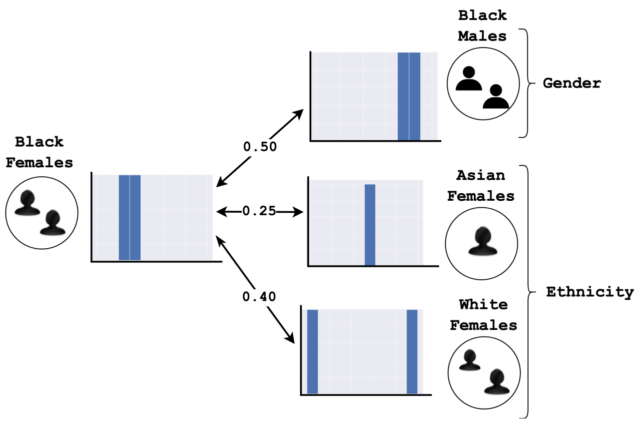

Figure 4: The unfairness of "Black Females" based on the ranking in Table 3 using EMD is $\frac{0.70+0.50+0.30}{3}$ = 0.50.

Since the actual scores of each worker for a query and location, $f_q^l(w)$ is not always available (no job marketplace makes that score available), we rely on the rank of workers $rank(w, q, l)$ to compute their relevance for a query and location. The rank of workers for a pair (q, l) is available since it can be observed in the results of running q at l. We can hence compute $rel_q^l(w)$, the relevance score of a worker as follows:

$$rel_q^l(w) = 1 - \frac{rank(w, q, l)}{N}$$

where $rank(w, q, l)$ denotes the rank of worker w for query q at location l as shown in Table 3, and N is the number of workers in the resultset, here set to 10. The relevance scores generated for all workers in our example are reported in Table 3.

To compute the EMD unfairness of Black Females for this query at this location, we generate a histogram for Black Females and each of the comparable groups based on the relevance scores $rel_q^l(w)$ computed for workers. We then compute the average EMD between the histogram of Black Females and each of the comparable groups' histograms.

3.3.2 *Exposure Unfairness.*

In the exposure notion of fairness, the intuition is that higher ranked workers receive more exposure as people tend to only examine top-ranked results. Thus, each worker receives an exposure inversely proportional to her rank $d_{<g,q,l>}$ as follows. First, for every $w \in g$, we compute her exposure as:

$$exp_q^l(w) = \frac{1}{log(1 + rank(w, q, l))}$$

We also compute the relevance of worker $w \in g$ as $rel_q^l(w)$ as defined above. Now, the exposure of a group of workers g is set to:

$$exp_q^l(g) = \frac{\sum_{w \in g} exp_q^l(w)}{\sum_{g' \in g \cup_{a \in A(g)} variants(g,a)} \sum_{w \in g'} exp_q^l(w)}$$

Similarly, we define the relevance of a group g as:

$$rel_q^l(g) = \frac{\sum_{w \in g} rel_q^l(w)}{\sum_{g' \in g \cup_{a \in A(g)} variants(g,a)} \sum_{w \in g'} rel_q^l(w)}$$

Next, we assume that each group g should receive exposure proportional to its relevance. We thus measure deviation from the ideal exposure using the L1-norm as the unfairness of a group g: $d_{<g,q,l>} = |exp_q^l(g) - rel_q^l(g)|$.

Figure 5 illustrates how the exposure unfairness of Black Females, g, is calculated. To compute the exposure unfairness of Black Females for this query in the given location, we compute the exposure and relevance of all Black Female workers (bold in Table 2) and the workers belonging to their comparable groups (* in Table 2) using $f_q^l(w)$ and ranking shown in 3. We then sum up the exposure and relevance values for all Black Females workers and the comparable groups separately.

3.4 Notation Generalization

We have used $d_{<g,q,l>}$ to refer to the unfairness for group g for the job-related query q at location l. This value is obtained by contrasting the ranking for group g with the ranking of all its comparable groups. Unfairness can also be computed for several job-related queries and at multiple locations. For a set of queries $Q \subseteq \mathcal{Q}$ and a set of locations $L \subseteq \mathcal{L}$, we can compute the unfairness for group g as follows:

$$d_{<g,Q,L>} = \text{avg}_{q \in Q, l \in L}\, d_{<g,q,l>}$$

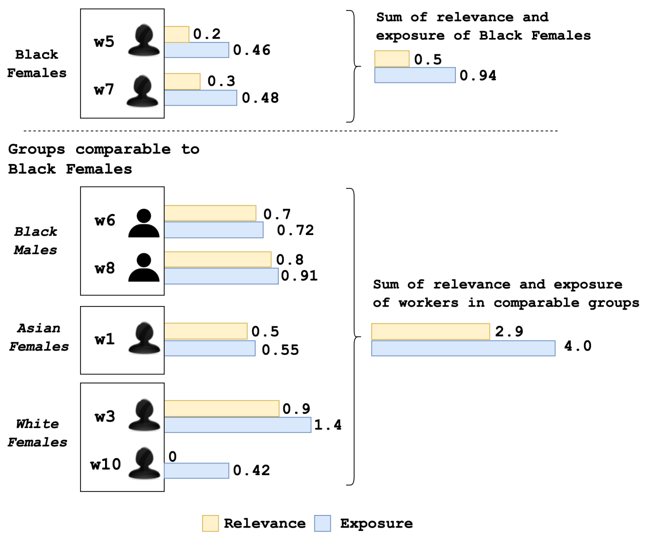

Figure 5: Computing the unfairness for "Black Females" based on the ranking in Table 3. The exposure of Black Females is $\frac{0.94}{0.94+4.0} = 0.19$**. Its relevance is** $\frac{0.5}{0.5+2.9} = 0.15$**. Its unfairness is** $0.19 - 0.15 = 0.04$**.**

Similarly, we could compute the unfairness for a set of groups $G \subseteq \mathcal{G}$ at a location $l \in \mathcal{L}$ for all queries in $Q \subseteq \mathcal{Q}$ as follows:

$$d_{<G,Q,l>} = \text{avg}_{g \in G, q \in Q}\, d_{<g,q,l>}$$

Finally, we could also compute the unfairness for a set of groups $G \subseteq \mathcal{G}$ for a given query $q \in \mathcal{Q}$ at all locations $L \subseteq \mathcal{L}$ as follows:

$$d_{<G,q,L>} = \text{avg}_{g \in G, l \in L}\, d_{<g,q,l>}$$

4 PROBLEMS AND ALGORITHMS

In this section, we first provide two generic problem formulations that capture the variety of group fairness questions we may ask (Section 4.1). We then describe the algorithms we designed to solve those problems (Section 4.2).

4.1 Problem Variants

To formulate a generic problem, we will use the term *dimension* to refer to one of group, query or location. Our first problem aims to quantify how well a site treats groups for different queries and at different locations. The problem returns instances of a chosen dimension, e.g., groups, and aggregates their unfairness values along the two others, e.g., queries and locations.

Problem 1 (Fairness Quantification). *Given R a dimension to be returned and two other dimensions AGG1 and AGG2 to be aggregated, return the k results in R for which the site is most/least unfair, where the unfairness for each result $r \in R$, $d_{<AGG1,AGG2,r>}$, is computed as:* $\text{avg}_{agg1 \in AGG1,\, agg2 \in AGG2}\, d_{<agg1,agg2,r>}$

There are 3 instances of this problem: one where R is a set of groups, one where it is a set of queries, and the third one where it is a set of locations.

When R is a set of groups, the problem, referred to as *group-fairness*, returns k groups for which the site is most/least unfair. For instance, it could be used to find *the 5 groups for which the site is least unfair with respect to all queries at all locations* or to answer the question: *Out of Black Males, Asian Males, Asian Females, and White Females, what are the 2 groups for which the site, say Google job search, is the most unfair?*

When R is a set of queries, the problem, referred to as *query-fairness* returns k queries which are the most/least unfair. This instance of the problem can address questions such as *what are the 5 least unfair queries at all locations?* or *which 2 queries are black males most likely to get in the West Coast?*

Finally, when R refers to locations, the problem, referred to as *location-fairness* addresses questions such as *Which 3 locations are the easiest to find a job at?* or *out of NYC, Boston and Washington DC, what is the least unfair location for women looking for an event staffing job on a given site, say TaskRabbit?*

Our second problem formulation aims to capture comparisons between two dimensions. It admits two dimensions to compare, e.g. males and females, or NYC and San Francisco, or cleaning services and event staffing, and it returns a breakdown of comparison dimensions into sub-dimensions whose fairness comparison differs from the comparison of the input dimensions.

Problem 2 (Fairness Comparison). *Given two comparison dimensions r_1 and r_2, and a breakdown dimension B, return all $b \in B$ s.t.* $d_{<r_1,b>} >= d_{<r_2,b>} \wedge d_{<r_1,B>} <= d_{<r_2,B>}$ $\vee d_{<r_1,b>} <= d_{<r_2,b>} \wedge d_{<r_1,B>} >= d_{<r_2,B>}$

The first instance of our comparison problem is referred to as *group-comparison* in which r_1 and r_2 are demographic groups. For example, when r_1 refers to Males, r_2 to Females, and B to locations, fairness comparison returns all locations where the comparison between males and females differs from that of all males and females. Table 4 shows an example. In this case, our problem returns the unfairness values of males and females at those two locations that compare differently from all locations.

Table 4: Comparison between Male and Female workers in Oklahoma City and Salt Lake City differ from the overall

Group-comparison	Males	Females
All	0.48	0.74
Oklahoma City, OK	0.853	0.732
Salt Lake City, UT	0.933	0.553

The second instance of our comparison problem is referred to as *query-comparison*. For example, if r_1 is lawn mowing and r_2 furniture mounting and B is ethnicity, fairness comparison returns all ethnicities for which the comparison between lawn mowing and furniture mounting differs from the whole population. For instance, our problem finds that ethnicity Black must be returned because the unfairness values between lawn mowing and furniture mounting for blacks compare differently from all ethnicities.

The third instance of our comparison problem is referred to as *location-comparison*. For example when r_1 is California, and r_2 is Arizona, and B is outdoor home services, fairness comparison returns all queries related to outdoor home services (e.g., lawn mowing, garage cleaning, patio painting, etc), for which the comparison in California and Arizona differs from all outdoor home services. Our problem returns the jobs garage cleaning and patio painting because the unfairness values between California and

Arizona for those two jobs are different from all outdoor home services.

4.2 Algorithms

The computational complexity of our problems calls for designing scalable solutions. In this section, we propose adaptations of Fagin's algorithms to solve our problems. We first describe the indices we generate: *group-based*, *query-based*, and *location-based*.

The *group-based* indices associate to every (q, l) pair an inverted index where groups are sorted in descending order based on $d_{<g,q,l>}$.

The *query-based* indices associate to every (g, l) pair an inverted index where queries q are sorted in descending order based on $d_{<g,q,l>}$.

The *location-based* indices associate to every (g, q) pair an inverted index where locations l are sorted in descending order based on $d_{<g,q,l>}$. Table 5 shows an illustration of the three types of indices.

Table 5: Group-based, query-based, location-based indices

$I_{(q,l)}$

.	.
g_j	$d(g_j, q, l)$
.	.

$I_{(g,l)}$

.	.
q_j	$d(q_j, g, l)$
.	.

$I_{(g,q)}$

.	.
l_j	$d(g, q, l_j)$
.	.

Algorithm 1 is an adaption of Fagin's Threshold Algorithm [10] for the *group-fairness* instance of our problem. It finds the k groups for which the site is most unfair. The algorithm takes as input a set of groups G, a set of queries Q and a set of locations L, and returns k groups. It makes use of the group-based indices (Table 5).

All other instances of Problem 1 including query-fairness, location-fairness and their bottom k versions, are adaptations of Algorithm 1.

Algorithm 2 solves our second problem (Problem 2) for the *group-comparison* instance of our problem. It takes as input 2 groups g_1 and g_2 and a breakdown dimension L. It first calls Algorithm 3 to compute the fairness values of g_1 and g_2 for all values of L and all queries Q. It then calls the query-based index to sum up all the values for all the queries by scanning the index for each location and for each of the two groups. Finally, it returns only those locations for which the order on unfairness values for the two groups is reversed. All other instances of Problem 2 including query-comparison and location-comparison are adaptations of Algorithm 2.

Algorithm 3 computes the fairness for a group g for all queries in Q and all locations in L. It takes as input a group g, a set of queries Q and a set of locations L, and returns the average unfairness value for g over all queries and locations.

5 EXPERIMENTS

Our experiments use real data collected from TaskRabbit and Google Search and were conducted from June to August 2019. We first describe the overall setup for each platform and then report the results.

5.1 Experimental setup

5.1.1 TaskRabbit setup. TaskRabbit is an online marketplace that matches freelance labor with local demand, allowing consumers to find immediate help with everyday tasks.

Algorithm 1 findTopKGroups(G: a set of groups, Q: a set of queries, L: a set of locations, k: an integer)

```
1: $topk \leftarrow createMinHeap()$
2: Initialize $|Q| * |L|$ cursors to 0
3: $\tau \leftarrow +\infty$
4: while $topk.minValue() < \tau$ or $topk.size() < k$ do
5:     $\tau \leftarrow 0$
6:     for $q \in Q$ do
7:         for $l \in L$ do
8:             $(g, d_{<g,q,l>}) \leftarrow I_{(q,l)}.find(cur_{(q,l)})$   ▷ Read entry in $I_{(q,l)}$ pointed to by cursor $cur_{(q,l)}$
9:             $d_{<g,Q,L>} \leftarrow d_{<g,q,l>}$
10:            $\tau \leftarrow \tau + d_{<g,q,l>}$
11:            for $q' \in Q$ do
12:                for $l' \in L$ do
13:                    if $q' \neq q$ or $l' \neq l$ then
14:                        $d_{<g,q',l'>} \leftarrow I_{(q',l')}.find(g)$   ▷ Perform a random access on $I_{(q',l')}$ to retrieve the unfairness value of $g$ for the pair $(q', l')$
15:                        $d_{<g,Q,L>} \leftarrow d_{<g,Q,L>} + d_{<g,q',l'>}$
16:                    end if
17:                end for
18:            end for
19:            $d_{<g,Q,L>} \leftarrow d_{<g,Q,L>}/(|Q| * |L|)$
20:            if $topk.size() < k$ then
21:                $topk.insert(g, d_{<g,Q,L>})$
22:            else
23:                if $topk.minValue() < d_{<g,Q,L>}$ then
24:                    $topk.pop()$
25:                    $topk.insert(g, d_{<g,Q,L>})$
26:                end if
27:            end if
28:            $cur_{(q,l)} \leftarrow cur_{(q,l)} + 1$
29:        end for
30:    end for
31:    $\tau \leftarrow \tau/(|Q| * |L|)$
32: end while
33: return $topk$
```

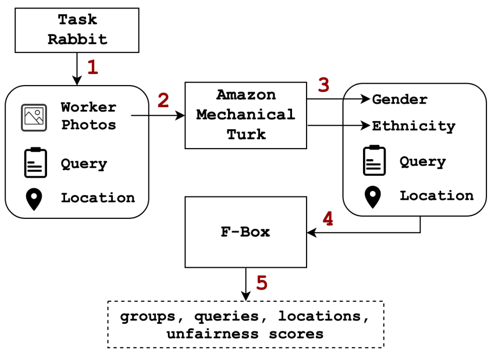

Figure 6: Flow of TaskRabbit Experiments

TaskRabbit is supported in 56 different cities mostly in the US. For each location, we retrieved all jobs offered in that location. We thus generated a total of 5,361 job-related queries, where each query is a combination of a job and a location, e.g., *Home Cleaning* in *New York*.

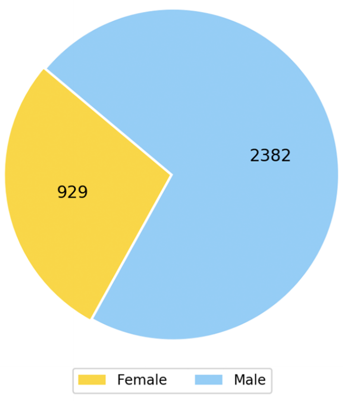

Figure 7: Gender breakdown

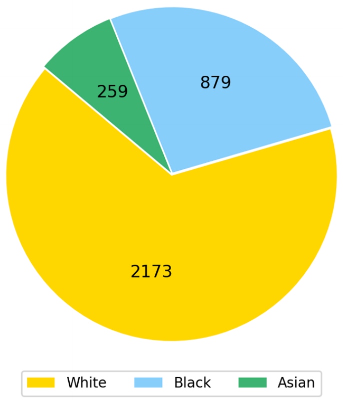

Figure 8: Ethnic breakdown

Algorithm 2 CompareGroups(Groups: g_1, g_2, L: a set of locations as breakdown, Q: a set of queries)

```
1:  $loc \leftarrow \emptyset$
2:  $d_{<g_1,Q,L>} \leftarrow ComputeGroupUnfairness(g_1, Q, L)$
3:  $d_{(<g_2,Q,L>} \leftarrow ComputeGroupUnfairness(g_2, Q, L)$
4:  for $l \in L$ do
5:      $sum_1 \leftarrow 0$
6:      $sum_2 \leftarrow 0$
7:      $cur_1 \leftarrow 0$
8:      $cur_2 \leftarrow 0$
9:      for $q \in Q$ do
10:         $sum_1 + = I_{(g_1,l)}.find(cur_1)$
11:         $sum_2 + = I_{(g_2,l)}.find(cur_2)$
12:         $cur_1 \leftarrow cur_1 + 1$
13:         $cur_2 \leftarrow cur_2 + 1$
14:     end for
15:     if $reversed(sum_1, sum_2, d_{<g_1,Q,L>}, d_{<g_2,Q,L>})$ then
16:         $loc + = l$
17:     end if
18: end for
19: return $loc$
```

Algorithm 3 ComputeGroupUnfairness(g: a group, Q: a set of queries, L: a set of locations)

```
1: $sum \leftarrow 0$
2: for $q \in |Q|$ do
3:     for $l \in |L|$ do
4:         $sum \leftarrow sum + I_{(q,l)}.find(g)$        ▷ Perform a random
   access on $I_{(q,l)}$ to retrieve the unfairness value of $g$ for the
   pair $(q, l)$
5:     end for
6: end for
7: return $sum/(|Q| * |L|)$
```

Figure 6 summarizes the flow of the TaskRabbit experiment. Our algorithms are encapsulated in the F-Box. For each one of the 5,361 queries, we extracted the rank of each tasker, their badges, reviews, profile pictures, and hourly rates, where the number of taskers returned per query was limited to 50. Since the demographics of the taskers were not readily available on the platform, we asked workers on Amazon Mechanical Turk (AMT)[6] to indicate the gender and ethnicity of the TaskRabbit taskers based on their profile pictures. The taskers were given pre-defined categories for gender = {Male, Female} and ethnicity = {Asian, Black, White}. Each profile picture was labeled by three different contributors on AMT and a majority vote determined the final label.

The gender and ethnic breakdowns of the taskers in our dataset are shown in Figures 7 and 8. Overall, we had a total of 3,311 unique taskers in our crawled dataset, the majority of which were male ($\approx$ 72%) and white ($\approx$ 66%).

5.1.2 Google Search setup. Google Search personalizes queries based on a user's profile which includes user data, activity, and saved preferences. While personalization can be beneficial to users, it may introduce the possibility of unfairness, which we aim to observe.

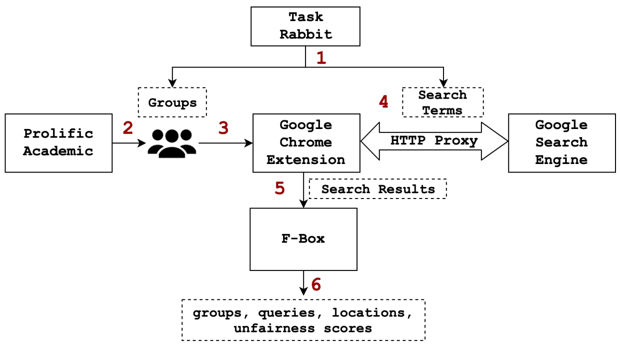

Figure 9: Flow of Google job search Experiments

We designed the experiments to ensure that variations in the search results are largely based on differences in profiles rather than other known noise sources identified in related work such as carry-over-effect, geolocation, distributed infrastructure, and A/B testing [12].

The flow of the Google Search experiment is summarized in Figure 9. We first derived user groups of interest and equivalent Google search terms from data crawled from TaskRabbit. We then setup user studies on Prolific Academic[7] and recruited participants, who belong to those groups. We asked those participants

[6]https://mturk.com
[7]https://prolific.co

Table 6: Sample TaskRabbit queries and equivalent Google search terms

TaskRabbit Query	Location	Equivalent Google Search Terms
run errand	London, UK	*run errand jobs near London UK, errand service jobs near London UK, errand runner jobs near London, UK, errands and odd jobs near London, UK, jobs running errands for seniors near London, UK*
yard work	New York City, NY	*yard work jobs near New York City, NY, yard worker near New York City, NY, lawn work needed near New York City, NY, yard help needed near New York City, NY, yard work help wanted near New York City, NY*

to use our Google Chrome extension that automatically executes on Google the search queries derived. Finally, we processed the results and provided them as input to the F-Box and recorded unfairness values.

Search Queries. For our Google Search experiments, we selected 20 queries (the top 10 and bottom 10 frequently searched queries) and their corresponding locations from data crawled in TaskRabbit. From this list, we chose those from 10 unique locations. We then generated equivalent search terms using Google Keyword Planner, a tool that outputs a list of search terms similar or related to a given search string and a location. We shortlisted 50 formulations for each query, manually examined them, then chose 5 search terms whose results are similar to the original term. Table 6 shows sample queries from TaskRabbit and their equivalent Google search terms.

Groups. The combination of pre-defined categories for gender = {Male, Female} and ethnicity = {Asian, Black, White} results in six groups: Asian Male, Asian Female, Black Male, Black Female, White Male, and White Female.

We recruited an average of 3 participants per study through Prolific Academic, a crowdsourcing platform that allows researchers to recruit participants who have been categorized through the platform's screening mechanism.

User Study. Given the search terms and the groups, we have a total of 60 studies. Each study is composed of two tasks. In the first task, a participant is asked to set her browsing language to English and install our Google Chrome extension that runs the search terms. Participants who are able to successfully complete the first task are invited to do a second task where they are asked whether they think the instructions of the first task were clear and whether the reward is fair. The reward for each task is 0.50 GBP.

Given the distribution of workers on Prolific Academic, we ended up with 10 locations, namely London, UK, New York City, NY, Los Angeles, CA, Boston, MA, Bristol, UK, Charlotte, NC, Pittsburg, PA, Birmingham, UK, Manchester, UK and Detroit, MI. For those 10 locations, we have five categories of jobs: yard work, general cleaning, event staffing, moving job and run errand. Table 7 shows the number of locations per job that we collected search results for.

Google Chrome Extension and noise handling. We developed a Google Chrome extension that automatically executes the Google search terms. The extension runs the five search terms every 12 minutes to minimize noise due to the carry-over effect. Meanwhile, every search term is executed at least twice to account for noise caused by A/B testing. The extension also sets the browser's location to a fixed location and uses a proxy so that all queries originate from the same location thus minimizing noise caused by distributed infrastructure and different geolocations. The search results are then inserted to a Google Sheets document. We emphasized to the participants that we store no identifying information about them.

Table 7: Number of locations per job

Job	Location
yard work	4
general cleaning	3
event staffing	1
moving job	1
run errand	1

5.2 Fairness quantification

5.2.1 TaskRabbit fairness quantification. We report the results of solving our fairness quantification problem (Problem 1 in Section 4.1) for groups, queries and locations using both EMD and exposure to measure unfairness (see Sections 3.3.1 and 3.3.2 for their formal definitions).

Table 8 reports all groups in TaskRabbit ranked by their decreasing unfairness values (both EMD and exposure). We can see that the two measures agree on the top 7 groups for whom TaskRabbit is the most unfair: *Asian Females and Asian Males are the ones most discriminated against.*

Table 9 reports all job types in TaskRabbit ranked by their decreasing unfairness values (both EMD and exposure). The two measures largely agree on the ranking showing that *Handyman and Yard Work are the most unfair jobs and that Furniture Assembly and Delivery, are the fairest.*

Since the number of locations is large, we report the top and bottom 10 locations in Tables 10 and 11 respectively. The results show that *Birmingham, UK and Oklahoma City, OK are the least fair while Chicago and San Francisco are the fairest locations across all jobs.*

We also report the fairest/unfairest locations for some jobs and the fairest/unfairest jobs for some locations. *For Handyman and Run Errands, the fairest location is San Francisco Bay Area, CA for both when using EMD and, when using exposure, it is Boston, MA for Handyman, and San Francisco Bay Area, CA for Run Errands. The unfairest location for both jobs is Birmingham, UK when using EMD.*

For Birmingham, Detroit, and Nashville, the fairest jobs are Delivery and Furniture Assembly for all, and the unfairest are Yard Work, General Cleaning, and General Cleaning, respectively. For Philadelphia, San Diego and Chicago, the fairest jobs are Delivery, Furniture Assembly, and Delivery, respectively, and the unfairest is Yard Work for Birmingham, Detroit, and Run Errands for Nashville.

Table 8: EMD and Exposure of all groups in TaskRabbit, *ranked from the unfairest to the fairest.*

Group	EMD	Group	Exposure
Asian Female	0.876	Asian Female	0.821
Asian Male	0.755	Asian Male	0.662
Black Female	0.726	Black Female	0.615
Asian	0.694	Asian	0.594
Black Male	0.578	Black Male	0.413
White Female	0.542	White Female	0.359
Black	0.498	Black	0.341
Male	0.468	Female	0.299
Female	0.468	White Male	0.154
White	0.448	Male	0.117
White Male	0.421	White	0.104

Table 9: EMD and Exposure for all jobs in TaskRabbit, *ranked from the unfairest to the fairest.*

Job	EMD	Job	Exposure
Handyman	0.692	Handyman	0.515
Event Staffing	0.639	Event Staffing	0.504
General Cleaning	0.611	General Cleaning	0.456
Yard Work	0.672	Yard Work	0.5
Moving	0.604	Moving	0.418
Delivery	0.499	Furniture Assembly	0.383
Furniture Assembly	0.541	Delivery	0.331
Run Errands	0.519	Run Errands	0.352

Table 10: 10 unfairest locations using EMD and Exposure, *ranked from the unfairest to the fairest.*

City	EMD	City	Exposure
Birmingham, UK	1	Birmingham, UK	0.926
Oklahoma City, OK	0.998	Oklahoma City, OK	0.819
Bristol, UK	0.91	Bristol, UK	0.761
Manchester, UK	0.851	Manchester, UK	0.739
New Haven, CT	0.838	New Haven, CT	0.67
Milwaukee, WI	0.824	Memphis, TN	0.668
Indianapolis, IN	0.815	Milwaukee, WI	0.668
Nashville, TN	0.808	Charlotte, NC	0.643
Detroit, MI	0.806	Nashville, TN	0.637

Table 11: 10 fairest locations using EMD and Exposure, *ranked from the fairest to the unfairest.*

City	EMD	City	Exposure
Chicago, IL	0.274	Chicago, IL	0.107
San Francisco, CA	0.286	San Francisco, CA	0.12
Washington, DC	0.329	Boston, MA	0.169
Los Angeles, CA	0.33	Washington, DC	0.174
Boston, MA	0.353	Los Angeles, CA	0.189
Atlanta, GA	0.4	Houston, TX	0.217
Houston, TX	0.417	Atlanta, GA	0.234

San Diego, CA	0.454	Philadelphia, PA	0.273

In summary, our results demonstrate the flexibility and expressiveness provided by solving the fairness quantification problem for groups, queries and locations. They also provide the ability to generate hypotheses to be tested across platforms, in our case from TaskRabbit to Google job search.

5.2.2 Google fairness quantification. We ran our unfairness quantification algorithm (Algorithm 1) on the data crawled from Google Search. Our algorithm found that regardless of the metrics we use, Kendall Tau or Jaccard Index, *the most discriminated against group is White Females and the least is Black Males.* This indicates that search results between White Females were the most different, whereas those for Black Males were the most similar.

When quantifying unfairness for locations, we found that *Washington, DC is deemed the fairest* indicating no difference in search results between users at this location using both Jaccard Index and Kendall Tau. On the other hand, *London, UK is deemed the unfairest location.*

Finally, for queries, we found that using both metrics, *Yard Work jobs are deemed the most unfair whereas Furniture Assembly jobs are deemed the most fair.*

5.3 Fairness comparison

5.3.1 TaskRabbit fairness comparison. We report the results of solving our fairness comparison problem (Problem 2 in Section 4.1) in Tables 12, 13, 14 and 15. The tables only report *the locations, demographics, and jobs that differ from the overall comparison.*

Table 12: Comparison between Male and Female workers after including locations using Exposure. *The listed locations are the ones for which Females are treated more fairly than Males, which differs from the overall comparison.*

Group-comparison	Males	Females
All	**0.117**	**0.299**
Charlotte, NC	0.399	0.345
Chicago, IL	0.062	0.062
Nashville, TN	0.330	0.309
Norfolk, VA	0.331	0.168
San Francisco Bay Area, CA	0.084	0.084
St. Louis, MO	0.255	0.190

Table 13: Comparison between Lawn Mowing and Event Decorating workers after including Ethnicity using EMD. *Caucasians are the ones for which the comparison between Lawn Mowing jobs and Event Decorating jobs is different from the whole population, showing that Lawn Mowing jobs are fairer than Event Decorating for Caucasians.*

Job-comparison	Lawn Mowing	Event Decorating
All	**0.674**	**0.613**
White	0.552	0.569

In summary, we can conclude that overall, EMD and Exposure yield the same observations when solving the fairness comparison problem on TaskRabbit.

Table 14: Comparison between Lawn Mowing and Event Decorating jobs after including Ethnicity using Exposure. ***Unlike Table 13, in this case blacks are the ones for whom Lawn Mowing jobs are fairer than Event Decorating. This warrants further investigation in the future.***

Job-comparison	Lawn Mowing	Event Decorating
All	**0.500**	**0.442**
Black	0.445	0.453

Table 15: Comparison between San Francisco Bay Area and Chicago after including General Cleaning jobs using EMD. ***San Francisco is shown to be fairer for all jobs but the trend is inverted for the listed jobs.***

Location-comparison	San Francisco Bay Area, CA	Chicago, IL
All	**0.213**	**0.233**
Back To Organized	0.198	0.135
Organize & Declutter	0.224	0.191
Organize Closet	0.174	0.153

5.3.2 Google fairness comparison. Similarly to TaskRabbit, we report the results of solving our fairness comparison problem (Problem 2 in Section 4.1) in Tables 16, 17, 18, 19, 20, and 21. *The tables show the cases that differ from the overall comparison.*

Table 16: Comparison between Male and Female workers after including locations using Kendall Tau. ***The listed locations are the ones for which Females are treated more fairly than Males, which differs from the overall comparison.***

Group-comparison	Males	Females
All	**0.537**	**0.552**
Birmingham, UK	0.906	0.901
Bristol, UK	0.921	0.918
Detroit, MI	0.928	0.901
New York City, NY	0.913	0.906

Table 17: Comparison between Male and Female workers after including locations using Jaccard. ***The results differ from the ones in Table 16 because the overall results differ. This warrants further investigation in the future.***

Group-comparison	Males	Females
All	**0.395**	**0.393**
Boston, MA	0.894	0.896
Charlotte, NC	0.893	0.901
London, UK	0.776	0.785
Los Angeles, CA	0.875	0.878
Manchester, UK	0.869	0.875
Pittsburgh, PA	0.877	0.88

In summary, we observed that Kendall Tau and Jaccard report mostly similar results when solving the fairness comparison problem on Google job search. This is quite encouraging and merits further investigation in future work.

Table 18: Comparison between Running Errands jobs and General Cleaning jobs after including Ethnicity using Kendall Tau.

Job-comparison	Running Errands	General Cleaning
All	**0.927**	**0.926**
Black	0.927	0.950
Asian	0.925	0.938

Table 19: Comparison between Running Errands jobs and General cleaning jobs after including Ethnicity using Jaccard. ***The results differ from those reported in Table 18. This warrants further investigation in the future.***

Job-comparison	Running Errands	General Cleaning
All	**0.902**	**0.887**
Black	0.903	0.94

Table 20: Comparison between Boston, MA and Bristol, UK after including General Cleaning jobs using Kendall Tau. This result is similar to the one reported in Table 21.

Group Comparison	Boston, MA	Bristol, UK
All	**0.641**	**0.689**
office cleaning jobs	0.735	0.627
private cleaning jobs	0.572	0.398

Table 21: Comparison between Boston, MA and Bristol, UK after including General Cleaning jobs using Jaccard. This result is similar to the one reported in Table 20.

Group Comparison	Boston, MA	Bristol, UK
All	**0.447**	**0.603**
private cleaning jobs	0.403	0.364

6 CONCLUSION

We develop a framework to study fairness in job search and a detailed empirical evaluation of two sites: Google job search and TaskRabbit. We formulate two generic problems. Our first problem returns the k least/most unfair dimensions, i.e., the k groups for which a site is most/least unfair, the k least/most unfair jobs (queries), or the k least/most unfair locations. Our second problem captures comparisons between two dimensions. It admits two dimensions to compare, e.g. males and females, or NYC and San Francisco, or cleaning services and event staffing, and it returns a breakdown of those dimensions that exhibits different unfairness values (for instance, on TaskRabbit, while females are discriminated against when compared to males, this trend is inverted in California). We apply threshold-based algorithms to solve our problems. We report the results of extensive experiments on real datasets from TaskRabbit and Google job search.

Our framework can be used to generate hypotheses and verify them across sites. That is what we did from TaskRabbit to Google job search. It can also be used to verify hypotheses by solving the comparison problem. As a result, one could use it in iterative scenarios where the purpose is to explore and compare fairness. We are currently designing such exploratory scenarios.

ABSTRACT

Many e-commerce platforms serve as an intermediary between companies and consumers, receiving a commission per purchase. To increase sales, these platforms tend to offer as many items as possible. However, in many situations a reduced subset of the items should be offered for sale, e.g., when opening an express delivery branch, starting operations in a new region, or disposing of redundant items to improve data quality and decrease maintenance costs. In all these cases it is imperative to select a reduced inventory which maximally covers consumer needs. A naïve, yet popular, solution is to focus on the top selling items. This however ignores the hidden relations between items, and in particular the tendency of shoppers to buy, in the absence of an item they are looking for, a satisfying alternative.

In this paper we introduce the *Preference Cover problem*, and investigate its application to practical inventory reduction. Given a large set of items, a bound on the number of items that can be retained and consumer preferences in terms of items popularity and suitability as alternatives, the goal is to select a reduced inventory which maximizes the likelihood of a purchase. We first model the problem via a dedicated weighted directed graph which captures the relevant information, then study two problem variants, which differ in their interpretation of the probabilistic dependencies between consumer preferences. We prove both variants are NP-hard, and characterize their approximation hardness. Since in the practical application the overall number of items and the bound on the reduced item set are very large - in the order of magnitude of millions - we propose a highly parallelizable and scalable algorithm along with approximation guarantees. Finally, we present an end-to-end solution that fits the real-world e-commerce application, and provide an extensive set of experiments demonstrating the efficiency and effectiveness of our solution.

1 INTRODUCTION

Due to the rapid growth of the e-commerce industry, online selling has become one of the most trending businesses of today. Many e-commerce platforms serve as an intermediary between companies and consumers, receiving a commission per purchase. To increase the number of sales, such sites tend to offer a large number of items[1]. Nonetheless, they often pursue complementary objectives where selecting and offering a reduced inventory is required. Common such scenarios, reported by our industry collaborators, are the following:

Launching an express delivery store. When large companies provide express delivery services (alongside existing services) offering items for same-day-delivery, these items should be available in different warehouses for immediate shipping. It is not feasible to ensure immediate availability, in terms of storage space and maintenance overhead, except for a significantly reduced inventory, as seen for example in the Amazon Prime same-day-delivery catalog, which offers a small percentage of the entire inventory.

Opening a branch overseas. When e-commerce platforms start operations in new regions, it is often done gradually, initially offering a small backlog of items. This is in part because one needs to require the vendors to ship abroad, with regulations often restricting the number of products that are allowed to be distributed. A notable example is AliExpress (consumer facing branch of Alibaba), which due to regulations restricts the number of items offered for shipping abroad.

Reducing maintenance costs. Maintaining large inventories incurs substantial data maintenance overhead (e.g., in data cleaning, validation, entity resolution and semantic enhancement [5]). Hence, companies periodically dispose of some small percentage of items deemed to be least valuable.

These examples demonstrate the need to select a reduced inventory that minimizes the loss in the number of sales. A naïve, yet popular, solution is to focus on the top selling items. This approach however entirely ignores the *hidden* relations between items. In particular, studies show that consumers are flexible, and when searching for a specific item are often willing to buy in its absence what they consider to be a reasonable alternative [34]. For example, in the absence of a specific 19" LG TV a customer may be willing to settle for a slightly bigger LG TV or for the same size TV from Samsung. Retaining a set of items which are not only popular in-and-of-themselves, but are also likely to "cover" the inventory and serve as suitable alternatives for omitted items, can significantly improve the overall satisfaction of the customers.

To model consumer preferences and item alternatives we use a *preference graph* - a directed graph with weights on both the nodes and the edges. The nodes correspond to the items, and the node weights reflect the items' purchase popularity (% out of total sold items). A (directed) edge from item A to item B indicates that, in A's absence, consumers consider B as a possible alternative[2]. The edge weight reflects the probability that a consumer is willing to buy B as an alternative to A, if A is missing. (We discuss how edge weights are derived via customary techniques from click-stream data, commonly available to e-commerce companies, in the Experiments Section.)

We use the *preference graph* to devise effective algorithms for the selection of items. However, before presenting our results, let us first illustrate through a simple example how the information provided in the graph is employed.

Example 1.1. Consider the preference graph depicted in Figure 1. Assume that of the five available items we wish to choose two. We can see that A is the best selling item (purchased by 33% of customers) while D is the least sold (6%). We can also see that consumers interested in E are likely to settle in its absence for D, but will not transitively buy C. Such behavior is common, for instance, when D (resp. C) is a one-step upgrade of E (D): people are often flexible and willing to add a small amount of

[1]Note that "item" here refers to a specific item type from a specific seller, e.g., Silver iPhone Xs 256GB by Best Buy, rather than to individual instances of this item.

[2]We assume that all transitive relationships, when/if exists, are directly represented in the graph by single edges.

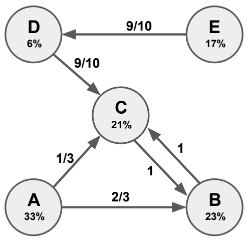

Figure 1: Sample graph of items

money in return for an upgrade, but a two-steps delta may be overly expensive. We can also see that consumers interested in C (B) will settle in its absence for B (C), and that B is a more likely replacement for A than C. Selecting the two best-sold items, A and B, is likely to satisfy about 77% of the customers (those interested in C, who in its absence are likely to purchase B, and those interested in A and B). Interestingly, a more careful analysis (which we only describe here intuitively and will formalize later in the paper) shows that in fact retaining B and D (the least sold item!) is the optimal solution, covering 87.3% of requests. Intuitively this is because B covers most requests for A, B, and C, whereas D covers itself and most of E. In this simple example the sets of requests served by the two retained items are disjoint, but a similar analysis can be applied to general overlapping cases.

The probability of a purchase is contingent on the dependencies between choosing different alternatives. Such dependencies can be extremely complicated, hence a practical model should simplify them in a manner which approximates well real life settings. We define in this paper two variants of the Preference Cover problem, which we have observed to be most prevalent in real-world e-commerce applications (see technical discussion in Section 5.2), the *Independent* and the *Normalized* variants. These variants differ by the semantics of edge dependencies. The Independent variant assumes independence between all alternatives. Whereas, the Normalized variant assumes that each consumer considers at most one item as an alternative she will actually buy, and thus the sum of weights of outgoing edges from any item is bounded by 1 (hence the name Normalized). In the experiments section, we show that both variants capture real-world consumer behavior. We will discuss the similarity and differences between these two problem variants (and when each is suitable) in depth in the following sections and propose effective algorithms to solve both.

To get an idea on what one may hope to achieve in terms of efficiency, we first study the computational complexity of the two problem variants. We prove that both are NP-hard but have different approximation bounds. Nevertheless, we devise a single greedy scheme that, with only minor adaptations, is able to support both variants, providing in both cases approximation guarantees. For the Independent variant we also prove this to be the optimal approximation ratio (matching the inapproximability bound we proved). For the Normalized variant, we show (by proving equivalence to the Max Vertex Cover problem) that while tighter theoretical upper bounds do exist, their corresponding algorithms are not scalable and thus impractical for our setting. Indeed, in the e-commerce application that we study here, both the overall number of available items and the number of items to be selected are very large - in the order of magnitude of millions. Thus, scalability is critical. Our solution consequently trades off the tightness of approximation guarantee in return for improved performance.

The simple greedy scheme which we use to solve both problem variants is highly parallelizable and scalable. It further has the added value of allowing to directly solve the complementary minimization problem, where, instead of an upper bound on the number of items to retain, one is given a lower bound on the percentage of item requests that should be covered, and the goal is to identify the smallest set of items that achieves the required coverage. Note that a naive solution for this complementary problem can be obtained via binary search on the target set size, by running any algorithm for the original problem. But this incurs a $O(\log n)$ factor overhead, n being the number of available items. Our direct greedy approach allows to avoid this overhead.

Our contributions can be summarized as follows.

(1) We formulate the Preference Cover problem and propose a graph-based model to capture it, with two natural possible variants.
(2) We study the theoretical computational complexity of the two problem variants and prove their NP-hardness and approximation hardness.
(3) We propose efficient algorithms to solve both variants, and prove their approximation guarantees.
(4) To demonstrate the practicality of our approach we describe the process of creating the preference graph from data available to actual e-commerce companies, based on well agreed upon inference methods in e-commerce research.
(5) We present an extensive experimental study, based on real-world data from a large e-commerce company, for both variants of the problem, demonstrating the effectiveness and efficiency of our algorithms.

Finally, we note that in the problem setting that we study here (which is common to many intermediary platforms [1]) the commission-per-purchase (or the perceived gain per purchase) is considered fixed and the intermediary platform is indifferent to the items' cost/revenue or required physical storage. Extending our work to support varying revenues and storage considerations, in a scalable manner, is an intriguing future work. We overview, in the Related Work, results in the field of operational research that incorporate such factors but in more complex models that do not lend to practical big data solutions. Other lines of work that bear resemblance to ours are recommendation systems and query results diversification. However, as we explain in the Related Work, the optimization problems they study differ from ours, yielding different complexity results and algorithms.

A first prototype of our system was implemented with help of our industry collaborators, and demonstrated at CIKM'19 [15]. The short paper accompanying the demonstration gives only a brief overview of the system architecture, whereas the present work provides a comprehensive description of the underlying model, algorithms and applications.

Paper outline. Section 2 provides the necessary definitions and formalism behind our problem. Sections 3 and 4 each study one of the two variants of our problem. Implementation and experimental studies are presented in Section 5. Finally, the related work appears in Section 6, and we conclude in Section 7.

2 PRELIMINARIES

We introduce here the *Preference Cover* problem. We start by formally describing the general model along with two concrete variants - the Independent and the Normalized variants.

Recall that the main motivation for our problem is an e-commerce setting, where consumers are interested in specific items but, if not available, may be willing to settle for some alternatives. Given a bound on the number of different item types a store may offer, our goal is to retain those which maximize the likelihood of purchase.

Formally, we represent consumer preferences via a *Preference Graph* which, along with an integer k, serve as input for the Preference Cover problem. A preference graph $G = (V, E, W_V, W_E)$ is a directed graph with weighted vertices and edges. The vertex set V corresponds to n items. For each vertex $v \in V$, its weight, $W_V(v) \in [0, 1]$, is defined as the probability of v being requested by a consumer. The sum of all node weights is therefore 1. We say that u is a *neighbor* of v if there exists an outgoing edge from v into u. The neighbors of a node v are all the items that are considered by consumers as possible alternatives. For each edge from v into a neighbor node u, its weight, $W_E(v, u) \in (0, 1]$, implies the probability of u matching a request for v as an alternative. We explain later how these edge weights are computed and interpreted. For simplicity we omit in the sequel subscripts of weighting functions when clear from context.

Given a number k, our goal is to choose a subset $S \subseteq V$ of k items, marking them as *retained*. Given a request for item v, if it is retained, the request is considered *matched*. Otherwise, if v is not retained, a request has some probability of being matched by another retained neighboring item of v, as indicated by the weights of edges outgoing from v into its retained neighbors. We define a target function $C : 2^V \rightarrow [0, 1]$, s.t. assuming S is the retained set of items, $C(S)$ is the probability a request drawn from the distribution indicated by the node weights is matched. The *Preference Cover problem* aims to compute $\arg\max_{S, |S|=k} C(S)$. We are ultimately only interested in whether or not a request is matched, and it makes no difference theoretically which item matches it. This corresponds to a real-life setting where intermediary platforms value the selling of each item as equally beneficial, and accordingly seek to maximize the number of sales.

We term $C(\cdot)$ as the *Cover function*, and say that the value $C(S)$ is the *cover of* S. Similarly, we call the probability a request for v is matched by a retained set S as the cover of v by S.

An explicit formula for computing $C(\cdot)$ is contingent on the dependencies, if such exist, between the probabilities indicated by the edges. In this paper we study two variants of the problem which, as our analysis of real data indicates, approximate well common real life scenarios: the *Independent* variant assumes that the probabilities modeled by edges are independent, while the *Normalized* variant assumes that each consumer considers at most one item as a most suitable alternative. In both cases, the goal is to retain the set of items which covers most of the predicted requests as implied by the preferences model.

In both variants when considering alternatives for a request for item v, we only take into account v's immediate neighbors. This is because, as mentioned earlier, the possible transitive processes of considering an alternative followed by an alternative to that alternative and so on is already taken into account when constructing the graph and assigning edge weights, which means, intuitively, that the preference graph is the transitive closure of a graph modeling the probabilities to correspond to such replacement paths.

We now formally describe the two variants we study in this paper. In the presentation below, given a retained set S we denote the retained neighbors of node v by $R_v(S) = \{u | (v, u) \in E, u \in S\}$

2.1 Independent variant

In the *Independent* variant we assume complete independence between the edges. Namely, the probability a given alternative matches a request is not affected by whether or not a different alternative matches it. Thus, the probability of the event of **not** matching a request for a non-retained item v, which occurs when no retained alternative is suitable, is, due to independence, the product of all such probabilities, $\prod_{u \in R_v(S)}(1 - W(v, u))$. The probability of the complement of this event, which is matching the request, is $1 - \prod_{u \in R_v(S)}(1 - W(v, u))$. We next formally define the Independent variant of the Preference Cover problem.

Definition 2.1 (IPC_k). Given a preference graph G and an integer k, the Independent Preference Cover problem (IPC_k) is computing $\arg\max_{S, |S|=k} C(S)$, where

$$C(S) = \sum_{v \in S} W(v) + \sum_{v \in V \setminus S} \left[W(v) \cdot (1 - \prod_{u \in R_v(S)} (1 - W(v, u))) \right]$$

The first addend is due to requests for retained items being matched with probability 1. The second addend corresponds to summing over all items not in S, for each such item v adding the probability it is both requested ($W(v)$) and covered by S ($(1 - \prod_{u \in R_v(S)}(1 - W(v, u)))$). Recall that we are computing the purchasing probability of a single consumer session, which in the hypothetical case where all items are available would have resulted in a purchase. The overall expected number of sales, given only S is retained, is thus the number of such sessions times $C(S)$. Cases where a consumer is looking to purchase several items, or several copies of the same items, are modeled as separate sessions.

2.2 Normalized Variant

In the *Normalized* variant we assume that each consumer considers at most one item as a suitable alternative (i.e. the item she will actually buy). Neighbors are therefore dependent, in the sense that for any requested item v, a retained neighbor matching the request implies that all other neighbors do not. It follows that the sum of the weights of all edges outgoing from any given node is at most 1, and given a request for a non-retained item v, the probability it is matched is $\sum_{u \in R_v(S)} W(v, u)$. We next formally define the Normalized variant of the Preference Cover problem.

Definition 2.2 (NPC_k). Given a preference graph G and an integer k, the Normalized Preference Cover problem (NPC_k) is computing $\arg\max_{S, |S|=k} C(S)$, where

$$C(S) = \sum_{v \in S} W(v) + \sum_{v \in V \setminus S} \left[W(v) \cdot \sum_{u \in R_v(S)} W(v, u) \right]$$

Here again the first addend, $\sum_{v \in S} W(v)$, is due to requests for retained items being matched with probability 1. The second addend corresponds to summing over all items not in S, and for each such item v adding the probability it is both requested ($W(v)$) and covered by S ($\sum_{u \in R_v(S)} W(v, u)$).

We discuss the choice of these particular variants and which real-life settings they correspond to in Section 5. Intuitively, the Independent variant asserts that the opinion on the suitability of a given alternative is not demonstrated to be strongly dependent for most consumers on their opinion of other alternatives. The dependencies are either insignificant overall or tend to cancel out when summed over the entire user base. In contrast, the Normalized variant is suited for domains where it is demonstrated that consumer requests are often very specific in nature, and the number of suitable alternatives is very small, which the Normalized variant models as a single alternative at most per request (though this can be a different alternative per each request for the same item). Finally, note that the weight of a node does not necessarily represent the probability of a premeditated and explicit request for the item, rather, more generally, the probability, given all items are available and a purchase is made, of this specific item being the one purchased.

2.3 Set functions

We next present some general definitions and results pertaining to set functions ($f : 2^V \to \mathbb{R}$, given universe V), which will be useful in the following sections for formally characterizing $C(\cdot)$.

Definition 2.3. f is **nonnegative** if $\forall S \subseteq V$: $f(S) \geq 0$.

Definition 2.4. f is **monotone** if $\forall S \subseteq V, \forall v \in V$: $f(S \cup \{v\}) \geq f(S)$.

Definition 2.5. f is **submodular** if $\forall S \subseteq T \subseteq V, \forall v \in V$: $f(S \cup \{v\}) - f(S) \geq f(T \cup \{v\}) - f(T)$.

The following is a key result in submodular optimization.

LEMMA 2.6 ([22]). *Given universe V, $k \leq |V|$, and a nonnegative, monotone submodular function $f : 2^V \to \mathbb{R}$, there exists a polynomial algorithm achieving an approximation ratio of at least $(1 - \frac{1}{e})$ in maximizing $f(\cdot)$ over subsets of size k. This algorithm, at each of its k iterations, selects an element maximizing the marginal gain to $f(\cdot)$.*

2.4 Related problems

Finally, we present definitions and results pertaining to related problems, which will also serve us in the formal analysis.

Definition 2.7. In the *Directed Max Dominating Set Problem (DS_k)* the input is a directed graph and a number k, and the goal is to find a subset of the vertices of size k such that the number of vertices adjacent to this subset is maximized.

Definition 2.8. In the *Max Vertex Cover Problem (VC_k)* the input is a number k and an undirected graph (self edges allowed) with positive weights assigned to its edges, and the goal is to select a subset of the vertices of size k such that the weight of edges incident to this subset is maximized.

We now provide hardness results pertaining to the above problems. The following theorem was proven in [21] for undirected graphs, but trivially extends to directed graphs, as undirected graphs are a special case where for each edge there exists a parallel edge in the opposite direction.

THEOREM 2.9. *[21, 25] The DS_k problem is NP-hard. It has no polynomial approximation algorithm of a factor higher than (1-1/e), unless $P = NP$. The problem is NP-hard even when the maximal degree in the graph is bounded by a constant.*

THEOREM 2.10. *[14, 27] The VC_k problem is NP-hard, and is hard to approximate to within $(1 - \delta)$ factor for some (small) $\delta > 0$, unless $P = NP$. Moreover, VC_k is NP-hard even for graphs of degree at most 3.*

Tighter approximation hardness bounds for VC_k are not known, and existing algorithms are discussed in Section 3.2. We also note that the NP-hardness of the bounded degree cases in both of the above theorems was proven by [14] and [25] for the minimization versions of the Vertex Cover (VC) and Dominating Set (DS) problems, resp. In the minimization versions the goal is to find the smallest set covering the entire graph. However, the hardness extends to our top-k versions, as VC (resp. DS) can be solved by solving VC_k (resp. DS_k) at most n times for varying values of k.

In each of the following two sections we study in detail one of the two variants of the Preference Cover problem. We analyze the Normalized variant first, as it is more complicated technically. Moreover, part of the discussion of the Normalized variant (in particular the proposed algorithm) applies, with minor adaptations, to the Independent variant as well.

Table 1: Approximation ratios of the greedy algorithm and best known polynomial algorithms for VC_k

Range of k/n	Greedy Algorithm	Best Known
$o(1)$	$(1 - 1/e)$	0.75+ϵ (SDP) [11]
$\Theta(1)$, [0, ≈0.39)	$(1 - 1/e)$	0.92 (SDP) [19]
(≈0.39, ≈0.72)	$(1 - (1 - \frac{k}{n})^2)$	0.92 (SDP) [19]
(≈0.72, 0.74)	$(1 - (1 - \frac{k}{n})^2)$	≈0.93 (SDP) [17]
[0.74, 1]	$(1 - (1 - \frac{k}{n})^2)$	$(1 - (1 - \frac{k}{n})^2)$ [11]

3 NORMALIZED VARIANT

3.1 Theoretical Analysis

We begin this section by studying the complexity and the approximation hardness of NPC_k, the Normalized variant of the Preference Cover problem. In both these respects we prove an equivalence to the VC_k problem, which has been studied extensively in the literature, implying in particular that both upper and lower bounds on the approximation of VC_k apply for NPC_k as well. We then discuss algorithms for solving NPC_k. Here again we utilize the equivalence to VC_k to adapt its known algorithms to our setting. Concretely, we present the currently best known approaches in terms of the approximation ratio guarantee, which vary for different ranges of k, and discuss their performance w.r.t. scalability. We note the trade-off between performance and approximation guarantees, and as our goal is to provide a scalable solution for big data settings, we focus on a fast algorithm, for which we provide an efficient parallelizable implementation, and demonstrate it to be highly scalable in our experiments. Moreover, its approximation factor is the best known for high values of k, and is not far off for lower ranges. We further argue that all algorithms known to provide a better approximation guarantee for lower ranges are not scalable at all. We discuss additional advantages of our approach in Section 3.2.

THEOREM 3.1. *The NPC_k problem is hard to approximate to within a $(1 - \delta)$ factor for some (small) $\delta > 0$, unless $P = NP$. The problem is NP-hard, even when the maximal degree (disregarding edge orientation) is 3. Furthermore, any α-approximation algorithm for VC_k implies an α-approximation algorithm for NPC_k, and vice versa.*

PROOF. We first reduce NPC_k to VC_k (Definition 2.8), and show that any α-approximation algorithm for VC_k implies an algorithm for NPC_k with the same factor. Given an instance $I = \langle G, k \rangle$ of NPC_k, we add a self edge to every node whose sum of outgoing edge weights is less than 1, and assign to it the weight which completes the total outgoing weight to 1. This added weight intuitively represents the relative part of requests for this item which cannot be covered by any alternative. Observe that this change has no bearing on the cover function $C(\cdot)$, as when a node is retained, its weight is covered entirely all the same. Next we reduce this instance I to an instance $I' = \langle G', k \rangle$ of VC_k, such that G' has the same nodes as G only without weights, the same edges only without orientation, and the weight of every edge (v, u) changes from $W(v, u)$ to $W(v) \cdot W(v, u)$ (multiplied by the weight of its origin node). Note that G' may have pairs of nodes connected by 2 parallel edges, if edges in both directions connected these nodes in G. This is equivalent, w.r.t. VC_k, to replacing both edges with a single edge whose weight is the combined weight of the original two. However, we do not combine parallel edges, as we analyze their weight contributions separately.

We now argue that for any choice of a node set $S \subseteq V$, its cover weight in G' is equal to the cover $C(S)$ in G. Indeed, let E_S denote all edges that are **outgoing** from a node in S in G, then the sum of weights of the edges in G' originating from E_S is exactly $\sum_{v \in S} W(v)$, which corresponds to the first addend in the formula in Definition 2.2 (each node in S contributes its weight to $C(S)$); considering all remaining edges adjacent to S in G' which are not in E_S: the sum of weights of all such edges originating in any given node $v \notin S$ is $W(v) \cdot \sum_{u \in R_v(S)} W(v, u)$ (recall that $R_v(S) = \{u|(v, u) \in E, u \in S\}$), which, when summing over all such $v \notin S$, is exactly the remaining addend in the formula for $C(S)$, thus proving the equivalence.

As for the other direction, which is proving that NPC_k is just as hard to approximate as VC_k, from which the NP-hardness and hardness of approximation follow, assume we are given an instance $I' = \langle G', k \rangle$ of VC_k. We reduce it to an instance $I = \langle G, k \rangle$ of NPC_k such that all nodes in G are the same as in G', and the edges are also the same with the orientation chosen arbitrarily. Now for any node v let M_v denote the sum of weights of all its outgoing edges at this point, then we set $W(v) = M_v$, and for every outgoing edge e from v, we change its weight from its original weight in G', denoted by $W'(e)$ to $W(e) = \frac{W'(e)}{M_v}$. It follows that the sum of weights of all outgoing edges from any given node, which has at least one such edge, is 1. We set the weight of any node without any outgoing edges adjacent to it to 0.

Following this reduction the sum of weights of all nodes, denoted by N, is not necessarily 1. This requirement over the sum of node weights is due to the semantics of the problem, and is computationally insignificant. Indeed, we can normalize, and divide all node weights by N, and denote the resulting graph $\hat{G}$. It follows that the cover of any solution S, including the optimal solution, changes after this normalization from $C(S)$ in G to $\frac{C(S)}{N}$ in $\hat{G}$, and thus the approximation ratio is not changed. Given an α-approximation algorithm for NPC_k, we run it over the normalized graph $\hat{G}$, and it follows that this solution has the same ratio for the non-normalized instance I of NPC_k. Finally, observe that if we reduce I to an instance of VC_k, as we described in the first direction of the proof, we once again get I' (multiplying edge weights by the original node weight cancels out their normalization by the same factor), implying, by the same logic as before, that for any set S its cover weight in G' equals $C(S)$ in G. Therefore, the same node set S guarantees an α-approximation of the original VC_k instance. Note that as the reduction preserves the maximal degree, it follows that NPC_k is NP-hard for maximal degree 3. □

Due to the equivalence to VC_k, tight inapproximability bounds for NPC_k are also not known. We discuss below existing approximation algorithms, as VC_k algorithms can be adapted to NPC_k maintaining the same approximation factors. For a recent review of VC_k results see [19].

3.2 Algorithms

In this section we discuss algorithms for NPC_k, and focus on the implementation of a greedy algorithm, which we argue to be by far the most scalable option, on top of having high approximation guarantees.

The equivalence of NPC_k to VC_k combined with the linear approximation-preserving reductions described in the proof of Theorem 3.1, imply that when looking for an algorithm for NPC_k, one should examine the algorithms known for VC_k, an extensively studied problem. The algorithms providing the best known approximation guarantees vary for different ranges of k. Detailed results are presented in Table 1 (the second column pertains to a greedy algorithm on which we focus in the sequel). Nevertheless, for $k < 0.74n$, all top algorithms are based on the same core technique of semidefinite programming (SDP). SDP is a much more general extension of linear programming (LP). An algorithm based on LP also exists [2], with an approximation factor of 0.75. These SDP (and LP) based algorithms are important mainly for the theoretical analysis of the problem, in particular finding out the best approximation ratios. On the other hand, these solutions are not scalable, especially for big data settings, as they are known for having an impractical running time, even for medium sized programs [7, 37] (for example, the number of constraints in the program, as devised in [11], is of order $O(n^3)$).

Algorithm 1: Greedy Algorithm

```
Input: G, k
1 $S = \emptyset$
2 foreach $1 \le i \le k$ do
3     foreach $v \in V \setminus S$ do
4         $C(S \cup v) = \text{Gain}(S, v)$
5     $\hat{v} = \arg\max_v C(S \cup v)$
6     $S, C(S) \leftarrow \text{AddNode}(S, \hat{v}, C(S))$
7 return $S, C(S)$
```

Another approach is a greedy algorithm, introduced in [16], and analyzed by [11] to have an approximation factor of $max\{(1 - 1/e), (1-(1-\frac{k}{n})^2)\}$. This factor positively correlates with k, and for $k \ge 0.74n$ it is the best known guarantee, exceeding a 0.93 factor. To the best of our knowledge, any algorithm which surpasses the approximation guarantee of the greedy algorithm, for any range of k, is based on SDP or LP. The greedy algorithm, unlike these alternatives, lends itself to an efficient implementation. As our goal is to provide a practical solution, we focus on the greedy algorithm, which we implement and evaluate. The implementation we provide is adapted directly into our setting without a reduction to VC_k. It is parallelizable, and as we prove in the experiments (Section 5), highly scalable even for graphs containing millions of nodes. Additional advantages of this approach are discussed towards the end of this section. As mentioned, Table 1 depicts, for various ranges of k, the best known approximation factor, alongside the factor of the greedy algorithm.

Greedy Algorithm The greedy algorithm (Algorithm 1) incidentally applies schematically for both the Normalized and the Independent variants (with latent distinctions, described in the next section, devoted to IPC_k, the Independent variant). We use an array I of size n, with an entry $I[v]$ for each $v \in V$, eventually set to the probability of v being both requested and matched by the produced solution S (the product of $W(v)$ and the cover of v by S). The summation of all entries in I, as indicated in Definition 2.2, equals $C(S)$. For simplicity, we assume the preference graph G and the array I are *global variables*, with I initialized to zeros.

Algorithm 1 maintains an initially empty solution set S (line 1). At each of its k iterations (line 2), it goes over all nodes currently not in S (line 3), and for each such node it computes the gain to $C(S)$ obtained by adding it to S (line 5). The node that maximized this gain is then chosen (line 6) and is added to S, with $C(S)$ updated accordingly (line 7). Finally, after completing k iterations, S and $C(S)$ are returned (line 8).

Algorithm 2: Gain - Normalized

```
Input: S, v
Global: G, I
1 $g = W(v) - I[v]$
2 foreach $u \in V \setminus S$ s.t. $W(u, v) \in E$ do
3     $g$ += $W(u) \cdot W(u, v)$
4 return $g$
```

Algorithm 3: AddNode - Normalized

```
Input: S, v, C(S)
Global: G, I
1 $S \leftarrow S \cup \{v\}$
2 $C(S)$ += $W(v) - I[v]$
3 $I[v] = W(v)$
4 foreach $u \in V \setminus S$ s.t. $W(u, v) \in E$ do
5     $C(S)$ += $W(u) \cdot W(u, v)$
6     $I[u]$ += $W(u) \cdot W(u, v)$
7 return $S, C(S)$
```

The procedures *Gain* (Algorithm 2) and *AddNode* (Algorithm 3) are conceptually similar as both compute the marginal effects of adding a given node, with the main distinction being that *AddNode* also updates accordingly I and $C(S)$.

In Algorithm 3, line 1 adds to S the node v which was chosen in Algorithm 1 as maximizing the marginal gain. Line 2 adds to $C(S)$ the gain in the cover of itself and line 3 updates $I[v]$ to $W(v)$ as the newly added node covers itself completely. Next we iterate over all nodes outside of S with an edge into v, and for each such node u, we compute the marginal gain to its cover by v, and add it to $I[u]$ and $C(S)$ (lines 5 and 6, resp.). We can see that after each call to Algorithm 3 the array I is updated with each entry set to the contribution of covering the corresponding node by S to $C(S)$. As we mentioned, Algorithm 2 is the same as Algorithm 3, only focusing solely on the marginal gain, without updating I and $C(S)$.

Although we adapted the greedy algorithm directly to preference graphs, without reducing to VC_k, it is easy to show along the same lines as the proof of Theorem 3.1, that a reduction to VC_k would have resulted in choosing the same nodes. Hence, the approximation factor of $max\{(1 - 1/e), (1 - (1 - \frac{k}{n})^2)\}$, proven for VC_k in [11], holds here as well.

To illustrate the operation of Algorithm 1, consider the following example.

Example 3.2. Recall the preference graph depicted in Figure 1 and assume $k = 2$. The algorithm first computes the gain obtained by selecting each node and retains the most beneficial, which is B (66%, covering $W(B)$, $W(C)$ and 2/3 of $W(A)$). After B is retained, the algorithm proceeds to the second and final iteration, to choose the next node with the highest marginal gain, which is D. D itself is requested only by 6% of consumers, while A and C are 22% and 33%, resp. However, B being selected in the previous step reduces A's and C's marginal gain to 11% (the 1/3 of $W(A)$ corresponding to consumers not accepting B as an alternative to A) and 0% (all consumers who wanted C are happy to get B instead), resp. On other hand, D covers 6% (itself) and 15.3% (9/10 of $W(E)$ - consumers that wanted E, but also agree to have D as alternative), which gives a total of 21.3%. Finally, the retained items, B and D, cover 87.3% of consumer preferences (which in this case is also the optimal possible pair).

Performance Analysis We now analyze the complexity of the greedy algorithm. Let $d(v)$ denote the **incoming** degree of a node v, and let D denote the maximum incoming degree over all nodes. Observe that in both Algorithms 2 and 3 the number of operations performed is $\Theta(d(v)) = O(D)$ (v is the node whose marginal gain is evaluated). For each of the k iterations, Algorithm 2 is called $O(n)$ times, hence the overall time complexity is $O(nkD)$.

Furthermore, the algorithm is highly parallelizable. When Algorithm 1 iterates in line 3 over $O(n)$ nodes to compute their marginal gain, computations for each node are independent, and can be performed in parallel. Moreover, in each such call to Algorithm 2 (or 3) the iteration in line 2 over the $O(D)$ nodes adjacent to the added node can also be done in parallel. Concretely, for $N < nD$ threads, the complexity of each of the k iterations becomes $O(\frac{nD}{N})$ resulting in an overall $O(k + \frac{nkD}{N})$. The space complexity of the algorithm (excluding the input, which we treat as read-only), is $O(|V|)$ for storing I. We can also reduce the space complexity to $O(k)$ by doing away with I, at the expense of computing the value $I[v]$ from scratch in line 1 of Algorithm 2 (line 2 in Algorithm 3), which takes $O(D)$ operations, and does not affect the overall complexity.

Additional Advantages Finally, we identify several additional benefits of our greedy algorithm. First, we can return I as part of the output. This enables to efficiently compute, for each non retained item u, its cover by S, which equals $\frac{I[u]}{W(u)}$. This provides important information about which item requests are affected by reducing the inventory and to what extent. Moreover, the incremental nature of the greedy approach, when the retained set is produced in the order in which the nodes were added to it, can provide solutions to related instances and problems. Namely, an ordered solution S of size k, also produces the solution for any $k' < k$, which is the first k' nodes in S (the same solution that running the algorithm with k' would have produced). Therefore, solving for $k = n$ provides at once the solutions for all k values, and, moreover, directly provides (an approximated) solution for the related problem where the goal is to retain the smallest set, such that the cover exceeds a given threshold.

4 INDEPENDENT VARIANT

4.1 Theoretical Analysis

We now study the theoretical properties of IPC_k, the Independent variant, and our proposed algorithm. We first prove our main result, stating that IPC_k is NP-hard (even given a constant bound on node degrees), and has a tight approximation factor of $(1 - 1/e)$ by a polynomial time algorithm. In fact, this factor is achieved by the same greedy approach as the one discussed in Section 3 for NPC_k, with small adjustments. The adaptations that need to be performed to previously presented algorithms and analysis of the adapted algorithms are then discussed in detail in Section 4.2.

THEOREM 4.1. *The IPC_k problem has a tight approximation bound of $(1 - 1/e)$ in polynomial time, unless P=NP. Moreover, it is NP-hard, even given a constant bound on the maximal node degree (disregarding edge orientation).*

PROOF. To prove hardness of approximation (and thereby the NP-hardness), we assume an α-approximation algorithm for IPC_k, and reduce an instance $I' = \langle G', k\rangle$ of DS_k to an instance $I = \langle G, k\rangle$ of IPC_k, such that an α-approximation solution is implied

Algorithm 4: Gain - Independent

```
Input: S, v
Global: G, I
1 $g = W(v) - I[v]$
2 foreach $u \in V \setminus S$ s.t. $W(u,v) \in E$ do
3     $g \mathrel{+}= W(u,v) \cdot (W(u) - I[u])$
4 return $g$
```

for DS_k. The hardness results then follow from Theorem 2.9. The reduction preserves the maximal degree, implying NP-hardness even given a constant bound on it. Concretely, G has the same nodes and edges as G', except all edge orientations are **reversed**. All edges are assigned the weight 1, and all nodes are assigned the weight $\frac{1}{n}$.

We argue that for any solution $S \subseteq V$, the number of vertices it dominates[3] in G' is $n \cdot C(S)$ ($C(S)$ is the cover of S in G), proving the same approximation ratio. To see this, observe that all $|S|$ nodes in S dominate themselves in G', which corresponds to the first addend in the formula in Definition 2.1 (the sum of weights of nodes in S) which equals $\frac{|S|}{n}$. The remaining nodes dominated by S in G' form the set of all nodes outside of S that have an incoming edge from S, denoted by T. This corresponds to the remaining addend in the formula for $C(S)$, which (as the edges in G are reversed w.r.t. G') is the cover of the set of nodes outside of S with an outgoing edge into S in G, which equals $\sum_{v \in T} \frac{1}{n} = \frac{|T|}{n}$. Overall, we see that there is a fixed ratio of $\frac{1}{n}$ between the values of the target functions of the two problems for any S, proving the equivalence of the approximation. This proves a $(1-1/e)$ hardness bound on the approximation of IPC_k.

To show this bound is tight, we prove that all conditions specified in Lemma 2.6 (the function is nonnegative, monotone and submodular) hold for $C(\cdot)$, implying that a greedy incremental algorithm maximizing the marginal gain at each of its k iterations guarantees a $(1-1/e)$ approximation. Indeed, these properties are evident from the formula in Definition 2.1. $C(\cdot)$ is by definition nonnegative. The addition of any node to the solution maximally covers itself, and can only increase the cover of any other node (it decreases the product $\prod_{u \in R_v(S)}(1 - W(v,u))$ in the formula for $C(S)$, increasing the overall value), which proves monotonicity. Finally, $C(\cdot)$ is submodular: given two sets $S \subset T \subseteq V$ and a node u', we show that $f(S \cup \{u'\}) - f(S) \geq f(T \cup \{u'\}) - f(T)$. If u' belongs to any of these two sets then this follows trivially. Otherwise, as T covered u' at least as much as S (due to monotonicity), the complete covering of u' after its addition is at most the same for T compared to S. As for any other node v (which has an edge into u', as otherwise adding u' can have no effect on it): if $v \in T$ and $v \notin S$, then T already covered it completely, and the addition of u' to T adds nothing. Otherwise ($v \notin T$), for S and T, resp., the effect is that both $\prod_{u \in R_v(S)}(1 - W(v,u))$ and $\prod_{u \in R_v(T)}(1 - W(v,u))$ are multiplied by the $(1 - W(v,u'))$. As the second product (with T) is not bigger than the first (with S), then the additive difference after multiplying it by $(1 - W(v,u'))$ is also not bigger, leading to an overall smaller (or equal) increase in the cover (when added to T). As the increase in the cover of every node is not bigger when adding to T, submodularity follows.

□

[3]A vertex is dominated by a solution S, if it is either in S or has an edge incoming from some node in S.

Algorithm 5: AddNode - Independent

```
Input: S, v, C(S)
Global: G, I
1 $S \leftarrow S \cup \{v\}$
2 $C(S) \mathrel{+}= W(v) - I[v]$
3 $I[v] = W(v)$
4 foreach $u \in V \setminus S$ s.t. $W(u,v) \in E$ do
5     $C(S) \mathrel{+}= W(u,v) \cdot (W(u) - I[u])$
6     $I[u] \mathrel{+}= W(u,v) \cdot (W(u) - I[u])$
7 return $S, C(S)$
```

4.2 Greedy Algorithm

We now discuss our proposed algorithm for IPC_k. Here again we opt for the same greedy approach as presented in Section 3.2 for NPC_k, which for IPC_k guarantees an optimal $(1 - 1/e)$ approximation factor, following Theorems 4.1 and 2.9. Moreover, the algorithm scheme is also depicted in Algorithm 1, with the distinction that the procedures *Gain* and *AddNode*, called, resp., in lines 4 and 6, have different implementations (resp., Algorithm 4 instead of Algorithm 2 and Algorithm 5 instead of Algorithm 3). These procedures, however, remain analogous to their counterparts for NPC_k (Algorithms 2 and 3), as the adjustments only reflect the technical difference between the formulas for $C(\cdot)$ in Definitions 2.1 and 2.2. Therefore, we do not discuss the algorithm in detail, as this is largely covered in Section 3.2, but rather focus on the distinctions from the NPC_k implementation.

Recall that I is an array, initialized with zeros, with an entry for each $v \in V$, denoted by $I[v]$, eventually set to the probability of v being both requested and matched by the produced solution S, and hence the summation of all entries in I equals $C(S)$. We once again set it to be a global variable whose value is saved between calls. In Algorithm 4 line 1 remains the same as in the analogous Algorithm 2, as in both variants it holds that a retained node is completely covered by itself. Line 3, however, is different. It pertains to the marginal gain obtained by adding the node v in the cover of node u, which has v as a neighbor. Let S and S' denote the solution set before and after resp., adding v, and let $I_S[u]$ and $I_{S'}[u]$ denote the correct value of $I[u]$ for solutions S and S', resp. The marginal gain by v over u is $I_{S'}[u] - I_S[u]$, which after doing the algebra is simplified into $W(u,v) \cdot (W(u) - I[u])$. This is the gain appearing in Line 3 of Algorithm 4. The correctness of this expression follows a straightforward computation, which we omit to avoid convoluted notation, and instead provide the intuition. Note that the computation of the probability u **not** being covered by S is the product of the probabilities of all its retained neighbours not being suitable alternatives. This probability can be easily computed from $I_S[u]$ (see the second sum in the formula in 2.1). The only change in S' is that this product is now multiplied by the probability v is also not a suitable alternative, which is $(1 - W(u,v))$. Therefore, when computing the product pertaining to S' (which implies $I_{S'}[u]$), we can reuse the computed product for S (implied by $I_S[u]$), and reduce the number of operations in computing the marginal gain to $O(1)$ per each such u. Moreover, the similarity of the computations for $I_S[u]$ and $I_{S'}[u]$ allows the simplification of the expression for the marginal gain. The adjustments made in Algorithm 5 are completely analogous.

Performance Analysis Following exactly the same considerations as in the NPC_k implementation (Section 3.2), both Algorithms 4 and 5 have the same time complexity, hence the overall

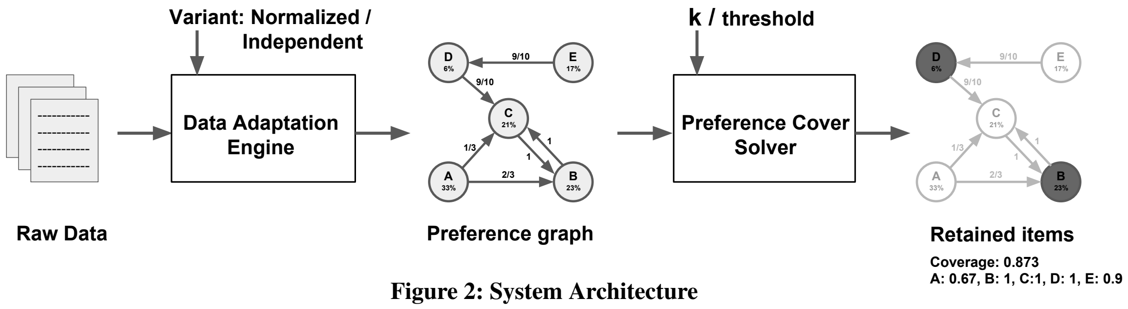

Figure 2: System Architecture

complexity of the greedy algorithm is $O(nkD)$ here as well (recall that D denotes the maximal incoming degree of a node in G). The potential parallelization is also the same, thus the complexity for $N < nD$ threads becomes $O(k + \frac{nkD}{N})$, same as in Section 3.2. As for the space complexity (excluding the input), while it is also $O(n)$, due to storing I, in the IPC_k case it is no longer true that we can do away with I to reduce the space to $O(k)$, without sacrificing efficiency (here the computation of the marginal gain is more reliant on previous computations). Finally, the additional benefits pertaining to the incremental nature of the greedy approach remain the same as for NPC_k, as described at the end of Section 3.2.

5 IMPLEMENTATION AND EXPERIMENTS

We start this section by describing the system architecture, focusing on the flow from raw data to a suggested list of k retained items. Afterwards, we discuss how real-life e-commerce data can be adapted to construct the preference graph. Then, we describe the experimental setup, where we introduce the real-life datasets we used for the experiments, and describe concretely which adaptations we made to these datasets to fit our models. Finally, we present the evaluation results.

5.1 System Architecture

The system architecture, depicted in Figure 2, demonstrates the end-to-end flow. The system consists of two main modules: the *Data Adaptation Engine* and the *Preference Cover Solver*. The *Data Adaptation Engine* takes as input the raw e-commerce data and the variant (Normalized or Independent), and builds the corresponding preference graph. Detailed discussion about what type of raw data is necessary, which of the two variants to choose in a given situation, and how the adaptation is actually performed is presented in the following section (Section 5.2). The constructed preference graph is then passed as input to the Preference Cover Solver, along with k, the desired number of retained items. The solver runs Algorithm 1, adapted to the specific variant (calling Algorithms 2 and 3 for the Normalized variant, and Algorithms 4 and 5, resp., for the Independent variant). The solver produces a list S of retained items (in the order in which the items were added by the algorithm), accompanied with metadata, such as $C(S)$ (the cover achieved by S), and the coverage percentage of every item (implied by the array I, used in our algorithms), i.e. how well the item is covered by the retained alternatives in S (the coverage of retained items is obviously 100%). For example, the rightmost part of Figure 2 highlights the produced set of retained items, B and D (for the input of $k = 2$ and the preference graph depicted in the center of Figure 2, originally introduced in Figure 1 as part of Example 1.1). The coverage of the non-retained item C is also 100%, since it is completely covered by B. The coverage of items A and E is 67% and 90% since they are covered by B and D, resp.

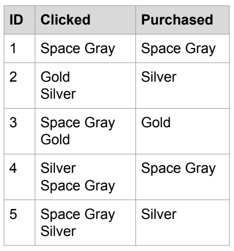
Note that, as explained at the end of in Section 3.2, the same architecture can be used to also solve the complementary problem where the goal is to retain the smallest set of items, such that the cover exceeds a given threshold.

5.2 Adaptation of Raw Data

As mentioned in previous sections, adapting e-commerce data into our graph model is an essential phase, which is also incorporated in our architecture. E-commerce platforms collect tracking data from browsing sessions to learn consumer patterns and preferences to improve the shopping experience and increase revenue. The data is often stored in the format of a clickstream, consisting of the history of events performed by consumers during browsing, grouped by sessions. The information included in the clickstream usually contains the session id, date and time, search query, search page results, clicks, add-to-cart events, purchases and consumer related information, such as username, IP address, geolocation, etc. To ensure wide applicability, we assume that the available clickstreams include only minimal basic information: clicks and purchases grouped by sessions (which is true for most existing platforms and datasets [3])[4].

Graph construction process We now discuss the process of constructing a preference graph from the raw data. Recall that our model captures a session by identifying the “desired” item, which, if available, is the item the consumer would buy, and otherwise outgoing edges indicate her willingness to purchase concrete alternatives. Therefore, ideally, we would like to have for each session information identifying the desired item (for example, a search query specifying it explicitly), as well as a sufficient number of sessions where the specified item is not available, so as to accurately capture the suitability of alternatives, implied by the items purchased instead. However, in real life, when considering the main store which offers the product catalog in its entirety (which is the source for inferring the what-if probabilities necessary for curating the store with the limited inventory), it is overwhelmingly the case that all relevant items in a user session are in-stock. While this allows to identify the desired item as the one purchased[5], and derive an accurate estimation of each item’s relative popularity, it is, nevertheless, harder to approximate user preferences pertaining to alternatives. In light of this limitation, we can use clicks on each item to estimate its suitability as an alternative to the purchased item. We note that assuming strong positive correlation between clicks and an intention to buy is a common practice employed by analysts in many e-commerce companies, when modeling consumer preferences[6], and it is also suggested in relevant studies [26, 32]. When viewing each click as an intention to buy (as an alternative), it is possible to overestimate this actual willingness to make a purchase, likely resulting in a diminished probability assigned to the event where no alternative is suitable. This can be

[4]One may also use semantic similarity between items to approximate edge weights, however we do not pursue this direction here.
[5]Sessions with no purchase, as all items are assumed to be available, are not driven by an intention to buy, and hence do not affect our modeling.
[6]Based on private conversations with analysts in multiple companies.



ID	Clicked	Purchased

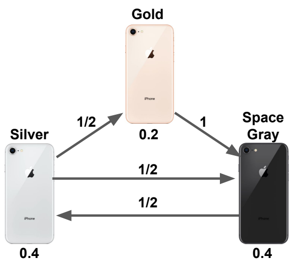
3	Space Gray Gold	Gold
4	Silver Space Gray	Space Gray
5	Space Gray Silver	Silver

a) Sample of sessions



b) Corresponding preference graph

Figure 3: Preference graph construction process

addressed by a more refined learning process where more variables are taken into account, subsequently normalizing the edge weights by a corrective factor. For example, by considering the amount of time spent viewing each item [32]. However, discussing such methods in detail is beyond the scope of this paper.

In view of the discussion above, we construct the preference graph, given clickstream data containing clicks and purchases per session, in the following way. The nodes in the graph correspond to the items. The node weights are assigned the percentage of purchases of an item out of total number of purchases. An edge from A to B exists only if the data contains a session where A was purchased, and B was clicked. The weight assigned to this edge is the fraction out of all sessions where A was purchased, in which B was also clicked.

Note that, it may seem at first logical to learn the edges in the opposite direction, i.e. to assign the weight of and edge from A to B based on sessions where A was clicked and later B was purchased, such that the edge direction “matches" the order of the operations. However, this does not fit the semantics of our model. Namely, we assume a “requested item" is bought with probability 1 when in stock, and an edge from A to B refers to sessions where A is a requested item which is out of stock, and B is an alternative. Since in most cases (and in the available data in particular) the items are in stock (examining only data where a desired item is out of stock will reduce the size of the relevant sessions to several thousands), clicking on A when available and then choosing another item implies that A is not the requested item. The other direction, which we opt for, is arguably more logical, given sessions where all relevant items are in stock, as the purchased item is almost certainly the most preferred item, and clicks on other items serve as considering these items as alternatives. Moreover, when estimating the weights of edges between A and B, we purposely avoid taking into account sessions where both A and B were clicked but neither was purchased. This is because the edges do not represent browsing probabilities (i.e. the probability B is clicked on next, when currently A is view, or vice versa), rather purchasing probabilities. Thus, our graph can intuitively be viewed as a transitive closure of a graph modeling “browsing" probabilities, with the purchased item viewed last (see discussion in Section 2). Observe that for items rarely clicked, the low number of corresponding sessions allows for more noise and the derived correlations to alternatives are less reliable. However, rarely clicked items have also (by definition) low weights, and hence these "noisier" items correspondingly have negligible influence over solution, as it focuses on more popular items.

How to choose the variant Finally, we explain when each of our two variants is a suitable choice given the data. We note that we focus in this work on these two models for edge dependencies, as in our inspection of clickstreams, we observed that in almost all cases one of the variants fits the data (in an approximated manner described next). Nevertheless, it is of course theoretically possible for other dependencies to exist, fitting neither of our models. We leave the adaptation of our techniques to such cases for future work, as here we focus on dependency schemes we have observed to be particularly prevalent.

The Normalized variant models the data well when at most one item, apart from the one purchased, was clicked. In practice it is unlikely any data perfectly adheres to this rule. However, when exceptions are rare we consider this to be a good approximation. In our experiments we applied the Normalized variant when in at least 90% of the sessions at most one alternative was clicked. In such datasets, when processing sessions where $t > 1$ other items were clicked, we “normalized” by counting each as a $\frac{1}{t}$-fraction of a click.

As for the Independent variant, it fits well when for any 2 alternatives (w.r.t. a given desired item) the fraction of sessions in which one was clicked remains the same when conditioned on clicking on the other (counting the fraction only out of sessions where the other was clicked). Once again, expecting any data to demonstrate such complete independence is not realistic. We, therefore, consider the Independent variant to be a reasonable approximation, when the following condition holds. We use a common measure for dependence of random variables, known as *Normalized mutual information* [31], which produces a value in $[0, 1]$, such that 1 indicates total dependence and 0 total independence. For any given item, we compute this measure for all pairs of alternatives, and take the average. Finally, we take the weighted average of these averages over all desired items, corresponding to the node weights (such that the average is not skewed by rarely purchased items)[7]. If this measure is below 0.1, analogously to the 90% cutoff in the Normalized variant, then we consider the Independent variant to be a a fitting choice of model.

To illustrate the process described above, consider Figure 3a, depicting a tiny sample of sessions taken from a real-life clickstream of users that purchased an iPhone 8 256GB. This smartphone comes in 3 different colors: Silver, Gold and Space Gray. The clickstream consists of these 3 items and 5 sessions, each ending in a purchase. The corresponding preference graph is depicted in Figure 3b. There are 2 purchases of the Space Gray iPhone, 2 of Silver and 1 of Gold. Hence, the node weights are 0.4, 0.4 and 0.2, resp. Out of the 2 times the Silver iPhone was purchased, each of the other 2 phones was clicked exactly once. Hence, the edge weights from Silver to Gold and Space Gray are $1/2$. Whereas, from the 2 sessions where Space Gray phone was purchased, one had no other clicks, and the other had 1 click on Silver. Hence, there is an edge from Space Gray to Silver with weight $1/2$. Finally, the Gold iPhone was purchased once, and in that session the Space Gray phone was clicked as well. Hence, there is a single edge of weight 1 from Gold to Space Gray. As for the problem variant, it is clear that the Normalized variant is a good fit, since no session implies more than one alternative.

Note that given a more detailed clickstream, an e-commerce platform can construct a more precise graph. For example, one can analyze the clickstream and combine with the information about out-of-stock items to find which items were purchased instead. Another idea for improvement is using the search query text and filter out items from the clickstream that are not matching the user’s intent. However, as mentioned before, such information is

[7]Of course, other thresholds and statistical distances can be applied just as well.

Table 2: The datasets used in the experiments

DS	Sessions	Purchases	Items	Edges
PE	10,782,918	10,782,918	1,921,701	9,250,131
PF	8,630,541	8,630,541	1,681,625	7,182,318
PM	8,154,160	8,154,160	1,396,674	5,826,429
YC	9,249,729	259,579	52,739	249,008

not always available in sufficient volume, hence it can be used as an enhancement on top of the proposed solution to adjust the weights. In general, more sophisticated data can be collected, with more resources invested in its analysis, resulting in a refined module for constructing the graph, which comes in place of our Data Adaptation Engine, with the rest of the architecture remaining the same. The methods we focus on here are chosen to fit actual information currently available to most e-commerce platforms.

5.3 Experimental Setup

We implemented our system using Python, and ran the experiments on a server with 128GB RAM and 32 cores. To evaluate our solution, we have performed a set of extensive experiments, both on a publicly available real-world dataset and on a bigger (private) dataset provided by a large e-commerce company[8]. We compare our approach to 4 baselines, using 4 evaluation methods.

Datasets. The first dataset, provided by a large e-commerce company, contains 5M items and 27M sessions, all ending with a single item purchase (we specifically requested such sessions). The dataset is private and comes as three independent parts, divided by domains - Electronics (PE), Fashion (PF) and Motors (PM). Due to its size, this dataset is particularly useful for scalability tests. The second dataset, marked as YC, is a public dataset, which was provided by the company YooChoose for the RecSys 2015 Challenge [3]. This dataset contains a clickstream with approximately 260K sessions ending in a single item purchase, covering a 6 month period in 2014 (from April 1st to September 30th). We have included this publicly available data, to allow the reader to reproduce the results.

The summary of these datasets is presented in Table 2. It includes the number of sessions, purchases, items and edges. Recall our discussion at the end of Section 5.2 regarding the conditions we set for each variant to fit a given dataset. It follows that the YC, PE and PF datasets fit the Independent variant, as in all three datasets our proposed independence measure is below 0.1. The PM dataset (whose items are parts and accessories for automobiles), however, is better captured by the Normalized variant, as in its sessions few alternatives were considered prior to purchasing. In particular, the percentage of sessions implying no more than a single alternative is above 90%.

Algorithms. We compare 5 different algorithms, over the same inputs (each input consists of a preference graph and a size bound k). The experiments are performed separately for both variants of the problem, and hence the following algorithms have in fact two versions, each with minor adaptations in accordance with the difference in the computation of the coverage function. We refer to the Normalized and Independent versions of the corresponding algorithm as NAME-**N** and NAME-**I**, resp. We next describe our selected algorithms.

[8]Company name omitted due to privacy considerations.

- **Greedy** - Our proposed greedy algorithm (Algorithm 1).
- **BF** - A brute-force algorithm that evaluates all subsets of size k, and returns a set with the highest coverage. We use this baseline as it is the only one which guarantees the optimal solution, implying the exact approximation ratios achieved by our algorithm.
- **TopK-W** - An algorithm returning the top-k items by weight. This is the naïve baseline that considers each item individually without taking alternatives into account.
- **TopK-C** - An algorithm that returns the top-k items with the highest Coverage. This is a refined version of the previous baseline, which takes alternatives into account, however not from a global viewpoint as in our solution.
- **Random** - An algorithm that returns k items in a random manner. This is the simplest baseline.

Note that we did not include any SDP or LP based approximation algorithms, as they are not at all scalable (see discussion in section 3.2).

Evaluation Methods. We performed 4 complementary types of experiments to evaluate our end-to-end solution.

First, to examine the actual approximation factors Greedy attains in practice, we compare its coverage to that of BF, which is of course optimal. Greedy has a theoretical approximation guarantee in each variant, however it refers to the worst case, and in practice may achieve much better results. Moreover, we show in these experiments that approximation is necessary, as BF has impractical running times even on tiny inputs.

To show the quality of our algorithm in terms of the coverage it obtains on real-life high-scale data, we compare it to all other baselines, except BF, as it cannot scale to handle real-life data.

To demonstrate the scalability and parallelizability of our solution, in our third set of experiments we run it both on a single thread, varying the number of items (nodes), as well as on graphs of fixed size, varying the number of cores.

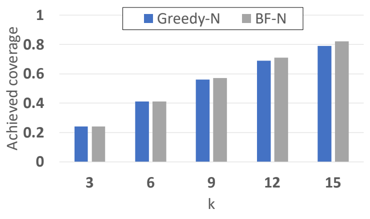
The fourth set of experiments was performed for the complementary minimization problem, where we set different thresholds and aim to find the smallest retained set whose cover exceeds the given threshold. We compare our adapted algorithm to analogous adaptations of the other algorithms, to demonstrate its effectiveness in terms of the size of the retained set.

5.4 Evaluation Results

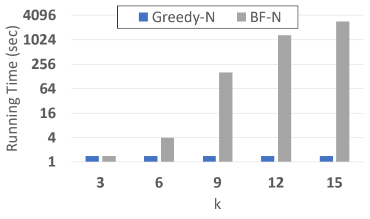
We present the results for the experiments detailed above.

Comparison to Brute Force. The brute-force algorithm does not scale to big graphs, since even for $n = 30$ and $k = 15$, there are $155M$ possible solutions. We show here a representative comparison of the algorithms on a subset of the YC dataset, reduced to 30 products (similar results were obtained for small subsets of all datasets). Figure 4a depicts the coverage achieved by Greedy compared to the optimal coverage achieved by BF. Figure 4b depicts (in log scale) the running times in seconds, over the Normalized variant (the Independent variant showed similar trends, hence omitted). We can see that the coverage of Greedy is very close to optimal, while having significantly better running times.

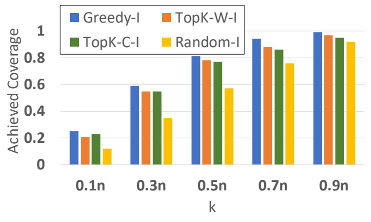
Coverage Quality. We compared all algorithms in terms of the achieved coverage quality, over all datasets. Figure 4c depicts the results on the YC dataset (Independent variant) for $k \in \{0.1n, 0.3n, ..., 0.9n\}$. The results over all other datasets (which include the Normalized variant) demonstrate a similar trend, hence omitted. BF cannot scale beyond small networks, and is excluded



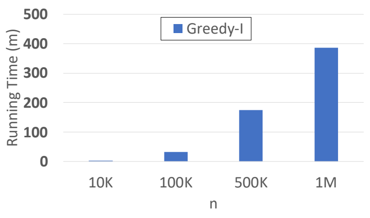
(a) Coverage of Greedy vs BF (Norm.)



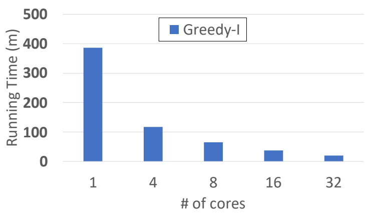
(b) Running time of Greedy vs BF (Norm.)



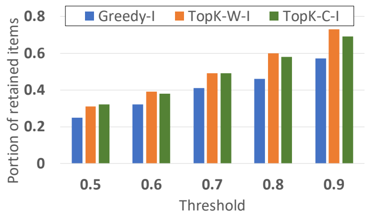
(c) Coverage Quality of all competitors



(d) Scalability of Greedy



(e) Parallelizability of Greedy



(f) Complementary problem

Figure 4: Experimental results

from this experiment. As expected, Greedy is the top performing algorithm, while TopK-W and TopK-C lag behind, since they do not take into account, resp., alternatives, or overlaps in covers by different items. Random also achieves bad results (taking the best across 10 executions) as it makes no use of information pertaining to the popularity of items or their alternatives.

Scalability and Parallelizability. We performed the scalability tests on graphs of various sizes over all datasets. Note that we present only the running times of the algorithm, as the graph construction is considered to be an offline phase, hence not included in the measurements. Figure 4d depicts the running time of Greedy for $n \in \{10K, 100K, 500K, 1M\}$ and $k = 5K$, performed on subsets of the largest dataset (PE), while over other datasets similar trends were demonstrated, hence not shown here. The parallelizability analysis of Greedy, depicted in Figure 4e, was performed over the same dataset and an input graph of fixed size for varying the number of cores: 1, 4, 8, 16 and 32. The results show almost perfect parallelization, which scales well as the number of cores grows. For example, the execution of Greedy on 1 core compared to 32 cores runs 20x times faster.

Complementary problem. We conclude this section by evaluating our approach when adapted to the complementary minimization problem (as explained at the end of Section 3.2). The goal is to find the smallest set whose coverage exceeds a given threshold. Figure 4f depicts the results, in terms of the size of the produced set, obtained by our algorithm, when executed over the YC dataset (Independent variant), for thresholds $\in \{0.5, 0.6, 0.7, 0.8, 0.9\}$, compared to the results obtained by TopK-W and TopK-C. These algorithms were also adapted to perform a binary search over a sorted list of nodes (by the relevant metric - weight or coverage, resp.), choosing the smallest prefix to exceed the threshold. The results demonstrate that the superiority of our approach carries over into this version of the problem, as it outperforms other baselines, producing a much smaller set. The results over the other datasets (and the Normalized variant) are similar.

6 RELATED WORK

E-commerce related problems attracted the interest of many researchers in recent years. Some extensively studied problems are product classification [9, 33], product ranking in search results [18] and automatic product content generation [10, 24]. Of such problems close to us in spirit are works on *diversity* [36], producing the top k most collectively dissimilar elements, typically out of a result set to a given search query. This relates to a similar concept in our problem, where we aim to avoid retaining items that match the same requests. The resemblance is even greater when elements are weighted by importance and there is a requirement, such as in [8], that each non-selected element is covered by a similar selected item, relating to our aim of choosing popular items and items covering as alternatives non-retained items. Nevertheless, there are many differences between their models and ours. Importantly, unlike in diversification problems, we do not aim to maximize diversity, rather it is a feature which is, to some extent, typical of good solutions to our problem, yet not at all necessary. Moreover, even when diversity is a constraint and the items are weighted [8], the goal is to maximize the total weight of the selection, in contrast to our model, where one must also (partially) count weights of adjacent items, which is a crucial property. Furthermore, as our edges represent choice probabilities (rather than item dissimilarity), we can support this original concept of covering neighboring items to a concrete and partial extent, which along with the aforementioned distinctions lead to vast differences in the algorithmic solutions and concrete computations.

Another line of work similar to ours is recommendations [28], as it also deals with selecting a subset of items to increase purchasing probability. However, there are important qualitative and quantitative differences. Primarily, recommendations are typically personalized w.r.t. a given user (and often a given product as well), and deal with a far smaller k. Some works on recommendations that derive product alternatives [20] may potentially serve as basis for another method of computing edge weights in preference graphs. We intend to investigate this approach in future work.

Other existing works in e-commerce that deal with finding top-k beneficial products to offer [35] focus on setting prices such that the predicted revenue (including costs) is maximized. However, in contrast to our models, they do not take into account consumers opting for alternatives.

Closest to our work is a subfield of Operations Research called Assortment Optimization. These works typically employ more complex models such as the Markov chain choice model [4, 23], multinomial logit model [29] and nested logit model [12]. The considered Markov chain model bears some resemblance to our Normalized variant, but is more complicated due to the consideration of varying item revenues and/or multiple-step graph paths (which are directly captured in our model by transitive edges). Consequently, their algorithms are also more complex and the work is geared towards theoretical analysis of the model rather than practical evaluation. The experiments, when exist, consider small scale item sets (order of 1000 items) [4], and the results are not scalable to big data. Furthermore, they mostly use synthetic datasets, and the process of model derivation from real-life data (which our end-to-end solution includes), is not considered there.

Our model is inspired by research in behavioral economics. In particular, [30] observed that consumers experience increased anxiety and are less likely to take action when faced with too wide of a selection. Additionally, [34] demonstrated that consumers, when searching for a specific item, are often willing to buy in its absence what they consider to be a reasonably satisfying alternative.

Our work draws on results in classical Top-k cover problems in graphs [13, 16]. Most notable is the Max Vertex Cover problem (VC_k) [11, 19], which was discussed in detail in Section 3. An existing direction in the study VC_k, whose practical adaptation to our setting would be an intriguing future work, is devising algorithms for graphs with bounded degree [13], as this special case arises in practice in our model. Similar problems include Max dominating set and Max edge domination [21]. All these problems can be viewed as special cases of the more abstract Maximum Coverage problem [6]. Moreover, each of these problems is strongly related to its more extensively researched variant, such as the Vertex Cover problem [25], where k is unspecified, and the goal is to find the smallest subset such that the entire graph is covered. Theoretical bounds and algorithms can often be adapted from one variant to the other, which is also the case for our problem as well, as discussed in Sections 3 and 4.

7 CONCLUSION

This paper introduces the *Preference Cover problem*, which aims to select a reduced inventory maximizing the likelihood of a purchase. We model consumer preferences via a *preference graph* and study two problem variants, *Normalized* and *Independent*, which differ in their interpretation of the probabilistic dependencies between the suitability of different alternatives. We study their approximation hardness, and since the overall number of items, and the bound on the retained set, tend to be very large in this context (in the order of magnitude of millions), we propose highly parallelizable and scalable algorithms that come with approximation guarantees. Finally, we present an end-to-end solution that maps real-world data into our model, and provide an extensive set of experiments on multiple datasets, demonstrating the efficiency and effectiveness of our approach.

In the problem setting studied here (which is common to intermediary e-commerce platforms [1]) the commission-per-purchase is considered fixed and the goal is to maximize the number of sales. Extending our work to support varying per-item revenues and storage considerations is an intriguing future work. Another interesting direction we are currently pursuing is incremental maintenance in response to changes over time.

ABSTRACT

In big data ecosystems, it is becoming inevitable to query data that span multiple heterogeneous data sources (remote systems) to build meaningful querying and analytical workflows. Existing work that aims at unifying heterogeneous systems into a single architecture lacks the fundamental aspect of efficient cost estimation of SQL-based operators over remote systems. The problem is fundamental because all modern optimizers are cost-based, and without accurate cost estimation for each query operator, the generated plans can be way off the optimal plan. Nevertheless, the problem is mostly overlooked by existing systems because the focus is either on homogeneous distributed RDBMSs in which cost estimation is already extensively studied, or on fully heterogeneous engines in which SQL querying and SQL query optimization are not applicable (or at least are not the core problem). In this paper, we propose a comprehensive remote-system cost estimation module for SQL operators, which is a core module within the Teradata IntelliSphere architecture. The proposed module encompasses three costing approaches, namely *logical-operator*, *sub-operator*, and *hybrid* approaches, which are suitable for black box, open box, and a mix of black and open box systems, respectively. The cost estimation module leverages analytical and deep learning models with novel techniques for efficient extrapolation when needed. The techniques presented in this paper are modular and can be adopted by other systems. Extensive experimental evaluation shows the practicality and efficiency of the proposed system.

1 INTRODUCTION

There has been an increasing necessity, especially in big data applications, for managing and querying data that span multiple heterogeneous data sources (remote systems) [12, 13, 31]. The number of the remote system types is increasing dramatically, each system has unique inherent characteristics and processing capabilities, some systems are *openbox* with well-known internal details while others are *blackbox* with very little knowledge about their internals—and many levels in between, and each system offers different levels of sophistication w.r.t. query planning and optimization. Although such interconnectivity and interoperability create unprecedented opportunities for advanced analytics and data sciences, the unification of such diverse systems in a single architecture and the orchestration of the overall processing among them represent a classical challenging problem of many facets.

*Dr. Eltabakh is a faculty in the Computer Science Department at Worcester Polytechnic Institute, MA, USA (meltabakh@wpi.edu).

Several architectures have been proposed to address different aspects of the problem including *federated systems* [8, 11, 24], *polystore systems* [13], and *data integration and warehousing systems* [10, 12, 28, 31]. A big bulk of federated systems' research has focused on distributed relational database systems where distributed transaction processing, concurrency control, recovery control, and replica management have been extensively studied [9, 14, 20, 24]. Other research focuses on heterogeneous federated systems, where schema mapping, query translation, conflict management, and mediation design are the core addressed issues [10, 12, 28, 31]. More recent polystore systems, e.g., the BigDAWG system [13], target transparent unification and access across multiple backend systems of different data models, e.g., array, graph, streaming, and relational models. Although query optimization is a core component of BigDAWG, building an advanced cost estimation module is not the current focus as reported in [13]. Finally, the data integration and warehousing systems focus on offline data integration issues in contrast to online ad-hoc querying and query optimization.

"Teradata IntelliSphere" [4] is a project that shares a common theme with the aforementioned systems, i.e., accessing data across multiple heterogeneous data sources. In the *IntelliSphere* architecture (See Figure 1), Teradata is the master engine and the communication point with the end-users. The other underlying sources (called *remote systems*) are heterogeneous, but they are all assumed to have SQL-like interface (even if the internal execution is not SQL). This covers a wide spectrum of systems such as Hive [25, 26], SparkSQL [7], Presto [27], Impala [22], and other RDBMSs [1, 2, 23]. Therefore, *IntelliSphere*'s query language is SQL, and Teradata is responsible for building a SQL query plan and deciding where each SQL operator, e.g., join or aggregation, will execute on one of the *IntelliSphere*'s systems (either Teradata or a remote system).

In this paper, we focus on one fundamental aspect of *IntelliSphere*, which is the *cost estimation of a given SQL operator over remote systems*. The *"cost"* in our context is basically the elapsed execution time of a SQL operator on the remote system. The problem is fundamental because all modern optimizers (including Teradata's optimizer) are cost-based, and without accurate cost estimation for each query operator, the generated plans can be way off the optimal plan. Evidently, in the popular pay-as-you-go cloud model, bad execution plans can have unacceptable time and monetary overheads. Despite the importance of the problem, it is briefly touched by existing systems because as highlighted above, and will be elaborated on further in Section 6, each of the existing systems focuses on other aspects of the big problem.

Accurately estimating a remote operator cost is a challenging problem because: 1) Some remote systems are *openbox* where experts can inject a lot of details about them into *IntelliSphere* while other systems are *blackbox* with very little knowledge on how they execute. 2) Two remote systems, e.g., Hive and Impala, may offer entirely different set of algorithms to physically implement a given operator, e.g., joining two tables, and thus whatever learned from one system does not necessarily apply to another system. 3) Within a single remote system, it is not trivial for *IntelliSphere* to predict which physical algorithm, possibly from several candidates, will be used for a given operation. And 4) Putting the simplistic assumption that all remote systems are blackboxes and the only way to learn their behavior is by submitting many queries as in [13] is not a practical scalable solution. This is because, as we will show in the paper, such approach of learning is very expensive and should be used as a last resort instead of the default and only solution.

In this paper, we propose a comprehensive remote-system cost estimation module for SQL operators that addresses the challenges highlighted above. To be specific, the costing metric that we try to measure in this project is the *elapsed execution time within the remote system*. This time encapsulates and reflects other detailed costs, e.g., query compilation, scheduling, I/O and CPU costs within the remote system. We assume that the network costs, e.g., establishing a connection and data transfer back and forth, are learned through some other mechanisms, which are outside the scope of this paper. Ultimately, the Teradata optimizer will combine multiple costs together to come up with a final cost for the SQL operator, and based on that it decides where to execute the operator. The techniques presented in this paper focus only on estimating the elapsed execution time, which is a major factor in the cost equation.

We propose three costing approaches, namely *logical-operator*, *sub-operator*, and *hybrid* approaches, which are suitable for *blackbox*, *openbox*, and a mix of black and open box systems, respectively. The cost estimation module leverages analytical models as well as deep learning models within the different approaches. We show that although the deep learning models are good in capturing non-linear cost estimation, they fall short in providing accurate estimations for un-seen (un-trained) ranges. To overcome this limitation, we propose *online remedy* and *offline tuning* phases to enhance the estimation quality.

The key contributions of the paper are summarized as follows:

• Proposing a comprehensive remote-system cost estimation module for SQL operators, that encompasses three approaches, namely *logical-operator* (*logical-op*), *sub-operator* (*sub-op*), and *hybrid* approaches. Each of the *logical-op* and *sub-op* approaches has pros, cons, and applicability cases. The *hybrid* approach combines their advantages.

• Leveraging both analytical cost models and deep learning models within the different costing approaches. The deep learning models are empowered with online remedy and offline tuning phases to ensure high quality estimations even for un-trained ranges.

• The proposed cost estimation module is modular, and due to its applicability to openbox and blackbox systems, it can be easily adopted by and integrated within other systems such as polystore systems.

• Evaluating the proposed cost estimation module empirically in the context of Teradata and Hive as a proof of concept. Extensions to other systems such as SparkSQL, Presto, and Impala follow the same methodology. The results show the effectiveness of the proposed module compared to the state-of-art approaches.

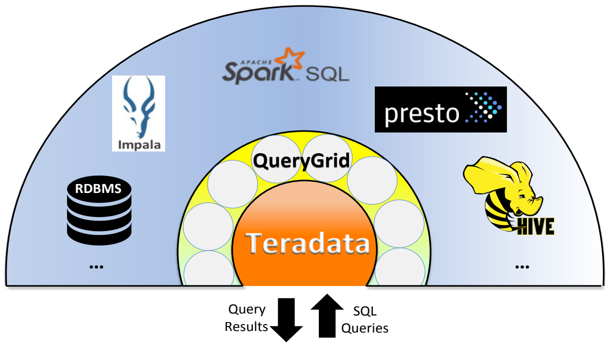

Figure 1: Teradata IntelliSphere Architecture.

The rest of the paper is organized as follows. In Section 2, we present the architecture of the *IntelliSphere* system and introduce the problem definition. In Sections 3, 4, and 5, we describe the details of the three costing approaches: *logical-op*, *sub-op*, and *hybrid*, respectively. In Section 6, we overview the related work, and in Section 7, we present the experimental evaluation of the system. Finally, Section 8 contains the conclusion remarks.

2 TERADATA INTELLISPHERE

In this section, we overview a simplified architecture of the *Teradata IntelliSphere* system [4] and the basic workflow components related to this paper[1]. *Teradata IntelliSphere* is designed to be a cost-effective and scalable analytical ecosystem that offers numerous software solutions to ingest, access, and manage big data across multiple heterogeneous data sources. For the purpose of this paper, we focus on the following basic components of the architecture (See Figure 1):

Teradata: The master engine in the entire architecture is the Teradata Database [2]. It also represents the communication point with the end-users. It receives a user's query in the form of a SQL query, generates a cost-based efficient query plan where each SQL operator is scheduled for execution on one of the *IntelliSphere*'s systems, combines the results, and passes the final answer back to the user.

Remote Systems: The underlying heterogeneous data sources are referred to as *remote systems*. They are all assumed to have SQL-like interface where they can receive a SQL operation such as a *join*, *aggregation*, *filter*, and *projection*, perform the computations of that operation and return the results back to Teradata. It is possible that the internal execution of a remote system is different from the relational DBMS model, e.g, Hive's internal execution is map-reduce. And it is also possible that a remote system may not support some of the SQL operations, e.g., a remote system may not have the capability to perform a join operation.

Remote System Profile: Each remote system registers in the *IntelliSphere* architecture through a profile. This profile describes the remote system setup, e.g., a cluster configuration, and the capabilities of the remote system, e.g., what operations it can or cannot support. The profile is constructed during the registration step, and can be modified afterwards as needed. We will use the profile extensively to store all metadata information related to the cost estimation module as will be described in the following sections.

QueryGrid: It is the communication layer that facilitates the transfer of data across the involved systems [3]. Several QueryGrid

[1]*Teradata IntelliSphere* is a more comprehensive architecture with features and functionalities beyond what is presented in this paper. We only highlight the aspects related to our paper.

connectors are built to enable queries to access tables stored in remote systems. The differentiating factor between Teradata's QueryGrid technology and other connectors is that it works in conjunction with the query processing engines to optimize the overall execution. For example, simple predicates—in a well-defined language—can be passed to QueryGrid for execution on-the-fly while the data is being transferred from one system to another. This capability can save unnecessary scanning of a local data, writing back to the file system after evaluating the predicate, and then passing the results to the QueryGrid for transfer.

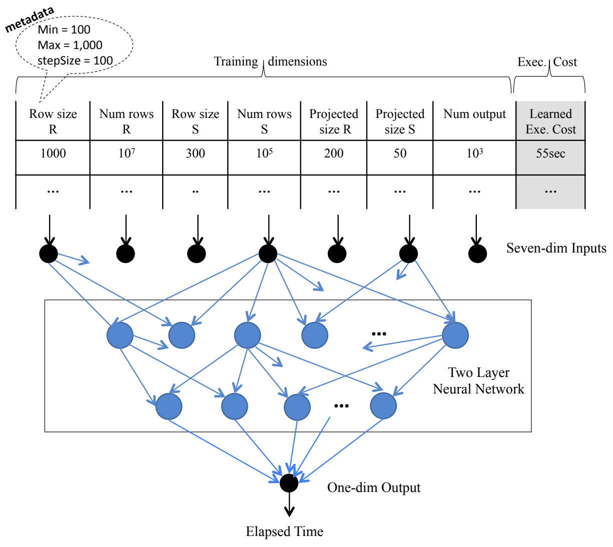
Data Storage, Statistics, and Transfer: A given dataset consists of a set of tables $\{T_1, T_2, ..., T_k\}$, where each table is stored on one of the *IntelliSphere*'s systems (Teradata or a remote system). Any remote table is registered inside Teradata as a *foreign table*—and thus Teradata knows its schema and location. As a result, a single SQL query can seamlessly reference multiple foreign tables across several remote systems. We assume that Teradata can collect basic statistics on remote tables, e.g., the number of rows, average row size, the number of distinct values in each column, etc. Such information is either already available on the remote system or Teradata can estimate them by submitting some queries over the data. Regarding the transfer of data, the data cannot be transferred directly between two remote systems, instead it can be only transferred between a remote system and Teradata.

Query Plans: As in standard RDBMSs, Teradata generates many equivalent SQL query plans during the optimization phase, and part of that is deciding on where each operator will execute—which clearly implies different costs depending on the host system. To limit the search space, *IntelliSphere* considers scheduling an operator only on a remote system that owns the input data (or part of it) or the Teradata system. For example, assume joining two relations R and S, where R is stored in Hive and S is stored in Presto. Then, there are three possibilities for placing the join operator, either on Hive (and S will be passed to Teradata and then to Hive), on Presto (and R will be passed to Teradata and then to Presto), or on Teradata (and both R and S will be passed to Teradata). The results computed on a remote system do not have to be immediately transferred to Teradata, instead they may remain on that remote system for further computations, and then at some point in the query, the results will be transferred to Teradata.

Problem at Hand and Design Assumptions: Given the setup described above, *IntelliSphere* leverages the full-fledged capabilities of Teradata's mature optimizer in generating efficient cost-based query plans. The only missing piece is estimating an operator's cost were it to be executed on a remote system. As highlighted in Section 1, this cost involves several factors, we only focus on estimating the wall-clock elapsed execution time within the remote system. Therefore, while estimating the execution cost, we assume that the needed data is already on the remote system—and thus the network communication and data transfer costs are out of the picture [2].

Supervised ecosystem: The learning and model building step for a given remote system is performed only once when the remote system is added to the *IntelliSphere* ecosystem. Therefore, the learned models are for specific cluster configuration, access methods, physical data layout, etc. The *IntelliSphere* ecosystem is supervised in the sense that changes to a remote system, e.g., adding or removing nodes, creating or dropping indexes, re-partitioning

[2]Teradata can estimate the amount of data that need to be sent to the remote system as well as the output size that will be sent back to Teradata. Based on these estimates, other costs such as the the network cost and data transfer are estimated.



Row size R	Num rows R	Row size S	Num rows S	Projected size R	Projected size S	Num output	Learned Exe. Cost
1000	10^7	300	10^5	200	50	10^3	55sec
...	...	..	...	...	...	...	...

Figure 2: Logical-Operator Costing for Join Operator.

the data, etc., are known to Teradata. Such changes, would require re-doing the learning phase from scratch.

Stable workload: Another underlying assumption is to have a roughly consistent workload on the remote system. That is, the workload during the training and model construction phase should roughly remain the same while executing users' queries later. In our experiments, we assume the remote system is dedicated to the submitted queries and no other workloads are running. Supervised ecosystem and stable workloads are the same assumptions used in almost all other related work [15, 21, 30], otherwise it is impossible to predict the remote system behavior.

Integration in bigger query plans: In Teradata, the cost of a SQL query operator includes several low-level factors such as the I/O costs, e.g., index scans, disk page accesses for data, and CPU costs, e.g., hash table creation, hash table lookup, records merge or sort, etc. Ultimately, these costs are translated to an estimated execution time cost per operator. As such, the estimated execution time for the remote operators fit directly in bigger plans.

3 LOGICAL-OPERATOR COSTING

One approach for estimating a remote operator cost is the *Logical-Operator Costing* (*logical-op costing* for short). In this approach, the training and learning phase is performed at the logical operator level, e.g., join and aggregation operators. This is the approach used in other systems, e.g., BigDAWG [13]. The main idea of the logical-op costing is to build a relatively large set of training queries, execute them on the remote system, and build a model for the target operator. The key advantage is that it requires no knowledge about the internal execution of the remote system, e.g., it does not need to know which physical join algorithm is used to perform the join. In other words, the remote system is treated as a blackbox. However, the main drawback is that to build a reasonably accurate model for a given operator, it would require a large number of queries to cover a wide range of possible configurations. This would certainly require a prolonged training phase and potentially consume valuable resources. In the following, we describe in detail the phases involved in this costing approach.

Building a training dataset: In general, the more complex the logical operator and the more variations in physically implementing it, the more training queries are needed to build its corresponding model. We created logical-op training models for the join and aggregation operators. For the join operator, the training model has seven dimensions, which include the *row size* and the *number of rows* in each of the two tables, the *sum of the projected attribute sizes* from the each table, and the *number of output rows* (See Figure 2). For the aggregation operator, the model has four dimensions, which include the *number of input rows*, *input row size*, *number of output rows*, and *output row size*.

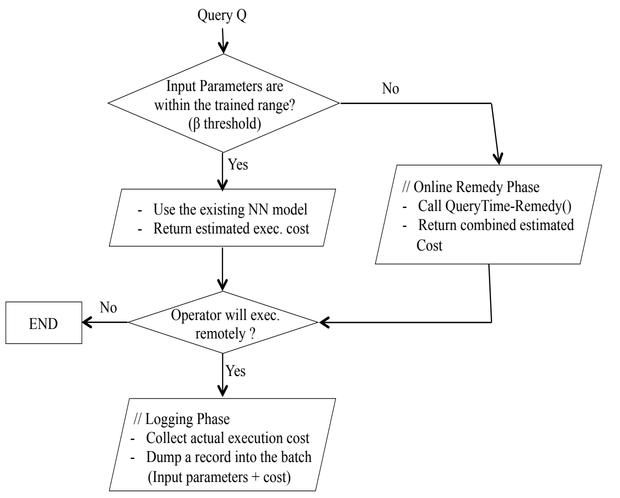
Coming up with appropriate training dimensions is crucial and requires some level of expertise. On one hand, we need to minimize the number of dimensions because the number of queries grows exponentially when adding more dimensions. On the other hand, we need to capture enough parameters in order to model the targeted operator accurately. Based on our team's experience with the Teradata query optimizer, we selected the highlighted dimensions as the representative dimensions for the join and aggregation operators.

The next step is to assign for each dimension a domain reflecting the possible training values that this dimension may take. In some applications, there can be samples of existing data or workloads to help selecting the appropriate domain for each dimension. Otherwise, we start with reasonable assignments, and then a continuous learning phase will help to gradually expand the domains as the system observes and executes more queries (as will be explained later).

Assume dimension i has a domain d_i of size $|d_i|$, then the total number of configurations in the training set for one operator is computed as $\prod_{i=1}^{k} |d_i|$, where k is the number of dimensions. For example, as illustrated in Figure 2, each row represents one configuration, which maps to a single query over the remote system. After executing the queries, each configuration will be labeled with the observed execution cost. This step of executing the queries over the remote system can be very expensive, e.g., it may take days if the number of queries is large.

Building a costing model: The next step in the logical-op costing is to build a model from the observed costs. For that purpose, regression or neural network models can be used. We experimented with both, and we found out that linear regression models introduce more errors as will be demonstrated in the experiment section (around three times larger w.r.t the root-mean-square error RMSE). This is primarily because the number of data points can be large, e.g., in thousands, the number of input dimensions can be also large, and the relationship between the inputs and outputs might not be linear—especially for complex operators like join and aggregation. Simple light-weight neural networks tend to be more accurate under such complex modeling. For that reason, we opt for the neural network model in the rest of the paper.

There is no rule of thumb for deciding on the optimal neural network structure. Typically, two or three hidden layers are enough for not highly-complex problems [18]. Therefore, we fix the number of layers to two for both the join and aggregation operators. And then we use a cross-validation technique to determine the number of nodes (neurons) in each layer [16]. More specifically, we vary the number of nodes in the 1^{st} layer between the number of inputs (7 for join, and 4 for aggregation) and the double of that number, and vary the number of nodes in the 2^{nd} layer between three and half the number of the 1^{st} layer's nodes. Then, for each topology, we use a cross validation test involving 70% of data as training and 30% as a test to measure the accuracy of the network.



Query Q
Input Parameters are within the trained range? (β threshold)

- Dump a record into the batch (Input parameters + cost)

Figure 3: Logical-Operator Costing: cost-estimation flow chart at query time.

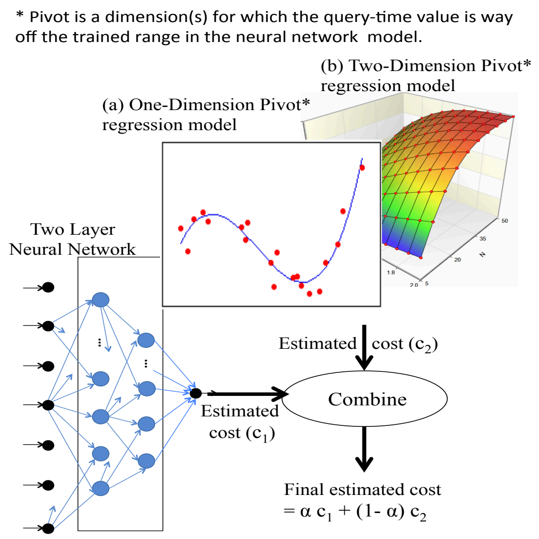
Finally, we select the topology that introduces the least root-mean-square error (RMSE). Figure 2 shows the neural network model over the seven-dimension inputs for the join operator.

Usage and model expansion: In the typical scenarios, the constructed model is directly used at query time to estimate the cost of a remote operator. Given an operator that is candidate for execution on a remote system, e.g., a join operator where one of the input relations is on that remote system, the system calculates and/or estimates the input parameters for the operator's model. For example, the seven input parameters illustrated in Figure 2 need to be estimated for the join operator. These parameters are then fed to the neural network model to predict the output value, which represents the estimated cost (See the flowchart in Figure 3).

The estimation process is straightforward as long as all the input parameters fall within (or in the proximity of) the ranges on which the neural network is trained. However, in the cases where one or more parameters are way off the trained ranges, the model may not provide accurate estimation. This is because neural networks are good in capturing complex relationships but not good in extrapolating out-of-range values.

In real deployment systems like Teradata *IntelliSphere* these cases need to be adequately handled. Therefore, we propose a two-phase solution that consists of an *online query-time remedy phase* and an *offline batch tuning phase*. The online remedy phase provides an immediate best-guess estimation to the operator at hand to continue the query optimization and execution. Whereas, the offline batch tuning phase provides a mechanism for readjusting and tuning the neural network from the actual logged executions. Both phases are described in detail below.

Online Remedy Phase: The main idea of the online remedy phase is presented in Figures 3 and 4. Initially, the system maintains metadata information for each input dimension in the training set of a given operator. This metadata includes the covered range using *min* and *max* boundaries and a *stepSize*. For example, Figure 2 shows the metadata of the *Row size* dimension, which indicates the training covers the range from 100 to $1,000$ bytes and the step size is 100. Now, if the current query at hand involves a join where the estimated row size is $10,000$ bytes, the system will detect that this parameter is way off the trained range, and will not get the estimate by relying only on the neural



* Pivot is a dimension(s) for which the query-time value is way off the trained range in the neural network model.

network model, but instead it will trigger the execution of the `QueryTime-Remedy()` procedure (See the top diamond box in Figure 3). More specifically, if the value of a given dimension is outside the *[min, max]* range by more than $\beta * stepSize$, where $\beta > 1$ is a configuration parameter, then that dimension is considered way off the trained range. The procedure on the fly builds a regression model and combine it with the neural network model to come up with the final estimate as illustrated in Figure 4.

Lets illustrate the construction of the regression model using a simple scenario. Assume a join query Q that involves only one dimension, say *Row size of R*, where its estimated value is way off the trained range in the neural network. We refer to that dimension as the *Pivot* dimension. All other dimensions (refer to them as $D_{inRange}$) are within the trained range. The `QueryTime-Remedy()` procedure extracts a set of training records of size k, where k is a system parameter, having the following properties: (1) their values in the $D_{inRange}$ dimensions are matching (or very close) to the corresponding values in Q, and (2) their values in the *Pivot* dimension are the immediate successors and/or predecessors of the corresponding value in Q. This set should represent the closest possible training points to the query point. The pivot values in this set are then extracted and used to build a regression model. The algorithm can be extended to handle more than one pivot dimension as illustrated in Figure 4.

The `QueryTime-Remedy()` procedure uses the constructed regression model to extrapolate on the pivot dimension(s) and predict the cost. This cost is then combined with the estimated cost from the neural network model to come up with the final cost (See Figure 4). The reason we combine the two costs is that they capture different and complementary factors. The neural network captures the complex relationship between the input parameters and the output but cannot extrapolate. In contrast, the regression model can extrapolate but oblivious to the other dimensions. The costs are combined using a weighted factor α $(0 < \alpha < 1)$ as illustrated in Figure 4. Initially, α is set to 0.5, and as the system executes more queries, α gets automatically adjusted to narrow the gap between the estimated and actual execution times.

Offline Tuning Phase: Whenever *IntelliSphere* executes a remote operator on an external system (depending on the optimizer's decision), it captures the actual execution cost and pushes this information to a log (See the bottom diamond box in Figure 3). Periodically, this log is fed to the neural network model to tune its structure with the new observed data.

One interesting detail to highlight here is the mechanism for updating the metadata information of the training dataset at the end of the tuning phase. Recall that a metadata information is maintained for each dimension in a training set including the *min, max, stepSize* values. When a log gets executed to update the neural network model, the metadata gets also updated. More specifically, the *[min, max]* range gets expanded if the log has entries with out-of-range values. However, this expansion takes place only if a continuity in the training points is maintained. For example, referring to the metadata in Figure 2, if the log has some entries with out-of-range values or the 1^{st} dimension like $8,000$ and $10,000$ bytes, then the current range will remain intact because there are many missing points between that range and the new values, i.e., continuity will be broken. Instead, more information is added to the metadata to indicate that training dataset of $8,000$ and $10,000$ bytes

The implication of this expansion strategy is that when a new join query comes and it includes an out-of-range value for the 1^{st} dimension, say $6,000$ bytes, the system will still trigger the *online remedy phase* highlighted in Figure 4 to come up with the final estimated cost instead of relying only on the neural network model. The positive thing is that the prediction from both the neural network and the regression models are getting better because they take into account the previous log records even if the [*min, max*] range has not been modified.

4 SUB-OPERATOR COSTING

Another approach for remote operator costing is what we refer to as *sub-operator costing* (or *sub-op costing* for short). In this approach, the learning and training is performed at the granularity of small building block operators, e.g., scan, shuffle, sort, read, and write operations. And then, the higher-level query operators, e.g., join and aggregation, are expressed as formulas on top of the sub-ops. The main advantage is that learning the cost of each sub-op is relatively straightforward and fast because: (1) The number of dimensions in a training set for each sub-op is typically very small (only two or three), (2) As a result of the low-dimensionality, the number of needed training queries is very small—which saves training time and cost, and (3) The logic and behavior of each sub op is relatively simple and thus linear regression is typically enough to model most of these sub ops.

On the other hand, the main disadvantage of the sub-op approach is that it requires a great deal of knowledge about the remote system, which may not be available in some cases. For example, it requires identifying a set of the building block operators (the sub ops) that is sufficient to accurately model the query operators. It also requires understanding the different algorithms of the physical implementations for the different operators, e.g., a join operator can have four or five different physical algorithms such as broadcast join, re-distribution hash join, etc., and defining a formula to express each algorithm in terms of the sub ops. Evidently, if such level of knowledge is not already available, then it takes a long time to collect with these details.

Identifying sub operators and costing formulas: The first step in this approach is to identify the key sub operators of the

Basic (Mandatory)	Read (DFS) [1]	r_D	Reading a record from dist. file system
	Write (DFS) [2]	w_D	Writing a record to dist. file system
	Read (Local)	r_L	Reading a record from local file system
	Write (Local) [3]	w_L	Writing a record to local file system
	Shuffle	f	Shuffle a record between machine
	Broadcast [4]	b	Broadcast a record to all machines
	Sort	o	Main memory sort cost per record
	Scan	c	Main memory scan cost per record
Specific (Optional)	HashTable Build [5]	h_I	Inserting a record into hash table
	HashTable Probe	h_P	Probing a hash table
	Rec Merge	m	Merging two records

[1] Query that reads from HDFS and does not produce any output.
[2] Query that reads from HDFS and writes back to HDFS. Subtract r_D from the measured values
[3] Query that reads from HDFS and writes content to local file. And then subtract r_D from the measured values
[4] Query that reads from HDFS, produces no output, and broadcasts a file (distributed cache) to all nodes (without reading it). Subtract r_D from the measured values
[5] Query that reads from HDFS, builds a hash table for each HDFS block, and does not produce any output. Subtract r_D from the measured values

Figure 5: List of Common Sub Operators in Remote Systems. Additional sub ops can be defined specifically for certain remote systems.

remote system, which may differ from one system to another. However, in the majority of the modern distributed systems, which have shared-nothing architecture in common, these sub operators typically include: *reading from disk, writing to disk, shuffling across machines, in-memory sorting,* and *scanning a memory block*. Other more specific sub operators include *insertion into a hash table, probing a hash table,* and *merging two records*.

In Figure 5, we highlight a list of the key and common sub operators and categorize them into two categories, namely *Basic* and *Specific*. The sub operators under the *Basic* category are kind of mandatory to learn, otherwise it would not make sense for the corresponding remote system to be costed using this approach. The other sub operators are good to have, but missing them is not a hinder to this approach because either they are specific to few query operators, they are not dominating factors in the cost formulas in which they participate, or *IntelliSphere* can provide rough default values for them. We will provide more details and examples in this section for these sub operators.

It is worth to highlight that Teradata costing mechanism is based on the *sub-op costing* approach. It is highly reliable, efficient to use for estimation, and easy to calibrate and extrapolate whenever needed. Given that all engine details are known, Teradata optimizer maintains a long and detailed list of sub operators. In contrast, for remote systems, it is more practical to assume limited knowledge about them. That is why we try to capture a minimal, but sufficient, set of sub ops as highlighted in Figure 5.

After defining the sub operators, each query operator for which a costing model need to be built, e.g., join and aggregation, need to be expressed as a composition of the sub operators. Since each of these query operators can have multiple physical implementations carrying significantly different costs, it is important for a technical expert to know the list of physical algorithms that are supported by the remote system for a given query operator. For example, Hive supports five types of join algorithms, which are: *Shuffle Join*, *Broadcast Join*, *Bucket Map Join*, *Sort Merge Bucket Join*, and *Skew Join* [19]. Similarly, Spark supports five join algorithms, which are: *Broadcast Hash Join*, *Shuffle Hash Join*, *SortMerge Join*, *Broadcast NestedLoop Join*, and *Cartesian Product Join*. Each of these algorithms need to be expressed in terms of the defined sub operators.

In Figure 6, we provide a detailed example using the *Broadcast Join* algorithm between two relations *R* and *S*, where *S* is assumed to be the small relation. The top part of the figure shows the algorithm workflow while the bottom part shows the corresponding cost formula. The algorithm starts by reading the small relation *S* from the distributed file system, e.g., HDFS, and broadcasting it to all workers, and it gets stored locally on each machine. Then each task—in Hadoop terminology, it is called a *map task*—executes the loop illustrated in Figure 6. Basically, each task reads relation *S* and builds a main memory hash table, and then reads one block from the big relation *R* and for each record in that block, it probes *S*'s hash table for possible joins. The read block from *R* is assumed to be on the local disk because most distributed systems try to achieve data locality by putting the computational task on the machine storing the data. Previous studies have shown that although data locality is a best effort mechanism, it is achieved more than 90% of times. The last step in the workflow is for the task to write its output back to the distributed file system[3].

The costing formula in Figure 6 has almost one-to-one mapping to the steps in the workflow. We use the notation | | to indicate the cardinality (number of records) of an input. The term `NumTaskWaves` represents the number of cascaded tasks executed on a single machine. It is computed as total number of tasks in the join job divided by the total number of parallelism in the system, i.e., the total number of cores. Notice that the values for factors such as `NumTaskWaves`, `|Block(R)|`, and `|TaskOutput|` are calculated and/or estimated by another module in the *IntelliSphere* system different from the costing module and that module is outside the scope of this paper.

Building a training dataset: The upfront effort put in specifying the sub ops and the cost formulas will pay of by simplifying the subsequent phases of the sub-op costing approach. For the training dataset, what is needed is to build a set of queries for each of the sub ops to learn its cost in the remote system. Since each sub op is *primitive*, the number of dimensions in its training dataset is very small. In fact, we found it enough for almost all sub operators under the *Basic* category (Refer to Figure 5) to have only two dimensions in the training dataset, which are the *number of records* and *record size*. The only exception is the *Broadcast* sub operator, which requires a third dimension, which is the *number of machines*.

Since the number of dimensions is small, and additionally the number of values assigned to each dimension is also small (because the sub op models are easy to extrapolate as we will discuss later), the number of records in the training set becomes very small. In fact, it is between one to two orders of magnitudes smaller than that of the logical-operator approach, which introduces a significant reduction in the training time and cost over a remote system.

For measuring the cost (execution time) for each sub-op, we avoided instrumenting and injecting special code inside the remote system since such instrumentation may not be feasible for some remote systems. Instead, we submitted primitive queries that execute specific type of operations, and from that we extracted the values of the individual sub-ops. In Figure 5, we show examples

[3]Cost formulas for other join algorithms can be derived in the same manner. We omitted them from the paper due to space limitations.

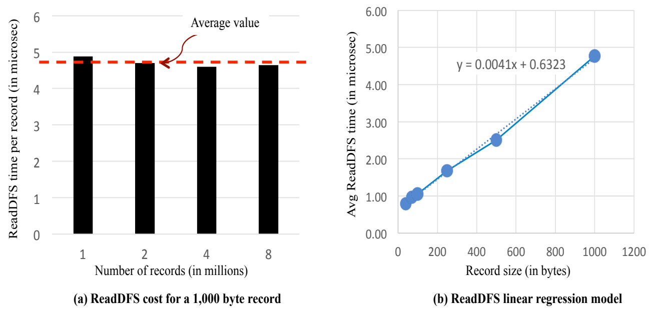

Figure 7: Sub-Op Costing Model for ReadDFS Operator.

of these queries and how they can be used to measure specific sub-ops.

Building a costing model: In this step, a cost model is built for each sub operator. For simplicity, we will focus our discussion on the majority of the sub ops, which involve two dimensions in the training set, i.e., *number of records* and *record size*. It is possible to consider these two dimensions as separate (orthogonal) dimensions while building the model. However, we experimentally observed that the model can be further simplified because for a given record size, say s, the measurements across the other dimension (the records' number) are very similar to each other. Therefore, it is practical to group the measurements by the record size, and compute the average across the varying number of records. In Figure 7(a), we illustrate this observation. The experiment is measuring the *ReadDFS* (Reading from distributed file system) cost for a record size of 1,000 bytes under varying number of records. The dotted line shows the average value. Similar findings are observed for other record sizes and other sub operators.

Based on this observation, a simple linear regression costing model can be built as depicted in Figure 7(b) for the *ReadDFS* operator. As can be noticed a big advantage of the sub-op costing approach is that most sub-ops have simple and tight linear regression models that can be easily learned from small training dataset (more results will be presented in Section 7). Moreover, these models are easy to extrapolate for un-seen values, which is not the case for the more complex neural network models presented in Section 3.

Usage: At query time, lets say a join query between R and S, the first thing to be done by the *IntelliSphere* cardinality estimation module is to provide the required cardinalities and statistics, e.g., the cardinality of each relation, the number of distinct values in the join keys, the average number of records per key, etc. Then, if the operator at hand has only one physical implementation in the remote system, then *IntelliSphere* uses the corresponding cost formula to estimate the cost. Otherwise, if there are multiple possibilities, which is the case for the join operator (Refer to Figures 6), then *IntelliSphere* needs to predict which algorithm the remote system will use.

Predicting the remote system choice is tricky, especially for complex systems such as other relational databases, e.g., DB2, SQL Server, or Oracle. Yet, it is more straightforward for systems like Hive and Spark. Lets take the join operator, which has the most algorithmic variations, as an example. Although it has five algorithms in Hive and Spark, most of the choices can be easily eliminated based on some observations. For example, if the relation in Teradata side, say S, which will be sent to the remote system is not partitioned by the join key—which *IntelliSphere* should know—then the choices of *Bucket Map Join* and *Sort Merge Bucket Join* in the case of Hive can be eliminated. Even if S is partitioned on the join key, but there is no way to tell the remote system such property after the data transfer, then still the two choices above can be safely eliminated. If the join is not Cartesian product, then the choices of *Broadcast NestedLoop Join* and *Cartesian Product Join* in the case of Spark can be eliminated. If both join relations are quite large, then the choices of *Broadcast Join* either in Hive or Spark can be eliminated.

These observations, or what we refer to them as *"Applicability Rules"*, are defined by the technical experts while defining the cost formula for each possible algorithm. *IntelliSphere* uses them at query time to eliminate inapplicable choices based on the cardinalities and statistics at hand. Finally, if there are still multiple possible choices, then the system can either take the highest cost (assuming the worst case scenario), the average cost, or the *"in-house comparable"* cost. The *in-house comparable* cost is applicable when the remote system is another relational database system. In this case, *IntelliSphere* assumes that the remote system will pick the algorithm that Teradata would have picked were the data in-house.

5 HYBRID-OPERATOR COSTING

As highlighted in Sections 3 and 4, each of the sub-op and logical-op approaches has pros and cons. Such tradeoff between the two approaches and the diverse remote systems available nowadays in the Big Data ecosystem call for a hybrid approach that can combine the advantages of both worlds.

In Figure 8, we provide a summary comparison between the two approaches. In general, the sub-op costing model can be significantly superior w.r.t the training cost, training time, and the ease of extrapolation given that a detailed knowledge on the remote systems is already available. Otherwise, the logical-op model would be the favorite.

	Sub-Op Costing	Logical-Op Costing
Modeled Operators	Low-level building block operators such as read, write, scan, and re-distribute	Logical query operators such as join and aggregation
Parameter Space (# dimensions in the training dataset per operator)	The parameter space is small. Most sub-ops need only two dimensions in their training dataset ***Example:*** "read", "write", and "re-distribute" each has two dimensions, i.e., (1) number of records, and (2) record size	The parameter space tend to be large and the number of dimensions is high. ***Example:*** "join" has at least seven dimensions including: (1) record size in R, (2) Number of records in R, (3) record size in S, (4) Number of records in S, (5) projected output record size from R, (6) projected output record size from S, and (7) number of output records
Size of training dataset (# of training queries per operator)	Small, because the parameter space is small	Can be very large because the parameter space is usually large
Training Time	Shorter	Longer
Ability to Extrapolate	Easier	Harder
Remote System Assumption	Open box	Black box
Remote System Prerequisites (Knowledge)	- Knowledge on how logical operators, e.g., join or aggregation, get physically implemented - Knowledge o what types of sub-ops operators to model - Knowledge on how to express logical operators in terms of the sub operators	None. No internal knowledge of the remote system is needed
Model Continuous Tuning (especially for un-seen values)	Less critical because extrapolation is straightforward	More critical because for complex models, extrapolation is not straightforward
Maintenance under change or addition of algorithms in remote system (E.g., adding a new join algorithm)	- Need to change or add a cost formula for the modified or added algorithm - Add the applicability rules indicating the cases under which the new algorithm is applicable	- Need to partially re-run queries from the training set that (hopefully) trigger the modified or new algorithm to learn its execution pattern

Figure 8: Comparison between Sub-Op and Logical-Op Costing Approaches.

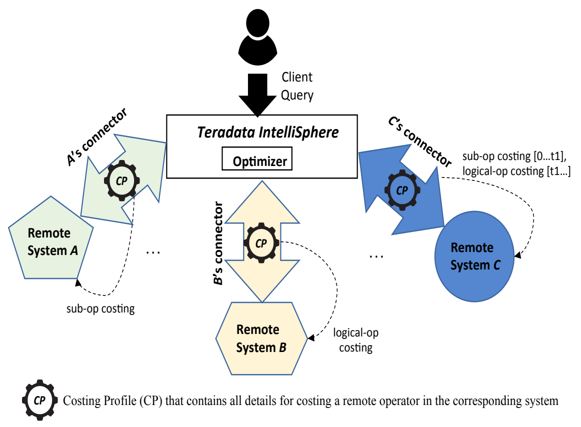

Figure 9: Overview on the Hybrid Costing Model.

The main idea of the hybrid approach is depicted in Figure 9. Basically, the Teradata *IntelliSphere* architecture will connect and communicate with different remote systems using one of the two costing approaches. The choice depends on several factors including whether or not there is enough knowledge about the remote system, and whether or not the resources allow for a prolonged training phases—which can be days in the case of logical-ops .

For example, referring to Figure 9, remote system *A* can be a well-known openbox system, e.g., Hive or Spark, and in this case the sub-op costing can be the model of choice. In contrast, remote system *B* is a blackbox and its workload and resources allow for a prolonged training phase, in this case the logical-op costing model is a good choice. On the other hand, remote system *C* has little knowledge known about it and its workload and resources do not allow for a dedicated several-days training phase (for logical-op training). In this case, an approximate sub-op costing can be applied to *C*—even if not highly accurate—until the more extensive training for the logical-op costing is performed, which may span weeks, and then *C* switches from the sub-op costing to the logical-op costing. The *IntelliSphere* architecture provides such flexibility.

As highlighted in Figure 9, each remote system has a *costing profile (CP)* containing all needed details based on its costing model. For example, for the sub-op costing, it includes a list of the sub-ops, a list of the physical algorithms for each logical operator, the costing formula of each algorithm, and the applicability rules for each algorithm. For the logical-op costing, it includes the neural network model for each operator, the metadata information of the training dataset, plus other information. Updating the costing profile information instantaneously reflects on the remote table costing. Although not currently supported in *IntelliSphere*, the hybrid approach is also applicable within a single system. That is, some operators, e.g., selection and aggregation, can be trained using the logical-op approach, while other higher-dimensional operators such as joins can be trained using the sub-op approach. The CP profile is flexible enough to store different costing models for different operators. We plan to explore this extension in the near future.

6 RELATED WORK

Accessing and querying datasets that span multiple heterogeneous data sources is a complex problem, and several systems and architectures have been proposed to address certain aspects of the problem. In this section, we overview these related systems and emphasize the differences to the *IntelliSphere* system.

Federated Systems: Federated systems provide a virtual layer of a unified access and management over a collection of data sources [8, 11, 24]. The federation can be over a collection of homogeneous relational databases, e.g., distributed DBMSs (Category I), and most of the research in this category focuses on distributed transaction processing, replica management, recovery control, and concurrency control [14, 20, 24].

Systems such as [30] belong to Category I, and they address the cost model issue across multi relational databases by dividing the workload into multiple query classes, then sample a subset of queries from each class and submit them to the remote database(s). The objective is to learn the corresponding unknown coefficients of the cost equation using statistical regression models. This approach is similar to our proposed logical-op learning, however in their work they did not consider the sub-op costing, which some times has clear advantage of the logical-op costing especially when dealing with heterogeneous systems.

The federation can also be over a collection of heterogeneous data sources (Category II), and the focus of this category is on building unified data and representation models, query translation, mediation design, data extraction, schema matching and coalescing, and conflict and resolution management [10, 12, 28, 31]. *IntelliSphere* is fundamentally different from these systems because IntelliSphere's focus is on efficient query plan generation and remote operator cost estimation.

Some work under Category II such as that proposed in [21] addresses the costing in such heterogeneous data sources. However, their assumed sources are not limited to SQL-like operators, e.g., the sources can be web search engines, image processing systems, CAD systems, etc. In this setting, the authors proposed wrappers around each source that acts as a *mini-optimizer* and feeds a global optimizer with the estimated costs for a given operation. The developers of the remote systems need to code these wrappers and augment in them optimizer-like logic to derive the cost of the different possible operations on these remote systems. IntelliSphere is fundamentally different from that work because our focus is only on the costing of SQL operators, e.g., selection, projection, join, aggregation, etc. For that, there are no strong justifications for the complexity of adding a wrapper's layer and the non-trivial task of coding a mini-optimizer for each remote system.

Polystore Systems: The key characteristic of the polystore systems, e.g., the BigDAWG system [13], is that they provide transparent access across multiple engines of different data models, e.g., relational, graph, NoSQL, array, and steaming engines. In BigDAWG, the underlying sources are grouped into islands by their data model type, and then each source has a *"shim"* which acts as the source's communication wrapper. BigDAWG addresses issues including location transparency, casting among the different data models, unified query language, and query planning and optimization across the islands.

The *IntelliSphere* system is distinct from the polystore systems in the following: (1) *IntelliSphere* is not a polystore system because it assumes a common relational-like data model for all underlying data sources with a SQL-like interface. Therefore, *IntelliSphere* does not focus on issues such as casting among the different data models and building a unified query language. (2) Although cost estimation is a fundamental issue in BigDAWG, it is briefly touched and the system is currently using primitive approaches as a first step [13]. In contrast, *IntelliSphere* introduces a comprehensive cost estimation module for efficient query plan generation across the underlying systems. The innovations presented in this project can be certainly leveraged by other systems such as the BigDAWG system.

Table naming convention: T_{x_y} (in total 120 tables)

- x (number of records): {k x 10^4, k x 10^5, k x 10^6, k x 10^7}, where $k \in \{1, 2, 4, 6, 8\}$
  Total configurations: 20
- y (record size): {40, 70, 100, 250, 500, 1000}
  Total configurations: 6

Table Schema: (a_1 , a_2, a_5, a_{10}, a_{20}, a_{50}, a_{100}, z, dummy)
- Each column a_i is of type Integer
- Duplication rate of column a_i is *i* (e.g., each value in a_5 is duplicated 5 times)
- Column *z* is of type Integer, where all values are zeros
- Column *dummy* is of type Character, and is used to reach a specific record size

Aggregation Queries:
- The aggregation factor (shrinking factor in the number of records) is achieved by aggregating over a specific column a_i to get a factor of *i*
- The number of aggregate functions computed varies from 1 to 5. All are of type SUM()

Join Queries:
- The join condition between R and S is fixed to R.a_1 = S.a_1 (which are unique-value columns)
- The output cardinality of the join is thus the cardinality of the smaller table.
  (The values in the smaller table are subset of the values in the larger table)
- To provide more flexibility on the output cardinality, an extra condition is added in the form of (R.a_1 + S.z < threshold). Since S.z is always zero, we can precisely control the selectivity of this predicate before producing the output. Combined with the join condition, the output selectivity is controlled to be 100%, 50%, 25%, or 1% of the smaller table cardinality.

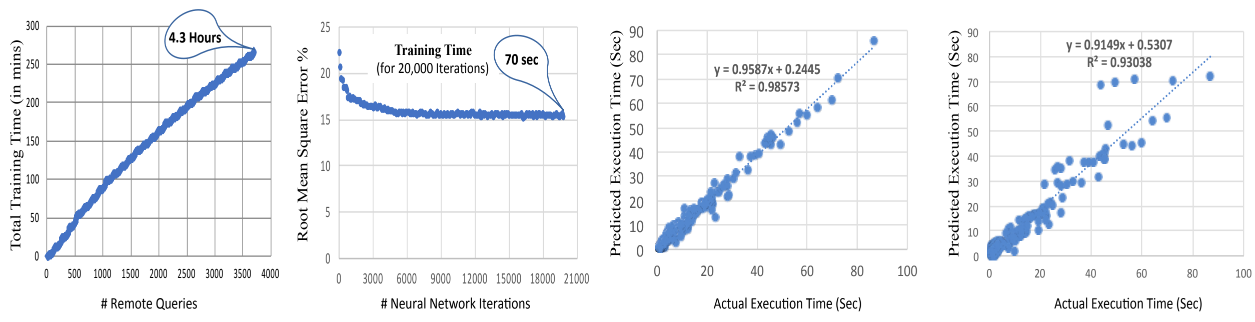
Figure 10: Experimental Setup and Synthetic Dataset Description.

Advanced Learning in Query Optimization: Learning-based models have been studied for both static and dynamic query workloads at coarse-grained plan-level models to fine-grained operator-level models [6]. Machine learning techniques have been also used in the context of query optimizers [17, 29]. The LEO project [17] uses model-based techniques to create self-tuning query optimizer by producing better cost estimates. The work in [29] uses regression techniques to create cost models for XML operators. And the work in [5] proposes building analytical models for query mix interaction to determine good execution schedules. The *IntelliSphere* system combines both the analytical models and machine learning techniques into its cost estimation module.

7 EXPERIMENTAL EVALUATION

In this section, we experimentally evaluate the various techniques of the *IntelliSphere*'s cost estimation module. As a proof of concept, we study the learning of one remote system, which is Hive/Hadoop. We focus on evaluating the *aggregation* and *join* operators since they are the most expensive operators in the relational model.

Cluster and Dataset Description: The Hive VM cluster has a total of four nodes, one master node and three data nodes. The total HDFS size is 445GBs divided equally across the data nodes. Each node has 8GBs of memory and two CPU cores model Intel(R) E5-2697@2.7GHz. We used synthetic datasets in which we generated 120 tables. The details of the generated tables are summarized in Figure 10. As presented in the figure, we created 20 different configurations for the number of records, and 6 different configurations for the record size. All tables have the same schema as indicated in the figure. The schema is designed such that the



(a) Query Training Cost (b) Neural Network Conversion Error (c) Neural Network Model Accuracy (d) Linear Regression Model Accuracy

Figure 11: Aggregation Logical-Operator: Training Costing & Accuracy over the remote system.

different columns will have different duplication factor, which facilitates the design of the aggregation and join queries to produce specific output cardinalities. Overall, the generated dataset occupies around 45% of the total HDFS capacity (including the default three-fold replication).

Logical-Op Evaluation: In Figures 11 and 12, we present the logical-op evaluation for the aggregation and join operators, respectively. Recall that the aggregation operator has four parameters (four dimensions) training dataset, which are the *number of input rows*, *input row size*, *number of output rows*, and *output row size*. We created a total of approximately 3,700 aggregation queries by varying the target table (from the 120 available ones), and the shrinking factor and the number of computed aggregates as highlighted in Figure 10. Figure 11(a) shows the cumulative training time needed to execute the queries over the remote system ($\sim$ 4.3 Hours).

The collected cost values are then fed to train a neural network model. As discussed in Section 3, the topology of the network has two layers, and the number of nodes in each layer is decided using a cross-validation technique. We omit such details from this section since it is not part of our core contributions. The neural network is trained using 70% of the data points, and then the accuracy is measured using the remaining 30% of the data points. Figure 11(b) illustrates the convergence of the model. It reaches a steady state after 7,000 to 9,000 iterations. The figures shows a total of 20,000 iterations (x-axis), and the y-axis represents the error percentage, which is measured as ($e \times 100/v$), where e is the root mean square error (REMS), and v is the average execution time over all queries. The entire network training takes negligible time ($\sim$ 70 Seconds).

After building the model, the test dataset (30%) is used to test the neural network model accuracy, which is presented in Figure 11(c). The figure shows very high agreement between the actual (x-axis) and estimated (y-axis) execution times. This indicates that the four-parameter model is a good model for the aggregation operator, and that the neural network model can capture the relationship between the inputs and outputs with high precision. In Figure 11(d), we illustrate the model accuracy under a linear regression model instead of the neural network model. For the aggregation operation, the linear regression model shows a reasonable accuracy, although it is still lower than the neural network model.

Figure 12 illustrates the training cost and accuracy of the join logical operator. The operator has seven dimensions training set (refer to Figure 2). We created a training set of 4,000 queries by varying the possibilities in each dimension according to the procedure highlighted in Figure 10. Figure 12(a) shows that the training time is really high ($\sim$ 26 Hours). It is worth highlighting that our testing cluster is small, and with bigger clusters, more training configurations need to be covered. Hence, the training time shown in Figures 11(a) and 12(a) can easily grow by an order of magnitude.

In Figure 12(b), we show the convergence and error percentage of the trained neural network model over the training dataset. And Figure 12(c) shows how well the model can learn the execution pattern. We tested the accuracy using the test dataset (30% of the entire data), and the model shows good linear correlation. In Figure 12(d), we illustrate the model accuracy under a linear regression model instead of the neural network model. Unlike the aggregation query type in which the linear regression performed relatively well, in the case of the join queries, the regression model performed poorly and could not capture the execution pattern. Therefore, we believe that for logical operators, it is more accurate and stable to use the neural network model.

Sub-Op Evaluation: For the sub-operator costing approach, the training of each sub-op needs only few number of queries, e.g., in the range of few 10s of queries. As mentioned in Section 4, we did not instrument the remote system to measure the execution time of the sub-op, but instead used primitive queries as presented in Figure 5. Figure 13(a) shows the training time for a number of queries ranging from 6 to 32, which is few minutes. The results from those queries are then used to construct a linear regression model for each sub-op. Figures 13(c), 13(d), and 13(e) illustrate the model of the *WriteDFS*, *Shuffle*, and *Rec Merge* sub-ops, respectively.

As we discussed in Section 4 while presenting the *ReadDFS* sub-op (Figure 7), we do not construct a separate sub-op model under different dataset sizes (number of rows). Instead, for each record size, say k bytes, we perform four experiments with varying number of rows (1, 2, 4, and 8 millions), and then use the average value to construct a single linear regression model for each sub-op. This average value is shown to be a good-enough representation across datasets as confirmed by the results in Figure 13(b) (for the *WriteDFS* sub-op as an example), and earlier in Figure 7(a) for the *ReadDFS* sub-op.

For the *Hash Build* sub-op an interesting behavior is observed, which is that the results actually resemble two distinct models (See Figure 13(f)). This is because the sub-op is sensitive to whether the hash table fits in memory or not. We experimented with both cases and constructed a model for each case. Recall that the *Hash Build* sub-op is primarily used in the hash join algorithm, where the smaller of the two joined relations is broadcasted to all machines,

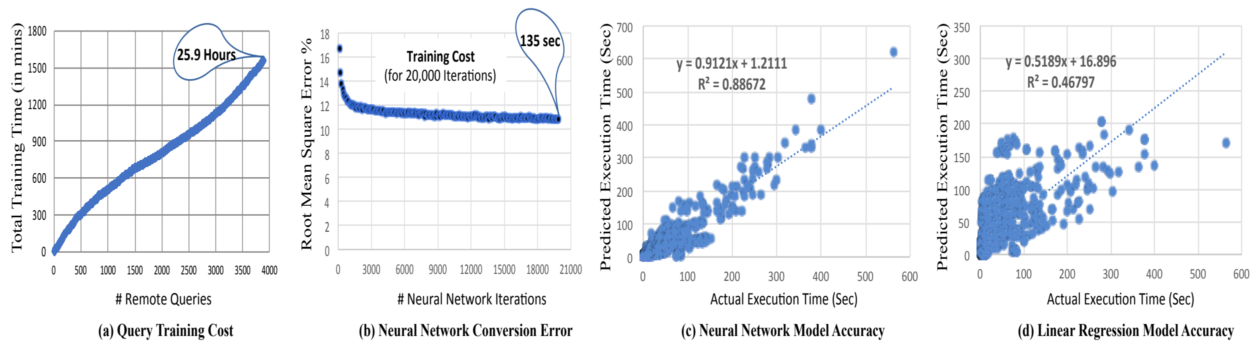


Figure 12: Join Logical-Operator: Training Costing & Accuracy over the remote system.

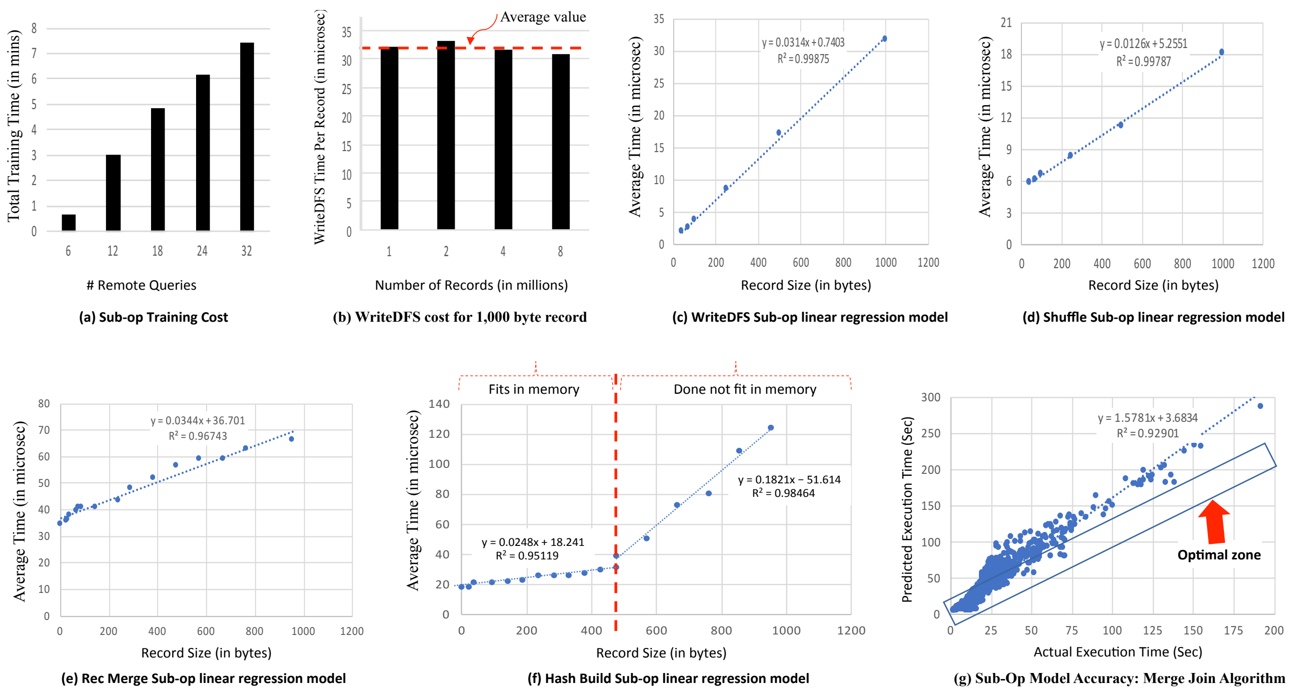

Figure 13: Sub-Op Model: Training Costing & Accuracy over the remote system.

and each machine will build a hash table for this smaller relation. Therefore, given a specific cluster configuration, if the broadcasted relation fits in memory, i.e., falls in the L.H.S area of the vertical dotted line in Figure 13(f), then the corresponding model is used. Otherwise, the system can predict that the broadcasted relation will not fit in memory, and hence the other model is used.

Finally, Figure 13(g) shows the results from combining multiple sub-ops in an analytical formula to estimate the merge join algorithm. Recall that such formula is provided by the domain expert and stored in the remote system profile (Refer to Figures 6). As the results show, the sub-op costing approach provides very good estimation. We found that the sub-op approach slightly tends to overestimate the cost (and similar trend is observed for other algorithms as well), which is a typical trend even within RDBMSs.

Estimation for Out-of-Range Inputs:

In Figure 14, we study the accuracy of the different costing approaches when estimating out-of-range values. This is a typical scenario because an initial training dataset—even if large in size—cannot cover every possible scenario. In this experiment, we studied the merge join algorithm. Both the sub-op and logical-op approaches are trained using datasets of up-to 8x10^6 records

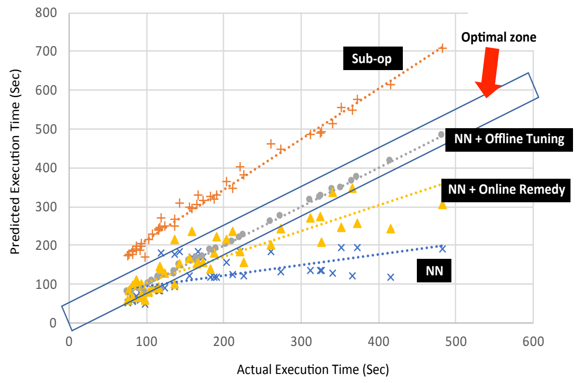

Figure 14: Evaluation of Out-of-Range Prediction Models: Merge Join Algorithm (Fixed α = 0.5).

with different record sizes. Then, the models are constructed from this training dataset. The figure shows the estimation accuracy for a set of new queries, where the number of input records is 20x10^6, while the record sizes are within the trained ranges. We generated 45 queries with different configurations, e.g., in some configurations only one of the join table is out-of-range and in

Table 1: Online Remedy Technique: Automatically Adjusting the Cost-Combining Factor α.

	Batch 1	Batch 2	Batch 3	Batch 4	Batch 5
α	0.5	0.62	0.66	0.57	0.71
RMES%	16.32%	12.6%	12.2%	10.87%	9.1%

other configurations both tables are out-of-range. We compared the estimation accuracy of the *sub-op* approach with that of the *logical-op* approach (the neural network "NN" model).

The results show that the sub-op approach is relatively consistent and can easily extrapolate its trained range to cover out-of-range values. However, due to the non-linearity in the neural network model (the "NN" line), its accuracy degrades and cannot extrapolate well. Interestingly, with the *Online Remedy* technique (Introduced in Figure 4), the accuracy of the estimation improves significantly as depicted in the figure. In this experiment, we fix α (the cost-combining factor) to 0.5.

We also measured the accuracy of the offline tuning phase as follows. We randomly divided the new out-of-range queries (45 in total) into two batches of sizes 70% and 30% roughly. The observed execution times from the 70% batch are added to the neural network model before executing the remaining 30%. And then, the accuracy of remaining 30% is measured. As Figure 14 shows the model adjusts its weights and nicely learns to provide accurate estimations for the new ranges.

Finally, to measure how well the system can adjust the cost-combining factor α in the *Online Remedy* technique (Refer to Figure 4), and its effect on the performance, we performed the following experiment. We initially set $\alpha = 0.5$, and then we randomly divide the 45 out-of-range queries into 5 batches each of size 9. After the execution of each batch, the system adjusts α to minimize the root-mean-square error percentage (RMSE%) of the previously executed batches. The RMSE% is computed as $(e \times 100/v)$, where e is the root-mean-square error (REMS) of a given batch, and v is the average execution time over all queries within that batch. The new value of α is then used for the cost estimation of the subsequent batch. In Table 1, we present the changes of the α values across batches along with the RMSE% for each batch. The results show a trend towards putting a higher weight on the cost factor produced from the neural network, but still the cost produced from the linear regression extrapolation contributes to the final cost by a 30% to 40%.

In summary, as Figure 14 shows, combining the two costs seems effective during the online estimation until the systems collects enough points and applies the offline tuning phase over the neural network model.

8 CONCLUSION

We presented a comprehensive cost estimation module, which is part of the *Teradata IntelliSphere* project. This work addresses a fundamental problem in the modern big data ecosystems, which is the need to efficiently access and query data across multiple heterogenous sources (remote systems). In order to generate efficient execution plans, accurate cost estimation on the remote systems is an essential building block step. We proposed three costing approaches, namely *logical-op*, *sub-op*, and *hybrid* approaches. They cover the spectrum of blackbox, openbox, and a mix of such systems. We demonstrated that none of the *logical-op* or *sub-op* approaches is superior (or practical) in all cases, and thus a hybrid approach should be deployed. We also presented the pros, cons, and applicability cases of each approach. Given the complexity of the problem, we integrated deep learning and analytical models within the proposed cost estimation module. Moreover, we proposed techniques for enhancing the estimation quality for the out-of-range (un-seen) values. As part of future work, we plan to study more types of remote systems such as SparkSQL and Impala.

ABSTRACT

Entropy maximization is the only principled approach to combine several (partial) selectivity estimates to an estimate for a full conjunction. However, this approach has no appearance in database management systems. We conjecture that the main reason is a lack of implementations with good performance. Indeed, the originally proposed iterative scaling algorithm has a slow convergence rate and high complexity in each iteration. As an alternative, we propose to use a method based on Newton's algorithm to solve the entropy maximization problem. Further, we show how this general approach can be implemented very efficiently for both CPUs and GPUs. Our experiments show that our CPU and GPU implementation is more than 4 orders of magnitude faster than the state-of-the-art method for the most complex problem it could handle. For even more complex problems our new GPU implementation outperforms our CPU implementation by more than 43x. In a few milliseconds it is now possible to compute all partial selectivities for complex conjunctive predicates with 20 or more predicates. We strongly believe that the proposed implementation is ready for production-grade database management systems.

1 INTRODUCTION

Query optimizers need precise cardinality estimates to generate query execution plans of high quality. Basic approaches to estimate result cardinalities rely on the assumptions that values are uniformly distributed and the selectivities of predicates are independent. Increasingly sophisticated techniques were proposed to address the uniform distribution assumption and also correlation between predicates, see [1, 6] for comprehensive surveys. However, the space consumption and maintenance effort for all combinations of multi-column histograms [12], samples [3], or statistics on views [7] exponentially grows with the number of columns considered. For this reason, these statistics are generated only for a few out of all possible column subsets. We address the challenge how to integrate estimates produced from these sources of statistics consistently. Note that in general sampling alone is not sufficient because it can result in highly imprecise estimates, and thus other synopsis have to be used [11, 15].

Markl et al. [9] observed that the query optimizer makes suboptimal plan choices despite the rich statistics at hand to find the optimal plan because *fleeing to ignorance* seems to be the most reasonable choice. They suggested the maximum entropy method to exploit all available knowledge and to handle inconsistent and missing information in a consistent way. Consider for example the following scenario. Assume we have three predicates p_0, p_1, p_2 whose selectivities are estimated to be $s_0 = 0.5$, $s_1 = 0.5$, and $s_2 = 0.5$. Further assume that the combined selectivity for $p_0 \wedge p_1$ is $s_{01} = 0.4$ and for $p_1 \wedge p_2$ is $s_{12} = 0.1$. These selectivities could be estimates produced from single column histograms, 2-dimensional histograms, and/or sampling. The question is what is the selectivity of the whole conjunct $p_0 \wedge p_1 \wedge p_2$? The answer given by entropy maximization (as proposed by Markl et al. [9]) is 0.08, which clearly deviates from the estimate $0.5 * 0.5 * 0.5 = 0.125$ produced under the independence assumption. Clearly, the estimate produced under the independence assumption is inconsistent since it is larger than the selectivity of $p_1 \wedge p_2$. Indeed, it is widely known that the independence assumption (1) does not hold in general and (2) leads to bad cardinality estimates and, consequently, (3) leads to suboptimal query execution plans [8].

In order to derive the missing selectivity values, Markl et al. propose to find the unique vector $x = (x_0, x_1, \dots x_{2^z-1})$ (for z predicates) that maximizes the entropy

$$H(s) = \sum_i -x_i \log x_i$$

subject to the constraints given by the known selectivities. A formal definition requires some preliminaries and will be given in Sec. 2. Maximizing entropy can be seen as a generalization of the independence assumption limited to the case of unknown selectivities. Since the known selectivities are possibly derived from several synopsis, the problem may become inconsistent. In this case, a *corrector step* is necessary. Since different correctors have been proposed in the literature (e.g., [9, 10]), we assume in this paper that the problem on hand is consistent.

To solve the entropy maximization problem, Markl et al. use *iterative scaling*. However, this algorithm is known to have very slow convergence [2, p82] and, additionally, has a relatively high asymptotic complexity of $O(m^2 * n)$ in each iteration, where m is the number of known selectivities, z the number of predicates and $n = 2^z$. For example, for eight predicates, iterative scaling needs on average 260 iterations and 115 ms whereas a Newton-based algorithm needs 10 iterations and 0.14 ms on a system with an Intel i7-4790 CPU. For scenarios with even more predicates iterative scaling quickly becomes too slow to be practical while our new Newton-based algorithm on the CPU and even more so on the GPU are able to calculate a solution in a few milliseconds. Hence, with our method we can avoid strategies like partitioning the set of predicates to reduce the problem size that can be found in real-world scenarios [9].

Notation	Description
$p_0, \ldots, p_{z-1}$	z predicates
$N = \{0, \ldots, z-1\}$	set of all predicate indices
$n = 2^z$	abbreviation
$T \subseteq 2^N$	set of indices of known selectivities
$m = \|T\|$	number of known selectivities
β_T	vector of known selectivities
C	complete design matrix
D	(partial) design matrix
$s(p)$	selectivity of predicate p
Bit-wise operations	**Description**
$\|$	bit-wise or
&	bit-wise and
˜	bit-wise complement
$i \subseteq j$	boolean function returning $j = (i\|j)$

Table 1: Notation

In this paper, we propose to use a Newton-based algorithm to solve the entropy maximization problem. We formalize the problem as a series of vector- and matrix operations. However, a naive implementation of these operations fails to achieve the performance requirements for this method. Hence, we discuss in depth how to efficiently implement this algorithm and show that it is vastly superior to both iterative scaling and the naive implementation of the Newton method. We elaborate on the efficient implementation for both the CPU and the GPU.

The rest of the paper is organized as follows. Section 2 formally introduces the problem as a series of vector- and matrix operations. Section 3 describes and evaluates the (almost) straightforward implementation and the optimized implementation of Newton's algorithm for the CPU. Section 4 describes and evaluates our GPU implementation of the algorithm. Section 5 reviews how entropy maximization can be integrated into query optimizers and concludes the paper.

2 PROBLEM FORMALIZATION

In this section, we present an elegant way to formalize the maximum entropy method for selectivity estimation. This is a necessity since standard entropy maximization algorithms require a matrix-based representation of the problem, which is not yet readily available. Only this matrix-based representation of the problem will allow us to derive an efficient algorithms.

2.1 Design Matrix

Since we need a matrix representation of the problem, we need to heavily deviate from the notation of Markl et al. [9]. However, in our opinion, the resulting representation is much more elegant. From the notation of Markl et al. [9], we only keep the letter T to denote the indices of the known selectivities. For convenience, the most important parts of the notation are summarized in Table 1. The lower part contains the notation for bit-wise operations, which will be required for our efficient implementations.

2.1.1 Conjunctions of (Simple) Predicates (β). Consider a conjunctive query

$$p_0 \wedge \ldots \wedge p_{z-1}$$

of z predicates. These may be selection predicates or join predicates [9].

Let $N = \{0, \ldots, z-1\}$ be the set of numbers from 0 to $z-1$. Then, all subsets $X \subseteq N$ can be represented as a bit-vector of length z denoted by bv(X) where the set bits indicate the indexes of those elements of N which are also included in the subset X. Further, this bit-vector can be interpreted as a binary number. We make no distinction between the bit-vector and the integer it represents and use whatever is more convenient. For example, we use the notation $i \subseteq j$ to denote the fact that i has a '1' only in those positions where j has a '1', i.e., $j = i|j$ holds.

For any $X \subseteq N$ define the formula

$$\beta(X) := \wedge_{i \in X}\, p_i$$

i.e., $\beta(X)$ is the conjunction of all predicates p_i whose index i is contained in X. The following table gives a complete overview for $z = 3$, where we order bits from least significant to most significant:

bv(X)	$\beta(X)$
1=100	p_0
2=010	p_1
3=110	$p_0 \wedge p_1$
4=001	p_2
5=101	$p_0 \wedge p_2$
6=011	$p_1 \wedge p_2$
7=111	$p_0 \wedge p_1 \wedge p_2$

where the first column gives the integer value and its bit-vector representation of the index set X and the second column the corresponding conjunction of predicates contained in X. We use $\beta(i)$ instead of $\beta(X)$ if i is the bit-vector/integer representation of some X.

The selectivity of $\beta(X)$, i.e., the probability of $\beta(X)$ being true is denoted by $\beta(X)$. A special case occurs for the empty set. The empty conjunct is always true. Thus $\beta(\emptyset) = \beta(0) = 1$.

2.1.2 Complete Conjuncts (γ). A conjunction of literals containing all predicates either positively or negatively is called *complete conjunct* (*atom* by Markl et al., also *minterm*). For $n = 3$, the following table contains a list of all complete conjuncts:

i	$\gamma(i)$				
0=000	$\neg p_0$	$\wedge$	$\neg p_1$	$\wedge$	$\neg p_2$
1=100	p_0	$\wedge$	$\neg p_1$	$\wedge$	$\neg p_2$
2=010	$\neg p_0$	$\wedge$	p_1	$\wedge$	$\neg p_2$
3=110	p_0	$\wedge$	p_1	$\wedge$	$\neg p_2$
4=001	$\neg p_0$	$\wedge$	$\neg p_1$	$\wedge$	p_2
5=101	p_0	$\wedge$	$\neg p_1$	$\wedge$	p_2
6=011	$\neg p_0$	$\wedge$	p_1	$\wedge$	p_2
7=111	p_0	$\wedge$	p_1	$\wedge$	p_2

Note that two different complete conjuncts can never be true simultaneously. The complete conjuncts have been indexed by their bit-vector representation, where a positive atom corresponds to '1' and a negative atom corresponds to '0'. For a given $X \subseteq N$, denote by $\gamma(X)$ the complete conjunct X:

$$\gamma(X) := \bigwedge_{i \in X} p_i \;\wedge\; \bigwedge_{i \notin X} \neg p_i$$

The probability of a complete conjunct $\gamma(X)$ for some X being true is denoted by $\gamma(X)$.

2.1.3 Correspondence between β and γ. For a given $X \subseteq N$, the bit-vectors y of the complete conjuncts $\gamma(Z)$ contributing to $\beta(X)$ can be expressed as all the bit-vectors y which contain a '1' at least at those positions where the bit-vector representation bv(X) of X contains a '1'. That is

$$\{y | y \supseteq \text{bv}(X)\}.$$

Consider $X = \{0\}$ ($\hat{=}100$). Then

$$\begin{array}{rcllllll} \beta(X) & = & s(& p_0 & \wedge & \neg p_1 & \wedge & \neg p_2 &)+ \\ & & s(& p_0 & \wedge & p_1 & \wedge & \neg p_2 &)+ \\ & & s(& p_0 & \wedge & \neg p_1 & \wedge & p_2 &)+ \\ & & s(& p_0 & \wedge & p_1 & \wedge & p_2 &), \end{array}$$

where $s(p)$ denotes the selectivity of the complete conjunct p. For $X = \{0, 1\}$ ($\hat{=}110$):

$$\beta(X) = s(p_0 \wedge p_1 \wedge \neg p_2) + s(p_0 \wedge p_1 \wedge p_2).$$

As a special case, we get for $X = \emptyset$ ($\hat{=}000$) that all complete conjuncts contribute to $\beta(\emptyset)$. Further, the sum of them must be one. Consequently, we always assume that the empty set is contained in the set of known selectivities T, i.e., $\emptyset \in T$.

2.1.4 Complete Design Matrix C. In case $T = 2^N$, all selectivities are known. Define $n = 2^z$. Then, we define the *complete design matrix* $A \in \mathbb{R}^{n,n}$ as

$$C = (c_{i,j}) = \begin{cases} 1 & \text{if } i \subseteq j \\ 0 & \text{else} \end{cases}$$

where we use indices in $[0, 2^z - 1]$. Note that C is unit upper triangular, nonsingular, positive definite, and persymmetric.

For $z = 3$, we have

$$C = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 0 & 1 & 0 & 1 & 0 & 1 \\ 0 & 0 & 1 & 1 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

This design matrix helps us to go from probabilities for complete conjuncts to selectivities for positive conjuncts. Let $b = (\beta(0), ..., \beta(n-1))^t$ the column vector containing all the selectivities $\beta(X)$ for all $X \in 2^N$ and $x = (\gamma(0), ..., \gamma(n-1))^t$ the column vector containing all the selectivities for all complete conjuncts. Then,

$$Cx = b$$

holds.

2.2 The (Partial) Design Matrix D

We first establish some notation to eliminate rows and columns in some matrix A. Let $A \in \mathbb{R}^{n,n}$ be some matrix. Let $T \subseteq \{0, \ldots, n-1\}$, $m := |T|$, be a set of column indices. Then, we denote by $A|_{c(T)}$ the matrix where only the columns in T are retained. Likewise, we denote by $A|_{r(T)}$ the matrix derived by retaining only the rows in T. These operations can be expressed via matrix multiplication. For an index set T with $m = |T|$, we define the matrix $E^{m,n,T} \in \mathbb{R}^{m,n}$ as

$$E_{m,n,T}(i, j) = \begin{cases} 1 & \text{if } j = T[i] \\ 0 & \text{else} \end{cases}$$

where $T[i]$ denotes the i-th element of the sorted index set T. For example, for $m = 4$, $n = 8$, $T = \{1, 3, 5, 7\}$, we get

$$E_{4,8,T} = \begin{pmatrix} 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

```
NewtonA($b(= \beta_T), T, \epsilon$)
1  $w = 0$
2  $x = \exp(-1)$
3  while ($\delta > \epsilon$)
4      $A = D\text{diag}(x)D^t$
5      solve $Ay = b - Dx$
6      $w = w + y$
7      $x = \exp(D^t w - 1)$
8      $\delta = ||b - Dx||$
9  return ($x$, $Cx$)
```

Figure 1: Newton Variant A [2, p73]

Then, for $A \in R^{n,n}$

$$\begin{array}{rcl} A|_{r(T)} & = & E_{m,n,T}A \\ A|_{c(T)} & = & A(E_{m,n,T})^t \end{array}$$

holds. For a given subset $T \subseteq \{0, \ldots, n-1\}$ (of known selectivities), we retain only those rows from the complete design matrix C for which there is an entry in T. We define the problem specific *(partial) design matrix* D for T as

$$D := C|_{r(T)} = E_{m,n,T}C \in \mathbb{R}^{m,n} \tag{1}$$

where $m := |T|$. Clearly, the rank of D is m.

2.3 Problem Definition

For z predicates, a given vector β_T of known selectivities and indices T thereof, the idea of Markl et al. is to find the solution to $Dx = \beta_T$ that maximizes the entropy of the solution vector x [9]. That is, the problem to solve can be specified as

$$\underset{x}{\text{argmax}} \sum_{i=0}^{n-1} -x_i \log x_i \text{ subject to } Dx = \beta_T \text{ and } x \geq 0 \tag{2}$$

where $n = 2^z$. Note that, we must have that $\sum_{i=1}^{n-1} x_i = 1$, but this is implied since we assume that $\emptyset \in T$ always holds.

3 EFFICIENT CPU IMPLEMENTATION

In this section, we first discuss an implementation of Newton's algorithm to solve the entropy maximization problem that is directly derived from [2]. Due to the matrix-based formalization of our problem, the algorithm is readily applicable and we call this Variant A, and it represents the state-of-the-art implementation of Newton's algorithm. This algorithm it's rather inefficient since its steps require multiplications of large vectors and matrices. We improve this by devising a method for how these matrix and vector operations can be computed very efficiently. This leads us to Variant B of Newton's algorithm. Finally, we evaluate the runtime of both variants on an Intel CPU and compare it with the iterative scaling which was used by Markl et al.

3.1 Newton Variant A

Markl et al. propose to use iterative scaling to solve the optimization problem in Eqn. 2 [9]. However, it is well-known that iterative scaling converges very slowly [2, p82]. In contrast, a Newton-based approach exhibits local quadratic convergence [2, p73]. We thus selected a Newton-based algorithm applied to the dual problem of Eqn. 2:

$$\underset{w}{\text{argmin}} \exp(D^t w - 1)^t \vec{1} - \beta_T^t w \tag{3}$$

as the basis of our work, where we suppose that the set $\{x \in \mathbb{R}^n : Dx = \beta_T,\ x \geq 0\}$ has a nonempty interior (see also [2, p55]).

Fig. 1 shows the code of a Newton-based algorithm to solve the maximum entropy problem defined in Sec. 2.3. As input, it receives the vectors b and T of known selectivities and their indices, and some $\epsilon > 0$ used in the stop criterion. It returns the solution x maximizing the entropy and the vector Cx containing the β-selectivities for all possible conjuncts. Although T does not occur in the body of Fig. 1, it is used in the definition of the design matrix D (see Eqn. 1).

The steps in the algorithm differ vastly in complexity. The initializations of w and x have complexity $O(n)$ and $O(m)$, respectively, and are thus rather uncritical. The calculation of $w = w + z$ in Line 6 has complexity $O(m)$ and is thus rather uncritical, too.

The calculation of $A = D\text{diag}(x)D^t$ in Line 4 can be very expensive if implemented literally. Note that diag(x) is a diagonal $(n \times n)$-matrix with x on its diagonal. Using standard matrix multiplication, the complexity of this step is $O(m{*}n^2{+}m^2{*}n)$. However diag(x) contains only zero's besides the diagonal and thus a more efficient procedure which does not rely on materializing diag(x) can be devised:

```
GET_DDIAGXDT($D, x$)
1  for ($0 \leq i < m, 0 \leq j < m$)
2      $s = 0$
3      for ($0 \leq k < n$)
4          $s$ += $D[i,k] * x[k] * D[j,k]$
5      $A(i,j) = s$
6  return $A$
```

This procedure has complexity $O(m^2 * n)$ and is thus far better than the naive approach using matrix multiplication.

In step (5), we need to solve $Ay = b - Dx$ for y. Calculating Dx has complexity $O(m * n)$. To solve the equation, note that the (m, m) matrix $A = D\text{diag}(x)D'$ calculated in step (2) is symmetric, non-singular, and positive definite. Thus, the efficient Cholesky decomposition [5, p237] can be applied to derive a lower triangular matrix L with $A = LL^t$. Then, we derive the solution y using back substitution [4, p89]. The complexity of this procedure is $O(m^3)$.

In step (7), we need to calculate $D^t w$, which has complexity $O(m * n)$. Step (8) with complexity $O(m)$ is uncritical again, as Dx has been calculated in step (5) already.

In step (9), we need to calculate the product of the complete design matrix C with the primal solution vector x. Using standard matrix multiplication this step has complexity $O(m * n)$.

The complexities of the steps become visible when profiling Newton Variant A for $z = 8 \ldots 10$: roughly 80% of the runtime is spent in procedure GET_DDIAXDT.

3.2 Newton Variant B

As we will see in below, a careful analysis of the structure of the complete design matrix C allows us to derive a reduction-based algorithm that avoids redundant computations resulting in an algorithm for Newton's method with lower computational complexity than the state-of-the-art algorithm from Sec 3.1.

3.2.1 Recursive Characterization of C. The complete design matrix C can also be defined recursively. Denote by $C_z \in \mathbb{R}^{n \times n}$ with $n = 2^z$ the complete design matrix for z predicates. Then

$$C_0 = (1)$$

and

$$C_{z+1} = \begin{bmatrix} C_z & C_z \\ 0 & C_z \end{bmatrix}$$

characterize the complete design matrix C. Another possibility to define C is to use the Kronecker product $\otimes$ [5, p337]. With

$$C_1 = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}$$

we have

$$C_{z+1} = C_1 \otimes C_z$$

3.2.2 Efficient Calculation of Cx and $C^t x$. Let us turn to calculating Cx for some vector $x \in \mathbb{R}^n$, which we need to do efficiently for our Newton-based algorithm. If we cut $x \in \mathbb{R}^n$ into two halves $x_1, x_2 \in \mathbb{R}^{n/2}$, we observe that

$$C_z x = \begin{pmatrix} C_{z-1} & C_{z-1} \\ 0 & C_{z-1} \end{pmatrix} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} = \begin{pmatrix} C_{z-1}x_1 + C_{z-1}x_2 \\ C_{z-1}x_2 \end{pmatrix} \qquad (4)$$

The term $C_{z-1}x_2$ occurs twice but has to be calculated only once. Based on this observation, it is easy to implement a recursive procedure calculating $C_z x$ in $O(z2^z)$, i.e. $O(nlogn)$ substituting $n = 2^z$. As a major contribution of this paper, we are now able to reduce the algorithmic complexity of the newton method from $O(n^2)$ down to $O(nlogn)$.

In order to avoid the overhead of recursion, we provide an efficient iterative algorithm. We assume that the in/out argument `Cx` has been initialized with x. Further, `vp_add` is an AVX2-based implementation to add two vectors of length h.

```
void get_Cx(double* Cx, uint z)
1  w = h = s = t = 0;
2  n = 1 << z;
3  for (w = 2; w <= n; w <<= 1) // width
4      for (s = 0; s < n; s+ = w) // start of first half
5          h = (w >> 1); // half of width
6          t = s + h; // start of second half
7          vp_add(Cx + s, Cx + t, h);
```

A procedure to efficiently calculate $C^t y$ can be devised similarly by replacing `Cx` by `Ctx` and `vp_add(Cx + s, Cx + t, h)` by `vp_add(Ctx + t, Ctx + s, h)`. We call this algorithm `get_Ctx` to w'.

3.2.3 Efficient Calculation of Dx and $D^t x$. First remember that for $n = 2^z$, z being the number of predicates, (1) the complete design matrix C is of dimension (n, n) and (2) the design matrix D is of dimension (m, n). where in typical applications m will be much smaller than $n = 2^z$.

As we have seen in Sec. 3.2.2, calculating Cx in Line 9 can be implemented very efficiently. By exploiting the definition of D in Eqn. 1, we can evaluate $Dx = E_{m,n,T}Cx$ efficiently by first calculating Cx and then picking the components contained in T. This has to be done only once to calculate the expressions Dx in Lines 5 and 8, and Cx in Line 9. Further, $C^t x$ can be calculated efficiently using algorithm `get_Ctx`. Thus, calculating $D^t w$ in step (7) can be implemented efficiently by exploiting the fact that $D^t = C^t E^T_{m,n,T}$. We can embed w into a vector w' in $\mathbb{R}^n$ via

$$w'[j] = \begin{cases} w[i] & \text{if } j = T[i] \text{ for some } i \\ 0 & \text{else} \end{cases}$$

$(0 \leq i < m, 0 \leq j < n)$ and apply algorithm `get_Ctx`.

3.2.4 Efficient calculation of $D\mathrm{diag}(x)D^t$. Next, we discuss an efficient implementation of step (4). As we have already calculated Cx, we now show that it is possible to calculate $(D\mathrm{diag}(x)D^t)$ from Cx. We start with an efficient algorithm to calculate

$$(C\mathrm{diag}(v)C^t).$$

Observe that $(\mathrm{diag}(v)C^t) = (C\mathrm{diag}(v))^t$. Further,

$$(C\mathrm{diag}(x))[j,k] = \sum_{l=0}^{n-1} c_{j,l}\mathrm{diag}(x)[l,k] = c_{j,k}x_k$$

Thus, using

$$\begin{aligned}(C\mathrm{diag}(x)C^t)[i,j] &= \sum_{k=0}^{n-1} c_{i,k}(C\mathrm{diag}(x))^t[k,j] \\ &= \sum_{k=0}^{n-1} c_{i,k}(C\mathrm{diag}(x))[j,k] \\ &= \sum_{k=0}^{n-1} c_{i,k}c_{j,k}x_k \\ &= \sum_{(i|j)\subseteq k} x_k \\ &= (Cx)[i|j]\end{aligned}$$

we can calculate $(C\mathrm{diag}(x)C^t)$ from Cx. Since

$$\begin{aligned}D\mathrm{diag}(x)D^t &= (E_{m,n,T}C)\mathrm{diag}(x)(E_{m,n,T}C)^t \\ &= E_{m,n,T}(C\mathrm{diag}(x)C^t)E^t_{m,n,T}\end{aligned}$$

we can use Cx to fill $(D\mathrm{diag}(x)D^t) \in \mathbb{R}^{m,m}$ via

$$(D\mathrm{diag}(x)D^t)[i,j] = (Cx)[T[i] \mid T[j]] \tag{5}$$

for $0 \le i, j < m$.

3.3 Evaluation

In order to evaluate the implementations of the two variants of Newton's algorithm and the iterative scaling used by Markl et al., we need to generate entropy maximization problems. Since generation of β selectivities easily leads to inconsistencies, we generate a random vector x of size n containing positive integers interpreted as cardinalities for all complete conjuncts γ. Dividing each x_i by $\sum_i x_i$ results in γ-selectivities. Calculating $b = Cx$ results in a complete set of consistent β-selectivities. From these, we select the subset T of known selectivities by extracting selectivities for single predicates and conjunctions of two or three predicates. In practice, not all pairs or triples will be available. Thus, the runtimes reported in the experiments below can be seen as loose upper bounds on the runtime in practice.

We use the stopping criterion $||b/Dx||_q \le \epsilon$ where b/Dx denotes component-wise division,

$$||y||_q := \max_i(\max(y_i, 1/y_i)),$$

and $\epsilon = 1 + 10^{-8}$.

We implemented iterative scaling and the two variants of our Newton-based algorithm in C++ and compiled them with g++ version 7.2.1 with option -O3. The experiments where run on a system with an Intel i7-4790 CPU. Note that this CPU with Haswell architecture had a better single-thread performance than a newer server CPU with Skylake architecture. We report the average execution time of 777 generated problems for each number z of predicates. Our implementation runs in single-threaded mode.

Figures 2 and 3 show the average runtime of our CPU implementation versus the runtime of iterative scaling (as proposed by Markl et al. [9]) if the set of known selectivities T contains all unary and additionally all binary or ternary conjuncts. Column z contains the number of predicates considered and column m contains the number of known selectivities. Besides the average runtime in milliseconds, we include the average number of iterations.

As one can see, our Newton-based implementation is much more efficient than the originally proposed iterative scaling algorithm. For ten conjuncts the runtime of iterative scaling already exceeds one second. Further, as expected, Newton Variant B is much more efficient than Newton Variant A.

		Newton Var. A	Newton Var. B		Iterative Scaling

Figure 3: Newton vs. Iterative Scaling

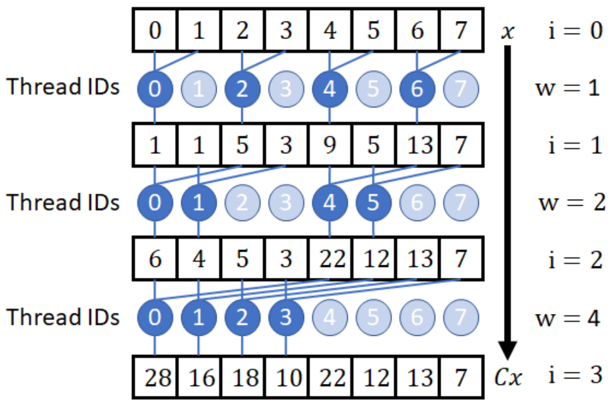

Figure 4: Scheme of the efficient GPU implementation of Cx **for an initial** $x = 0, 1, \ldots, 7$

Figure 2 shows that for up to ten predicates, the runtime to calculate all selectivities needed by the query optimizer is below 0.5 milliseconds if Newton Variant B is used, i.e. three orders of magnitude faster than iterative scaling. However, somewhere between 11 and 20 predicates, depending on the context (e.g., ad hoc queries vs. repeated execution), even the runtimes of our optimized Newton Variant B implementation becomes too high. In particular, Figure 2 indicates that the Newton Variant B with 13 predicates exceeds one second of runtime, while our new method B finishes even 20 conjuncts in less than a second.

In general the runtimes are higher when the problems contain all unary, binary or ternary conjuncts. As can be seen in Figure 3, iterative scaling needs almost 26 seconds for 10 predicates while our new Newton method with Variant B calculates these problems in about 4 milliseconds, i.e. more than 4 orders of magnitude faster. The naive implementation of Newton's method in Variant A needs more then ten seconds runtime for 15 predicates while Variant B is nearly 4 orders of magnitude faster for the same problems.

The increasing runtimes as we consider more and more complex predicates motivated us to pursue a GPU implementation.

4 EFFICIENT GPU IMPLEMENTATION

In this section we describe how the Newton algorithm can be implemented efficiently on a modern GPU. We first explain the multi-threaded GPU implementation of Variant B presented in Sec. 3.2. After that we present experimental results of our implementation using CUDA 10.0 on an NVIDIA Tesla V100 GPU.

4.1 Newton Variant B on the GPU

We discuss how Variant B of Newton's method can be implemented on an NVIDIA GPU. We focus our presentation on the implementation of Cx because, as we have seen in Sec. 3.2, this operation is at the heart of the implementation of steps (4), (7), (8) and (9) of the Newton algorithm presented in Figure 1. We also point out how the remaining step (5), the Cholesky decomposition, is implemented efficiently on the GPU. Finally we outline how we organize our code in kernels of the end-to-end implementation.

4.1.1 GPU Implementation of Cx and $C^t x$. As the NVIDIA V100 GPU used in our experiments offers an abundance of 5120 CUDA cores, we need to extend the implementation of `get_Cx` presented in Sec. 3.2.2 to support massive multi-threading. Figure 4 illustrates the parallelization scheme we use in our implementation. Here, the required operations for calculating Cx are shown for $x = \{0, 1, 2, 3, 4, 5, 6, 7\}$ and $z = 3$. Boxes represent the contents of x after each iteration i, and dark (light) blue circles represent active (inactive) CUDA threads. In each iteration, every active thread performs one addition and stores the result. The connecting blue lines indicate the flow of data. In every iteration half of the GPU threads are active while the other half is idle. While this may seem wasteful, it allows us to use a simple mapping from thread-id to accessed memory addresses. A more effective use of the GPU threads would require a more complex mapping. In fact, we did not find an efficient way to map thread-ids to memory addresses while keeping all threads active all the time. As the maximum number of threads per thread block for the Tesla V100 is 1024, the first ten iterations of our scheme can be performed without requiring communication between different thread blocks. During these ten iterations we make use of the GPUs shared memory, and access to global memory is only required once when loading x into shared memory and once when writing Cx back to global memory. This is beneficial because compared to global memory, shared memory on the NVIDIA V100 GPU offers lower latency and significantly higher bandwidth. Hence, for $z \leq 10$ we use the kernel using shared memory shown in Listing 1. In every iteration of the outer loop we advance with processing vector x by the number of available threads. Note, that for z predicates we have $n = 2^z$ elements to process, i.e. for $z = 15$ we have $2^{15} = 32768$ elements to process. The inner loop in Listing 1 adds the elements as illustrated in Figure 4.

For $z > 10$, no efficient shared memory implementation is possible as threads of one thread block would need to access shared memory allocated in another thread block. This is not possible, and as a consequence all memory accesses have to go to global memory. This requires global synchronization through individual kernel launches. We call this global kernel to compute Cx once for every $z > 10$. It is shown in Listing 2. In our implementation we use templates to generate these calls at compile time. The parameter `direction` allows us to not only calculate Cx but also to calculate $C^t x$. When `direction` is set to 1, the algorithm proceeds backwards, giving us $C^t x$. This is needed in step (7) of the Newton algorithm where we use the product $D^t w$.

Recall that steps (4), (7), (8) and (9) in the Newton algorithm shown in Figure 1 build upon or use the calculation of Cx. This is why we do not describe the implementation of these steps in detail here. The basic ideas are similar to the ones presented for the computation of Cx.

4.1.2 Cholesky Solver. As for the CPU implementation presented in Sec 3.1, solving $Ay = b - Dx$ for y in step (5) of the Newton algorithm shown in Figure 1 can be done using Cholesky decomposition [5, p237]. Fortunately, we can use the cuSolver library from the CUDA toolkit [16] for large problems, i.e. for $m \geq 40$. First, we rely on `cusolverDnDpotrf` to factorize A in a kernel call. Then, we call the kernel `cusolverDnDpotrs` where we pass $b - Dx$ as argument and get y as result of step (5).

As multiple kernel calls are involved in these steps, and each kernel call implies a call overhead of approximately $5 - 10\mu s$, we also implement a variant of the Cholesky decomposition using only a single kernel call. We use this kernel as a solver for small problems, i.e. $m < 40$. The implementation is based on [13] and calculates the solution of the system of equations via

Listing 1: Kernel to compute Cx in shared memory

```
template <int BLOCK_SIZE_X>
__global__ void getCxShared(double* __restrict__ const x, const unsigned int z,
                            const bool direction=0) {
    unsigned int stride = blockDim.x * gridDim.x;
    __shared__ double xShared[BLOCK_SIZE_X];
    unsigned int end = (1<<z);
    for(int globalIdx = threadIdx.x+blockDim.x*blockIdx.x; globalIdx < end; globalIdx+=stride) {
        xShared[threadIdx.x] = x[globalIdx];
        __syncthreads();
        for(int w = 1; w < BLOCK_SIZE_X; w<<=1) {
            if((threadIdx.x/w)%2 == direction) {
                xShared[threadIdx.x]+=xShared[threadIdx.x+w-direction*2*w];
            }
            __syncthreads();
        }
        x[globalIdx] = xShared[threadIdx.x];
    }
}
```

Listing 2: Kernel to compute Cx in global memory

```
template <unsigned int iteration>
__global__ void getCxGlobal(double* __restrict__ const x, const bool direction=0) {
    static constexpr auto offset = 1U << iteration;
    const int myGlobalIdx = threadIdx.x+blockDim.x*blockIdx.x;
    const int blockOffset = (blockIdx.x*1024/offset)*2*offset;
    const int myElementIdx = offset*direction + blockOffset + myGlobalIdx%offset;
    x[myElementIdx]+=x[myElementIdx+offset -2*direction*offset];
}
```

Gaussian elimination without pivoting. It is implemented to run in a single thread block using shared memory. In our experiments, this reduced the end-to-end runtimes of the Newton algorithm by $0.2 - 0.4ms$. However, as the CPU implementation is still faster than the GPU for such small problems this alternative is not really needed.

4.1.3 End-To-End GPU Implementation. We now describe how the various kernels are combined to implement Newton's algorithm on the GPU. In Figure 5, we can only present pseudo code as all the GPU code taken together is several hundred lines long. The initialization in steps (1) - (3) and the main loop are realized in function `NewtonB_GPU`.

While the logic of the loop is the same as in Figure 1 for the CPU code we organize the code to minimize the number of kernel calls. For example, in step (5) we compute both $D\text{diag}(x)D^t$ and also $b - Dx$ in a single kernel call to `buildMatrixA`. In this kernel we first compute Cx calling `getCxShared` and then, if $z > 10$, we call `getCxGlobal` in a loop for every $10 < w \leq z$. In the second step of kernel `buildMatrixA`, we gather from Cx the elements for Dx and $A = D\text{diag}(x)D^t$ as explained in Sec 3.2.3 and Eqn 5 in Sec 3.2.4. In Sec 4.1.2 we explain how we implement step (6) of the loop in function `NewtonB_GPU`, i.e. using the cuSolver library of CUDA for larger problems. Step (7) computes $w = w - y$ using thrust::transform from Thrust, the CUDA C++ template library [16]. Then, step (8) fuses steps (7) and the computation of $b - Dx$ in step (8) of the CPU-based code from Figure 1 into a single kernel `productOfDtw`. This kernel first distributes vector w into x, and then `productOfDtw` uses the logic of `get_Cx_GPU` to compute $D^t w$ using direction = 1 as parameter to handle the transposed matrix; see Sec 3.2.3. As part of this computation we can also calculate the vectors u_{old}, u_{new} and x in the same kernel. Notice, that after the call to `productOfDtw` the vector u_{old} contains the element-wise delta of the last loop iteration. We use this vector in step (9) to determine δ to check for convergence of the algorithm. In our GPU implementation we use the L_∞ norm and $\epsilon = 10^{-8}$. Because of the local quadratic convergence of the Newton algorithm we found that the norm used to check for convergence had virtually no impact on the convergence of the algorithm. If convergence is reached, we return the solution of the Newton algorithm in step (11) by doing one final call to get_Cx_GPU(x,0).

4.2 Evaluation

To evaluate the performance of the GPU-based implementation of the Newton algorithm presented in Sec 4.1, we generated the same entropy maximization problems as in Sec 3.3. We compiled the Newton algorithm using gcc 7.3.1 for the host code and CUDA 10.0 for the kernels on the GPU and compiled them with g++ -O3

The experiments where run on a system with an Intel Xeon E7-8890v3, i.e., using a CPU from the same hardware generation as we used for the evaluation of the CPU-based implementation in Sec 3.3. The system was equipped with a PCI-attached NVIDIA Tesla V100 GPU with 16GB of HBM2 memory. We report the average execution time of the generated problems for different numbers of predicates, z. During the experiments, the host code on the CPU was running in a single thread; virtually all computation was done on the GPU. We remark that the runtimes for the CPU implementations reported in Sec 3.3 used a single thread on the host. The GPU implementation we used here performs busy waiting on the host. With CUDA 10.1 the graph feature

```
GET_CX_GPU($x$, $direction$)
1  $y$ = getCxShared(x,direction)
2  for $w = 1$ to $z - 10$
3      $Cx$ = getCxGlobal<10 + w>($y$,direction)
4  return $Cx$

BUILDMATRIXA($b, x$)
1  $Cx$ = get_Cx_GPU(x,0)
2  (A, $Dx$) = distribute $Cx$ to $A$ and $Dx$ using Sec 3.2.3 and Sec 3.2.4
3  return (A, $Dx$)

PRODUCTOFDTW($w$)
1  $D^t w = 0$
2  distribute $w$ into $x$
3  $D^t w$ = get_Cx_GPU(x,1)
4  together with get_Cx_GPU(x,1), in the same kernel also compute
5      $x = \exp(-D^t w)$
6      $u_{new} = x/\exp(1)$
7      $u_{old} = u_{old} - u_{new}$
8  return ($D^t w, u_{old}, u_{new}, x$)

NEWTONB_GPU($b(= \beta_T), T, \epsilon$)
 1  $w = 0$
 2  $b = b * \exp(1)$
 3  $x = 1$
 4  while ($\delta > \epsilon$)
 5      (A, $Dx$) = buildMatrixA(b, x)
 6      solve $Ay = b - Dx$ for $y$ using cuSolver
 7      $w = w - y$
 8      ($D^t w, u_{old}, u_{new}, x$) = productOfDtw(w)
 9      $\delta = ||u_{old}||_\infty$
10      swap($u_{old}, u_{new}$)
11  return (get_Cx_GPU(x,0))
```

Figure 5: GPU version of Newton Variant B

became available which allows to model the graph of kernels and reduce the call overheads for the kernels. Furthermore, the graph recapture feature introduce with CUDA 10.2. supports passing parameters to these graphs further reducing the call overheads of the GPU. With this the GPU implementation may become faster for smaller problems, but an initial overhead to create and instantiate the graph of about 0.4ms would remain. For larger problems these overheads become insignificant.

In Figure 6 we present the runtime for configurations with different complexity. As in Sec 3.3 column z contains the number of predicates considered and column m contains the number of known selectivities.

The runtimes in the third column in Figure 6 are reported for problems where the set of known selectivities T contains all unary and additionally all binary conjuncts. In this setup, the GPU is faster than the fastest CPU implementation for 13 or more predicates. For 20 predicates the runtime of the fastest CPU implementation was 480 ms (see Figure 2) while the GPU implementation only needs 18 ms, i.e. speed-up of 27x. Furthermore, the NVIDIA V100 GPU is able to compute problems with 25 predicates in only 632 ms. In comparison, the state-of-the art method based on iterative scaling presented by Markl et al. [9] already needs more than one second to compute the result for only 10 predicates (see Figure 2).

The runtimes in the fifth column in Figure 6 refer to problems where the set of known selectivities T contains all unary, binary

Figure 6: GPU implementation of Variant B of Newton's algorithm

and ternary conjuncts. Here, the GPU is faster than our fastest CPU-based implementation for 10 or more predicates. For 20 predicates the GPU-based implementation is more than 43 times faster than our fastest CPU-based implementation. Such a complex problem could not be solved in a reasonable time by the state-of-the art method based on iterative scaling [9]. According to Figure 3, that implementation processed problems with 10 predicates in almost 26 seconds while our GPU-based implementation finishes this task in only 3.5 ms, i.e. almost five orders of magnitude faster.

5 DISCUSSION AND CONCLUSION

Query optimizers rely on several sources to estimate the selectivity of complex conjunctive predicates. Many database systems use elaborate methods to serve selectivity estimation, e.g., multi-column histograms [12], samples [3], statistics on views [7] or even query feedback [14].

Entropy maximization as proposed by Markl et al. [9] considers all available information to derive a consistent estimate for all partial conjuncts of a predicate. However, as the runtimes for iterative scaling are prohibitively high already for 8 predicates, Markl et al. suggests to partition the problem into smaller conjuncts assuming independence between the selectivities of the predicates of the partitions. This risks loosing valuable information from the set of known selectivities.

With the formalization of the entropy maximization problem as a series of vector- and matrix operations we are able to derive efficient implementations for this problem using the Newton algorithm. As our CPU based algorithm is more than 4 orders of magnitude faster than the iterative scaling for the most complex problem it could handle, entropy maximization becomes a feasible option even for complex predicates without sacrificing the quality of the cardinality estimates. Even more, the new implementations can be applied to conjuncts with 18 predicates for the CPU or even 25 predicates for the GPU with runtimes of less than a second making partitioning the input problem irrelevant for virtually all scenarios. While Markl et al. already explained in detail how to integrate the maximum entropy method into query optimizers, we conclude that using the implementation techniques presented in this paper, entropy maximization is ready to be included into production-grade database management systems.

ABSTRACT

Motivated by our experience in building the Enterprise Knowledge Graph of Italian companies for the Central Bank of Italy, in this paper we present an in-depth case analysis of company ownership graphs, graphs having company ownership as a central concept. In particular, we study and introduce three industrially relevant problems related to such graphs: company control, asset eligibility and detection of personal links. We formally characterize the problems and present Vada-Link, a framework based on state-of-the-art approaches for knowledge representation and reasoning. With our methodology and system, we solve the problems at hand in a scalable, model-independent and generalizable way. We illustrate the favourable architectural properties of Vada-Link and give experimental evaluation of the approach.

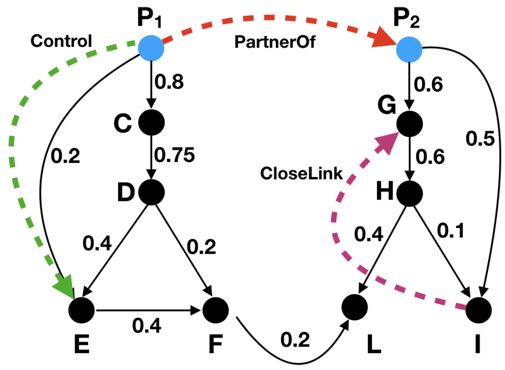

Figure 1: Sample excerpt of a company ownership KG.

1 INTRODUCTION

This paper is motivated by our experience in building the *Enterprise Knowledge Graph* of Italian companies for Banca d'Italia, the central bank of Italy.

Company ownership graphs are central objects in corporate economics [9, 19, 23, 36] and are of high importance for central banks, financial authorities and national statistical offices, to solve relevant problems in different areas: *banking supervision*, *credit-worthiness evaluation*, *anti-money laundering*, *insurance fraud detection*, *economic and statistical research* and many more. As shown in Figure 1, in such graphs, *ownership* is the core concept: nodes are companies and persons (black resp. blue nodes), and ownership edges (black solid links) are labelled with the fraction of shares that a company or person x owns of a company y. Company graphs are helpful in many situations.

One first important problem that can be solved with such graphs is *company control* (also effectively formalized in the context of logic programming [18]), which amounts to deciding whether a company x controls a company y, that is, x can push decisions through in y having the vote majority. Consider the graph in Figure 1: P_1 controls C, D (via C), E (since it controls D, which owns 40% of E and P_1 directly owns 20% of it), and F (via E and D). Similarly, P_2 controls all its descendants except for L. Apparently, P_1 exerts no control on L either.

A second particularly representative application of company graphs is in the context of *collateral eligibility* (also known as *asset eligibility* or *close link*) problem, which consists of estimating the risk to grant a specific loan to a company x that is backed by collateral issued by another company y. According to European Central Bank regulations [1], company y cannot act as a guarantor for x if it is too "close" to it in terms of ownership; the regulation gives a detailed definition for this concept of *closely-linked entity*, which includes: "the two companies must not be owned by a common third party entity, which owns more than 20% of both". With respect to Figure 1, we see that, for example, G and I are closely linked since P_2 owns more than 20% of both.[1]

Besides financial relationships, *personal or family connections* enable much broader use of such company graphs: detecting *family businesses* or studying the real dispersion of control [21] are just two such applications. In our example in Figure 1, knowing that P_1 and P_2 have personal connections –e.g., are married– allows to deduce that, in fact, P_1 and P_2 together control L. Likely, they act as a single center of interest: L is in fact a family business, with control in the hands of a single family, with P_1 and P_2 together controlling 60% of it. Similarly, although D and G do not strictly fulfil the definition of close link, as P_1 and P_2 have a personal connection, there is very low risk differentiation between them and so it is reasonable to prevent G from acting as a guarantor for D or vice versa.

In all the above settings, and indeed in many more, it is our experience that the links representing relevant relationships in the financial realm are not immediately available in data stores. For instance, there are no enterprise graphs readily providing company control relationships, close links or family connections. Reasons fall mostly into four categories: (i) such links represent non-trivial relationships, whose calculation is complex and is not

[*]The views and opinions expressed in this paper are those of the authors and do not necessarily reflect the official policy or position of Banca d'Italia. This work is supported by the EPSRC grant EP/M025268/1, the Vienna Science and Technology Fund (WWTF) grant VRG18-013, and the EC grant 809965.

[1]Actually, here we are forcing the concept of close links to include individuals.

typically done while building the enterprise data stores, for example in the ETL (Extract, Transform, Load) jobs; (ii) the enterprise data stores are mainly relational and neglect specific connections because they are not easily navigable without a graph-based technology; (iii) edges between entities in different data stores are ignored because enterprise databases follow a siloed approach; (iv) edges are considered less trustworthy (lower data quality) than the entities they connect, and so are skipped.

Contribution. In this paper, we focus on the industrial context of the ownership graph of Banca d'Italia and provide the following contributions:

- We provide a compact but formal characterization of the problems of company control, asset eligibility and detection of personal connections over ownership graphs. We argue that the three problems belong to a much broader class, which we name *knowledge graph augmentation*, (KG augmentation). By KG augmentation, we wish to characterize a special case of *link prediction* [29], the key problem of predicting hidden links in network structures, where the emphasis is on the need for a careful combination of the extensional data (existing nodes and edges) and the available domain knowledge.
- We present Vada-Link, a framework for the solution of KG augmentation problems, leveraging state-of-the-art methodologies for *logic-based reasoning* [14, 24], which provide a very good balance between computational complexity of the reasoning task, being PTIME in data complexity, and expressive power, thanks to logic-based *Knowledge Representation and Reasoning* (KRR) languages such as Vadalog [14]. In fact, Vadalog captures full *Datalog* [18, 27] and is able to express SPARQL queries under set semantics and the entailment regime for OWL 2 QL [24].
- From the structured enterprise data stores, we build a *Property Graph* [3] (PG) –a graph with labelled nodes and edges– and model KG augmentation problems as *reasoning tasks* on a *Knowledge Graphs* (KG), based on such PG. In particular, here a KG is a data model combining an *extensional component*, that is, the data from the enterprise data stores, with a formal representation of the domain of interest, the *intensional component*, expressed in some KRR language. KGs typically represent domains that are well suited for being modeled as *property graphs* complemented with rules that express domain knowledge.
- We argue that our approach is general and can be used to augment KGs with new links that can be deterministically or heuristically deduced from a combination of extensional data and domain knowledge. In particular, we motivate that our approach is *schema independent*, as it is not coupled to a specific graph structure (i.e., specific types for nodes, edges and their properties), but relies on meta-level concepts describing graph constructs. At the same time, our solution is *problem aware*, as specific reasoning steps adopt *polymorphic behaviour*, depending on the specific problem. Moreover, our approach is *data model independent*, in the sense that the extensional component can be based on diverse data sources.
- With our KG-based approach, we build a *company knowledge graph*, where the PG of the ownership graph represents the extensional component of the KG and the hidden links, object of the above problems, are obtained by combining a logic-based intensional definition of their specification, i.e., the intensional component of the KG, with the extensional component. Our solution provides an approach to KG augmentation that shows at the same time high accuracy and efficiency, achieved by *multi-level clustering* of the search space, with techniques inspired by record linkage experience [20]. In particular, in the KG intensional component, we combine highly selective feature-based clustering with *neighborhood-preserving embeddings*: the former technique avoids quadratic blow-up of the search space, while the latter enhances accuracy by recognizing graph-based similarities of the entities.
- We exploit the framework to build our company knowledge graph. We motivate that our solution has very favourable properties: it is scalable, since it uses a tractable logic fragment, Vadalog [14] and reduces the search space via multi-level clustering; it is understandable, IT-independent and modifiable thanks to the adoption of a fully declarative approach; Vada-Link decisions are explainable and unambiguous, as the semantics of Vadalog is based on that of Datalog, well known in the database community [2].
- We provide extensive experimental evaluation of Vada-Link.

KG augmentation. In Vada-Link, we structure our link prediction tasks into two of subgoals. First, a *clustering task*, where we aim at grouping the nodes into candidate clusters in order to limit the search space of connected nodes. This allows to overcome the need to compare a quadratic number of nodes, which would make the approach infeasible. Clustering is performed with a combination deterministic rule-based choices and embedding techniques, e.g., *node2vec* [26], which allows to exploit not only the textual or numeric features of edges, but also their structural properties, such as: specific shared neighbours (along with their properties, etc.), topological role nodes and so on.

Clearly, clustering requires a preliminary *feature engineering phase*, needed to individuate the most informative features, which is however out of the scope of this paper. The second subgoal is a *multi-class classification problem*, where we aim at assigning each pair of nodes a link class, if any.

Related work. Different research areas and data management problems can be seen as related to Vada-Link. Link prediction is the problem of discovering links between nodes in network structures: it is relevant in social network analysis [29] and a variety of approaches have been recently proposed, e.g. [39]. In this work, we refer to a different setting, which we called Knowledge Graph augmentation: it is the problem of inferring connections that are necessarily present on the basis of a combination of extensional knowledge and domain experience. In this sense, we borrow techniques that are common in link prediction, e.g. node2vec [26] for clustering purposes, but we do not use them to make linking decisions, which are taken only via logic-based reasoning. In the context of KGs, there have been some proposals for link prediction approaches [28, 32]. However, unlike our approach, the emphasis is still on guessing new connections that cannot be deduced from existing data.

In this paper, for our goals, we borrow from the vast experience of the database community in *record linkage* [20], which is a different yet closely related problem. It consists in deciding whether two records without a common database identifier actually refer to the same real-world entity. Here, the problem is different as we are deciding whether two different real-world entities have some relationship and, if so, its type. Nevertheless, we inherit ideas for search space reduction, namely *blocking* and feature-based *probabilistic record linkage*, adapting them in the context of knowledge graphs. In doing so, we also rely in our experience in formulating and solving data science and data integration problems in a declarative context and in Vadalog in particular [11]. Finally, the general theoretical setting, including the definition of basic data models (e.g., property graphs), is also shared with the *graph querying* community [15].

Overview. The remainder of the paper is organized as follows. In Section 2 we describe our industrial setting of the company ownership graph at Banca d'Italia. In Section 3, we introduce the background of Vadalog-based KGs, graph embeddings as well as the foundations of our approach. In Section 4 we present the details of Vada-Link. In Section 5 we illustrate the architecture of the system, while Section 6 shows experimental evaluation. We draw our conclusions in Section 7.

2 INDUSTRIAL SETTING: AUGMENTING OWNERSHIP GRAPHS

A central bank needs data about companies to pursue a number of core institutional goals. In particular, the Bank of Italy owns the database of Italian companies, provided by the Italian Chambers of Commerce. Although the database is extremely rich and comprehensive, we shall see that many of the problems of interest that cannot easily be solved using traditional query languages can be concisely formulated as reasoning tasks on knowledge graphs. We show how to build such a company knowledge graph, in particular to identify hidden links between the involved entities in various scenarios. Such problems can be easily represented as a KG augmentation problem: given an input graph, we seek new edges that improve the connectivity of the graph to gain the ability to find new and undiscovered patterns. Let us start with a high-level description of the database.

The Italian Company Database. The database provided by the Italian Chambers of Commerce contains several features for each company such as legal name, address, incorporation date, legal form, shareholders and so on. A shareholder can be either a person or company. For persons, we find the associated personal data, such as first name, surname, date and place of birth, sex, home address, and so on. Detailed shareholding structure is also available: for each shareholder the database contains the actual share as well as the type of legal right associated to each share (ownership, bare ownership and so on).

The database at our disposal contains data from 2005 to 2018. If we see the database as a graph, where companies and persons are nodes and shareholding is represented by edges, on average, for each year the graph has $4.059M$ nodes and $3.960M$ edges. There are $4.058M$ Strongly Connected Components (SCC), composed on average of one node, and more than $600K$ Weakly Connected Components (WCC), composed on average of 6 nodes, resulting in an high level of fragmentation. Interestingly, the largest SCC has only 15 nodes, while the largest WCC has more than one million nodes. The *average in-* and *out-degree* of each node is ≈ 1 and that the *average clustering coefficient* is ≈ 0.0084, very low when compared to the number of nodes and edges. Furthermore, it is interesting to observe that the *maximum in-degree* of a node is more than $5K$ and the *maximum out-degree* is more than $28K$ nodes. We also observe a high number of self-loops, almost $3K$, i.e., companies that own shares of themselves, which could be referred to the buy-back phenomenon [4]. The resulting graph shows a scale-free network structure, as most real-world networks [7, 22, 34]: the degree distribution follows a power-law and there are several nodes in the network that act as hubs.

Use Cases. Let us introduce three relevant problems in the context of this database considering Figure 2.

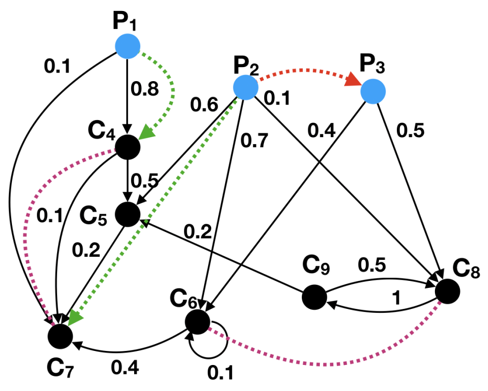

Figure 2: Italian Company Graph. Red-dashed edges represent personal connections, green-dashed edges represent control links, magenta-dashed edges are close-links.

(1) Does P_2 control C_7? More generally, we want to understand if a company or a person exerts control, through the majority of voting rights, on another company, i.e., the *Company Control* problem.
(2) Are companies C_6 and C_8 closely related? More generally, we want to understand whether there exists a link between two companies based on high overlap of shares, i.e., the *close link* problem.
(3) Are there personal/family links between the persons in the company graph? More generally, we wish to *detect personal connections* and label them, on the basis of the kind of relationship.

Solving the third problem allows us to see the first two under a new light: are there a groups of people (e.g., of the same family) in control of a certain company? Are two companies closely related because of the personal ties between their shareholders?

Towards a formalization of the above problems, we propose a graph-based representation of the company database, for which we need some preliminary notions.

Definition 2.1. A (regular) *Property Graph* (PG) is a tuple of the form $G = (N, E, \rho, \lambda, \sigma)$, where:

- N is a finite set of nodes;
- E (disjoint from N) is a finite set of edges;
- *incidence function* $\rho : E \longrightarrow N^n$ is a total function that associates each edge in E with an n-tuple of nodes from N –we will consider $n = 2$ from hereinafter;
- the *labelling function* $\lambda : (N \cup E) \longrightarrow \mathbf{L}$ is a partial function that associates nodes/edges with a label from a set $\mathbf{L}$;
- $\sigma : (N \cup E) \times \mathbf{P} \longrightarrow \mathbf{V}$ is a partial function that associates nodes/edges with properties from $\mathbf{P}$ to a value from a set $\mathbf{V}$ for each property.

The provided company database can be represented in terms of a property graph, as follows.

Definition 2.2. A *Company Graph* is a property graph $G = (N, E, \rho, \lambda, \sigma)$, such that:

- N contains companies and persons;
- E are shareholding edges, from companies to companies or persons to companies;
- the labeling set $\mathbf{L}$ is defined as $\{C, P, S\}$, where C stands for a Company node and P stands for a Person node; S represents a Shareholding edge;

- each node n has an identifier $x \in \mathbf{P}$, with value $\sigma(n, x)$, and a set of properties (or features) $f_1, \ldots, f_m$, with values $\sigma(n, f_1), \ldots, \sigma(n, f_m)$;
- each edge e has share amount w with value $\sigma(e, w) \in (0, 1] \subseteq \mathbb{R}$.

Figure 2 shows an example of the Company Graph. Let us introduce the definitions for the industrial use cases of our interest.

The Company Control Problem. Let us start with that of company control, with an effective formulation presented in the context of logic programming [18].

Definition 2.3. A company (or a person) x *controls* a company y, if: (i) x directly owns more than 50% of y; or, (ii) x controls a set of companies that jointly (i.e., summing the share amounts), and possibly together with x, own more than 50% of y.

Example 2.4. Referring to Figure 2: P_1 controls C_4 by means of a direct 80% edge; P_2 controls C_7, via C_5 and C_6. Green-dashed edges represent the resulting control links.

The Close Link Problem. For the second use case, we need to define the notion of *accumulated ownership* of a company or person x over a company y.

Definition 2.5. Let G be a Company Graph and let ϕ_{xy} be finite the set of all the s simple paths from x to y. Let ϕ_{ij}^m, with $1 \leq m \leq s$, be each of such paths.
The *accumulated ownership* $\Phi_G(x, y)$ of x over y is:

$$\Phi_G(x, y) = \sum_{\phi_{xy}^m \in \phi_{xy}} W(\phi_{xy}^m) \tag{1}$$

where:

$$W(\phi_{xy}^m) = \prod_{e \in \phi_{xy}^m} \sigma(e, w). \tag{2}$$

Starting from Definition 2.5, we can now define *Close Links*.

Definition 2.6. Given a Company Graph G, there is a *Close Link* relationship between a pair of companies x and y for a threshold $t \in (0, 1] \subseteq \mathbb{R}$ if: (i) $\Phi_G(x, y) \geq t$; or, (ii) $\Phi_G(y, x) \geq t$; or, (iii) there exists a person or company z s.t. $\Phi_G(z, x) \geq t$, $\Phi_G(z, y) \geq t$.

Example 2.7. Let us refer to Figure 2 and consider $t = 0.2$. We have that P_3 owns 40% of C_6 and 50% of C_8, therefore they are in close link relationship by Definition 2.6-(iii). Also, since $\Phi_G(C_4, C_7) = 0.2$, it follows that C_4 and C_7 are in close link relationships by Definition 2.6-(i).

Detecting Personal Connections. As we have seen, detecting personal connections enables insightful analyses, including the possibility to achieve more comprehensive view of company control and close links. In particular, we are interested in family relationships of various degrees, i.e. "PartnerOf", "SiblingOf", and so on. Many different models to predict family links exist. We adopt a simple one and, as common in these cases, we define the presence of a family link between x and y with a multi-feature Bayesian classifier. For a given feature f_i, we compute the conditional probability $p_i = P(L_{xy} \mid d(f_i^x, f_i^y) < T_f)$ of having a link L_{xy}, given that some distance between the feature values is under a given threshold for that feature (e.g., Levenshtein distance between two strings "name" of person). The probability p_i and threshold T_f can be estimated by observing $P(d(f_i^x, f_i^y) < T_f \mid L_{xy})$ from training data and given the a priori likelihood of $P(d(f_i^x, f_i^y) < T_f)$ and $P(L)$. Then, we combine all the conditional probabilities p_i into p by applying *Graham Combination* [25]:

$$p = \frac{\prod_{i=1}^n p_i}{\prod_{i=1}^n p_i + \prod_{i=1}^n (1 - p_i)} \tag{3}$$

Finally, a family link exists whenever $p > T$, where T is an established confidence threshold.

Knowing family connections, we can extend Definitions 2.3 and 2.6 to a more general setting. Let us define a family F as a set of persons directly or indirectly connected by personal links.

Definition 2.8. A family F *controls* a company y if: (i) a person $x \in F$ controls y according to Definition 2.3; or, (ii) F controls a (possibly empty) set of companies that jointly, and possibly together with direct ownerships of $\{x_1, \ldots, x_n\} \subseteq F$ (i.e., summing the share amounts), directly own more than 50% of y.

Definition 2.9. Given a Company Graph G, there is a *Close Link* relation between a pair of companies x and y for a threshold $t \in (0, 1] \subseteq \mathbb{R}$ if: (i) Definition 2.6 holds; or, (ii) there exist two persons z_1 and z_2 ($z_1 \neq z_2$) s.t. $z_1, z_2 \in F$, where F is a family, and $\Phi_G(z_1, x) \geq t$ and $\Phi_G(z_2, y) \geq t$.

Example 2.10. Referring to Figure 2, the red-dashed edge between P_2 and P_3 represent "PartnerOf" relationship. For example, P_2 and P_3 are in the same family. Neither P_2 nor P_3 control C_8 singularly. Yet, they have a jointly ownership of 60%; so, their family controls C_8. Also, C_5 and C_8 are closely linked, via P_2 that owns the 60% of C_5 and P_3 that owns 50% of C_8.

The major limitation to answer the illustrated business cases is the translation of all the above definitions into computationally infeasible algorithms due to the dimension of the graph and the complexity of the problems. For example, the close link definition resorts to the ownership definition, and not only: with regard to the third condition of Definition 2.6, the so-called third-party requires to look for a comparison of all existing ownership of companies linked to the third-party entity and a check of the fixed threshold passing. This involves finding all simple paths between pairs of nodes, a paradigmatic computationally hard problem in complexity theory, technically in the #P class [38]. Finding family connections is also challenging, requiring exhaustive comparison of all pairs of persons. Therefore, the intensional part of the company knowledge graph is urgently needed.

3 RELATIONAL GRAPH REPRESENTATION

In order to present the full detail of our KG-based solutions to the settings illustrated in Section 2, let us introduce some basic notions and see how we use them to model and reason on company graphs.

Knowledge Graphs (KG). Along the lines given in [10], we define a KG as a semi-structured data model composed of three components: (i) a *ground extensional component* (or simply extensional component), that is, a set of relational constructs for schema and data, which can be effectively modeled as a *property graph*; (ii) an *intensional component*, that is, a set of *inference rules* over the constructs of the ground extensional component; (iii) a *derived extensional component* that can be produced as the result of the application of the inference rules over the ground extensional component (with the so-called "reasoning" process).

In order to fulfil (i), we adopt a mapping of PG constructs into relational constructs. Let us introduce the background for both and describe our mapping.

Relational Foundations. Let **C**, **N**, and **V** be disjoint countably infinite sets of *constants*, *(labeled) nulls* and (regular) *variables*, respectively. A *(relational) schema* **S** is a finite set of relation symbols (or predicates) with associated arity. A *term* is either a constant or variable. An *atom* over **S** is an expression of the form $R(\bar{v})$, where $R \in \mathbf{S}$ is of arity $n > 0$ and $\bar{v}$ is an n-tuple of terms. A *database instance* (or simply *database*) over **S** associates to each relation symbol in **S** a relation of the respective arity over the domain of constants and nulls. The members of relations are called *tuples*. By some abuse of notations, we sometimes use the terms tuple and fact interchangeably.

Relational Representation for PGs. We map constructs of PGs into relational terms as follows. L-labelled nodes $n \in N$ (with $L_n \in \mathbf{L}$) are represented by facts $L(\hat{c}_x, c_f^1, c_f^2, \ldots, c_f^n)$ of predicate L, where for each property (feature) $f_i \in \mathbf{P}$, we have a constant term c_f^i of L of value $\sigma(n, f_i)$. Note that here we assume a total ordering of property names, so we can map them into positional atom terms and no ambiguity arises (a non-positional perspective could be easily adopted as well). We also assume every node has an identifier x, whose value $\hat{c}_x = \sigma(n, x)$ identifies its facts.

We map each L_e-labelled edge $e \in E$, into facts of predicate L_e: $L_e(\hat{c}_x^1, \ldots, \hat{c}_x^k, f_1, \ldots, f_m)$, where for each argument i of the incidence function ρ, there is a constant term $\hat{c}_x^i$ of L_e with value $\sigma(n, x)$, where $n = \rho(e)[i]$ and x is n identifier, and for each feature $f_i \in \mathbf{P}$ of e there is a constant c_f^i of L_e with value $\sigma(e, f_i)$.

Observe that node and edge labels operate at schema level and map into predicate names. Properties and identifiers are at instance level and define term values for facts representing nodes and edges. With this premises given, in our setting the extensional component of a KG is therefore a database instance representing the PG by means of the mapping described above.

Example 3.1. The extensional component of a KG based on the PG in Figure 1 has the following relational representation.
Company(C), Company(D), Company(E), Company(F), Company(G), Company(H), Company(I), Company(L), Person(P_1), Person(P_2), Own($P_1, C, 0.8$), Own($C, D, 0.75$), Own($D, E, 0.4$), Own($D, F, 0.2$), Own($E, F, 0.4$), Own($P_1, E, 0.2$), Own($P_2, G, 0.6$), Own($G, H, 0.6$), Own($H, L, 0.4$), Own($H, I, 0.1$), Own($P_2, I, 0.5$), Own($F, L, 0.2$).

Inference Rules. We describe the intensional components of KGs with logical inference rules in the Vadalog language. At the core of Vadalog, there is Warded Datalog$^{\pm}$ [12, 14] a language part of the Datalog$^{\pm}$ family [17]. Datalog$^{\pm}$ languages consists of *existential rules*, which generalize Datalog rules with existential quantification in rule heads, so that a rule is a first-order sentence of the form: $\forall\bar{x}\forall\bar{y}(\varphi(\bar{x}, \bar{y}) \rightarrow \exists\bar{z}\, \psi(\bar{x}, \bar{z}))$, where φ (the *body*) and ψ (the *head*) are conjunctions of atoms with constants and variables. For brevity, we write this existential rule as $\varphi(\bar{x}, \bar{y}) \rightarrow \exists\bar{z}\, \psi(\bar{x}, \bar{z})$ and replace $\wedge$ with comma to denote conjunction of atoms. The semantics of such rule is intuitively as follows: for each fact $\varphi(\bar{t}, \bar{t}')$ that occurs in an instance I, then there exists a tuple $\bar{t}''$ of constants and nulls such that the facts $\psi(\bar{t}, \bar{t}'')$ are also in I. More formally, the semantics of a set of existential rules Σ over a database D, denoted $\Sigma(D)$, is defined via the well-known *chase procedure* [2]: new facts are added to D by the chase (possibly involving null values to satisfy existentially quantified variables) until $\Sigma(D)$ satisfies all the existential rules of Σ.

Example 3.2. The following rules define intensional edges linking persons with companies they are influential on (e.g., in the sense of control on company decisions). By Rule (1) a person x affects a company c she owns; her spouse also affects the company by Rule (2). Rules (3) and (4) generate Spouse edges, having a validity interval from t_1 to t_2, from Married edges.

(1) Person(x), Own(x, c, v) $\rightarrow$ Influence(x, c).
(2) Own(x, c, v), Spouse(x, y, t_1, t_2) $\rightarrow$ Influence(y, c).
(3) Married(x, y) $\rightarrow \exists t_1, t_2$ Spouse(x, y, t_1, t_2).
(4) Spouse(x, y, t_1, t_2) $\rightarrow$ Spouse(y, x, t_1, t_2).

4 THE VADA-LINK FRAMEWORK

In this section we focus on Vada-Link and describe in detail our technique for KG augmentation.

Algorithm 1 Basic KG augmentation algorithm.
Input: $G = (N, E, \rho, \lambda, \sigma)$, C: link classes
Output: $U = (N, E', \rho', \lambda', \sigma)$

```
1: $U \leftarrow G$
2: changed ← true
3: **while** changed **do**
4:     changed ← false
5:     $\mathbf{K} \leftarrow$ *GraphEmbedClust*($U$)
6:     **for** $K \in \mathbf{K}$ **do**                                  ▷ First level
7:         $\mathbf{B} \leftarrow$ *GenerateBlocks*($K$)
8:         **for** $B(N_B, E_B, \rho_B, \lambda_B, \sigma_B) \in \mathbf{B}$ **do**       ▷ Second level
9:             **for** $p_1, p_2 \in N_B, c \in C$ **do**
10:                **if** *Candidate*($p_1, p_2, c$) *and* $e \notin E_B$ **then**
11:                    add $e$ to $E_B$
12:                    set $\rho_B(e) = (p_1, p_2)$
13:                    set $\lambda_B(e, \text{TYPE}) = C$.
14:                    changed ← true
15: **return** U
```

Algorithm 1 presents a high-level overview of the approach. We take as input a property graph G and return a property graph U, which is obtained by adding the predicted edges. In our industrial case introduced in Section 2, the property graph is a company graph and the predicted links can be a control relationship, a close link relationship, or a family link.

The overall approach consists in a double level of clustering (which we will also call *blocking*) of the graph: after the first grouping, possible links between nodes are searched only within a single cluster in order to limit the number of needed comparisons. We start from a clustering **K** (line 5) performed by the function *GraphEmbedClust*. We compute a node embedding of the whole graph U: nodes are mapped into multi-dimensional vectors, whose distance reflects the similarity of the nodes, evaluated on the basis of both their features and role in the graph topology. Then each cluster K is in turn partitioned into a more specific clustering **B** (line 7) by the function *GenerateBlocks*. The search for nodes to be linked is then performed within each cluster B and for each type $c \in C$ of links by *Candidate* (line 10). If an edge is to be created for the considered nodes, it is labeled with the proper type (lines 11-13). Once all clusters B in **B** have been used to enrich U with new edges, first-level clustering via graph embedding is recursively applied (line 5). The algorithm proceeds until no changes occur. Finally, U is returned.

The Knowledge Graph. We implemented the core KG augmentation logic of Vada-Link described in Algorithm 1 with a Vadalog KG, where G is the ground extensional component and the intensional component is defined by three set of rules, encoding the prediction logic for the edges to be added to G to obtain U. The first set of rules (Algorithm 2) is the *input mapping*: they take as input the relational representation of one specific PG, as defined in Section 3 (for example that of the company graph) and transform it into higher-level concepts: generic nodes, generic edges and types and properties for those nodes and edges. The second set of rules (Algorithm 3) is the actual *link prediction logic*: it contains the core reasoning process giving rise to new edges; it operates on generic nodes and edges. Finally, the third set of rules (Algorithm 4) is the output mapping: it transforms the high-level generic links that have been created by the link prediction logic into their relational representation in the PG.

Let us now analyse the details of the three sets of rules.

Algorithm 2 Input mapping for the company PG.

```
(1) $\text{Company}(\text{name}, \text{addr}, \text{inc. date}, \text{leg. form}, \ldots),$
    $z = \#\text{sk}_c(\text{name}) \rightarrow$
    $\text{Node}(z, \text{name}, \text{addr}, \text{inc. date}, \text{leg. form}), \text{NodeType}(z, \text{Comp}).$
(2) $\text{Person}(\text{name}, \text{birth}, \text{addr}, \ldots),$
    $z = \#\text{sk}_p(\text{name}) \rightarrow$
    $\text{Node}(z, \text{name}, \text{birth}, \text{addr}, \ldots), \text{NodeType}(z, \text{Person}).$
(3) $\text{Own}(x, y, \text{amount}, \text{right}, \ldots), \text{right} = \text{pers.share} \rightarrow$
    $\exists z\ \text{Link}(z, \#\text{sk}_p(x), \#\text{sk}_c(y), \text{amount}, \text{right}, \ldots),$
    $\text{EdgeType}(z, \text{Shareholding}).$
(4) $\text{Own}(x, y, \text{amount}, \text{right}, \ldots), \text{right} = \text{comp.share} \rightarrow$
    $\exists z\ \text{Link}(z, \#\text{sk}_c(x), \#\text{sk}_c(y), \text{amount}, \text{right}, \ldots),$
    $\text{EdgeType}(z, \text{Shareholding}).$
```

The ground extensional component is modeled by means of three atoms: `Company`, `Person` and `Own`. `Company` and `Person` hold the basic features for companies and persons, respectively –the feature names are self explanatory– and are identified by `name`; `Own` connects a person/company with name x to a company with name y, when x is a shareholder of y and contains the respective features, such as `amount` and type (`right`) of share. Clearly, here we are assuming that `name` is a valid unique identifier for the sake of simplicity, while in practice fiscal code or other more appropriate codes are used. Rule (1) upgrades companies into generic `Nodes` of `NodeType` "Company" (quotes are omitted in the rules for readability). Similarly, Rule (2) upgrades persons. For simplicity of presentation and without loss of generality, here we assume that atoms are variadic (denoting extra terms with "…") so as to support an arbitrary number of features; coherence is guaranteed by the adoption of a positional perspective in our relational representation of PGs and by nodes and edges being typed. Clearly, we could replace variadic nodes and edges with $\text{Feature}(x, f, v)$ atoms, explicitly representing a feature f of value v for node x.

Both Rules (1) and (2) use functions denoted by #sk, namely *Skolem functors*, to generate node identifiers. Skolem functors are often used in variants of Datalog with OID invention, where identifiers need to be generated [5, 16] with specific properties: (i) *determinism*: repeated applications of the same functor on the same argument yield the same OID –this will be useful to generate edges; (ii) *injectivity*: there are no distinct domain elements yielding the same OID –for instance, no different companies will be assigned the same OID; (iii) *disjoint range*: different Skolem functors cannot produce the same OID –in case a company and a person have the same name, $\#\text{sk}_c$ and $\#\text{sk}_p$ will produce different OIDs. Vadalog supports Skolem functors in this form.

Rule (3) and Rule (4) upgrade ownership into generic `Links` with an `EdgeType` depending on the type of ownership: `pers.share` for persons holding companies, `comp.share`, in the case of a company owning a company. We adopt existential quantification to generate OIDs for `Links` and Skolem functors to obtain the OIDs of the `Nodes` associated to names x and y.

Observe that the application order of the rules is irrelevant: thanks to determinism of Skolem functors, `Links` can be generated even before the respective `Nodes` for companies and persons.

Algorithm 3 Vadalog KG augmentation logic.

```
(1) $\text{Node}(x, f_1^x, \ldots, f_n^x), \text{Link}(e, v, w, f_1^e, \ldots, f_m^e),$
    $\text{NodeType}(x, t_n), \text{EdgeType}(e, t_e),$
    $b_1 = \#\text{GraphEmbedClust}(f_1^x, \ldots, f_n^x, f_1^e, \ldots, f_m^e, t_n, t_e, \langle e \rangle),$
    $b_2 = \#\text{GenerateBlocks}(f_1^x, \ldots, f_n^x, t_n) \rightarrow \text{Block}(b_1, b_2, x)$
(2) $\text{Node}(x, f_1^x, \ldots, f_n^x), \text{Node}(y, f_1^y, \ldots, f_n^y),$
    $\text{NodeType}(x, t_n), \text{NodeType}(y, t_n), x \neq y,$
    $\text{Block}(b_1, b_2, x), \text{Block}(b_1, b_2, y), \text{LinkClass}(t),$
    $\text{Candidate}(x, y, t) \rightarrow \exists z\ \text{Link}(z, x, y, \ldots), \text{EdgeType}(z, t).$
```

Algorithm 3 represents the core prediction logic of Vada-Link. For every node x, Rule (1) considers all the edges e of the graph and positions x into a two-level nested clustering structure represented by the atom `Block`, where b_1 and b_2 are the clustering levels. The first clustering is established by applying the function #GraphEmbedClust, which wraps a function call to a specific clustering algorithm based on node embedding (details in Section 4.1). It takes as input the features of x, all the edges e of the graph along with their features, the respective types t_n and t_e and returns the identifier b_1 of the first-level cluster. The second-level clustering is determined by applying the function #Generate-Blocks, whose resulting cluster identifier b_2 only depends on the node properties and type.

Some discussion of the use of functions in our solution is needed. #GenerateBlocks is a *fact-level function* (details in Section 4.2) and its semantics is quite straightforward: for a specific binding of the function arguments that is part of its domain, a value for b_1 is produced. The function is in some sense polymorphic: depending on the type t_n of the involved nodes, a specific semantics is applied to decide the target cluster on the basis of the node features. For example, if the node represents a person, a specific algorithm may rely on last names or addresses; in case of companies, the industrial sector may be relevant, and so on.

#GraphEmbedClust is a *monotonic aggregation function*. Aggregation functions are adopted in various settings making use of logical formalism and the need for a careful definition arises in all of them, especially in the presence of model based semantics [31]. Among the various types of aggregation that Vadalog features [13], in our solution we adopt the monotonic one [37], which respects monotonicity w.r.t. to set containment. Intuitively, aggregation is provided in the form stateful fact-level functions, which memorize the current aggregate value; subsequent invocations of a function then yield updated values for the aggregate so as that the "final value" is the actually desired aggregate value. Thanks to monotonicity, such final value can be easily identified as the minimum/maximum value. In order to decide the first-level clustering for node x, the function #GraphEmbedClust takes as input the node features, an edge e with its features, and the node and edge types t_n and t_e; for a given node x, whenever the function is activated for a new edge e (notation $\langle e \rangle$ denotes that e is such an aggregation contributor), a more accurate clustering is possible and a new, greater value for b_1 is returned. In fact, #GraphEmbedClust wraps the invocation of a node2vec primitive (some details in Section 4.1), whose precision depends on the portion of the graph that is available to it.

For every second-level cluster defined by a `Block` fact, Rule (2) exhaustively considers all the pairs of nodes x and y and for every possible `LinkClass` t (wrt our case many exist: Control, CloseLink, ParentOf, PartnerOf, etc.); the `Candidate` predicate (details in Section 4.3) is used decide whether a `Link` from x to y must be produced or not. If the case, a new t-typed edge is created. Observe that Rule (2) compares only the pairs of nodes in the same sub-cluster (identified by b_1 and b_2).

Algorithm 4 Output mapping for the company PG.

```
(1) $\text{Link}(z, x, y), \text{EdgeType}(z, \text{Control}) \rightarrow \text{Control}(x, y)$.
(2) $\text{Link}(z, x, y), \text{EdgeType}(z, \text{CloseLink}) \rightarrow \text{CloseLink}(x, y)$.
(3) $\text{Link}(z, x, y), \text{EdgeType}(z, \text{ParentOf}) \rightarrow \text{ParentOf}(x, y)$.
(4) $\text{Link}(z, x, y), \text{EdgeType}(z, \text{PartnerOf}) \rightarrow \text{PartnerOf}(x, y)$.
```

Algorithm 4 is the output mapping, actually transforming the predicted edges back into the PG language. With reference to our industrial case, Rules (1) and (2) generate `Control` and `CloseLink` links, respectively. Rules (3) and (4) exemplify possible family links, and many more exist.

4.1 Clustering with Node Embeddings

Embeddings are mappings of real-world objects into high dimensional real-valued vectors that guarantee specific, e.g. geometric, properties reflecting the semantic relationships between the objects. Typically, embeddings are based on some similarity or neighbourhood notion, like in word embeddings [6]. The function #GraphEmbedClust in Rule (1) of Algorithm 3 implements a graph embedding, specifically a *node embedding*, that is, mappings of graph nodes into vectors so that network node neighbourhood is preserved. Specific algorithms learn node embeddings with different random walk strategies, resulting in the optimization of different measures as a consequence. In the function we adopt *node2vec* [26], a particularly interesting embedding which optimizes both network vicinity and network role of a node. We map graph nodes into vectors with 128 dimensions, in such a way that their distance preserves feature-based node similarity as well as neighbourhood, e.g., the so-called "homophily", that is, nodes having the same friend nodes are considered similar. We also apply a preliminary dimensionality reduction step based on T-SNE (*t-distributed stochastic neighbor embedding spectral clustering*) [35]. The #GraphEmbedClust is *polymorphic* in the sense that depending on the types t_n and t_e of involved nodes and edges, it adopts different embedding strategies, which highlight the topological peculiarity of the problem. For instance, it is indeed common that persons having largely overlapping groups of family members are in turn connected by a family relationship; conversely, companies in hold of overlapping sets of shares of other companies, tend to be part of the same group.

Clustering based on graph embeddings shows to be particularly useful in the industrial cases at hand, since it includes in the same clusters candidates that would be far in terms of their descriptive features. This goes beyond the textual or numeric features of companies and persons. Moreover, the interplay between different types of links is also interesting: for example, it is our experience that people in hold of overlapping sets of shares tend to be family members; vice versa, companies owned by overlapping sets of people tend to be part of the same group. The combination of quantitative features and structural graph property is also noteworthy. People owning certain patterns of shares of the same company tend to have family connections.

4.2 Generating Blocks

#GenerateBlocks in Rule (1) of Algorithm 3 reduces the search space for link candidates by sub-clustering. In particular, the function takes as input a vector of features of a node x (a person or a company in our case), belonging to first-level cluster b_1 and returns the identifier b_2 of a second-level cluster. Note that a careful choice the features, *feature engineering phase*, is fundamental: in VADA-LINK, we modularize out this highly domain dependent aspect into the specific implementations of #GenerateBlocks, so that the overall solution is general and ad-hoc tuning is possible whenever new business domains arise.

VADA-LINK provides different pluggable implementations for various domains. In most of the cases sub-clustering can be determined on the basis of well-known hashing or partitioning techniques. We support intuitive declarative specifications of auxiliary functions in VADALOG as follows:

$$\text{Hash}(h, f_1, \ldots, f_n), \text{Features}(f_1, \ldots, f_n) \rightarrow \text{Ans}(h).$$

Here, the `Feature` atom binds to the vector of features taken as input by #GenerateBlocks; with a join with the `Hash` atom, the functionally dependent hash value h is returned. The above rule is clearly complemented by the set of facts defining the underlying `hash` relation. Conventionally the `Ans` atom denotes the function return value. Alternative implementations could be based on Skolem functors as follows:

$$h = \#\text{Sk}_h(f_1, \ldots, f_n), \text{Features}(f_1, \ldots, f_n) \rightarrow \text{Ans}(h).$$

4.3 Generating Matching Candidates

The possible candidates to be linked are matched by the polymorphic `Candidate` predicate, which has different implementations, depending on type of link to be predicted. Let us show how this is applied in our cases.

Algorithm 5 `Candidate` predicate for company control.

```
(1) $\text{Node}(x, f_1, \ldots, f_n), \text{NodeType}(x, \text{Company}) \rightarrow$
        $\text{Candidate}(x, x, \text{Control})$.
(2) $\text{Candidate}(x, z, \text{Control}), \text{Link}(u, z, y, w)$
    $\text{EdgeType}(\text{u}, \text{Shareholding}), msum(\text{w}, \langle \text{z} \rangle) > 0.5$
        $\rightarrow \text{Candidate}(x, y, \text{Control})$.
```

The VADALOG rules in Algorithm 5 define candidate companies to be linked by a control relationship, according to Definition 2.3. Such relationship holds for a company on itself (Rule (1)); then, whenever a company x controls a set of companies z that jointly own more than 50% of a company y, then x controls y.

Algorithm 6 defines companies that are in close link relationships (with threshold T) according to Definition 2.6. Rule (1) and (2) calculate accumulated ownership for companies x and y, according to Definition 2.5. Rule (3) gives the base case for close links: accumulated ownership greater than or equal to 20% is a close link. Close links are symmetric, by Rule (4). Finally, if a company z owns a significant share of both x and y, they are a close link by Rule (5).

Algorithm 6 `Candidate` predicate for close links.

```
(1) $Link(z, x, y, w), EdgeType(z, Shareholding) \rightarrow AccOwn(x, y, w)$.
(2) $Link(u, x, z, w_1), EdgeType(u, Shareholding), AccOwn(z, y, w_2), v = msum(w_1 \cdot w_2, \langle z \rangle) \rightarrow AccOwn(x, y, v)$.
(3) $AccOwn(x, y, w), w \geq T \rightarrow Candidate(x, y, CloseLink)$.
(4) $Candidate(y, x, CloseLink) \rightarrow Candidate(x, y, CloseLink)$.
(5) $AccOwn(z, x, w_1), AccOwn(z, y, w_2), w_1 \geq T, w_1 \geq T, \rightarrow Candidate(x, y, CloseLink)$.
```

Algorithm 7 `Candidate` predicate for PartnerOf.

```
$Node(x, f_1^x \dots f_n^x), Node(y, f_1^y \dots f_n^y), NodeType(x, Person), NodeType(y, Person), \#LinkProbability(f_1^x \dots f_n^x, f_1^y \dots f_n^y) > T \rightarrow Candidate(x, y, PartnerOf)$.
```

Algorithm 7 defines a pair of candidate persons that have a family connection. In the example, the function #LinkProbability implements Equation 3 of Section 2. Here we consider the "PartnerOf" relationship, but similar algorithms are valid for all personal connection types.

We are now able to extend company control and close link detection to support the presence of families. For the sake of space, we omit here VADALOG rules generating "Family" nodes F and "Family" links connecting persons to their family.

Algorithm 8 `Candidate` predicate for family control.

```
(1) $Node(F, f_1^F, \dots, f_n^F), NodeType(F, Family), Link(z, x, F), EdgeType(z, Family), Link(v, x, y), EdgeType(v, Control) \rightarrow Candidate(F, y, Control)$.
(2) $Candidate(F, x, Control), Link(z, x, y, w), EdgeType(z, Shareholding), msum(w, \langle x \rangle) > 0.5 \rightarrow Candidate(F, y, Control)$.
(3) $Link(u, i, F), EdgeType(u, Family), Link(z, i, y, w), EdgeType(z, Shareholding), msum(w, \langle i \rangle) > 0.5 \rightarrow Candidate(F, y, Control)$.
```

Rules (1) Algorithm 8 implement condition (i) of Definition 2.8, while Rules (2) and (3) implement condition (ii) by accounting for the contribution on y of both the companies x controlled by F and the direct ownership of members of F. Technically, the two monotonic summations of Rules (2) and (3) contribute to the same total, one for each $\langle F, y \rangle$ pair.

Algorithm 9 `Candidate` predicate for family close link.

```
(1) $Link(z, i, F), EdgeType(z, Family), Link(k, j, F), EdgeType(k, Family), i \neq j, AccOwn(i, x, v), v \geq 0.2, AccOwn(j, y, w), w \geq 0.2, \rightarrow Candidate(x, y, CloseLink)$.
```

Finally, Algorithm 9 extends Algorithm 6 and implements part (ii) of Definition 2.9.

4.4 Discussion

We conclude the section with some informal arguments about termination, correctness and properties of our approach. I.e., Algorithms 2, 3 and 4 terminate and, in particular, Algorithm 3 correctly adds the required edges as defined in Algorithm 1.

Termination. As we have touched on in Section 3, the semantics of a set of existential rules Σ is given by the chase procedure, where new facts are added to database D (the extensional component), until $\Sigma(D)$ satisfies all the rules. We argue that in our case $\Sigma(D)$ is always finite.

- Algorithms 2 and 4 are non-recursive, therefore each rule adds a finite number of facts to $\Sigma(D)$, because of the finiteness of the extensional component.
- Algorithm 3 is recursive, as `Links` generated by Rule (2) appear in the body of Rule (1) –edges recursively improve the embeddings. The number of `Links` that can be generated by Rule (2) is finite and, in the worst case, it amounts to $|N|^2 \times C$, where N are the PG nodes and C is the number of possible link types. Therefore, Rule (2) produces a finite number of facts in $\Sigma(D)$, up to renaming of link identifiers z. Technically, the VADALOG chase procedure applies isomorphism check to prevent the generation of redundant facts. Therefore, Rule (1) produces a finite number of clusterings $\langle b_1, b_2 \rangle$, since it can fire in the worst case for every single edge in E plus all the ones introduced by Rule (2). Therefore Algorithm 3 always terminates.
- Special care must be paid in the specific polymorphic implementations of the `Candidate` predicate. Observe that in our settings, Algorithms presented in Section 4.3, in the worst case enumerate all the graph paths, and so always terminate.

Correctness. Let us show that each element (e.g., a company or a person) is correctly assigned to a single cluster and pairwise comparison is correctly performed inside each of them and for all possible link classes, as defined in Algorithm 1.

- The nested clustering is produced by the joint use of functions #GraphEmbedClust and #GenerateBlocks within Rule (1) of Algorithm 3. They are both applied to each node and the generated identifiers, b_1 and b_2, appear as terms the head of Rule (1) as well as the node x. As a consequence, because of set semantics, every node x is assigned to a unique pair $\langle b_1, b_2 \rangle$.
- In the body of Rule (2) of Algorithm 3, the two `Node` atoms operate on all pairs of nodes $\langle x, y \rangle$ such that x and y share the clustering configuration $\langle b_1, b_2 \rangle$. Therefore, no other elements are involved in the comparison performed by the `Candidate` predicate. Moreover, Rule (2) fires for each possible class t of `LinkClasses` and so, eventually, all possible triples $\langle x, y, t \rangle$, with $\langle x, t \rangle$ in the same cluster are evaluated.

A broader consideration of the overall correctness and completeness of the approach applied to the specific problems over company ownership graphs is necessary. All the implementations of the `Candidate` predicate we presented in Section 4.3 are deterministic, in the sense that they apply a priori conditions that encode the domain knowledge and produce a linking decision. Clearly, `Candidate` may be implemented as a statistical model, but still, this decision remains deterministic. The specific configuration of the clustering mechanism, i.e., the specific implementations of #GraphEmbedClust and #GenerateBlocks, determines which pairs of nodes are considered by `Candidate` and, as we will see in Section 6, this is the main key to achieving scalability. Hence, if two nodes x and y are supposed to be connected by a t-typed edge e and the recursive clustering mechanism always assigns them to different blocks, the final result will not be complete and miss e. It is the responsibility of the data engineer to strike an acceptable balance between completeness and granularity of clustering from case to case.

Finally, observe that the correctness of the links predicted by Vada-Link depends on the correctness/statistical robustness of the single implementations of `Candidate`, which is problem dependent and out of the scope of this paper.

Complexity. In the average case, clustering allows for linear behaviour, as we experimentally show in Section 6. In the worst case, i.e., all nodes are assigned to the same cluster, the approach performs $|N|^2 \times C$ comparisons, where N are the nodes in the extensional components and C the number of possible link types. However, with highly dense graphs, complexity is dominated by that of #GraphEmbedClust since node2vec has quadratic complexity in the graph branching factor [33]. Also, the complexity of the specific implementations of `Candidate` must be taken into consideration from case to case, as it could be dominating, for example with problems that require path enumeration. Full complexity characterization of company graph problems is beyond the scope of this paper. However, we point out that the complexity of `Candidate` can be controlled by a careful choice of the sub-fragment of Vadalog language. In fact, if the task is described in *Warded Datalog*$^\pm$, the fragment at the core of the Vadalog language, there is the formal guarantee of polynomial complexity [12].

Properties of the approach. Our approach is *schema and model independent*. It is schema independent in the sense that Vada-Link is able to perform KG augmentation regardless of the specific input PGs. This independence is achieved by means of a preliminary "promotion" of the relational representation of the extensional component into a generic graph model (Algorithm 2), with abstract constructs (nodes, edges, features, types). The link prediction logic is then applied within the generic graph, with specific polymorphic implementations of `Candidate` for each problem, encoded in Vadalog in terms of these high-level constructs. In this sense, the approach is also *problem aware*. Finally, the generated links are mapped again into the specific graph schema with Algorithm 4.

The approach is model independent in the sense that the extensional component can originate from heterogeneous data sources, even based on different data models (relational, object oriented, XML, NoSQL models), under the condition it can be imported into the relational representation of PGs described in Section 3.

Finally, it is worth remarking that our prediction technique is based on a kind of *reinforcement principle* because the positively predicted edges in turn help new predictions. In fact, the first-level clustering in Algorithm 3 is gradually improved with new edges being considered from both the ground ones and those generated by Rule (2).

5 THE ARCHITECTURE OF VADA-LINK

The development of enterprise applications using KGs is still a largely unexplored area and design methodologies as well as architectural patterns are gradually emerging. In [10], we proposed a set of architectural principles for the design of KG-based applications; in the following, we briefly motivate how those principles are satisfied by Vada-Link architecture.

- *Assign the immediately known, original information to the ground extensional component of the KG.* In fact, Algorithm 2 embodies the construction of a property graph exactly holding the information available in the company database. Besides the simple mapping, we clearly perform data cleaning and quality enhancement steps, whose details are omitted in this work.
- *For the schema design of the extensional component, adopt well-known conceptual modeling techniques.* In Vada-Link, we provide a relational representation of the extensional data (Section 3) that respects consolidated design and data normalization practices: relevant entities, persons, ownerships and companies in the case at hand, reflect into standalone relations, incorporating identifiers as well as the specific features as attributes.
- *Use extensional rules to model sophisticated and reasoning intensive business rules.* We represent the logic needed to generate the links in the form of declarative specifications. More concretely, with respect to the company KG, we consider multiple kinds of links (close links, company control, family relationships) and for each of them propose a Vadalog program representing it.
- *Keep business logic in the applications (do not let it drift into the KG intensional component).* We carefully separate the business logic of the client applications, that is, the software components using our KG for internal purposes (e.g., economic research, anti-money laundering, etc.) from any logic needed to generate the links. The Vadalog rules represent only the latter, whereas the application business logic resides within the application components. We choose not to implement each polymorphic variant of generation of clusters and evaluation of matching candidates (Sections 4.2 and 4.3) in a dedicated software module. First, such module would be highly coupled to data and hardly explainable or modifiable; more in general, the advantages of declarative approaches in the KG realm are largely acknowledged [30]. In our case, the adoption of logic-based rules appears particularly effective under three perspectives. *Understandability*: it is our experience that business users approach and appreciate human-readable rules instead of pure code; *modifiability*: given by the combination of high abstraction level and compactness of code (20-30 lines of Vadalog rules against 1K+ lines of Python code for the three cases at hand); *IT independence*: avoiding the strong coupling to a specific programming language.

Figure 3 shows the full functional architecture of Vada-Link. Its goal is building a KG from an existing source database. To this aim, data fetched from the RDBMS are enriched with features and extensions from external sources, with common ETL jobs.

The enriched dataset is then used as input to build the extensional component of the KG, that is, the property graph. Our *graph-building pipeline* takes as input an arbitrary database schema and maps it into the relational representation for PGs described in Section 3. The property graph is stored into a *Neo4J* server. The set of Vadalog rules in Algorithms 2, 3 and 4 are stored into a dedicated repository and executed by Vadalog. Enterprise applications interact with the KG via a *reasoning API*. Full details about Vadalog architecture are in [14].

6 EXPERIMENTS

In this section, we provide an experimental evaluation our approach to KG augmentation. The goal of the section is to highlight the scalability and accuracy of the overall approach in Vada-Link and not focussing on the specific Vadalog implementations of the three problems. In fact, out of the three KG augmentation problems we have presented, for the goal of this section we concentrate on the detection of family connections, which is at the same time straightforward but helpful to stress the system. Specific performance tests on complex reasoning tasks, including company control, can be found in [12, 14].

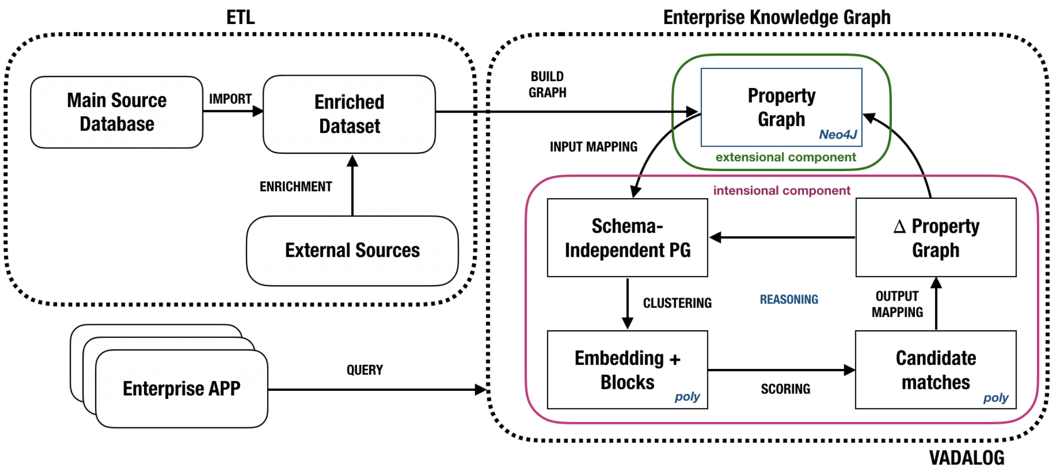

Figure 3: The functional architecture of Vada-Link**.**

We validate Vada-Link on both real-world and artificial data, showing that it exhibits good scalability and accuracy.

Datasets. The *real-world data* we use in the following experiments is the database of Italian companies of Banca d'Italia, as described in Section 2. For the *synthetic data*, we developed a graph generator. In particular, since company networks tend to be *scale-free networks* (see Section 2), we built different artificial graphs by adopting Barábasi algorithm [8] for the generation of scale-free networks, varying the number of nodes and the graph density. For each node, we randomly generated 6 features, out of distributions respecting their statistical properties.

Software and hardware configuration. We ran the experiments on a MacBook with 1.8 GHz Intel Core i5 and 4 GB 1600 MHz DDR3 memory. Vada-Link has been compiled with JDK 1.8.0_4 and clustering functions executed with Python 3.2.3.

6.1 Evaluating Scalability

We tested the scalability of Vada-Link in a number of settings, varying both the graph topology (e.g., number of nodes, density) and the data distribution, inducing different clustering structures.

Varying number of nodes. We investigate the impact of the number of nodes on the performance of Vada-Link. For the *real-world case*, we built 20 scenarios with subsets from the Italian company graph presented in Section 2, with ≈ 1-100k nodes representing persons. In order to stress the system even more with *synthetic data*, we built 6 artificial graphs with ≈ 1-10k nodes, having the same scale-free topology as the real-world graphs, but much higher density. We performed each experiment 10 times and averaged the elapsed times.

Results. The results for real-world data are reported in Figure 4(a). Vada-Link shows good scalability: execution time (blue line) grows slightly more than linearly with the number of nodes and remains under 20 seconds for 10k nodes. The trend is significantly far from quadratic growth, which we would expect with the naive approach consisting of exhaustive all-pairs comparison (red line). Figure 4(b) shows the results for synthetic data. Although the elapsed times are higher by one order of magnitude, which we explain with the highly dense topology of the generated artificial data, the trend is still linear and the approach effective.

Varying the number of clusters. We seek to observe the impact of the number of clusters on the overall execution time. To this end, we crafted a *real-world-like* experiment adopting the company graph presented in Section 2 and artificially tweaking the value of some features. As we have illustrated in Sections 4.1 and 4.2, our clustering technique is based on a recursive combination of node2vec (first-level clustering) and feature based blocking (second-level clustering); in particular, in Section 4.2 we have shown that the assignment to a second-level cluster is decided on the basis of a deterministic mapping –via hashing or Skolem functors– of a feature vector $f_1, \ldots, f_n$ into a cluster identifier. In this experiment, we alter the value of k of such n features in order to hijack the mapping into an increasing number of clusters of decreasing size and observe how this affects elapsed time. We extract values for the vector $f_1, \ldots, f_k$ from a discrete multivariate uniform distribution over the sample space $S_1, \ldots, S_k$. To induce more (fewer) and smaller (bigger) clusters, we restrict (expand) the cardinality of the domain of $S_1 \times \ldots \times S_k$. Specifically, we mapped $f_1, \ldots, f_n$ into ≈ 1-500 clusters.

Results. Figure 4(c) confirms that, as usual in clustering approaches, effective application of Vada-Link calls for a careful feature engineering phase: the selectivity of the features, i.e., the number of distinct values in the domain, and the cardinality of their domain affect the number and size of the clusters. For example, searching for the "siblingOf" relationship among people of the same last name and age range, would lead to clusters including thousands of persons, since certain last names are notably more common than others. Resorting to specific features, for example address vicinity or geographic area, could highly reduce the search space. Also, while the above considerations are somehow intrinsic and common to any clustering approach, in Vada-Link, the adoption of a hybrid node2vec/feature-based clustering combined within a recursive self-improving approach make it easier to strike a good balance between number of clusters (and hence elapsed time) and recall, as we shall see in Section 6.2.

Varying the density. In this experiment we investigate the impact of the density of the graph on the performance of Vada-Link. To this end, we built 4 artificial scenarios, *superdense*, *dense*, *normal*, *sparse*, corresponding to graphs of increasing density, and measured execution time for subset of these graphs of 1-1k nodes.

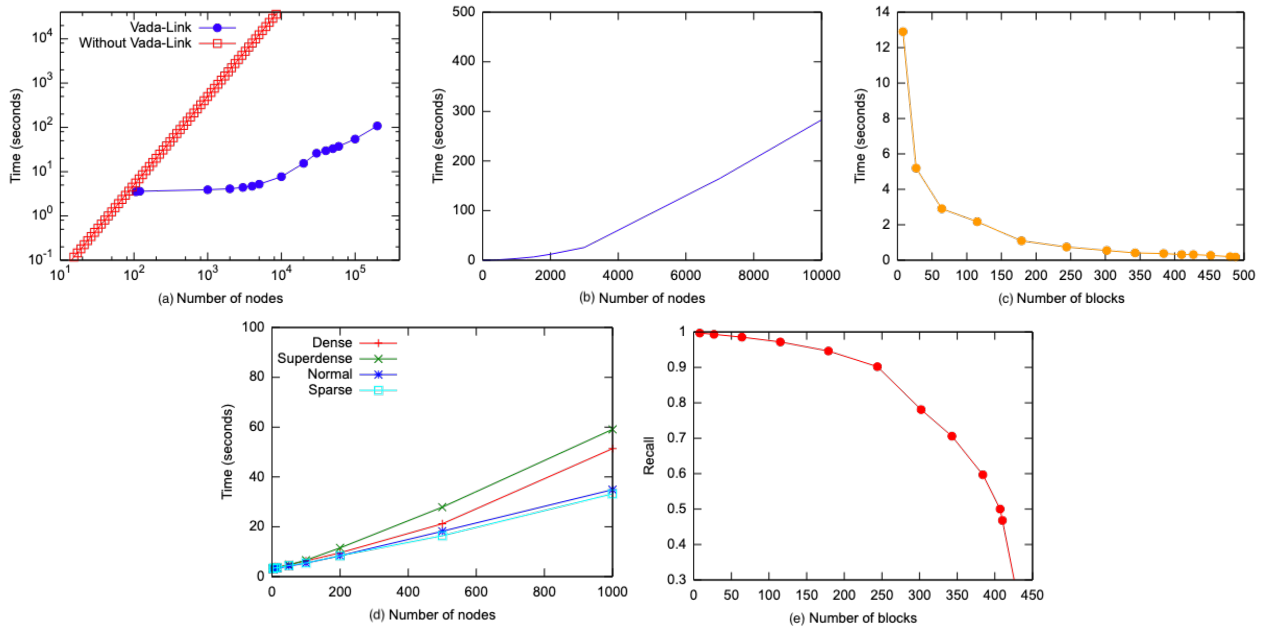

Figure 4: Analysis of Vada-Link execution time, depending on: (a) number of nodes in the graph (real-world data from the graph of Italian companies); (b) number of nodes in the graph (synthetic data); (c) number and size of the clusters (real-world data); (d) graph density (synthetic data). Analysis of Vada-Link recall, depending on: (e) number and size of the clusters (synthetic data).

Results. The results, shown in Figure 4(d), highlight that the performance of Vada-Link is influenced by the density of the considered graph. In particular, we notice an increase of the elapsed times, especially significant for more than 500 nodes. For lower values, sparse, normal and dense show similar trends, whilst superdense is slower, with ≈30 seconds for 500 nodes. The trend is amplified for greater values, with superlinear growth for dense and superdense. While for second-level clustering, #GenerateBlocks in Algorithm 3 is not affected by node density by construction, since it only considers node features, both first-level clustering (#GraphEmbedClust) and the implementations of `Candidate` predicate are. Node2vec needs to process a number of random walks that grows with the density; nevertheless, once a density is fixed, it scales almost linearly with the number of nodes, as also experimentally shown in [26]. Also the behaviour of `Candidate` is highly dependent on the considered KG augmentation problem. For example, detection of family connections have good scalability w.r.t. density as evident in Figure 4(d). Company control and close link detections are more challenging (specific experiments in [12, 14]). Nevertheless, thanks to clustering, Vada-Link can achieve good behaviour also in this case, clearly at the cost of loss in accuracy.

6.2 Evaluating Accuracy

As typically done in the validation of link prediction settings [26], we consider a graph with some edges arbitrarily removed; then, it is our goal to predict those missing edges and in so-doing we are interested in recall, i.e., how many of those removed edges we have recovered. We wish to infer the connections that need to be present and whose definitions are expressed by the polymorphic but deterministic implementations of the `Candidate` predicate, for example, Algorithm 7.

In some settings, `Candidate` implements certain models, like in the case of company control and asset eligibility, for which we would just need to discuss correctness from case to case; in others, `Candidate` encodes a classification model, for which the usual validation methodologies (confusion matrix, accuracy, precision, recall, ROC, AUC, etc.) would be valuable. This is indeed the case of the detection of family connections, our third setting. However, our goal here is not to concentrate on the statistical properties of specific link prediction models: in fact, besides our simple but effective Bayesian approach, more sophisticated models can be plugged in into Vada-Link, each with specific fine tuning. Instead, here our interest is in evaluating the overall tradeoff between scalability and recall.

Varying the number of clusters. We seek to observe the impact of the number of clusters on the recall of Vada-Link. We artificially built 10 random graphs S_i (with $1 \leq i \leq 10$) having the same number of nodes, topology and features as the real-world graph presented in Section 2. For each of them, we ran Vada-Link in “no cluster mode”, that is, we forced the system to concentrate all nodes inside one single cluster in order to produce all the theoretically possible links by means of the naive exhaustive comparison. Therefore, for each subgraph S_i we produced an augmented one $\hat{S}_i$. Then, from each $\hat{S}_i$, we randomly selected 10 edge sets Θ_{ij} (with $1 \leq j \leq 10$), each containing 20% of the predicted links and generated new subgraphs $S^{\Theta_{ij}}$ without those edges. For each $S^{\Theta_{ij}}$ we ran Vada-Link by varying the number of clusters with 20 configurations from 1 to 500, with the technique described in Section 6.1. For each case and cluster, we obtained an augmented graph $\hat{S}^{\Theta_{ij}}$ and computed the recall R_{ijc} as the fraction of edges cardinality $|E(\hat{S}^{\Theta_{ij}})|/|E(\hat{S}_i)|$, that is, the percentage of removed edges that have been recovered. For each of the 20 clusters, we averaged the 100 computed recall R_{ij}.

Results. Figure 4(e) shows how recall decreases with the number of clusters: It is clearly maximum for the single cluster case; then, the recall obtained for 20 clusters, 99.4%, is certainly acceptable for our use cases and, in general reasonable for industrial settings in ownership graphs. We then observe 98.6% for 50 clusters and the approach becomes ineffective for more than 400 clusters, with a recall steadily under 50%. A comparison with Figure 4(c) is interesting and confirms that with more than 10 clusters, processing time is under 10 seconds. This implies that for our case, an effective balance between efficiency and recall is between 10 and 20 clusters. More generally, Figure 4(e) shows a slow decrease of recall, which proves the robustness of Vada-Link. We explain that with the recursive interaction between first- and second-level clustering we have in Algorithm 3. Whenever in a second-level cluster new links are predicted, they are used by the aggregate function #GraphEmbedClust to improve the embedding and provide better first-level grouping and, as a consequence, increase the likelihood that in the second-level clustering, #GenerateBlocks considers new candidates. In other words, the recursive interplay between the two clustering functions compensate for increases in the number of clusters and contributes to a favourable balance between scalability and recall.

7 CONCLUSION

Company ownership graphs confront us with several problems, relevant in the financial realm. Discovering company control, reasoning on asset eligibility or finding out family connections are three interesting examples we focus on in this paper, motivated by the construction of the Enterprise Knowledge Graph of Banca d'Italia. Many more such settings exist, all with the common goal of enriching the company graph with new links. The need for actionable solutions is felt by the the national central banks of the European system, the national statistical offices and many more financial authorities

In this paper, we proposed Vada-Link, a new approach for the creation of valuable links in company graphs that leverages the vast amount of domain knowledge typically present in financial realm. On the basis of recent developments in the KG research area, we model the input graph as the extensional component of a logic-defined KG, where domain knowledge is encoded in Vadalog and link prediction is operated as a reasoning task within the KG. We discussed several favourable properties of our approach, which is general and applies to different data models and schemas. We also discussed the architecture of Vada-Link and provided experimental evaluation, highlighting good performance. We believe that with Vada-Link we are shedding light on problems of the financial realm that have specific scientific relevance per se and a graph- and logic-based view on them can certainly contribute to their full characterization.

ABSTRACT

Medical knowledge bases (KBs) are known to be vital for tasks like clinical decision support and medical question answering, since they provide well-structured relational information between entities. One of the main challenges for querying a medical KB is the mismatch between the terms in the KB and the colloquial and imprecise terminology used in user queries. To address this challenge, we propose a domain-specific query relaxation approach that leverages rich medical domain vocabularies and their semantic relationships from external knowledge sources, such as taxonomies, ontologies, and semantic networks, to expand the vocabulary of KBs. Our main goal is to expand both the set of queries that we can answer, as well as the set of answers to the queries, over the medical KB. We introduce a lightweight adaptation method to customize and incorporate external knowledge sources to work with the existing KB, and propose a novel similarity metric to leverage the information content in the KB, the structural information in the external knowledge source, and the contextual information from user queries. We implement our proposed techniques for a medical KB, and use SNOMED CT as the external knowledge source. We experimentally demonstrate the effectiveness of our proposed method and the improved quality of query results in terms of both precision and recall, compared to state-of-the-art approaches. Finally, we conduct user studies to evaluate how much a conversational interface can benefit from our proposed method in terms of its query capability on the medical KB.

1 INTRODUCTION

Medical knowledge bases (KBs) provide structured information about medical entities (such as drugs and diseases) and their relationships, which are invaluable in medical applications. Such KBs are often created from medical information sources, including medical literature, patient data, claims data, etc, and offer deep domain specialization with rich and detailed information, which is known to be vital for domain-specific tasks like clinical decision support and medical question answering. The medical KBs are different from cross-domain large-scale KBs such as DBpedia [5] and Freebase [9] which provide well-structured, encyclopedic knowledge but with less detail and precision.

When querying medical KBs, the users do not always formulate their queries precisely to match the terms in the KB, especially when they use natural language. For example, users are likely to use informal words, phrases, or abbreviations of certain terms in their natural language queries, which makes matching the mentioned entities to the medical KB a non-trivial task. Query relaxation [18] is one of the most prominent techniques used for query answering, allowing more domain-specific terms in user queries. Instead of returning no or incomplete answers, query relaxation can transform the query in a way that the user's intent is better represented, greatly improving the flexibility and usability of a medical KB.

The problem of query relaxation has been extensively studied in information retrieval and database systems with the goal of returning information beyond what is specified by a standard query [17, 26]. However, the techniques, traditionally designed for formally defined query languages such as SQL, cannot handle the complexity from natural language queries that involve complex semantic constraints and logic [37, 43]. Hence, they often fail to ensure query answering with high precision and recall. Recent work [3, 8, 14] demonstrated that deep learning models built at word or sentence level can be used for semantic similarity estimation. However, these methods demand high-quality training data, which is critical and expensive in reality.

In this paper, we focus on a medical KB (*MED*) which contains medication, disease and toxicology information to support informed diagnosis and treatment decisions for evidence-based clinical decisions and patient education. We observe that this and similar medical KBs can be further enriched by external knowledge sources, such as medical ontologies, taxonomies, and semantic networks (e.g., Unified Medical Language System [40], SNOMED Clinical Terms [38], and Gene Ontology [12]). These knowledge sources can be exploited by query relaxation to expand query answers.

We introduce a novel query relaxation method that leverages rich domain vocabularies and their semantic relationships from external medical knowledge sources, which largely consist of subsumption relationships (e.g., $A \sqsubseteq B$, where A and B are concepts in the external knowledge source). We first find the concept corresponding to a given query term in the external knowledge source, and then relax the term by exploring the concept's neighborhood to identify semantically related concepts.

The rich domain vocabulary and structural information of external knowledge sources empower query relaxation to generalize or specialize query terms beyond syntactic matching. However, external knowledge sources such as SNOMED CT are often not customized to the application's requirements. Using external knowledge sources without proper adaptation may introduce semantically unrelated information into the results, leading to low precision and recall. To provide high-quality results, a query relaxation method has to address the following challenges.

External knowledge source ingestion. External knowledge sources are often comprehensive, consisting of an excessive amount of information describing a domain. The given KB is often substantially smaller than the external knowledge sources.

*Rebecca Geis is currently a graduate student at Technische Universität Darmstadt.

This makes it challenging to identify semantically related results from the external knowledge source. For example, given a query *"what drugs treat pertussis"*, there might be no drug directly associated with *"pertussis"* in the given KB. Instead, a generalized clinical finding, *"bronchitis"*, in the KB has corresponding drug information. However, the distance (i.e., the number of hops) between *"pertussis"* and *"bronchitis"* in SNOMED CT is large, making it difficult for query relaxation to identify the semantic similarity between the two terms. Worse yet, many findings closer in distance but not semantically related might be returned as well, causing low-precision results.

Exploiting the query context. Contextual information has significant impact on the semantic correctness of the relaxed results. For example, a user may ask *"what drugs treat psychogenic fever"*, in which case the context is *"treatment"* and *"psychogenic fever"* is a query term in the given medical KB. This term appears in SNOMED CT as the name of a clinical finding, with both *"hyperpyrexia"* and *"hypothermia"* being similar findings. However, in the context of *"treatment"*, drugs for *"hypothermia"* should not be returned, as *"hypothermia"* is the opposite of *"hyperpyrexia"* and *"psychogenic fever"*.

To address these challenges, we propose a novel two-phase query relaxation method, consisting of external knowledge source ingestion phase and the online query relaxation phase. We implemented our techniques for the medical KB (*MED*), and used SNOMED CT as the external knowledge source. The main contributions of this paper are as follows.

• We present a lightweight, yet effective offline ingestion process that customizes the external knowledge source to the given KB.

• We propose a novel similarity metric to identify semantically related concepts, leveraging (*i*) the information content in the KB, (*ii*) the structural information in the external knowledge source, and (*iii*) the contextual information from the user query.

• We introduce a programmatic way to incorporate our method into two state-of-the-art systems, a conversational system [21] and a natural language query (NLQ) system [23, 35] for the medical KB, using SNOMED CT as the external knowledge source.

• Our experiments show that our query relaxation method for the medical KB outperforms state-of-the-art methods, including deep learning-based ones, in precision and recall. We also conduct a user study demonstrating how our query relaxation method improves the response quality of a conversational system.

Outline. The rest of the paper is organized as follows. In Section 2, we introduce the basic concepts used in this paper, and in Section 3, we provide an overview of our query relaxation approach. Section 4 describes context generation, extraction, and management. Section 5 introduces our query relaxation method in detail. We explain how to integrate our query relaxation technique into two natural language interface systems in Section 6, and provide experimental results in Section 7. We review related work in Section 8, and conclude in Section 9.

2 BACKGROUND

2.1 Knowledge Base

Following the standard notation of description logic [6], we assume that a KB is given in the form of TBox and ABox. In this paper, TBox is referred to as *domain ontology* and ABox is referred to as *instances* or data.

The domain ontology describes the concepts relevant to the domain, and the relationships (roles) among different concepts. The concepts associated with a relationship are provided by the domain (i.e., source) and range (i.e., destination) constraints of this relationship. The *context* of a query term used in a query can be represented by a relationship and its associated concepts from the domain ontology.

Figure 1 shows a fragment of a sample medical domain ontology. The concept *"Finding"* connects to both concepts *"Indication"* and *"Risk"* through the relationship *"hasFinding"*. This shows that *"Finding"* can be potentially used in two different contexts (i.e., *Risk-hasFinding-Finding* and *Indication-hasFinding-Finding*). Two example queries could be *"which drugs have the risk of **causing** diabetes"* and *"which drugs **treat** diabetes"*, where the query term is *"diabetes"*.

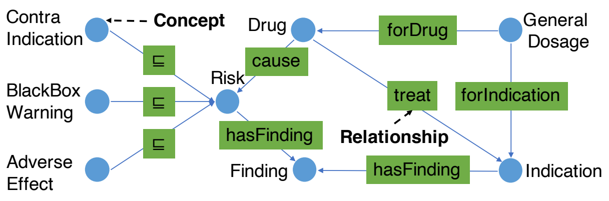

Figure 1: Snippet of a medical ontology.

The instances (data) of the given KB are stored separately for query answering as shown in Figure 3. For example, *"fever"* and *"renal impairment"* are two instances of *"Finding"*. We assume that our input is in the form of a query term and its associated context. Following the previous example, the input to our query relaxation method would be [diabetes, *Risk-hasFinding-Finding*] or [diabetes, *Indication-hasFinding-Finding*]. Recent technologies [1, 21, 28] have been designed to extract the contextual information from natural language questions. In this paper, our method is integrated with Watson Assistant [21] to receive the contextual information, and finds semantically related instances for a given query term with high precision and recall. We provide more details on how we bootstrap the conversation space in Section 4.

2.2 External Knowledge Source

In this work, we utilize the rich medical domain vocabularies and their semantic relationships from external knowledge sources such as ontologies, semantic networks, and knowledge graphs. In particular, we are interested in the subsumption relationships in the form of $A \sqsubseteq B$, where A and B are concepts in the external knowledge source. In this case, we say that A *specializes* B, and that B *generalizes* A. We refer to the direct and implied (by transitivity) specializations of a concept A, excluding A, as the *descendants* of A. We assume that the external knowledge source is a directed acyclic graph (DAG), in which a top concept (owl:Thing in OWL) is the root and every concept is a descendant of the root. To avoid confusion with the concepts of the domain ontology, we refer to the concepts in the external knowledge source as *external concepts*.

2.3 Semantic Similarity Measures

Semantic similarity measures estimate the similarity between concepts, and are commonly used in various processing tasks (e.g., entity resolution [10, 15], link prediction [27], change detection [22]). The knowledge-based approach to semantic similarity exploits taxonomies like WordNet. Typically, path finding measures and information content (IC) measures are two common categories in knowledge-based approaches [19]. In addition to a knowledge source, the IC approach can leverage a frequency value $freq(A)$, accounting for the number of times a concept A is mentioned in a document corpus, to compute the similarity between concepts. Specifically, the IC of a concept A is defined as the inverse of the log of the concept's frequency [25, 34]:

$$IC(A) = -log(freq(A)), \tag{1}$$

where $freq(A)$ is recursively defined as:

$$freq(A) = |A| + \sum_{A_i \sqsubseteq A} freq(A_i), \tag{2}$$

with $|A|$ being the number of times concept A is directly mentioned in the document corpus, and A_i being the direct descendants of A in the taxonomy. The intuition is that the more general a concept is, the more likely it is that the concept or its descendants appear in the corpus. We describe how we compute this equation in the next section.

The IC-based similarity measure compares the IC of a pair of concepts to the IC of their Least Common Subsumer (LCS)[1]. The greater the IC of the LCS (i.e., the more specific the LCS), the more similar is the pair of concepts:

$$sim_{IC}(A, B) = \frac{2 \times IC(lcs(A, B))}{IC(A) + IC(B)}. \tag{3}$$

In general, the IC similarity measure is shown to outperform other approaches on various semantic similarity benchmarks [2, 19, 29]. Hence we adopt the above IC similarity measure and further integrate it with the structural information in the external knowledge source, as well as the contextual information from the natural language query.

3 APPROACH OVERVIEW

In this section, we provide an overview of our query relaxation method, as shown in Figure 2. We propose a two-phase approach: an offline phase, in which we construct context specifications, as well as incorporate an external knowledge source into the given KB, and an online phase, in which we take a query term associated with a context, and return the semantically related results as answers for the query.

Offline phase. In the offline phase, also called external knowledge source ingestion, we perform the following tasks: (i) we initialize a set of possible contexts based on the domain ontology, and optionally generate training examples for context classification (if needed by natural language interface (NLI) system), (ii) we compute the frequency of each external concept in the external knowledge source with respect to the associated contexts, and (iii) we generate mappings between instance data in the knowledge base and external concepts in the external knowledge source.

To initialize the set of possible contexts, we traverse the domain ontology and return all the relationships, along with their source and destination concepts. Those relationships constitute the set of possible contexts, which we provide to the NLI system. We can also provide labeled data for training a context classifier in the NLI system if required (described in Section 4).

To compute the frequency of each external concept, we leverage the document corpus from which the given knowledge base

[1]A LCS of two concepts always exists in the external knowledge source. When multiple LCSs exist, we choose the one with the shortest path to the pair of concepts. If multiple LCSs have equal distance to the pair of concepts, we use the average IC of these LCSs for the similarity measure.

is curated. Additionally, we differentiate the frequency of the external concepts with respect to different contexts, as described in Section 5.1.

To map the instance data from the given KB to the external concepts in the external knowledge source, we provide three alternative methods, depending on the accuracy requirement from the application. Specifically, these methods include matching the instance data and external concepts with exactly the same names (exact match), very similar names in terms of edit distance, or similar names in terms of word embeddings, as described in Section 7.2.

Online phase. In the online phase, also called online query relaxation, we receives as input a [query term, context] pair and perform the following tasks: (i) we search for an external concept Q corresponding to the query term in the external knowledge source, and (ii) we retrieve the top-k similar external concepts having corresponding matching instances in the KB to Q as the answers.

To identify an external concept Q that corresponds to the input query term, we follow a similar process used in the offline external knowledge source ingestion: we identify Q as the external concept whose name either matches with the exact query term, or is very similar in terms of either edit distance or word embeddings. Additionally, several knowledge sources (e.g., SNOMED CT[2], DrugBank[3], DBpedia[4]) may offer a more sophisticated lookup service, which we can also utilize to find such mappings.

Finally, having identified the external concept Q that corresponds to the input query term, we retrieve its top-k similar external concepts that have corresponding instances in the given KB. For the similarity computation, we leverage the information content from the KB, the structural information in the external knowledge source, as well as the contextual information from the query, as described in Section 5.2.

4 CONTEXT SPECIFICATION

As explained in Section 2.1, the context can be represented by a relationship and its associated concepts from the domain ontology. In this section, we provide a brief overview of: (*i*) how our method provides the necessary information that an NLI system requires for context recognition, and (*ii*) how the conversational context differs from simple question answering. We note that the process of context recognition is orthogonal to our method, and we refer the reader to [33] for more details.

Context generation and extraction. Context reflects the intent or goal expressed in the user query/input[5]. NLI systems typically use a learning-based model to identify the intent for a given user query within the current conversation. As a consequence, most of these systems require as input the specification of all possible contexts expected in a given workload with labeled query examples for training the intent classifier. These contexts are usually based on (*i*) the purpose of the application and the scope of questions that it intends to handle, (*ii*) the anticipated set of questions that the users might ask within the scope of the application.

To feed such NLI system with training data, we need to follow a two-step process. The first step is to generate all possible contexts, based on the domain ontology. For this step, we traverse the domain ontology and extract all relationships, along with their associated concepts, i.e., their source and destination concepts. Since a context can be represented by a relationship, we define the set of possible contexts (i.e., possible labels for training data) as the set of relationships.

The second step is to associate a query workload to the generated contexts. There are different options for this step, which go beyond the scope of this work. One simple approach is to retrieve an existing query workload, and ask domain experts to label each query in the workload with the most relevant context. Once we have such an annotated query workload, we can either stop the process here, or we can further enrich the query workload. For enriching the query workload, we can replace identified instances with other instances of the same concept. For example, we can generate more queries in our workload from a given query *"what drugs treat fever"*, labeled with the context *Indication-hasFinding-Finding*), by replacing *"fever"* with other instances of *"Finding"*, such as *"headache"*, *"sore throat"*, and *"pain in throat"*.

The result of this two-step process is a set of queries, each labeled with a context, which we can provide to a NLI system as training data for context recognition.

Context management. In Figure 2, we show two alternative NLI systems that can benefit from our query relaxation method. The main difference between a conversational system and a natural language query system is that the latter can be stateless. Namely, a conversational system needs to keep track of the conversational flow, i.e., the state of the dialogue and its history. This way, the current context can be inferred from the previous state, even if not explicitly mentioned in the current query. For example, if the current query is *"what about fever?"*, there is no clear context, if this query is processed individually. However, if it is processed as part of a conversation, in which the previous query was *"which drugs treat diabetes"*, then a conversational system can infer that the previous context *Indication-hasFinding-Finding*) remains unchanged. More details on that subject can be found in [23]. On the other hand, a natural language query system typically handles contexts in one-shot queries without considering previously asked queries.

[5]We use the terms context and intent interchangeably in this section.

5 QUERY RELAXATION METHOD

Our query relaxation method has two phases, the offline external knowledge source ingestion and the online query relaxation. In this section, we first focus on describing how to customize and incorporate an external knowledge source into the given KB, and then we show how to use the adapted knowledge sources in online query relaxation.

5.1 External Knowledge Source Ingestion

The external knowledge source ingestion addresses the following two issues. First, we need to count the frequency $freq(A)$ of an external concept A (Equation 2) based on the corpus from where the given medical KB is curated. Its frequency should reflect the context in which the concept is used. Second, the external knowledge source typically contains an excessive amount of information in terms of domain vocabulary and relationships. It is imperative to customize and incorporate the external knowledge source in accordance with the given KB for query relaxation.

Concept frequency. First, we need to map the instances from the given KB to their corresponding external concepts in the external knowledge source, as illustrated in Figure 3. A variety of techniques can be leveraged to produce such mappings, ranging from exact string matching, approximate string matching using edit distance, to word embeddings. In this paper, we use these techniques in a pluggable fashion, and we compare the effectiveness of these algorithms in the experimental evaluation. If an instance is mapped to an external concept, then this concept is marked with a flag (the concepts in yellow in Figure 3). The online query relaxation only returns flagged concepts as semantically related results to a given query term, since the given KB only contains information about those concepts.

Next, as mentioned earlier, a concept could be used in different contexts depending on the natural language query, and the semantic meaning can be completely different in different contexts. For example, a condition treated by a drug is different from an adverse effect (i.e., condition) caused by the same drug. In this case, having a single frequency associated with a concept (Equation 2) would not be sufficient to capture the semantic differences over all possible contexts.

To resolve this issue, we identify all the contexts where an external concept A can be used. Specifically, we use the relationships associated to a concept in the domain ontology as the contexts of A, if an instance of this concept is mapped to A. Then, we compute the concept frequency with respect to each context. The online query relaxation phase chooses the appropriate concept frequency according to the query context as described later in this section.

To compute the frequency of external concepts, we assume that the KB is curated based on a document corpus, and we count the number of times that each external concept name is mentioned within this corpus. To account for the sparsity of certain concept names in the corpus, the concept frequency is further adjusted based on the number of documents in which the concept name appears. For example, *"asthma"* is mentioned in 54 drug descriptions in DrugBank [16], whereas *"lung cancer"* has only a handful of associated specialty drugs. Hence, we utilize the commonly used tf-idf weighting to alleviate this bias.

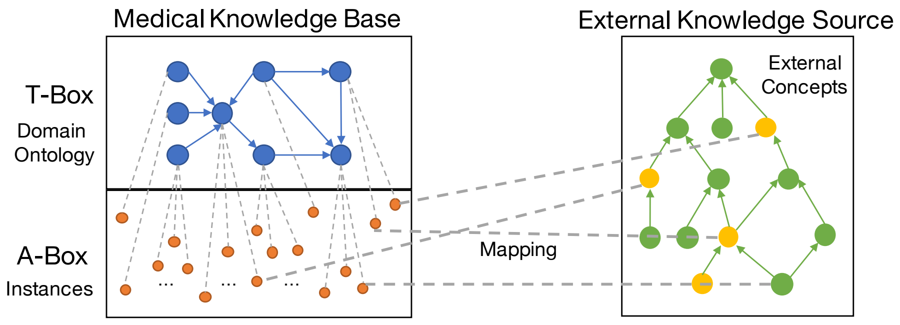

Figure 3: External knowledge source ingestion.

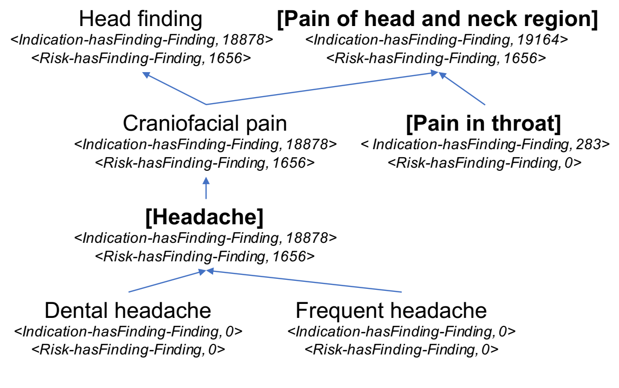
Example 1. In the medical ontology depicted in Figure 1, the concept *"Finding"* is connected to both *"Indication"* and *"Risk"*. In this case, the external concepts associated with instances of *"Finding"*, have two concept frequencies corresponding to the contexts *"Indication-hasFinding-Finding"* and *"Risk-hasFinding-Finding"*. Depending on the query context, one of the concept frequencies is used in query relaxation. In Figure 4, we show a snippet of SNOMED CT with the external concept frequency populated. The external concepts in brackets are all mapped from different instances of *"Finding"* in the domain KB, so they can be used in two different contexts (*"Indication-hasFinding-Finding"* and *"Risk-hasFinding-Finding"*). Hence, they are associated with two concept frequencies. For example, *"headache"* is the only direct descendant of *"craniofacial pain"*, and the frequency of *"craniofacial pain"* is the frequency of itself, together with the one of *"headache"*. Accordingly, the frequency of *"pain of head and neck region"* is a summation of the frequencies of *"craniofacial pain"*, *"pain in throat"*, and itself, which is 19164 (i.e., 18878 + 283 + 3) in the context of *"Indication-hasFinding-Finding"* and 1656 in the context of *"Risk-hasFinding-Finding"*.



Head finding

<Indication-hasFinding-Finding, 0>
<Risk-hasFinding-Finding, 0>
Frequent headache
<Indication-hasFinding-Finding, 0>
<Risk-hasFinding-Finding, 0>

Figure 4: Snippet of SNOMED CT with frequencies.

Finally, all of these frequencies are normalized between [0, 1], which corresponds to the probability of a concept appearing in the corpus. The root concept has the highest normalized frequency of 1, because all concepts in the external knowledge source are its descendants.

Sparsity of external knowledge source. The commonly used external knowledge sources, such as SNOMED CT, are comprehensive, consisting of an excessive amount of information describing the domain. They often consist of rich domain vocabularies associated with deep hierarchies. On the contrary, the given KB is often relatively smaller compared to the external knowledge source. Therefore, only a small subset of the external concepts may have corresponding instances in the KB. Any pair of concepts could be connected through multiple intermediate ones, which makes finding semantically related concepts prohibitively time-consuming for an online system. One straightforward approach would be computing the pairwise similarity between all concepts offline. However, this leads to unnecessary computations and space consumption, since most of these precomputed similarities may not even be used during the online query relaxation.

In the offline ingestion phase, we alleviate the above issue by introducing additional application-specific edges to the external knowledge source. Specifically, an additional directed edge is introduced from an external concept A to an external concept B, if all the following conditions are satisfied: (1) A and B are not directly connected (i.e., one-hop neighbors), (2) A is a descendant of B, and (3) at least one of the two concepts has a corresponding instance in the given KB. Consequently, they become one-hop neighbors with respect to the application. The distance between two external concepts is attached to the new edge so that the original semantic information between two concepts is preserved. This way, external concepts come closer, avoiding unnecessary delays in the online query relaxation phase.

[Chronic kidney disease stage 1 due to benign hypertension]
2-hop
2-hop
3-hop
3-hop

Figure 5: External knowledge source customization.

Example 2. In Figure 5, *"chronic kidney disease stage 1 due to hypertension"* is 3 hops away from *"kidney disease"*, which has a corresponding instance in the KB. By introducing an additional edge (the dashed line) between these two external concepts, they are only 1 hop away. Therefore, more semantically related concepts are within a close distance, and the semantic similarity between two external concepts remains unchanged since the original path information (3-hop) between them is attached to the new edge.

Overall, the offline external knowledge source ingestion process is summarized in Algorithm 1. The algorithm receives as input the medical KB (as domain ontology O and instances I) and the external knowledge source EKS, and it returns the set of possible contexts C, the frequencies F of the external concepts for each context, the mappings M from instances to external concepts, and the set of external concepts that are marked with a flag FEC. The algorithm consists of 3 almost independent procedures: context generation, mappings, and concept frequency. Additionally, for efficiency, sparsity of external knowledge source is also handled in the same loop as concept frequency, even though one does not depend on the other.

In Lines 1-4, we create the set of possible contexts, based on the domain ontology's relationship, along with their domains (source concepts) and ranges (destination concepts). In Lines 5-11, we find an external concept A as a mapping for every instance $i \in I$, if such exists, based on a chosen mapping function, and return the set of mappings M. At the end of this loop, the set FEC contains all the external concepts that have been marked with a flag, i.e., all the external concepts that have a corresponding instance in I. In Line 12, we sort the external concepts in topological order, such that the descendants precede their ancestors (note that EKS is a DAG). This way, we can easily compute the frequency of each external concept for a given context (Lines 14-18), using the recursive function of Equation 2. Since the external concepts are already topologically sorted, we add application-specific edges to alleviate the sparsity of EKS in the same loop (Lines 19-23). Specifically, in Line 21, we add an edge from external concept A to external concept B, when all three conditions (previously described) are satisfied, while attaching their original distance (as $|shortestPath(A, B)|$) to the new edge.

Time complexity analysis. The time complexity of external knowledge source ingestion can be broken down into the following parts. First, creating all possible contexts requires iterating through all relationships ($|R|$) in the domain ontology. Hence the time complexity is $\Theta(|R|)$. Second, the time complexity of finding an external concept A for every instance depends on the chosen method. For example, using word embeddings to find mappings requires $\Theta(|I| \cdot Cost(lookup))$, where $|I|$ denotes the total number of instances and $Cost(lookup)$ denotes the constant cost of embedding lookup for each instance. If an approximate string matching algorithm is used, then the time complexity becomes $O(|I| \cdot mn)$, where $O(mn)$ denotes the time complexity of typical approximate string matching algorithm (m and n are the lengths of two strings). Third, topological sorting of all external concepts requires $O(|V| + |E|)$ time complexity, assuming that V is the set of concepts and E is the set of relationships in the external knowledge source. Fourth, the time complexity of computing frequency of each external concept for all possible context is $O(|V| \cdot AVG(contexts))$, where $AVG(contexts)$ denotes the average number of contexts per concept in the domain ontology. Regarding adding application-specific edges to EKS, we ignore its time complexity since the number of concepts satisfying is much less than $|V|$. In summary, the total time complexity is $\Theta(|R|) + \Theta(|I| \cdot Cost(lookup)) + O(|V| + |E|) + O(|V| \cdot AVG(contexts))$. Note that the external knowledge source ingestion is an offline process that is executed only once.

Algorithm 1 Knowledge Source Ingestion Algorithm.

```
Input: Domain ontology $O$, Instances $I$, External Knowledge
       Source $EKS$

14: while $Q$ is not empty do
15:     $A \leftarrow Q.next()$
16:     for each $c \in C$ do
17:         $F \leftarrow F \cup \{(A, c, freq(A))\}$          // see Equation 2
18:     end for
        // External knowledge source customization
19:     for each $B \in ancestors(A, EKS) \setminus parents(A, EKS)$ do
20:         if $A \in FEC$ or $B \in FEC$ then
21:             $EKS.addEdge(A, |shortestPath(A, B)|, B)$
22:         end if
23:     end for
24:     $Q.remove(A)$
25: end while
26: return $C, F, M, FEC$
```

5.2 Online Query Relaxation

Given a query term, the goal of online query relaxation is to identify the semantically related instances contained in the given KB by leveraging the external knowledge source. In this subsection, we present a novel similarity measure that leverages the information content from the medical KB, the structural information in the external knowledge source, as well as the contextual information from the query.

Contextual information. As described earlier, the possible contexts of a query term mapped to a concept in the domain ontology, are the relationships of the concept to its adjacent concepts. With the contextual information, the online query relaxation phase can choose the appropriate concept frequency to use in Equation 2.

Example 3. For the query *"what are the risks of using aspirin"*, the context is *"Drug-cause-Risk"*. As shown in Figure 1, *"Risk"* has three descendants *"Black Box Warning"*, *"Adverse Effect"*, and *"Contra Indication"*. Assuming that the query term *"aspirin"* cannot be found in the given KB, then the online query relaxation would consider related conditions in the context of *"Drug-cause-Risk"*. Hence, the concept frequency used for the similarity measure should be the total frequency of all three descendants of *"Risk"*.

In case the contextual information is not available for online query relaxation, our method can aggregate the frequencies (i.e., all possible contexts) associated with an external concept. As verified in the experimental evaluation section, the contextual information greatly improves the quality of the results.

Structural (Path) information. As described above, external knowledge sources contain generalization and specialization relationships between concepts. Generalizing the query term in a user query may cause information loss [24]. For example, as shown in Figure 4, *"headache"* can be generalized to *"craniofacial pain"*, which can in turn be generalized as *"pain of head and neck region"* including *"pain in throat"*. Apparently, *"pain in throat"* no longer describes pain in head, even if it is as close to *"craniofacial pain"* as *"frequent headache"*.

In this case, solely relying on the IC similarity measure (Equation 3) with contextual information can be insufficient as it cannot differentiate the semantic difference between specialization (i.e., the opposite direction of subsumption edges in the external knowledge source) and generalization (i.e., following the direction of subsumption edges). We tackle this challenge by assigning different weights to generalization and specialization in the external knowledge source. The weight of a path connecting two external concepts A and B is thus computed as:

$$p_{A,B} = \prod_{i}^{|D|} w_i^{D-i}, \tag{4}$$

where the distance between external concepts A and B is $|D|$, and w_i indicates the weight of the i-th edge from A to B. The intuition is that we penalize a generalization and the penalty is more if it appears early on in a path from A to B. In fact, such distinction helps us to better capture the semantic similarity between a pair of concepts based on their relative locations in the external knowledge source.

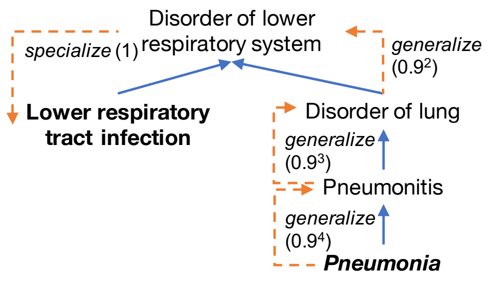
To learn the weights of both generalization and specialization, simple statistical regression analysis [7] such as logistic regression can be used. In our empirical study, the weights of generalization and specialization are set to 0.9 and 1, respectively.

Example 4. In Figure 6, the penalty associated with the path (dashed orange lines) connecting two external concepts can be different, depending on which concept corresponds to the query term. In this example, there are 4 hops between *"pneumonia"* and *"lower respiratory tract infection"*. If the query term is *"pneumonia"*, it would be penalized more as the first 3 hops in the path starting from *"pneumonia"* to *"lower respiratory tract infection"* are all generalizations (Figure 6(a)). On the other hand, if the query term is *"lower respiratory tract infection"*, it only suffers from one generalization at the beginning (Figure 6(b)).

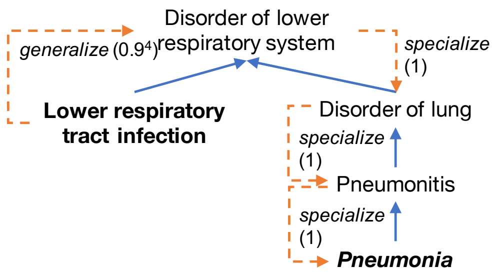
Putting it all together. Overall, the online query relaxation uses a novel similarity measure, which takes as input the information content, the contextual information, and the structural information to find semantically related concepts.

$$sim(A, B) = p_{A,B} \times sim_{IC}(A, B). \tag{5}$$

For a given query term, the query relaxation method first finds the corresponding external concept A in the external knowledge source. Then, it searches for the concepts within a distance r from A. Last, our method retrieves the pre-computed similarity between A and each external concept in its neighborhood. Top-k relaxed results are returned based on their similarity scores, where k is application-specific and defined by users. The radius r can be set in different ways. Namely, it can be set as a fixed value by empirical studies, or dynamically decided if a fixed r cannot provide k results.



(a) Path 1: From Pneumonia (query term) to Lower respiratory tract infection.



(b) Path 2: From Lower respiratory tract infection (query term) to Pneumonia.

Figure 6: Example of paths between two external concepts.

Overall, the online query relaxation process is summarized in Algorithm 2. The algorithm receives as input a query term q, along with its associated context c, the instances I from the given KB, the external knowledge source EKS, the set of external concepts that are marked with a flag FEC, the mappings M from I to EKS concepts, the radius r and an integer k, and it returns the top-k results Res from I.

Algorithm 2 Online Query Relaxation Algorithm.

```
Input: Query term $q$, Context $c$, Instances $I$, External Knowledge
    Source $EKS$, Flagged external concepts $FEC$, Mappings $M$,
    radius $r$, integer $k$
Output: Top-$k$ results $Res \subseteq I$
1: $A \leftarrow mapping(q, EKS)$ // concept $A$ corresponds to $q$ in $EKS$
   ▷ candidates are flagged concepts within radius $r$ from $A$
2: $Candidates \leftarrow neighbors(A, EKS, r) \cap FEC$
3: $sort(Candidates, sim(A, B))$          // Equation 5 for context $c$
4: $Res \leftarrow \emptyset$
5: while $|Res| \leq k$ and $|Candidates| > 0$ do
6:     $B \leftarrow Candidates.pop()$ // get next element and remove it
7:     $Res \leftarrow Res \cup \{i|(i, B) \in M\}$
8: end while
9: return $Res$
```

In Line 1, we retrieve the external concept A that corresponds to the query term q, using the same mapping function as in Algorithm 1. Then, we get the set of candidate external concepts within radius r from A, which are marked with a flag, i.e., members of FEC (Line 2), and we sort them in descending order of similarity to A (Line 3). Finally, we iterate through the sorted candidates and add to the results Res the instances i that map to those candidates, until k results have been retrieved, or there are no more candidates (Lines 5-8).

Time complexity analysis. For online query relaxation, we again assume that V is the set of concepts in the external knowledge source and the total number of flagged external concepts FEC is N. Then finding a corresponding external concept A corresponding to the query term q requires $O(|V|)$ time in the worst case. Returning all flagged external concepts within radius r from A requires $O(N)$ time in the worst case (i.e., r is large enough to include all flagged external concepts). Sorting these candidates and returning the top-k results take $\Theta(NlogN)$ and $\Theta(k)$ time, respectively. Hence, the total time complexity of online query relaxation is $\Theta(NlogN)$.

6 APPLICATIONS OF QUERY RELAXATION

Our proposed method is applicable and beneficial to various natural language interface systems, including conversational systems, question and answer systems, as well as natural language query systems to KBs. In this section, we describe how to integrate the query relaxation method with two state-of-the-art systems for the medical data set *MED*, that is used to support evidence-based clinical decisions and patient education, and SNOMED CT as the external knowledge source, since it is one of the most comprehensive and widely used medical knowledge sources.

6.1 Integration with a Conversational System

In the following, we describe how we extended a conversational system [33] that is built on top of IBM Watson Assistant [21], to include query relaxation. The query relaxation method is implemented in Java and is deployed on IBM Cloud™ to interact with Watson Assistant. The medical data set is stored in IBM Db2® Database and the external knowledge source (SNOMED CT) is stored in a graph database (i.e., JanusGraph[6]).

As described in Section 4, the possible intents (i.e., contexts) are bootstrapped based on the domain ontology, and our query relaxation method provides training examples to Watson Assistant for intent classification. At query time, Watson Assistant provides the input to our query relaxation method in the form of a [query term, context] pair.

In this case, the context comes from the intent classifier of the conversational system. Regarding the query term, Watson Assistant extracts entity mentions from an input natural language query[7] and passes the unknown entity mentions as query terms to our relaxation method. Next, we showcase two scenarios in which our query relaxation are used (Figures 7 and 8).

The first scenario is to expand the set of queries by using query relaxation when there is no answer in the KB for the user query. For example, when the query term (*"pyelectasia"*) is unknown (i.e., no matching concept in the given KB), Watson Assistant triggers the query relaxation method to find a list of semantically related concepts that are contained in the given KB by utilizing the external knowledge source (i.e., SNOMED CT). As shown in Figure 7, these additional concepts are then used as a means to "repair" the conversation and smoothly redirect the user to the information contained in the KB. Consequently, the conversation can continue with follow-up questions around the expanded result, *"kidney disease"*. Without our query relaxation, Watson

You can also ask a series of questions about the same drug:
What is the adult dose of digoxin for heart failure?
Renal dosing?
Contraindications?
Adverse effects?

What drug treats pyelectasia
I've found multiple results for condition. Which one are you looking for?
- Kidney disease
- Renal impairment
- Disorder of the urinary system

Kidney disease
Is it for Adult or Pediatric?
adult
Here are the drugs used for adult kidney disease:
Effective
- Anemia in chronic kidney disease, In patients on dialysis and not on dialysis, to decrease the need for red blood cell transfusion
  - Epoetin Alfa
  - Epoetin Alfa-epbx
- Autosomal dominant polycystic kidney disease

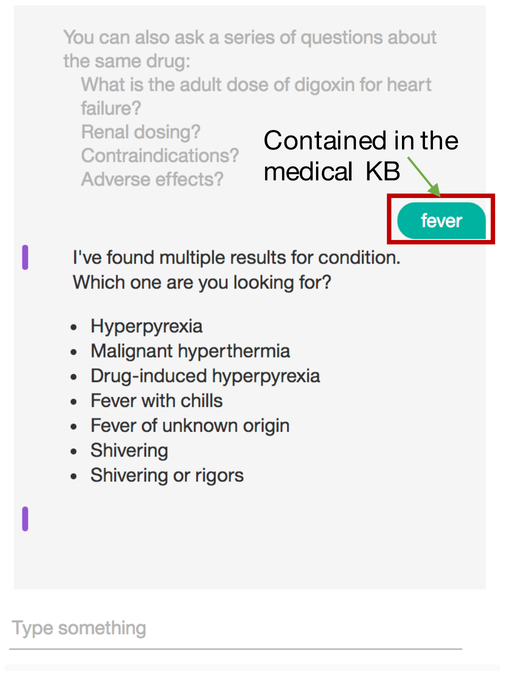
Figure 7: Integration with Watson Assistant (Scenario 1).

Assistant would not be able to return any useful information except replying messages such as *"I don't understand"*. Worse yet, it may return irrelevant and incorrect information to the user, as illustrated in Section 7.2.

In the second scenario, we use query relaxation to expand query answers beyond what matches to the query term in the KB directly. As seen in Figure 8, the query term (*"fever"*) is identified by Watson Assistant as an instance of the concept (*Finding*) in the medical KB. Without query relaxation, identifying *"fever"* as *Finding* triggers one predefined intent *"Indication-hasFinding-Finding"* in Watson Assistant. Hence, the information such as syndromes and treatments for *"fever"* would be returned to the user. With our query relaxation method for concept expansion, 7 additional concepts related to *"fever"* are returned before providing any information specific to *"fever"*. Hence, it offers more opportunities for the user to explore the information contained in the given knowledge base.

6.2 Integration with a Natural Language Query System

Currently, we are also working on incorporating our method with a natural language query (NLQ) system [23, 35]. The NLQ system is different from the previously described conversational system as it targets one-shot complex queries. In this case, the NLQ system receives a natural language query as input and interprets it over the domain ontology to produce a structured query such as SQL. The proposed query relaxation method is utilized to increase the flexibility and robustness of query interpretation.



You can also ask a series of questions about the same drug:

What is the adult dose of digoxin for heart failure?

Renal dosing?

Contraindications?

Adverse effects?

fever

I've found multiple results for condition. Which one are you looking for?

- Hyperpyrexia
- Malignant hyperthermia
- Drug-induced hyperpyrexia
- Fever with chills
- Fever of unknown origin
- Shivering
- Shivering or rigors

Figure 8: Integration with Watson Assistant (Scenario 2).

We outline the solution with a running example from the medical domain as captured in Figure 1 for the query: *"What are the risks caused by using Aspirin with pyelectasia"*.

Evidence generation. In the very first step, the NLQ system tries to identify all the different mentions of ontology elements in the input natural language query [35]. The NLQ system iterates through all the word tokens in the query and collects evidences of one or more elements which have been referenced in the input query. These elements can be concepts or relationships in the domain ontology, as well as the instances of those concepts in the knowledge base.

In general, a token can match multiple elements in the ontology. For example, the token *"risks"* is mapped to a concept *"Risk"*, and the phrase *"caused by"* is mapped to *"cause"* relationship in the ontology. *"Aspirin"* is mapped to the concept of *"Drug"*.

There are two types of evidence: (*i*) a *metadata* evidence is generated by matching the token to the ontology elements (e.g., *"Risk"*), and (*ii*) a *data-value* evidence is generated by looking up a token in the knowledge base (e.g., *"Aspirin"*). The evidence for a token can either be *metadata* or *data-value*, but not both [35].

Due to the colloquial and imprecise terminology used in natural language queries, our query relaxation method is particularly useful to increase the capability of query understanding. The NLQ system relies on the semantically related results from our query relaxation method to match a token to either a metadata or a data-value evidence. The NLQ system associates these semantically relevant results with ontology elements on the fly, as shown in Figure 9. Again, if *"pyelectasia"* is not contained in either domain ontology or knowledge base, our query relaxation returns semantically relevant results (e.g., *"kidney disease"*, *"nephropathy"*, etc.), which can be then mapped to the concept of *"Finding"* in the domain ontology.

Interpretation generation. Note that only one element from the evidence set of each token corresponds to the correct query. In this phase, the NLQ system tries all such combination of elements

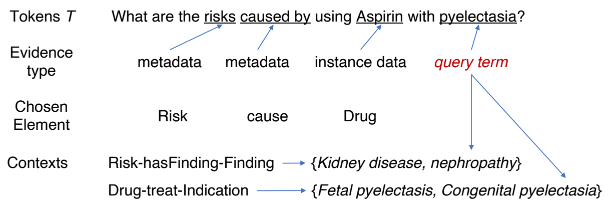


Figure 9: Evidence set.

from each evidence set. Each such combination, called *selection set*, is used to generate an interpretation, which is represented as a sub-graph in the semantic graph connecting one evidence for each token for each ontology element [35]. This semantically grounds the words in the input query to specific contexts by referring to elements in the semantic graph. Connecting these referred elements produces a unique interpretation for the given natural language query based on the ontology semantics.

For each selection set, a sub-tree, called *Interpretation Tree*, is computed, which uniquely identifies the relationship paths among the evidences in the selected set [35]. It is computed by connecting all the elements in the selected set in the semantic graph and satisfying the following constraint. The NLQ system uses a Steiner-tree-based algorithm [35] and ranks the interpretations according to their compactness to generate an interpretation of minimal size for a selected set. Note that query relaxation returns a similarity score associated with each result value. We are currently extending the ranking algorithm to take this ranking score into account, in addition to compactness.

For example, the top ranked interpretation as found from selected set is *ITree* = { (*Drug* ⟶ *cause* ⟶ *Risk* ⟶ *hasFinding* ⟶ *Finding*), (*Drug* ⟶ *treat* ⟶ *Indication* ⟶ *hasFinding* ⟶ *Finding*) }. Two interpretations have the same compactness. In this case, if we take into consideration the similarity scores associated with the relaxed results, the former interpretation would be more preferable since *"Kidney disease"* is the most semantically similar concept to the search term *"pyelectasia"*.

7 EXPERIMENTAL EVALUATION

In this section, we describe experiments using a medical data set (*MED*) to show the efficacy of our proposed query relaxation method in terms of precision, recall, and F1-score. We also conduct user studies, in which we use Watson Assistant as the conversational interface.

7.1 Experimental Setup

Data set. We use a medical data set (*MED*) that is used to support evidence-based clinical decisions and patient education. The total size of this data set is around 1.2 GB. The ontology corresponding to *MED* consists of 43 concepts and 58 relationships. We chose SNOMED CT as the external knowledge source since it consists of comprehensive information regarding terms, synonyms, and definitions used in clinical documentation and reporting.

Users. 20 Subject Matter Experts (SMEs) participated in our experiments. They all have deep knowledge and understanding of the medical domain, and are able to distinguish between a correct and a wrong answer.

Methodologies. We conducted two sets of experiments to evaluate the efficacy of our proposed query relaxation method with respect to precision and recall. First, we show the superiority of our method compared to alternative methods. Second, a user study demonstrates the benefit of applying our query relaxation method in a conversational system.

7.2 Evaluation Results

Precision and recall. We chose 100 commonly used concepts of medical conditions, and used the methods described below to identify the semantically related concepts. The participants were asked to evaluate whether these relaxed concepts are indeed related to the given ones.

We first study the effectiveness of the methods used for mapping instances from the given KB to the external knowledge source, including exact string matching (*EXACT*), approximate string matching with an edit-distance threshold $\tau = 2$ (*EDIT*), and a variant of word embedding to support longer pieces of text [3] (*EMBEDDING*). Table 1 reports *Precision*, *Recall* as well as *F1-score* of these three mapping methods.

We observe that word embedding achieves the best overall result quality. This provides our query relaxation method a solid foundation to identify semantically related concepts in the neighborhood of these concepts. On the contrary, exact and approximate string matching suffer from lower recall compared to the word embedding method. Hence we used word embeddings in the rest of the experiments as the matching method.

Table 1: Accuracy of mapping methods.

Methods	Precision	Recall	F1
EXACT	**100**	83.33	90.01
EDIT	96.36	88.33	92.17
EMBEDDING	96.49	**91.67**	**94.02**

Next, we compare our proposed query relaxation method (*QR*) against its variants as well as alternative approaches, including our proposed method without the frequency information from the corpus (*QR-no-corpus*), our proposed method without the contextual information (*QR-no-context*), a baseline IC-based semantic measure (*IC*) [2], a baseline method [3, 8] using both pre-trained embeddings [32] (*Embedding-pre-trained*) and embeddings we trained on a given medical document corpus (*Embedding-trained*).

Table 2: Overall effectiveness.

Methods	P@10	R@10	F1
QR	**90.51**	**82.64**	**86.40**
QR-no-context	85.45	77.27	81.15
QR-no-corpus	78.23	70.91	74.39
IC	75.55	68.18	71.68
Embedding-pre-trained	66.14	60.13	62.99
Embedding-trained	79.37	71.81	75.40

Table 2 reports *Precision@10*, *Recall@10* as well as *F1-score* against the *MED* data set. *Precision@10* corresponds to the number of relevant results among the top 10 returned concepts, *Recall@10* is the proportion of relevant results found in the top 10 returned concepts to the total number of relevant results, and *F1-score* is the harmonic mean of *Precision@10* and *Recall@10*. Our proposed methods including (*QR-no-corpus* and *QR-no-context*) are more accurate than the baseline *IC*. Specifically, we observe that *QR-no-context* still returns higher quality results than the baseline *IC*. This shows that differentiating specialization and generalization relationships helps capturing the semantic similarity between a pair of concepts. It is not surprising that *QR-no-context* further improves the result quality when the frequency information is available from the corpus. Regarding *Embedding-pre-trained*, we observe that it achieves the lowest precision and recall among all methods. This is expected as the model was trained on a different medical corpus and many of the words contained in SNOMED CT are out of its vocabulary. For the embedding of multi-word query terms, we used the average its words' embeddings. The result quality of *Embedding-trained* is much improved as we trained the embedding model on our medical document corpus, and the embedding of a (multi-word) query term is further computed based on [3]. However, without the contextual information from the query, many concepts in the given KB are cluttered with the query term in the low-dimensional vector space. Hence the quality of *Embedding-trained* is still not as good as *QR*. In summary, our method *QR*, which incorporates both the frequency information from the corpus, as well as the context from the query, achieves the highest precision and recall.

User study. In this user study, participants were asked to complete two tasks to evaluate the query understanding capability of a conversational system with and without our query relaxation method. The participants were allowed to get familiar with the conversational system over the given KB. In task 1 (*T1*), we asked participants to come up with 20 questions around 20 given concepts (i.e., condition names). For example, the participant may ask "what drugs are used to treat [*condition*]" or "what drugs cause [*condition*]". In task 2 (*T2*), the participants were allowed to come up with 10 questions of their own choice about anything in *MED*.

The participants were then asked to grade the quality of the relaxed results in a scale of 1-5. If the system returns a correct response in the first attempt, it receives 5 points. If the system fails to return a correct response, the participants can rephrase their questions for at most 4 more times. Each time a wrong result is returned, the participant subtracts a point. For example, if the correct answer is returned after 3 attempts (i.e., 2 failed attempts) the participant gives in total 5-2 = 3 points. In addition to the score, we also asked the participants to provide detailed feedback.

Table 3: Watson Assistant with and without QR.

	QR		***no QR***	
Score	***T1***	***T2***	***T1***	***T2***
1 (Very dissatisfied)	2.1%	10.55%	13.06%	11.11%
2 (Dissatisfied)	10.35%	11.07%	16.87%	38.26%
3 (Okay)	25.59%	29.33%	36.29%	30.85%
4 (Satisfied)	35.21%	33.37%	18.25%	12.47%
5 (Very satisfied)	26.85%	15.68%	15.53%	7.31%
AVG	3.73	3.31	3.06	2.67

Table 3 shows the aggregated grades received by our query relaxation method for the two tasks described above. The numbers in the table show the percentage of each particular grade. Clearly, the conversation system with query relaxation achieves a substantially higher score than the one without query relaxation in both tasks. The average grades of the system with query relaxation in both tasks are 20% higher than the ones without relaxation. Specifically, our query relaxation method performed slightly better in *T1* than *T2*. The reasons are that the questions used in *T2* were completely from the participants and a non-trivial number of questions (9 out of 200) do not have an answer in the given KB, as opposed to *T1*, where 20 concepts were provided to the users. Moreover, the feedback from the participants indicates that the lower grades in Table 3 are due to other reasons orthogonal to the quality of our query relaxation method.

Specifically, there are 7 incidences in which the expected answers are not contained in the given KB (*MED*). There are 11 incidences where the users complained about the conversational flow irrespective of the query relaxation results. For example, some users prefer smaller number of interactions with the conversational system in order to complete their tasks. Some users failed to follow the instructions, and hence ran into unexpected follow-up questions. Moreover, there are 10 incidences that the users did not provide any negative feedback but gave a low grade such as 1 or 3. Last but not the least, the SMEs reported 6 instances that the amount of information returned is overwhelming even though the relaxed results are semantically correct. All these cases resulted in low grades, including 1, 2, and 3. Note that all the above cases are counted in Table 3. One straightforward solution to address these issues would be to incorporate the user's relevance feedback [39] in the query relaxation method, and to progressively improve the relaxed results.

8 RELATED WORK

Natural language querying over KBs. Several approaches have been recently investigated to build natural language interfaces to KBs. In [13], query templates are learned from KBs and question answering corpora. Wang et al. [41] leverage terms and their relationships from a web corpus and map them to related concepts using a KB. Then, a random walk-based algorithm is proposed for understanding the terms in a given query. The semantic parsing methods proposed in [4] use a domain-independent representation derived from combinatory categorical grammar parsers. Most recently, a supervised learning framework [20] is introduced to exploit sentence embedding for the medical question answering task. However, they usually require a large labeled corpus or pairs of questions and answers. Our approach is complementary to these methods since they only focus on answering queries with 'strict' execution, which often results in no answers. Our query relaxation expands the domain vocabulary used in queries and provides more semantically related results.

Query relaxation for databases. The database community has developed query relaxation methods that return information beyond a standard query. Query relaxation expands the query selection criteria to include additional relevant information, often by consulting a semantic model of the data domain. Gaasterland [18] introduces query relaxation techniques in deductive databases, using logic rules to specify legal relaxation constraints. Query relaxation [11] is introduced to relational databases using type-abstraction hierarchies to find semantically similar query results. A taxonomy-based relational algebra is proposed to extend the capability of selection and join by relating values occurring in the tuples with values in the query using the taxonomy [26]. Poulovassilis et al. [31] applied query approximation and query relaxation techniques based on RDFS inference rules to the evaluation of conjunctive regular path queries (CRPQs) over graph data. Our approach is different from the above work as we leverage external knowledge sources to expand the domain vocabulary. Further, our approach uses the domain ontology and context information to differentiate the semantic subtleties among instances.

Semantic similarity measures. Among various semantic measures, path finding measure [42] is based on the shortest path separating concepts, which traverses the LCS of two concepts. IC-based measures can be estimated solely from the structure of a taxonomy [36], or from the distribution of concepts in a text corpus and a taxonomy [34]. Our semantic similarity measure is designed upon these measures and overcomes their limitations by utilizing the domain ontology to differentiate the semantic subtleties. Hence our method can achieve significant gain of recall without sacrificing the precision.

Recent works demonstrated that deep learning models built at word [8, 30] or sentence [3, 14] level can be used for semantic similarity estimation. However, these methods demand high quality training data sets, which is critical and expensive in reality. Moreover, directly applying word or sentence embeddings to our problem is not sufficient since the structural and contextual information are not considered when the model is trained. Hence, we use word and sentence embeddings for linking the given KB to the external knowledge source and build our similarity measure on top of it.

9 CONCLUSION

In this paper, we present a novel two-phase query relaxation method that leverages external knowledge sources to expand answers for querying medical KBs. We introduce a novel similarity metric to empower our query relaxation method to identify semantically related concepts. Our method is successfully integrated with two exemplary systems, a conversational system and a natural language query system, respectively. Our experiments show that our query relaxation method for the medical KB outperforms state-of-the-art methods, including deep learning-based ones, in precision and recall. We also conduct a user study demonstrating how our query relaxation method expands the query results and improves their quality for medical KBs.

ABSTRACT

In the context of urbanization and the rapid growth of energy demand, understanding the spatial and temporal dynamics of urban energy use is crucial for identifying energy-saving potentials. In this demo, we present a visual analysis tool, VAP, that allows users to explore the dynamics of urban energy use at different spatial and temporal scales. In contrast to traditional statistical and machine learning methods, the visual analysis based tool focuses on analytical thinking, user interactions and answering business questions by examining different visual analysis views. In the demonstration, conference attendees will interact with VAP and learn its capabilities in discovering typical consumption patterns and spatio-temporal shift patterns from a real-world case study of electricity.

1 INTRODUCTION

In recent years, the availability of high-resolution energy consumption data has exploded at an unprecedented rate, along with the diffusion of smart metering technology. The energy sector is increasingly in need of advanced tools and methods to gain insights from big smart meter data sets for decision-making purposes [1]. However, traditional statistical and machine learning methods fail or are too complex to answer some central business questions such as *"What is the consumption trend or pattern over time?"* and *"Does mass mobility affect energy demand?"*. On the other hand, these questions can be much easier to answer through visual analysis supported by human cognitive capabilities. The visual analysis focuses on analytical reasoning, facilitated by interactive user interfaces, and exploring the views that most effectively answer these questions [2]. The visual analysis encompasses several disciplines, including geographic information systems, information visualization, and data computing. Visual analysis has been employed in bioinformatics, physics, astronomy, and climate, but until now rarely in energy.

The most relevant work we have found is the tool implemented in [3] to study energy consumption in the Chicago area in connection with census data. This tool supports the disaggregation analysis on several spatial levels, but without further functionalities, e.g. for the analysis of spatio-temporal patterns and demand shifts caused by mass behaviors. However, much research has been attempted on spatio-temporal data analysis, which involves the identification of object spatial positions at specific moments, e.g., [2], and the detection of anomalies such as traffic congestion [4], cyber attacks [5], medical diagnoses [6] and more. We believe that there is great potential for visual analysis in the applications of energy management systems, because especially many areas in this sector can achieve better results efficiently and effectively with the help of visual analysis. Among others, these include the study of consumer behaviors and living habits, the planning of energy supply, the development of energy strategies and the design of personalized services.

In this demo, we introduce a visual analysis tool, *VAP*, to support the study of urban energy consumption patterns and dynamics on different spatial and temporal scales. This tool is unique in at least two ways:

- Unlike traditional segmentation analysis, which uses clustering algorithms to find typical patterns, VAP supports typical pattern recognition through visual mining. High-dimensional time series are first reduced to low-dimensional data points, and closely placed together on a view according to their similarity, then users can identify patterns by interactively selecting the points on the view. Therefore, pattern recognition is an interactive process embedded in human cognitive recognition. The identified patterns represent customers with similar consumption behaviors or habits, which can be used to develop targeting demand-response programs, forecast energy consumption, and provide personalized services.
- VAP supports the analysis of energy shift patterns in different spatial and temporal scales. The variation in energy demand over time has been studied intensively, while the variation in demand across different spatial spaces has rarely been studied. The demand shift patterns can be identified and visualized with VAP, and the shifts in high energy demand over time can help utilities plan energy distribution and improve energy flexibility.

In Section 2, we will describe the visual analysis framework, the tool, and the pattern discovery methods. In Section 3, we will outline the demonstration scenarios that illustrate how VAP can be used to discover typical patterns and shift patterns of energy demand through visual analysis in a real-world case study. The conference attendees can interact with VAP by first asking business questions, then probing the answers through interactions with the tool, and finally gaining knowledge from the visualized outcomes. This demo presents the elements that drive research for visual analysis in the energy sector, and provides an outlook

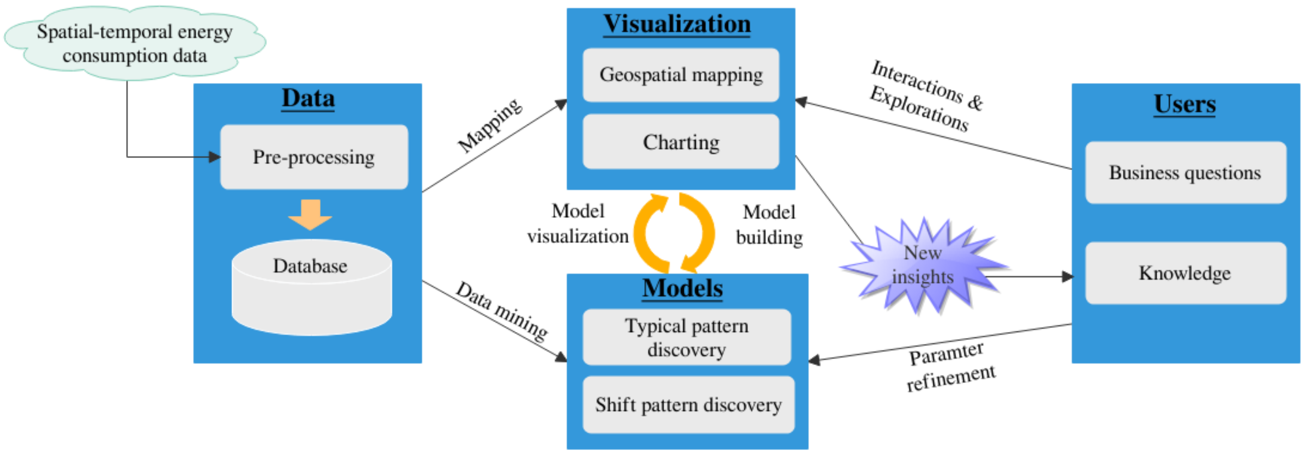

Figure 1: Overview of the visual analysis framework for spatio-temporal pattern discovery

on the use potentials on a higher spatial scale as well as on other urban energy uses.

Through the demonstration of VAP, we hope to increase the awareness of the emerging technologies for the domain-specific applications within the data management community. We also hope that this demonstration will stimulate the research of applying new database technologies in the applications for smart energy systems, including data acquisition, processing, storage, analysis and visualization. We plan to make the code open-source and create an online demonstration version for others to use, experience and extend.

2 APPROACH

Visual analysis aims to help users gain insights into the data by interacting with the visual diagrams that interpret the data. The overview of the visual analysis framework is illustrated in Figure 1, which integrates the components including Data, Models, Visualization and Users. The data for this demo is spatio-temporal energy consumption data from smart meters. The data were preprocessed, including removal of anomalies and correction of missing values. To derive knowledge from the data, the models including typical pattern recognition and spatio-temporal shift pattern recognition were implemented. The visualization aids in the presentation of the analysis results, knowledge generation and communication with users. Users typically gain knowledge by first asking business questions and then exploring analytical views to answer their questions. This is an iterative process of discovering knowledge from the data and refining parameters of the models.

2.1 Pattern recognition models

VAP supports typical consumption pattern discovery and spatial-temporal shift pattern discovery of energy demand using the visual analysis method. The two pattern recognition models are described as follows.

Typical pattern discovery model. Typical consumption patterns are often used to segment customer groups for offering personalized services in the energy sector. In order to visually analyze typical consumption patterns, high-dimensional time series must first be reduced to a lower dimension so that it can be displayed in a low-dimensional space. The proposed model supports the t-distributed Stochastic Neighbor Embedding (t-SNE) [7] and the Multi-Dimensional Scaling (MDS) [8] for high-dimensional time series data reduction. The positions of the resulting low-dimensional data points on the view are determined by minimizing the Kullback-Leibler divergence defined as follows.

$$KL(P\|P') = \sum_{i\neq j} P_{ij} \log \frac{P_{ij}}{P'_{ij}} \tag{1}$$

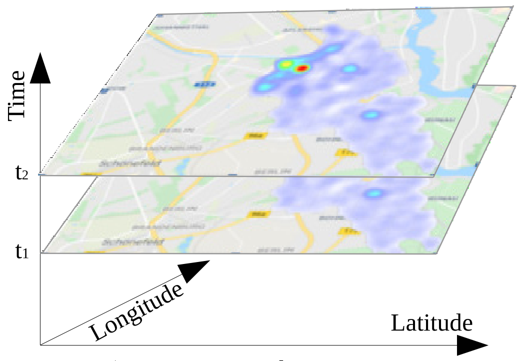
where P_{ij} is the similarity probability distribution between the high-dimensional objects, o_i and o_j, while P'_{ij} is the similarity probability distribution between the reduced low-dimensional objects, o'_i and o'_j. Here, the Pearson correlation coefficient is used as the distance metric for calculating the similarity as it can be better to reflect the correlation of the trend between two time series [9]. The similarity probability distribution of the low-dimensional objects can be obtained by:

$$P'_{ij} = \frac{\left(1 + \left\|o'_i - o'_j\right\|^2\right)^{-1}}{\sum_{k\neq l}\left(1 + \left\|o'_k - o'_l\right\|^2\right)^{-1}} \tag{2}$$

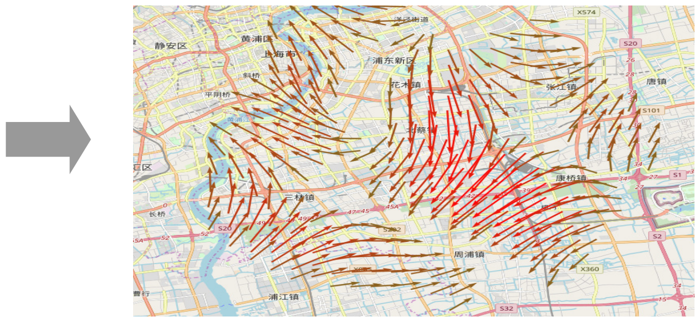
where k and l are the indices of the objects; and $\|\cdot\|$ represents the distance. The similarity probability determines whether the two objects should be placed closely or far away on the view, i.e. the more similar, the closer.

With the reduced data points, typical patterns of energy consumption can be interactively identified by selecting the closely placed points on the view in a low-dimensional space.

Shift pattern discovery model. This model is used to capture the changes of high energy demand locations over time. The shift pattern of energy demand is essential for planning the energy supply between different geographical areas. For example, the high-demand area may shift from commercial to residential when people go home after work. This can be happening within the time interval of 1 - 2 hours, but the detection of demand shifts is helpful for energy supply planning. Here, we use the flow map method [10] to visualize the spatial migration of high-energy demand flow, which implies the flow between spatially different areas. Figure 2 illustrates the flow map method with a schematic diagram. First, the spatio-temporal distributions of the discrete energy demand are expressed as two different density-strength maps over the time from t_1 to t_2 (see Figure 2a). The density strength map can be obtained using a kernel density estimation method (KDE). Then, the flows are obtained by the difference between the strength maps in two time steps. The resulting flow

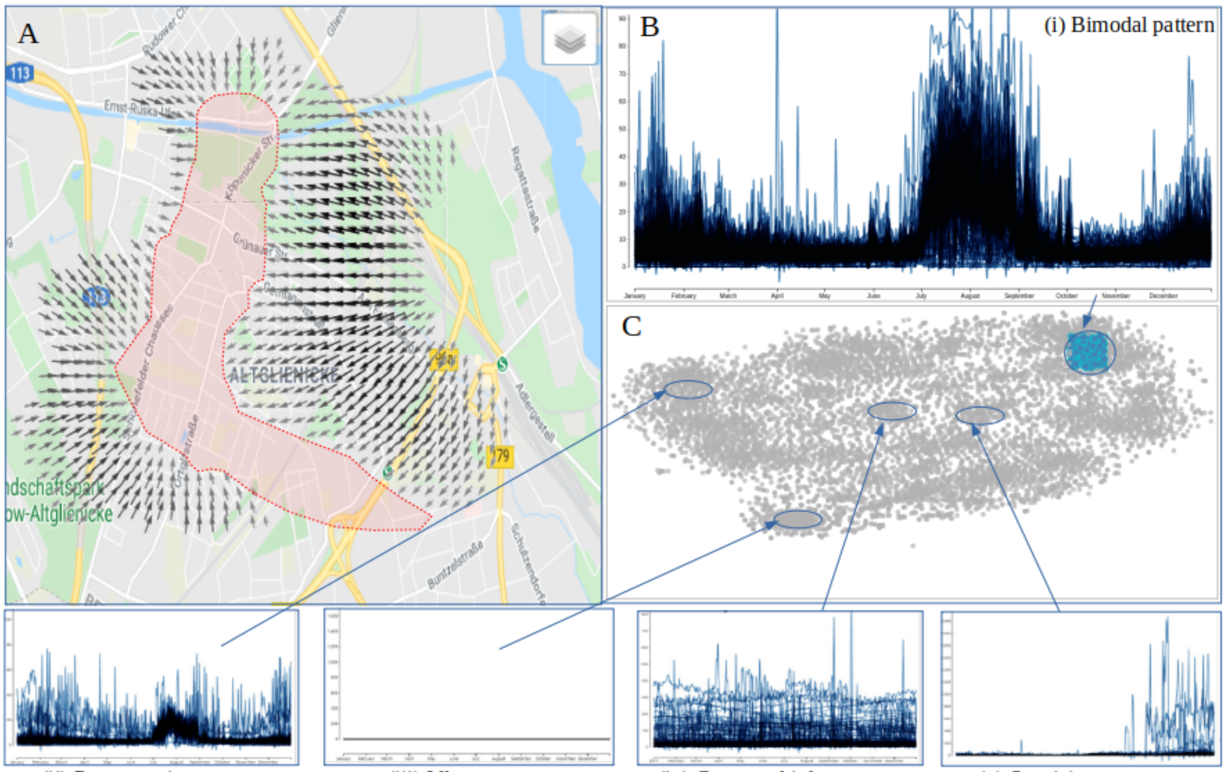


a) Density strength map over time



b) Spatio-temporal shift patterns

Figure 2: Flow map method for shift pattern discovery



(ii) Power-saving pattern (iii) Idle pattern (iv) Constant high pattern (v) Suspicious pattern

Figure 3: Spatio-temporal pattern discovery using VAP

map represents the spatio-temporal shifts of high energy demand (see Figure 2b).

The method is formalized in the following. Let $x_1, x_2, ..., x_n$ be the discrete geographical locations of the customers, x_i denoted as a vector $(lon_i, lat_i)^T$ of longitude and latitude. The density of a position of x in a 2D space is defined as follows:

$$\widehat{f}_{2D}(x) = \frac{1}{n}\sum_{i=1}^{n} c_i K_h(x - x_i) = \frac{1}{nh}\sum_{i=1}^{n} c_i K\left(\frac{x - x_i}{h}\right) \quad (3)$$

where n is the sample size, c_i is a normalized value of the average energy consumption used to re-weight the demand strength with respect to the geographical distribution, and h is the bandwidth of the kernel K_h. Gaussian kernel is used in the implementation, but note that other kernels can also be used. Since the Gaussian kernel can cover a larger spatial area for the changes, and it has a lower computation complexity compared with other kernels with exponential functions. The flow patterns representing the energy demand shift between t_1 and t_2 can be expressed as the density difference as follows:

$$Shift(x)|_{(t_1,t_2)} = \widehat{f}_{2D}(x)|_{t_2} - \widehat{f}_{2D}(x)|_{t_1} \quad (4)$$

2.2 Visual analysis tool

The visual analysis tool VAP is implemented as a web application with an architecture of three layers *data layer, logic layer* and *presentation layer*. In the data layer, PostgreSQL is used as the database management system, with PostGIS added to support spatial data processing. In the logic layer, all algorithms are implemented in Python, including the typical pattern discovery and spatio-temporal RESTful APIs are implemented to exchange JSON-formatted data between client and server. In the presentation layer, HTML5, CSS and JavaScript are used to implement the user interface (see Figure 3). Especially the JavaScript library, Leaflet.js [11], is used for the visualization of Scalable Vector Graphics (SVG) and the mapping. The flow patterns are displayed as colored arrows on the map, and the color depth represents the rate of change of the flow patterns; the darker the color, the higher the rate. The JavaScript library d3.js [12] is used for time series visualization.

Figure 3 shows the main user interface of VAP, which consists of the three views: A, B, and C. View A displays the spatial information of the clustered customers. This view supports users in selecting different map types, displaying the geographical positions of customers with markers, and visualizing the spatial distribution density with a heat map and spatio-temporal shift patterns with flow vectors. View B shows the time series for the customers selected in view C. This view visualizes the typical consumption pattern for all selected customers. View C is an interactive navigator that allows users to explore different energy consumption patterns by selecting the points by clicking and dragging. The closer the points are to each other, the more similar the patterns will be.

VAP supports visual analysis for any type of energy consumption with spatial information. The design of the database model can be interpolated with specific energy data sets in real use cases. Figure 3 illustrates an example for the visual analysis of an electricity consumption data set (note: the coordinates are offset for anonymization), where five typical patterns were discovered, including (i) bimodal pattern, (ii) energy-saving pattern, (iii) idle pattern, (iv) constant high pattern and (v) suspicious pattern. View A and B shows the flow map and the aggregated consumption pattern for the customers selected in the reduced 2D space in view C, respectively. The pattern is a bimodal pattern with a peak in winter and summer, respectively, which may be caused by the use of electrical heating and cooling appliances. The other four typical patterns can be interpreted in a similar way by examining the consumer behaviors or habits of customers, which will be explained in the demonstration. In view A, the area covered by the arrows is a commercial area, while the area pointed to by the arrows is a residential area (i.e. the light red area). This flow map indicates that the area with high energy demand is shifted to the residential area when people go home after work.

3 DEMONSTRATION

We will use a real-world electricity consumption data set for the demonstration. We will introduce the system architecture, the visual analysis process and how to use the tool to solve practical problems in energy planning. Conference attendees will interact with the tool to perform visual analysis on the data, i.e., ask business questions, answer questions through the exploration of the views and acquire knowledge. In particular, the participants will interactively discover typical and shift patterns of electricity consumption with VAP. We aim to help participants learn more about visual analysis for energy decision makings, explore the approaches for energy demand-side management, and raise their awareness of energy savings. Two demo scenarios will be presented during the conference.

S1: Typical patterns discovery. In this demo scenario, conference attendees will interact with VAP by investigating typical energy consumption patterns and identifying the spatial distribution of customers in the study area. We will explain to the participants the meaning of each identified pattern and the reason behind it. First, an attendee can start by asking questions, e.g., *who are the early birds with a morning peak between 5:00–7:00?* They investigate the customers of interest by selecting the points at different places on the view. Second, the attendees will study the transition of consumption patterns based on point similarity (or point spacing) in 2D space. They select the closely placed points continuously, and observe the pattern transition over the spatial space. Third, they can select the scatter plots generated by different dimensional reduction methods, including t-SNE and MDS, observe difference and compare capabilities in typical pattern discovery. Fourth, we will run the k-mean algorithm on the sampled data to discover typical patterns, compare the results, and explain the advantages of using the visual analysis method.

S2: Spatio-temporal shift pattern discovery. In this demo scenario, conference attendees will examine the patterns of the energy demand interactively, and we will explain the discovered shift patterns accordingly. First, an attendee examines the shift patterns by varying the temporal granular intervals, including hourly, every four hours, daily, weekly, monthly, quarterly, and yearly. They can then learn the sensitivity of the shift pattern changes against different time granularity. Second, they select different customer groups according to the consumption intensity in a quartile value ranging from 30% to 90%. They can then learn the sensitivity against different energy consumption intensities. Third, we can further demonstrate the shift pattern dynamics through a simulation. If, for example, the data are fed to the system in a short time interval, e.g., every 10 seconds, we can observe the changes of patterns in near real time.

4 CONCLUSION

We presented a visual analysis framework and a tool that supports both spatial and temporal pattern analysis for smart energy systems. We described the technique of dimension reduction and discussed how to reduce and visualize high dimensional data to a low dimensional space. We described and demonstrated the discovery of typical consumption patterns and spatial-temporal shift patterns of energy demand using a real case study. The demonstration validated the plausibility of the proposed visual analysis framework and the effectiveness of the tool in knowledge discovery through user interactions.

Chronos: The Swiss Army Knife for Database Evaluations

Marco Vogt Alexander Stiemer Sein Coray Heiko Schuldt

Department of Mathematics and Computer Science
University of Basel, Switzerland

ABSTRACT

Systems evaluations are an important part of empirical research in computer science. Such evaluations encompass the systematic assessment of the run-time characteristics of systems based on one or several parameters. Considering all possible parameter settings is often a very tedious and time-consuming task with many manual activities, or at least the manual creation of evaluation scripts. Ideally, the thorough evaluation of a complete evaluation space can be fully automated. This includes the set-up of the evaluation, its execution, and the subsequent analysis of the results. In this paper, we introduce Chronos, a system for the automation of the entire evaluation workflow. While Chronos has originally been built for database systems evaluations, its generic approach also allows its usage in other domains. We show how Chronos can be deployed for a concrete database evaluation, the comparative performance analysis of different storage engines in MongoDB.

1 INTRODUCTION

Scientific practice considers the development of novel theories and their empirical evaluation. In computer science, empirical evidence is to a large extent obtained by the systematic evaluation of systems. Essentially, such a systematic evaluation includes the thorough assessment of the quantitative behavior of a system based on one or several parameters. This means that systems need to be run over and over again with a modified set of parameters. This is a tedious and highly repetitive task, but essential for obtaining insights into the run-time characteristics of the system under evaluation (SuE).

In the database community, systems evaluations are mostly based on benchmarks that combine test data and certain access characteristics (queries). Systems evaluations need to be tailored to the characteristics of an SuE and to the parameters of the latter that determine their behavior. Nevertheless, the overall evaluation workflows, seen from a high-level perspective, show quite some commonalities even across systems. First, the SuE needs to be set up with the exact parameters of a particular evaluation run. This also contains the configuration of the SuE — in the database world, this includes the generation of benchmark data and their ingestion into the system. Second, the SuE needs to undergo a warm-up phase, for instance filling internal buffers, to make sure that the behavior of the SuE reflects a realistic use. Third, the actual evaluation is run. In the case of a database benchmark, this is the execution of the predefined queries in a given query mix. The evaluation finally generates data which at the end needs to be analyzed.

In most cases, these steps are implemented to a large extent by means of manual activities and are highly repetitive. Even in cases of (semi-)automated evaluations, they need to be re-started over and over again with varying parameters.

Ideally, a complete set of evaluation runs that systematically and thoroughly assess a given parameter space of an SuE can be fully automated. The only requirement on an SuE is that its evaluation workflow does not require any human interaction, allowing such SuEs to be evaluated using a generic evaluation toolkit. In order to provide systems *Evaluations-as-a-Service (EaaS)*, such a toolkit, once linked to the SuE, has to fulfill the following requirements: (i) It has to feature an easy to use UI for defining new experiments, for scheduling their execution, for monitoring their progress, and for analyzing their results. (ii) The toolkit has to support different SuEs at the same time and in particular parallel executions of benchmarks of these systems. (iii) To allow SuEs to be considered in long-running evaluations, the toolkit has to exhibit a high level of reliability. This includes an automated failure handling and the recovery of failed evaluation runs. (iv) The toolkit has to provide mechanisms for archiving the results of the evaluations as well as of all parameter settings which have led to these results. (v) Already existing evaluation clients should be easily integrable into the toolkit which also has to support developers in building new clients. (vi) The toolkit has to offer a large set of basic analysis functions (e.g., different types of diagrams), support the extension by custom ones, and provide standard metrics for measurements (e.g., execution time). Finally, (vii) it should be easy to apply the toolkit to new SUEs.

In this paper, we introduce Chronos, a generic evaluation toolkit for systematic systems evaluations. The contribution of this paper is twofold: First, we describe the functionality of Chronos which automates the entire evaluation workflow and assists users in the analysis and visualization of the evaluation results. Second, we demonstrate how Chronos can be configured for the evaluation of different SuEs and for the systematic analysis of a complete evaluation space by using two different storage engines in MongoDB[1] as running example.

Since its first version, Chronos has been used for the evaluation of several research prototypes, including ADAM$_{pro}$ [6], Beowulf [9], Icarus [10], and Polypheny-DB [11] as well as in various student evaluation activities. It has been released on GitHub[2] under the MIT open source license.

The remainder of this paper is structured as follows: In Section 2 we introduce Chronos and Section 3 shows Chronos at work. Section 4 discusses related work and Section 5 concludes.

2 CHRONOS

Chronos is a toolkit for defining, monitoring, and analyzing the results of evaluations. It consists out of two main building blocks (see Figure 1): First, *Chronos Control* (in green), the heart of the evaluation toolkit that provides a web UI and a RESTful API for managing evaluations; second, the *Chronos Agents* (in red)

which interact with the (existing) evaluation clients and which leverage the REST API to get the required information to perform the evaluations. While it is possible to write a custom Chronos Agent, there is also a generic Chronos Agent available for Java. This allows to easily integrate Chronos into existing projects. In this section, we present the implementation of Chronos and how to integrate it into existing projects.

2.1 Data Model

The data model of Chronos contains projects, experiments, evaluations, jobs, systems, and deployments.

Project. A project is an organizational unit which groups experiments and allows multiple users to collaborate on a specific evaluation. Access permissions are handled at the level of projects so that every member of a project has access to all experiments, evaluations, and their results. Users can archive entire projects, i.e., make their evaluation settings and the results persistent.

Experiment. An experiment is the definition of an evaluation with all its parameters; when executed, it results in the creation of an evaluation. Like projects, experiments can be archived.

Evaluation. An evaluation is the run of an experiment and consists of one or multiple jobs. If the objective of an evaluation is, for example, to compare the performance of two storage engines of a database system for different numbers of threads, every job would execute the benchmark for a specific number of threads for each engine. Depending on the evaluation, the execution of jobs can be parallelized if there are multiple identical deployments of the SuE.

Job. A job is a subset of an evaluation, e.g., the run of a benchmark for a specific set of parameters and a given DB storage engine. The result of every job is stored together with its log output. A job can be in one of the following states: *scheduled*, *running*, *finished*, *aborted*, or *failed*. Jobs which are in the status *scheduled* or *running* can be aborted and those which are *failed* can be re-scheduled.

Result. A result belongs to a job and consists of a JSON and a zip file. Every data item which is required for the analysis within Chronos Control is stored in the JSON file. Additional results can be stored in the zip file (e.g., for further analysis outside of Chronos).

System. A system is the internal representation of an SuE. For every SuE, it is defined which parameters the SuE expects, how the results are structured, and how they should be visualized.

Deployment. A deployment is an instance of an SuE in a specific environment. There can be multiple deployments of an SuE at the same time. Deployments serve two purposes: First, they allow to simultaneously execute evaluations in different (hardware) environments or different versions of the SuE; second, they allow to parallelize the evaluation in case of multiple identical deployments.

2.2 Implementation

In the following section, we give details on the implementation of Chronos' architecture as depicted in Figure 1.

Chronos Control. It is designed as a web application allowing the management and analysis of evaluations using common web browsers. It offers a RESTful web service for clients benchmarking the SuEs. Chronos Control has only a few run-time requirements: Apache HTTP Server[3], PHP[4], MySQL[5] or MariaDB[6], and git[7]. For the SuE extensions, Mercurial[8] is also supported. The provided installation script handles the complete setup of Chronos including the creation of the necessary database schema and user account.

User Interface. Chronos' web UI is based on Bootstrap[9] and comes with an advanced session and role-based user management to support the deployment in a multi-user environment. A key feature of the Web UI is its modular architecture which enables the easy integration of different SuEs. For every SuE, only the available parameters for an experiment and information on how the results are to be visualized have to be specified. Both can be done completely UI-based. Chronos Control therefore provides several parameter and diagram types. Parameter types include Boolean, check box, and value types as well intervals and ratios. For the result visualization, Chronos provides bar, line, and pie diagrams. If more parameter types and diagrams are required, the built-in set of types can be extended by providing an external repository containing PHP scripts with additional implementations.

REST Interface. Chronos' REST API is used for both the clients requesting information to perform their benchmarks (e.g., requesting job descriptions or submitting results) and for the integration of the Chronos toolkit into existing evaluation workflows. For this, the API offers methods to, for example, schedule an evaluation which is caused by a successful build of the SuEs build bot. To support the smooth evolution of Chronos, the API is versioned. This allows new clients to simultaneously use the newly developed features while other clients still use older versions of the REST API.

Chronos Agent. Chronos Agents are clients or client libraries connecting to Chronos' REST API that perform or trigger the actual evaluation workload. Agents are essential to link existing or newly developed evaluation clients of the SuEs with Chronos. An agent can be implemented in any language supporting the

Figure 2: Configuration of a System in Chronos' Web UI

access to the RESTful web service. Along with Chronos Control, we provide a reference implementation of a generic agent library written in Java (also available on GitHub[2]). This reference implementation handles all the communication with Chronos Control including the upload of the results via HTTP or FTP. The latter allows to use a different server or a NAS for storing the results which also reduces the load and storage requirements on the Chronos Control server. During its run, the agent periodically sends the output of the logger to Chronos Control and the agent library allows to easily update the progress of the evaluation. Furthermore, the agent library already measures basic metrics which are returned to Chronos Control along with the results.

Integrating the Chronos Agent library into an existing evaluation client is the only part which requires programming. All other steps can be done completely UI-based. However, the required amount of programming is rather negligible, since the agent library already provides an interface with all necessary methods to be implemented. Depending on the existing evaluation client, this usually narrows down to calling already existing methods of the evaluation client.

3 CHRONOS AT WORK

In this section, we present the two main workflows supported by Chronos: First, the registration of an SuE in the Chronos toolkit, and second, the necessary steps to perform an actual evaluation.

The first workflow demonstrates how easy it is to integrate the Chronos Agent into an existing evaluation client using the Java library. After building a Chronos-enabled evaluation client and setting-up an instance of the SuE, it needs to be registered in Chronos Control. This can be done by either specifying the parameters required for the evaluation client and the SuE in Chronos Control or by providing a path to a git or mercurial repository. Figure 2 shows the overview page of a system in the Chronos Web UI. Once the system has been created and its parameters have been configured, the first workflow is finished and Chronos is ready for executing evaluations against this SuE.

The second workflow starts with the creation of a project. Afterwards, one or multiple experiments are defined (Figure 3a). To schedule work for a Chronos Agent, an evaluation needs to be created which consists of one or multiple jobs as depicted in Figure 3b. Figure 3c shows the overview page of a job providing the current status of the job including its progress and the log output. Furthermore, it allows to abort a scheduled or running job or to reschedule a failed one. The timeline shows all events associated with this job. When the Chronos Agent has finished its work, the evaluation results are visualized (Figure 3d).

The separation of experiments and evaluations comes in handy if certain evaluations need to be repeated multiple times. This is the case during the development of an SuE, for example, in the bug-fixing phase, or for the quality assurance monitoring the performance of an SuE over subsequent change sets.

A demonstration that has been prepared to show Chronos' capabilities considers two workflows using the comparative evaluation of two storage engines of MongoDB (wiredTiger and mmapv1) as an example. This demonstration allows to create short running evaluations for the two MongoDB deployments and to directly analyze the results in the Chronos Web UI.

The MongoDB Chronos agent is available on GitHub[2] and the demo that will be presented at the conference is summarized in a short video[10] that shows how Chronos can be used for the comparative evaluation of the two storage engines of MongoDB.

4 RELATED WORK

Like the Chronos toolkit, the *PEEL framework* introduced in [1] automates the evaluation process and helps improving the reproducibility of evaluations. PEEL, however, is designed with a focus on Machine Learning applications running on frameworks like Hadoop MapReduce, Spark, Flink, and others. In PEEL, the SuE and the experiments are described using XML or Scala classes. These documents are compiled into a bundle containing the PEEL framework, the required configuration, and the evaluation data sets. The bundle is then deployed on the target machine running the SuE.

PROVA! [7] is a distributed workflow and system management tool for benchmarks on HPC systems. It allows to easily benchmark applications on different systems and architectures. Similar to Chronos it visualizes the results. While Chronos is a general-purpose tool for all kinds of evaluations and benchmarks with a focus on database evaluations, PROVA! is specifically tailored to the HPC domain.

OLTP-Bench [5] is a benchmarking framework which provides implementations for in total 15 different transactional, web-oriented, and feature testing benchmarks including YCSB [4], TPC-C[11], and CH-benCHmark [3]. In contrast to OLTP-Bench, Chronos addresses the complete evaluation workflow and thus also includes the definition of the experiments and the analysis of the results. However, a combination of Chronos (automation of the evaluation workflow) and OLTP-Bench (definition of various benchmarks) would even further facilitate the definition, set-up, execution, and analysis of evaluations. In our future work, we thus plan to develop a Chronos Agent that wraps the OLTP-Bench so as to combine both systems.

The *TREET* testbed [8] allows developers of trust and reputation systems (e.g., online marketplaces) to evaluate their systems using standardized test cases. Further, TREET can be flexibly extended with custom agents and test cases allowing the testing of the developer's application. Like Chronos, but for a different domain, TREET supports the execution of experiments and the comparison between different trust and reputation systems.

5 CONCLUSION

In this paper, we have presented the evaluation toolkit Chronos, a first step towards the concept of Evaluation-as-a-Service. Chronos automates the entire evaluation workflow and assists users in the results analysis. The Chronos toolkit is available on

skyex: an R Package for Entity Linkage

ABSTRACT

As the data is becoming bigger, more heterogeneous, and originating from different sources, the availability of the same information in different forms leads to various entity linkage problems. We demonstrate our skyex package, an R package that supports all three steps of entity linkage: blocking, pairwise comparison, and labeling. Thus, the user can solve the whole process using skyex, but not necessarily; the skyex modules are independent, meaning that the user can easily integrate them with other packages or even other environments. Additionally, we are the first to provide the implementation of two skyline-based algorithms (*SkyEx-F* and *SkyEx-D*) that can label the compared pairs without the need for weights, scoring functions, etc. skyex supports the typical workflow of entity linkage, using minimalist, user-friendly function calls.

1 INTRODUCTION

The *entity linkage* problem, sometimes called *data matching*, *entity resolution*, *duplicate detection*, *reconciliation*, etc., detects different records that belong to the same entity. Even though the process varies in different domains, the main steps are the same: blocking, pairwise comparison, and labeling the pairs (Fig.1). The entity linkage process starts with a set of entities that might contain duplicates. First, a blocking method is used to group entities that show a certain level of similarity and are of interest to compare further. Then, the pairwise comparison step compares the entities in the same blocks, e.g., using similarity metrics of the attributes of the entities or comparing the structure of their connections. Finally, the labeling step decides whether a pair of candidates belongs to the same entity or not. The entity linkage process results in a set of labeled pairs.

We present an R package, skyex, that supports all three steps of the entity linkage problem. In the labeling step, we provide the novel *SkyEx-F* and *SkyEx-D* algorithms in [6, 8]. The R language is in the top five languages of data science, and even more importantly, R is the second most used software in data science scientific papers, corresponding to 50,000 articles [1]. Moreover, R is used by different industries besides academia, such as healthcare, government, insurance, etc., where entity resolution is a common obstacle [2]. The current entity linkage tools [1–4, 9–11] offer rule-based solutions with blocking and comparison functions [3, 10], crowdsourcing solutions [4, 9], or machine learning solutions [1, 2, 11]. In contrast to all the current tools, we contribute with a Labeling module that implements two novel algorithms (*SkyEx-F* and *SkyEx-D*) [6, 8], which can label the pairs without the need of weights, scoring functions, or exhaustive experiments. In order to support the full entity linkage workflow, we provide functions to perform blocking based on text and spatial attributes, and we offer a module for textual, spatial, semantic pairwise comparison. Similarly to [2], we support analysis and visualization functions that assist in the interpretation of the results and assessing the quality of the labeling. Analogously to [11] that uses Python, skyex uses the R ecosystem and can be easily integrated with other packages, in contrast to the current standalone tools. Finally, we demonstrate the different scenarios that can be supported by our tool using three real-world datasets. Overall, skyex solves the entity linkage problem with minimal effort and background knowledge.

The remainder of the paper continues with the functionalities covered by our skyex package in Section 2, a description of our on-site demonstration in Section 3, and finally, concluding in Section 4.

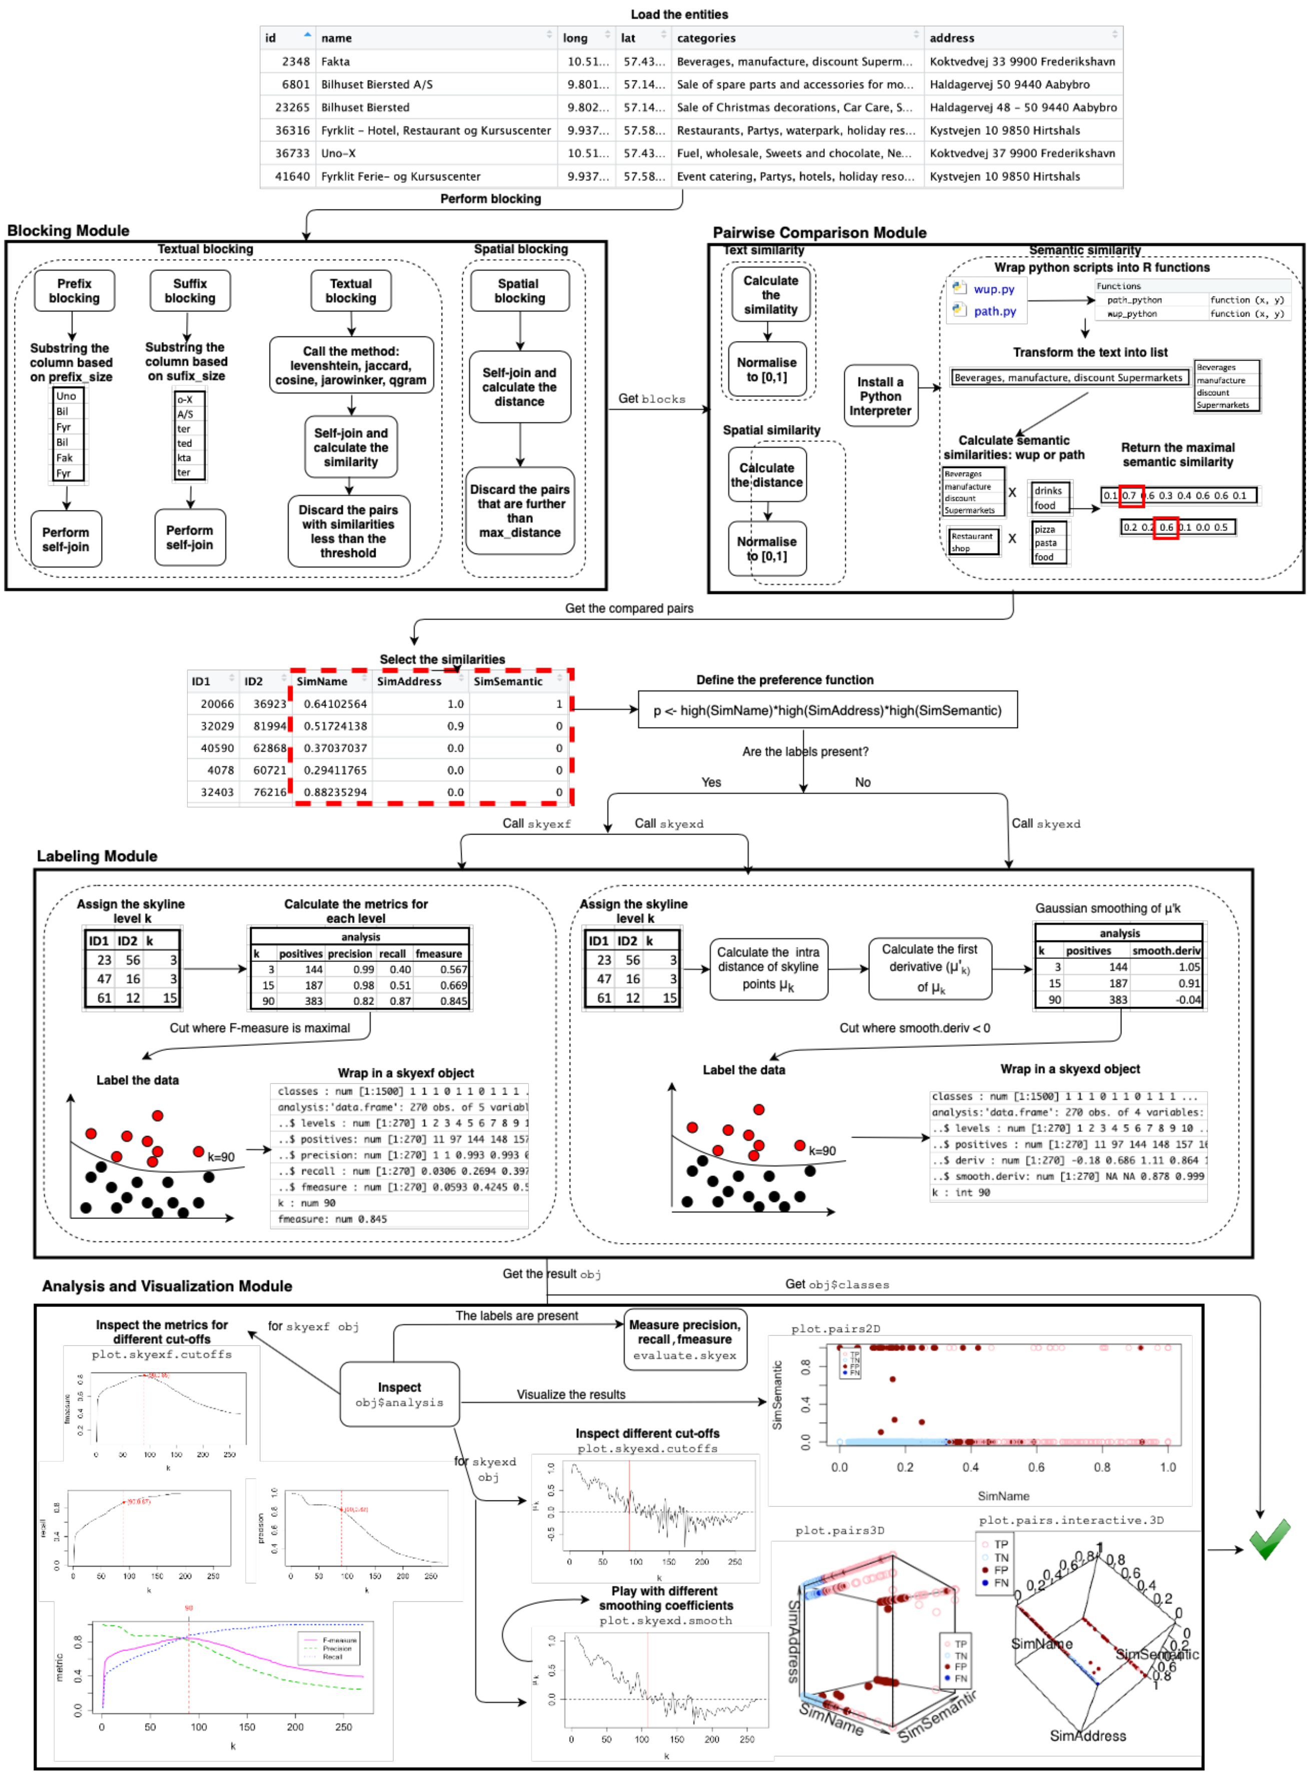
2 SKYEX PACKAGE FUNCTIONALITIES

The skyex package is composed of 17 functions corresponding to four main modules: Blocking, Pairwise Comparison, Labeling, and Analysis and Visualization. The workflow of using skyex is illustrated in Fig. 2. The user starts with a dataframe (a common data type for storing tables in R) of entities. In order to illustrate the workflow and our functions, we will use a real-world dataset of spatial entities extracted as in [5] and used in the experiments of [8]. The dataset contains spatial entities in the North Denmark region, originating from four sources, Google Places, Yelp, Krak (online yellow pages in Denmark, www.krak.dk), and Foursquare. We also introduce the running example of six records of entities (entities) from this dataset in Fig. 2, which are identified by an ID, by geographic coordinates latitude and longitude, categories that explain the type of spatial entity, and the address.

Blocking module. After loading the data, we can use a blocking technique (textual or spatial) from the Blocking module. The textual blocking is executed by the textual.blocking function, choosing a similarity metric among *levenshtein*, *cosine*, *jaccard*, *jaro-winker*, and *qgram*, and setting a maximal distance allowed. For example, textual.blocking on the attribute "name" with *levenshtein* and maximal distance 4 will group the entities with names "Bilhuset Biersted A/S" and "Bilhuset Biersted" (from entities in Fig. 2). Note that textual.blocking is accurate but time-consuming. Alternatively, prefix.blocking and suffix.blocking produce faster results. Besides, in some domains, e.g., for species names, these methods can be more relevant than textual blocking. For spatial entities, being spatially close is often a better indicator of block quality than the name. For example, two records with the same name, e.g., Fakta supermarkets in different cities, are two different entities. spatial.blocking creates blocks of entities that are at most *max_distance* meters apart. The code snippets for these blocking methods are as follows:



Load the entities

```

Pairwise Comparison module. The Blocking module outputs a dataframe of pairs, which saves the user from the task of having to create the pairs from each block. The Pairwise Comparison module offers three functions that compare text syntactically and semantically, as well as spatial attributes. Moreover, all three functions output normalized values, which can be directly used in the Labeling module. `text.similarity` calculates the similarity of the pairs based on a text attribute using similarity metrics such as *levenshtein*, *cosine*, *jaccard*, *jaro-winker*. *levenshtein* similarity is calculated using the formula in [7, 8] in order to return a normalized value. `spatial.similarity` also requires a maximal distance for the normalization. For example, for a $max\_distance = 70$, "Uno-X" and "Fakta" will have a similarity of 0.0, because their distance of 83 meters is beyond the threshold. In the case of Bilhuset Biersted A/S and Bilhuset Biersted, this distance is 63 meters, which translates to a similarity of 0.09.

Regarding the semantic similarity, our work in [8] uses the Wu&Palmer metric from Wordnet. There exists a `wordnet` library in R, but it does not provide the metrics. Moreover, Wu&Palmer needs the whole path of both words that need to be compared, which in R, it could be resolved only through recursive calls. Through experimentation, this implementation turned out to be non-efficient. Thus, we include two Python scripts in the `skyex` package for two different metrics in Wordnet. These scripts are wrapped in R functions; thus, the user only needs to have a Python interpreter installed and give its path to the R function. The code for the pairwise comparisons is as follows:

```
#Text similarity using cosine
blocks$SimName<-text.similarity(data=blocks, method = "cosine",
                 column1 = "name.x", column2 = "name.y")
#Spatial similarity with max_distance=70
blocks$SimSpatial<-spatial.similarity(data=blocks, lat1 = "lat.x",
                    long1 = "long.x", lat2 = "lat.y", long2 = "long.y",
                    max_distance = 70)
#Semantic similarity with Wu&Palmer
blocks$SimSemantic<-semantic.similarity(data=blocks,
                     column1 = "categories.x", column2 = "categories.y",
                     pythonpath = "/Users/..", method = "wup" )
```

Labeling module. After the pairs are compared, the user can decide which similarities should go into the labeling process. Usually, he would select those similarities that are likely to indicate a match, e.g., the similarity of the names of the entities. We will consider the similarity of the name "SimName", the similarity of the address "SimAddress", and the semantic similarity of the categories "SimSemantic" as in [8]. Then, the user decides on the preference function for the Pareto Optimality calculations. In our case, we prefer a high value for each similarity. Depending on the availability of the labels, the user can choose between running `skyexf` or `skyexd`, corresponding to the threshold-based *SkyEx-F*, or to the fully unsupervised *SkyEx-D*, respectively [6]. *SkyEx-F* finds that skyline level k that separates best the classes and maximizes the F-measure. It starts with assigning the skyline to all the points and then checking different cut-offs while measuring precision, recall, and f-measure. Finally, it labels the data, and the `skyexf obj` is returned, containing the classes, an analysis data frame, the proposed cut-off k, and the corresponding f-measure.

For unlabeled data, *SkyEx-D* finds the skyline level k where the mean distance of the points in the positive class starts to drop, meaning that we are entering the denser area of the negative class. It starts by assigning the corresponding skyline to each point; then, calculating the cumulative mean distance in the positive class and its first derivative; later, finding where the first derivative becomes negative for the first time. Finally, *SkyEx-D* labels the data and wraps the classes, the analysis data frame, and the proposed cut-off k in a `skyexd obj`. Detailed explanations about both algorithms can be found in [6]. Our `skyex` package hides all the details above from the user, meaning that the processes inside the dotted line boxes (Fig. 2) are performed simply by the `skyexf` and `skyexd` function calls. The script for running both algorithms, storing the results of each labeling algorithm in separate objects, and attaching the predicted classes to the dataset is as follows:

```
#Define the preference
p<-high(SimName)*high(SimSemantic)*high(SimAddress)
#Call SkyEx-F algorithm and store the result in f.obj
f.obj<-skyexf(data=blocks, p=p, label="Class",posclass=1, negclass=0)
#Call SkyEx-D algorithm and store the result in d.obj
d.obj<-skyexd(data=blocks, p=p, simlist=c("SimName", "SimSemantic",
        "SimAddress"), posclass=1, negclass=0, smooth.coefficient=5)
blocks$fpred<-f.obj$classes
blocks$dpred<-d.obj$classes
```

We thus provide a labeling procedure that can be used with only two lines of code: defining the preference and calling the labeling function. However, for a more knowledgeable user, we offer the possibility to do analysis and visualize the results through the Analysis and Visualization module.

Analysis and Visualization module. To illustrate the analysis of the labeling, we will use the 1500 manually-labeled pairs in [8]. Additionally, this dataset is also available in our package under the name `pairsManual` and can be loaded simply by `data(pairsManual)`. The Analysis and Visualization module needs the output of the Labeling module as input, which is a `skyexd` or `skyexf` object. The raw analysis can be accessed simply by calling the dataframe `analysis` from *obj* (inspect `obj$analysis` in Fig. 2). In the case of a `skyexf` object, `analysis` contains all the cut-offs, the size of the positive class, precision, recall, and f-measure. In order to facilitate the exploration of `analysis`, the user can call `plot.skyexf.cutoffs`, which produces graphs that monitor the evolution of the metrics when passing to the deeper skylines (see Fig. 2). `plot.skyexf.cutoffs` by default plots the f-measure. However, it is possible to plot the precision and the recall separately, and also all metrics together. The code snippets for plotting the f-measure (first two), the precision, the recall, and all the metrics are as follows:

```
plot.skyexf.cutoffs(f.obj)
plot.skyexf.cutoffs(f.obj, "fmeasure")
plot.skyexf.cutoffs(f.obj, "precision")
plot.skyexf.cutoffs(f.obj, "recall")
plot.skyexf.cutoffs(f.obj, "all")
```

The resulting plots from the above script on `pairsManual` are shown in Fig. 2 in the Analysis and Visualization module. Understandably, precision is high in the first skylines because it is very likely that the pairs in the first skylines that we label as positives are actual positives, but it degrades while moving in deeper cut-offs. On the contrary, recall is always increasing, the more we label as positive, the more likely it is to find an actual positive. The F-measure gives the trade-off between both metrics. All graphs show the suggested cut-off by `f.obj` in the red dotted line. However, the user can explore different trade-offs for his problem. In that case, plotting all metrics in a graph (the last script) gives a better overview.

In the case of a `skyexd` object, `analysis` keeps the cut-offs, the size of the positive class, the first derivative, and the smoothed values. Similarly, `plot.skyexd.cutoffs` aids exploring the raw `analysis` by plotting the smoothed first derivative function for each cut-off. If the plot looks too "smoothed" or too "raw", it is possible to play with different smoothing coefficients without having to re-run `skyexd` again by calling `plot.skyexd.smooth`. (see the code below). Fig. 2 shows the analysis of `skyexd`, which was run with `smooth.coefficient=5`, and also the results of `plot.skyexd.smooth(d.obj, 10)`. The higher the smoothing coefficient, the higher the cut-off k, since smoother values push the cut-off towards deeper skylines.

```
#Plot the first derivative and the current cut-off k
plot.skyexd.cutoffs(d.obj)
#Smooth the first derivative with 10
plot.skyexd.smooth(d.obj, 10)
```

`evaluate.skyex` can also be called as in the code below, to measure precision, recall, and f-measure when the labels are available. The values of these metrics will be printed in the console.

```
evaluate.skyex(prediction=d.obj$classes, labels=data$Class, posclass = 1)
```

Additionally, we offer user-friendly functions to plot the data and the *obj* results. We offer 2D plots, 3D plots, and interactive 3D plots, where the user can play and move the dimensions while looking at the data. The color of the points reflects if the pair is a true positive TP (an actual positive labeled as positive), a true negative TN (an actual negative labeled as negative), a false positive FP (an actual negative labeled as positive), and a false negative FN (an actual positive labeled as negative). The user can decide to change the colors of the points based on his preference. The code for these plots is as follows:

```
#Plot 2D using SimName and SimSemantic
plot.pairs2D(data=data, sim1="SimName", sim2="SimSemantic",
          prediction=f.obj$classes, labels=data$Class, posclass = 1)
#Plot 3D using SimName, SimSemantic, and SimAddress
plot.pairs3D(data=data, sim1="SimName", sim2="SimSemantic",sim3="SimAddress",
          prediction=f.obj$classes, labels=data$Class, posclass = 1)
#Plot 3D interactive plot using SimName, SimSemantic, and SimAddress
plot.pairs.interactive.3D(data=data, sim1="SimName", sim2="SimSemantic",
          sim3="SimAddress", prediction=f.obj$classes,
          labels=data$Class, posclass = 1)
```

Fig. 2 shows the results of `pairsManual` with the three types of plots. These graphs can also be considered as an analysis since they show the problems with labeling and where to locate them. For example, it is noticeable that we have a bigger problem with the false positives then with the false negatives, thus if precision is fundamental to the domain, we could go back to the analysis and evaluation module and consider a smaller k for the cut-off. The interactive 3D plot offers a better view of the data points since it is possible to move and rotate the graph.

Summary. The workflow of `skyex` supports typical entity linkage tasks, from blocking to evaluating the quality of the labels. The Blocking, Pairwise Comparison, and Labeling modules are completely independent, which means that the user can decide to perform his own methods and still be able to connect to the workflow of `skyex`. The labeling task can be as simple as just calling two lines of code to get the classes and as detailed as performing analysis, playing with the parameters, visualizing the labels, and highlighting the errors, etc. Moreover, the user can always go back, choosing new similarities and new preferences until the results are satisfactory. The `skyex` package is dependent on `rPref`, `dplyr`, `fields`, `rgl`, `plot3D`, `smoother`, `fuzzyjoin`, `stringr`, `stringdist`, `geosphere`, `reticulate`, and `pracma` which support some basic functionalities in our functions. `skyexf` and `skyexd`) scale relatively well for an R environment; e.g. they run in less than a minute for 50,000 pairs, less than 15 minutes for 150,000 pairs, and around 1 hour for 300,000 pairs.

3 DEMONSTRATION OVERVIEW

In the on-site demonstration, the user can download `skyex`[3], which is publicly available in GitHub, by following the README instructions, or use our pre-installed R environment. We will provide three datasets: `entities` (2814 spatial entities in the North Denmark region with an ID, name, categories, and address) [8], `restaurants`[4] (a collection of 864 restaurant records with name, address, city, and type), and `pairsManual` (1500 labeled pairs with pre-compared similarities of the name, address, and categories) [8]. Additionally, we have published a full video[5] demonstrating our functionalities for all three datasets, and a short video[6] for the `restaurants` dataset. We will provide example scripts, which the user can adapt based on his preference. The user will start with different blocking techniques on `entities` and `restaurants`, discussing with us what would be a good blocking technique for this dataset. Afterwards, he can play with different similarity metrics and different thresholds for the pairwise comparison. Later, the user can decide either to continue with the dataset of pairs he created so far from `entities` and `restaurants`, or move to the pre-compared `pairsManual` and play with the labeling parameters. The user can try both algorithms and will be guided by us through the Analysis and Visualization module. He can try the visualizations (including the interactive plotting) in order to detect problems with the labeling. Finally, he can discuss with us the applicability of the method across domains and possibilities for improvement.

4 CONCLUSIONS AND FUTURE WORK

We introduced the `skyex` package, a user-friendly R package that supports all three steps of the entity linkage process. We demonstrated the functions of `skyex` with scripts and sample data, and supported the full workflow of the user. We showed that our Labeling module could solve the labeling problem with only two lines of code, but at the same time, offer the possibility for deeper analysis for the knowledgeable user. As future work, we intend to work on the scalability of our tool for big data, as well as on a similar package in Python.

ABSTRACT

This demo proposes MeSQuaL, a system for profiling and checking data quality before further tasks, such as data analytics and machine learning. MeSQuaL extends SQL for querying relational data with constraints on data quality and facilitates the verification of statistical tests. The system includes: (1) a query interpreter for SQuaL, the SQL-extended language we propose for declaring and querying data with data quality checks and statistical tests; (2) an extensible library of user-defined functions for profiling the data and computing various data quality indicators; and (3) a user interface for declaring data quality constraints, profiling data, monitoring data quality with SQuaL queries, and visualizing the results via data quality dashboards. We showcase our system in action with various scenarios on real-world data sets and show its usability for monitoring data quality over time and checking the quality of data on-demand.

1 INTRODUCTION

Assessing data quality is challenging and requires the detection and elimination of a variety of data quality problems, such as errors, duplicate, inconsistent, obsolete, and incomplete information [3, 10]. A wide range of methods for statistical analysis, constraint mining, consistency checking, and duplicate elimination has to be used [6] and their specifications can be complex for various reasons:

• *Data quality checking is a highly domain- and task-specific problem.* Data quality is multidimensional. A plethora of measurable dimensions can be used to characterize the quality of data with various indicators (e.g., value accuracy, consistency, completeness, freshness, or absence of duplicate records). Multiple techniques can be implemented to evaluate each dimension whose specification ultimately depends on the requirements of the user, the task at hand, and the application domain. Moreover, depending on the machine learning (ML) task, statistical assumptions must be verified before applying a given ML model, and the test results may ultimately influence the data preparation with a selection of specific data transformations accordingly.

• *Data quality checking is inherently a human-in-the-loop (HIL) process.* The user needs a tool offering a flexible and declarative way to define, evaluate, and check various data quality indicators and query the data with some data quality requirements in mind that can be made explicit.

• *Data quality checking is a continuous process.* Data quality may vary over time due to the temporal and dynamic nature of the data and the evolving real world, but also as a consequence of various data cleaning and repairing actions. This bears the need

for monitoring the quality of different versions of the database and the quality of query results.

Our Approach. To deal with these challenges, we believe that it is essential to build tools that enable the data scientists to specify and verify data quality requirements in a declarative way. In particular, tools for analyzing data quality, testing statistical assumptions, and monitoring data quality continuously to provide insights about the data glitches and help in selecting appropriate data preparation and cleaning strategies. In this demo, we present MeSQuaL that we built for this purpose.

2 MESQUAL OVERVIEW

Architecture. As in Fig. 1, MeSQuaL consists of two main components: (1) the SQuaL query interpreter enabling the declaration of contracts for data quality checking and SQL queries extended with QWITH statement; (2) the Data Quality and Tests (DQT) `Manager` that operates over three types of RDBMS (Oracle, MySQL, and PostgreSQL) storing the data and related metadata. Our framework provides: (1) several built-in functions for data quality checking and statistical tests; (2) the possibility to call functions in `Python`, `Java`, `C++`, `R`, and `OCaml`; or (3) the possibility to define custom command-line calls to a UDFs (User-Defined Functions). Once a quality contract is declared in SQuaL with a list of dimensions, associated UDFs, and constraints, the `DQT Manager` computes the corresponding data quality indicators and stores them as metadata. SQuaL query result and visualization are displayed via a Grafana graphical interface[1].

```

Figure 5: SQuaL query example

SQuaL Syntax. Each step of a data quality checking scenario can be expressed in SQuaL, the SQL-extended language we implemented on top of each RDBMS. The grammar of SQuaL is provided in Fig. 2. A user can easily express data quality concerns and requirements either re-using the library of UDFs we provide with MeSQuaL or, depending on his/her programming skills, adding new functions and codes in `Python`, `Java`, `C++`, `R`, or `OCaml` to check the quality of data and test other hypotheses.

• **Contract type.** Data quality measures and indicators can be expressed via the declaration of *quality contract types*. In the ⟨`contracttype`⟩ statement of the grammar in Fig. 2, a contract type statement creates (or replaces) a contract type as a list of quality dimensions of interest. Each dimension indicator is computed by a UDF. Once the *contract type* is created and UDFs are loaded, it can be instantiated as a contract with constraints on the pre-declared dimensions and later on, invoked in SQuaL queries. A dimension is defined by a ⟨*dimension-name*⟩, the path of its UDF, and the language in which the UDF is implemented. Fig. 3 presents several examples of *contract type* declarations.

• **Contract.** A quality contract, described by the ⟨*contract*⟩ statement in Fig. 2, derives from one (or more) pre-existing contract type(s) and is a set of one-sided range constraints on the dimensions declared in the contract type(s). Constraints are simple comparison expressions involving the pre-declared dimension, and a reference value. Fig. 4 presents several examples of contract declaration based on the contract types declared in the examples of Fig. 3. The `DQT Manager` executes the contracts on-demand when they are invoked in the QWITH statement of a SQuaL query.

• **Qwith Query.** In a SQuaL query, described in the grammar in Fig. 2 by the ⟨*squal-query*⟩ statement, the QWITH operator can be used to extend and constraint a regular SQL query result as illustrated in Fig. 5. It can be applied to the whole database or to a query as it adds constraints to the semantics of the SQL query and returns the query result that satisfies the quality requirements defined in the contract types and contract instances with the UDFs executed by the `DQT Manager`. Additionally, QWITH can be used inside nested SQL queries.

Note that before declaring and creating data quality contract types and contract instances using SQuaL, an important and challenging task in dealing with real-world (possibly dirty) data is data exploration to better understand the reasons for poor data quality and how it can affect the processes that consume the data. Since data exploration is out of the scope of this demo and not directly enabled by our system, we assume that data exploration should be achieved before and externally for the adequate specifications of the contract types, instances, and constraints.

Goals. In this demo, we showcase the principal features of MeSQuaL:

• *Seamless integration of user-defined functions and constraints in the query language* to compute and check various dimensions of data quality. A common way to use our system is to declare the data quality dimensions of interest, bind and invoke the functions that compute relevant quality indicators (as shown in Fig. 3 with `CheckQDB` contract type for example), and query the data with constraints on these indicators using QWITH statement of our query language (as illustrated in Fig. 5);

Figure 6: Screenshot of MeSQuaL's User Interface with Dynamic Dashboards

• *Continuous data-quality checking and monitoring.* MeSQuaL results can help the user in defining or comparing various methods for checking and profiling the quality of data over time, selecting the most appropriate ones, or refining the data quality checking process, and select the most appropriate contracts to monitor continuously;

• *Statistical testing.* Interactive hypothesis testing allows the user to check various statistical assumptions on the data distributions and make sure that the data conform to the requirements of a given ML model (as in Fig. 3 with StatTests contract type);

• *Efficient profiling of data quality indicators and visualization of static and dynamic profiles* showing the evolution of data quality over time with the Monitoring Panel $\boxed{\text{E}}$ in Fig. 6.

To increase the automation of data quality checking, we claim that there is a need for augmenting database management systems with a flexible and declarative way to declare, check, and monitor the quality of data, independently from the data model, format, or application, and this actually motivated the design of MeSQuaL.

3 DEMONSTRATION SCENARIOS

We will demonstrate MeSQuaL using two domain-specific data sets: the clinical database MIMIC-III[2] [7] and the ChicagoDataset from the Array of Things[3] real-time urban data (AoT) [5]. The users can examine and query the data sets and explore the data quality checking functions available in MeSQuaL to gain a sense of its usability. We will guide the users through the following scenarios.

[2]https://physionet.org/content/mimiciii/1.4/
[3]https://aot-file-browser.plenar.io/data-sets

1) **Declaring data quality indicators and constraints.** This scenario is dedicated to showcase the use of the SQuaL language for creating and using relevant contract types and contract instances to specify data quality checks and submit SQL queries extended with QWITH statement. In Panel $\boxed{\text{C}}$ of Fig. 6, the users can explore available contract types and contract instances predefined for the data set, like CheckQDB contract type and CheckBeforeAnalysis contract proposed in Fig. 3 and Fig. 4 that will check the completeness, uniqueness, consistency, or outlyingness of the data. The users will be able to declare new data quality checks and rules, and query the data sets with SQuaL in Panel $\boxed{\text{A}}$. For the query of Fig. 5, Panel $\boxed{\text{B}}$ presents the results on ChicagoDataset and red gauges of Panel $\boxed{\text{D}}$ show that neither the constraints on data consistency and completeness are satisfied by the queried data of ozone sensors ('o3'), nor the constraints defined in RegressionAssumptions contract. As presented in Table 1, other SQuaL queries including nested SQuaL queries (e.g., Q_8) will be tested to show the usability of our system.

2) **Evaluating the applicability of learning models with declarative statistical hypothesis testing.** In this scenario, the user will see in more detail how MeSQuaL can be used to declare various statistical tests, and visualize which data lead to violations of some statistical assumptions or other requirements of various ML models. For example, before the application of a linear regression over a data set, at least four critical assumptions need to be verified: normality, linearity, homoscedasticity, and absence of multicollinearity. Using StatTests contract type instantiated by RegressionAssumptions contract (defined in Fig. 3 and Fig. 4) available in the contract explorer (Panel $\boxed{\text{C}}$), the user will easily check if the statistical properties are met by the query results. The attendees will notice that new contracts can be added in a flexible and modular way, and they will explore our library of tests, inspect the logs of previous queries and

Table 1: SQuaL Query examples of the demo

	Q_2	CREATE CONTRACT RegressionAssumptions (StatTests.autocorrelation > 0 AND StatTests.autocorrelation < 4 AND StatTests.multicollinearity <= 4 AND StatTests.heteroscedasticity < 0.05 AND StatTests.SWerrorNormality < 0.05);	28.3	-	2550.8	2579.1
AoT	Q_3	{ SELECT * FROM ChicagoDataset } QWITH CheckQDB.completeness> 0.95;	32.9	587.2	566.2	1186.3
	Q_4	{ SELECT * FROM ChicagoDataset } QWITH CheckBeforeAnalysis AND RegressionAssumptions;	274.6	499.6	500.4	1274.6
	Q_5	{ SELECT timestamp, node_id,value_raw,valuehrf FROM ChicagoDataset WHERE ChicagoDataset.sensor = ’o3’ } QWITH CheckBeforeAnalysis AND CheckQDB.completeness> 0.95;	214.2	21.5	784.7	1020.4
MIMIC-III	Q_6	{ SELECT * FROM Admissions } QWITH CheckQDB.completeness> 0.95;	42.1	346.8	472.3	861.2
	Q_7	{ SELECT * FROM Admissions WHERE Admissions.insurance = ’Private’ } QWITH CheckBeforeAnalysis AND CheckQDB.completeness> 0.95;	237.0	154.1	493.8	884.9
	Q_8	{ SELECT gender, dob, admittime FROM Admissions INNER JOIN (SELECT * FROM Patients WHERE dob < ’2090-12-12 00:00:00’ QWITH CheckQDB.completeness> 0.95) as Pat ON Admissions.subject_id=Pat.subject_id; } QWITH CheckQDB.completeness> 0.95;	318.9	16.6	1610.1	1945.6

checks (Panel $\boxed{\text{F}}$), and reload the visualization of some previous SQuaL queries (from Panel $\boxed{\text{C}}$). MeSQuaL combines the declarative and scripting approaches for querying the data and checking various assumptions simultaneously. It facilitates notably the data preparation choices to meet the requirements of some ML algorithms. Since the declared contracts are independent of the data sets, they can be reused whenever the assumptions and data quality checks need to be checked.

3) **Monitoring the evolution of data quality indicators.** In this last scenario, the attendees will see the possibilities offered by MeSQuaL for monitoring the evolution of data quality indicators in Panel $\boxed{\text{E}}$. Once declared, contract types and contract instances are stored as metadata and executed regularly by MeSQuaL’s `DQT Manager` via its configuration to schedule recurring SQuaL queries. The user can act as a DBA and define various thresholds for the declared data quality indicators to alert when some results are suspicious. Using the `AoT ChicagoDataset`, the attendees will see how MeSQuaL facilitates the continuous monitoring of data quality indicators to detect, for instance, inconsistent data from neighboring air pollution sensors or intermittent sensor failures with the use of the library of UDFs provided by MeSQuaL. Using MeSQuaL’s user interface shown in Fig. 6, the user can visualize the declared data quality indicators and spot the periodic or punctual errors in the data over time in Panel $\boxed{\text{E}}$.

4 RELATED WORK

Data quality has been extensively studied by the database community in the last decades [3, 10] with a line of data cleansing commodity systems and tools that can detect anomalies and reduce the burden on data scientists for data repairing and data preparation in the context of ML pipelines [1, 2, 8, 9, 13]. MeSQuaL is similar to some extent to two main operational data validation systems: (1) Google TensorFlow Data Validation (TFDV) system [4], used in production, is a library for exploring and validating ML data, including schema inspection and anomaly detection, such as missing features, out-of-range values, or wrong feature types, and (2) the Amazon system implementing unit-tests for data verification has been proposed in [11, 12]; it offers a declarative API that allows users to define checks on their data by composing a variety of available constraints. However, the main drawback of these systems is that they do not provide the user with (1) the possibility to interact with the data quality checking process, (2) the flexibility to declare new data quality metrics with user-defined functions, or constraints for data quality checks, and (3) the extension of the query language to check the results with respect to data quality requirements and constraints.

The key novelty of MeSQuaL is to provide the user with a framework for checking the quality of their relational data by declaring UDFs and constraints using SQuaL, an SQL-like query language extension for querying data and checking on-demand the quality of the results.

ABSTRACT

Facility placement has been receiving considerable research attention due to the proliferation of GPS equipped mobile devices. Establishing new facilities has a wide spectrum of applications including billboard placement, wildlife monitoring, supermarket/restaurant placement, etc. In all these applications, finding the best position to place a facility can lead to the optimal benefit given plenty of target users, which are associated with many historical position logs, e.g., user check-in data, wildlife monitor logs. In this work, we demonstrate a general system, namely MALOS, for answering the majority of facility placement problems given movement logs of a series of target users. Specifically, MALOS leverages on three academic works in the following scenarios. Find the best one/k position/s to place one/k new facilities in order that the overall benefit can be maximized; find one position to place an extra facility given that there are k existing facilities in different places, such that the overall benefit can be maximized. Notably, in MALOS we consider only the geographical issues that are common in all facility placement applications and choose not to take into account the specialized factors that vary across applications, such as billboard size, restaurant type, etc. We shall provide an opportunity for demonstration users to experience all kinds of these facility placement queries with a real-world historical movement logs and corresponding maps interface.

1 INTRODUCTION

Facility placement has been receiving considerable research attention due to the proliferation of GPS equipped mobile devices. Establishing new facilities has a wide spectrum of applications, for example, setting up billboards, monitoring wildlife, running restaurants, building charge stations and urban planning. Majorities of existing research work focus on solving a specific problem, such as setting up billboards or running restaurants, etc. If we change the application, these researches cannot be applied directly to the new one. Therefore, we are motivated to design a general system to address facility placement problem, namely Movement-Aware LOcation Selection system (MALOS).

Compared with the maximum coverage problem of existing work [7], the advantages of MALOS are as follows. Firstly, as a ready-to-use integrated system, instead of loading offline dataset as input, MALOS incorporates a data acquisition module that collects historical check-in data from the Internet and is updated in real-time; secondly, [7] can only be applied in outdoor advertising applications but fails to fit in other applications. In comparison, we take into account the common factor of different facility placement applications, i.e., distance, and allows user-configuration for other factors specialized for particular scenarios. Thirdly, MALOS is a general system that supports up to three different use cases, while [7] considers only one of them.

MALOS is a *general* movement-aware facility placement system, where *general* can be interpreted as follows: 1) We generalize the common spatial-correlated issues within facility placement applications, and avoid falling into application-dependent factors, *e.g.,* size and price of billboard, categories of restaurant and etc., which can be extremely different across applications. 2) We consider the following representative scenarios in facility placement, given the historical movement logs for a large scale of users.

- *Place-One*: query the optimal location which can influence the maximum moving objects [6].
- *Place-k*: return k locations which can influence the largest number of moving objects [4].
- *Incremental-One*: add a location into the existing locations set which could provide the best marginal [1].

Our key contributions in this work are summarized as follows.

- We develop a general system based on user movement data, namely MALOS, answering general facility placement queries with user-friendly browser-based interface.
- The system provides three different queries to meet the major requirements for facility placement applications.
- We provide a module to further incorporate check-ins data for each moving object in real-time.

The rest of the demonstration proposal is organized as follows. Section 2 formally defines the specific queries supported by MALOS. Then, we introduce MALOS system in Section 3. Section 4 offers the demonstration details. Finally, Section 5 concludes the demonstration.

2 DEFINITION OF QUERIES

In this section, we will introduce the definitions of three queries mentioned before.

Definition 2.1 (Place-One). Given a set of candidate locations C, a set of moving objects Ω, a certain distance-based probability function PF and a user-specified influence threshold τ, the *Place-One* query aims to find the optimal candidate $c \in C$ such that $\forall c' \in C - \{c\}, inf(c) \geq inf(c')$, where $inf(c)$ is the number of moving objects in Ω that are influenced by c [6].

Definition 2.2 (Place-k). Given a set of candidate locations $C = \{c_1, c_2, ..., c_n\}$, a set of moving objects Ω and the budget number of new facilities $k(k \leq n)$. *Place-k* aims to find $\exists S \subseteq C$ to maximize $\sigma(S)$. $\sigma(S)$ denotes the total number of moving objects that are influenced by candidate set S [4].

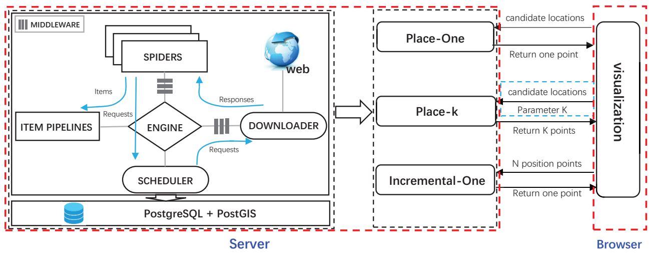

Figure 1: Architecture of MALOS.

Definition 2.3 (Incremental-One). Given a set of candidate locations C, a spatial network graph $G(V, E)$, a set of existing facilities F and a set of moving objects Ω, each of whose movement can be modeled as a set of reference locations, *Incremental-One* aims to find the optimal location c among a set C of query candidates such that $\forall c' \in C, \Delta(c) \geq \Delta(c')$, where $\Delta(c)$ is expected reduction of total distance for c [1].

In particular, in our default settings, we follow the same suggestions from original corresponding academic works for different queries. For instance, in *Place-One*, the probability of a user checking-in at a point-of-interest decays as the power-law of the distance between them. We set the distance-based probability function PF as $\rho(d_0 + dist(c, p))^{-\lambda}$ by default as suggested in [6], where ρ is a factor to describe behavior pattern, d_0 is a distance factor, $dist(c, p)$ is the distance between candidate c and position of moving object p, λ is a exponential factor to configure the mapping from distance to influence probability. In MALOS system, the default values of the number of candidates, probability threshold τ, behavior factor ρ, and exponential factor λ are 600, 0.7, 0.9, and 1.0, respectively. In fact, it can also be manually adapted to other functions by MALOS users.

3 MALOS PROTYPE

In this section, we cover the framework of MALOS, the acquisition of check-in data, modeling of check-in data in database and interaction with data.

3.1 The MALOS architecture

MALOS adopts the browser-server model and is implemented with JavaScript and Java, built on top of PostgreSQL. MALOS implements three algorithms: PINOCCHIO algorithm [6], GreedyPS algorithm [4] and Local Network Based (LNB) algorithm [1]. However, MALOS is not a simple aggregation of these three algorithms, which consider only how to address particular use cases given the data sources. Instead, as a real-time and ready-to-use system, MALOS has to additionally address two other grand challenges, 1) where and how to get the data these algorithms rely on; 2) how to store the data such that these algorithms can be efficiently carried out. Our solutions towards both challenges are discussed in detail within Section 3.2 and 3.3, respectively.

The architecture of MALOS is shown in Figure 1, which includes data acquisition, query processing and visualization modules. The data acquisition module obtains the historical position logs from third-party resources (e.g., Sina Weibo, Twitter). In order to efficiently crawl data from the web, we use the Scrapy architecture, which can efficiently obtain historical location check-in data to ensure real-time performance [5]. Users submit query requests through the browser, which executes a particular facility placement algorithm (*Place-One*, *Place-k* or *Incremental-One*) based on the request. Finally, the results are returned to the users, and are displayed over a Map interface (*e.g.,* Google Maps, Baidu Map) in the browser.

3.2 Data acquisition

How to obtain moving users' historical position data is a first challenge for MALOS. At present, there are two direct ways to address it, one is to be authorized to obtain real-time data directly from giant LBS (location-based service) enterprises (e.g., Uber, Google), the other is to cooperate with government departments. However, neither of them is easy to be carried out for ordinary companies. In this end, MALOS system aims to provide a friendly usage for general public users, who are unable to get the data through the ways discussed above. Therefore, we developed a general web crawler to obtain the historical locations of people through third-party services.

In MALOS system, we use Scrapy framework [5] to collect data. Scrapy is an excellent open source framework for quick crawling of web sites and extracting structured data. There are mainly seven components in Scrapy. Scrapy *Engine* is responsible for controlling the data flow between all components of the system. *Scheduler* receives requests from the engine and enqueues them for further usage by the engine. *Downloader* is responsible for fetching web pages and feeding them to the engine which, in turn, feeds them to the spiders. *Spiders* are custom classes written by us to parse responses and extract items from them or additional URLs to follow. *Item Pipeline* is responsible for processing items once they have been extracted by the spiders. *Downloader Middlewares* are specific hooks that sit between the Engine and the Downloader; and process requests (resp., responses) when they pass from the Engine to the Downloader (resp., Downloader to the Engine). *Spider Middlewares* are specific hooks that sit between the Engine and the Spiders; they are able to process spider input (responses) and output (items and requests). The framework also provides a convenient mechanism for extending Scrapy functionality by plugging custom code.

We present a feasible crawling strategy for MALOS (By default, the crawling site of the MALOS system is Weibo). First, we select one (or more) seed users in a region as the initial target, which is determined by the geographic location label in the personal information list. For each crawled object, we grab personal information in turn, locations of historical check-ins in all Weibo pages, as well as fans list and follower list. Then, add the two lists in the upper level watchlist to the crawl object list. Following this iteration, the reptile radiation can be formed, which takes the seed user as the core and diffuses outward layer by layer. In fact, there are a lot of records with noise information, such as some vulgar marketing numbers. Therefore, we need to set a threshold value for the captured object to determine whether the user is a target user. In MALOS, we parameterize a target moving user as follows: the number of message < 5000, fans < 5000, follower < 5000.

Given the above strategy, Scrapy in MALOS works as follows (illustrated in the left part of Figure 1). When the web *Spider* starts, it will extract each URL from the start URL of a seed user and encapsulate it into a request, which will be sent to the *Engine*. Then the requests are passed over to the *Scheduler* and form a queue. The first item in the queue will be sent to *Downloader* for retrieving the corresponding content. The response file returned from the *Downloader* will be handed over to a parse method. Finally, the parse method calls the a predefined XPath to extract the check-in data from the crawled page content.

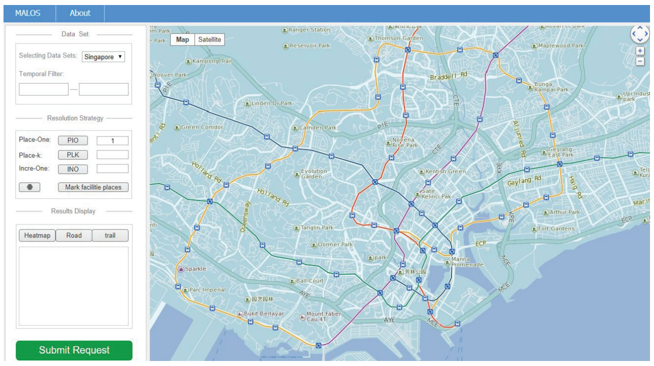

Figure 2: The browser interface of MALOS.

In order to meet our requirements, we customize these components by defining some parameters as followings.

ROBOTSTXT_OBEY = False
DOWNLOAD_DELAY = 0.1
CONCURRENT_REQUESTS = 16

3.3 Storage of check-in data

The check-in data reflects the spatio-temporal behavior of the moving object. It generally includes user ID, check-in location, timestamp, check-in area, etc. The check-in location sequence with time mark constitutes the user's historical positions logs. Based on the check-in records, we are able to construct historical positions logs for each individual Weibo user we have crawled. In particular, in PostgreSQL we present the following schema for user historical positions logs.

CI_PAIR (USER_ID varchar(40), LAT real, LNG real, CI_Time timestamp, CITY varchar(256));

Each CI_PAIR object stores the position of a moving user at a particular timestamp. Multiple records of a user are combined to form a spatial-temporal movement history.

We store the dataset in PostgreSQL (version 11.6) extended by PostGIS[1]. In addition to using the embedded distance calculation function ST_Distance ($geometry\ g1, geometry\ g2$), MALOS system extends the integration of PLACEONE($dataset$), PLACEK($dataset, parameter\_k$) and INCREONE ($dataset$, $parameter\_k$) functions into the PostgreSQL database. The extensions are basically customized functions that define specific query processing algorithms. As a mild coupling external module, the extensions can be easily distributed and maintained.

3.4 Usage of MALOS in facility placement

In MALOS system, data operations are initiated by users from browser side. The browser side offers two panels, the function panel and the map panel [2]. The function panel provides the interfaces to users for obtaining check-in data and generating queries. The map panel shows a map that illustrates the returned objects given the required query input of system users.

Users interact with the system through the function panel. The function panel provides data acquisition interaction function and location query interaction function. Note that in case that API authentication settings for real-time crawling mode may require troublesome modifications, in the demonstration we also provide an alternative mode to allow the system to load offline track data.

The MALOS system mainly provides users with three functions: *Place-One*, *Place-k* and *Incremental-One*. *Place-One* and *Place-k* functions are mainly for users who have not yet deployed any facility and want to select locations to deploy new ones in some candidate areas, which can also be manually set by the system users. *Place-One*, which aims to find the optimal location from a set of candidates to place a new facility such that a score (*i.e.,* benefit or influence on some given objects) can be maximized. Further, a user can specify a constraint k to perform *Place-k*, which indicates the number of candidate locations the user plan to choose. Considering that there are existing facilities, and users may intend to expand the scale of the facility network by opening a new one, the system provides *Incremental-One* function, which allows users to enter a series of existing facilities locations as constraints for location selection. Different algorithms with respect to each of these use cases have been implemented in MALOS system.

The *Place-One* function is addressed using PINOCCHIO algorithm. PINOCCHIO algorithm employs the R-tree structure to build geographic data index, then leverages two pruning rules based on a novel distance measure. With the help of influence arcs (IA) rule, it identify the candidates that influence the object. For the remnant candidates, non-influence boundary (NIB) rule is used to exclude those cannot influence the object. Lastly, the remnant candidates are verified.

The *Place-k* function is solved by GreedyPS algorithm. GreedyPS algorithm first calculates the set of objects affected by all candidates. Then it maps these sets to w bitmaps. Finally, it selects the candidates with the largest number of '1' in bitmaps until K is in each iteration process.

The *Incremental-One* function is addressed via LNB algorithm. It first constructs an index structure, Local Network Table (LNT), based on network locality. With the help of LNT, we initialize a Max Heap LNH ordered by $\Delta^+(v_i v_j)$, which is the upper bound of expected reduction of total distance (ERD) if a facility is built on edge $v_i v_j$. Then it iteratively checks the top candidate c in LNH. If $\Delta(ol)$ of current optimal candidate ol is greater than ERD upper bound for the top edge in LNH, the validation is finished. Otherwise, for every reference location whose local network covers $v_i v_j$, it needs to calculate $\Delta(c)$ through relevant rules. If a better candidate is found, it updates ol by c and eventually the optimal answer can be obtained, where $\Delta(c)$ is ERD for c.

After the request is processed by the server, the objects retrieved are returned. In order to enable users to observe the data intuitively, we need to visually present the spatial and temporal distribution of trajectory data. Visual comparison is one of the most fundamental and common visualization tasks [3]. Thus, we add a thermal layer, where we provide users with two types of density maps, namely, heatmap and roadmap. The thermal layer demonstrates the distribution density of the target trajectory in the geographic location by overlaying different color blocks on the map. In case that the volume of the check-in location data heat layer does not clearly reflect the trajectories of the crowd, we extensively add a trajectory layer to the system. The trajectory layer distinguishes the trajectories of different people by different colors, and reflects the overall trend of the trajectories by sampling method, which enhances the interaction experience for users. The marker layer provides a solution for visually presenting the results returned by the server and marking the input location points by users. For the *Incremental-One* function, a user does not need to enter the specific latitude and longitude coordinates of the existing facility in the system function panel. It is only necessary to find the location of the facility in the map panel and perform correlated marking on the marker layer.

4 DEMONSTRATION

In our demonstration, as discussed before, we additionally implement an offline mode within MALOS system, in case there is troublesome modification for crawler API settings that is brought by the network connection issues. In offline mode, we adopt real-world check-in data in Singapore[2] to give users the opportunity to interact with MALOS and experience how the system can be used to select the location of facilities. The browser interfaces of MALOS has been shown in Figure 2. Users can use the system to find the best location of facilities in various scenarios, including *Place-One*, *Place-k* and *Incremental-One*.

4.1 Data loading and request submission

First, the user needs to select a target city to place the facility, and then select a function in the function panel to initiate the request. In MALOS system, we provide a list of cities for users to choose. For offline mode, the city can be only configured as Singapore. When the user selects a region where he wants to deploy the facilities, the map panel will automatically switches to focus on the corresponding area, and the server loads the historical check-in locations within the region. As shown in Figure 2, when the system loads the offline Singapore dataset, and the map panel also switches to Singapore. To specify the interested location, an audience can select a fine-grained location by drawing a rectangle on map panel (the latitude and longitude of the location are obtained using the Map API). For the *Incremental-One* function, the MALOS system allows users to enter some request constraints before running it. A user can enter a constant k to indicate the number of locations need to be picked. As illustrated in Figure 3, user enters a constant of 5 and marks five locations on the map to indicate the currently deployed facilities. The results display list also shows the longitude and latitude of these five facilities for user input verification.

4.2 Visualization and results display

Users can also explore the distribution of urban population information by visualization. There are three kinds of visualization methods, namely, heatmap, roadmap and trajectory-map for users to choose. As shown in Figure 4, heatmap is shown. In heatmap and roadmap, the darker the color, the greater the population density. The trajectory map shows the migration path of the crowd, and users can view the spatial and temporal distribution of urban population. As illustrated in Figure 3, when the query results are returned to the browser, the result objects are displayed in both the map panel and the result list. At the same time, users can further explore the surrounding environment of the recommended location by the system with the visualization.

[2]The default trajectory data source can be found in the github of PINOCCHIO listed in our MALOS project homepage: https://lihuixidian.github.io/malos/

5 CONCLUSION

In this demonstration, we present a general facility placement system, namely MALOS. MALOS solves a group of representative facility placement problems based on historical check-in location data that comes from the Internet and is updated in real time. MALOS adopts the browser-server model and provides an easy-to-use interface to answer *Place-One*, *Place-k* and *Incremental-One* queries. The queries cover the majority of facility placement problems given historical movement logs of massive users. Moreover, the system focuses on geographical issues that are general in all facility placement applications, and avoids taking into account application-dependent factors, such as the size of billboard, etc. In this way, the system can be used as a basic framework and easily adapted to different applications by taking into account extra specific application-aware factors.

ABSTRACT

This demonstration paper focuses on transportation-related queries within a city that go beyond simple routing and that are of interest to different types of users. For instance, individual users could be interested in which modes of transport are more effective to reach a set of alternative locations at a given time of the day, whereas urban planners could be interested in the effect that adding/removing a bus line would have in connecting regions of a city, e.g., a residential neighborhood and downtown. Given that context and using real data from the city of Berlin, we introduce RRAMEN, an interactive tool which is well equipped to support different city-scale mobility-related queries by different types of users.

1 MOTIVATION

Mobility within a city is both an important problem from an individual point of view as well as a higher level concern from a planning perspective. In sync with the current efforts towards mitigating climate change, we believe that there should be, whenever possible, a concerted effort to incentivize the use of public transportation systems. A few of the many worthy goals that can be accomplished with better public transportation systems are reducing traffic, therefore gas consumption, pollution and noise, reducing the need to dedicate large spaces for parking, thus creating more space for people, reducing costs associated with road maintenance, etc. Hence, there is a clear need for better (or complementary) tools that can support/promote a shift from using private vehicles on a regular basis towards public transit. This is the context that implicitly motivates our discussions and contributions in this paper. Also, in keeping with the above and for the purpose of this demonstration, but without loss of generality, we constrain ourselves to two modes of transport, public transit and private vehicles, and two types of users, individuals and urban planners.

Individual users are likely familiar with mobile routing solutions, e.g., Google Maps[1]. Those apps are typically designed for end-to-end routing (possibly setting some intermediate points, between origin and destination). Some of these apps also allow users to compare the efficiency of different modes of transport, e.g., public transit, private cars, bike and walking. However, as we will discuss shortly, comparing modes of transport is a use-case that is not easily contemplated by current apps but which is nonetheless of practical interest to individuals in the sense that it can, even if in a subtle manner, persuade them towards using public transportation. Additionally, we consider the role of urban planners. These individuals are interested in transportation from a collective rather than individual perspective and could make use of tools that help them in that respect.

Many existing systems, e.g., SANET [5], TransCad[2], and ISOGA [4], provide algorithmic solutions that enable the evaluation of public transportation systems through accessibility and/or reachability analysis [2, 8]. Another common approach employed by systems such as TRANSIMS [7], is the analysis of transportation systems through simulation. While the aforementioned systems can provide insight for the design and evaluation of transportation networks, they also come with the shortcoming of examining modes of transport in *isolation*. In many real-world scenarios though, users are more interested in the efficiency of a mode of transport in comparison to other available ones.

Towards the goal of investigating the compromises between different modes of transport from different perspectives, we recently proposed the notion of Relative Reachability [3]:

> Given a set of modes of transport and a source location, the *Relative Reachability* (RR) determines the mode of transport which minimizes arrival time at a given destination location. (As we shall discuss later, this concept can be extend to multiple destinations and/or regions.)

Given this context, our main goal in this demonstration paper is to present RRAMEN[3], a web-based tool which leverages on the RR concept in order to support different types of users with different needs. Towards this goal, in what follows, we discuss the data model underneath RRAMEN, along with its potential users and queries of interest. Next, we discuss in more detail a few queries reflecting the motivation above, while at the same time illustrating how RRAMEN can be used to answer these queries.

2 OVERVIEW OF RRAMEN

RRAMEN is a tool for Relative Reachability Analysis on Multimodal NEtworks that enables users to process a variety of RR queries and visualize the results. Our system is implemented in Python using the NetworkX[4] package for modelling the network, uses PostGIS[5] to store road and public transportation network data, and employs Mapbox[6] to display the map and visualize results. Figure 1 shows RRAMEN's interface. On the top left-hand side the user can define the source(s) and the destination(s), which

can be either a single location, multiple locations or a region. The user can easily select these by clicking on the map. We note that while the processing of some queries is a computationally interesting topic, this paper focuses on discussing their applicability and on how RRAMEN can be used in practice.

In order to answer the queries supported by RRAMEN, we first obtain the road network (including footpaths) from Open Street Map (OSM)[7]. A PostGIS table is created to store the road networks' edges with their length, maximum speed, allowed transportation modes and geometry. To mimic how traffic fluctuates during a day, we assign to each edge of the network a speed distribution similar to the one illustrated in Figure 2. To compute such a distribution, we obtain the maximum allowed speed for each edge from OSM, split the day into a fixed number of time intervals (twenty four) and introduce a penalty that reduces the maximum speed during rush hour. Naturally, this assumption is orthogonal to RRAMEN's operation, i.e., should one have the actual speed distribution for each edge of the network, that could be easily integrated into RRAMEN.

Next, we obtain public transit data from GTFS[8] feeds, which include transit information such as stops, routes, trips and schedules. Such information is stored in a set of relational tables in PostGIS. For each route, we first extract the stop sequence covered by it. Then, for each existing route-stop pair, we create a node and add it to the public transit network. For instance, consider the stop shown in Figure 3 represented by a dotted box. There are three routes, R_1, R_2 and R_3, passing through the stop and, consequently, three nodes are created for that stop. Moreover, all nodes within a stop are directly connected to each other through an edge, the cost of which is given by the time to transfer from one route to another. Such a transfer time is extracted from the GTFS feed whenever available or set to 0 otherwise. Next, consecutive stops of a route are connected through an edge which is associated with a timetable containing the departure/arrival times for the corresponding route represented by that edge.

Finally, we build a multimodal network following the time-dependent model [6]. To connect the public transit network with the road network we create links from each stop to its closest road edge, as shown in Figure 3. More specifically, we first create a parent node P for each stop that acts as an entrance point, and we connect all route nodes within the stop to P with zero-cost edges. Then we look for the closest road edge (u, v) to P. If the closest point to P is u (or v), we add a link edge from P to u (or v). Otherwise, a new node w is created along with two new edges (u, w) and (w, v) and a link edge is added from P to w. The cost of the link edge is given by the travel time on foot.

To process RR queries, RRAMEN employs variants of Barrett's algorithm for the language constrained shortest path [1]. We note that RRAMEN can build routes that use a combination of public transit modes, i.e., bus, train or tram, and walking, as well as driving and walking. In the latter case, we assume that a user can walk to where his/her car is parked, drive and possibly walk again to the destination. Due to lack of more fine-grained data, we make the optimistic assumption that when using a private car one parks as close as possible to the source location and to the destination.

RRAMEN can support a variety of types of users and queries. Table 1 shows two types of users and queries that would be well supported by RRAMEN. Note that while many of the requirements of individual users can also be addressed using existing route planning systems by executing multiple (independent) queries, RRAMEN makes the exploration and the decision making process much easier. Furthermore, while it is true that some users will choose a transportation mode regardless of the RR of the destination, we believe that allowing one to make such choices quickly and easily is of practical value. In particular, it may incentivize one to make choices that favour the use of public transit.

3 DEMONSTRATION SCENARIOS

In this section, we use real data from the city of Berlin to demonstrate how RRAMEN can be used in practice by individual users as well as urban planners. Note that while in the following discussion each query is associated with a particular type of user, RRAMEN imposes no such binding by design.

3.1 Individual users

Single source-multiple destinations. Consider a user who is at home and wishes to watch a movie which is showing in a

[7]https://www.openstreetmap.org/
[8]https://developers.google.com/transit/gtfs/reference

Table 1: Sample users and queries supported by RRAMEN

Users		Queries (location-wise)	
Individual Users	**Urban Planners**	**One-to-many / Many-to-one**	**Many-to-many**
Can use RRAMEN to find easily reachable facilities within a city, or to make decisions related to their commute.	Can study transportation systems and the impact of changes on them.	Queries from a single source to multiple destinations or from multiple sources to a single destination.	Queries from multiple sources to multiple destinations (which can also model regions).

number of movie theatres. The choice of theatre could be based on how convenient it would be to reach that theatre w.r.t. the means of transportation considered. Figure 1 illustrates this type of one-to-many scenario, where the source is denoted by an orange marker and the destinations are denoted by green markers. The result of this query reveals that the two locations on the left half of the map (denoted by blue dots) have an arrival time earlier by public transportation than by car. Likewise, the other three possible destinations have an earlier arrival time by car.

In addition to determining the RRs for all destinations, the user may be interested in the actual arrival time at a given destination (using either means of transportation). For that he/she would simply click on the destination which would cause not only the arrival times to be displayed but also the actual suggested routes. This is illustrated in Figure 4 where we "zoom in" on the map in order to show only the relevant part of the interface[9].

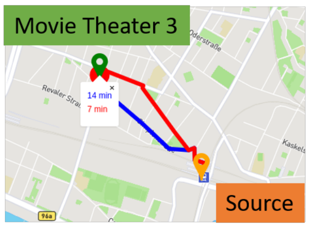

Figure 4: Arrival times for Movie Theatre 3, along with the routes by both public transit and private car.

Now, one may ask, what is the practical relevance of such a query? Naturally, there are trade-offs to be considered. For instance, if a user measures convenience by not having to look and (very likely) pay for parking and/or being able to have a drink or two after watching the movie, he/she would choose to go to some movie theatre using public transit regardless of its RR. Also, if a movie theatre that can be reached faster by public transit is far away, the user may choose a closer one to be reached by car, even with the associated overhead. Either way, RRAMEN empowers the user to consider such tradeoffs by him/herself.

Multiple sources-single destination. Let us now consider a scenario that is sort of the "reverse" of the one above. Consider a user that is moving to a city to work at a certain location and is looking for a place to rent. One criterion to choose where to live may be how convenient it would be for him/her to reach his/her workplace by public transit whenever his/her working shift starts. In this case, it would be useful to see the RRs of different rental units. An important difference of this scenario w.r.t. the previous one, is that in the previous scenario the RRs are computed w.r.t. the destinations (which theatre would be more convenient to reach from home), whereas now the RRs are computed w.r.t. the sources (from which potential apartment it would be more convenient to reach the workplace).

[9]Due to limited space, in what follows we show just the map part of the interface.

Figures 5 and 6 show the RRs of five apartments (orange markers) w.r.t. the working place of the user (green marker) at two different times, 7:30am and 5:30pm, respectively. By comparing the two figures we observe that the RR of all apartments but #4 remain the same. That is, if the user is interested in using public transportation, then apartments #3 and #5 are the best choices. We can imagine the case where apartment #4 may be a good choice if one is typically carpooling in the morning but riding a bus in the afternoon. The main point here is that, again, a single query returns the best available options to the user, leaving the final decision to him/herself.

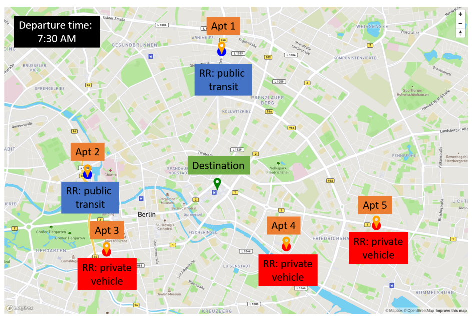

Figure 5: RR for apartments early in the morning.

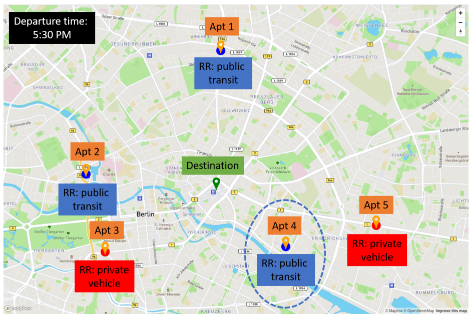

Figure 6: RR for apartments late in the afternoon. Note that Apartment #4's RR is different from earlier in the day.

Single source-region destination. Similar to the example above, one may want to consider living in a neighborhood that offers good transportation options towards a region on weekends. Figure 7 shows such a scenario at 8am, where the source is denoted by the orange marker and the destination region (say, the entertainment district) is determined by a polygon drawn by the user. We note that, besides selecting one or more destination points or sources as done in the scenarios above, RRAMEN allows the user to draw a region or select from a pre-determined set of regions, e.g., municipalities. As one can see in Figure 7, each point (node in the network) is either coloured blue or red (depending on whether the arrival time is earlier by public transit or

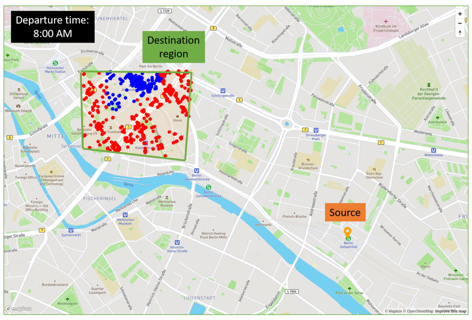

Figure 7: RR of points in a region w.r.t. a single source location at 8am.

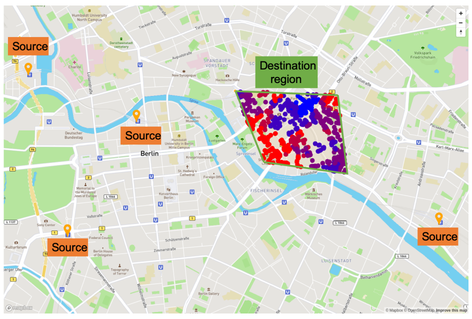

Figure 9: RR of all points within a region w.r.t. multiple source locations

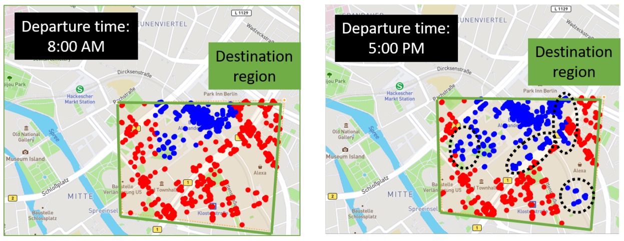

Figure 8: Same scenario of Figure 7 for 8am and 5pm. The dotted circles highlight the changed RRs.

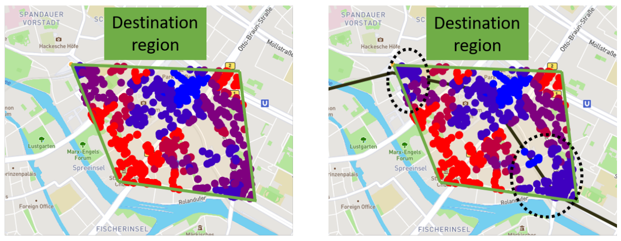

Current RRs (i.e., before adding the new train line) Resulting RRs <u>after</u> adding the new train line

Figure 10: Detailed view before and after adding a new train line. The dotted circles highlight the changed RRs.

car, respectively). Interestingly, if the departure time were to be set to 5pm, the RRs within the destination region change quite a lot, as shown in Figure 8. Once again, by changing a single parameter in RRAMEN's interface the user can be better informed before making his/her decision.

3.2 Urban Planner

Multiple sources-region destination. Here we envision a scenario where a planner would select a number of representative points in the city, e.g., shopping malls, and identify their RR w.r.t. a region, e.g., downtown. While on the surface this may seem similar to the multiple sources-single destination query discussed earlier, there is a fundamental difference. For the earlier query each source location had its own RR, whereas for the current query, the RR for each one of the potential destination locations within the target region reflects an average over the RRs computed from all different source locations. Figure 9 illustrates this scenario, where the colors of each point reflect how much more likely it is for a transportation mode to be the most efficient w.r.t. the source locations. That is, the closer to red (or blue) the more likely it is, over the set of source locations, that private cars (or public transit) reach that point earlier.

Multiple sources-region destination before-after analysis. The following discussion is a natural follow-up from the previous one and depicts a scenario that may reflect best the usefulness of RRAMEN for an urban planner. What would happen if more resources were allocated to the public transportation system? For example, what would happen if one new train line was added? Figure 10 illustrates such a before-after comparison. One can clearly see that the northwest and southwest corners of the region in the figure on the right have more blue points than in the figure on the left. That is, by adding one additional train line, the RR of some locations would "flip" towards public transit, which we believe should be one of the goals of an urban planner. A similar analysis can be done in case one removes transit lines and/or removes (or adds) thoroughfares for private cars.

4 CONCLUSION

We presented RRAMEN, a web-based tool based on the concept of Relative Reachability, the main goal of which is to aid individual users and urban planners (among others) in making informed choices and evaluating changes w.r.t. a city's transportation network. There are a few interesting directions for further work, such as taking into account the demographics of a city when evaluating how changes impact a city's population at large. From a computational aspect, it would be also interesting to consider incremental and parallel/distributed computation models to scale up the overall efficiency of the the tool.

ABSTRACT

JedAI is an open-source toolkit that allows for building and benchmarking thousands of schema-agnostic Entity Resolution (ER) pipelines through a non-learning, blocking-based end-to-end workflow. In this paper, we present its latest release, JedAI^3, which conveys two new end-to-end workflows: one for budget-agnostic ER that is based on similarity joins, and one for budget-aware (i.e., progressive) ER. This version also adds support for pre-trained word or character embeddings and connects JedAI to the Python data analysis ecosystem. Overall, these enhancements provide JedAI with features offered by no other ER tool, especially in the schema- and domain-agnostic context.

1 INTRODUCTION

Entity Resolution (ER) aims to detect *duplicates*, i.e., different entity profiles that describe the same real-world objects. It is a core data integration task, with many applications that range from knowledge bases to question answering [8]. Yet, the available systems focus exclusively on *batch ER*, which is carried out in a budget-agnostic, offline way that imposes no strict constraints on temporal or computational resources. This means that they do not support *progressive ER*, which is carried out in a budget-aware manner that determines specific time frames or resources (e.g., by executing a fixed number of comparisons).

Even for batch ER, though, the existing tools have significant limitations: they cover the end-to-end pipeline partially, they constitute stand-alone systems with a limited variety of methods (usually the methods proposed by their creators), they apply only to a specific data type (i.e., structured or semi-structured data), or they require power users, providing insufficient guidelines on how to perform ER efficiently and effectively [8]. Another major disadvantage of existing tools is that they typically disregard the bulk of similarity join algorithms that allow for detecting pairs of duplicates in a rather efficient way.

Magellan resolves most of these issues, but is restricted to *Clean-Clean ER*, i.e., the task of detecting duplicate profiles across two overlapping, but individually duplicate-free datasets. This means that Magellan cannot tackle *Dirty ER*, i.e., the task of resolving the entities of a single dataset that contains duplicates in itself. Moreover, Magellan applies exclusively to relational data, it lacks a GUI, merely offering a command-line interface, and

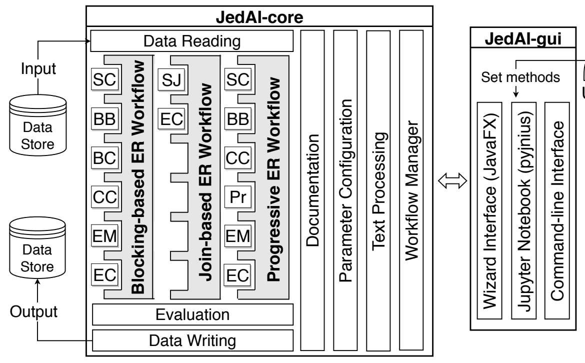

Figure 1: JedAI's architecture.

requires heavy user involvement. Its goal is actually to facilitate the development of tailor-made methods for the data at hand [8].

Java gEneric DAta Integration (JedAI) Toolkit [15] goes beyond existing ER tools by focusing on non-learning, schema- and structure-agnostic methods, which apply seamlessly to both structured and semi-structured data. At the same time, JedAI requires minimal human intervention, as neither domain knowledge nor training sets are needed. At its core lies a blocking-based end-to-end ER workflow, which is implemented by JedAI-core[1], conveying numerous state-of-the-art methods in each step. These methods can be mixed and matched to form thousands of ER pipelines that can be easily benchmarked through the wizard-like interface of its desktop application, JedAI-gui[2]. Thus, JedAI fulfills the main challenges arising in data integration [5]: the development of extensible, open-source[3] tools and the provision of solutions that apply to data of any structuredness - even unstructured (free-text) data. These new capabilities are exhibited through a live demonstration that involves user interaction.

In more detail, this demonstration presents the latest release of JedAI^3, which significantly enhances the core blocking-based workflow: it connects it with the Python ecosystem (see Section 5.1) and enriches it with pre-trained embeddings and with new techniques and capabilities per workflow step (see Section 2.1). Most importantly, JedAI now supports two new workflows: one based on similarity joins (Section 3) and one implementing budget-aware ER pipelines (Section 4). These enhancements equip JedAI with unique features that are offered by no other ER tool, especially in a schema- and domain-agnostic context.

Figure 3: Three matching rules along with their performance over established datasets.

2 BATCH, BLOCKING-BASED ER WORKFLOW

Figure 2(a) depicts the budget-agnostic, blocking-based end-to-end ER workflow of JedAI. It consists of the following steps.

1) *Data Reading* loads from disk the dataset(s) to be processed and the golden standard. The JedAI data model accommodates both structured (relational databases, CSV) and semi-structured (SPARQL endpoints, CSV, XML, OWL and RDF) data as well as any mixture of those.

2) *Schema Clustering* groups together attributes that share similar names and/or values, but are not necessarily semantically equivalent. It is an optional step that is suitable for highly heterogeneous datasets with hundreds of different attribute names. In these settings, it significantly improves the overall precision with no impact on recall [15, 18].

3) *Block Building* clusters similar entities into blocks so as to drastically reduce the candidate match space. It includes most of the state-of-the-art methods, using their schema-agnostic adaptation [13], which extracts multiple blocking keys from each entity and places it into multiple blocks. The resulting *overlapping* blocks contain high levels of redundancy, achieving high recall at the cost of low precision [13], due to two types of unnecessary comparisons [13]: (i) the *redundant* ones, which are repeated across different blocks, and (ii) the *superfluous* ones, which involve non-matching entities.

4) *Block Cleaning* is an optional step that cleans the original blocks from both types of unnecessary comparisons, improving their precision at a negligible cost in recall. All available methods are complementary and can be combined.

5) *Comparison Cleaning* is another optional step that targets both types of unnecessary comparisons. It operates at the level of individual comparisons, achieving higher accuracy at the cost of a higher time complexity. Several methods are included, primarily Meta-blocking techniques [14, 18].

6) *Entity Matching* implements schema-agnostic methods for assessing the value similarity of all entity pairs in the final set of blocks. These methods can be combined with various similarity measures and graph or bag representation models from the Text Processing component (see Figure 1). The end result is a *similarity graph*, where the nodes correspond to entities, and the weighted edges connect compared entities.

7) *Entity Clustering* includes the main methods that are typically used for partitioning the nodes of the similarity graph into equivalence clusters, such that every cluster corresponds to a distinct real-world object [6].

8) *Evaluation* uses the golden standard of the selected dataset in order to compute several measures for effectiveness and time efficiency. The user may store intermediate or end results through the *Data Writing* functionality.

2.1 New features

This workflow has been enriched with support for embeddings, which lie at the core of the latest ER works that are based on deep learning [4, 12]. JedAI supports any pre-trained character- (e.g., fastText [1]) and word-level embeddings (e.g., Glove [17], word2vec [11]). The user is only required to provide a path to an embeddings file in CSV form. These embeddings can be used in two steps: (i) in Block Building, combining them with LSH as in [4], and (ii) in Entity Matching, providing external, contextual information for the computation of value similarities, which is particularly useful for noisy entity profiles [12].

Another major improvement is the combination of multiple Entity Matching methods. It is now possible to select any (reasonable) number of algorithms, similarity measures and representation models for comparing the candidate matches that are contained in a set of blocks. For example, it is possible to combine the traditional bag-of-words model with the popular word2vec embeddings, each coupled with a different similarity measure. JedAI combines the similarity scores produced by the individual methods and normalizes them into the $[0, 1]$ interval.

Finally, several steps of this workflow have been enriched with new techniques. For example, Data Reading and Data Writing now support HDT and JSON files, while Entity Clustering conveys two new algorithms for Clean-Clean ER that are designed for solving the assignment problem: an efficient approximation called *Row-Column Proxy Clustering* [9], and a heuristic algorithm called *Assignment Problem Heuristic Clustering* [2].

3 JOIN-BASED ER WORKFLOW (NEW)

Similarity joins [7, 10] constitute a rather efficient alternative to blocking-based ER, especially for structured data that conforms to a schema of known quality. These joins accelerate the execution of matching rules and are combined with an Entity Clustering algorithm for high effectiveness [6], as shown in Figure 2(b). For example, consider the atomic (R1, R2) and composite (R3) matching rules in Figure 3, which exhibit very high effectiveness in combination with Connected Components clustering over established benchmark datasets [13].

JedAI-core now implements the workflow in Figure 2(b), conveying a library with the state-of-the-art string [7] and set [10] similarity join techniques. Most of them require that the user is familiar with the schema describing the entity profiles so as to select the most suitable attribute names. JedAI-gui facilitates this process through the *data exploration* feature, which allows for observing the schema and the values of entity profiles. Most importantly, JedAI goes beyond this schema-aware approach, applying similarity joins to semi-structured data through a schema-agnostic transformation that considers all tokens (or q-grams) in all attribute values (e.g., R2 in Figure 3). The only caveat comes from the resulting low similarity thresholds that render inapplicable character-based and token-based methods that are crafted for much larger thresholds [7, 10]. JedAI covers such cases by incorporating novel join techniques that inherently support low similarity thresholds, like SilkMoth [3] and Atlas [21].

The list of the character- and token-based similarity joins that are currently supported by JedAI appears in Figure 4. It entails

Similarity Join Methods		Prioritization Methods
Token-based	Character-based	1) Local Progressive Sorted Neighborhood
1) AllPairs	1) AllPairs	2) Global Progressive Sorted Neighborhood
2) PPJoin	2) FastSS	3) Progressive Block Scheduling
3) SilkMoth	3) PassJoin	4) Progressive Entity Scheduling
	4) EdJoin	5) Progressive Global Top Comparisons
		6) Progressive Local Top Comparisons

Figure 5: JedAI-gui reporting the performance of a Progressive ER workflow (a) and its benchmark screen (b).

most state-of-the-art approaches, as determined by recent experimental analyses [7, 10]. Any combination of matching rules and similarity join techniques is allowed to form atomic and composite schema-based or schema-agnostic pipelines. These can be readily juxtaposed to more complex blocking-based ones, providing a unique feature that is offered by no other relevant tool.

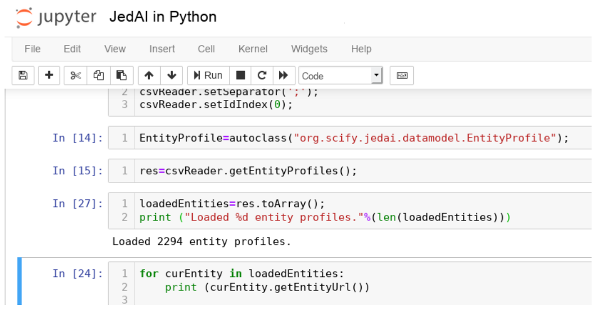
4 PROGRESSIVE ER WORKFLOW (NEW)

Progressive ER applies to *budget-aware applications*, which have limited computational or time resources. These limitations can only be addressed in a *pay-as-you-go* way that provides the best possible *partial solution* in the context of the available resources. For example, the Google dataset search system has indexed ~26 billion datasets [5], which can only be resolved progressively.

Schema-based progressive methods have been proposed [16, 20], but JedAI exclusively considers domain-agnostic ones [19], implementing the workflow in Figure 2(c). The first four steps are common with the blocking-based ER workflow, which is depicted in Figure 2(a). The only difference is that Data Reading also receives as input the user-specified *budget*, either in terms of the maximum running time or the maximum number of executed comparisons. Next, *Prioritization* is applied, assigning a weight to all entities, comparisons or blocks in order to schedule their processing in decreasing likelihood that they involve duplicates. Then, the top-weighted entity pairs are iteratively emitted, one at a time, in order to compare the corresponding entity descriptions (Entity Matching). Finally, the Evaluation estimates the rate of detected duplicates per comparison, i.e., the evolution of recall as more comparisons are executed. The resulting diagram is used for estimating the area under curve, which is analogous to performance - see Figure 5(a).

JedAI implements the Prioritization methods in Figure 4, which can be distinguished into two types:

i) Inspired by Sorted Neighborhood (SN), the *sort-based methods* rely on the similarity of blocking keys. They produce a list of entities by sorting all descriptions alphabetically, according to the corresponding blocking keys. In the schema-agnostic context, every token forms a blocking key and thus, every entity appears in the list as many times as the number of its distinct attribute value tokens. To avoid the large number of redundant



```
    csvReader.setSeparator(';');
    csvReader.setIdIndex(0);

In [14]:  EntityProfile=autoclass("org.scify.jedai.datamodel.EntityProfile");

In [15]:  res=csvReader.getEntityProfiles();

In [27]:  loadedEntities=res.toArray();
          print ("Loaded %d entity profiles."%(len(loadedEntities)))

          Loaded 2294 entity profiles.

In [24]:  for curEntity in loadedEntities:
              print (curEntity.getEntityUrl())
```

Figure 6: JedAI in Python.

comparisons and the arbitrary ordering of entities with identical keys, *Local Schema-agnostic Progressive SN* [19] weights all comparisons within the current window size via a schema-agnostic function that considers the frequency of appearance of every entity in the list along with the co-occurrence frequency of entity pairs for the current window size. The *Global Schema-agnostic Progressive SN* [19] does the same, but for a predetermined range of windows, eliminating their redundant comparisons.

ii) The *hash-based methods* are based on identical, schema-agnostic blocking keys and the resulting overlapping blocks. Similar to Meta-blocking, they assign a weight to every pair of candidate matches, assuming that their similarity is proportional to the number of blocks they share [14]. *Progressive Block Scheduling* [19] orders the blocks in ascending number of comparisons and then prioritizes all comparisons in the current block, by ordering them in decreasing weight. *Progressive Profile Scheduling* [19] orders entities in decreasing average weight of the corresponding candidate matches and then prioritizes all comparisons involving the current entity by ordering them in decreasing weight. *Progressive Global (Local) Top Comparisons* considers the top-K weights over the entire blocking graph (per entity), where K is derived from the given budget.

5 USER INTERFACE

Up to v2.1, JedAI offered two interfaces for user interaction [15]: (i) the desktop application, JedAI-gui, which offers a graphical interface, and (ii) the command-line interface implemented by JedAI-core. Both of them allow for constructing any combination of the available methods in the context of the blocking-based end-to-end ER workflow. Especially, JedAI-core conveys the Documentation module (see Figure 1), which facilitates the use and configuration of ER methods. It also enables the benchmarking of different workflows or configurations over a particular dataset through the workbench window, which summarizes the outcome of all runs and maintains details about the performance and the configuration of every step [15] (see Figure 5(b)).

5.1 New features

JedAI[3] extends both interfaces so that they cover all new features discussed above. The command-line interface has also been enriched with documentation support: at any step, the user is able to retrieve information about individual methods or specific parameters, thus facilitating their use. JedAI-core has also been augmented with a Python wrapper based on `pyjnius`, thus facilitating its adoption by the large user base of Python data analytics (see Figure 6). For example, the new wrapper allows for integrating JedAI with popular frameworks like `scikit`[4] for machine learning and `NLTK`[5] for natural language processing.

[4]https://scikit-learn.org
[5]https://www.nltk.org

6 DEMONSTRATION SCENARIOS

In this demo, we will present JedAI through a live interaction with users so as to highlight all new features discussed above. First, the user is asked to choose among the available interfaces: command-line, JedAI-gui or a Jupyter notebook. Then, she is asked to select one dataset among a set of carefully selected ones, which are easy to comprehend, yet interesting for an ER application, while involving both a structured and a semi-structured part (e.g., CSV-XML). These settings lay the ground for the following demo scenarios that showcase JedAI's functionalities.

1. Versatility. In this scenario, we compare the new ER workflows supported by JedAI with the blocking-based one that lies at the core of the previous version. Four different workflows are involved in this process:

(1) The user builds a traditional blocking-based workflow to be applied to the selected dataset.
(2) The same workflow is enhanced with word embeddings so as to examine the effect of deep learning techniques on improving accuracy.
(3) The user is asked to form a join-based end-to-end ER workflow with matching rules of arbitrary complexity; this might seem a complex procedure, but in reality, JedAI's data visualization feature simplifies it to a large extent.
(4) The user forms a Progressive ER workflow and applies it to the same dataset.

In all cases, the user can manually configure all methods, or use the recommended default parameter values. JedAI's workbench functionality allows to easily compare the performance of these fundamentally different workflows, assessing their pros and cons.

2. Automatic Configuration. In this scenario, we fine-tune the configuration parameters of the above four workflows in one of the available automatic ways, i.e., through random or grid search in a step-by-step or a holistic approach. Thus, the goal of this scenario is three-fold: (i) to test how well users can manually tune the parameters, (ii) to evaluate how close the default parameter values are to the "optimal" ones, and (iii) to compare the four workflows in terms of their best possible performance. For example, the performance of the fine-tuned progressive workflow demonstrates the minimum number of comparisons that are required for achieving sufficiently high recall. How close are the other three workflows to this ideal case? Again, JedAI's workbench functionality, the first for such a tool, renders these complex comparative process into a simple procedure.

3. Scalability. This last scenario focuses on the time efficiency of the selected workflows. The results of the previous scenarios advise us beforehand about the relative running time of the selected workflows, as JedAI's workbench feature reports both effectiveness and efficiency measures. Here, though, we examine how well each workflow scales to datasets of increasing size (10K, 50K, 100K, 500K, 1M and 2M entities), which have been derived from the selected dataset using artificial noise. This scenario demonstrates how workflows with similar running times over small datasets might end up differing by orders of magnitude. Most importantly, JedAI's workbench reports the running time per workflow step, thus facilitating the detection of bottlenecks.

Finally, it is worth stressing that during our demonstration, we will take special care to explain to users how to make the most of JedAI's functionalities, emphasizing the new features. Note also that most of the features listed above are demonstrated for the first time, and are not supported by any other ER system.

7 CONCLUSIONS

JedAI[3] is an open-source ER tool with 4 unique characteristics: (i) Based on blocking and similarity joins, it implements two different end-to-end workflows for batch ER that allow for composing millions of pipelines. (ii) It supports pre-trained embeddings of any kind. (iii) It supports budget-aware ER, enabling thousands of schema-agnostic progressive workflows. (iv) It can be integrated with Python's data analysis ecosystem. These capabilities will be exhibited through a live demonstration with user interaction.

ABSTRACT

Text values are valuable information in relational database systems for analysis and machine learning (ML) tasks. Since ML techniques depend on numerical input representations, word embeddings are increasingly utilized to convert symbolic representations such as text into meaningful numbers. However, those models do not incorporate the context-specific semantics of text values in the database. To significantly improve the representation of text values occurring in DBMS, we propose a novel retrofitting approach called Retro which considers both, the semantics of the word embedding and the relational schema. Based on this, we developed RetroLive, an interactive system, that allows exploring how the retrofitted embeddings improve the performance for various ML and integration tasks. Moreover, the demo includes several interactive visualizations to explore the characteristics of the adapted vectors and their connection to the relational database.

1 INTRODUCTION

Due to their appealing properties, word embedding techniques such as word2vec [8], GloVe [9] or fastText [2] have become conventional wisdom in many research fields such as NLP or information retrieval to represent text values. These word vectors are trained by processing large text corpora, e.g. the GloVe embedding[1] was trained on a corpus with 840 billion tokens. These embeddings are typically used to convert text values in a meaningful numerical representations used as input for ML tasks. However, a naïve application of a word embedding model is not sufficient to represent the meaning of text values in a database which is often more specific than the meaning in the natural language. Thus, we aim for additionally incorporating information given by the disposition of the text values in the database schema into the embedding, e.g. which words appear in the same column or are related. Therefore, we developed a relational retrofitting approach called Retro [5] which is able to automatically derive high-quality numerical representations of textual data residing in databases without any manual effort.

[1]https://nlp.stanford.edu/projects/glove/

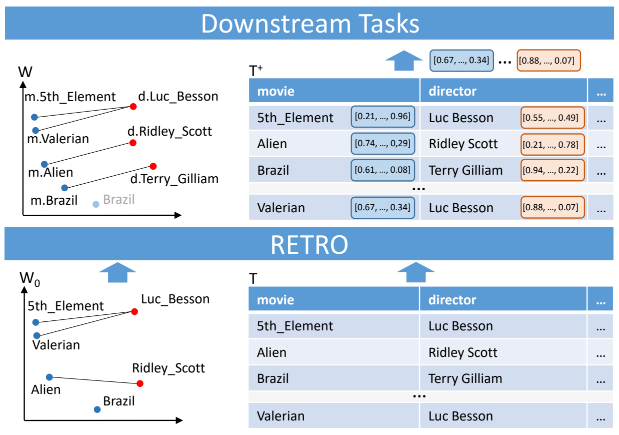

Figure 1: Relational Retrofitting: basis word embedding W^0 and relation T (left), retrofitted word embedding W and augmented relation T^+

Relational Retrofitting. Figure 1 provides a small example sketching the main principles of the relational retrofitting process. Retro expects a database and a word embedding as input, e.g. a movie table T that should be retrofitted into a pre-trained word embedding W_0. W_0 can be generated using well-known text embedding techniques. Those models are able to generate embeddings capturing syntactic and semantic relations between words, such as word analogies, gender-inflections, or geographical relationships. To provide vector representations for textual information in databases one could simply reuse the vectors of pre-trained embeddings, e.g. map each term from T to a term-vector pair in W_0.

However, there often will be a semantic mismatch between word embeddings and textual information in databases:

1) Given the movie table, it is known that all entities within the movie column must be movies, although some of the titles, such as "Brazil" or "Alien", may be interpreted differently by the word embedding model.

2) T provides a specific amount of relation types like the movie-director, whereas in the word embedding representation W_0 large amounts of implicit relations are modeled, e.g. if the director of a movie is also the producer or one of the actors this might be represented in the word embedding although not explicitly visible.

3) Terms in T which occurring infrequent in the general domain can not be modeled accurately by word embedding models.

For instance word2vec has a limited vocabulary according to a frequency threshold. Many terms appearing in a database will therefore have no counter-part within the embedding.
Therefore, we developed Retro [5] which incorporates the database semantics and augments all terms in database relation by a dense vector representation. In the context of our movie example, Retro would generate a new embedding for "Terry Gilliam" which should be close to other directors and their respective vectors. Furthermore, Retro would create vectors for all other textual values in the movie table that encode the semantics given by the pre-trained word embeddings and the database. On one hand, this ensures that vectors appearing in the same column, such as movies or directors, are close to each other. On the other hand, this ensures that movie-director pairs can be resolved. These vectors are ready-to-use for a wide range of ML, retrieval and data cleaning tasks such as classification, regression, null value imputation, entity resolution, and many more.
Demonstration. Our web-based demo called RetroLive showcases our novel retrofitting approach and guides the user through the whole retrofitting process. The demo provides different database schemas and target word embeddings the users can choose from and allows to explore their data statistics and characteristics. Additionally, RetroLive allows to set and fine-tune the various hyperparameters of the retrofitting learning problem. The impact of the hyperparameter values, the input data characteristic and target embeddings can be studied in detail using either 2-dimensional projections or by using word similarity and analogy benchmarks. To demonstrate the usefulness of the embedding generated by the relational retrofitting approach, RetroLive comes with various pre-defined extrinsic evaluation tasks for classification and regression. Furthermore, the users are able to define their own machine learning tasks. Finally, the demo includes several baseline approaches such as the node embedding technique DeepWalk [10] and the original retrofitting approach [4] from Faruqui et al.

2 RETRO – BACKGROUND

Retro aims at combining word embeddings with relational text data to generate good vector representations for text values residing within databases. Therefore, our relational retrofitting approach learns a matrix of vector representations $W = (\boldsymbol{v_1}, \dots \boldsymbol{v_n})$ with $\boldsymbol{v_i} \in \mathbb{R}^D$ for every unique text value $T = (\boldsymbol{t_1}, \dots \boldsymbol{t_n})$ in a database. To find initial word vectors for every text value, we tokenize the them based on the vocabulary of the basis word embedding model and build centroid vectors which is a convenient way to obtain a representation of text values consisting of multiple tokens [1, 11]. These vectors are stored in a matrix $W^0 = (\boldsymbol{v}'_1, \dots \boldsymbol{v}'_n)$ forming the basis for the retrofitting process. Besides, *columnar and relational connections* are extracted from the database (see Section 2.1). This encompasses semantic relations between text values, which are derived from the relational schema. Those connections are used to create a representation capturing the context of the text value in the database and thus help to preserve their semantics more accurately compared to a plain word embedding representation. In order to apply node embedding techniques like DeepWalk [10], all information is condensed into a common graph representation shortly presented in Section 2.2. The core procedure of the relational retrofitting is the adaption of the basis vectors W^0. This is performed by solving an optimization problem detailed further in Section 2.3.

2.1 Extracting Relational Information

One can derive different structural relations from the alignment of text values in the relational schema.
Columnar Connections: Text values with the same attribute, i.e. appearing in the same column, usually form hyponyms of a common hypernym (similar to subclass superclass relations). Thus, they share a lot of common properties which typically leads to similarity. We capture this information and assign each text value t_i to its column $C(i)$.
Relational Connections: Relations exhibit from the co-occurrence of text values in the same row as well as from foreign key relations. Those relations are important to characterize the semantics of text value in the database. We define a set of relation types R which is specific for a certain pair of text value columns. Those columns are related because they are either part of the same table or there exists a foreign key relationship between their tables. For every relation type $r \in R$ there is a set E_r containing the tuples of related text value ids. Relation types are directed. Accordingly, there is an inverted counterpart $\bar{r}$ for each relation r with $E_{\bar{r}} = \{(j,i)|(i,j) \in E_r\}$.

2.2 Graph Generation

A graph representation is a pre-requisite for training node embeddings such as DeepWalk [10] which serve as a strong baseline for Retro. To compile a graph $G = (V, E)$ the text values extracted by the tokenization process together with columnar and relational connections (Section 2.1) are combined. The node-set $V = V_C \cup V_T$ consists of text value nodes V_T for every distinct text value in a database column and blank nodes for every column V_C. The edge set $E = \bigcup_{r \in R} E_r \cup E_C$ consists of a set of edges E_r for every relational type and edges E_C connecting text values of one column to a common category node.

2.3 Optimization Problem

Retro considers relational and columnar connections (see Section 2.1) to retrofit an initial embedding. Accordingly, we define a loss function Ψ adapting embeddings to be similar to their basis word embedding representation W^0, the embeddings appearing in the same column, and related embeddings.

$$\Psi(W) = \sum_{i=1}^{n} \left[\alpha_i ||\boldsymbol{v_i} - \boldsymbol{v}'_i||^2 + \beta_i \Psi_C(\boldsymbol{v_i}, W) + \Psi_R(\boldsymbol{v_i}, W)\right] \tag{1}$$

The columnar loss is defined by Ψ_C and treats every embedding $\boldsymbol{v_i}$ to be similar to the constant centroid $\boldsymbol{c_i}$ of the basis embeddings of text values in the same column $C(i)$.

$$\Psi_C(\boldsymbol{v_i}, W) = ||\boldsymbol{v_i} - \boldsymbol{c_i}||^2 \quad \boldsymbol{c_i} = \frac{\sum_{j \in C(i)} \boldsymbol{v}'_j}{|C(i)|} \tag{2}$$

The relational loss Ψ_R treats embeddings v_i and v_j to be similar if there exists a relation between them and dissimilar otherwise. E_r is the set of tuples where a relation r exists. $\widetilde{E_r}$ is the set of all tuples $(i, j) \notin E_r$ where i and j are part of relation r. Thus, each of both indices has to occur at least in one tuple of E_r.

$$\Psi_R(\boldsymbol{v_i}, W) = \sum_{r \in R} \left[\sum_{\substack{j:(i,j)\\ \in E_r}} \gamma_i^r ||\boldsymbol{v_i} - \boldsymbol{v_j}||^2 - \sum_{\substack{k:(i,k)\\ \in \widetilde{E_r}}} \delta_i^r ||\boldsymbol{v_i} - \boldsymbol{v_k}||^2\right] \tag{3}$$

α, β, γ and δ are hyperparameters. Ψ has to be a convex function. In [5] we proved the convexity of Ψ for hyperparameter configurations fulfilling the following inequation:

$$\forall r \in R, i \in \{1, \ldots, n\} \quad (\alpha_i \geq 0, \quad \beta_i \geq 0, \quad \gamma_i^r \geq 0) \qquad (4)$$

$$\forall \boldsymbol{v_i} \in W \quad (4\alpha_i - \sum_{r \in R} \sum_{j:(i,j) \in \widetilde{E_r}} \delta_i^r \geq 0)$$

Given the property of convexity, an iterative algorithm can be used to minimize Ψ. Using sparse matrix calculations this can be done in parallel with linear time complexity according to the number of text values in W. Details are outlined in [5].

3 SYSTEM OVERVIEW

RetroLive is a fully functional system built on top of PostgreSQL. The front-end is a web application managing the provided input databases and embeddings (Section 3.1), controlling the relational retrofitting process (Section 2) and performs several ML tasks (Section 3.2). The system overview is depicted in Figure 2.
Based on an input *database schema* (①) and a target word embedding wodel (②) a so-called *basis word embedding* (③) is created which encodes each text value in the database as a dense vector. These vectors together with the extracted relational schema information (④) comprise the input for the relation retrofitting which returns a retrofitted embedding (⑤). In addition, a *graph representation* (⑦) of the text value relations (see Section 2.2) is generated and used to create node embeddings (⑧) which serve as a strong baseline for our approach. Moreover, the *graph representation* is used to apply the original retrofitting approach of Faruqui et al. (⑥). The basis word embeddings, node embeddings, simple and relational retrofitted embeddings are used to train and test ML models (⑨).

3.1 Datasets

The deployment used for the demonstration contains several preloaded database schemas and target word embeddings. Additionally, it provides several baseline embeddings.
Relational datasets: We prepared three datasets and imported them into PostgreSQL: The Movie Database (TMDB)[2], Google Play Store Apps[3] and Open Food Facts [4] which are all very popular datasets on Kaggle with a significant portion of textual data.
Target Word Embeddings: We used the popular 300 dimensional Google News embeddings[5] and an English fastText[6] model as target word embeddings for our retrofitting process.
Baseline Embeddings: We applied the original retrofitting approach [4] using the proposed standard parameter configuration of $\alpha_i = 1$ and the reciprocal of the outdegree of i for β_i within 20 iterations. DeepWalk (DW) is trained with its standard parameters and a 300 dimensions representation size.

3.2 ML Tasks

To demonstrate the usefulness of the relational retrofitting, the user can perform different *extrinsic* evaluation tasks, such as binary classification, missing value imputation and link prediction, on the embeddings generated with the relational retrofitting approach as well as the various baseline embeddings.
RetroLive comes with a set of pre-defined ML models:
Binary Classification: Text values can be assigned to two distinct classes by a classifier, e.g. we defined the task to distinguish

[2]https://www.kaggle.com/rounakbanik/the-movies-dataset
[3]https://www.kaggle.com/lava18/google-play-store-apps/
[4]https://www.kaggle.com/openfoodfacts/world-food-facts
[5]https://code.google.com/archive/p/word2vec/
[6]https://github.com/facebookresearch/fastText/blob/master/docs/pretrained-vectors.md

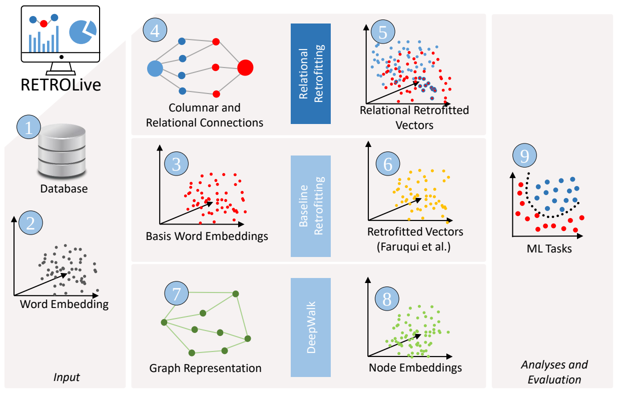

Figure 2: System Overview

US-American and non-US-American directors in TMDB.
Regression: Regression tasks assign input data points to a related numerical value, e.g. the budget or revenue in US dollar for a movie title.
Null Value Imputation: Text values are assigned to one category out of a finite set of category values, e.g. the "original language" of a movie or the app category for apps in the Google Play Store Apps dataset.
Link Prediction: The link prediction problem is typically defined on graphs where the goal is to predict links that are missing or likely to be created in the future. In our case, we consider the link prediction task for a specific relation to predict missing foreign key relations.
Our models consist of different multi-layer dense neural networks that can be applied on the generated node embeddings, pre-trained word embeddings, and our retrofitted embeddings. Details on the specific neural network architectures for all ML models are given in [5]. All experiments are repeated multiple times to obtain the distribution of the accuracy values.

4 DEMONSTRATOR WALKTHROUGH

Users access RetroLive through an interactive web interface shown in Figure 3 where they can configure and explore the whole relational retrofitting process. There are six main views:
Config and Retrofit: Those views allow to choose the database (three are pre-defined) and the target word embedding and configure the retrofitting process by setting the hyperparameters (Ⓐ). If the retrofitting is done on the same data used for the ML Task (e.g. to predict the genres of movies expressed in the database by foreign key relations), users can blacklist specific relations for the retrofitting in the config view. Further, the relational retrofitting process can be triggered and monitored (Ⓑ).
Results: In this view the user can inspect the extracted relational information (see Section 2.2) from the input schema in form of graph (Ⓒ). Additionally, the embedding statistics for each text column are presented (Ⓓ).
Analysis: In the analysis view, the users can inspect the characteristic of the retrofitted embeddings and compare them with the plain input word embedding. An interactive histogram (Ⓔ) shows the distribution of the cosine similarity between the plain word vectors and the retrofitted vectors, i.e. to which degree certain vectors have been changed during the retrofitting process. The user can click on the individual bins to see additional information, e.g. in how many relations certain terms have been

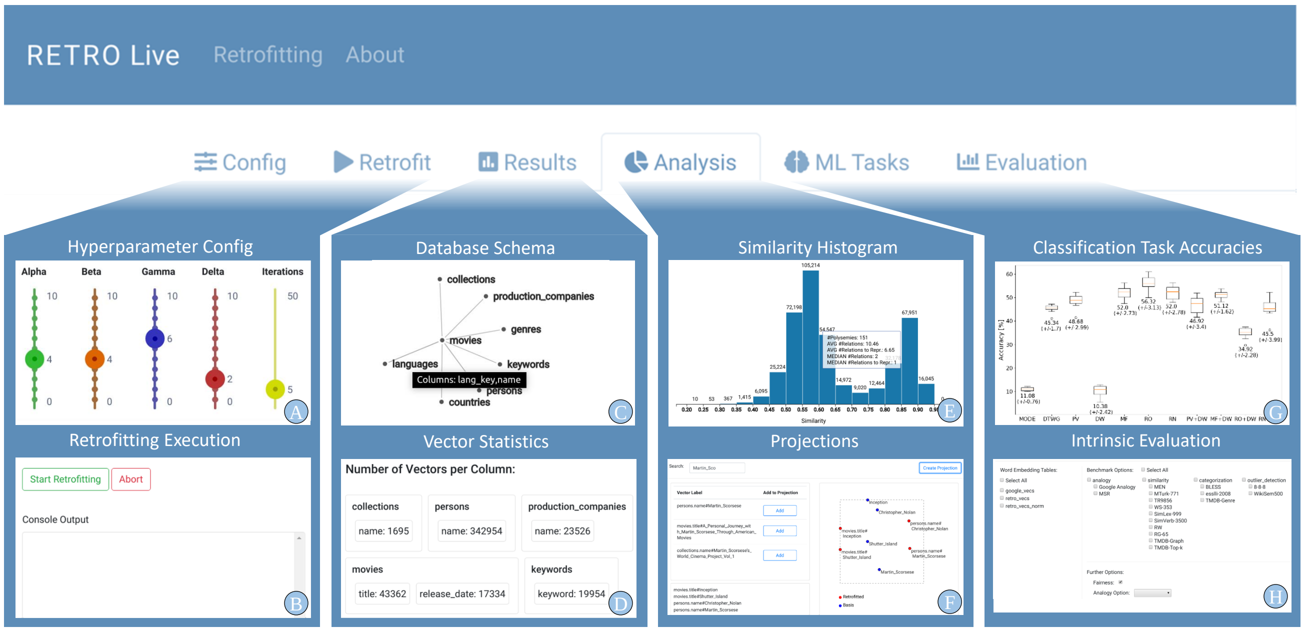

Figure 3: Demo User Interface

involved or in how many different columns a term appeared or to get a complete list of embeddings in the selected bin. Moreover, a 2-dimensional projection (PCA) shows the user-selected plain text and retrofitted vectors (F). In context of the TMDB database example, it can be seen that the vectors for movies and directors are arbitrarily distributed in the word embedding (red). However, after applying relational retrofitting the movie and director vectors (blue) are clustered and the difference vectors between movie and director pairs are of same length and orientation.
ML Tasks: To show the benefits of relation retrofitting the users can run different ML tasks (Section 3.2). The users select the embedding model (retrofitted, node, plain, etc.) they want to use for the given task. Training and testing data is retrieved from the database using pre-defined SQL queries which can be also modified by the user. Diagrams visualize the results (G).
Evaluation: Our demonstrator includes 14 intrinsic evaluation tasks to test word similarity, e.g. SimLex999 [6] MEN [3] or analogies, e.g. Google Analogy [7] (H). Here, the users can investigate whether original retrofitting and relational retrofitting affect the intrinsic task performance compared to plain word embeddings.

5 CONCLUSION

In this paper, we presented RetroLive, a novel system which allows generating retrofitted embeddings for an arbitrary database in a fully automated fashion. Participants can experience first-hand the power of relational retrofitting by tuning different hyperparameters, playing with different input datasets and investigating the effect of using a rich set of visualizations. Our demonstration highlights the potential of relational retrofitted vectors which achieve very good results for machine learning tasks like regression, binary, and multi-class classification. RetroLive also implements state-of-the-art baselines such as DeepWalk and the approach of Faruqui et al. which are both out-performed. Our system is publicly available under the permissive MIT license[7].

ABSTRACT

Record-level matching rules are chains of similarity join predicates on multiple attributes employed to join records that refer to the same real-world object when an explicit foreign key is not available on the data sets at hand. They are widely employed from data scientists and practitioners that work with data lakes, open data, and data in the wild.

We present RulER, the first tool that allows to efficiently execute record-level matching rules on parallel and distributed systems—we developed that on top of Apache Spark to leverage on its vast ecosystem of libraries and wide adoption. In this demo, we show how RulER can be easily employed for data preparation tasks (i.e., to join data sets to be consumed by data analytic tasks) and to support the user in debugging record-level matching rules. Finally, we demonstrate how our execution strategy of the record-level matching rules—introduced by RulER—is up to 3 times faster than the naïve concatenation of similarity join predicates.

1 INTRODUCTION

Combining data sets that bare information about the same real-world objects is an everyday task for practitioners that work with structured and semi-structured data. Frequently (e.g., when dealing with data lakes or when integrating open data with proprietary data) data sets do not have explicit keys that can be used for a traditional *equi-join* [4, 8, 9]. When that happens, a common solution is to perform a *similarity join* [6], i.e., to join records that have an attribute value similar above a certain threshold, according to a given similarity measure, as in the following example:

Example 1.1 (Similarity Join). *Given two product data sets, join all the record pairs with the Jaccard similarity of the product names above 0.8.*

A plethora of algorithms have been proposed in the last decades to efficiently execute the similarity join considering a single attribute, i.e., *attribute-level matching rules* (see [6] for a survey). At their core, all these algorithms try to prune the candidate pairs of records, on the basis of a single-attribute predicate—to alleviate the quadratic complexity of the problem.

Interestingly, only a few works had been focused on studying how to execute *record-level matching rules*, i.e., the combination of multiple similarity join predicates on multiple attributes (see section 2.1.1). Yet, this kind of rules permits to specify more flexible rules to match records, as in the following example:

Example 1.2 (Record-level matching rule). *Given two product data sets, join all the record pairs that have a Jaccard similarity of the product names above 0.8, or that have a Jaccard similarity of the description that is above 0.6 and the edit distance of the manufacturer lower than 3.*

Furthermore, record-level matching rules can be used to represent *decision trees* [1], hence learned with machine learning algorithms when training data is available. As a matter of fact, a decision tree for binary classification (i.e., classification of *matching/not-matching* records) can be naturally represented with DNF (disjunctive normal form) predicates—the same consideration can be done for a forest of trees.

To the best of our knowledge, no techniques have been proposed to leverage on distributed and parallel computing for scaling record-level matching rules. The benefit is twofold: *(i)* distributed computation allows to scale to large data sets that cannot be handled with a single machine; *(ii)* parallel execution reduces the execution times (3 time faster in our experiments). As a matter of fact, being able to efficiently execute similarity join is crucial when time is a critical component, e.g., when users are involved in the process. For instance, in exploratory search in a data lake [7], users typically look for related data sets and low latency in performing similarity join is required for enabling the user's interactive exploration. Also, when debugging record-level matching rules, users typically try different configurations of similarity metrics, thresholds, and attributes. Hence, enabling fast execution of such rules can significantly save user' time.

Contribution. We present RulER, a tool that enables users to efficiently execute record-level matching rules to join large data sets on distributed parallel systems. In particular, we implemented RulER on top of Apache Spark[1], to leverage on its vast ecosystem of libraries and tools for data preparation, and machine learning. In this demonstration, we will showcase RulER on several real-world data sets; attendees will write their own matching rules through Jupyter notebooks, and explore and analyze the results. We will demonstrate how to employ RulER both in a data preparation pipeline and to debug record-level matching rules. We implemented state-of-the-art similarity join algorithms for Spark that can be employed to build chains of similarity join predicates (i.e., to mimic record-level matching rules). Attendees will run such similarity join chains and verify that RulER is actually significantly faster (up to an order of magnitude) and more convenient to program such rules thanks to its APIs.

2 TOOL ARCHITECTURE

2.1 Preliminaries

2.1.1 Record-level matching rules. In RulER, matching rules are written in Disjunctive Normal Form (DNF), i.e., as a *disjunction* (logical *OR*) of *conjunctions* (logical *AND*) of similarity join predicates on multiple attribute (i.e., at the *record level*). This design choice is driven by the fact that DNF matching rules are easy to read and thus to debug, in practice. Moreover, DNFs can be employed to represent the trained model of a decision tree (or

[1]https://spark.apache.org/

of a random forest), hence suitable for exploiting labelled data. In this demonstration, we focus on how to scale DNF matching rules and we do not investigate how to generate *good* DNFs (i.e., decision trees/random forests) starting from training data.

To the best of our knowledge, the only related work tackling this problem is [1], which focuses on single-node execution, borrowing optimization techniques from the traditional relational database approaches. Similarly, [5] focuses on how to optimize multi-attribute similarity join, but only for conjunctions of predicates (i.e., not for DNF).

2.1.2 Similarity join with prefix index. The naïve solution for similarity join (i.e., each predicate of a DNF) is to enumerate and compare every pair of records, i.e., highly inefficient and not feasible on large data sets. To reduce the task complexity, different approaches were proposed in literature [2, 10–12]. All these approaches adopt a filter-verification pattern: *(i)* first an index is used to obtain a set of pre-candidates (e.g., prefix filter); *(ii)* the pre-candidates are filtered using a set of filters that are fast to apply; *(iii)* the resulting candidate pairs are probed with the similarity function to generate the final result.

The most efficient technique to obtain the pre-candidates efficiently is the *prefix filter* [2], which works as follows. Given a set of strings (the values of an attribute in a table, for instance), a pre-processing function is applied to each string to obtain a set of elements (e.g., tokens or n-grams, etc.). These elements are then sorted according to a global order, usually by their not decreasing document frequency of the elements (i.e., $1/\#(strings\ containing\ that\ element)$)—typically infrequent elements yield fewer candidate pairs [2]. Then, for each sorted set of elements only the first π are considered, i.e., the *prefixes*. A pair of element $\langle r_i, r_j \rangle$ can be safely pruned if their prefixes have no common elements. The prefix size depends on the adopted similarity function and threshold. For example, the prefix filter for the overlap similarity is defined as follows: given two sets, r_i and r_j, and an overlap threshold t; if $|r_i \cap r_j| \geq t$, then there is at least one common element within the π_{r_i}-prefix of r_i and the π_{r_j}-prefix of r_j, where $r = |r_j| - t + 1$ and $s = |r_j| - t + 1$.

An example of prefix filtering is reported in Figure 1. The prefixes, assuming an overlap threshold $t = 4$ are highlighted in grey. Since the two prefixes do not share any element, the pair $\langle r_i, r_j \rangle$ can be pruned. The intuition behind this is that the 3 remaining elements to check can provide at most a similarity of 3, that is not enough to reach the requested threshold t.

Figure 1: Prefix filtering example: The pair $\langle r_i, r_j \rangle$ can be pruned since the prefixes (in grey) have no common elements. The elements to check can provide at most an overlap similarity of 3 (or a Jaccard similarity of $3/8$).

The prefix filter can be adapted to work with many similarity measures like Jaccard, Dice, Cosine, Overlap [11] and Edit Distance [10], and it is employed by best performing similarity join algorithms [6].

The state-of-the-art distributed and parallel similarity join algorithms [3] partition the candidate pair of records according to the entry in the prefix index, i.e., for each element in the index, all the corresponding pairs of candidates are assigned to a computational node—more optimizations can be performed, but at their core, this is how parallelization is achieved by existing

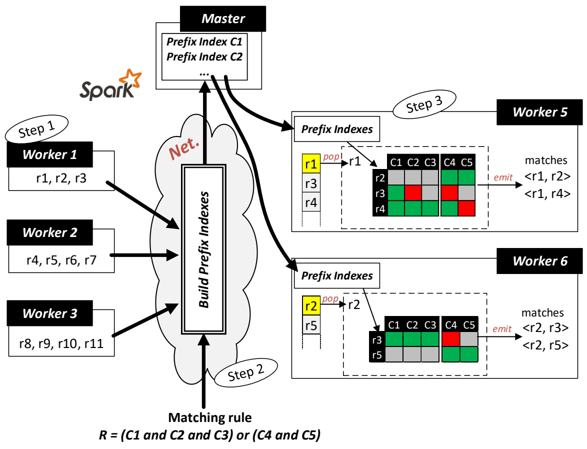

Figure 2: RulER execution model: green cells represents executed and passed rules; red cells executed that do not pass the rules; grey cells not executed rules.

algorithms. So, if two different similarity join conditions are considered (e.g., two different similarity measures on two different attributes), existing algorithms would create two different prefix indexes and generate two completely different parallelization strategies. Thus, given a fixed number of computational nodes, by employing existing algorithms, the only way to get the complete result of multiple similarity joins (i.e., the predicates of the matching rule) is to perform the joins in series and then combine the result sets.

2.2 The RulER execution model

The main intuition of RulER is to exploit the prefix indexes—one prefix index for each predicate of the matching rule—to build a graph structure, which is then employed to iterate over the records (the nodes of the graph), efficiently applying the rules and keep only the candidates (the edges of the graph) that pass the whole rule. In other words, RulER adopts a record-based parallelization approach; in contrast to the existing algorithms, which adopt a prefix-based parallelization approach on a single predicate at a time.

Example 2.1 (Distributed and parallel matching rule with RulER). *Given a matching rule $R = (C1 \wedge C2 \wedge C3) \vee (C4 \wedge C5)$, in which each Cx is a similarity join predicate (e.g., Jaccard Similarity title ≥ 0.8). An example of how RulER executes R is outlined in Figure 2. First, a prefix index is built on the basis of the record-level matching rules expressed in the main matching rule R. Then, the index is distributed to each worker. Each worker iterates over each record in its partition extracting the possible candidates from the prefix index. The rules are applied to each candidate. If more rules are in or it is possible to avoid computing the other rules when one of them is verified, e.g., with r1-r2 the rule $(C1 \wedge C2 \wedge C3)$ is not verified since the pair passes the rule $(C4 \wedge C5)$. Otherwise, if more rules are in and, it is possible to avoid the computation when one of them fails, for example for the pair r1-r3 C2 fails, so C3 has not to be computed.*

2.2.1 The algorithm. The RulER matching rule algorithm is outlined in Algorithm 1. The presented algorithm is the self-join version for sake of the presentation; adapting it for joining two different data sets is straightforward. The algorithm takes as input a collection of records and a record-level matching rule $\mathcal{M}$ and gives as output the set of record pairs that satisfy $\mathcal{M}$. Recall that $\mathcal{M}$ is in DNF, i.e., it is composed of sets of predicates P_j in *logical or*, each set P_j contains predicates p_k in *logical and*. First of all, the values of attributes are converted into sets of elements (Line 1) according to the matching rule requirements (e.g., n-grams, trigrams, tokens, etc.); then the prefix indexes are built to find the candidate pairs (line 2)—one prefix index is needed for each predicate p_k of the matching rule. The prefix indexes are sent in broadcast to each node (line 3) to be available to each computational node (called *worker*). Then, each worker iterates over its portion of records (lines 5-6), and performs the following operations for each record r_i. First, a set of candidates for r_i is initialized as an empty set C_{r_i} (line 7). Second, for each set P_j, a set of candidates C_{P_j} is initialized as an empty set (lines 8-9) and for each $p_k \in P_j$ the candidates C_{r_i,p_k} that can match with r_i are extracted using the prefix indexes (lines 10-11). Third, the candidates C_{r_i,p_k} are pruned by removing those that already passed one of the previous P_j set of predicates (line 14), and those that did not passed previous $p_k \in P_j$ predicates (lines 15-16). Fourth, the retained candidates are probed with other filters that further improve the efficiency of the overall process (e.g., length filter, position filter, etc. [10, 11]) according to the rule (line 18). Since p_k is in *logical and* with the previous predicates, only the candidates that pass the filters are kept. Finally, the resulting candidates from P_j are added to C_{r_i} (line 20).

2.2.2 Difference operator. RulER implements a method to perform the difference between the result pairs generated by two matching rules, i.e., given two matching rules $\mathcal{M}_1$, $\mathcal{M}_2$ it efficiently performs the difference of the result sets $res(\mathcal{M}_1) \setminus res(\mathcal{M}_2)$. Since the algorithm works at record level it is possible to perform a fine control on the application of the rules: when a record r_i is processed first $\mathcal{M}_1$ is checked, so to get $res(\mathcal{M}_1, r_i)$; then, $\mathcal{M}_2$ is applied only on the records $r_j \in res(\mathcal{M}_1, r_i)$, avoiding to compute it on the whole pairs again, retaining only the records r_j that do not satisfy $\mathcal{M}_2$ (i.e., $res(\mathcal{M}_1) \setminus res(\mathcal{M}_2)$).

Algorithm 1 RulER core

```
Input: $R$ collection of records to join
Input: $\mathcal{M}$ matching rule in DNF
Output: $C$, the pairs of records that can satisfy $\mathcal{M}$
1: $R_T \leftarrow getElements(R, \mathcal{M})$
2: $I \leftarrow buildPrefixIndexes(R_T, \mathcal{M})$
3: broadcast($I$)
4: $C \leftarrow \{\}$ //Candidate pairs
5: foreach partition $part \in R_T$
6:   for each $r_i \in part$ do
7:     $C_{r_i} \leftarrow \{\}$ //Candidates for $r_i$
8:     for each $P_j \in \mathcal{M}$ do //For each set of predicates in logical or
9:       $C_{P_j} \leftarrow \{\}$ //Candidates that satisfy $P_j$
10:      for each $p_k \in P_j$ do //For each predicate in logical and
11:        $C_{r_i,p_k} \leftarrow I(p_k, r_i)$ //Gets the candidates from the prefix index
12:        /*Removes candidates that already passed previous predicates in or
13:        and those that did not pass previous predicates in and*/
14:        $C_{r_i,p_k} \leftarrow C_{r_i,p_k} - C_{r_i}$
15:        if $C_{P_j} \neq \emptyset$ then
16:          $C_{r_i,p_k} \leftarrow C_{r_i,p_k} \cap C_{P_j}$
17:        /*Applies filters (length, positional, ...)*/
18:        $C_{P_j} \leftarrow applyFilters(r_i, C_{r_i,p_k}, p_k)$
19:      $C_{r_i} \leftarrow C_{r_i} \cup C_{P_j}$
20:    $C.append(C_{r_i})$
```

3 DEMONSTRATION SCENARIO

During the demonstration, participants will try RulER[2] on several scenarios and data sets by means of Jupyter Notebooks[3]. Users will be guided in: defining custom matching rules for a practical data preparation task (Section 3.1); debugging a matching rule (Section 3.2); and compare the efficiency of RulER w.r.t. existing state-of-the-art similarity joins (Section 3.3). Multiple scenarios and data sets (e.g., products, movies, books, finance, etc.) on which it is possible to try our RulER are available, but for sake of the presentation we describe only some of them in the following.

3.1 Data preparation scenario

In this scenario we use two movies data sets `Rotten Tomatoes`[4] and `Roger Erbert`[5]. The former gather users' ratings about movies, the latter critics' ratings. There is no foreign key between the two data sets. We ask the attendee to discover if there is a correlation between the ratings given by the users with the ones given by the critics. To do that, we need to define a matching rule to integrate the two data sets, then we compute the Pearson correlation on the obtained results. We ask to the attendee to write a record-level matching rule, for instance: $(\text{"}movie\_name\text{"}, \text{"}Title\text{"}, JS, 0.8) \wedge (\text{"}actors\text{"}, \text{"}Cast\text{"}, JS, 0.5)$, That means that the JS between the names of the movies must be greater or equal than 0.8 and the JS between the actors of the movies must be greater or equal than 0.5. After the matching, it is possible to obtain a scatter plot of the ratings, and compute the Pearsons correlation rating given by critics and the rating given by users on the same movie.

Figure 3 shows how simple is to use RulER. The user has just to: include RulER library (line 1), load the data as Spark Dataframe (lines 3-4), define the rules (lines 6-7) and combine them to obtain the final matching rule (line 9). Finally, the matching rule can be used to join the two dataframes with the *joinWithRules* method (line 11).

3.2 Matching rule debugging scenario

In this scenario we show how RulER can be used to efficiently debug different matching rules by using the difference operator. In particular, given two matching rules $\mathcal{M}_1$, $\mathcal{M}_2$ we will show how to use RulER to find the matches provided by the first rule that are not present in the matches provided by the second one, i.e. how to perform the difference between the two result sets $res(\mathcal{M}_1) \setminus res(\mathcal{M}_2)$. An example is shown in Figure 4. First, two matching rules are defined: in the first one the records are aligned by using the *title* and the *director* of the movies, while in the latter by using the *title* and the *cast*. Then, a new debugging rule is created using the difference operator defined in RulER. Finally, the debugging rule is applied to the dataset, obtaining the matches generated by $m1$ that are not generated by $m2$.

3.3 RulER efficiency demonstration

In this scenario we connect to a Spark cluster and use a subset of the IMDB data set[6] that contains records about movies, providing different fields that can be used to generate matching rules (e.g. movie title, cast, director, plot, etc.).

[2] We implemented RulER in Scala and made it open source: https://github.com/Gaglia88/ruler

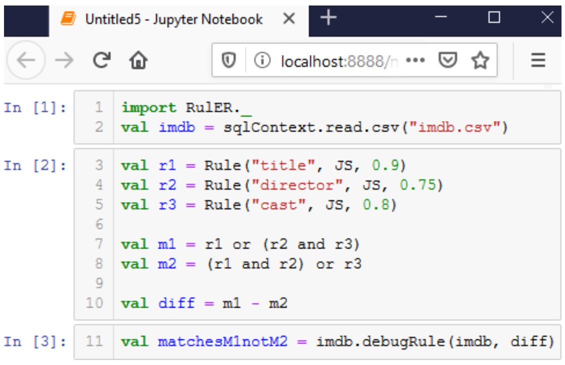
Figure 3: RulER usage example.



```
In [1]:  import RulER._
         val imdb = sqlContext.read.csv("imdb.csv")

In [2]:  val r1 = Rule("title", JS, 0.9)
         val r2 = Rule("director", JS, 0.75)
         val r3 = Rule("cast", JS, 0.8)

         val m1 = r1 or (r2 and r3)
         val m2 = (r1 and r2) or r3

         val diff = m1 - m2

In [3]:  val matchesM1notM2 = imdb.debugRule(imdb, diff)
```

Figure 4: Rule's debugging example.

We show how difficult is to write a complex rule by using existing similarity join algorithms w.r.t. the use of RulER. Moreover, RulER is much more faster. Figure 6 presents this scenario. To execute the rule as a similarity join chain, we use EDJoin [10] to perform a similarity join based on Edit Distance and PPJoin [11] to perform a similarity join based on Jaccard Similarity. The matching rule written by chaining similarity joins is expressed in lines 13-16. Note that, each rule provides a partial result and then the partial results of each rule have to be combined (line 16). If two rules are in *and* the partial results have to be intersected; if they are in *or* they have to be merged. To merge two candidate sets and avoid duplicates, a *distinct* operation has to be performed. The *distinct* and the *intersection* are very expensive operations in Spark because they require a *shuffling* since the same pairs have to be computed by the same worker.

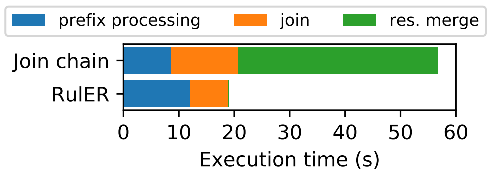


Figure 5: Execution time of RulER vs the execution time of the join chain in Figure 6.

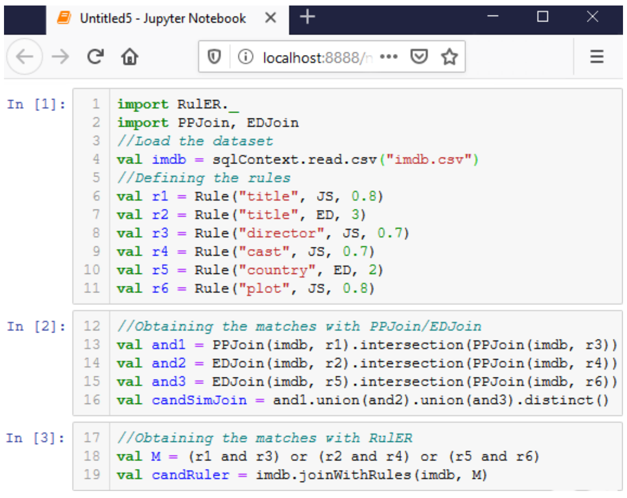
Figure 5 shows the execution time of both the solutions. For the join chain, the prefix indexing and join times are computed as the sum of each join. The RulER indexing time is higher due to the time requested to broadcast the index, but the join time is faster. Moreover, RulER does not need to merge the partial results, that is the costly task of the join chain, which makes it highly inefficient.



```
In [1]:   1  import RulER._
          2  import PPJoin, EDJoin
          3  //Load the dataset
          4  val imdb = sqlContext.read.csv("imdb.csv")
          5  //Defining the rules
          6  val r1 = Rule("title", JS, 0.8)
          7  val r2 = Rule("title", ED, 3)
          8  val r3 = Rule("director", JS, 0.7)
          9  val r4 = Rule("cast", JS, 0.7)
         10  val r5 = Rule("country", ED, 2)
         11  val r6 = Rule("plot", JS, 0.8)

In [2]:  12  //Obtaining the matches with PPJoin/EDJoin
         13  val and1 = PPJoin(imdb, r1).intersection(PPJoin(imdb, r3))
         14  val and2 = EDJoin(imdb, r2).intersection(PPJoin(imdb, r4))
         15  val and3 = EDJoin(imdb, r5).intersection(PPJoin(imdb, r6))
         16  val candSimJoin = and1.union(and2).union(and3).distinct()

In [3]:  17  //Obtaining the matches with RulER
         18  val M = (r1 and r3) or (r2 and r4) or (r5 and r6)
         19  val candRuler = imdb.joinWithRules(imdb, M)
```

ABSTRACT

Schema mapping generation identifies how data sets can be combined to create views that are relevant to an application. Where the data sets to be combined lack declared relationships, such as foreign keys, schema mapping generation can be considered to be *in the wild*. In this paper, we describe an approach to schema mapping generation in the context of open government data, in particular, the London Datastore. Mapping generation is informed by inferred profiling data about the data sets and their relationships, where the data sets are made available as csv files. We outline the mapping generation algorithm, and describe a demonstration of the approach, in which the user can: *(i)* specify the target to be populated by the generated mappings over a collection of sources from The London Datastore; *(ii)* browse the generated candidate mappings and the evidence that informed their creation; and *(iii)* steer the mapping generation process, to make use of preferred sources and dependable profiling results.

1 INTRODUCTION

Given a collection of source datasets, some metadata about them, and a target schema, schema mapping generation produces a collection of views that provide ways of populating the target from the sources. Mapping generation is important because the data of relevance to an application or an analysis is often not immediately available in a single, suitable, integrated form.

Most work on mapping generation has assumed that the source and the target benefit from declared constraints, for example in the form of primary and foreign keys (e.g., as in the seminal work on Clio and its descendents, as reviewed in [5]). However, with the growing availability of open data sets, and the emergence of data lakes, mapping generation over independently produced data sets, with minimal explicit metadata, is arguably even more necessary than for well-defined schemas.

We refer to mapping generation over data sets without declared relationships as *in the wild*. Mapping generation must, among other things, take into account relationships between data sources, and, in this paper, we assume that candidate keys and (partial) inclusion dependencies have been inferred through data profiling [1]. Then, to deploy schema mapping generation in the wild, the following are required:

(1) *A way of exploring the space of candidate mappings.* We use a dynamic programming algorithm to identify promising mappings, referred to as *Dynamap* [8].
(2) *A way of displaying to the user these mappings, their properties, and the evidence on which they build.* As (1) builds on necessarily speculative profiling data, the results of mapping generation must be able to be reviewed by users, for example to ensure that joins are building on inclusion dependencies that represent valid real-world relationships.
(3) *A way to enable the user to steer the mapping generation process.* As (2) may identify issues with generated mappings, users must be able to steer the mapping generation process away from unsuitable decisions, for example by ruling out the use of certain inclusion dependencies.

To show (1) to (3) in practice, we demonstrate our mapping generation algorithm, and its associated user interface, in use with data from The London Datastore[1], which provides hundreds of data sets providing diverse information about London.

The remainder of the paper is structured as follows. Section 2 provides some details on The London Datastore. Our mapping generation approach is reviewed in Section 3. The demonstration in Section 4 shows an example of viewing a generated mapping and understanding it based on its properties and the evidence based on which it was created. The user can steer mapping generation based on the presented information. Section 5 concludes.

2 OPEN DATA CASE STUDY: THE LONDON DATASTORE

Open government data is published in a collection of national, regional, city or topic-based portals, with a view to increasing transparency and informing decision making [3]. The London Datastore is a representive example of a city data repository, providing data sets across a range of topic areas, including transport, employment, housing, health and education. These datasets come from a variety of publishers, including local and national government departments, and many of the data sets use consistent, generous licenses. The London Datastore supports both search and browse interfaces, and allows data sets to be downloaded in a variety of formats.

The demonstration uses comma-separated-value file data sets, released under the UK Open Government License[2]. Typically files contain from a few tens of rows (e.g., there are numerous data sets that have one row for each London Borough, of which there are *33*), to a few thousand rows (e.g., there are around 5000 rows in a data set of modelled household income estimates at a particular, rather fine, area granularity). There may be few (e.g., 2) to many columns in each table (e.g., there are hundreds of columns in a ward atlas table, describing different properties of an electoral ward).

Figure 1: London datasets example

Figure 1 contains fragments (i.e., shows subsets of both tuples and attributes of the tables) from three tables in The London Datastore that are used in our running example. The tables in Figure 1 show population statistics for different London areas and (possibly their corresponding) crime rates[3].

3 MAPPING GENERATION IN DYNAMAP

In this section, we illustrate mapping generation in Dynamap with an example over The London Datastore.

The problem and some evidence. The *problem* is that of generating a set of mappings that populate a *target* table from a set of *source* tables. The target table definition provides only the names of the columns, and the source table definitions contain only column names and their associated values. Mapping generation techniques have been developed that use different types of evidence, including declared constraints [5], data examples [2] and feedback [4]. In Dynamap, the *evidence* used to inform mapping generation is *matches* between *source* and *target* attributes, and (partial) *inclusion dependencies*, both of which can be inferred using standard profiling algorithms [1]. In Figure 1, the *target* requires information about population and employment statistics per area (first 7 attributes), together with the corresponding number of offences in each area (last attribute). Also, Figure 1 shows the detected profile data on the represented sources: 10 inclusion dependencies (represented by arrows, where their direction is from the dependent to the referenced source) and 12 candidate keys (annotated with *[CK]*). The *overlap* (θ) is the fraction of the distinct values in the dependent attribute that are found in the referenced attribute. In the example, eight inclusion dependencies are partial ($\theta \in (0, 1)$) and two are full ($\theta = 1.0$).

Exploring the search space. Mapping generation is typically a search problem, either using generic (e.g., [6]) or bespoke (e.g., [5]) algorithms. In Dynamap, the space of candidate mappings is every way of combining the sources using *union* or *join* operations, where union compatibility is detected by comparing matches with the target and join operations are based on full or partial inclusion dependencies. We explore the search space using dynamic programming, but with pruning to ensure that only promising parts of the space are actually visited. As a result, mappings are constructed bottom-up, from pairs of tables, then from tables with intermediate mappings containing two tables, etc. For example, in Figure 1, a first step could be to merge *Indices of deprivation* with *London borough profiles* by joining on *Area* attributes, and then, their result intermediate mapping could be merged further with the *crime rates* table through join on either *Code* or *Area/Borough* attributes.

Annotating candidate mappings. As the search must combine pairs of intermediate mappings, we need to know the candidate keys of candidate mappings and their (partial) inclusion dependencies. These need to be derived during the search process, as it is not computationally viable to evaluate (i.e., materialize) every candidate mapping and run a profiler on it. The derived profile information is also used to compute a fitness, which represents the predicted fraction of complete rows. Formulas have been developed for propagating profiling data through unions and joins [8]. For example, in Figure 1, after joining *Indices of deprivation* with *London borough profiles* on *Area*, their corresponding inclusion dependencies and candidate keys are propagated such that it shows the relationship between the newly created intermediate mapping and the *crime rates* table. Based on this propagated profiling data, the mapping generation system can detect that the new mapping will produce *Area* and *Code* values that are overlapping with *Borough* and *Code* in *crime rates*, thus, it concludes that they can be joined on one of the overlapping attribute pairs.

4 DEMONSTRATION

Mapping generation in the wild will be demonstrated through hands-on experience generating and examining mappings over datasets from The London Datastore, in the context of the Data Preparer[4] data integration and cleaning platform, a descendent of the VADA Architecture [7]. Users interact with the system via a web interface; our goals are to demonstrate: *(i)* how data profiling can be used to provide information about the properties of the data sets; *(ii)* how this evidence can be used by Dynamap to combine sources in plausible ways; *(iii)* how users can review the candidate mappings, and the evidence on which they are based; and *(iv)* how users can steer the mapping generation process, for example by excluding schema elements or profiling data that are not relevant to the result.

Figure 2 shows an example that extends the one in Figure 1 by adding to it three other sources containing data about house and population density, national insurance registrations, and statistics on the population from the local authorities. Although the demonstration will support different ways of using the system, one approach would involve the following steps.

Browse the available sources. The interface supports search and browse over the sources that are input to the system.

Define a target. The user can interactively name a target table and its attributes, or edit an existing target to add/remove attributes. The target table used throughout is that from Figure 1.

Generate mappings and view the result. Given some source tables and a target, the user can ask the system to generate a result,

[3]Due to space limitations, throughout the rest of this paper, the figures contain attribute and table names capped at 15 characters.

Figure 2: Mapping explanation tree and associated information

which means running a matcher, a data profiler (for detecting candidate keys and partial/full inclusion dependencies), mapping generation and result display.

View a candidate mapping. From the result, the user can ask the system to explain how the generated mappings were produced. Each generated mapping has *(i)* a view that has the schema of the chosen target table and that shows how the target is populated once the mapping is executed (e.g., ❶ in Figure 2), and *(ii)* a *mapping explanation*. Each mapping is *explained* through the help of a tree view where the user can understand in which order the sources were merged and which operators were used to merge them. Figure 2 shows how six sources are merged through five joins by a mapping. The *root* of the tree is the chosen target table and the leaves of the tree are the input sources merged by the mapping. The intermediate nodes represent the incremental build-up of the explained mapping, starting with the merge of the leaves (the sources) and reaching the target when all sources were merged or when no other merge opportunities could be identified. As mentioned in Section 3, the mappings are constructed in a bottom-up fashion, and this is shown by the tree representation, where each intermediate mapping has two corresponding nodes in the tree: *(i)* an *operation* node (e.g., ③ in Figure 2), and *(ii)* a *L/R* node (e.g., ②, ④, ⑤). The *operation* node is used to show which was the chosen operation between the two operands, and (if present) the join condition. As explained in [8], the operations considered by Dynamap are union, (equi) join or full outer join; different combinations of profiling data lead to different operations, e.g., a candidate key whose attributes share a partial inclusion dependency can lead to a full outer join, while a full inclusion dependency can lead to a join. The *L/R* node shows whether the newly created intermediate mapping is the **l**eft or **r**ight operand in the next operation (if any). For example, in Figure 2, the *national insurance* table (①) is represented as the left operand (②) for the join operation represented in node ③.

Understand a mapping. For understanding mappings, the user can interact with the *mapping explanation tree* and drill down on the evidence that informed its creation. The interaction is done by clicking on the three types of nodes, i.e., *leaf*, *L/R*, and *operation* nodes, each revealing evidence for that merge step:
Leaf node. Clicking on a leaf node leads to a snippet of the initial source that it represents. This helps the user understand the dataset information and whether it was semantically correct to merge it with the other sources in the mapping. This helps to decide whether to keep or discard a source from the search. For instance, after clicking on *national insurance* (①) a snippet of the source appears (❺). It can be observed from it that the source contains data about national insurance registrations, which is relevant to the chosen target that requires employment data.
L/R node. Clicking on a *L/R* node shows information about each attribute of that intermediate mapping: *(i)* the target attribute

that it matches (if any), and *(ii)* the provenance of the distinct values in the attribute. The information about the value provenance is shown as set operations based on how the parent attributes were merged, e.g., the result of joined attributes contains the intersection of their values. This helps to understand if a match is inappropriate or if source attributes were incorrectly merged. In Figure 2, to understand how the *national insurance* source contributes to the target, the user needs to click on its corresponding *L* node (②), for which the information about the attributes appears (❹) so they learn that this source contributes with both *Area* and *NIN registration* values to the target (highlighted in blue in ❹). Node ④ is another example of *L/R* node that corresponds to the result of the join on *Area* between *national insurance* and *indices of deprivation* datasets (③). The attribute information for this intermediate mapping shows that its *Area* attribute contains the intersection of the values from *Area* attributes in *national insurance* and *indices of deprivation*, while the rest of the attributes are not merged.

Operation node. Clicking on an *operation* node shows the profiling data that was used to choose a certain merge operation. The information shown contains a table listing inclusion dependencies and another table for candidate keys. This helps decide whether the used profiling data is meaningful. In Figure 2, to understand how the *national insurance* dataset is merged with *indices of deprivation*, the user accesses the information about their merge by clicking on the corresponding *operation* node (③). This shows the profiling data that was used to decide their join on *Area* (❸), which comprises two candidate keys on *Area* attributes in both sources that share one full inclusion dependency.

Steer mapping generation. Understanding the generated mappings can be crucial in the selection of proper mappings to populate a target. Thus, a user can understand if the chosen sources should be merged or not, or if Dynamap was misled by any faulty matches or profiling data. After the user explores the mapping explanation and pins down any wrong decisions, they can alter through the interface the input that previously led to incorrect merges. The steering can be done through *(i)* adding/deleting source-to-target matches, e.g., remove those between a source attribute that represents a different concept than the one required by the target, *(ii)* removing misleading inclusion dependencies, e.g., remove those between semantically different source attributes that have common values, *(iii)* removing candidate keys on attributes which should not be keys, but were detected due to the (possibly) scarce data in the source, or *(iv)* removing unnecessary datasets from the search space. For example, in Figure 2, the merge opportunities that Dynamap finds seem correct as all joined attributes are suitable pairs in terms of their meaning and value overlap. However, the snippet of the target (❶) shows that many tuples have the same attribute values, for which only the *Population* values differ, indicating there might be an incorrect join with the source(s) that contributes to the *Population* attribute. By accessing the attribute information (❼) corresponding to the last merge in the mapping (⑤) it is shown that the value provenance of *Population* is from the *housing density* source. The next step is to analyze the data in the source by clicking on the corresponding leaf node (⑥) for which a snippet of its extent (❻) is shown. Analyzing the dataset fragment, it can be observed that the match is incorrect although the *Population* attribute in *housing density* has exactly the same name as the target, which makes it seem a correct match. The two attributes represent different types of population: in the source, the population information is per ward, not per area as required by the target. Thus, it can be concluded that the match is inaccurate. In such situations, it is not straightforward to differentiate between two (possibly close) semantic meanings, especially when the attributes contain numerical values. Learning about this incorrect match, the user steers the mapping generation process by discarding the *Population* match. After a new rerun of the mapping generation process with the updated input, the new resulting mappings produce sensible results in terms of aligned data per area. However, given that the *housing density* source does not contribute anything else to the target, it is automatically eliminated from the search space, thus, the new mappings do not involve it.

5 CONCLUSIONS

We have illustrated mapping generation in the wild with open data. Not only do we produce useful mappings, but also the system is transparent – the user can see what has been done, and steer the production of future mappings by altering and/or correcting the three types of input: inaccurate matches, misleading profiling data (candidate keys and inclusion dependencies), and unnecessary sources.

The problem of automated mapping generation might seem as an overly-engineered approach when the number of input sources is small and an expert user can hand-craft the mappings. However, the problem becomes increasingly complicated when tens or hundreds of sources are involved and they have a plethora of merge opportunities. Thus, automating mapping generation becomes an essential component for data integration. Moreover, given autonomous input sources, finding correct mappings completely automatically might become an unfeasible task. This gives rise to the problem of understanding complex mappings that involve numerous, autonomous sources. Helping the user understand the mappings leads to steering the mapping generation process by providing proper input, based on which the system can make correct decisions.

ABSTRACT

There is an increasing demand from domain experts for tools that assist them to extract information about the scientific progress and technological innovations from bibliographic archives such as the Web of Science, arXiv, PubMed, etc. Topic evolution graphs track the evolution of science by identifying and analyzing science evolution patterns like the emergence and decay of research topics or the split of one research topic into several subtopics, etc. Building such topic evolution networks for extracting meaningful evolution patterns is still a difficult task requiring the tuning of several technical parameters. In our demonstration, we present our prototype implementation of a generic topic evolution model for representing and filtering evolution patterns extracted from very large document archives.

1 INTRODUCTION

Revealing meaningful evolution patterns from document archives has many applications and can be used to synthetize narratives from datasets accross multiple domains, including new stories, research papers, legal cases and works of literature [12]. The study of science evolution can help *philosophers and historians* of science [10] to test their theories with data, *researchers* to position their work in its scientific context, *policy makers* to foster innovation and get key indicators for decision-making processes, *industry* to evaluate the potential for innovation and technological transfer, *librarians* to classify scientific documents, etc.

Scientific evolution can broadly be studied by adopting a cognitive view or a social view on evolution dynamics. The cognitive view emphasizes the shared knowledge and the change of ideas (Kuhn's approach [10]), whereas the social view takes account of authorship and social interaction (e.g., citation graphs) [7, 13]. Bibliographic archives often include both kinds of information and there also exist methods which also combine both views to study science evolution [8]. In the interdisciplinary EPIQUE project[1] we adopt the cognitive view for modeling science evolution and assume that the evolution only depends on the content of the documents. Whereas this choice clearly reduces the expressivity of our evolution model it also decreases the "social" bias and detects more easily possible interactions between scientific ideas and contributions independently of any particular scientific community.

The goal of topic evolution networks is to track complex temporal changes by epoch-wise topic discovery and temporal similarity graphs aligning topics of different epochs. Existing evolution network based frameworks mainly can be distinguished by the chosen topic extraction and alignment methods. [4] comes up with a method to enable a bottom-up reconstruction of the dynamics of scientific fields. They generate topics by word co-occurrence graphs and align inter-temporal topics by Jaccard similarity [9]. [1] generates topics by a Hierarchical Dirichlet Process (HDP) [14] and uses Bhattacharyya similarity [2], representing the gradual speciation and convergence similar to biologic evolution, for identifying topic alignments. The alignment process also applies (asymmetric) Kullback-Leibler divergence (KLD) for detecting topic split and merge. [11] introduces a novel approach to the early detection of research topics by using the Computer Science Ontology[2] to model research topics in the Rexplore system. They apply a Clique Percolation Method (ACPM) for analyzing the dynamics between existent topics. Other examples of science evolution studies explore how "cognitive science" as a field has changed over the last three decades [6] or analyze topic evolution patterns (split, merge and knowledge transfer) in the field of Information retrieval (IR) [5].

The goal of our work is to develop a general framework which is easier to use by domain experts who can ignore the details of the underlying topic analysis methods. The contributions presented in our demonstration can be summarized as follows:

- We propose a generic topic evolution model enabling the specification and extraction of meaningful topic evolution patterns independently of a particular topic extraction method.
- We define high-level measures for estimating the quality of the topic extraction process and for characterizing the structural and quantitative evolution of topics during a time period. This enables the experts to tune the topic extraction process and explore large topic evolution graphs by defining complex topic evolution patterns.
- We implemented a scalable prototype on top of Apache Spark for processing large scientific corpora containing millions of documents and finding meaningful topic evolution graphs for both stable topics and highly evolving ones.

2 TOPIC EVOLUTION MODEL

Topic evolution graphs: We consider a *corpus* C of time-stamped documents, a set of *periods* P and a set of terms V (*vocabulary*). Let $\mathcal{M} : 2^C \rightarrow 2^{\mathbb{R}^{|V|}}$ be a *topic extraction method* generating for a subset of documents $C' \subseteq C$ a set of (sparse) weighted term vectors $\mathcal{M}(C') \subseteq \mathbb{R}^{|V|}$. We denote by $C_p \subseteq C$ the corpus of documents with timestamp $p \in P$ and by $T_p = \mathcal{M}(C_p)$ the *topic descriptions* extracted from the documents C_p of period p using topic extraction method $\mathcal{M}$. A *topic* $t \in T_p$ is then defined by a couple $t = (d, p)$ where $d \in \mathcal{M}(C_p)$. We will denote by $t.d$ the *topic description* and by $t.p$ the *topic period*. Observe that topics from different periods may share the same description. For example in Figure 1, P has 3 periods: $p1$="2000 – 2002", $p2$="2002 – 2004" $p3$="2004 – 2006", T_{p1} contains topics 54 to 92, and topic $92 = (d, p1)$, where d is a weighted vector containing

[1]This work was funded by French ANR-16-CE38-0002-01 project EPIQUE.

[2]http://cso.kmi.open.ac.uk/

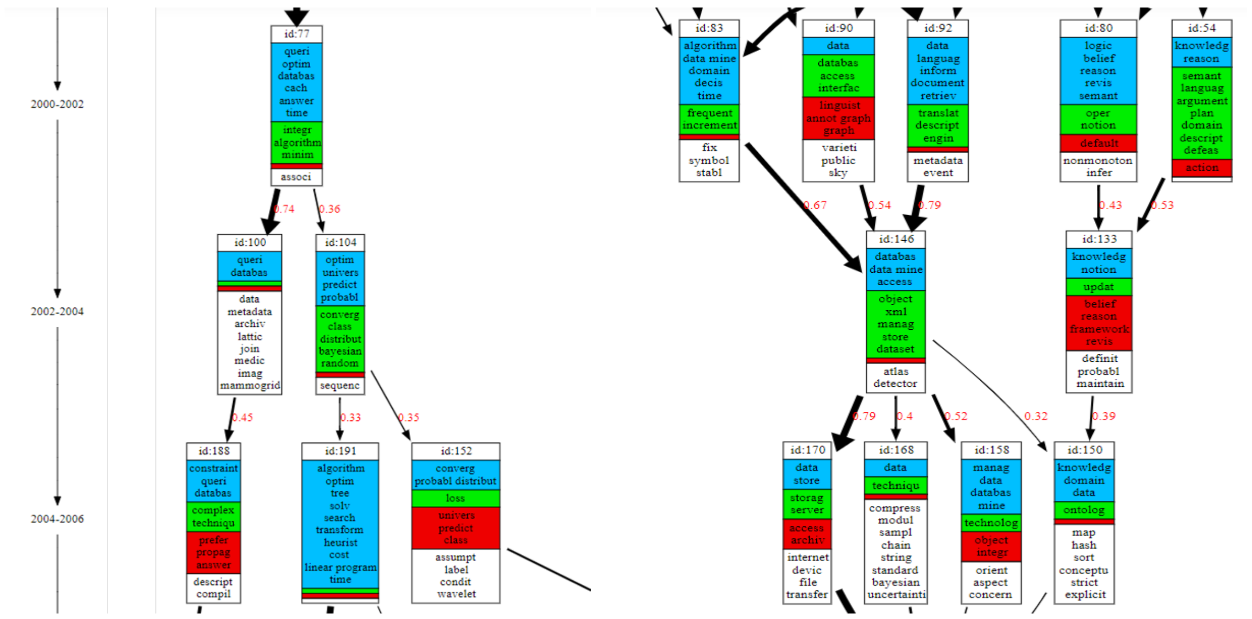

Figure 1: Pivot topics containing term "database" extracted from arXiv, green = emerging terms, blue = stable terms, red = decaying terms

terms "*queri*", "*optim*", "*databas*"... We define a *topic evolution function sim* : $T \times T \longrightarrow [0,1]$ estimating the *similarity* between topics in T. For example in Figure 1, the similarity measure depends on the topic description and estimates their semantic proximity using *cosine* similarity. The similarity between topic 77 and topic 100 is $sim(77,100) = 0.74$.

Based on the topic evolution function, we define a *topic evolution graph* as a directed labeled *multistage* graph $G_\beta = (T, E, sim, \beta)$ over topics T where the edges E connect all topics from consecutive periods with similarity higher or equal to some threshold β: $E = \{(t_i, t_j) \in T | sim(t_i, t_j) \geq \beta \wedge t_j.p = t_i.p + 1\}$.

Topic labeling: For visualization, we assume that all topics t of some evolution graph G_β are labeled by the top-k highest weighted terms in the topic description $t.d$. Let $t.l$ be the top-k highest weighted terms in $t.d$ and $t.l_p \subseteq t.l$ and $t.l_f \subseteq t.l$ be the subsets of *past* and *future* terms which appear, respectively, in the ancestor topics and in the descendant topics of t. Then, the terms in some topic vector $t.l$ are partitioned into the following four subsets of :

- *emerging* future terms $t.l_e = t.l_f - t.l_p$ which do not exist in past topics,
- *decaying* past terms $t.l_d = t.l_p - t.l_f$ which do not exist in future topics,
- *stable* terms $t.l_g = t.l_p \cap t.l_f$ which exist in the past and the future topics of t, and
- *specific* terms $t.l_s = t.l - (t.l_p \cup t.l_f)$ which neither exist in the past nor in the future topics of t.

The quadruple $[t.l_e, t.l_d, t.l_g, t.l_s]$ is called the *term label* of t.

Figure 1 shows two snippets of a single topic evolution graph extracted from the arXiv[3] corpus for the category DB (databases). Although the number of documents of category DB are limited, the generated graphs still generate meaningful evolution patterns. Emerging terms are shown in green boxes, decaying term boxes are colored in red, stable terms which exist both in ancestor topics and in descendant topics are grouped in blue boxes and specific terms which appear only in current topic are in white boxes. The thickness of edges reflects the similarity between topics. Several topics in both subgraphs contain the term "database" and we can observe different evolution patterns. The left hand graph shows that in period 2002-2004, topic 77 ("databases, queries, optimization, integration") split into topics 100 and 188 ("databases, queries and constraints") and topics 104, 191, 152 ("prediction, probability, random"). The right subgraph covers the same period with topics related to "data mining" (83), "data access interfaces" (90), "information retrieval" (92), "logics, semantics" (80) and "knowledge, reasoning" (54). The first three topics converge in 2002-2004 into a single topic on "object, xml, store, data mining" (146) which splits in the period of 2004-2006 into "storage servers" (170), "data mining and management" (158) and "knowledge and ontologies" (150).

Pivot evolution graphs: Threshold β strongly influences the complexity of the obtained evolution graphs. It is easy to see that $G_{\beta'}$ is a subgraph of G_β for all $\beta' \geq \beta$ and G_0 is the complete graph connecting all topics of two consecutive periods. More exactly, higher β values generate more "linear" graphs with many isolated topics, whereas lower values generate more complex graphs containing a variety of potentially interesting structures. Observe also that, whereas the pivot graph complexity of the same topic increases with decreasing β, high β thresholds might still generate complex pivot graphs and vice-versa. Analyzing science evolution by using topic evolution graphs then becomes a complex task which consist in computing and visually exploring multiple graphs for different β values. To solve this problem, we propose a different approach which allows users to formulate *filtering queries* for selecting interesting *subgraphs* with meaningful measures from a set of evolution graphs defined by a set of β thresholds. For this, we decompose topic evolution graphs into the set of all connected subgraphs defined by all paths containing a given topic t (one graph per topic). More formally, a *pivot evolution graph* $G_\beta(t) = (T', E', sim, \beta)$ *of topic* t in G_β is the subgraph of G_β which contains t and all *ancestors* and *descendants* of t. The subgraph of $G_\beta(t)$ containing all nodes which are reachable

[3]https://arxiv.org/

from t by a path is called the *future* of t, denoted by $F_\beta(t)$, and the subgraph of nodes which can reach t through a path is called the *past* of t, denoted by $P_\beta(t)$. The couple (t, β) is called a *pivot topic* with pivot graph $G_\beta(t)$, future $F_\beta(t)$ and past $P_\beta(t)$. It is easy to see that if t_1 appears in the future (past) of t_2, then the future (past) of t_1 is a subgraph of the future (past) of t_2 and t_2 appears in the past (future) of t_1. This property can be exploited to filter topics *wrt.* future and past topics (see the definition of Connection Filters below).

The evolution of topics within their evolution graphs can be characterized by the following metrics:

- The *liveliness* $live(G_\beta(t))$, of a pivot topic (t, β) is defined by the diameter (longest path length) of its pivot graph $G_\beta(t)$. A high liveliness value describes a long living topic, whereas a value equal to 0 corresponds to an isolated topic without ancestors and descendants. The liveliness $live(P_\beta(t))$ of t in its past estimates the "age" of t *wrt.* the first period, whereas $live(F_\beta(t))$ returns the "life expectation" of t (in its future).
- The *relative evolution degree* $revol(G_\beta(t))$ of a pivot topic (t, β) is defined by the average topic dissimilarity (edge) weight in $G_\beta(t)$. A low relative evolution degree states that most topics are connected to very similar topics, *i.e.*, most topics in $G_\beta(t)$ evolve slowly. On the other hand, a high value signifies that most topics have an important "semantic gap". By definition, $revol(G_\beta(t)) \geq \beta$.
- The *pivot evolution degree* $pevol(G_\beta(t))$ of a pivot topic (t, β) is defined by the average dissimilarity of all topics in $G_\beta(t)$ with respect to the pivot topic t. A low pivot evolution degree signifies that the pivot topic does not evolve a lot (all other topics are similar), whereas a high value indicates that the pivot topic evolves rapidly .
- The *split degree* $split(G_\beta(t))$ of a pivot topic (t, β) is defined by the average outdegree of $G_\beta(t)$. A low value signifies that the topics evolve along linear paths and a high value signifies that the topics split into several future sub-topics.
- The *convergence degree* $conv(G_\beta(t))$ of a pivot topic (t, β) is defined by the average indegree of $G_\beta(t)$. A low value signifies that many topics depend on a single parent topic and a high value signifies that many topics are the result of the fusion of past topics.

Evolution Pattern Filters: The previous evolution metrics characterize the the evolution of a topic in some evolution graph G_β. Combined with other filters on the topic labels and the graph structure, it is possible to filter pivot topics satisfying rich evolution patterns within a set of evolution graphs G_{β_i}, $1 \leq i \leq n$.

Term Filters select pivot graphs with respect to the pivot topic labels. In particular, they can be applied to filter pivot graphs *wrt.* to their emerging, decaying, stable, and specific terms.

Temporal Filters allow experts to filter the pivot topics situated within a certain time period.

Pattern Filters can filter topics by their pivot graph structure along their liveliness, split degree and convergence degree.

Evolution Filters are applied to filter topics by their relative and pivot evolution degrees.

The previous filters are applied to sets of pivot topics and can be combined with the following other kinds of operators:

Connection Filters are binary operators which select all pivot topics that are connected to at least one pivot topic in some other set of topics.

Temporal Projection allows to restrict structural, evolution and connection filters to the past or the future of the pivot topics.

Set Operators allow to combine two sets of topics by union, intersection and difference.

Ordering Operators sort pivot topics by their attributes, such as the topic period, its liveliness, evolution degree etc.

3 WORKFLOW AND IMPLEMENTATION

Figure 2 illustrates the overall workflow which takes as input a corpus of documents split into several, possibly overlapping time periods (the same document might appear in two periods).

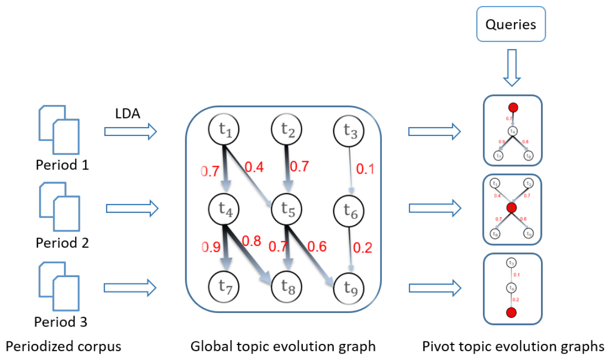

Figure 2: Topic evolution model of EPIQUE

All documents within a period are processed by LDA [3] to generate a set of topics which are aligned to produce a single topic evolution graph G_{β_0} for some small alignment threshold β_0. This global evolution graph is then transformed into n families of pivot evolution graphs defined by a set of alignment thresholds $\beta_i > \beta_0$, $1 \leq i \leq n$. Each family contains the pivot graphs $G_{\beta_i}(t)$ of all pivot topics (t, β_i). The final database contains $n \times |T|$ pivot graphs where $|T|$ is the number of topics in G_{β_0}. These graphs can then be queried using the filters defined in Section 2.

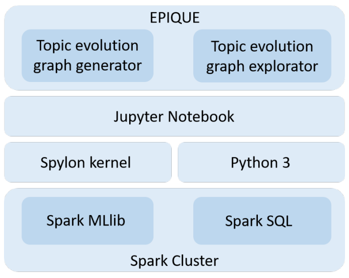

Figure 3: EPIQUE web application architecture

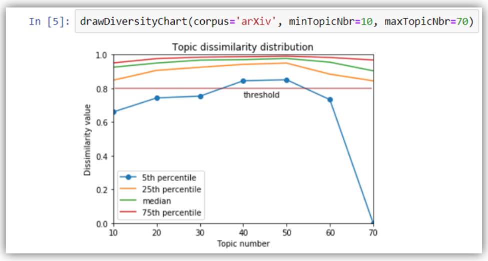
Figure 3 gives an overview of the architecture of our web application implemented on top of Apache Spark and Jupyter Notebook. The entire process to study science evolution over a corpus is split into two steps for building the pivot evolution graphs and for interactively exploring these graphs. Each step corresponds to a separate user interface. The evolution graph generation is implemented in Scala and exectued through the Spylon[4] kernel. Evolution graph exploration uses a standard Python kernel to take advantage of advanced Python 3 graphical user interface libraries for facilitating user interaction.

[4]https://github.com/Valassis-Digital-Media/spylon-kernel

4 DEMONSTRATION

Our EPIQUE prototype allows the audience to easily and intuitively generate high-quality evolution graphs and explore them. Among the corpora we have prepared in several domains, our demonstration focuses on the evolution of computer science based on the ArXiv corpus. We propose two interactive demonstration scenarios[5].



```
In [5]: drawDiversityChart(corpus='arXiv', minTopicNbr=10, maxTopicNbr=70)
```

Figure 4: Screenshot: topic diversity evaluation

Scenario 1 The audience selects or uploads a corpus of documents with a vocabulary of terms pre-processed by an on-line text-mining tool Gargantext[6] and specifies the time periods through sliding window over a global time period. Then, the LDA topic model is generated for each period. LDA requires a vocabulary and a number of topics to be generated. This number obviously influences the diversity of the resulting topics. Therefore, the application first generates a set of topic models for different topic numbers per period. The user can then visualize the diversity of the extracted topic models (topic dissimilairty distribution) and choose the model with the highest diversity for each period. A topic diversity distribution for different topic numbers is reported as shown in Figure 4 and, for example, by observing the 5th percentile values (blue line), the user can retain one of the two models (40 or 50 topics per period) that achieves 95% of pairwise dissimilarities above 0.8.

Then, the topics of consecutive periods are aligned and all pivot topic evolution graphs are generated along with their main temporal, structural and evolution indicators: *liveliness*, *split degree*, etc. All topic labels are also generated automatically in this step.

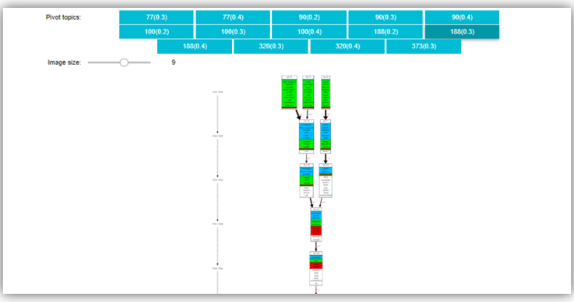


Figure 5: Screenshot: pivot topic evolution graph visualization

In the next step, the user specifies its exploration goal through an intuitive declarative query-by-example interface (as shown in the demonstration video[5]) and visualizes pivot topic evolution graphs as shown in Figure 5. These graphs are pre-computed in the last step to ensure fast query answer display.

We showcase a search for topic graphs containing a given term (*e.g.*, database) or set of terms suggested by the audience. Besides the topic content, the audience can search for topic graphs on their shape as well. We also prepared 10 predefined query templates for a typical shapes of high interest such as (i) topics that split in distinct 5+ years long branches, (ii) topic graphs with low *relative evolution degree* and high end-to-end *pivot evolution degree*. We also demonstrate more complex queries combining several query templates to build, for example, *concept drift* queries looking for pivot topics that contain emerging terms originating from other, "older" topics which are not part of their past pivot subgraph.

Scenario 2 In the second scenario, we will provide the audience with the possibility to prepare their own corpus using the Gargantext service which is also part of the EPIQUE project. Gargantext includes a number of bibliographic archives like Pubmed, Web of Science, etc. and allows to create domain specific document collections and vocabularies which are then processed by the same workflow as in Scenario 1.

5 FUTURE WORK

In the next step, we intend to optimize the computation of pivot topic evolution graphs and exploit the LDA document-topic matrix for enriching the analysis. Additionally, we plan to integrate other topic extraction methods than LDA. This prototype will also be used to validate our evolution model with philosophers of science to define and extract complex evolution patterns from different scientific domains.

ABSTRACT

Specialized worker profiles of crowdsourcing platforms may contain a large amount of identifying and possibly sensitive personal information (e.g., personal preferences, skills, available slots, available devices) raising strong privacy concerns. This led to the design of privacy-preserving crowdsourcing platforms, that aim at enabling efficient crowdsourcing processes while providing strong privacy guarantees even when the platform is not fully trusted. We propose a demonstration of the PKD algorithm, a privacy-preserving space partitioning algorithm dedicated to enabling secondary usages of worker profiles within privacy-preserving crowdsourcing platforms by combining differentially private perturbation with additively-homomorphic encryption. The demonstration scenario showcases the PKD algorithm by illustrating its use for enabling requesters tune their tasks according to the actual distribution of worker profiles while providing sound privacy guarantees.

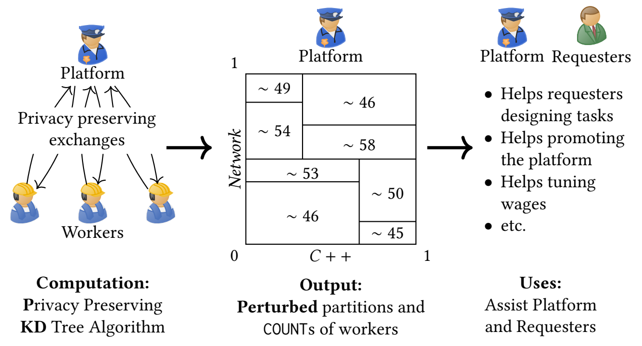

Figure 1: Overview of the PKD algorithm: supporting secondary usages of worker profiles with privacy guarantees

1 INTRODUCTION

Crowdsourcing platforms are online intermediates between requesters and workers: workers have skills and look for tasks, while requesters propose tasks that require specific skills. Crowdsourcing platforms are used in various application domains such as micro-tasks[1] or specialized software engineering[2]. Their efficiency, either for matching tasks to profiles (the primary usage of profiles) or for giving to requesters insights about the distribution of skills available within the population in order, e.g., to attract new requesters or to let requesters fine-tune their tasks according to the actual population of workers[3] (secondary usage of profiles), depends especially on the detailed information contained within worker profiles. A profile may indeed contain an arbitrary amount of information: professional or personal skills, daily availabilities, minimum wages, diplomas, professional experiences, centers of interest and personal preferences, devices owned and available, *etc.*

However fine grain worker profiles can be highly identifying or sensitive and privacy scandals have shown that those platforms are not immune to negligence or misbehaviours[4]. In a context where users expect crowdsourcing platforms to protect their personal data [Xia et al. 2017] and laws firmly require businesses and public organizations to safeguard the privacy of individuals (such as the European GDPR[5] or the California Consumer Privacy Act[6]) , designing and implementing sound privacy-preserving crowdsourcing processes is of utmost importance.

In this demonstration, we present the PKD algorithm [Duguépéroux and Allard 2019], a privacy-preserving space partitioning algorithm dedicated to enabling a wide range of secondary usages of worker profiles within privacy-preserving crowdsourcing platforms (see Figure 1). The PKD algorithm is distributed between a set of distrustful workers and an untrusted platform and builds on differentially private perturbation and additively-homomorphic encryption in order to compute a hierarchical partitioning of the skills of workers together with the approximate number of workers per partition. No raw worker profile is ever communicated to any other participant during the computation. The output of the PKD algorithm can be used for computing multi-dimensional COUNTs over worker profiles. The security of the PKD algorithm relies on composable security models in order to integrate well with privacy-preserving solutions to primary usages [Béziaud et al. 2017; Kajino 2015] without jeopardizing the privacy guarantees.

The demonstration scenario showcases the use of the PKD algorithm for letting requesters tune their tasks according to the actual population of workers, all this with sound privacy guarantees. The demonstration scenario essentially illustrates the impact of knowing the distribution of workers when tuning a task, and sheds the light on the tradeoff between privacy and utility within privacy-preserving crowdsourcing platforms, showing that a high privacy level can be guaranteed while still allowing high-standard secondary usages.

2 PRIVACY-PRESERVING INFORMED TASK-TUNING: AN OVERVIEW

2.1 Preliminaries

2.1.1 Participants. Three types of participants collaborate together during our crowdsourcing process. Workers are interested in solving tasks relevant to their profile, requesters propose tasks to be solved by appropriate workers, and the platform supports the intermediation. The number of skills n is fixed. A worker profile $p \in P$ is represented by an n-dimensional vector of floats where each value $p[j] \in [0, 1]$ represents the degree of competency of the profile p with respect to skill j. A task $t \in T$ is made of two parts. The first part is the meta-data containing the requirements needed to perform the task. We model it as an n-dimensional vector of ranges over skills (*i.e.,* a subspace of the space of profiles). The second part is the detailed task description provided by the requester (an arbitrary bitstring). In this work, we focus on the metadata part.

We assume that the participants are equipped with today's commodity hardware (i.e., the typical CPU/bandwidth/storage resources of a personal computer). However, we expect the platform to be available 24/7, similarly to a traditional client/server setting.

2.1.2 Security. We assume that all participants follow the *honest-but-curious* attack model: they may use any information disclosed along the algorithm to infer information about profiles, but they do not step outside the protocol.

As stated in Definition 1, the privacy model satisfied by the PKD algorithm is a computational variant of the well-known *differential privacy* model [Dwork 2006] called ϵ_κ-SIM-CDP [Mironov et al. 2009] (see the proofs in the technical report [Duguépéroux and Allard 2019]).

Definition 1 (ϵ_κ-SIM-CDP privacy [Mironov et al. 2009] (simplified)). *The randomized function f_κ provides ϵ_κ-SIM-CDP if there exists a function F_κ that satisfies ϵ-differential privacy and a negligible function $negl(\cdot)$, such that for every set of worker profiles $\mathcal{P}$, every probabilistic polynomial time adversary A_κ, every auxiliary background knowledge $\zeta_\kappa \in \{0, 1\}^*$, it holds that:*

$$|\Pr[\mathsf{A}_k(\mathsf{f}_\kappa(\mathcal{P}, \zeta_\kappa)) = 1] - \Pr[\mathsf{A}_k(\mathsf{F}_\kappa(\mathcal{P}, \zeta_\kappa)) = 1]| \le negl(\kappa)$$

The original ϵ-differential privacy model applies to a randomized function f and aims at hiding the impact of any possible individual value on the possible outputs of f, often by adding random noise to it. Computational variants of differential privacy are especially relevant when differentially private perturbation and semantically secure encryption are used jointly, as done within the PKD algorithm. First, the differentially private perturbation scheme used by the PKD algorithm is the Geometric mechanism [Ghosh et al. 2012]. It consists essentially in sampling a two-sided geometric distribution parameterized by the differential privacy parameter ϵ and by the aggregate to be perturbed. It benefits from the following nice properties: it is designed for perturbing integers, and the sampling can be easily distributed over workers (infinite divisibility of the two-sided geometric distribution [Duguépéroux and Allard 2019]). Second, the PKD algorithm makes use of an *additively homomorphic encryption scheme.* Additively-homomorphic encryption schemes essentially allow to perform addition operations over encrypted data. Any additively-homomorphic encryption scheme fits our approach as long as it provides *semantic security guarantees* (usual security guarantees), *additively-homomorphic encryption* (possibility to perform additively homomorphic sums) and *non-interactive threshold decryption* (allows the decryption key to be split in K key-shares, such that a complete decryption requires to perform independently $T \le K$ partial decryption by distinct key-shares). The Damgard-Jurik cryptosystem [Damgård and Jurik 2001], a generalization of Paillier [Paillier 1999], is an instance of encryption scheme that provides the desired properties. We refer the interested reader to the original paper for details [Damgård and Jurik 2001].

2.1.3 Quality. Roughly speaking, we evaluate the quality achieved by the outputs of the PKD algorithm by measuring the average absolute error between (approximate) counts estimated through its outputs and the corresponding exact counts computed on the raw, non-protected, worker profiles. We refer the interested reader to the technical report [Duguépéroux and Allard 2019] for more details on the quality definition and on the experimental results.

2.2 The PKD algorithm

The PKD algorithm is an adaptation of the well-known centralized KD-Tree construction algorithm [Bentley 1975], to a context where no central server is trusted, and the result is private. The resulting KD-Tree is used to estimate the underlying *multidimensional* distribution of workers (e.g., to let requesters tune their tasks accordingly). Each worker holds his profile locally and engages with the platform and other workers in the execution of the PKD algorithm. The PKD algorithm consists essentially in splitting recursively the space of skills in two and stops when a termination criterion is met (e.g., fixed number of splits). The split is performed by choosing one dimension d at each iteration (e.g., considering on dimension after the other), projecting the set of skills on d, and forming two partitions around the median. The PKD algorithm outputs a binary tree where each node is a partition of the space of skills with the (perturbed) number of worker profiles it contains. The key operation of the PKD algorithm is the distributed privacy-preserving computation of medians. It is implemented by building at each iteration the (perturbed) histogram of the dimension being split and using the histogram in order to estimate the median. This histogram results from the privacy-preserving aggregation, on the platform, of the local histograms of workers. The following execution steps synthesize the computation of a perturbed histogram over the dimension d:

(1) Each worker locally instantiates his local histogram over the dimension d such that all the bins are set to 0 except the bin within which the worker's skill degree on d falls, set to 1.
(2) Each worker locally adds a *noise-share* to each bin, where a noise-share is a random variable such that the sum of a fixed number of noise-shares follows the two-sided geometric distribution. Recall (1) that the two-sided geometric distribution is infinitely divisible, and (2) that the addition to an integer of a random variable sampled from a two-sided geometric distribution well parameterized satisfies differential privacy (see above).
(3) Each worker encrypts each of its bins with the additively-homomorphic encryption scheme and sends it to the platform.

(4) The platform sums up all the encrypted histograms received from workers (bin per bin).
(5) The workers and the platform collaboratively decrypt the resulting encrypted histogram building on the threshold decryption feature of the encryption scheme (see above). The platform thus obtains the perturbed "summed up" histogram.
(6) The platform estimates the median based on the histogram, splits the dimension d around it, and either iterates on each of the two resulting partitions, or stops the algorithm if a termination criteria is met (e.g., sufficient number of splits).

The PKD algorithm further improves the quality of the counts of the hierarchy of partitions by post-processing them based on constrained inference techniques (see [Cormode et al. 2012; Hay et al. 2010] for details). A complete description of the PKD algorithm together with thorough experimental results are available in [Duguépéroux and Allard 2019].

2.3 Informed Task Tuning

The partitioning of the space of skills output by the PKD algorithm enables the computation of multi-dimensional COUNTs over the space of skills of the actual population of workers. A large variety of usages can be envisioned. We focus in this paper on a precise illustration that consists in publishing the partitioning of the space to requesters, and letting them tune their tasks according to the actual distribution of skills. For example, through an appropriate *task tuning helper*, provided by the platform or implemented on behalf of the requester, the latter could define wages according to the scarcity of a profile, or tune the skills required by a task such that they fit the profiles of a sufficiently high number of workers which results in lower pickup times.

3 DEMONSTRATION

This demonstration illustrates the PKD algorithm by (1) allowing its execution on a wide variety of parameters (e.g., various populations of workers, different numbers of iteration, different values of the ϵ privacy parameter) and (2) allowing the audience to create tasks matching the population of workers through a simple *task tuning* helper. The demonstration platform is centralized and simulates the distributed components of the PKD algorithm. We present below the technicals details of the demonstration platform, the parameters that can be set up by the audience (called *mutable* parameter) , the parameters that are fixed, and the demonstration scenario.

3.1 Platform

Figure 2 depicts the demonstration platform. The demonstration is implemented as a web application running through a single docker-compose file. In this file, several services handle every aspect of the application without any configuration or installation (except for docker and docker-compose, which are not specific to this demonstration). The first service and the core of the application is a Python Django web server used to serve the web interface and handle the commands issued by the demonstrator. The user interface, served by Django consists in simple HTML pages using the CSS framework Bootstrap for the design and ViewJS scripts for the dynamic components. A second service handles the long tasks in the background that cannot reasonably

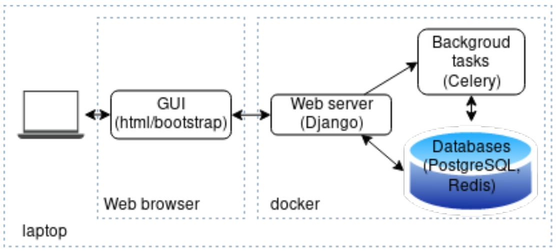

Figure 2: The demonstration runs on a single laptop executing the demonstration platform: the web server (Python Django), the background tasks handler (Celery) and the databases (PostgreSQL and Redis). The demonstration is accessible through a web interface (e.g., on the browser of the demonstration laptop).

be handled by Django without causing a loss of the user experience (i.e., tasks that last more than a few seconds such as the PKD algorithm and the CSV import of the workers). This service is written in Python with the Celery framework. Databases required by the application (PostgreSQL and Redis), to handle data persistency, are directly embedded in the docker-compose file. The homomorphic encryption features are disabled in order to reduce computation time for the demonstration. Indeed, for the sake of simplicity, all distributed operations, normally done by distinct workers, are done locally by the demonstration platform[7]. In particular, worker profiles are stored locally rather than being hold by individual workers, and the encrypted sum of histograms is replaced by a cleartext sum. These simplifications have no consequence on the output of the PKD algorithm. The source code of the demonstration is available publicly [8] and can be executed on a laptop where docker is installed (no configuration is required).

3.2 Parameters

In this demonstration we let the audience set various parameters, while others are fixed to default values. Default parameters are chosen to reflect plausible real-life settings while keeping the computation time reasonable. In particular, we limit the number of skills (e.g., 2 or 3 skills chosen by the audience) and the number of workers (e.g., a few hundreds instead of a few thousands in a real-life system).

The audience is able to set the skills, the worker profiles (either manually or automatically) and the PKD algorithm parameters. For these parameters, we also provide default values to help the audience: the differential privacy security parameter ($\epsilon = 0.1$), the number of splits for the partitioning ($splits = 7$) and the number of bins of histograms ($bins = 10$). Finally, the audience can tune tasks to fit with the previously defined workers.

Note that the termination criteria must be chosen carefully because it limits the number of splits of the space of skills[9]. The dimensions that are not part of the sequence will simply be ignored. The number of dimensions in workers profiles, and their respective priorities, is closely related to the application domain (e.g., How specific does the crowdsourcing process need to be?). In this paper, we make no assumption on the relative importance of dimensions.

[7]In a real-life scenario, encrypted operations would be performed in parallel by workers and the platform itself, which greatly reduces the costs
[8]https://gitlab.inria.fr/crowdguard-public/implems/pkd-demo
[9]It also impacts the overall computation time and quality of the estimation

3.3 Datasets

Three populations of workers are available by default: two populations are generated synthetically (i.e., through our `UNIF` worker generator that samples skill levels uniformly at random and our `ONESPE` worker generator that choses one strong skill uniformly at random for each worker and sets a low skill level to all others skills - see [Duguépéroux and Allard 2019] for details), and one population is computed from the public *Stackoverflow* dataset[10]. Additionally, the audience can instantiate a set of workers manually. Additional arbitrary populations of workers defined by the audience can be imported. Our platform accepts `CSV` files, such that each line is defined by three columns, as shown in Figure 3.

`UserID` (int)	`SkillID` (int)	`SkillLevel` (float in [0; 1])
12	3	0.4

Figure 3: Format of a worker dataset and illustration on a single worker.

3.4 Scenario

The demonstration scenario presents a simple execution sequence allowing the audience to observe the different steps of the PKD algorithm and to use the task tuning module. It concentrates on the task design, only the necessary information about the distribution of workers is displayed. A strong focus has been put on the simplicity and the clarity of the GUI which includes all the explanations needed to understand intuitively each step of the demonstration. The GUI is divided into a sequence of screens, where each screen is dedicated to a specific step of the execution sequence. First, an introduction screen presents the demonstration and its objective. Second, the audience choses the set of skills to consider. Third, the audience can launch the workers import (according to the various methods described above, including the import of a `CSV` file from the audience). Additional information about the distribution of skills within the dataset chosen is displayed through a Notebook document and commented. Fourth, the `PKD` algorithm is executed on the population of workers defined and outputs the space partitioning computed. Finally and most importantly, the audience uses our simple task tuning helper in order to tune a few tasks (1) without any information on the underlying population (default method within privacy-preserving crowdsourcing platforms) and (2) with the hierarchy of partitions computed by the `PKD` algorithm. Figure 4 shows the screen dedicated to tuning the task with information from the hierarchy of partitions. Optionnally, in order to observe the privacy/utility tradeoff, the audience is invited to explore the hierarchy of partitions and inspect the impact of the differentially private perturbation by comparing the perturbed counts to the exact unperturbed number of workers within each partition.

[10] We consider that a user is a worker, tags of posts are skills, and skill levels are a simple popularity score computed from the number of up-votes of each post. See https://gitlab.inria.fr/crowdguard-public/data/workers-stackoverflow for more details (i.e., description of the method and pre-processing scripts).

ABSTRACT

Applications for the Internet of Things (IoT) face several challenges when it comes to exploiting the underlying infrastructure for data management operations efficiently. IoT infrastructures consist of heterogeneous compute nodes and geographically distributed network topologies. Today's IoT applications offload data management to cloud-based stream processing engines (SPEs). However, this offloading represents a severe bottleneck that might hinder upcoming large-scale IoT applications in the future. In our demonstration, we showcase this problem using a public transport application as a potential large-scale IoT application. Our application consists of an interactive map for monitoring public transport vehicles and current demand. We implement this application on top of NebulaStream (NES), a new data management system that is designed for the IoT. In contrast to common cloud-based SPEs, NES answers queries by unifying cloud, fog, and sensor nodes under one system. Thus, NES minimizes network traffic and avoids resource over-utilization by considering the physical network topology and available compute nodes. The goal of this demonstration is to reveal the shortcomings of current system designs for large-scale IoT applications. Furthermore, we showcase how NES addresses these shortcomings and thus enables future large-scale IoT applications.

1 INTRODUCTION

Applications for the IoT, such as reporting and monitoring dashboards, consist of real-time data preprocessing and data mining tasks. Such applications visualize high-velocity data streams, resulting from large sensor networks, which flow through heterogeneous hardware and network topologies to the cloud.

Sensor streams naturally match the stream processing programming abstractions provided by cloud-based SPEs. Thus today's IoT applications use such systems to offload data management tasks. SPEs exploit the on-demand scalability of cloud resources to process compute-intensive data management workloads efficiently. However, state-of-the-art SPEs, such as Apache Flink [4], were designed for cloud environments composed of homogeneous high-performance hardware, where nodes are interconnected through high-speed network connections.

In contrast, IoT infrastructures have different characteristics regarding compute nodes and network connections [3]. In this new type of infrastructure, nodes are heterogeneous, geographically distributed, and sparsely interconnected through unstable networks. Geographically distributed sensor nodes continuously generate data, resulting in a large number of data streams with small-sized records. Intermediate nodes, also called fog nodes, provide network resources to route sensor data to the cloud. Certain nodes provide compute resources that support executing data management tasks. In particular, intermediate nodes range from low-end devices, such as system-on-a-chip devices, to high-end nodes, e.g., desktop computers and server racks. Cloud-based SPEs ignore intermediate nodes when distributing their load, hindering IoT applications from scaling beyond the cloud.

To scale data management tasks on all participating devices of an IoT infrastructure, the design of data management systems must be revisited. Recent work points out that to exploit resources of every node in an IoT infrastructure, data management systems must employ infrastructure-aware execution strategies [11]. A data management system for the IoT should leverage the scale-out capabilities of the cloud, and at the same time, exploit the resources of intermediate nodes. In particular, cloud nodes can scale resources for compute-intensive tasks within the cloud, while intermediate nodes apply fog computing techniques [6–8] to reduce intermediate results. As a result, network traffic and cloud resources are minimized. However, cloud-based approaches utilize intermediate nodes only to forward data.

NebulaStream [11] is an application and data management platform designed for the upcoming IoT era. NES addresses the mentioned IoT challenges by unifying sensor, fog, and cloud nodes into a single system. To this end, NES combines research from sensor network, distributed, and database system communities. This allows NES to transparently optimize and efficiently execute data management workloads across IoT infrastructures. The unified sensor-fog-cloud approach enables scaling the number of sensors in data management and visualization applications.

In our demonstration, we simulate an IoT infrastructure with Raspberry PIs and showcase a visualization application for a public transport system. Our application aims to provide real-time monitoring for public transport systems and suggestions for vehicle rescheduling. Therefore, it detects critical geographical areas, i.e., underserved areas with high demand. Our GUI consists of an interactive map, which visualizes real-time public transport vehicles and potential passengers. During the demonstration, visitors will interact with the map by filtering objects and configuring the clustering algorithm employed for critical area detection.

Furthermore, visitors will explore potential execution strategies for data management tasks on IoT infrastructures. We demonstrate how all participating nodes of a public transport system can be part of a query and how this influences performance and resource utilization. Our application demonstrates both centralized system designs and new designs enabled by NES. Overall, we showcase that in contrast to cloud-based SPEs, NES allows large-scale applications on IoT infrastructures, and thus enables a variety of upcoming IoT application use cases.

The rest of this paper is structured as follows. In Section 2, we discuss IoT application scenarios and challenges related to data management. In Section 3, we provide a brief overview of NES's design and architecture. After that, in Section 4, we present our demonstration scenario and finally conclude in Section 5.

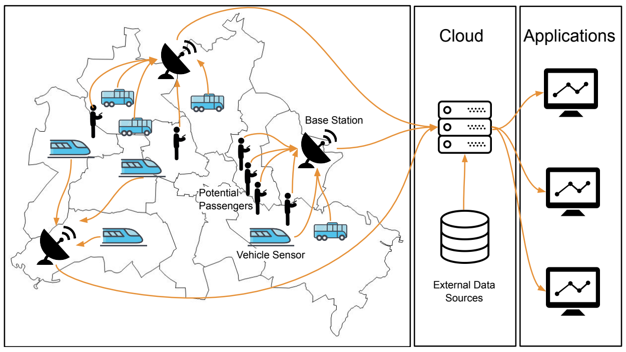

Figure 1: Exemplary IoT Infrastructure.

2 DATA MANAGEMENT IN THE IOT

In the following, we introduce a representative IoT scenario (Section 2.1) and discuss data management challenges (Section 2.2).

2.1 IoT Application Scenarios

In Figure 1, we illustrate a public transport system as a representative large-scale IoT scenario. In our scenario, the cloud hosts applications, i.e., a real-time dashboard that monitors the underlying IoT infrastructure. The infrastructure consists of geographically distributed and constantly moving sensors, base stations, and cloud nodes. In particular, potential passengers with mobile phones and vehicles with attached sensors move within a city and transmit measurements to base stations in regular time intervals. Base stations are geographically distributed nodes that collect and forward sensor streams to the cloud. Cloud nodes receive the data from the base stations and enrich it with external sources, e.g., databases with weather or air pollution data. Finally, applications consume the preprocessed sensor stream, apply additional processing, and visualize the result for users.

Public transport agencies could employ such applications to enable various smart city optimizations. Examples include rescheduling vehicles based on the demand of potential passengers, air pollution reduction by traffic light control mechanisms, and ad-hoc route planning to cope with traffic jams.

2.2 IoT Infrastructure Challenges

Today's IoT applications use data acquisition systems for data ingestion [7, 9, 10] and cloud-based SPEs for data management operations. IoT infrastructures differ significantly from cloud infrastructures, and thus pose several challenges for data management operations. Zeuch et al. [11] point out that cloud-based SPEs rely on assumptions that IoT infrastructures violate. First, fog and cloud paradigms assume different network topologies. In particular, processing nodes in cloud-based SPEs are densely connected, i.e., each node has stable connections with all other nodes. In contrast, the physical IoT topology predefines the network paths from data sources (sensors) to data sinks (cloud). Therefore, every node accesses only the subset of data that is routed through it. For example, in the IoT infrastructure depicted in Figure 1, base stations located in the west of the city are not able to directly access sensor streams that are generated on the east of the city.

Second, both paradigms expect different types of input streams. In an IoT infrastructure, millions of sensors constantly produce data streams. Those streams consist of small records that possibly capture physical phenomena, such as earthquakes, and might produce data at infrequent intervals. In contrast, cloud-based SPEs expect a few large-volume data streams at constant producing intervals. Furthermore, to ingest the sensor streams, cloud-based systems utilize message brokers, such as Apache Kafka.

In sum, IoT applications relying on cloud-based data management paradigms do not exploit intermediate nodes. The assumptions of cloud-based SPEs regarding physical topologies and types of incoming streams do not hold in IoT infrastructures.

3 NEBULASTREAM PLATFORM OVERVIEW

In the following, we present specific aspects of NES. We refer the reader to our previous work [11] for a detailed description of NES. First, in Section 3.1, we outline the limitations of cloud-based SPEs that prevent applications from exploiting IoT infrastructures. After that, we describe NES and its architecture in Section 3.2.

3.1 Limitations of State-of-the-art SPEs

In the following, we discuss two important features that hinder cloud-based SPEs to efficiently support future IoT scenarios.

Exploiting Intermediate Nodes: Applications relying on cloud-based SPEs do not exploit all participating heterogeneous intermediate and sensor nodes, since data management tasks are executed only in the cloud layer. For example, consider a simple aggregation task, e.g., counting the number of vehicles per geographical area. To execute this task, cloud-based systems would have to wait until intermediate nodes propagate data to the cloud. However, in the described IoT infrastructure, intermediate nodes can execute this task at an earlier stage and forward pre-aggregated intermediate results.

Minimizing Network Resources: If a set of running queries requires only a subset of the sensor data, acquisitional data processing avoids redundant sensor reads [7]. Another technique to further reduce network traffic between sensors and cloud is to adapt sensor sampling frequencies based on the query requirements [9]. For example, a vehicle could acquire and send its data only if it is located in a certain area [11]. These techniques are not available in cloud-based SPEs, but allow for scaling IoT data processing by minimizing redundant data traffic.

3.2 Architecture

In the following, we describe NES's architecture, illustrated in Figure 2. We focus only on the components that are related to our application scenario and omit components that are out of the scope of this demonstration, e.g., fault-tolerance mechanisms.

Optimization: NES exposes APIs for common data processing operations, as found in cloud-bases SPEs, extending those with fog-specific abstractions. IoT applications, e.g., our visualization application, submit queries to the underlying data streams, both ad-hoc and long-running. To allow for multi-query optimization, the *Query Manager* maintains a catalog of submitted queries. Query optimization and execution in NES proceeds as follows. First, NES translates user queries to logical query plans. After that, the plan is handed over to the optimizer. The *NES Optimizer* consults the *NES Topology Manager*, which provides information about the infrastructure status and the performance statistics. After optimizing the execution plan, it is handed over to the *NES Deployment Manager*.

Deployment and Execution: NES's execution plan maps segmented sub-plans to participating intermediate, or cloud nodes. Each segment contains processing instructions (tasks), as well as information about I/O operations. The NES Deployment Manager is responsible for transmitting the sub-plans to each node. After receiving a sub-plan, a node initializes the necessary network connections and starts the execution utilizing its task scheduler.

Monitoring: During runtime, the NES Topology Manager monitors the execution, and reacts to changes incrementally, e.g., by transitioning smoothly between execution plans. To this end, the NES Topology Manager collects hardware statistics, such as CPU and main memory utilization, and additional metadata, such as selectivities and data distributions. NES nodes are designed to handle several scenarios autonomously, e.g., transient network failures. Once failed network connections are restored, topology updates are propagated to the Topology Manager.

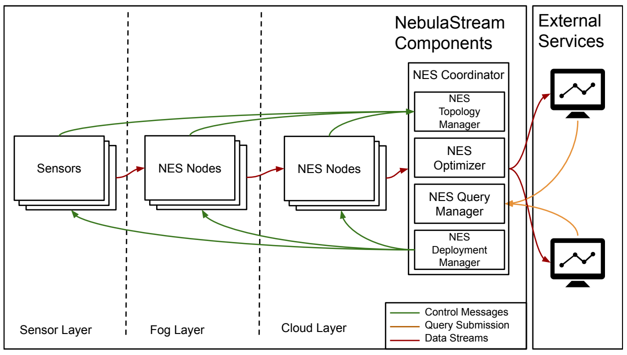

Figure 2: Simplified NES architecture overview.

The holistic view of the underlying infrastructure and the submitted queries allow NES to optimize for specific combinations of queries and topologies. In contrast, cloud-based SPEs handle incoming queries independently and schedule queries with external cluster resource management frameworks. Its characteristics allow NES to overcome limitations of cloud-based SPEs in IoT infrastructures, and to offer scalable data management for the upcoming IoT application scenarios.

4 DEMONSTRATION

In the following, we describe our user interface (Section 4.1), demonstration setup (Section 4.2), and application (Section 4.3).

4.1 User Interface

Visitors interact with our application through a GUI, as shown in Figure 3. Our GUI consists of an interactive map, which includes moving objects that are either potential passengers or public transport vehicles (trains, buses, etc.). Our application aims at detecting crowded geographical areas, that public transport vehicles underserve. The application clusters potential passengers according to their geolocation. When public transport vehicles underserve a cluster of potential passengers, our application notifies the visitor by highlighting the respective clusters on the map. The resulting notifications are useful for public transport agencies, e.g., to schedule vehicles for crowded areas.

Additionally, our GUI allows filtering by moving the visible map area and by selecting vehicle types. The visitor configures the visible objects and the clustering algorithm by changing parameters, e.g., object distance and cluster size, as shown in Figure 3 ①. A main feature is choosing between processing modes ② that represent the solution space for IoT applications. To show the implications of each mode, we provide performance metrics, such as ad-hoc application statistics ③ and resource utilization ④. Our demonstration aims at showcasing the strengths and weaknesses of each solution in a hands-on experience.

4.2 Demo Setup

In the following, we describe the setup of our demonstration.

Hardware: For our demonstration scenario, we assume a topology where each public transport vehicle carries a sensor transmitting information to base stations at regular time intervals. Potential passengers send their geolocation to base stations, e.g., through a mobile application. We use Raspberry PIs as base stations (fog nodes), and a mobile workstation as a cloud node.

Software: Our application consists of a frontend and a backend component. The backend uses NES to offload data management operations. The backend acts as a sink for NES, i.e., it is an intermediator between multiple user frontends and NES. It coordinates query transmission to NES, forwarding results to connected frontends. Our application backend is implemented in Python and utilizes the Flask microframework. The frontend is implemented in Javascript, utilizes websockets for communication, Leaflet for its map, and Grafana for monitoring.

Dataset: We simulated two sensor streams to compose our dataset. First, we simulated vehicle sensor data using real-world *General Transit Feed Specification* datasets [1] (enhanced with vehicle occupancy). Second, we simulated potential passengers using the *Simulation of Urban Mobility* (SUMO) generator [2]. We merge the two resulting datasets, and partition them by geolocation, to resemble geographically distributed base stations. We utilize sensor data from the city of Berlin, however, our application supports all sensor streams following the GTFS schema.

4.3 Application

We highlight two aspects of an IoT data management application scenario. First, we describe our deployment process, during which our application transforms user queries to execution plans and deploys them on the underlying nodes. Second, we demonstrate several execution strategies by deploying different execution plans and revealing their implications on resource utilization.

4.3.1 Query and Deployment. Every time a visitor interacts with the map and its options, our application sends NES a new query with the following parametrized operations.

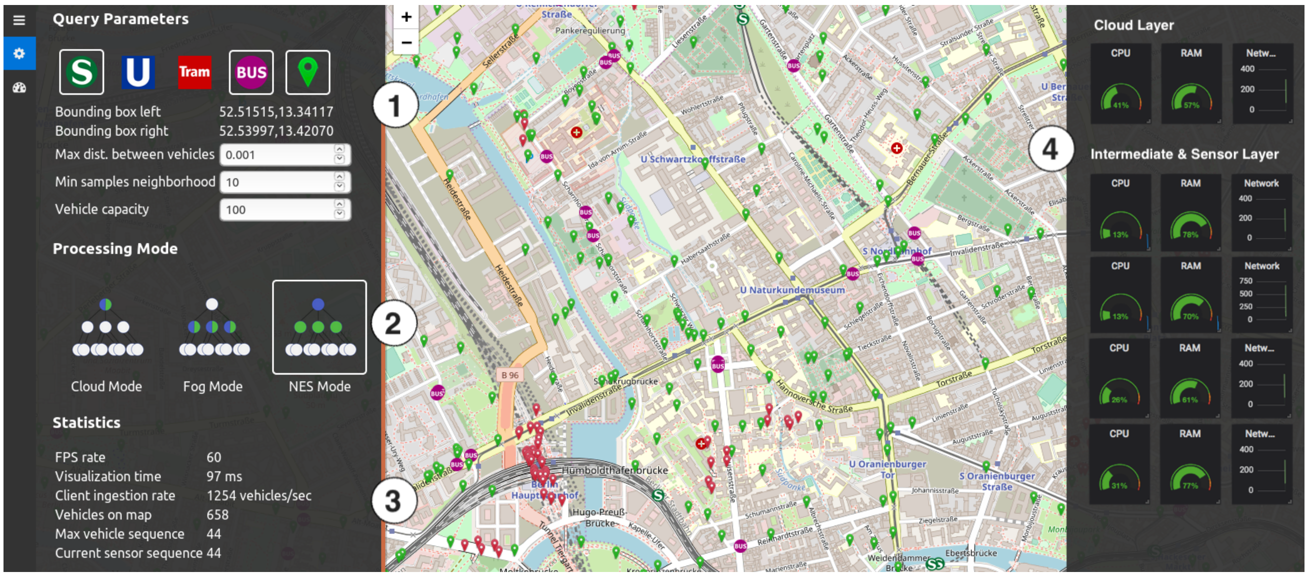
Map Bounding Box: These parameters filter vehicles and potential passengers located within a bounding box. The bounding box is defined by two coordinates and is automatically computed by the map area currently viewed by the visitor.

Vehicles and Passengers: These parameters filter potential passengers and selected vehicle types, e.g., bus, train, or subway.

Clustering: These parameters, e.g., object distance and cluster size, are related to our clustering algorithm (DBSCAN [5]).

Overall, our application composes and deploys queries that filter sensor records, cluster them by geolocation, calculate the average vehicle capacity within each cluster, and yield critical areas depending on user-defined thresholds.

In this application, NES allows us to reduce data as early as possible in the IoT infrastructure. Especially in visualization scenarios, data reduction is a key performance factor, and naturally occurs because users are seldomly interested in all sensor data. To this end, NES provides the option to filter data needed for visualization purposes already in the intermediate (fog) layer. The resulting data reduction is two-fold. First, NES uses on-demand data acquisition techniques to only gather sensor data that is currently required to answer a query. Second, NES uses intermediate nodes to evict unnecessary data close to the sensors. Both data reductions minimize the overall network traffic within the IoT infrastructure, as well as data that has to be sent to applications.



Query Parameters

Bounding box left 52.51515,13.34117
Bounding box right 52.53997,13.42070
Max dist. between vehicles 0.001
Min samples neighborhood 10
Vehicle capacity 100

Processing Mode

Cloud Mode | Fog Mode | NES Mode

Statistics

FPS rate 60
Visualization time 97 ms
Client ingestion rate 1254 vehicles/sec
Vehicles on map 658
Max vehicle sequence 44
Current sensor sequence 44

Figure 3: Demo GUI with potential passengers, buses, and trains. The application clusters potential passengers (green) by area density, and marks clusters red for insufficiently covered areas. The visitor may configure the query parameters (1), the processing modes (2), and observe query information (3) and runtime statistics about resource utilization (4).

4.3.2 Query Execution. In Section 3, we introduced the NES Optimizer, which produces, and evaluates potential execution plans. Each execution plan contains a mapping between NES operators and nodes in the IoT infrastructure. The optimizer would come up with three execution plans that resemble cloud-based, fog-based, and unified approaches, which we refer to as processing modes. Note that in our demonstration, we use NES to reproduce all processing modes.

The graphs in Figure 3 (2) illustrate the processing modes. Vertices represent sensor, fog and cloud nodes, while edges define the network connections between them. We color filter operations green, and clustering operations blue. In our demonstration, visitors can choose between the following three processing modes.

Cloud Mode: NES places all operations on the cloud, and utilizes the remaining nodes only for data forwarding. Performance metrics will reveal that the main workload gathers in the cloud layer, while resources of intermediate fog nodes remain unused.

Fog Mode: NES places all operations on the intermediate layer. Filtering on the fog reduces network traffic. CPU, and RAM utilization on the fog nodes increases significantly.

NES Mode: NES places filter operations on fog nodes and clustering operations on the cloud. Performance metrics show that network traffic, CPU and RAM utilization remain at moderate levels, since operations are evenly distributed.

In sum, our demonstration showcases how future data management systems allow exploiting all resources of an IoT infrastructure, instead of relying solely on the cloud. Our public transport monitoring system and its underlying topology resemble common IoT application scenarios.

5 CONCLUSION

In this paper, we highlighted data processing challenges in the IoT domain, and described a representative IoT scenario, a public transport system. Our application, a public transport monitoring system, visualizes vehicles and potential passengers on an interactive map, and detects underserved areas. Our application translates user actions on its GUI to NES queries. We offload data management tasks on the IoT infrastructure in different ways, using potential NES execution plans. The visitor can explore these execution plans and observe their implications on resource utilization. Our demonstration shows that existing systems do not address scaling data management on IoT infrastructures.

ABSTRACT

The processing of geo-distributed data streams is a key challenge for many Internet of Things (IoT) applications. Cloud-based SPEs process data centrally and thus require all data to be present in the cloud before processing. However, this centralized approach becomes a bottleneck for processing data from millions of geo-distributed sensors on a large scale IoT infrastructure. A new line of research extends the centralized cloud with decentralized fog devices to mitigate this bottleneck. One major challenge for an SPE in this unified fog-cloud environment is to fulfill user requirements by placing operators on fog or cloud nodes.

In this demonstration, we introduce *Governor*, an operator placement approach for a unified fog-cloud environment. Our approach consists of the *Governor placement process* and *Governor policies* (GPs). The Governor placement process utilizes heuristic-based GPs to optimize operator placement for a user query. Using GPs, administrators can control the operator placement process to fulfill specific Service-Level-Agreement (SLA). We implement Governor in the NebulaStream Platform (NES), a data and application management system for the IoT. We showcase the impact of GPs on operator placement for different example queries. Our demonstration invites participants to simulate the operator placement of queries and discover their characteristics. This demonstration represents a first step towards an efficient operator placement approach for upcoming IoT infrastructures with millions of sensors and thousands of queries.

1 INTRODUCTION

Over the last decade, the adoption of IoT devices has increased significantly [7]. Processing IoT data in real-time enables a wide range of new opportunities for businesses (e.g., smart homes, connected cars, health-care) [13]. Many IoT applications today are implemented using a cloud-based infrastructure. To perform the data processing, a continuous transfer of geo-distributed IoT data to a centralized data-center is required. Data processing frameworks such as Flink [2] and Spark [12] are designed for cloud-based environments and support efficient data analytics and virtually unlimited scaling. However, cloud-based processing of geo-distributed IoT data presents challenges for real-time and latency-sensitive applications. These challenges include high data transmission costs, delayed data processing, and high demand for cloud-resources [13].

Fog computing addresses these shortcomings by processing data closer to the source devices [1]. In particular, fog computing leverages intermediate compute nodes to perform data processing and thus minimizes data transfer between source IoT devices and cloud servers. However, in contrast to the robust and elastic cloud resources, the fog consists of limited, unreliable, and low-end heterogeneous nodes. On the one hand, the fog can apply in-network processing to reduce large volumes of data. On the other hand, the fog has to cope with unreliable nodes and intermittent failures [11, 13].

The NebulaStream Platform provides data analytics capabilities in a unified fog-cloud environment [13]. The proximity of computing resources to IoT devices in the fog, combined with nearly unlimited computing resources in the cloud, presents novel opportunities for IoT data processing and holistic optimizations. One major challenge in such an environment is the placement of query operators on compute nodes with regards to the unique infrastructure characteristics and specific SLA requirements. Recent work on operator placement in the cloud focuses mainly on network and compute resource efficiency but does not take the volatility and heterogeneity of the fog infrastructure into account [5, 8, 10]. In contrast, approaches for unified fog-cloud environments consider volatility and heterogeneity but only optimize for a specific goal, e.g., network efficiency or fault-tolerance [3, 4, 6]. Furthermore, current approaches do not allow administrators to specify SLA objectives (e.g., high-throughput, low resource consumption) for operator placement.

In this demonstration, we introduce *Governor*, a new fog-cloud operator placement approach that allows specifying custom SLA objectives. Our approach consists of a set of heuristic-based rules called *Governor policies* and a two-phase *Governor placement process*. Using GPs, we enable administrators to tune the Governor placement process for specific SLAs. The two phases of the Governor placement process are the following. First, the *path selection* phase identifies a set of paths between sensors, intermediate compute nodes, and the cloud. Second, the *operator assignment* phase assigns operators to the compute nodes residing on the identified paths. In this demonstration, we showcase our placement approach and the impact of different GPs using five example scenarios. Attendees of our demonstration can compare operator placements of custom queries for different GPs. Overall, our approach allows administrators to guide operator placement using GPs and finds effective operator mappings for large query plans over millions of sensors. In summary, our contributions are as follows:

(1) We introduce Governor for performing operator placement in a unified fog-cloud environment.
(2) We present five Governor Policies for example scenarios.
(3) We present a user interface that allows attendees to study the impact of different GPs on operator placement.

The rest of this paper is structured as follows. In Section 2, we introduce our Governor approach. In Section 3, we present our demonstration scenario and describe the overall system design. We discuss related work in Section 4 and conclude in Section 5.

2 GOVERNOR

Governor consists of Governor Policies and the Governor placement process. We introduce GPs in Section 2.1 and the Governor placement process in Section 2.2. After that, we showcase the

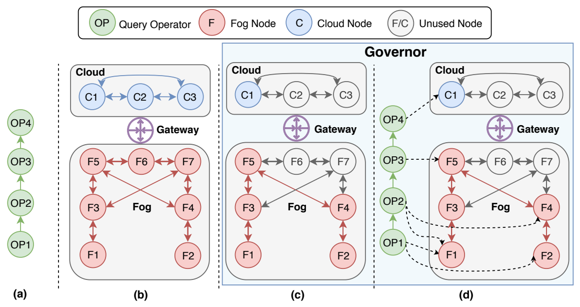

Figure 1: Governor placement process.

application of the Governor approach using example scenarios (see Section 2.3).

2.1 Governor Polices

Governor Policies are a fixed set of heuristic-based rules that guide the operator placement of a query. For example, to place a query with a SLA-objective high fault-tolerance SLA-objective, a GP selects all available network paths between source and sink nodes, and places replicated operators on different nodes along the selected paths. In case of an operator failure, another replica operator will take over the failed operator's workload, thereby achieving the fault-tolerance objective. Using GPs, the operator placement process will optimize the query execution for a specific SLA-objective. An administrator prepares the GP by selecting rules from a predefined catalog, which is maintained and updated by a domain expert. The rules are classified into two categories: *path selection* and *operator assignment*. The path selection rules guide the selection of a subset of all available paths. In contrast, the operator assignment rules guide the placement of operators on nodes on the selected paths. In general, a GP contains at least one rule from each category. However, an administrator can define several GPs, each aiming to optimize query placement for a unique SLA-objective using its distinct set of rules. Additionally, while different GPs can share individual rules, the combination of rules within a GP is unique.

2.2 Governor Placement Process

In this section, we describe how the Governor placement process performs the operator assignments while taking GPs into account. Figure 1 shows the steps necessary to place the operators of a query on a physical infrastructure. First, NES transforms a user query into a directed acyclic graph (DAG) that is composed of query operators and directed links among them, as shown in Figure 1(a). The query DAG Q is represented by $Q = \{O, L\}$ where O and L represent operators and directed links respectively. In the background, NES maintains an infrastructure graph containing compute nodes that are interconnected by network links (see Figure 1(b)). The infrastructure graph G is represented as $G = \{V, E\}$ where V and E represent vertices and edges respectively. Second, NES provides the query DAG, the infrastructure graph, and a GP to Governor for operator placement. Governor uses its placement process to assign the DAG operators on the infrastructure nodes while following the rules from GP.

The operator placement process consists of two phases: the *path selection phase* and the *operator assignment phase*. In the path selection phase, shown in Figure 1(c), Governor identifies the path between sources (IoT device) and the sink (cloud servers) node using the heuristics defined in the GP. The number of paths that are selected in the path selection phase ranges from all paths to just a specific path, and thus reduces the search space for the operator assignment phase. The path selection phase is crucial for large-scale IoT infrastructures containing thousands of heterogeneous nodes and millions of data sources. We make use of depth first search (DFS) algorithm for finding paths. The maximum number of source nodes in G is given by total number of vertices $|V|$. The worst-case runtime complexity for identifying paths between $|V|$ sources and sink node is represented by $O(|V|^3)$.

In the operator assignment phase, shown in Figure 1(d), Governor performs the operator placement on nodes along the selected paths. During the operator assignment phase, Governor distinguishes between *pinned* and *unpinned* operators. Pinned operators reside on a specific location, e.g., source operators on IoT devices and sink operators on cloud servers. In contrast, unpinned operators can be placed on any node along the selected paths (if resource constraints permit this). Common strategies would place non-blocking operators (e.g., filter, source, sink) close to the IoT devices and blocking operators with state (e.g., window, aggregation, join) close to the cloud servers. For a query DAG Q with $|O|$ operators and $|P|$ selected paths with average $|N|$ nodes, the worst-case runtime complexity of operator assignment phase is given by $O(|O| * |N| * |P|)$.

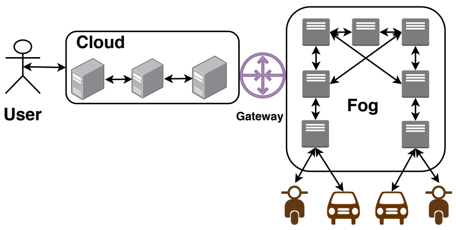

Figure 2: Infrastructure for a ride sharing services.

2.3 Governor in Action

In Figure 2, we show a representative IoT infrastructure for ride-sharing services such as ShareNow[1], WeShare[2], or Coup[3]. Vehicles with on-board computing units communicate with fog computing devices and transmit the operational information (e.g., location, user, or time information) to the fog infrastructure. While data is flowing through the fog into the cloud, fog nodes can apply processing. Users interact with the cloud-based system using a mobile application for locating, renting, or accessing various other services. Using this infrastructure, we present five example application scenarios:

(1) **Fast-response:** Realtime tracking of vehicle fleet.
(2) **Fail-safety:** Billing at the end of a trip.
(3) **Bursty-data:** Monitor vehicle statistics during usage.
(4) **Save-resource:** Health checks on IoT infrastructure.
(5) **Save-energy:** Save energy on battery-operated vehicles.

The presented scenarios have different SLA requirements, which guide their respective placement of operators. In Table 1, we present five example GPs for these scenarios. The *Low-Latency*, *Fault-Tolerance*, and *High-Throughput* GPs are focused primarily on the performance of queries. In contrast, the *Minimum Resource Consumption* and *Minimum Energy Consumption* GPs are focused on the performance of the infrastructure nodes. In the following, we use GPs from Table 1 and briefly discuss the placement process for the five application scenarios.

Fast-response requires fast event processing and delivery by performing early data computation and using low latency network links. The *Low-Latency* GP from Table 1 satisfies this SLA requirement. In the path selection phase, Governor selects distinct paths with low link latencies between source and sink

[1] www.sharenow.com [2] www.weshare.com [3] www.coup.com

	Low-Latency	**Fault-Tolerance**	**High-Throughput**	**Minimum Resource Consumption**	**Minimum Energy Consumption**
Path Selection Phase	• Distinct paths with low link latency	• All paths between sources and sink	• Distinct paths with high bandwidth capacity	• Common path between sources and sink	• Common path between sources and sink
Operator Assignment Phase	• Non-blocking operators closer to source • Replicate operators when possible	• Use shared nodes among selected paths • Replicate operators when possible	• Non-blocking operators closer to source • Blocking operators closer to sink	• Share intermediate operators among different sources • Avoid operator replication	• Non-blocking operators closer to source • Share intermediate operators among different sources • Avoid operator replication

Table 1: Five example Governor policies.

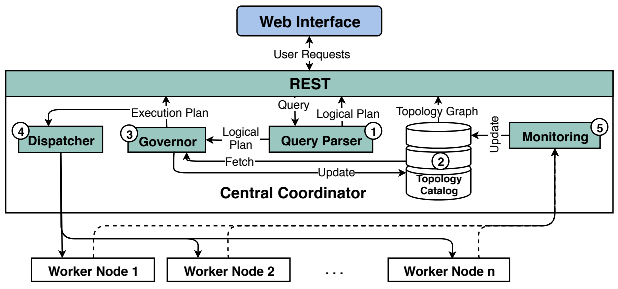

Figure 3: Demonstration system architecture.

nodes. In the operator assignment phase, Governor places all non-blocking operators close to the source operators and replicates the operators wherever possible to achieve high data parallelism [9].

Fail-safety requires events to be delivered irrespective of intermittent network or node failures by using alternative nodes or links for processing and data transfer. The *Fault-Tolerance* GP from Table 1 satisfies this SLA. In the path selection phase, Governor selects all possible paths between the sources and the sink nodes. In the operator assignment phase, Governor places operators on the nodes shared across multiple paths such that in the event of a path failure, another network path can be used for data delivery.

Bursty-data requires the query to handle a sudden burst of events by transmitting data using a high bandwidth link. The *High-Throughput* GP from Table 1 satisfies this SLA. In the path selection phase, Governor selects distinct paths with high bandwidth capacity between source and sink nodes. In the operator assignment phase, Governor places all non-blocking operators close to the source operator and all blocking operators close to the sink operator.

Save-resource requires the compute node to save resources by sharing query operators and preventing replications. The *Minimum Resource Consumption* GP from Table 1 satisfies this SLA. In the path selection phase, Governor selects a common path between source and sink nodes. In the operator assignment phase, Governor ensures a high degree of operator sharing among multiple sources contributing to the query.

Save-energy requires the compute nodes to save power either by reusing the existing query operators or by reducing the amount of data transmitted over the network. The *Minimum Energy Consumption* GP from Table 1 satisfies this SLA. Like for **Save-resource**, Governor selects a common path between source and sink nodes. However, in the operator assignment phase, Governor tries to place non-blocking operators closer to the source to reduce downstream data traffic and thus saving energy for transmission.

Governor uses a greedy approach for the operator placement, which can return a solution in a reasonable amount of time at the cost of sub-optimal placement decisions. In the future work, we will examine the response time-optimality trade-off in detail. Although Governor uses one query plan as an input, this query plan can be the outcome of a multi-query optimization process and thus may contain operators from multiple queries.

3 DEMONSTRATION

In Section 3.1, we introduce the architecture of our demonstration. After that, we present the web interface and describe the functions available for the attendees to explore in Section 3.2.

3.1 Demonstration System Architecture

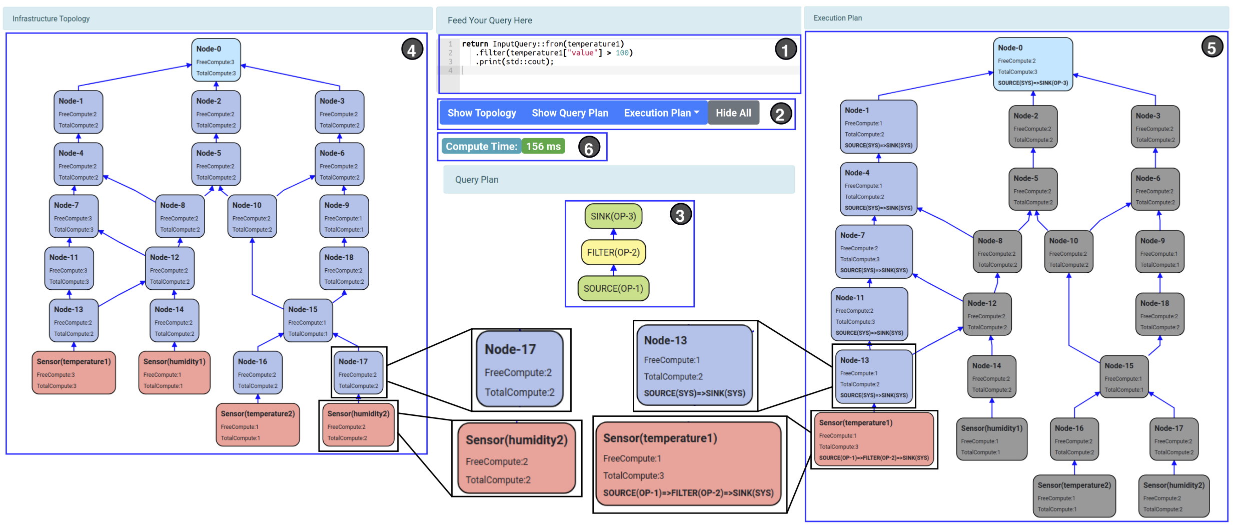
In Figure 3, we present the interaction among the web interface, the central coordinator, and the worker nodes. The web interface submits queries and retrieves information from NES over a REST interface, e.g., the DAG for currently deployed query or the infrastructure topology. The central coordinator node manages both the query placement and the deployment process. The worker nodes manage the execution of operators from different queries. We refer the reader to relevant literature for a detailed design overview of NES [13]. In this section, we will only cover aspects that affect the operator placement process of NES.

Inside the coordinator node, the queries are first validated and parsed into DAGs using the *Query Parser* ①. After that, Governor receives the logical query plan and fetches the information from the *Topology Catalog* ②. The topology catalog maintains the latest infrastructure graph, including information on resource availability and the set of deployed query operators on individual infrastructure nodes. Based on this information, *Governor* ③ creates the execution plan, which contains the operator placement information. Finally, the *Dispatcher* ④ receives the overall execution plan and forwards it to the respective worker nodes.

In an asynchronous second feedback loop, Governor updates the topology catalog with the operator placement information. Furthermore, worker nodes send regular updates to the *Monitoring* ⑤ system, which in turn updates the topology catalog.

3.2 Web Interface

Figure 4 shows the web interface that attendees can use to explore operator placement with Governor. Attendees have to write their queries into the text panel ① to explore different functionalities of the web interface. The central coordinator system from Figure 3 is responsible for parsing, validating, and returning the DAG for the input query. The button-panel ② on the web interface presents various options for interacting with the components of the demonstration system. First, attendees can click on the *Show Topology* button to fetch the infrastructure graph representing the latest state of compute nodes and network connections among them. The display panel ④ shows the returned infrastructure graph. Second, the button *Show Query Plan* triggers the query parser component, which returns a DAG of interconnected operators for the submitted user query in the text panel ①. The display panel ③ shows the query DAG. Third, the drop-down button *Execution Plan* presents a set of GPs for triggering Governor. Attendees can choose between any of the available GPs shown



```
return InputQuery::from(temperature1)
    .filter(temperature1["value"] > 100)
    .print(std::cout);
```

Figure 4: Demonstration system web interface.

in Table 1, i.e., Low-Latency, Fault-Tolerance, High-Throughput, Low Energy Consumption, and Low Resource Consumption. The display panel ⑤ will show the operator placement plan returned by Governor. The operator placement plan contains pinned, unpinned, as well as system-generated operators (e.g., forward operators) and their corresponding mappings on infrastructure nodes. Additionally, the time taken for the plan computation using the selected GP is shown in the UI ⑥.

Overall, attendees of our demonstration can explore the operator placement in a unified fog-cloud infrastructure. We will point out different options and their impact on particular characteristics. Using this demonstration, we present a first step towards an operator placement designed for upcoming IoT infrastructures with millions of sensors and thousands of queries.

4 RELATED WORK

In this section, we categorize related work from different research areas. One line of research covers operator placement approaches for a centralized computing infrastructure. Huang et al. offer a heuristic-based operator placement approach for optimizing with latency and throughput [8]. Kafil et al. consider heterogeneity within a distributed environment to find one optimum compute node to place all operators together [10]. Chatzistergiou et al. optimize the operator placement for inter-node network bottlenecks by reducing the number of nodes required to running a query [5]. In contrast, Governor allows a flexible and controlled operator placement strategy by enabling administrators to specify different optimization objectives within the same infrastructure.

Another line of research examines placement approaches for a unified fog-cloud environment. The approach presented by Veith et al. focuses mainly on minimizing total data processing latency [6]. However, this approach does not consider the node and link volatility within the fog as a factor that can significantly impact query execution. Cardellini et al. present a multi-objective operator placement approach [4]. However, their approach is not optimized for computing operator placements for a large scale IoT infrastructure. In contrast, Governor considers various characteristics of the fog-cloud infrastructure, including the high volatility that is commonly present in a fog infrastructure. Furthermore, Governor's two-phase approach using heuristics reduces the computation time for operator placement.

Overall, none of the previous approaches support defining flexible operator placement objectives. In contrast, Governor allows the administrator to specify different optimization goals using GPs for each query submission.

5 CONCLUSION

In this demonstration, we present Governor, a first step towards operator placement on IoT infrastructures with millions of sensors and thousands of queries. We demonstrate Governor's ability to accept custom Governor Policies with different optimization objectives for operator placement. In addition, we present five example policies and showcase their placement for five example application scenarios. In our demonstration, we will present the challenges as well as early solutions for operator placement in the future IoT era.

ABSTRACT

JSON established itself as a popular data format for representing data whose structure is irregular or unknown a priori. JSON collections are usually massive and schema-less. Inferring a schema describing the structure of these collections is crucial for formulating meaningful queries and for adopting schema-based optimizations.

In a recent work, we proposed a Map/Reduce schema inference approach that either infers a compact representation of the input collection or a precise description of every possible shape in the data. Since no level of precision is ideal, it is more appealing to give the analyst the freedom of choosing between different levels of precisions in an interactive fashion. In this paper we describe a schema inference system offering this important functionality.

1 INTRODUCTION

Borrowing flexibility from semistructured data models and simplicity from nested relational ones, JSON affirmed as a convenient and widely adopted data format for exchanging data between applications as well as for exporting data through Web API and/or public repositories. JSON datasets are usually retrieved from remote, uncontrolled sources, with partial, incomplete, or no schema information about the data. In these contexts, however, having a precise description of the structure of the data is of paramount importance, in order to design effective and efficient data processing pipelines. Schema inference, therefore, becomes a crucial operation enabling the formulation of meaningful queries and the adoption of well-known schema-based optimization techniques.

Several approaches and tools exist for inferring structural information from JSON data collections [13–15]. As pointed out in [10, 11], the common aspect of all these approaches is the extraction of some structural description with a precision that is fixed a priori, by the approach itself. While this methodology has the advantage of simplicity, it is in practice not satisfactory, since a JSON dataset can be rather (oftentimes highly) irregular in structure, and for this reason it can be typically described at different precision levels by a schema, while there exists no "best" precision level that can be fixed a priori. In general, one is interested in a description that is compact, easy to read even if it hides lots of details, typically in the first exploration steps, while in subsequent steps he/she is likely to be interested in a more precise, and therefore less succinct, schema description, where more details about the alternative shapes that can be found in the data are provided.

We believe that leaving the user the ability of tuning the level of precision of the inferred schema, by trying different possibilities and changing the level of details at different times, is an important feature, that existing techniques do not provide. With such a motivation in mind, in two recent works [9, 12], we devised, respectively, i) a Map/Reduce-based schema inference technique for massive JSON data that enables the user to choose, a priori, the level of precision of the inferred schema, and ii) a formal system which provides the user with mechanisms to interactively refine/expand the inferred schema, even locally, without the need of re-processing the data multiple times.

The goal of this demonstration is to showcase results and mechanisms provided by these two works, by means of an implementation of the parametric schema inference system [9] which is based on Spark and which interacts with a Web interface that the user can exploit to choose or submit a dataset of interest, and to play with the interactive schema inference process [12].

The user interacts with the system by choosing an existing, already analyzed, dataset, or by submitting a new one. The system initially returns to the user a succinct, but not very precise, schema, and the user then can explore it in order to decide where to get more precision, at several nesting levels: indeed, the user can choose to get a more detailed schema description at a given nesting level, while leaving the inner levels described in a more succinct fashion, hence at a lower degree of precision.

In the remainder of this article, Sections 2 and 3 introduce the parametric [9] and the interactive schema [12] inference techniques, while Section 4 details the architecture supporting our system and the demonstration scenario.

2 PARAMETRIC SCHEMA INFERENCE

The schema inference technique proposed in [9] is based on a Map/Reduce algorithm to ensure scalability. During the *map* phase, an input collection of JSON objects is processed by inferring a schema for each object in the collection. The *reduce* phase produces the final schema by invoking a commutative and associative function whose role is to *merge* the object schemas that are *equivalent*. Deciding whether two schemas are equivalent is a crucial aspect of our approach, as this allows one to choose between different precision levels. We rely on two main equivalence relations (kind equivalence and label equivalence), which we identified to be useful in practice, but our system, which is parametric, allows for using other equivalences defined by the user (see [9] for details).

When using the *kind* equivalence (K), every record type is equivalent to any other record type, and every array type is equivalent to any array type. Hence, this equivalence leads to merging all record types into a single one while indicating for each field whether it is optional or mandatory.

To illustrate, consider the following heterogeneous collection containing three JSON records and one array.

o_1 $\{a : 1, b : 2, d : \{e : 3, f : 4\}\}$
o_2 $\{a : 1, c : 2, d : \{g : 3, h : 4\}\}$
o_3 $\{a : 1, c : 2, d : \{e : 3, f : 4\}\}$
o_4 $[123, \text{"}abc\text{"}, \{a : 10, b : 20\}]$

The *map* phase yields for each value a corresponding schema. Essentially, atomic values are mapped to their corresponding atomic types (numbers to Num, etc), while complex constructs are processed recursively. The potentially heterogeneous content of arrays is concisely represented using the union (+) operator.

$o_1 \longrightarrow s_1 = \{a : \mathsf{Num}, b : \mathsf{Num}, d : \{e : \mathsf{Num}, f : \mathsf{Num}\}\}$
$o_2 \longrightarrow s_2 = \{a : \mathsf{Num}, c : \mathsf{Num}, d : \{g : \mathsf{Num}, h : \mathsf{Num}\}\}$
$o_3 \longrightarrow s_3 = \{a : \mathsf{Num}, c : \mathsf{Num}, d : \{e : \mathsf{Num}, f : \mathsf{Num}\}\}$
$o_4 \longrightarrow s_4 = [\mathsf{Num} + \mathsf{Str} + \{a : \mathsf{Num}, b : \mathsf{Num}\}]$

During the *reduce* phase, equivalent types are merged based on the chosen equivalence relation. The K equivalence merges all record types and yields a union of a record and array type, as follows:

$$\begin{aligned} S_3 = \{\ & a : \mathsf{Num}, b : \mathsf{Num?}, c : \mathsf{Num?}, \\ & d : \{e : \mathsf{Num?}, f : \mathsf{Num?}, g : \mathsf{Num?}, h : \mathsf{Num?}\} \\ \}\ & \\ +\ [\ & \mathsf{Num} + \mathsf{Str} + \{a : \mathsf{Num}, b : \mathsf{Num}\}] \end{aligned}$$

The record type reports all fields appearing in the merged record types from the *map* phase, while indicating whether they are mandatory or optional (this latter fact being indicated by decorating the fields with ?). For instance, a is a mandatory field of type Num, while b, c, and d are optional fields of type Num; furthermore, d values are objects whose fields are all optional.

Notation 2.1 *In the following, when a union schema $s_1 + \ldots + s_n$ is inferred by means of an equivalence $\mathcal{E}$, we will use the prefix notation $+_{\mathcal{E}}(s_1, \ldots, s_n)$, so that the inferred schema indicates which equivalence has been used in order to decide what schemas to merge in the inference process. For readability, we omit the $+_{\mathcal{E}}$ prefix for atomic types when they appear as a singleton.*

So for instance, we note S_3 as

$$\begin{aligned} S_3 = +_K(\ \{\ & a : \mathsf{Num}, b : \mathsf{Num?}, c : \mathsf{Num?}, \\ & d : +_K(\{e : \mathsf{Num?}, f : \mathsf{Num?}, g : \mathsf{Num?}, h : \mathsf{Num?}\}) \\ \}, & \\ [\ \ & +_K(\mathsf{Num},\ \mathsf{Str},\ \{a : \mathsf{Num}, b : \mathsf{Num}\})] \\ ) \end{aligned}$$

Concerning precision, it is worth observing that the above schema hides important correlation information like the fact that b and c never co-occur or the fact that fields e and f always occur together.

To derive a more precise schema, where records having different labels are kept separated, we use the *label* equivalence (L), according to which record types are equivalent only if they share the same top-level field labels. So, by means of the L equivalence only s_2 and s_3 are merged, thus obtaining:

$$\begin{aligned} S_4 = +_L(\ & \{\ a : \mathsf{Num},\ b : \mathsf{Num},\ d : \{e : \mathsf{Num}, f : \mathsf{Num}\}\}, \\ & \{\ a : \mathsf{Num}, c : \mathsf{Num}, \\ & \quad d : +_L(\{e : \mathsf{Num}, f : \mathsf{Num}\},\ \{g : \mathsf{Num}, h : \mathsf{Num}\}\ )\ \}, \\ & [\ +_L(\mathsf{Num}, \mathsf{Str}, \{a : \mathsf{Num}, b : \mathsf{Num}\}\ )] \\ ) \end{aligned}$$

The resulting inferred schema S_4 gives now a very detailed description of the records in the data by sacrificing conciseness.

However, in general, schemas are much larger than those in the above example, and this could be a complication for an analyst who wants a precise description of a specific part of the dataset/schema (for instance one specific record type) without being overwhelmed by a too large schema describing all the rest. In order to overcome this limitation, we show in the next section how inferred schemas can be interactively manipulated by the analyst, by preserving soundness (schemas obtained in the interaction all describe the dataset at hand).

3 INTERACTIVE SCHEMA INFERENCE

The interactive schema inference is very useful when it allows for describing the same data with different levels of precision-succinctness, so that parts of greater interest to the user are described with the finest precision, while parts with lower interest are described in a succinct way. The interactive schema inference proposed in [12] goes into this direction, and to show its effectiveness we illustrate below a possible interaction that the user can perform on the schema inferred from a real-life dataset, crawled from the official NYTimes API [5] and consisting in metadata about articles of the newspaper. This dataset is interesting for our problem since it features many irregularities at several levels, and discovering these irregularities, using a traditional type inference mechanism, may simply become unpractical.

A simplified version of the K type inferred from this dataset is depicted in Figure 1. This schema focuses on the *byline* part which describes the authors of the articles. By examining this schema, the user realizes that almost all the fields are optional and hence, she/he may want to dig deeper to investigate for a potential correlation between the different fields.

$$\begin{aligned} & +_K(\{\ \ docs : \\ & \quad +_K(\{\ \ byline : \\ & \quad\quad +_K(\{\ \ contributor : \mathsf{Str?} \\ & \quad\quad\quad organization : \mathsf{Str?} \\ & \quad\quad\quad original : \mathsf{Str?} \\ & \quad\quad\quad person : [+_K(\{fn : \mathsf{Str?}, \\ & \quad\quad\quad\quad ln : \mathsf{Str?}, \\ & \quad\quad\quad\quad mn : \mathsf{Str?}, \\ & \quad\quad\quad\quad org : \mathsf{Str?}\})\ \ ] \\ & \quad\quad\}) \\ & \quad\}) \\ & \}) \end{aligned}$$

Figure 1: The NYTimes K type.

The type resulting from refining the content of *byline* is depicted in Figure 2 and shows four possible situations which correspond to different combinations of the *contributor*, *organization*, and *original* fields, but, more interestingly, it reveals that the occurrence of *organization* implies that *person* has an empty array, while its absence coincides with the case where *person* contains an array with a record type. This observation can be explained by the fact that, when an article is written by an organization, the *person* field is not relevant and hence it contains an empty array and, conversely, when it is written by persons, the *organization* field is irrelevant and, hence, it just does not appear in the *byline* field.

Now that the user has gained some knowledge about the structure of the *byline* field, she/he may want to explore the *person*

4 DEMONSTRATION OVERVIEW

The objective of this demonstration is to help the attendees understand the features and the goals of our schema inference system. To this aim, attendees will be able to:

(i) infer schemas for real-life JSON datasets according to K and L;

(ii) explore the inferred schemas and interactively fine-tune their precision;

(iii) get a concrete representation of the inferred schemas in JSON Schema.

We first describe the architecture of our system as well as the setup of the demo, and then illustrate the demonstration scenarios we propose.

4.1 System Architecture and Setup Details

Our system is based on a web application implemented following the client-server architecture depicted in Figure 4. The web client is used for loading the JSON collection and for performing the interactive schema inference, while the web server is dedicated to storing the collection and to inferring the initial schema. The storage is supported by HDFS while the computation is ensured by Spark, as presented in [9]. The web client and the remote inference engine communicate through a REST API implemented in Python 3 using the Flask [2] library. The API requests from the client are processed by an orchestrator that coordinates between the storage and the inference modules in the server side. This coordination is ensured by API calls using two open source libraries: webHDFS [8] for communicating with the HDFS storage system, and livy [4] for submitting jobs to the Spark engine.

Upon receiving the input collection in JSONLines format [3], through the client, the server will store the collection on the HDFS then infers the L schema, using the Spark engine. The L schema is then sent to the client and used for inferring the K schema. The *schema visualizer* displays the K schema and translates the user actions into corresponding schema operations that are processed by the *schema manager*. These two modules coordinate during all the interaction session to fulfill the user requests.

The web client is implemented in Typescript [7] using the Angular 6 platform [1], which offers many advantages like modularity and the clean separation between the content of a web page and the program modifying its content; the schema inference module of the server is implemented in Scala and is fully described in [9].

A lightweight system showcasing the core features of the full-system is available online at [6]. Differently from the full-system that will be demonstrated at the conference, the lightweight system performs schema inference on the client side and hence, it is limited to processing small size documents.

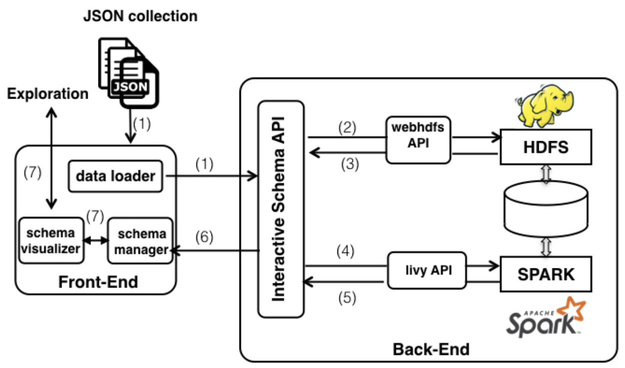

Figure 4: System architecture.

4.2 Demonstration Scenario

Our demonstration enables attendees to infer schemas for preloaded JSON datasets, to provide their own datasets, to explore the extracted schemas, and to fine-tune their precision, as well as to convert them in more popular schema languages like JSON Schema. The datasets we plan to use in our demo are described below.

The GitHub dataset corresponds to metadata generated upon pull requests issued by users willing to commit a new version of code. It takes 14GB of storage and contains 1 million JSON objects sharing the same top-level schema and only varying in their lower-level schema. All objects of this dataset consist exclusively of records nested up to four levels of nesting. Arrays are not used at all.

The Twitter dataset corresponds to metadata that are attached to the tweets shared by Twitter users. It takes 23 GB of storage and contains nearly 10 million records corresponding, in most cases, to tweet entities. A tiny fraction of these records corresponds to a specific API call meant to delete tweets using their ids.

Finally, the NYTimes dataset, which was partly described in Section 3, contains approximately 1.2 million records and reaches the size of 22GB. Its records feature both nested records and arrays, and are nested up to 7 levels. Most of the fields in records are associated to text data which explains the large size of this dataset compared to the previous ones.

Schema Inference. The attendee will start the demo by connecting the web interface to the remote engine, and by selecting a pre-loaded dataset for schema inference; alternatively, the attendee will request the system to load an external dataset by providing a URI. Once selected a dataset, the attendee will choose an inference algorithm to be used by the remote engine. While the focus of this demonstration is on the interactive refinement of K-based schemas, the attendee will also have the opportunity to directly infer a schema according to the L-based approach as well as to get basic statistics about the data (average object size, AST height, etc). Once the inference system has completed the schema extraction process, it will upload the inferred schema to the web interface.

Schema Exploration. After the inference of the K schema, the attendee will likely start to explore this schema through the web interface which allows the user to change the precision level of the schema without any further intervention of the remote inference engine.

Schema Translation. After having explored the inferred schema and (possibly) fine-tuned its precision level, the attendee will be able to translate the schema in a JSON Schema representation; by relying on this feature, the attendee will be able to exploit the schema in any system or application supporting this language, without the need to manually rephrase the schema.

5 RELATED WORK

The problem of inferring structural information from JSON received some attention as reviewed in our recent paper [9], where we outlined the improvements of our approach over state-of-the-art approaches for JSON schema inference, while the topic of interactive JSON schema inference was only recently addressed [12].

In the context of XML, the only work about interactive inference we are aware of relies on user intervention for recognizing regular expressions that are similar enough to be merged and for deriving sophisticated XML schemas expressing complex constructs like inheritance and derivation [16].

ABSTRACT

In this demo, we explain the working of ReProVide, a framework that integrates an on-the-fly reconfigurable FPGA-based SoC architecture with a DBMS for accelerated query processing. For this, a capability-aware optimization that can optimize and partition the queries is demonstrated. This optimization for the hardware is based on its capabilities. Our hardware can also generate statistics of the data while executing a query. In contrast to the existing approaches, this does not have any additional costs in terms of execution time. We will demonstrate how these statistics are later used by the DBMS to select the best plan from the search space using accurate cost values.

1 INTRODUCTION

Current trends in hardware technologies such as manycores, GPUs and field-programmable gate arrays (FPGAs) for data processing, NVRAM and open-channel SSDs for storage solutions and RDMA-capable high-speed network solutions are interesting candidates for the acceleration of database query processing on Big Data. In this scenario, the German DFG Priority Program no. 2037[1] on "Scalable Data Management for Future Hardware", funds research projects to develop new architectural concepts for data management systems that support both current as well as future hardware technologies. Our Reconfigurable data provider (ReProVide) project is one of them. The goal of the ReProVide project is to provide a new FPGA-based smart storage solution together with query optimization techniques, which considers the capabilities of the hardware for the scalable and powerful near-data processing of Big Data. The benefits of FPGA technology are pipelined processing of data at line rate (at least for non-blocking operators), energy-efficiency and speedup through parallelization, as well as the option of dynamic adaptation of the hardware through reconfiguration. In the ReProVide project, a generic FPGA architecture named ReProVide processing unit (RPU) for the efficient processing of database queries is developed. The goal of such an architecture is to serve as intelligent storage system and reconfigurable data (pre-) processing interface between diverse data sources and host systems requesting data from these sources. This can reduce network utilization and host workload as well as saving power to a great extent.

Integrating smart storage like RPUs into a database management system (DBMS) requires novel optimization techniques to (a) decide which operations are worthwhile to assign to the RPU, and which are not (*query partitioning* [2]) and (b) to determine how to map and execute the assigned (sub-)queries or database operators on the RPU (*query placement* [1]). For query partitioning, the DBMS query optimizer must take the characteristics of an RPU system into account. This involves considering which particular operators are actually supported by the RPU as not all operators and data types can be accelerated at line rate on FPGAs. It also includes using novel cost models for estimating the RPU performance which consider hardware reconfiguration overheads and make use of hardware-generated statistics of the data it currently stores. We therefore also investigate a novel hierarchical (multi-level) query-optimization technique where the global optimizer of the DBMS and the architecture-specific local optimizer of the RPU work together to obtain scalable query processing [2]. A bidirectional hint interface (see Fig. 1b) exchanging hints between global and local optimizer enables scalable optimization in both directions. i. e., globally and locally.

In this demo, we show how DBMS and RPU work together to process database queries with the goal of minimizing the overall execution time. We will demonstrate how our techniques abstract away the complex decision space of how to partition and execute queries on heterogeneous hardware. We furthermore will explain the underlying hardware concepts and optimization techniques.

2 SYSTEM OVERVIEW

2.1 ReProVide

The ReProVide system is a distributed/federated data-processing system which includes Apache Calcite as the DBMS as well as FPGA-based hardware (RPU) as the co-processor and the remote data storage (see Fig. 1a). ReProVide follows the idea of near-data processing, which means the RPU has the query-processing capabilities (near to data storage), that can be used for data (pre-)processing.

Apache Calcite[2] is a dynamic data-management framework that provides query processing, optimization, and query-language support to many data-processing system [5]. It is a complete query-processing system, except for data storage. The framework that Calcite provides for building databases allows to extend its set of rules, cost models, relational expressions, and user-defined functions. This property of Calcite has encouraged us to choose it as our DBMS for this project. Calcite provides data-provider federation through adapters. Hence it is possible to connect any number of databases to Calcite using their own adapter.

An RPU is implemented on a programmable SoC (multi-core CPU + FPGA) that serves as a data provider accessible via an Ethernet network. The data is stored in non-volatile storage such as solid-state disks (SSDs) and in volatile memory such as DDR-SDRAM, which is directly attached to and managed by the platform and can be processed by accelerators implemented

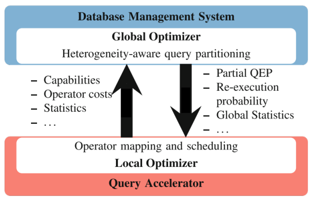
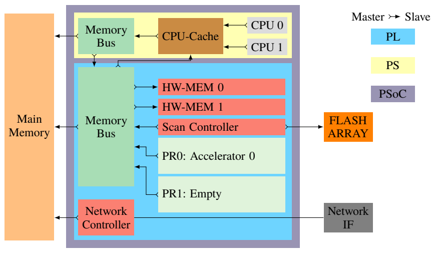
(a) ReProVide architecture



(b) Interplay of Global and Local Optimizer



(c) The architecture of an RPU [1]

Figure 1: (1a) shows the architecture diagram of ReProVide system. (1b) gives the interaction between co-operating optimizers in ReProVide. (1c) illustrates the RPU with the FPGA part (programmable logic (PL)) of the system on chip (SoC) colored blue and the processing system (PS) with its dual core processor colored yellow. Two partially reconfigurable regions (PRs) are available with *PR0* being configured with *Accelerator 0*.

in the Programmable Logic (PL/FPGA) part of the system. This design also enables an RPU to locally optimize the storage layout of the data with regards to availability, access latency, power consumption, and the access patterns of the hardware accelerators.

The interaction of the DBMS and ReProVide is sketched in Fig. 1b. Global optimization applies rules to the query-evaluation plan (QEP), with the major goal of partitioning the QEP into sub-trees and assigning some of them to the RPU (query partitioning). The local optimizer is responsible for finding the best implementation of a sub-tree on the RPU (query placement [1]).

The execution of a query mainly consists of three phases (see Fig. 2) : In the first phase, the local optimizer provides information on its capabilities. The global optimizer uses this information to decide, which operations of a QEP can be assigned to the RPU. Based on this the query will be partitioned. For finding the best partitioning, statistics of the data stored in the RPU can be requested. Generation of such statistics on streaming hardware comes at almost no cost [3] and can even be refined when subsequently accessing the same data (see section 4.2).

In the second phase, the sub-tree of QEP (partition) is passed from the global optimizer to the local optimizer, including some hints (e.g. re-execution probability, upper latency bound, a time budget for running the local optimizer). The local optimizer then selects the required accelerators, maps query operations to these accelerators, and schedules the reconfiguration of the accelerators specific to the operations that it receives. Based on the hints, the local optimizer can adjust buffer sizes for higher throughput but decreased latency until the first data is sent.

In the third and final phase, the query is executed and the results are returned to the host system.

2.2 RPU

The RPU constitutes a heterogeneous hardware/software system, as shown in Figure 1c. The table management is executed on one core of the processing system (PS). While the processing system could also process the full variety of operators and types, its performance may be limited. Thus, handling of the data is mostly dealt with within the programmable logic (PL). Requests are received via a high-speed network interface and forwarded to the management software for further processing. To relieve the processing system from the task of result transmission, a specialized Network Controller implemented in the static system allows sending the resulting data to the requesting host with minimum intervention from the management software.

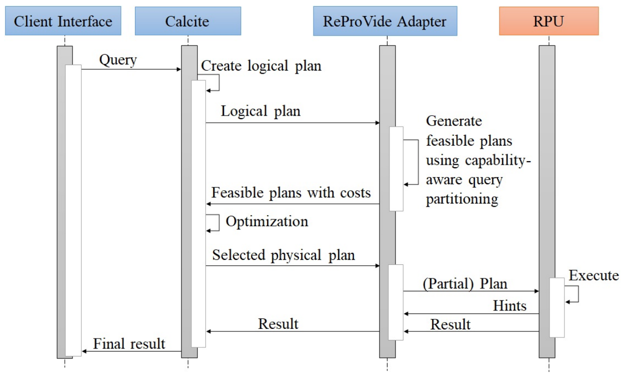


Figure 2: Sequence Diagram for the demonstrated query processing

RPUs include partially reconfigurable regions (PR) into which hardware accelerators can be dynamically loaded and which can be configured to process operations on streaming data. By means of hardware reconfiguration, different hardware accelerators can be loaded onto the FPGA for processing the locally-stored data before transmitting it to the requesting DBMS.

A dedicated and parameterizable hardware component called *Scan Controller* is responsible for data loading. The controller also has direct access to the attached FLASH storage to stream the relevant data to the accelerators. RPUs make use of a library of pre-synthesized reconfigurable hardware accelerators for query placement as the dynamic synthesis of a new hardware accelerator (query compilation) can take from minutes up to multiple hours. As such, the capabilities of a RPU are determined by the accelerators in the library: Operators for which no accelerators are available in the library cannot be executed on the RPU. Operators available span from simple filters on integer values to more complex filters such as regular expressions. Also accelerators for hash-joins have been developed. Please see [4, 15].

2.3 RPU-enabled DBMS

The implemented RPU-enabled DBMS is prototyped using Apache Calcite. We have implemented the *Global Optimizer* as follows.

Calcite allows to extend its rules for query optimization via adapters. The global optimizer must be tuned to act as a capability-aware optimizer by defining some additional rules (push-down

Figure 3: Query optimization by global optimizer.

rules) to consider the capabilities of RPU during the query optimization. These push-down rules define required operations and attributes which can be pushed down to RPU. The main purpose of the attribute push-down is to avoid unnecessary data transfer over the network and thus to reduce network traffic as well as host workload. These push-down rules are not RPU specific, and can be applied with any hardware configuration connected with Calcite but require the capabilities of the connected co-processor. As an example, consider the query below:

```
SELECT d_year, d_dow
FROM date_dim
WHERE d_day_name="Monday" AND
(d_year > 1900 OR d_moy > 4 )
ORDER BY d_year
```

Fig. 3a. shows the logical plan of the given query. The global optimizer (GO) partitions the query using push-down rules. In this example, the RPU is only capable (a) of doing Filter operations in the Where clause, so the Sort operation cannot be assigned to the RPU, and (b) it can either do String comparison or Integer comparison at a time. Hence, the Filter node is partitioned into a String comparison and an Integer comparison node. Only one can be pushed down to the RPU, so two plans are generated acc. to Fig.3b. Based on cost models and statistics, the GO now selects one alternative and converts it into a physical plan (see Fig. 3c).

3 EVALUATION

Initial measurements of our system were performed on Intel Core i9-7920x processor with CPU 2.90GHz × 24 and Memory 64 GiB. For comparison, PostgreSQL executed on the same system is used as a baseline for comparison. Please note that for the PostgreSQL baseline the data is available locally and, in contrast to our setup, has no network overhead involved. For the ReProVide setup, the RPU is connected via a 1Gb/s Ethernet. Both, the RPU and PostgreSQL are connected to Calcite using their respective software drivers. To evaluate the performance of our proposed system, we chose two different SELECT statements and varied the WHERE clause to test the influence of selectivity. As Table we used the date dimension of the TPC-DS benchmark suite. Figure 4 depicts the relative execution time difference of ReProVide versus PostgreSQL. Due to the run-to-completion implementation of this early version of the RPUs, we can observe a slowdown for the query (blue) with bigger tuple sizes of the result table: Overhead for allocating and synchronizing buffers depends on their sizes.

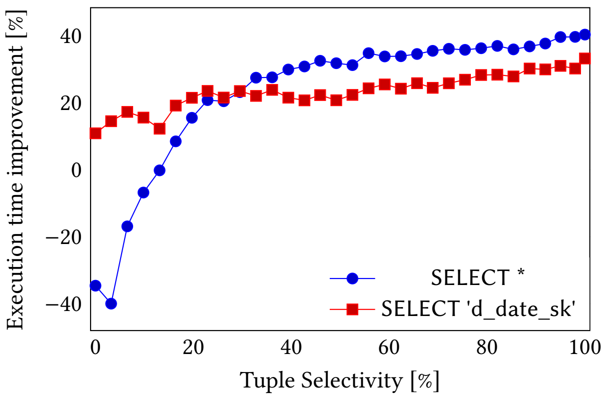

Figure 4: Relative execution time improvement vs. Tuple Selectivity. The improvement is calculated as $\frac{time_{PostgreSQL} - time_{ReProVide}}{time_{PostgreSQL}}$. One query (blue) selects all available attributes of the TPC-DS date dimension while the second query (red) only selects a single attribute.

This overhead is greatly reduced if only a small part (columns) will be present in the intermediate result (red) or the selectivity rises and the buffers become less and less oversized. Furthermore, as the RPU is network connected there is an initial latency to send the request and receive the results which PostgreSQL running in the same host doesn't suffer from. As one can see, even with PostgreSQL having these benefits and higher data transfer rates, our approach already shows benefits in terms of execution time reduction of up to 40%.

4 DEMONSTRATION WALKTHROUGH

For the demonstration, we will present all the above mentioned concepts to the conference attendees. They will be explained how to use our framework for executing their own queries. They do not require any prerequisite understanding about any of the hardware or software that we are using for demonstration. The demo includes a laptop where the DBMS (particularly Calcite) is running which will be connected with an FPGA board (RPU) using an Ethernet cable.

4.1 Query partition and execution

The conference attendees can select/ frame a query that they want to execute in our framework. When the attendee types in a query and presses the execute button, the query execution log will be displayed. The push-down rules are listed and possible execution plans generated by the global optimizer using those push-down rules are visualized. Furthermore, the selected plan for the execution and, finally, the result of the query (as depicted by Fig 5) are shown.

Figure 6: Statistics received from RPU

4.2 Online Statistics Visualization

One speciality of the RPU is the possibility to generate statistics such as histograms at almost zero cost during regular query execution runs [3]. The demo will present the refined histograms after new information is available in an event driven way to demonstrate that statistics can be refined without additional cost (see Fig 6). The statistics can then guide the optimizer to select the better plans with more accurate cost estimations.

5 RELATED WORKS

Research about the benefits of modern hardware, especially FPGAs and GPUs, for query accelerations is well exploited in recent years. [11–14] are studying the performance improvement when integrating FPGAs into CPU systems for query acceleration. Contrary, we are introducing a co-operating optimizer, where FPGA and CPU are interacting. Based on this interaction, a capability-aware optimization is implemented.

In [7] the statistics (histogram) have been generated as a side effect of query processing but with additional hardware resources while in our system, statistics are gathered during the execution of partial query[3].

Heterogeneity-aware query optimization has been studied extensively in [6, 8–10]. But other than the approaches they have implemented, a capability-aware optimization using the hints from the attached co-processor is used in our approach to find the best operations for them.

6 CONCLUSION AND FUTURE WORK

A reconfigurable near-data accelerator and a capability-aware global optimizer for a scalable and energy efficient execution of an SQL query processing is shown in this demo. In the current version, we are focusing on the query partition and on-the-fly reconfiguration of accelerators. In the future work, we would like to address multi-query optimization and common sub-expression evaluation.

ABSTRACT

The Big Data movement proposes data streaming systems to tame *velocity* and to enable *reactive* decision making. However, approaching such systems is still too complex due to the paradigm shift they require, i.e., moving from scalable batch processing to continuous data analysis and pattern detection.

Recently, declarative Languages are playing a crucial role in fostering the adoption of Stream Processing solutions. In particular, several key players introduce SQL extensions for stream processing. These new languages are currently playing a central role in fostering the stream processing paradigm shift. In this tutorial, we give an overview of the various languages for declarative querying interfaces big streaming data. To this extent, we discuss how the different Big Stream Processing Engines (BigSPE) interpret, execute, and optimize continuous queries expressed with SQL-like languages such as `KSQL`, `Flink-SQL`, and `Spark SQL`. Finally, we present the open research challenges in the domain.

KEYWORDS

Stream Processing, Data Stream Management Systems, Complex Event Processing, Streaming SQL

1 GOALS & OBJECTIVES

The world is accelerating; every day, hour, minute, and second the amount of data that we produce grows quicker. Initially, Big Data systems focused on scalable batch processing, and `MapReduce` [12] led the analytics market for more than a decade.

Recently, with the growing interest for (near) real-time insights, we observed a paradigm-shift, i.e., from *data at rest* and post-hoc analyses, to *data-in-motion* and continuous analyses. Thus, Big Data systems evolved to process streams with low latency and high throughput. Nowadays, the state of the art includes many alternative solutions, such as `Storm`, `Flink`, `Spark Structured Streaming`, and `Kafka Streams`) to name the most prominent ones.

Models for continuous data processing have been around for decades [15]. However, the advent of the Big-Data dramatically increased the popularity of data streams in several application domains. For example, developers aim at implementing efficient and effective analytics on massive flows of data for realizing the `Smart X` phenomena (e.g., Smart Home, Smart Hospital, Smart City). Stream processing systems are designed to support a large class of applications in which data are generated from multiple sources and are pushed asynchronously to servers which are responsible for processing them [13].

To facilitate the adoption, initially, most of the big stream processing systems provided their users with a set of API for implementing their applications. However, recently, the need for declarative stream processing languages has emerged to simplify common coding tasks; making code more readable and maintainable, and fostering the development of more complex applications. Thus, Big Data frameworks (e.g., `Flink` [9], `Spark` [3], `Kafka Streams`[1], and `Storm` [19]) are starting to develop their own SQL-like approaches (e.g., `Flink SQL`[2], `Beam SQL`[3], `KSQL`[4]) to declaratively tame data velocity.

In general, declarative languages are extremely useful when writing the optimal solution is harder than solving the problem itself. Indeed, they leverage compilers to catch programming mistakes and automatically transform and optimize code. They fill the gap between expert and normal users. They also increase the acceptance and usability of the system for the end-users. The aim of this tutorial is to provide an overview of the state-of-the-art of the ongoing research and development efforts in the domain of declarative languages for big streaming data processing. In particular, the goals of the tutorial are:

- providing an overview of the fundamental notions of processing streams with declarative languages;
- outlining the process of developing and deploying stream processing applications;
- offering an overview of state of the art for streaming query languages, with a deep-dive into optimization techniques and examples from prominent systems; and
- presenting open research challenges and future research directions in the field.

The content of this tutorial is highly relevant for EBDT-2020 attendees, as it focuses on database-related aspects that concern SQL-like domain-specific languages for stream processing.

2 TUTORIAL PROGRAM OUTLINE

The tutorial introduces the various approaches for declarative stream processing for Big Data. It is centered on providing motivations, models, and optimization techniques related to declarative Stream Processing languages, e.g., `EPL`, `KSQL`, `Flink-SQL` and `Spark Structured Streaming`. In the following, we provide an overview of program followed by a detailed description of the different lectures. Notably, we aim at preparing also practical examples and exercises for the audience to interact with the presented tools.

2.1 A Brief History of Stream Processing

During this part, we will focus on describing the motivations that led to the development of stream processing [20]. Besides, we present the state of the art, surveying from seminal models [5, 8] to the more recent ones [1, 17].

`SECRET` [8] is a model to explain the operational semantics of window-based SPEs. SECRET focuses on modeling stream-to-relation operators using four abstractions:

- the *Scope* function maps an event time instant to the time interval over which the computation will occur.
- the *Content* function maps a processing time instant to the subset of stream elements that occur during the event-time interval identified by the scope function.
- the *Report* dimension identifies the set of conditions under which the window content become visible to downstream operators.
- the *Tick* dimension shows the conditions that cause a report strategy to be evaluated.

The `Dataflow Model` [1] presented a fundamental shift on the approach of stream processing, leaving the user the choice of the appropriate trade-off between correctness, latency and cost. The model describes the processing model of Google Cloud Dataflow. In particular, it operates on streams of *(key, value)* pairs using the following primitives.

- *ParDo* for generic element-wise parallel processing producing zero or more output elements per input.
- *GroupByKey* for collecting data for a given key before sending them downstream for reduction.

Being data unbounded *GroupByKey* needs windowing in order to be able to decide when it can output. Windowing is usually treated as key modifier, this way GroupByKey will group also by window. The model addresses the problem of window completeness, claiming the Watermarking an insufficient mechanism to regulate out-of-order arrival. Therefore, the Dataflow Model introduces *Triggers* to provide multiple answers for any given window. Windows and Triggers are complementary operators. The former determines *when* data are grouped together for processing using event time; the latter determines *where* the results of groupings are emitted in processing time.

The `Stream and Table Duality` [17] includes three notions, i.e., *table*, *table changelog stream* and a *record* stream. The static view of an operator's state is a *table*, updated for each input record and has a primary key attribute. *Record* streams and *changelog* streams are special cases of streams. A *changelog* stream is the dynamic view of the result of an update operation on a table. The semantics of an update is defined over both keys and timestamps. Replaying a table changelog stream allows to materialize the operator result as a table. On the other hand, a *record stream* represents facts instead of updates. A record streams model immutable items and, thus, each record has a unique key. Stream processing operators are divided in *stateless* and *stateful* ones, may have one or multiple input streams and might be defined over special types of input streams only.

2.2 Big Stream Processing Engines

During this section of the tutorial, we provide an overview of the following Big Stream Processing Engines (BigSPE). Figure 1 reports the system publication timeline, indicating in light-grey to that are in the scope of the tutorial.

`Apache Flink` [9] is an open source platform for distributed stream and batch processing. Flink uses a streaming dataflow engine that provides data distribution, communication, and fault tolerance for distributed computations. Apache Flink features two relational APIs - the Table API and SQL - for unified stream and batch processing. Flink's Streaming SQL support is based on Apache Calcite which implements the SQL standard.

`Apache Spark` [3] is a general-purpose cluster computing system. It provides high-level APIs in Java, Scala, Python and R, and an optimized engine that supports general execution graphs. Spark's main abstraction are resilient distributed datasets (RDDs). An RDD is a collection of elements partitioned across the nodes of the cluster that can be operated on in parallel.

`Apache Kafka` [21] is a distributed streaming platform. Kafka is run as a cluster on one or more servers, called brokers, that can span multiple datacenters. The Kafka cluster stores streams of records in unbounded append only logs called topics. Each record consists of a key, a value, and a timestamp. *Kafka Streams* is a stream processing library built on top of Apache Kafka producer/consumer APIs. It is based on the Stream/Table duality model, which combines the Dataflow model and CQL.

2.3 Declarative Stream Processing Languages

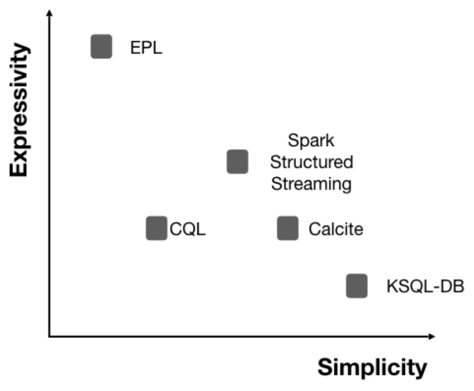

Figure 2: Expressiveness vs Simplicity w.r.t. Declarative Stream Processing Languages

In the context of Big Data Streams, declarative languages suffer from the absence of a shared formal framework that clarifies execution models and time-management approaches. Therefore, existing systems have developed their declarative languages with a primary focus on meeting specific industrial needs.

The `Continuous Query Language` (CQL) [2] is the first attempt to extend relational algebra to process streams of data. CQL defines three families of operators, i.e., Stream-to-Relation (S2R) operators that produce a relation from a stream, Relation-to-Relation (R2R) operators that produce a relation from one or more other relations, and Relation-to-Stream (R2S) operators that produce a stream from a relation. Combining these operators is it possible to define stream-to-stream transformations.

During this section, we survey existing declarative languages for stream processing. Influenced by CQL, BigSPEs' languages try to be as syntactically-close as possible to SQL focusing on usability at the cost of solid design principles like Codd's ones [10]. Following Cugola and Margara's classification [11], we will explain and compare them in terms of expressiveness and simplicity, as shown in Figure 2.

Flink SQL is based on Apache Calcite [7], i.e., a system that provides query parsing, planning, optimization, and execution of SQL queries on top of any data management system. Calcite leaves data storage and management to specialized engines. Flink relies on Calcite to offer a streaming-compliant SQL interface and an advanced query optimization layer. Any language construct used in Flink is also compliant to the SQL standard syntax. Listing 1 shows an example of Flink SQL query that counts the number of views per nation every hour and reporting every minute.

```
SELECT nation, COUNT(*)
FROM pageviews
GROUP BY HOP(rowtime,INTERVAL 1H,INTERVAL 1M), nation
```

Listing 1: Counting Page Views using Flink SQL.

Spark SQL [4] a Spark module for structured data processing. It provides a Dataframe API that can perform relational operations. Moreover, it relies on Catalyst, i.e., an extensible optimizer that allows custom optimization rules. The Dataframe API provides to Catalyst source metadata that allows it to perform optimizations. Structured Streaming [3] ports to Spark some of the Google DataFlow ideas, e.g., the separation between event-time and processing-time. Structured Streaming reuses the Spark SQL execution engine, Catalyst, and the code generator. To support streaming, Structured Streaming add the features to Spark SQL:(1) Triggers to control result reporting; (2) Time extractors to mark a column for event time;(3) Stateful operators to implement complex aggregations. Listing 2 shows the same query of Listing 1, but using Spark SQL.

```
val df = pageviews.groupBy(
  window($"timestamp", "1 hour", "1 minute"),$"nation"
).count()
```

Listing 2: Counting Page Views using Spark SQL.

KSQL [14] is a streaming SQL engine implemented on top of the Kafka Streams API. KSQL is directly based on the Stream Duality model [17]. Thus, it relies on two first-class constructs, i.e., Streams and Tables. To move between these abstractions, KSQL provides powerful stream processing capabilities such as joins, aggregations, event-time windowing, and many more. Listing **??** shows our example pageviews query using KSQL syntax.

```
CREATE TABLE analysis AS SELECT nation, COUNT(*)
FROM pageviews
WINDOW HOPPING (SIZE 1 HOUR, ADVANCE BY 1 MINUTE)
GROUP BY nation;
```

Listing 3: Counting Page Views using KSQL label

The presenters go in-depth regarding the languages above, focusing in particular on the following constructs [18]: (i) Filters and stateless operations; (ii) table-stream and stream-to-stream joins; (iii) windowing, aggregates, and stateful computations.

Finally, presenters will comment on the design of the languages above w.r.t. the Codd's principles:

- *Minimality*, i.e., a language should provide only a small set of needed language constructs so that different language constructs cannot express the same meaning;
- *Symmetry*, i.e., a language should ensure that the same language construct always expresses the same semantics regardless of the context it is used in; and
- *Orthogonality*, i.e., a language should guarantee that every meaningful combination its constructs is applicable.

2.4 Conclusion and Research Directions

This section closes the tutorial indicating ongoing research and industrial works. Moreover, we will ask the audience about the fact that SQL was not intended to be used with unbounded streams of data nor with the continuous semantics required to process them. Nevertheless, existing BigSPE are adopting it and a question naturally raises: *Can we consider BigSPE as databases?*

3 LEARNING OUTCOMES

The tutorial targets researchers, knowledge workers, and practitioners who want to understand the current state-of-the-art as well as the future directions of stream processing.

This tutorial includes relevant technologies and topics for people from IoT, as well as social media, pervasive health, ans oil industry, who have to analyze in massive amounts of streaming data. After attending this tutorial, the audience will have:

- Good understanding of the fundamental and main concepts of stream processing its models;

- An overview and detailed insight into declarative stream processing languages and the ongoing developments by big data streaming system in this domain;
- An overview of research directions in which the state-of-the-art can be improved.

The material of the tutorial will cover some of the work of the presenters on the topics of the tutorial, including [13, 16, 18]

4 PREVIOUS EDITIONS

The first version of this tutorial was presented at the DEBS 2019 conference[6]. It was a full-day tutorial, and it focused on the processing models behind declarative stream processing languages. With the tutorial, the presenters were invited to publish a companion short paper [18] and a website[7].

5 PRESENTERS & ORGANIZERS

Riccardo Tommasini is a research fellow at the University of Tartu, Estonia. Riccardo did his PhD at the Department of Electronics and Information of the Politecnico di Milano. His thesis, titled "Velocity on the Web", investigates the velocity aspects that concern the Web environment. His research interests span Stream Processing, Knowledge Graphs, Logics and Programming Languages. Riccardo's tutorial activities comprise Stream Reasoning Tutorials at ISWC 2017, ICWE 2018, ESWC 2019, and TheWebConf 2019, and DEBS 2019.

Sherif Sakr is the Head of Data Systems Group at the Institute of Computer Science, University of Tartu, Estonia. He received his PhD degree in Computer and Information Science from Konstanz University, Germany in 2007. He is currently the Editor-in-Chief of the Springer Encyclopedia of Big Data Technologies. His research interest include data and information management, big data processing systems, big data analytics and data science. Prof. Sakr has published more than 150 research papers in international journals and conferences. He delivered several tutorials in various conferences including WWW'12, IC2E'14, CAiSE'14, EDBT Summer School 2015, . The 2nd ScaDS International Summer School on Big Data 2016, The 3rd Keystone Training School on Keyword search in Big Linked Data 2017, DEBS 2019 and ISWC 2019.

Emanuele Della Valle is an Assistant Professor at the Department of Electronics and Information of the Politecnico di Milano. His research interests covered Big Data, Stream Processing, Semantic technologies, Data Science, Web Information Retrieval, and Service Oriented Architectures. His work on Stream Reasoning research filed was applied in analysing Social Media, Mobile Telecom and IoT data streams in collaboration with Telecom Italia, IBM, Siemens, Oracle, Indra, and Statoil. Emanuele presented several Stream Reasoning related tutorials at SemTech 2011, ESWC 2011, ISWC 2013, ESWC 2014, ISWC 2014, ISWC 2015, ISWC 2016, DEBS 2016, ISWC 2017 and KR 2018.

Hojjat Jafarpour is a Software Engineer and the creator of KSQL at Confluent. Before joining Confluent he has worked at NEC Labs, Informatica, Quantcast and Tidemark on various big data management projects. Hojjiat earned his PhD in computer science from UC Irvine, where he worked on scalable stream processing and publish/subscribe systems.

Entity Resolution: Past, Present and Yet-to-Come
From Structured to Heterogeneous, to Crowd-sourced, to Deep Learned

ABSTRACT

Entity Resolution (ER) lies at the core of data integration, with a bulk of research focusing on its effectiveness and its time efficiency. Most past relevant works were crafted for addressing Veracity over structured (relational) data. They typically rely on schema, expert and external knowledge to maximize accuracy. Part of these methods have been recently extended to process large volumes of data through massive parallelization techniques, such as the MapReduce paradigm. With the present advent of Big Web Data, the scope moved towards Variety, aiming to handle semi-structured data collections, with noisy and highly heterogeneous information. Relevant works adopt a novel, loosely schema-aware functionality that emphasizes scalability and robustness to noise. Another line of present research focuses on Velocity, i.e., processing data collections of a continuously increasing volume.

In this tutorial, we present the ER generations by discussing past, present, and yet-to-come mechanisms. For each generation, we outline the corresponding ER workflow along with the state-of-the-art methods per workflow step. Thus, we provide the participants with a deep understanding of the broad field of ER, highlighting the recent advances in crowd-sourcing and deep learning applications in this active research domain. We also equip them with practical skills in applying ER workflows through a hands-on session that involves our publicly available ER toolbox and data.

1 GOALS AND OBJECTIVES

Entity profiles assemble valuable information about real-world objects. Hence, entities constitute the core organizational unit of *structured* (e.g., relational databases) as well as *semi-structured data* (e.g., knowledge bases, such as DBPedia and Geonames). Various data management applications, such as query answering [47], are based on entity semantics and connections in order to improve their performance. Typically, these applications require the integration of different profiles that pertain to the same real-world object [11, 18]. The task of inter-linking and deduplicating (i.e., canonicalizing) data instances that describe the same real-world objects is called *Entity Resolution* (ER) [12].

ER is a relatively old problem that was mainly crafted for structured data, which were described by schemata of known semantics and quality [11]. This schema knowledge allowed experts to develop customized solutions that effectively addressed **Veracity**, i.e., the various forms of inconsistencies, noise or errors in entity profiles, which are introduced during manual data entry, or by the limitations of the automatic extraction techniques [23]. For even higher effectiveness, labelled instances are also typically used in order to automatically learn matching rules that simultaneously maximize precision and recall [48, 60, 61].

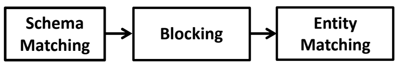

Figure 1: The workflow of the 1st and 2nd ER generations.

The *end-to-end* workflow implemented by **the 1st generation** of ER solutions is depicted in Figure 1 [11]. The first step, *Schema Matching*, creates mappings between the attributes of the input entities based on their relatedness, as inferred from the similarity of their structure, name and/or values [6, 45]. By identifying semantically identical attributes (e.g., “profession” and “job”), it facilitates the schema-aware functionality of the subsequent workflow steps.

The second step, which is called *Blocking*, addresses the quadratic time complexity, $O(n^2)$, of brute-force ER, which compares every entity profile with all others [11]. Blocking reduces the executed comparisons to a significant extent by sacrificing recall to a minor extent. It restricts the computational cost by comparing only the most similar entity profiles, as they are determined by signatures that are composed of (combinations of) parts of values that correspond to the most informative attribute names [11]. E.g., two person entities are likely matches if their addresses have the same zip code.

The entities that co-occur in at least one block are compared during the third step, which is called *Entity Matching*. This applies a combination of string similarity measures to the values of selected attribute names. The resulting degree of similarity is then used to assign the entity pairs into one of the three possible categories, i.e., `match`, `non-match` or `uncertain` [11]. In case of collective approaches, the latest decision is propagated to *neighboring entities*, i.e., entities connected with important relationships to the compared pair, so as to refine their matching likelihood [7, 16].

Note that each step accommodates both *learning-based* and *non-learning methods* [41]; the former methods leverage labelled instances to extract effective rules through a Machine Learning algorithm, while the latter methods rely on heuristics that capture expert or domain knowledge.

The same workflow lies at the core of **the 2nd generation**, which additionally targets **Volume**, i.e., the cases where the input data comprise (tens of) millions of entity profiles. Typically, this challenge is addressed through the new paradigm for *massive parallelization*, i.e., Map/Reduce [14]. Several techniques for Blocking [38] and Entity Matching [9] have been adapted to MapReduce so that they scale to voluminous datasets. Special care is also taken to avoid underutilization of the computational resources through Load Balancing techniques [39, 77].

A shift was marked by **the 3rd generation** of the ER end-to-end workflow, which is depicted in Figure 2. In addition to Veracity and Volume, its goal is to address **Variety**, which is caused by the unprecedented levels of schema heterogeneity and noise as well as the loose schema binding of unclear semantics [12, 17]. Instead of a database-like schema, there is a rich diversity of

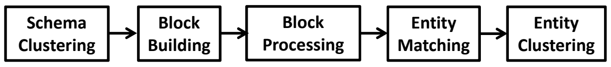

Figure 2: The workflow of the 3rd ER generation.

the domains. For example, there are ∼2,600 different vocabularies in the LOD cloud but only 109 from them are shared by more than one entity collection [22]. This results in hundreds, or even thousands, of different attributes with high entity frequency, rendering inapplicable the schema-aware methods of the first two generations [31, 54].

The first step in the new workflow is *Schema Clustering*, which clusters together attributes with similar values, regardless of their semantics. The goal is to improve the performance of the subsequent steps. E.g., Blocking uses the created schema clusters and the associated signatures (i.e., blocking keys) to split large blocks into smaller ones. This significantly enhances precision for a negligible (if any) impact on recall. This idea has been successfully applied to Blocking via Attribute Clustering [52] and to Meta-blocking via BLAST [62].

The second step, which is called *Block Building*, creates a set of blocks by disregarding schema knowledge and the ensuing human intervention completely. Through a schema-agnostic approach that leverages redundancy, it is inherently crafted for tackling the unprecedented levels of schema heterogeneity in semi-structured data. In this way, it yields blocks of very high recall, but very low precision, independently of human intervention and domain/expert knowledge [12, 54].

The third step of the workflow is *Block Processing*, which enhances precision to a significant extent at a limited, if any, cost in recall [52, 54, 56]. To this end, it refines the original blocks by efficiently removing comparisons that are repeated or involve non-matching entities. Its techniques are distinguished into two categories: the *Block Cleaning* ones operate at the coarse-grained level of entire blocks (e.g., Block Clustering [26]), while the *Comparison Cleaning* ones operate at the fine-grained level of individual comparisons (e.g., Meta-blocking [18, 53] and Blast [62]). In both cases, all techniques are generic and schema-agnostic by definition, thus applying naturally to both structured and semi-structured data [56].

Subsequently, *Entity Matching* executes all comparisons contained in the final set of blocks. Typically, this process depends heavily on neighbor similarity, using the entity relations in the semi-structured data. This is done through an iterative process that discovers duplicate entities gradually and propagates the latest matches to related entities that could benefit from them [42, 44, 66]. This step can also consider probabilistic matching of the entities, e.g., [1, 36].

The end result of Entity Matching is a *similarity graph*, which conveys a node for every entity and a weighted edge for every pair of entities that have been compared. This intermediate model is transformed into the final outcome of ER by *Entity Clustering* [34], which partitions the graph nodes into equivalence clusters - every cluster contains all duplicate entity profiles that actually correspond to the same real-world object. These techniques are schema-agnostic by default, as they exclusively consider the information contained in the similarity graph.

The 4th generation of ER goes beyond the previous ones, by also addressing **Velocity**. This pertains to the continuously increasing volume of available data that imposes special ER challenges, e.g., the data set can never be considered as final, and incoming data might alter the existing ones. To address them,

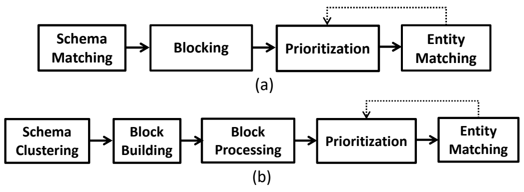

Figure 3: The end-to-end workflow of the 4th ER generation for (a) structured and (b) semi-structured data.

Progressive ER produces useful results in a pay-as-you-go manner before the full completion of ER. Figures 3(a) and (b) illustrate the schema-aware [58] and the schema-agnostic [63] workflows. *Incremental ER* [33] is another mechanism, which minimizes the cost for updating the existing results when new evidence becomes available. Some methods also consider that the new evidence might be conflicting with already processed data [36]. Another mechanism is *Query-driven ER* [4], which gradually resolves entities that are returned as results to incoming queries. A different mechanism is supporting queries for obtaining aggregate, statistical insights about the collection of resulting entities [35].

Note that all generations can be upgraded by exploiting **external knowledge** to achieve higher performance. To this category fall *Deep Learning* techniques for ER [20, 48], which incorporate contextual information in the form of word- or character-embeddings, and *Crowd-sourced ER* [13, 15, 24, 30, 32, 67–70, 72, 75], which relies on human feedback. These two approaches lie at the focus of the latest breakthroughs in ER.

After examining the four ER generations, our tutorial proceeds with a hands-on session that focuses on the state-of-the-art tools for end-to-end Entity Resolution, like Magellan [40]. We then present *JedAI* [57], which constitutes a comprehensive, open-source toolkit that implements most of the state-of-the-art methods for every step of the 3rd and 4th ER generations. Thus, it enables users to build versatile workflows on-the-fly and can be readily used both for experimentation and for integration in Entity Resolution applications. It is distributed under the Apache License 2.0 and, thus, it is suitable for both the academic and the commercial domain.

Overall, our tutorial provides researchers with a complete coverage of the state-of-the-art ER methods along with a discussion of the main open research problems. Practitioners get a good overview of the benefits of the primary ER methods and learn how to use them to improve the productivity of their businesses. They also learn to identify the methods or products that are more suitable for a particular task at hand, or better fit their general needs. Additionally, the audience and especially the developers of information integration tools benefit from the hands-on session, learning how to integrate (parts of) the JedAI Toolkit into their applications. Developers also become acquainted with novel ideas that could well improve their existing products.

Related Tutorials. Our tutorial provides for the first time a novel holistic and systematic view of the evolution of ER, stressing the current state-of-the-art in deep learning and crowd-sourcing applications. We categorize the main ER methods into four generations, going from those crafted for maximizing Veracity over structured data, all the way to those tackling Veracity, Volume, Variety and Velocity over semi-structured data. No other tutorial covers comprehensively large-scale, end-to-end ER for both structured and semi-structured data. Past tutorials on the subject [17, 27, 29, 65] focus either on one of these data types, or cover partially the end-to-end ER workflow.

2 SCOPE AND COVERAGE

Our tutorial aims to provide an overview of the state-of-the-art techniques for all generations of End-to-End ER, analyzing each one in a different session of ∼10 minutes. More emphasis is devoted to the approaches leveraging external knowledge in order to upgrade any workflow step in any generation (∼30 minutes), while a hands-on session discusses the main ER tools and demonstrates the latest version of JedAI (∼10 minutes). Together with the introduction, 5 minutes for questions and the conclusions, the intended duration of the tutorial is *1.5 hours.* The content of the individual sessions is outlined below:

I. Introduction and motivation
- Preliminaries on Entity Resolution [12, 18]
- Fundamental Assumptions, Principles and Definitions [23]

II. The 1st ER Generation: Tackling Veracity
- Schema Matching [6, 19]
- Blocking [11, 37, 61]
- Entity Matching [5, 16, 60]

III. The 2nd ER Generation: Tackling Volume and Veracity
- Parallel Blocking [38]
- Parallel Entity Matching [59]
- Load Balancing [39, 77]

IV. The 3rd ER Generation: Tackling Variety, Volume and Veracity
- Schema Clustering [52, 62]
- Block Building [50–52]: Parallel Methods [12]
- Block Processing [8, 26, 55, 56, 62]: Parallel Methods [21]
- Entity Matching [42, 44, 66]: Parallel Methods [9, 22]
- Entity Clustering [34]

V. The 4th ER Generation: Tackling Velocity, Variety, Volume and Veracity
- Progressive ER for (Semi-)Structured Data [58, 63, 76]
- Incremental Entity Resolution [33, 74]
- Query-Driven Entity Resolution [2–4, 71]
- Query Analytics for Entity Resolution [35, 64].

VI. Entity Resolution Revisited: Leveraging External Knowledge
- Deep Learning for Entity Resolution [20, 48]
- Crowd-sourced Entity Resolution:
  - Generating HITs [15, 43, 70]
  - Formulating HIts [25, 67–69, 72, 75]
  - Balancing accuracy and monetary cost [10, 28, 73, 78]
  - Restrict the labour cost [13, 30]

VII. Hands-on Session: ER tools
- The state-of-the-art end-to-end ER tools [40]
- The JedAI Open Source Toolkit [57]

VIII. Challenges and Final Remarks
- Automatic Parameter Configuration [46, 49]
- Multi-modal Entity Resolution
- Conclusions

3 INTENDED AUDIENCE AND MATERIAL

Our tutorial is example-driven, avoiding excessive technical details and proofs. As a result, there is no prerequisite knowledge, apart from a basic understanding of data management technology. This renders it suitable for a broad audience, covering not only students and researchers, but also practitioners and developers. In other words, it is intended for anyone with an interest in understanding the main techniques for scalable and robust end-to-end Entity Resolution over structured and semi-structured data, using both non-learning and learning-based techniques.

In addition to the theoretical background in the state-of-the-art in the field, the tutorial also presents available entity-related resources, enabling the participants to directly work on the particular domain. Discussed resources include available data as well as the state-of-the-art tools for performing end-to-end Entity Resolution, like Magellan [40] and JedAI [57], which can be readily used to tackle ER problems via numerous combinations of the most prominent methods.

Tutorial Material. The material of the tutorial is distributed through the conference website[1] as well as through a dedicated website[2]. In both locations, we also give pointers and guidelines for the ER toolkit that is used during the hands-on session. All relevant code is publicly released through the Apache License 2.0, which supports both academic and commercial uses.

4 PRESENTERS

The tutorial is given by three presenters:

(1) *George Papadakis* is a Research Fellow at the Department of Informatics of the University of Athens, Greece, and an Internal Auditor of Information Systems at the Public Power Company, the main electricity company in Greece.
(2) *Ekaterini Ioannou* is an Assistant Professor at the University of Tilburg, Netherlands.
(3) *Themis Palpanas* is a Senior Member of the French University Insitute (IUF), and a Professor of Computer Science at the University of Paris, France.

All authors have published papers related to Entity Resolution, focusing on the efficient management of large data collections as well as on addressing various challenges, such as uncertainty, volatility, and correlations.

Acknowledgements. This work was partially funded by the EU H2020 project ExtremeEarth (825258).

ABSTRACT

With the growing complexity of the available online information, search engines via rankings and recommender systems come to the rescue, providing suggestions to users about items of potential interest, from movies and products to news articles and even potential friends. Such results and suggestions aim at covering the user information needs and play an important role in guiding users' decisions and in forming their opinions.

However, the same technology, if not used responsibly, may lead to discrimination, amplify potential biases in the original data, restrict transparency and strengthen unfairness. For example, consider scenarios in which models based on biased data produce results that abet violence, decrease diversity, or have an adverse impact on economic policies.

While the potential benefits of rankings and recommenders are well-accepted and understood, the importance of using such systems in a fair manner has only recently attracted attention. In this tutorial, we cover recent advancements and highlight future research directions in this increasingly relevant research area.

1 INTRODUCTION

Currently, algorithmic systems driven by large amounts of data are increasingly being used in all aspects of society. Such systems offer enormous opportunities. They accelerate scientific discovery in all domains, including personalized medicine and smart weather forecasting, they automate tasks, they help in improving our life through personal assistants and recommendations, they have the potential of transforming society through open government, to name just a few of their benefits.

Often, such systems are being used to assist, or, even replace human decision making in diverse domains. Examples include software systems used in school admissions, housing, pricing of goods, credit score estimation, job applicant selection, and sentencing decisions in courts and surveillance. A prominent case is the COMPAS software used in courts in the US to assist bail and sentencing decisions through a risk assessment algorithm that predicts future crime.

The ubiquitous use of such systems may create possible threats of economic loss, social stigmatization, or even loss of liberty. For instance, a known study by ProPublica found that in COMPAS, the false positive rate for African American defendants, namely people labelled "high-risk" who did not re-offend, was nearly twice as high as that for white defendants [11]. Another well-known study shows that names used predominantly by men and women of colour are much more likely to generate ads related to arrest records [34].

Data-driven systems are also being employed by search and recommendation engines, social media tools, and news outlets, among others. Recent studies report that social media has become the main source of online news with more than 2.4 billion internet users, of which nearly 64.5% receive breaking news from social media instead of traditional sources [22]. Thus, to a great extent, such systems play a central role in shaping our experiences and influencing our perception of the world. Again, there are many reports questioning the output of such systems. For instance, a known study on search results showed evidence for stereotype exaggeration in images returned when people search for professional careers [16].

Fairness in rankings and recommenders. In this tutorial, we pay special attention to the concept of fairness in rankings and recommender systems. By fairness, we typically mean lack of discrimination. It is not correct to assume that insights achieved via computations on data are unbiased simply because data was collected automatically or processing was performed algorithmically. Bias may come from the algorithm, reflecting, for example, commercial or other preferences of its designers, or even from the actual data, for example, if a survey contains biased questions, or, if some specific population is misrepresented in the input data.

In this tutorial, we review a number of definitions of fairness that aim at addressing discrimination, bias amplification, and ensure fair treatment. We organize these definitions around the notions of individual and group fairness. We also present methods for achieving fairness in rankings and recommendations, taking a cross-type view, distinguishing them between pre-processing, in-processing and post-processing approaches. We conclude with a discussion of the new research directions that arise.

2 TUTORIAL OBJECTIVES

This tutorial aims at presenting a toolkit of definitions, models and methods used for ensuring fairness in rankings and recommendations. Our objectives are three-fold: (*a*) to provide a solid framework on a novel, quickly evolving, and impactful domain, (*b*) to highlight challenges and research paths for researchers and practitioners that work on problems in the intersection of recommender systems and databases, and (*c*) to show how fairness challenges manifest in other areas (e.g., cloud computation and job scheduling) and transfer findings from existing works in these areas.

For this purpose, we organize our tutorial along the following main axes: (i) Motivation and background for the need for fair rankings and recommendations, (ii) Modeling fairness in rankings and recommendations, (iii) Ensuring fair rankings and recommendations, and (iv) Fairness in computations, algorithms and systems, and open research challenges.

3 MOTIVATION AND BACKGROUND

Fairness has emerged as an important category of research for machine learning systems in many application areas. Extending this concept to rankings and recommendations is tricky. First, there is an essential tension between the goals of fairness and those of personalization. Inherent in the idea of personalization is that the best items for one user may be different than those for another. However, there are contexts in which equity across rankings and recommendation outcomes is a desirable goal. Furthermore, fairness is a multi-sided concept (e.g., [7, 8]), in which the impacts on multiple groups of individuals must be considered.

In this tutorial, we start by presenting motivating examples for the need for fair rankings and recommendations from several domains, including justice, ads, image search and others. We highlight possible causes of unfairness, such as biased or incomplete data, and algorithmic inefficiencies. We point out potential harms, such as filter bubbles, polarization, loss of opportunity, and discrimination.

We consider a number of different dimensions based on which we classify existing models and approaches. Firstly, we distinguish between the multiple viewpoints that fairness can have in recommendation systems, namely (*a*) fairness for the recommended items (e.g., [31]), (*b*) fairness for the users (e.g., [19, 38]), (*c*) fairness for groups of users (e.g., [1, 24, 29]) and (*d*) fairness for the item providers, and the recommendation platform (e.g., [25]). Furthermore, we distinguish the existing methods for achieving fairness in rankings and recommendations as: (*a*) pre-processing (e.g., [31]), (*b*) in-processing (e.g., [13]) and (*c*) post-processing approaches (e.g., [15]).

4 MODELING FAIRNESS

Fairness is a general term and coming up with a single definition or model is tricky. We start this part of the tutorial by reviewing definitions of fairness which, in general, ask for nondiscrimination of users or items, based on the values of one or more sensitive or protected attributes, such as gender or race. We organize the definitions with respect to the notions of *individual fairness*, i.e., treating similar individuals similarly [10, 18], and *group fairness*, i.e., treating different groups equally (e.g., nondiscrimination of sensitive groups) [2, 35].

We present a number of widely used models and definitions for fairness [23, 36], including:

- *Demographic (or statistical) parity* (e.g., [35]), stating that the proportion of each part of a protected class (e.g., gender) should take the positive outcome at equal rates.
- *Conditional statistical parity* (e.g., [36]), which defines statistical parity given a set of legitimate factors.
- *Equalized odds* (e.g., [2]), stating that the protected and unprotected groups should have equal rates for true positives and false positives.
- *Fairness through awareness* (e.g., [10]), stating that any two similar individuals should receive a similar outcome.
- *Counterfactual fairness* (e.g., [18]), stating that a decision for an individual is fair, if it is the same in both the actual world and a counterfactual world where the individual belongs to a different demographic group.
- *Calibration-based fairness* (e.g., [26]), stating that if a group receives a predicted probability p, at least a fraction p of its members should belong to the predicted class.

Next, we review how these models of fairness have been *extended in the case of ranked outputs*, including attention-based and probability-based approaches [3] as well as approaches based on pair-wise comparisons [4, 37]. Then, we look at how definitions of algorithmic fairness and fair ranking have been *adopted in recommender systems* (e.g., [31, 39]). Given that fairness is a multi-sided concept, we extend our taxonomy under the umbrella of recommender systems, considering that fairness can refer to suggested data items [31], users [19, 38], group of users [27, 29] or item providers. Finally, we investigate the notion of fairness in sequential and multi-round recommenders [5, 6, 25, 33], where the goal is to ensure fairness in a number of interactions between the users and the system. We also discuss fairness in the case of link recommendations in networks and related concepts of homogeneity, echo chambers and polarity [12].

This part of the tutorial concludes with a discourse on other related concepts, such as the relationship between fairness and diversity [9], recommendation independence, transparency [15] and feedback loops.

5 ENSURING FAIRNESS

In this section, we present methods for achieving fairness in rankings and recommendations. We first discuss the trade-offs among fairness, personalization and accuracy.

Taking a cross-type view, approaches can be distinguished as pre-processing, in-processing and post-processing.

- Pre-processing approaches target at transforming the data so that any underlying bias or discrimination is removed.
- In-processing approaches target at modifying existing or introducing new algorithms that result in fair rankings and recommendations, e.g., by removing bias.
- Post-processing approaches treat the algorithms for producing rankings and recommendations as black boxes, without changing their inner workings. To ensure fairness, they modify the output of the algorithm.

5.1 Recommenders

We first study fairness in systems that produce recommendations for individuals. These comprise the majority of existing recommender systems. We start by presenting *pre-processing approaches* that work on modifying the input to the recommender, for example, by appropriate sampling (e.g., [9]), by adding more data to the input (e.g., [31]), or by performing database repair [28]. Then, we focus on approaches for designing *fairness-aware algorithms*, that is, recommendation algorithms that produce fair recommendations. We will present algorithms for fairness-aware matrix factorization [7, 38], multi-armed bandits [13, 21] and deep learning recommenders (e.g., [6, 44]). For instance, we show that when fairness with respect to both consumers and to item providers is important, variants of the well-known sparse linear method (SLIM) can be used to negotiate the trade-off between fairness and accuracy and improve the balance of user and item neighborhoods [7]. Alternatively, we can augment the learning objective in matrix factorization by adding a smoothed variation of a fairness metric [38]. As another example, we present methods that mitigate bias to increase fairness by incorporating randomness in variational autoencoders recommenders (e.g., [6]). Finally, we present *post-processing approaches that modify the output of the recommenders* to ensure fairness (e.g., [15]).

Moving from individuals to groups, group recommendations have attracted significant research efforts for their importance in benefiting a group of users. However, maximizing the satisfaction of each group member while minimizing the unfairness between them is very challenging [20]. We study different *fair-aware algorithms for group recommenders* [20, 27, 29, 32].

5.2 Rankings

In order to guarantee fair rankings, *in-processing approaches* work with result generation procedures that allow the systematic control of the degree of unfairness in the output, by exploiting learning techniques, satisfying statistical parity, while preserving relevance [37, 43]. The work in [30] formulates fairness constraints on rankings, targeting at relevance maximization, in terms of exposure allocation. A learning-based in-processing approach is also used in [41] to reduce discrimination and inequality of opportunity in rankings, Here, the method learns a ranking function with an additional objective that reduces disparate exposure. A recent learning to rank approach, DELTR, looks at the average probability of items from a protected group to be ranked at the top position [42].

The *post-processing approach* of [40] aims at satisfying statistical tests of representativeness, when ranking items in a certain order, so as to ensure that the ratio of protected individuals that appear within a prefix of the ranking (namely, top-k) must be above a given proportion. The attention received by the items in different positions in the ranking is also not the same: items ranked in first positions are exposed to much more attention than the lower ones. [5] tackles the problem of having a ranking to be presented as a query result, where the items in the first positions have the same or very similar relevance. When it happens, there is a decision to be made of which items are being top-ranked and which are not. A solution to this situation, called amortized fairness, considers that the position index is a proxy for the level of attention an item is exposed, while the output of the prediction algorithm corresponds to the item relevance. Accumulated attention across a series of rankings should be proportional to accumulated relevance, as indicating long term ranking fairness.

6 OPEN ISSUES AND RESEARCH DIRECTIONS

In this section, we present a critical comparison of the existing work on ensuring fair rankings and recommendations, and the lessons learnt in these areas. Furthermore, we discuss open issues and new research directions that arise.

First, we present fairness concepts studied in different areas of computer science. Fairness is often a ubiquitous property of computations, algorithms, and systems beyond recommender systems. For instance, in federated stream processing systems, it is an open challenge how to ensure global fairness on processing quality experienced by queries [14]. Systems for processing big data such as Hadoop, Spark, and massively parallel databases, need to run workloads on behalf of multiple tenants simultaneously. The abundant disk-based storage in these systems is usually complemented by a smaller, but much faster, cache. Cache allocation strategies are required that speed up the overall workload while being fair to each tenant [17].

Then, we highlight a number of possible research directions. We start with the observation that even if there exist several definitions and models for representing fairness, coming from different research perspectives, these definitions and models are many times somewhat incomparable, hindering consistent understanding and treatment. Compiling existing definitions to produce new ones and evaluating their suitability in different domains and applications appears to be an open topic for further research. Fairness in recommendations is multi-sided, achieving fairness for all parties involved is also a topic that needs to be investigated further.

While the potential benefits of fairness are well-accepted nowadays, we still need to study the actual impact of fairness-enhancing algorithms. For example, extensive user studies are needed to evaluate the level of acceptance of the fairness-enhanced results by the users and the long term effect of these results on their own perceptions and preferences. Extensive studies that exploit feedback loops, should also be performed in this line of work, so as to investigate deeper the connections between the concepts of fairness, explainability and personalization. Moreover, it will be very advantageous to study comparatively the notions of equality, that ensures equal treatment, over equity, that ensures treatment based on needs. Operationalizing equity is a difficult task that often depends on the domain under study.

7 TUTORIAL INFORMATION

Motivation and Target Audience: The tutorial's topic lies in the core of the conference interests. The tutorial aims at researchers and students, as well as IT professionals and developers in searching, ranking and recommender systems, and the general data management community. Researchers and students will get a good introduction to the topic and get inspired by challenging research problems. Furthermore, IT professionals and developers will learn appropriate fairness-aware techniques to promote fairness in their systems. All the materials that will be used for the tutorial will be publicly available.
Prerequisites: The tutorial is carefully structured to accommodate both attendees unfamiliar with the topic and more experienced participants by providing required background knowledge, shared terminology and common understanding of the basic fairness-related concepts.
Intended Duration: We are aiming for a 90-minute tutorial.

8 PRESENTERS

Evaggelia Pitoura is a Prof. at the Univ. of Ioannina, Greece, where she also leads the Distributed Management of Data Laboratory. She received her PhD degree from Purdue Univ., USA. Her research interests are in the area of data management systems with a recent emphasis on social networks and responsible data management. Her publications include more than 150 articles in international journals (including TODS, TKDE, PVLDB) and conferences (including SIGMOD, ICDE, WWW) and a highly-cited book on mobile computing. Her research has been funded by the EC and national sources. She has served or serves on the editorial board of ACM TODS, VLDBJ, TKDE, DAPD and as a group leader, senior PC member, or co-chair of many international conferences (including PC chair of EDBT 2016 and ICDE 2012). She has more than 20 years experience in teaching. **Prior tutorials:** Temporal Graphs [eBISS'17], Social Graphs [BigDat'15], Data Graphs [SummerSOC'14], Personalization [ICDE'10], Mobile Computing [ICDE'03], Pervasive Computing [ICDE'00].

Georgia Koutrika is Research Director at Athena Research Center in Greece. She has more than 15 years of experience in multiple roles at HP Labs, IBM Almaden, and Stanford, building innovative solutions for recommendations, data analytics and exploration. Her work has been incorporated in commercial products, described in 9 granted patents and 18 patent applications in the US and worldwide, and published in more than 80 papers in top-tier conferences and journals. She is an ACM Distinguished Speaker and associate editor for TKDE and PVLDB. She has served or serves as PC member or co-chair of many conferences (including Demo PC chair of ACM SIGMOD 2018 and General Chair of ACM SIGMOD 2016). **Prior tutorials:** Recommender Systems [SIGMOD'18, EDBT'18, ICDE'15], Personalization [ICDE'10, ICDE'07, VLDB'05].

Kostas Stefanidis is an Assoc. Professor on Data Science at the Tampere University, Finland. He got his PhD in personalized data management from the Univ. of Ioannina, Greece. His research interests lie in the intersection of databases, information retrieval, data mining and the Web, and include personalization and recommender systems, and large-scale entity resolution and information integration. His publications include more than 80 papers in peer-reviewed conferences and journals, including SIGMOD, ICDE, and ACM TODS, and a book on entity resolution in the Web of data. He has 8 years experience in teaching. **Prior tutorials:** Recommender Systems [MUMIA Training School'14], Personalization [ICDE'10], Entity Resolution [ICDE'17, ESWC'16, WWW'14, CIKM'13].

ABSTRACT

NoSQL database systems are very popular in agile software development. Naturally, agile deployment goes hand-in-hand with database schema evolution. The main aim of this tutorial is to present to the audience the current state-of-the-art in continuous NoSQL schema evolution and data migration: (1) We present case studies on schema evolution in NoSQL databases; (2) we survey existing approaches to schema management and schema inference, as implemented in popular NoSQL database products, and also as proposed in academic research; (3) we present approaches for extracting schema versions; (4) we analyze different methods for efficient NoSQL data migration; and (5) we give an outlook on further research opportunities.

Duration: 1.5 hours

1 INTRODUCTION

Recent position papers demand more schema flexibility, such as the ability to handle variational data [3, 42]. Many agile software developers have long since turned towards NoSQL database systems such as *MongoDB*[1], *Couchbase*[2], or *ArangoDB*[3] which are schema-flexible, or even altogether schema-free. They allow to store datasets in different structural versions to co-exist.

Yet even when the database management system does not maintain an explicit schema, there is commonly an implicit schema, as the application code makes assumptions about the structure of the stored data. For instance, in Figure 1, the Java code in lines 1 through 9 implies a schema: An entity for person `Jo Bloggs` is created, and then persisted in the `people` collection.

```
1  List<Integer> books = Arrays.asList(27464, 747854);
2  DBObject person = new BasicDBObject("_id", "jo")
3                    .append("name", "Jo Bloggs")
4                    .append("address",
5                      new BasicDBObject("street", "123 Fake St")
6                        .append("city", "Faketon")
7                        .append("state", "MA")
8                        .append("zip", 12345))
9                    .append("books", books);
10 DBCollection collection = database.getCollection("people");
11 collection.insert(person);
```

Figure 1: Storing a person entity in MongoDB, using Java.[4]

[4]From "Getting Started with MongoDB and Java", https://www.mongodb.com/blog/post/getting-started-with-mongodb-and-java-part-i, published August 2014.

With each new release of the software, the application code evolves. Eventually, so will the implicit schema declarations. Then, data stored in the production system will have to be migrated accordingly. Yet writing custom migration scripts — which seems to be the common practice today — is error-prone and expensive. Thus, there is a dire need for well-principled tool support for long-term maintenance of NoSQL database schemas.

With the schema declared within the application layer, the burden of schema maintenance is shifted into the domain of the application developers. Accordingly, we observe various grass-roots efforts from the developer community to tackle schema evolution. Unfortunately, these solutions do not build upon the existing state-of-the-art in research. Overall, we see it as an opportunity for the database research community to contribute well-founded and practical solutions to real-world problems.

In this tutorial, we give an overview of schema management in agile development with NoSQL database systems. The authors proposing this tutorial have been publishing in this domain for over 6 years. We present the current state-of-the-art in research, as well as in practice. We cover inferring schema-on-read with outlier detection, deriving schema versions, the corresponding schema evolution operations matching between them, as well as the resulting data migration operations. Different migration strategies and their impact, such as the overall migration costs and the latency upon accessing an entity, are also discussed.

A strong point of this tutorial is that we motivate the problem domain by presenting an empirical study on NoSQL schema evolution in real-world applications. Moreover, we demo existing tools for NoSQL schema management, e.g., for schema design and schema extraction. Incorporating small, live demos, we put together a diverse and diverting tutorial.

2 OUTLINE

This 1.5-hour tutorial is split into five parts:

(1) **Case Studies (~15 min.)**. We present an empirical study on the schema imposed on NoSQL databases by applications, as well as the dynamics of NoSQL schema evolution.
(2) **NoSQL Schema Management (~20 min.)**. In this part we discuss different architectures and existing solutions for NoSQL schema management. Here, we present research approaches as well as first products.
(3) **NoSQL Evolution Management (~25 min.)**. We present solutions for NoSQL evolution management. Beside a language for declaring NoSQL schema evolution operations, we focus on approaches for extracting schema versions.
(4) **Data Migration (~20 min.)**. Based on the previous parts, we present different data migration strategies and discuss their quantitative assessment.
(5) **Future Opportunities (~10 min.)**. Finally, we outline open research problems as potential directions for further research, as well as current development in this area.

3 GOALS AND OBJECTIVES

3.1 Case Studies

For our introduction, we present an empirical study on real-world database applications, each backed by a schema-flexible NoSQL data store. We investigate whether developers denormalize their schema, as is the recommended practice in data modeling for NoSQL data stores, and also a research subject [4, 25]. Further, we analyze the entire project history, and with it, the evolution of the NoSQL schema. By looking at real-world evidence, we pinpoint characteristic problems (such as the increased frequency of schema changes). We discuss how existing solutions do not fully transfer (e.g., since they rely on the schema being declared explicitly, rather than being implicit in the code). Thus, existing solutions cannot address the needs of application developers. Finally, we state the desiderata for tackling NoSQL schema evolution, in preparation to the subsequent tutorial.

3.2 NoSQL Schema Management

NoSQL database systems differ with regard to schema support: There are *schema-free* systems without any native schema support (e.g. *Couchbase*, *CouchDB*[5], *Neo4j*[6]). Other systems offer optional schema support (e.g. *MongoDB*, *OrientDB*[7]; some of these systems support different schema modes: *schema-full* or *schema-flexible*). There are also schema-full systems, with a mandatory schema (e.g. *Cassandra*[8]). In addition, there are proposals for vendor-independent middleware that manages the NoSQL schema (e.g. the *Darwin* schema management component [45]).

3.2.1 *Capturing the NoSQL Schema.*

In our tutorial, we present three strategies how the NoSQL schema can be captured from a schema-free or schema-flexible data store: (a) In the tradition of textbook schema design, the NoSQL schema can be derived top-down from some conceptual model. (b) The schema may be extracted posthumously, given a data instance. (c) The schema may be also derived by static analysis of the application code. We now briefly discuss these options.

a) Forward Engineering/Schema-First. In forward engineering, or schema-first approaches, the schema is explicitly defined – for example with modeling tools such as *Hackolade*[9] or *erwin*[10]: Users of these tools draw extended entity relationship models or graphical visualizations of JSON Schema, which they can compile for a given NoSQL database system. The principles behind NoSQL schema design are being explored in academic research: In [1], a model-driven approach for designing NoSQL databases has been developed. The authors of [4] propose an abstract data model for NoSQL databases, which exploits the commonalities of various NoSQL systems. Another project [8] extends the schema-first approach and generates object-oriented class hierarchies. The class declarations actually represent entity collections, using Object-NoSQL mapper libraries such as Mongoose and Morphia.

Yet in agile development, the schema is often not fixed up front. Therefore, we next discuss schema reverse engineering.

b) Reverse Engineering from Data/Schema-on-Read. For processing data without explicit schema information, *reverse engineering* can be necessary. In the following we will refer to this approach as

[5]https://couchdb.apache.org/
[6]https://neo4j.com/
[7]https://orientdb.org/
[8]http://cassandra.apache.org/
[9]https://hackolade.com/
[10]https://erwin.com/products/erwin-dm-nosql/

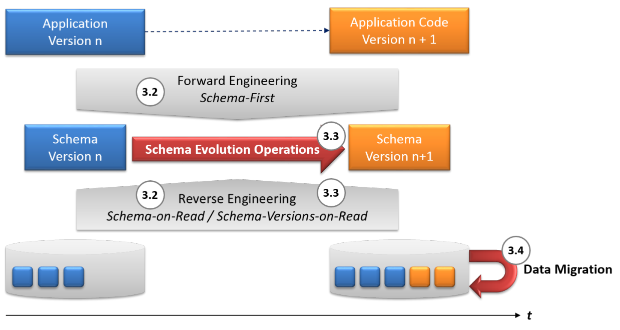

Figure 2: The Big Picture: Moving from schema version n (blue, shown to the left) to version $n + 1$ (orange, shown to the right), the persisted entities (blue) may not be immediately migrated. Rather, the data store now holds entities in both schema versions (blue and orange).

schema-on-read (this term is currently used differently in various Big Data/NoSQL application areas).

The general idea has been introduced in [22], based on an earlier approach for XML schema extraction in [26]: The implicit structural information from all entities is combined into a graph, from which the schema and statistics can be derived. The schema inference approach delivers a *schema overview*. The algorithm and its optimizations will be introduced.

Similar approaches [2, 13, 20, 33, 36] also infer a schema or generate conceptual models. The authors of [43] consider the challenge of designing schemas for existing JSON datasets as an interactive problem and present a roll-up/drill-down style interface for exploring collections of JSON records. In [5], schemas are inferred from datasets by typing the input according to a type system. This approach is designed for MapReduce-based, and thus highly scalable, execution. In [48], a descriptive schema is inferred, and documents are indexed by their structural properties, so that they may even be queried accordingly.

Certain (NoSQL) database design tools, such as *Hackolade* and *erwin*, also implement schema reverse engineering, and certain NoSQL database systems (for example MongoDB) come with similar features built-in.

Schema inference from existing data is also one of the subtasks in data lake analytics [29]. In data lakes, the "load-first, schema-later" paradigm requires a combination of schema inference with the inference of integrity constraints [12, 14, 30, 31], and further descriptions of the data content, such as the semantic data type [19]. Data cleaning methods are also based on reverse engineering of structure and frequencies of occurrence [32, 38].

c) Reverse Engineering from Code. Since the application code implicitly declares a schema, this schema may be extracted. This task is straightforward when applications use Object-NoSQL mapper libraries, since class declarations then map to collections of persisted entities. This approach is followed in [34, 39]. For application code without mapper libraries, we need to resort to more involved code analysis. For instance, in programmatically extracting a schema for collection `people` from the code in Figure 1, we might employ data flow analysis, as done in [49], to detect which statements characterize a collection.

3.2.2 *The Big Picture.*

Figure 2 gives an overview of NoSQL schema (evolution) management and data migration, which will accompany us through the entire tutorial. The left part of the figure visualizes the approaches of forward engineering and reverse engineering discussed so far (top-down vs. bottom-up).

If we want to consider not only a static view of the schema, but also its evolution along with the application code (illustrated by application versions n and $n + 1$ in the upper part, and two different versions of the database instance at two different times, in the lower part of Figure 2), new challenges arise. In our tutorial, we next discuss challenges and solutions for handling data in co-existing schema versions, especially schema evolution operations (represented by the right arrow in the center of the figure), as well as approaches for extracting not only a schema, but to also identifying different schema versions.

In the fourth part of the tutorial we then discuss various data migration strategies (symbolized by the self-referencing arrow on the bottom right of Figure 2).

3.3 NoSQL Schema Evolution Management

Handling different versions of data in a single database is becoming more and more important – in relational databases [3, 16, 42] as well as for different types of NoSQL databases [6, 40]. In this tutorial, we survey different approaches.

NoSQL Evolution Language. Most NoSQL database management systems do not provide a language capturing schema evolution operations. There are several proposals for such a language. For instance, the authors of [41] define a language originally for transformation between different NoSQL databases that can also be used for data migration within the same store [15]. In this tutorial, we present the NoSQL schema evolution language introduced in [40] for different types of NoSQL database systems, implemented in [45] and extended in [18] for multi-model data. The language contains operations that affect only one entity-type, or synonymously in MongoDB terminology, one collection (*single-type* operations are *add*, *delete*, and *rename*). For complex refactoring, operations that affect the entities of more than one entity type (*multi-type* operations *copy*, *move*, *split*, and *merge*) are available. Via these schema evolution operations (or schema modification operations by the terminology of [9]), the schema changes between consecutive versions of the application code can be declared. This mapping is sketched by the red arrow in the center of Figure 2.

Heterogeneity Classes. We capture the degree of structural heterogeneity in a data instance via the notion of heterogeneity classes, introduced in [27]. For example, persisted entities may be very homogeneous in their structure, or very heterogeneous. We outline the implications, present illustrative examples, and define the class-specific semantics of evolution operations.

Schema-Versions-on-Read. Whereas the *schema overview* presented in the second part of the tutorial delivers information on structures, data types, nesting of information, as well as information on required and optional parts, it does not capture the structural changes over time. For this reason, we present a further method, developed for inferring schema versions, as well as the changes between consecutive versions [21, 44]. Approaches for extracting *schema-versions-on-read* are based on a partial order of the data, e.g. based on timestamps. Besides schema inference, we can use the partial order to find out when and how structural information has changed and derive schema versions accordingly. Applying additional information on integrity constraints, we also can suggest evolution operations that have caused the schema changes [21]. To our knowledge, this functionality is not yet offered by any commercial products, but primarily implemented in research prototypes, e.g., [7, 35] for representing UML class model versions, and [21, 45] for generating JSON Schema versions as well as the matching evolution operations.

3.4 Data Migration

After identifying the schema evolution operations, the data can be migrated. There are various strategies, with different impacts on latency and migration effort. Traditionally, data migration is carried out *eagerly*, i.e., all data is migrated immediately when the schema changes. Since this can be expensive, especially in a cloud environment [11, 17], data can be migrated *lazily* [23, 37], so data is not migrated until it is actually accessed. This approach is preferable in databases where the share of "hot" data is relatively small compared to the total amount of data. The downside is that lazy migration adds latency to database reads and writes, since the data might still have to be migrated. Figure 3 visualizes the conflicting goals of monetary data migration costs (e.g., charged by a cloud provider) and latency overhead upon read or write access, for different migration strategies.

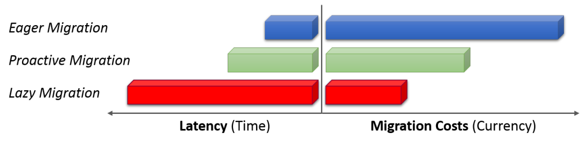

Figure 3: Tradeoffs in data migration (from [17]).

A compromise between the two competing goals is to migrate hot data *proactively* (one of the options in Figure 3). In [23] and [17], different proactive strategies are presented. Depending on the characteristics of the data, the workload, and the schema evolution operations, predictively migrating data promises good latency at moderate costs. In the tutorial, we give a detailed overview over such strategies and their tradeoffs. Further we discuss optimizations, such as the version jumps suggested in [23, 46]. In [17], we propose a first tool providing decision support for the challenge of choosing between migration strategies.

In addition to the impact on costs and latency, it should be noted that for all strategies except eager, the database system or the external schema management component must support *query rewriting*, since data may exist in previous (older) versions and therefore with a different structure than expected by the query [16, 28]. Depending on the heterogeneity class (c.f. Section 3.3), there are additional challenges to query rewriting [27].

In some cases, a *no migration* approach may be necessary, when auditing requires that datasets are preserved in their original version. Then, when an entity in a legacy version is accessed, we may migrate it lazily, but we preserve the original entity.

3.5 Future Opportunities

We finally discuss selected research opportunities related to NoSQL schema evolution and data migration.

Cost Models. For choosing an appropriate data migration strategy, appropriate cost models are needed. These cost models must take into account the characteristics of NoSQL database systems such as distribution, replication, the consistency concepts. A related challenge is the design of a suitable benchmark.

Multi-Model Data. Multi-model database systems like OrientDB, ArangoDB, and Cosmos DB[11] support more than one data model [24]. Similarly, polystores [10, 47] pose new challenges in our context. As we outline in [18], evolution in multi-model databases triggers further research questions, such as inter-model operations, the handling of global vs. local evolution operations, inference of multi-model schemas, and synchronizing migration over different models/systems.

4 INTENDED AUDIENCE AND MATERIAL

Our goal is to give EDBT attendees an overview of the challenges and the current state-of-the-art in both research and practice on NoSQL schema evolution and data migration. We will not assume any background in NoSQL database systems, making our tutorial appropriate for researchers, practitioners, and graduate students.

The material is available at https://tinyurl.com/evolving-nosql.

5 BIOGRAPHIES

ABSTRACT

A number of extensions to the classical notion of functional dependencies have been proposed to express and enforce application semantics. One of these extensions is that of order dependencies (ODs), which express rules involving order. The article entitled "Discovering Order Dependencies through Order Compatibility" by Consonni et al., published in the EDBT conference proceedings in March 2019, investigates the OD discovery problem. The authors claim to prove that their OD discovery algorithm, OCDDISCOVER, is *complete*, as well as being significantly more efficient in practice than the state-of-the-art. They further claim that the implementation of the existing FASTOD algorithm (ours)—we shared our code base with the authors—which they benchmark against is flawed, as OCDDISCOVER and FASTOD report different sets of ODs over the same data sets.

In this rebuttal, we show that their claim of completeness is, in fact, *not* true. OCDDISCOVER's pruning rules are overly aggressive, and prune parts of the search space that contain legitimate ODs. This is the reason their approach appears to be "faster" in practice. Finally, we show that Consonni et al. misinterpret our set-based canonical form for ODs, leading to an incorrect claim that our FASTOD implementation has an error.

1 INTRODUCTION

Integrity constraints specify the intended semantics of dataset attributes. They are commonly used in a number of application areas, such as schema design, data integration, data cleaning, and query optimization [2]. Past work focused primarily on *functional dependencies* (FDs). In recent years, several extensions to the notion of an FD have been studied, including that of *order dependencies* (ODs) [3, 5–8, 10]. FDs cannot capture relationships among attributes with naturally *ordered* domains, such as over timestamps, numbers, and strings, which are common in business data [9]. For example, consider Table 1, which shows employee tax records in which `tax` is calculated as a `percentage` of `salary`. Both `tax` and `percentage` are non-decreasing with `salary`.

Order dependencies naturally express such semantics. For a second example from Table 1, the OD <`salary` *orders* `group`, `subgroup`> holds. When the table is sorted by `salary`, it is also then sorted by `group` (with ties broken by `subgroup`). However, <`salary` *orders* `subgroup`, `group`> does *not* hold. This illustrates that the *order* in which attributes appear in the OD matters.

Table 1: Table with employee information.

#	ID	yr	posit	bin	sal	perc	tax	grp	subg
t1	10	19	secr	1	5K	20%	1K	A	III
t2	11	19	mngr	2	8K	25%	2K	C	II
t3	12	19	direct	3	10K	30%	3K	D	I
t4	10	18	secr	1	4.5K	20%	0.9K	A	III
t5	11	18	mngr	2	6K	25%	1.5K	C	I
t6	12	18	direct	3	8K	25%	2K	C	II

The theory of order dependencies subsumes that of functional dependencies. Any FD can be *mapped* to an equivalent OD by prefixing the left-hand-side attributes onto the right-hand side [8, 10]. For example, if `salary` *functionally determines* `tax`, then `salary` *orders* `salary, tax`.

The purpose of this article is to refute the following claims in Consonni et al. [3].

(1) The authors present a definition of *minimality* for order compatibility dependencies (OCDs). An OCD is a more specific form of order dependency in which two lists of attributes order each other, when taken together [8]. They claim that their definition of minimality is *complete*; that is, from it, one can recover all valid OCDs that hold over a given table.
(2) Given their definition of minimal OCDs, Consonni et al. [3] propose an algorithm to *discover* ODs via OCDs, which has factorial complexity in the number of attributes. They claim to prove that their algorithm produces a canonically *complete* set of ODs. (That is, a *minimal* set of ODs with respect to their definition, from which all the ODs which hold over the data could purportedly be inferred.)
(3) The authors claim that their experimental evaluation illustrates an *error* in our *implementation* of OD discovery algorithm (FASTOD) [6, 7], which leads to discovering many additional—and, purportedly, incorrect—dependencies. In spite of this claim of an "implementation error" in the FASTOD implementation that we provided them, they support via benchmark experiments that their algorithm, OCDDISCOVER, outperforms our algorithm, FASTOD.

We show that each of these three claims is incorrect, in turn.

(1) The definition of minimality in Consonni et al. [3]—insofar as its intended purpose is a *canonical* form—is incorrect. Their "canonical" form does not allow for the inference of *all* OCDs. It misses an important subclass of OCDs (and, respectively, ODs), any dependency which has a common prefix on the *left* and *right* (that is, repeated attributes at the beginning of the dependency).

(2) The claim of completeness of the OD discovery algorithm in Consonni et al. [3] is incorrect, as it relies upon their incorrect notion of "minimal" OCDs. Their conjecture that their algorithm is complete is incorrect; it is incomplete.
(3) Consonni et al. [3] misinterpret our set-based canonical form for ODs [6, 7] (which is equivalent to the list-based canonical form for ODs). This leads the authors to confuse set-based OCDs with ODs. Their claim that our implementation has an error arises from this, and their belief that their approach is complete. Consonni et al. [3] conclude that their algorithm is faster in practice, despite being significantly worse in asymptotic complexity. This arises in their benchmark experiments, however, due to the fact that their algorithm is incomplete.

In Section 2, we provide basic definitions and canonical forms for ODs. In Section 3, we analyze the completeness of OD discovery. In Section 4, we discuss the experimental evaluation conducted by Consonni et al. [3]. We conclude in Section 5.

2 FOUNDATIONS

2.1 Background

We use the following notational conventions.

Table 2: Notational conventions.

- **Relations. R** denotes a *relation schema* and **r** denotes a specific *table* instance. Letters from the beginning of the alphabet, A, B and C, denote single *attributes*. Additionally, t and s denote *tuples*, and t_{A} denotes the value of an attribute A in a tuple t.
- **Sets.** Letters from the end of the alphabet, $\mathcal{X}$, $\mathcal{Y}$ and $\mathcal{Z}$, denote *sets* of attributes. Also, $t_{\mathcal{X}}$ denotes the *projection* of a tuple t on $\mathcal{X}$. $\mathcal{XY}$ is shorthand for $\mathcal{X} \cup \mathcal{Y}$. The empty set of attributes is denoted as $\{\}$.
- **Lists. X**, **Y** and **Z** denote *lists*. The empty list of attributes is represented as [ ]. List $[\mathsf{A}, \mathsf{B}, \mathsf{C}]$ denotes an explicit list. $[\mathsf{A} \mid \mathbf{T}]$ denotes a list with the *head* A and the *tail* **T**. **XY** is shorthand for **X** concatenate **Y**. Set $\mathcal{X}$ denotes the *set* of elements in *list* **X**. $\mathbf{X}^p$ denotes any arbitrary permutation of list **X** or set $\mathcal{X}$. Given a set of attributes $\mathcal{X}$, for brevity, we state $\forall i$, X_i to indicate indices $[1, ..., i]$ that have valid ranges ($i \leq |\mathcal{X}|$).

We provide a summary of the relevant definitions. The operator '$\preceq_{\mathbf{X}}$' defines a *weak total order* over any set of tuples, where **X** denotes a list of attributes. Unless otherwise specified, numbers are ordered numerically, strings are ordered lexicographically and dates are ordered chronologically.

Definition 2.1. [6, 7] Let **X** be a list of attributes. For two tuples t and s, $\mathcal{X} \in \mathbf{R}$, $t \preceq_{\mathbf{X}} s$ if[1]
– $\mathbf{X} = [\,]$; or
– $\mathbf{X} = [\mathsf{A} \mid \mathbf{T}]$ and $t_{\mathsf{A}} < s_{\mathsf{A}}$; or
– $\mathbf{X} = [\mathsf{A} \mid \mathbf{T}]$, $t_{\mathsf{A}} = s_{\mathsf{A}}$, and $t \preceq_{\mathbf{T}} s$.
Let $t \prec_{\mathbf{X}} s$ if $t \preceq_{\mathbf{X}} s$ but $s \not\preceq_{\mathbf{X}} t$.

Next, we define order dependencies.

Definition 2.2. [3, 5–8, 10] Let **X** and **Y** be lists of attributes over a relation schema **R**. Table **r** over **R** *satisfies* an OD $\mathbf{X} \mapsto \mathbf{Y}$ ($\mathbf{r} \models \mathbf{X} \mapsto \mathbf{Y}$), read as **X** *orders* **Y**, if for all $t, s \in \mathbf{r}$, $t \preceq_{\mathbf{X}} s$ implies $t \preceq_{\mathbf{Y}} s$. $\mathbf{X} \mapsto \mathbf{Y}$ is said to *hold* for **R** ($\mathbf{R} \models \mathbf{X} \mapsto \mathbf{Y}$) if, for each admissible table instance **r** of **R**, table **r** satisfies $\mathbf{X} \mapsto \mathbf{Y}$. $\mathbf{X} \mapsto \mathbf{Y}$ is *trivial* if, for all **r**, $\mathbf{r} \models \mathbf{X} \mapsto \mathbf{Y}$. $\mathbf{X} \leftrightarrow \mathbf{Y}$, read as **X** and **Y** are *order equivalent*, if $\mathbf{X} \mapsto \mathbf{Y}$ and $\mathbf{Y} \mapsto \mathbf{X}$.

[1] By some conventions, "*iff*"—"if and only if—would be used here. The intent, in any case, is that the use of "if" defines completely the notion.

The OD $\mathbf{X} \mapsto \mathbf{Y}$ means that **Y** values are monotonically non-decreasing wrt **X** values. Thus, if a list of tuples is ordered by **X**, then it is also ordered by **Y**, but not necessarily vice versa.

Example 2.3. Consider Table 1 in which tax is calculated as a percentage of salary, and tax groups and subgroups are based on salary. Tax, percentage and group are not decreasing with salary. Furthermore, within the same group, subgroup is not decreasing with salary. Finally, within the same year, bin increases with salary. Thus, the following order dependencies hold in that table: [salary] $\mapsto$ [tax], [salary] $\mapsto$ [percentage], [salary] $\mapsto$ [group, subgroup] and [year, salary] $\mapsto$ [year, bin].

Definition 2.4. [3, 5, 8, 10] Two order specifications **X** and **Y** are *order compatible*, denoted as $\mathbf{X} \sim \mathbf{Y}$, if $\mathbf{XY} \leftrightarrow \mathbf{YX}$. ODs in the form of $\mathbf{X} \sim \mathbf{Y}$ are called order compatible dependencies (OCDs)

The empty list of attributes (i.e., [ ]) is order compatible with *any* list of attributes. There is a strong relationship between ODs and FDs. Any OD implies an FD, modulo lists and sets, however, not vice versa.

LEMMA 2.5. [8, 10] If $\mathbf{R} \models \mathbf{X} \mapsto \mathbf{Y}$ (OD), then $\mathbf{R} \models \mathcal{X} \to \mathcal{Y}$ (FD).

Also, there is a correspondence between FDs and ODs.

THEOREM 2.6. [8, 10] $\mathbf{R} \models \mathcal{X} \to \mathcal{Y}$ *iff* $\mathbf{X} \mapsto \mathbf{XY}$, for any list **X** over the attributes of $\mathcal{X}$ and any list **Y** over the attributes of $\mathcal{Y}$.

ODs can be violated in two ways.

THEOREM 2.7. [8, 10] $\mathbf{R} \models \mathbf{X} \mapsto \mathbf{Y}$ (OD) *iff* $\mathbf{R} \models \mathbf{X} \mapsto \mathbf{XY}$ (FD) and $\mathbf{X} \sim \mathbf{Y}$ (OCD).

We are now ready to explain the two sources of OD violations: *splits* and *swaps* [8, 10]. An OD $\mathbf{X} \mapsto \mathbf{Y}$ can be violated in two ways, as per Theorem 2.7.

Definition 2.8. [8, 10] A *split* wrt an OD $\mathbf{X} \mapsto \mathbf{XY}$ (FD) is a pair of tuples s and t such that $s_{\mathcal{X}} = t_{\mathcal{X}}$ but $s_{\mathcal{Y}} \neq t_{\mathcal{Y}}$.

Definition 2.9. [8, 10] A *swap* wrt $\mathbf{X} \sim \mathbf{Y}$ (OCD) is a pair of tuples s and t such that $s \prec_{\mathbf{X}} t$, but $t \prec_{\mathbf{Y}} s$.

Example 2.10. In Table 1, there are three splits with respect to the OD [position] $\mapsto$ [position, salary] because position does not functionally determine salary. The violating tuple pairs are *t1* and *t4*, *t2* and *t5*, and *t3* and *t6*. There is a swap with respect to [salary] $\sim$ [subgroup], e.g., over the pair of tuples *t1* and *t2*.

2.2 Canonical Forms

Consonni et al. [3] use a native list-based canonical form, which is based on decomposing an OD into a FD and an OCD [8, 10]. Recall that based on Theorem 2.7 "OD = FD + OCD", as $\mathbf{X} \mapsto \mathbf{Y}$ *iff* $\mathbf{X} \mapsto \mathbf{XY}$ (FD) and $\mathbf{X} \sim \mathbf{Y}$ (OCD). The authors exploit this relationship to guide their discovery algorithm through order compatibility. Since they use a list-based representation for ODs, this leads to factorial complexity of OD discovery in the number of attributes.

Expressing ODs in a natural way relies on lists of attributes, as in the SQL order-by statement. One might well wonder whether lists are inherently necessary. We provide a polynomial *mapping* of list-based ODs into *equivalent* set-based canonical ODs [6, 7]. The mapping allows us to develop an OD discovery algorithm that traverses a much smaller set-containment lattice (to identify candidates for ODs) rather than the list-containment lattice used in Consonni et al. [3].

Two tuples, t and s, are *equivalent* over a set of attributes $\mathcal{X}$ if $t_{\mathcal{X}} = s_{\mathcal{X}}$. An attribute set $\mathcal{X}$ partitions tuples into *equivalence classes* [4]. We denote the *equivalence class* of a tuple $t \in \mathbf{r}$ over a set $\mathcal{X}$ as $\mathcal{E}(t_{\mathcal{X}})$, i.e., $\mathcal{E}(t_{\mathcal{X}}) = \{s \in \mathbf{r} \mid s_{\mathcal{X}} = t_{\mathcal{X}}\}$. A *partition* of $\mathbf{r}$ over $\mathcal{X}$ is the set of equivalence classes, $\Pi_{\mathcal{X}} = \{\mathcal{E}(t_{\mathcal{X}}) \mid t \in \mathbf{r}\}$. For instance, in Table 1, $\mathcal{E}(t1_{\{\text{year}\}}) = \mathcal{E}(t2_{\{\text{year}\}}) = \mathcal{E}(t3_{\{\text{year}\}}) = \{t1, t2, t3\}$ and $\Pi_{\text{year}} = \{\{t1, t2, t3\}, \{t4, t5, t6\}\}$.

We now present a set-based *canonical form* for ODs.

Definition 2.11. [6, 7] An attribute A is a *constant* within each equivalence class over $\mathcal{X}$, denoted as $\mathcal{X}$: $[\,] \mapsto \mathsf{A}$, if $\mathbf{X}^p \mapsto \mathbf{X}^p\mathsf{A}$. Furthermore, two attributes, A and B, are order-compatible within each equivalence class wrt $\mathcal{X}$, denoted as $\mathcal{X}$: $\mathsf{A} \sim \mathsf{B}$, if $\mathbf{X}^p\mathsf{A} \sim \mathbf{X}^p\mathsf{B}$. ODs of the form of $\mathcal{X}$: $[\,] \mapsto \mathsf{A}$ and $\mathcal{X}$: $\mathsf{A} \sim \mathsf{B}$ are called *(set-based) canonical* ODs, and the set $\mathcal{X}$ is called a *context*.

Example 2.12. In Table 1, the attribute `bin` is a constant in the context of `position` (`posit`) written as {`position`}: $[\,] \mapsto$ `bin`, since $\mathcal{E}(t1_{\{\text{position}\}}) \models [\,] \mapsto$ `bin`, $\mathcal{E}(t2_{\{\text{position}\}}) \models [\,] \mapsto$ `bin` and $\mathcal{E}(t3_{\{\text{position}\}}) \models [\,] \mapsto$ `bin`. Also, there is no swap between `bin` and `salary` in the context of `year`, i.e., {`year`}: `bin` $\sim$ `salary`, since $\mathcal{E}(t1_{\{\text{year}\}}) \models$ `bin` $\sim$ `salary` and $\mathcal{E}(t4_{\{\text{year}\}}) \models$ `bin` $\sim$ `salary`.

Based on Theorem 2.13 and Theorem 2.14, list-based ODs in the form of FDs and OCDs, respectively, can be mapped into equivalent set-based ODs.

THEOREM 2.13. [6, 7] $\mathbf{R} \models \mathbf{X} \mapsto \mathbf{XY}$ *iff* $\forall \mathsf{A} \in \mathbf{Y}, \mathbf{R} \models \mathcal{X}$: $[\,] \mapsto \mathsf{A}$.

THEOREM 2.14. [6, 7] $\mathbf{R} \models \mathbf{X} \sim \mathbf{Y}$ *iff* $\forall i, j, \mathbf{R} \models \{\mathsf{X}_1, .., \mathsf{X}_{i-1}, \mathsf{Y}_1, .., \mathsf{Y}_{j-1}\}$: $\mathsf{X}_i \sim \mathsf{Y}_j$.

A list-based OD can be mapped into an equivalent set of set-based ODs via a polynomial mapping.

THEOREM 2.15. [6, 7] $\mathbf{R} \models \mathbf{X} \mapsto \mathbf{Y}$ *iff* $\forall \mathsf{A} \in \mathbf{Y}, \mathbf{R} \models \mathcal{X}$: $[\,] \mapsto \mathsf{A}$ and $\forall i, j, \mathbf{R} \models \{\mathsf{X}_1, .., \mathsf{X}_{i-1}, \mathsf{Y}_1, .., \mathsf{Y}_{j-1}\}$: $\mathsf{X}_i \sim \mathsf{Y}_j$.

Example 2.16. The OD [AB] $\mapsto$ [CD] can be mapped to the following equivalent canonical ODs: {A, B}: $[\,] \mapsto$ C, {A, B}: $[\,] \mapsto$ D, {}: A $\sim$ C, {A}: B $\sim$ C, {C}: A $\sim$ D, {A, C}: B $\sim$ D.

3 COMPLETENESS ANALYSIS

While the theoretical search space for FASTOD [6, 7] is $O(2^{|\mathbf{R}|})$, the search space for OCDDISCOVER [3] is $O(|\mathbf{R}|!)$, which is much larger as it traverses a lattice of attribute *permutations* (where $|\mathbf{R}|$ denotes the number of attributes over a relational schema $\mathbf{R}$). To mitigate the factorial complexity, the list-based algorithm in Consonni et al. [3] uses pruning rules. We show that, despite the authors' claim that their approach discovers a canonically complete set of ODs, their pruning rules lead to *incompleteness*.

Section 3 in Consonni et al. [3] addresses their completeness "proof" for their OD discovery algorithm. The authors introduce a notion of *minimality* of a set of dependencies which is incorrect. Herein, a set of dependencies is called *minimal*—as it is in previous work on FDs and ODs [4, 6, 7]—if *all* dependencies that logically hold over a relation schema $\mathbf{R}$ can be inferred from this minimal (canonical) set of dependencies.[2] That is, a set of dependencies $\mathcal{M}$ is *minimal* over a table $\mathbf{r}$, if $\{\mathbf{X} \mapsto \mathbf{Y} \mid \mathcal{M} \models \mathbf{X} \mapsto \mathbf{Y}\}$ is equivalent to $\{\mathbf{X} \mapsto \mathbf{Y} \mid \mathbf{r} \models \mathbf{X} \mapsto \mathbf{Y}\}$.

[2]In some previous work [1], minimal dependencies $\mathcal{M}$ also satisfy an additional condition that that no proper subset of $\mathcal{M}$ can be used to infer all dependencies.

Thus, one should be able to infer from a minimal set of dependencies via the inference rules (axioms), $\mathcal{I}$, *all* the dependencies that are valid over the given instance of the table. That is, $\{\mathbf{X} \mapsto \mathbf{Y} \mid \mathcal{M} \vdash_{\mathcal{I}} \mathbf{X} \mapsto \mathbf{Y}\}$ is equal to $\{\mathbf{X} \mapsto \mathbf{Y} \mid \mathbf{r} \models \mathbf{X} \mapsto \mathbf{Y}\}$. Consonni et al. [3] use the set of *sound* and *complete* OD inference rules, $\mathcal{I}$, from [9, 10].

Pruning applied by a dependency discovery algorithm, thus, must respect minimality. This allows for the *implicit* discovery of the full set of valid dependencies, and thus be deemed *complete*.

In [3], an attribute list is minimal if it has no embedded order dependency (the list of attributes is the shortest possible).

Definition 3.1. [3] An attribute list $\mathbf{X}$ is *minimal* if there is no other list of attributes $\mathbf{X}'$ such that:

- $\mathbf{X}'$ is smaller than $\mathbf{X}$, and
- $\mathbf{X} \leftrightarrow \mathbf{X}'$

Example 3.2. [A, B, A] is *not* minimal as [A, B, A] $\leftrightarrow$ [A, B].

It follows then that an OCD is minimal in [3] *if and only if* there are no repeated attributes in the OCD. That is, there are no repeated attributes within the *left* or within the *right* list of the minimal OCD, as each is a minimal attribute list, *and* there is no repeated attribute between *left* and *right*.

Definition 3.3. [3] An OCD $\mathbf{X} \sim \mathbf{Y}$ is *minimal* if

- $\mathbf{X}$ and $\mathbf{Y}$ are minimal attribute lists *and*
- $\mathcal{X} \cap \mathcal{Y} = \emptyset$.

Definition 3.3 of *minimality* with no permitted repeated attributes is at the heart of the incompleteness problem of [3], as it does not allow for the inference of all dependencies that are valid over the given table. Theorem 3.4 states this, that an OCD with a common prefix between *left* and *right* (repeated attributes) can hold over a table, while no OCD without repeated attributes holds. Our proof of Theorem 3.4 is by offering a counter-example to the completeness premise in [3].

THEOREM 3.4. $\mathbf{R} \not\models \mathbf{Y} \sim \mathbf{Z}$, $\mathbf{R} \not\models \mathbf{XY} \sim \mathbf{Z}$ and $\mathbf{R} \not\models \mathbf{Y} \sim \mathbf{XZ}$ do not imply $\mathbf{R} \not\models \mathbf{XY} \sim \mathbf{XZ}$

Proof

It suffices to construct a table in which the OCD of the form

- $\mathbf{XY} \sim \mathbf{XZ}$

holds, but OCDs

- $\mathbf{Y} \sim \mathbf{Z}$,
- $\mathbf{XY} \sim \mathbf{Z}$, and
- $\mathbf{Y} \sim \mathbf{XZ}$

do not.

Consider Table 3 constructed over attributes A, B and C. In Table 3, the OCD [A, B] $\sim$ [A, C] holds, but [B] $\sim$ [C], [AB] $\sim$ [C], and [B] $\sim$ [AC] do not. □

In [3], the authors only show—as is stated in Theorem 3.5 below—that OCDs of the form $\mathbf{XY} \sim \mathbf{XZ}$ can be derived from $\mathbf{Y} \sim \mathbf{Z}$ (Theorem 3.5 via Theorem 3.10 in [3]).

THEOREM 3.5. [3] If $\mathbf{R} \models \mathbf{Y} \sim \mathbf{Z}$, then $\mathbf{R} \models \mathbf{XY} \sim \mathbf{XZ}$

Theorem 3.5 in [3] is *true*. The flaw in the authors' logic is that this theorem proves only *one* direction (the "if" of an intended "if and only if"). The "only if" (not proved by the theorem) is implicitly assumed as *true*, while it assuredly is not. It follows that their claim of canonical completeness for their definition of minimal OCDs is incorrect (Section 3.3 in [3]). OCDs with common prefixes between their *left* and *right* attribute lists are *not* redundant, by Theorem 3.4. This leads to an *incomplete* approach for OD

Table 3: Incompleteness of OCDDISCOVER [3].

#	A	B	C

t2	1	1	0
t3	2	3	2
t4	3	2	3

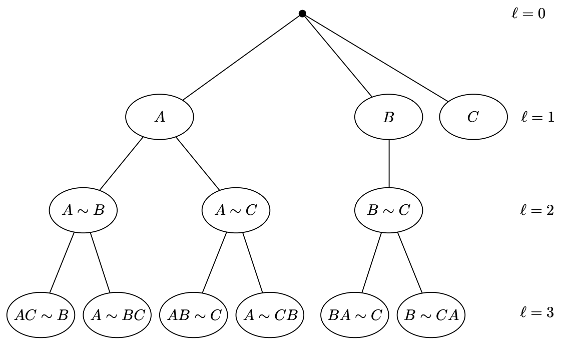

Figure 1: Lattice permutation tree for OCDDISCOVER [3].

discovery, as the recovery of the full set of valid dependencies is not possible.

Details of the OD discovery algorithm, OCDDISCOVER, by Consonni et al. [3] are presented in their Section 4. Let $\mathcal{U}$ be a set of attributes over a relation schema **R**. In the first level of the lattice, they generate candidates of the form $\mathsf{A} \sim \mathsf{B}$, where $\mathsf{A}, \mathsf{B} \in \mathcal{U}$ and $\mathsf{A} \neq \mathsf{B}$. (An OCD $\mathsf{B} \sim \mathsf{A}$ is not generated as it is equivalent to $\mathsf{A} \sim \mathsf{B}$.) At each level of the lattice (Fig. 1), if the candidate $\mathbf{X} \sim \mathbf{Y}$ is order compatible, they generate dependencies for the next level of the lattice. For each attribute not already present in the OCD, for each attribute $\mathsf{A} \in \mathcal{U} \setminus \{\mathcal{X} \cup \mathcal{Y}\}$, they add it to the right of each attribute list; i.e., $\mathbf{X}\mathsf{A} \sim \mathbf{Y}$ and $\mathbf{X} \sim \mathbf{Y}\mathsf{A}$. Thus, important OCDs with repeated attributes in a common prefix are never considered (as is consistent with their incorrect definition of minimality for OCDs). For example, an OCD [`year`, `month`] $\sim$ [`year`, `week`] would be missed. As a consequence, the authors do not discover ODs with repeated attributes, such as [`year`, `salary`] $\mapsto$ [`year`, `bin`] (recall Table 1).

In contrast, our FASTOD algorithm [6, 7] is *complete* for OD discovery. It does not miss dependencies with common prefixes. This is because the algorithm considers as candidates dependencies of the set-based form: OCD $\{\mathcal{X}\}$: $\mathsf{A} \sim \mathsf{B}$. This is built into the *context* of the set-based notation used in [6, 7], and cannot be missed when using this representation (see Theorem 2.14). Thus, dependencies with common prefixes are considered.

4 EXPERIMENTAL ANALYSIS

We demonstrate that the experimental analysis in Consonni et al. [3] that compares their OD discovery algorithm, OCDDISCOVER, with ours, FASTOD [6, 7], is incorrect. The authors misinterpret the set-based canonical representation for ODs as introduced in [6, 7] and as used in FASTOD. They conflate OCDs and ODs as we report them when evaluating the results. In [6, 7], we quantify the numbers of found FDs and OCDs. In [3], they incorrectly report these as the FDs and ODs, respectively, that we found. This occurs in their Table 6, where, for instance, they report 400 ODs and 89,571 FDs found by FASTOD, whereas this should be 400 OCDs and 89,571 FDs, respectively.

Table 4: Correctness of implementation for FASTOD [6].

#	A	B	C	D
t1	1	3	1	1
t2	2	3	3	2
t3	2	3	2	2
t4	2	5	2	2
t5	3	1	2	3
t6	4	4	4	2
t7	4	5	3	2

As a consequence of this misunderstanding of the set-based canonical representation for ODs [6, 7], the authors in [3] claim that the implementation of FASTOD finds ODs that are not present in the data. As an example of this, they provide the OD [B] $\mapsto$ [A, C] over Table 4 [3]. However, the FASTOD algorithm implementation in question finds the following ODs with respect to Table 4, where clearly the OD [B] $\mapsto$ [A, C] is not present.

(1) OCD {D}: A $\sim$ C
(2) OCD {C}: A $\sim$ D
(3) FD {A}:[ ] $\mapsto$ D
(4) OCD {B}: A $\sim$ D
(5) OCD {B}: C $\sim$ D
(6) OCD {B}: A $\sim$ C
(7) FD {B, C}:[ ] $\mapsto$ D
(8) FD {B, C}:[ ] $\mapsto$ A
(9) FD {A, B}:[ ] $\mapsto$ C
(10) OCD {C, D}: A $\sim$ B

The authors confuse the OCD {B}: A $\sim$ C with the OD [B] $\mapsto$ [A, C]. Consequently, they falsely assert that the reason the number of ODs found by OCDDISCOVER and FASTOD differ is due to an error in the implementation of FASTOD that we provided them.[3] The real reason that the number of reported dependencies differ, however, is, that OCDDISCOVER [3] is *incomplete*. The claim that they outperform the state-of-art despite a much worse asymptotic complexity, when tested in practice on real datasets, is invalid.

The authors in Consonni et al. [3] also state that FASTOD considers all columns to be of type string, while their code also considers real and integer numbers. While a minor point, we wish to clarify that the implementation we sent the authors does discover ODs over data types including real and integer numbers. The dependencies 1–10 reported in Table 4 remain the same, regardless of using numerical or string data type, given that the values are in the range of 1 to 5.

5 CONCLUSIONS

In this article, we have conducted a detailed analysis of the correctness of the results in the recent article by Consonni et al. [3] concerning the order dependency discovery problem. We have shown that, for the main claimed results related to the OD discovery problem, there are fundamental errors and omissions in the proof or experiments.

[3]While Consonni et al. [3] state that they were not able to isolate and resolve the root cause of what they felt was incorrect behavior in the implementation of FASTOD (which we had provided to them at their request for "ensuring fairness and reproducibility"), they never contacted us to help resolve it.
