Foreword

The International Conference on Extending Database Technology (EDBT) is a leading international forum for database researchers, developers, and users to present and discuss novel and cutting-edge ideas and techniques, and to showcase tools and experiences related to data management. Data management is an essential enabling technology that has applications in several scientific, business and social communities, and runs on diverse technical platforms associated with the web, enterprises, clouds and mobile devices. The database community has a continuing tradition of contributing with models, algorithms and architectures to the set of tools and applications that enable day-to-day functioning of our societies. Faced with the broad challenges of today's applications, data management technology constantly broadens its reach, exploiting new hardware and software to achieve innovative results and embracing new challenges in the years to come.

EDBT 2020 solicited submissions of original research contributions, descriptions of industrial solutions and applications, and proposals for tutorials and software demonstrations. We encouraged submissions of research papers related to all aspects of data management. We also encouraged submissions of visionary papers as well as innovative system papers and experimental analyses papers. In addition to long research paper submissions, EDBT 2020 again encouraged the submission of short research papers, which provide an excellent opportunity to describe significant work or research in progress that can foster the discussions at the conference. Short papers are presented as posters at plenary poster sessions of the conference. This year, they will also be communicated at a plenary lightning talks session.

The program committees of EDBT accepted 30 out of 151 submitted regular research papers, resulting in an acceptance rate of 20% for the research track; 26 out of 85 submitted short research papers, resulting in an acceptance rate of 31% for short research papers; 16 out of 37 demos, resulting in an acceptance rate of 43% for the demonstration track; and 10 out of 37 industrial and application papers, resulting in an acceptance rate of 27% for industrial and application papers. The papers will be presented in eight research paper sessions, three industrial and application sessions, as well as two plenary poster and demonstration sessions.

The program additionally features five workshops, one of which is the well-established DOLAP workshop that has successfully been co-located with EDBT since many years. Finally, the conference program includes four tutorials and an EDBT and ICDT joint session on climate change.

I would like to thank all authors for their contributions: a successful conference crucially depends on high-quality submissions. I also would like to thank all senior reviewers and reviewers for serving on the EDBT 2020 program committee, in particular for the high quality and timely handling of all reviews and discussions. This community service requires a lot of work on a tight schedule, and is what makes our research community function and ensures the sustained impact of our research. Thanks to their valuable effort we can look forward to an exciting program and attractive EDBT conference in Copenhagen from March 30–April 2, 2020.

A warm thanks to Anastasia Alaimaki and Tamer Özsu for serving on the Test-of-Time Award committee to select the paper from EDBT 2010 that has had the most lasting influence. Wook-shin Han, Erhard Rahm and Nesime Tatbul generously accepted to serve on the Best Paper committee. The EDBT 2020 program is the result of the joint effort of many people who shared their experience and time to contribute to the EDBT 2020 program and make the conference a great success. Alexander Boehm served as PC chair for industrial and application papers; George Fletcher as PC chair for the demonstration track; Dan Olteanu as tutorial chair; Alexandra Poulovassilis as workshop chair. My warmest thanks to all these people. The general chairs, Yongluan Zhou and Marcos Vaz Salles and the other local organizers worked hard to make all necessary arrangements for a successful event. Special thanks to Arijt Khan, the EDBT proceedings chair; Davide Mottin, the publicity chair; Bin Yang, the local executive chair; Boris Düdder, the sponsorship chair; Nanna Højholt, the finance chair and Yiwen Wang, the website chair, for tirelessly finding solutions for all our requests. Norman Paton was most helpful in advising and coordinating with the EDBT Executive Board. Last but not least, I would like to thank Marc H. Scholl for assembling the EDBT proceedings on openproceedings.org I hope that you find EDBT 2020 inspiring, enriching, and enjoyable and look forward to meeting you in Copenhagen.

Test-of-Time Award

Established in 2014, the Test-of-Time Award awarded by the Extended Database Technology (EDBT) Conference recognizes papers presented at EDBT Conferences that have had the most impact in terms of research, methodology, conceptual contribution, or transfer to practice over the past ten years.
The EDBT 2020 Test of Time Award committee was formed by Anastasia Ailamaki (Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland), Tamer Oszu (University of Waterloo, Canada), and Angela Bonifati (Lyon 1 University, France).

After careful consideration, the committee has decided to select the following paper from the EDBT 2010 conference as the EDBT ToT Award winner for 2020:

Optimizing joins in a map-reduce environment

by Foto Afrati and Jeff Ullman

published in EDBT 2010 Proceedings, pp. 99–110, DOI: 10.1145/1739041.1739056.

This paper presented optimization strategies for executing multi-way joins in a map-reduce environment. It focused on large-scale data and provided algorithms to choose the number of map-keys and shares in order to minimize the communication cost among the map and reduce processes.
The committee members agreed that this paper clearly pioneered the field of join processing in map-reduce environments. It has triggered substantial follow-up research and impact on big data processing in parallel and distributed architectures.

The EDBT Test-of-Time award for 2020 will be presented during the EDBT/ICDT 2020 Conference in Copenhagen, Denmark, as part of the Awards session on March 31, 2020.

Best Paper Award

The EDBT 2020 Best Paper Award committee was formed by Wook-shin Han (Postech, Korea), Erhard Rahm (University of Leipzig, Germany), Nesime Tatbul (Intel & MIT, USA), and Angela Bonifati (Lyon 1 University, France). After careful consideration, the committee has decided to select the following paper as the EDBT Best Paper for 2020:

Provenance for Probabilistic Logic Programs

by Shaobo Wang, Hui Lyu, Jaichi Zhang, Chenyuan Wu, Xinyi,Chen, Wenchao,Zhou, Boon Thau Loo, Susan B. Davidson, Chen Chen.

DOI: 10.5441/002/edbt.2020.14

Abstract: Despite the emergence of probabilistic logic programming (PLP) languages for data driven applications, there are currently no debugging tools based on provenance for PLP programs. In this paper, we propose a novel provenance model and system, called P3 (Provenance for Probabilistic logic Programs) for analyzing PLP programs. P3 enables four types of provenance queries: tra- ditional explanation queries, queries for finding the set of most important derivations within an approximate error, top-K most influential queries, and modification queries that enable us to modify tuple probabilities with fewest modifications to program or input data. We apply these queries into real-world scenar- ios and present theoretical analysis and practical algorithms for such queries. We have developed a prototype of P3, and our evaluation on real-world data demonstrates that the system can support a wide-range of provenance queries with explainable results. Moreover, the system maintains provenance and execute queries efficiently with low overhead.

The EDBT Best Paper Awards for 2020 will be presented during the EDBT/ICDT 2020 Conference in Copenhagen, Denmark, as part of the Awards session on March 31, 2020.

ABSTRACT

With the mind-blowing development of REST (REpresentational State Transfer) APIs (Application Programming Interfaces), many applications have been designed to harness their potential. As such, bots have recently become interesting interfaces to connect humans to APIs. Supervised approaches for building bots rely upon a large set of user utterances paired with API methods. Collecting such pairs is typically done by obtaining initial utterances for a given API method and paraphrasing them to obtain new variations. However, existing approaches for generating initial utterances (e.g., creating sentence templates) do not scale and are domain-specific, making bots expensive to maintain. The automatic generation of initial utterances can be considered as a supervised translation task in which an API method is translated into an utterance. However, the key challenge is the lack of training data for training domain-independent models. In this paper, we propose *API2CAN*, a dataset containing 14,370 pairs of API methods and utterances. The dataset is built by processing a large number of public APIs. However, deep-learning-based approaches such as sequence-to-sequence models require larger sets of training samples (ideally millions of samples). To mitigate the absence of such large datasets, we formalize and define resources in REST APIs, and we propose a delexicalization technique (by converting an API method and initial utterances to tagged sequences of resources) to let deep-learning-based approaches learn from such datasets.

1 INTRODUCTION

Much of the information we receive about the world is API-regulated. Essentially, APIs are used for connecting devices, managing data, and invoking services [1–3]. In particular, because of its simplicity, REST is the most dominant approach for designing Web APIs [4–6]. Meanwhile, thanks to the advances in machine learning and availability of web services, building natural language interfaces has gained attention by both researchers and organizations (e.g., Apple's Siri, Google's Virtual Assistant, IBM's Watson, Microsoft's Cortana). Natural language interfaces and virtual assistants serve a wide range of tasks by mapping user utterances (also called user expressions) into appropriate operations. Examples include reporting weather, booking flights, controlling home devices, and querying databases [1, 7–9]. Increasingly, organizations have started or plan to use capabilities arising from advances in cognitive computing to increase productivity, automate business processes, and extend the breadth of their business offering.

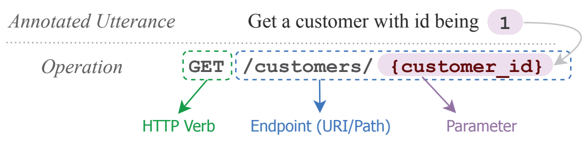
GET /customers/{customer_id}
get the first customer

Figure 1: Classical Training Data Generation Pipeline

To serve users' requests, virtual assistants often employ supervised models which require a large set of natural language utterances (e.g., *"get a customer with id being 1"*) paired with their corresponding executable forms (e.g., SQL queries, API calls, logical forms). The training pairs are used to learn the mappings between user utterances and executable forms. Given the popularity of REST APIs (based on the well-known HTTP protocol), we focus on one of the most common types of executable forms called *operations*. In REST APIs, an operation (also called API method) consists of an HTTP verb (e.g., GET, POST), an endpoint (e.g., `/customers`), and a set of parameters[1] (e.g., query parameters). Figure 2 shows different parts of a REST request in HTTP.

An annotated utterance is a corresponding natural language expression to an operation in which API parameters are labeled:



As shown in Figure 1, collecting such pairs is typically done in two steps: (i) obtaining initial utterances for each operation; and (ii) paraphrasing the initial utterances either automatically or manually (e.g., crowdsourcing) to new variations in order to live up to the richness in human languages [1, 7, 8]. Paraphrasing approaches (e.g., crowdsourcing, automatic paraphrasing systems) have made the second step less costly [7, 8, 10], but existing approaches for generating the initial sentences are still limited, and they are not scalable [8].

Existing solutions for generating initial utterances (also called canonical utterances) often involve employing domain experts to generate hand-crafted domain-specific grammars or templates [1, 8, 11]. Almond virtual assistant, as an example, relies on hand-crafted rules to generate initial utterances [8]. Such approaches

[1]In this paper, to show parameters of an operation, we use curly brackets with two parts separated by semicolon (e.g., {customer_id:1}): the first part gives the name of the parameter and the second part indicates a sample value for the parameter

Figure 2: Example of an HTTP POST Request

are domain-specific and costly since rules are generated by experts [1, 8, 11]. In other words, adding new APIs to a particular virtual assistant requires manual efforts for revising hand-crafted grammars to generate training samples for new domains. With the growing number of APIs and modifications of existing APIs, automated bot development has become paramount, especially for virtual assistants which aim at servicing a wide range of tasks [1, 8].

Supervised approaches such as sequence-to-sequence models can be used for translating *operations* to *canonical utterances*. However, the key challenge is the lack of training data (pairs of operations and canonical utterances) for training domain-independent models. In this paper, we propose *API2CAN*, a dataset containing 14,370 pairs of operations and canonical utterances. The dataset is generated automatically by processing a large set of OpenAPI specifications[2] (based on the description/summary of each operation). However, deep-learning-based approaches such as sequence-to-sequence models require much larger sets of samples to train from (ideally millions of training samples). That is to say, sequence-to-sequence models are easy to overfit small training datasets, and issues such as out of vocabulary words (OOV) can negatively impact their performance. To overcome such issues, we propose a delexicalization technique to convert an operation to a sequence of predefined tags (e.g., singleton, collection) based on RESTful principles and design guidelines (e.g., use of plural names for a collection of resources, using HTTP verbs). In summary, our contribution is three-folded:

- **A Dataset.** We propose a dataset called *API2CAN*, containing annotated canonical templates (a canonical utterance in which parameter values have been replaced with placeholders e.g., *"get a customer with id being «id»"*) for 14,370 operations of 985 REST APIs. We automatically built the dataset by processing a large set of OpenAPI specifications, and we converted operation descriptions to canonical templates based on a set of heuristics (e.g., extracting a candidate sentence, injecting parameter placeholders in the method descriptions, removing unnecessary words). We then split the dataset into three parts (test, train, and validation sets).
- **A Delexicalization Technique.** Deep-learning algorithms such as sequence-to-sequence models require millions of training pairs to learn from. To assist such models to learn from smaller datasets, we propose a delexicalization technique to convert input (operation) and output (canonical template) of such models to a sequence of predefined tags called *resource identifiers*. The proposed approach is based on the concept of *resource* in RESTful design. Particularly, we formalize various kinds of resources (e.g., collection, singleton) in REST APIs. Next, using the identified resource types, we propose a delexicalization technique to replace mentions of each *resource* (e.g., customers) with a corresponding resource identifier (e.g., Collection_1). As such, for a given operation (e.g., `GET /customers/{customer_id}`), the model learns to translate the delexicalized operation (e.g., `GET Collection_1 Singleton_1`) to a delexicalized canonical templates (e.g., "get a Collection_1 with Singleton_1 being «Singleton_1»"). A resource identifier consists of two parts: (1) the type of resource and (2) a number n which indicates n-th occurrence of a resource type in a given operation. Resource identifiers are then used in time of translation to lexicalize the output of the sequence-to-sequence model (e.g., "get a Collection_1 with Singleton_1 being «Singleton_1»") to generate a canonical template (e.g., "get a customer with customer id being «customer_id»"). Delexicalization is done to reduce the impact of OOV and force the model to learn the pattern of translating resources in an operation to a canonical template (rather than translating a sequence of words).
- **Analysis of Public REST APIs.** We analyze and give insight into a large set of public REST APIs. It includes how REST APIs are designed in practice and drifts from the RESTful principles (design guidelines such as using plural names, appropriate use of HTTP verbs). We also provide inside into distribution of parameters (e.g., parameter types and location) and how values can be sampled various types of parameters to generate canonical utterances out of canonical templates using API specifications (e.g., example values, similar parameters with sample values). Automatic sampling values for parameters is essential for automatic generation of canonical utterances because current bot development platforms (e.g., IBM Watson) require annotated utterances (not canonical templates with placeholders).

2 RELATED WORK

REST APIs. REST is an architectural style and a guideline of how to use the HTTP protocol[3] for designing Web services [12]. RESTful web services leverage HTTP using specific architectural principles (i,e., addressability, uniform interface) [13]. Since REST is just a guideline without standardization, it is not surprising that API developers only partially follow the guidelines or interpret REST in their own ways [5]. In particular, this paper is built upon one of the most important principles in REST, namely the *uniform interface* principle. According to this principle, resources must be accessed and manipulated using proper HTTP methods (e.g., DELETE, GET) and status codes (e.g. using "201" to show a resource is created, and "404" to show resource does not exist). The uniform interface requires API to be developed uniformly to ensure that API users can understand the functionality of each operation without reading tedious and long descriptions. To ensure uniform interface, API developers are required to follow design patterns (e.g., using plural names to name collection of resources, using lowercase letters in paths). Existing works have listed not only those patterns but also anti-patterns in designing interfaces of REST APIs [5, 14, 15]. Examples of anti-patterns

[2]previously known as Swagger specification

[3]REST isn't protocol-specific, but it is designed over HTTP nowadays

also include using underline in paths and adding file extensions in paths [4, 6].

In this paper, we build upon existing works on designing interfaces for REST APIs. In particular, we formalize resource types based on patterns and anti-patterns recognized in prior works and built a resource tagger to annotate the segments of a given operation with resource types.

Conversational Agents and Web APIs. Research on conversational agents (e.i., bots, chatbots, dialog systems, virtual assistants) dates back to decades ago [16]. However, there have been only a few targeting web APIs, particularly because of the lack of training samples [1–3]. In absence of training data, operations descriptions (e.g., having long descriptions containing unnecessary information) have been used for detecting the user's intent [3]. However, operations often lack proper descriptions, and operations descriptions may share the same vocabularies in a single API, making it difficult for the bot to differentiate between operations [3]. Moreover, these descriptions are rarely similar to the natural language utterances which are used by bot users to interact with bots. That is to say, these descriptions are originally written to document operations (not intended to be used for training bots) [2, 3].

Other approaches rely on domain experts for generating initial utterances [1, 7, 8]. These approaches include (i) natural language templates (a canonical utterance with placeholders) which are written by experts [17], and (ii) domain-specific grammars such as rules written for semantic parsers [1, 8]. Thus in either approach, manual effort is required to modify the templates of grammar if API specifications are changed. In the template-based approach, for each operation, a few templates are created in which entities are replaced with placeholders (e.g., *"search for a flight from* `ORIGIN` *to* `DESTINATION`"). Next, by feeding values (e.g., `ORIGIN=[Sydney]` and `DESTINATION=[Houston]`) to the placeholders canonical utterances are generated (e.g., *"search for a flight from Sydney to Houston"*). Likewise, generative grammars have been used by semantic parsers for generating canonical utterances [1, 17, 18]. In this approach, logical forms are automatically generated based on the expert-written grammar rules. The grammar is used to automatically produce canonical utterances for the randomly generated logical forms [1]. Both generative grammar and template-based approaches require human efforts, making them hard and costly to scale.

In our work, by adopting ideas from the principles of RESTful design and machine translation techniques, we tackle the main issue which is creating the canonical utterances for RESTful APIs. As opposed to current techniques such as generative-grammar-based or template-based approaches, the proposed approach is domain-independent and can automatically generate initial utterances without human efforts. We thus pave the way for automating the process of building virtual assistants, which serve a large number of tasks, by automating the process of training datasets for new/updated APIs.

User Utterance Acquisition Methods. Current approaches for obtaining training utterances usually involves three main paradigms: launching a prototype to get utterances from end-users, employing crowd workers, and using automatic paraphrasing techniques to paraphrase existing utterances [19].

In the prototype-based approach, a bot is built without any (rule-based methods) or with a small number of annotated utterances. Such prototypes are able to obtain utterances from users to further improve the bots based on supervised machine learning techniques [20]. However, in case of using supervised machine learning methods in building the prototype, collecting initial annotated user utterances is still needed. Collecting an initial set of training samples is essential since the prototype bot must be accurate enough to serve existing user's requests without turning them away from the bot.

```
paths:
  /customers/{customer_id}:
    get:
      description: gets a customer by its id,
      summary: returns a customer by its id,
      parameters:
      - {
          name: customer_id,
          in: path,
          description: customer identifier,
          required: true,
          type: string
        }
```

Figure 3: Excerpt of an OpenAPI Specification

Crowdsourcing has been also used extensively to obtain natural language corpora for conversational agents [1, 8, 17, 18]. In this approach, a canonical utterance is provided as a starting point, and workers are asked to paraphrase the expression to new variations. Automatic paraphrasing techniques have also been employed to automatically generate training data [21–24]. This is done by paraphrasing canonical utterances to obtain new utterances automatically. However, while automatic paraphrasing is scalable and potentially cheaper, even the state-of-art models fall short in producing sufficiently diverse paraphrasing [25], and fail in producing multiple semantically-correct paraphrases for a single expression [26–28]. Nevertheless, these automatic approaches are still beneficial for bootstrapping a bot.

In this paper, we propose a dataset and an automated, scalable, and domain-independent approach for generating canonical utterances. Generated canonical utterances can be next fed to either automatic paraphrasing systems or crowdsourcing techniques to generate training samples for task-oriented bots.

3 THE API2CAN DATASET

In this section, we explain the process of building the API2CAN dataset, and we provide its statistics (e.g., size).

3.1 API2CAN Generation Process

To generate the training dataset (pairs of operations and canonical utterances), we obtained OpenAPI specifications indexed in OpenAPI Directory[4]. OpenAPI Directory is a Wikipedia for REST APIs[5], and OpenAPI specification is a standard documentation format for REST APIs. As shown in Figure 3, the OpenAPI specification includes description, and information about the parameters (e.g., data types, examples) of each operation. We obtained the latest version of each API index in OpenAPI Directory, and totally collected 983 APIs, containing 18,277 operations in total (18.59 operation per an API on average). Finally, we generated canonical utterances for each of the extracted operations as described in the rest of this section and illustrated in Figure 4.

Candidate Sentence Extraction. We extract a candidate sentence from either the summary or description of the operation specification. For a given operation, the description (and summary) of the operation (e.g., *"gets a [customer] (#/definitions/-Customer) by id. The response contains ..."*) is pre-processed by

[4]https://github.com/APIs-guru/openapi-directory/tree/master/APIs

Extract a candidate sentence starting with a verb
gets the customer by id
Convert the candidate sentence to an imperative sentence
get the customer by id
Inject the path parameters using the CFG
get the customer with id being « id »
Canonical Template

Figure 4: Process of Canonical Utterance Extraction

removing HTML tags, lowercasing, and removing hyperlinks (e.g., *"gets a customer by id. the response contains ..."*) and then it is split into its sentences (e.g., "gets a customer by id.", "the response contains ..."). Next, the first sentence starting with a verb (e.g., *"gets a customer by id"*) is chosen as a potential canonical utterance, and its verb is converted to its imperative form (e.g., *"get a customer by id"*).

Parameter Injection While the extracted sentence is usually a proper English sentence, it cannot be considered as a user utterance. That is because the sentence often points to the parameters of the operation without specifying their values. For example, given an operation like "`GET /customers/{customer_id}`" the extracted sentence is often similar to sentences like *"get a customer by id"* or *"return a customer"*. However, we are interested in annotated canonical utterances such as *"get the customer with id being «id»"*, and *"get the customer when its id is «id»"*; where "«id»" is a sampled valued for `customer_id`. To consider parameter values in the extracted sentence, we created a context-free grammar (CFG) as briefly shown in Table 1. This grammar has been created based on our observations of how operation descriptions are written (how parameters are mentioned in the extracted candidate sentences) by API developers. With this grammar, a list of possible mentions of parameters in the operation description is generated (e.g., *"by customer id"*, *"based on id"*, *"with the specified id"*). Then the lengthiest mention found in the sentence is replaced with *"with NPN being «PN»"*, where *NPN* and *PN* are human-readable version of the parameter name (e.g., customer_id ⟶ customer id) and its actual name respectively (e.g., *"get a customer with customer id being «customer_id»"*).

We also observed that path parameters are not usually mentioned in operation descriptions in API specifications. For example, in an operation description like *"returns an account for a given customer"* the path parameter *accountId* and *customerId* are absent, but the lemmatized name of collections *"customer"* and *"account"* are present. By using the information obtained from detecting such resources (see Section 4.2), it is possible to convert the description into *"return an account with id being «customer_id» for a given customer with id being «account_id»"*.

In the process of generating the *API2CAN* dataset, a few types of parameters were automatically ignored. As such, we did not include *header parameters*[6] since they are mostly used for authentication, caching, or exchanging information such as *Content-Type* and *User-Agent*. Thus such parameters do not specify entities of users' intentions. Likewise, using a list of predefined parameter names (e.g., auth, v1.1), we automatically ignored *authentication* and *versioning parameters* because bot users are not expected to directly specify such parameters while talking to a bot. Moreover, since the payload of an operation can contain inner objects, we assume that all attributes in the expected payload of an operation are flattened. This is done by concatenating the ancestors' attributes with the inner objects' attributes. For instance, the parameters in the following payload are flattened to "customer name" and "customer surname":

```
{
  "customer": {
    "name": "string",
    "surname": "string"
  }
}
```

As such, we convert complex objects to a list of parameters that can be asked from a user during a conversation.

Table 1: Parameter Replacement Context Free Grammar

Rule	
$N \longrightarrow \{PN\}\|\{NPN\}\|\{LPN\}\|\{RN\}\|\{NRN\}\|\{LRN\}$	
$CPX \longrightarrow$ 'by' | 'based on' | 'by given' | 'based on given' | ...	
$R \longrightarrow N$ | CPX N | N CPX N	
{PN}	Parameter Name (e.g., "customer_id", "CustomerID", "CustomersID")
{NPN}	Normalized PN by splitting concatenated words and lowercasing (e.g., "customer id", "customers id")
{LPN}	Lemmatized NPN (e.g., "customer id")
{RN}	Resource Name (e.g., "Customers")
{NRN}	Normalized RN (e.g., "customers")
{RN}	Lemmatized NRN (e.g., "customer")

3.2 Dataset Statistics

By processing all API specifications, we were able to automatically generate a dataset called *API2CAN*[7] which includes 14,370 pairs of operations and their corresponding canonical utterances. We next divided the dataset into three parts as summarized in Table 2, and manually checked and corrected extracted utterances in the test dataset to ensure a fair assessment of models learned on the dataset[8].

Table 2: *API2CAN* Statistics

Dataset	APIs	Size
Train Dataset	858	13029
Validation Dataset	50	433
Test Dataset	50	908

Figure 5 shows the number of operations in *API2CAN* based on the HTTP verbs (e.g., GET, POST). As shown in Figure 5, the

[6]Header fields are components of the header section of request in the Hypertext Transfer Protocol (HTTP).
[7]https://github.com/mysilver/API2CAN
[8]Train and validation datasets will be also manually revised in near future

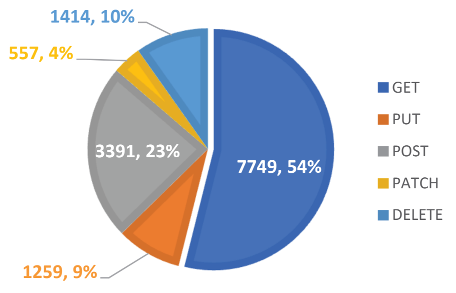

Figure 5: API2CAN Breakdown by HTTP Verb

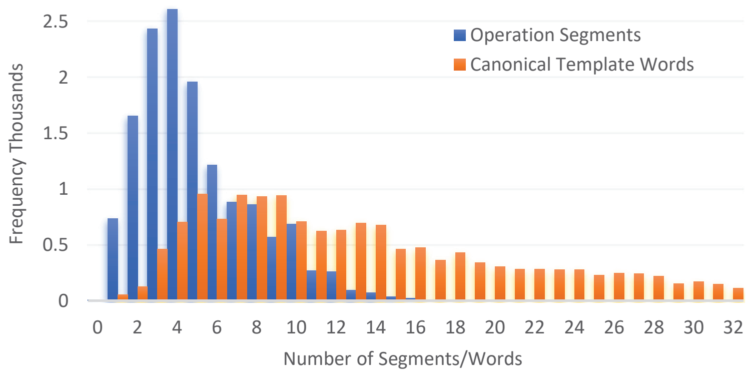

Figure 6: API2CAN Breakdown by Length

majority of operations are of GET methods which are usually used for retrieving information (e.g., *"get the list of customers"*), followed by POST methods which are usually used for creating resources (e.g., *"creating a new customer"*). The DELETE, PUT, and PATCH methods are also used for removing (e.g., *"delete a customer by id being «id»"*), replacing (e.g., *"replace a customer by id being «id»"*), and partially updating (e.g., *"update a customer by id being «id»"*) a resource.

Figure 6 also represents the distribution of number of segments in the operations[9] as well as the number of words in the generated canonical templates. As shown in Figure 6, many of the operations consist of less than 14 segments by 4 being the most common. Given the typical number of segments in the operations, Neural Machine Translation (NMT)-based approaches can be used for the generation of canonical sentences [29, 30]. On the other hand, the canonical sentences in the *API2CAN* dataset are longer. The reason behind having such lengthier utterances is the existence of parameters, and operations with more parameters tend to be lengthier. However, given the maximum length of canonical sentences, NMT-based approaches can still perform well [30].

4 NEURAL CANONICAL SENTENCE GENERATION

Neural Machine Translation (NMT) systems are usually based on encoder-decoder architecture to directly translate a sentence in one language to a sentence in a different language. As shown in Figure 7, generating a canonical template for a given operation can be also considered as a translation task. As such, the operation is encoded into a vector, and the vector is next decoded into an annotated canonical template. However, the main challenge in building such a translation model is the lack of a large training dataset. Since deep-learning models are data thirty, training requires a very large and diverse set of training samples (ideally millions of pairs of operations and their associating user utterances). As mentioned in the previous section, we automatically generated a dataset called *API2CAN*. However, such a dataset is still not large enough for training sequence-to-sequence models.

Having a large set of training samples requires a very large diverse set of operations as well. However, such a large set of APIs and operations is not available. One of the serious repercussions of the lack of such a set of operations is that training samples lack a very large number of possible words that can possibly appear in the operations (but did not appear in the training dataset). As a result, the models trained on such datasets will face many out-of-vocabulary words at runtime. To address this issue, we propose a delexicalization technique called *resource-based delexicalization*. As such, we reduce the impact of the out-of-vocabulary problem and force the model to learn the pattern of translating resources in an operation to a canonical template (instead of translating a sequence of words).

[9]For example, "`GET /customers/{customer_id}`" has two segments: "`customers`" and "`{customer_id}`"

4.1 Resources in REST

In RESTful design, primary data representation is called *resource*. A resource is an object with a type, associated data, relationships to other resources, and a set of HTTP verbs (e.g., GET, POST) that operate on it. Designing RESTful APIs often involves following conventions in structuring URIs (endpoints) and naming resources. Examples include using plural nouns for naming resources, using the "GET" method for retrieving a resource and using the "POST" method for creating a new resource.

In RESTful design, resources can be of various types. Most commonly, a resource can be a document or a collection. A document, which is also called *singleton resource*, represents a single instance of the resource. For example, "`/customers/{customer_id}`" represents a customer that is identified by a path parameter ("`customer_id`"). On the other hand, a *collection resource* represents all instances of a resource type such as "`/customers`". Resources can be also nested. As such, a resource may also contain a sub-collection ("`/customers/{customer_id} /accounts`"), or a singleton resource (e.g., "`/customers/{customer_id} /accounts/ {account_id}`"). In RESTful design, CRUD actions (create, retrieve, update and delete) over resources are shown by HTTP verbs (e.g., GET, POST). For example, "`GET /customers`" represents the action of getting the list of customers, and "`POST /customers`" indicates the action of creating a new customer. However, some actions might not fit into the world of conventional CRUD operations. In such cases, *controller* resources are used. *Controller* resources are like executable functions, with inputs and return-values. REST APIs rely on *action controllers* to perform application specific actions that cannot be logically mapped to one of the standard HTTP verbs. For example, an operation such as "`GET /customers/{customer_id}/activate`" can be used to activate a customer. Moreover, while it is unconventional, adjectives also are occasionally used for filtering resources. For example, "`GET /customers/activated`" means getting the list of all activated customers. In this paper, such adjectives are called *attribute controllers*.

While above-mentioned principles are followed by many API developers, there are still many APIs violate these principles. By manually exploring APIs and prior works [5, 14, 15], we identified some unconventional resource types used in designing operations as summarized in Table 3. A common drift from RESTful principles is the use of programming conventions in naming resources (e.g., "createActor", "get_customers"). Aggregation functions (e.g., sum, count) and expected output format of an operation (e.g., "json", "tsb", "txt") are also used in designing endpoints. Words similar to "search" (e.g. "query", "item-search") are used to indicate that the operation looks for resources based on given criteria. Moreover, collections are occasionally filtered/sorted by using keywords such as "filtered-by", "sort-by", or appending a resource name to "By" (e.g., "ByName", "ByID"). Segments in the endpoints may also indicate API versions (e.g., v1.12), or authentication endpoints (e.g., auth, login). Even though the aforementioned types of resources are against the conventional design guidelines of RESTful design, they are important to detect since still they are used by API developers in practice.

Table 3: Resource Types

Resource Type	Example
Collection	`/customers`
Singleton	`/customers/{customer_id}`
Action Controller	`/customers/{customer_id}/activate`
Attribute Controller	`/customers/activated`
API Specs	`/api/swagger.yaml`
Versioning	`/api/v1.2/search`
Function	`/AddNewCustomer`
Filtering	`/customers/ByGroup/{group-name}`
Search	`/customers/search`
Aggregation	`/customers/count`
File Extension	`/customers/json`
Authentication	`/api/auth`

4.2 Resource-based Delexicalization

In resource-based delexicalization, the input (API call) and output (canonical template) of the sequence-to-sequence model are converted to a sequence of resource identifiers as shown in Figure 7. This is done by replacing mentions of resources (e.g., customers, customer) with a corresponding resource identifier (e.g., Collection_1). A resource identifier consists of two parts: (i) the type of resource and (ii) a number *n* which indicates *n*-th occurrence of a resource type in a given operation. This number later is used in the lexicalization of the output of the sequence-to-sequence model to generate a canonical template.

To detect resource types, we used the *Resource Tagger* shown in Algorithm 1. We convert the raw sequence of words in a given operation (e.g., "`GET /customers/{customer_id}/accounts`") to a sequence of resource identifiers (e.g., "`get Collection_1 Singleton_1 Collection_2`"). Likewise, mentions of resources in the canonical templates are replaced with their corresponding resource identifiers (e.g., "get all `Collection_1` for the `Collection_2` with `Singleton_1` being `Singleton_1`"). The intuition behind the conversions is to help the model to focus on translating a sequence of resources instead of words.

Algorithm 1: Resource Tagger

```
Input: segments of the operation
Result: List of resources
resources ⟵ [];
i ⟵ size(segments);
for i ← length(segments) down to 1 do
    current ⟵ segments[i];
    resource ⟵ new Resource();
    resource.name ⟵ current;
    previous ⟵ $\phi$;
    if $i > 1$ then
        previous ⟵ segments[$i - 1$];
    end
    resource.type ⟵ "Unknown";
    if current is a path parameter then
        if previous is a plural noun and an identifier then
            resource.type ⟵ "Singleton";
            resource.collection ⟵ previous;
        else
            resource.type ⟵ "Unknown Param";
        end
    else
        if current starts with "by" then
            resource.type ⟵ "Filtering";
        else if current in ["count", "min", ...] then
            resource.type ⟵ "Aggregation";
        else if current in ["auth", "token", ...] then
            resource.type ⟵ "Authentication";
        else if current in ["pdf", "json", ...] then
            resource.type ⟵ "File Extension";
        else if current in ["version", "v1", ...] then
            resource.type ⟵ "Versioning";
        else if current in ["swagger.yaml", ...] then
            resource.type ⟵ "API Specs";
        else if any of ["search", "query", ...] in current then
            resource.type ⟵ "Search";
        else if current is a phrase and starts with a verb then
            resource.type ⟵ "Function";
        else if current is a plural noun then
            resource.type ⟵ "Collection"
        else if current is a verb then
            resource.type ⟵ "Action Controller";
        else if current is an adjective then
            resource.type ⟵ "Attribute Controller";
    end
    resources.append(resource);
end
return reversed(resources)
```

In the time of using the model for generating canonical templates, the tagged resource identifiers are replaced with their corresponding resource names (e.g., Collection_2 ⟶ customers). Meanwhile, in the process of replacing resource tags, occasionally grammatical errors might happen such as having plural nouns instead of singular forms. To make the final generated canonical template more robust, we used LanguageTool [10] (an

open-source tool for automatically detecting and correcting linguistically errors) to correct linguistic errors in the generated canonical templates.

5 PARAMETER VALUE SAMPLING

To obtain canonical utterances, values must be sampled for the parameters (placeholders) inside a given canonical template. The sampled values help to generate canonical utterances which are understandable sentences without any placeholders. Canonical utterances can be paraphrased later either automatically or manually by crowd-workers to diversify the training samples. In this section, we investigate how values can be sampled for parameters of REST APIs. More specifically, we identified five main sources as follows.

(1) **Common Parameters.** Parameters such as identifiers (e.g., customer_id), emails, and dates are ubiquitous in REST APIs. We built a set of such parameters paired with values. As such, a short random string or numeric value is generated for identifiers based on the parameter data type. Likewise, mock email addresses and dates are generated automatically.

(2) **API Invocation.** By invocation of API methods that return a list of resources (e.g., "`GET /customers`"), we can obtain a large number of values for various attributes (e.g., customer names, customer ids) of the resource. Such values are reliable since they correspond to real values of entities in the retrieved resources. Thus they can be used reliably to generate canonical utterances out of canonical templates.

(3) **OpenAPI Specification.** An OpenAPI specification may include an example or default values[11] for parameters of each operation. Since these values are generated by API owners, they are reliable. Moreover, API specification specifies the data-types of parameters. This can also be used to automatically generate values for parameters in the absence of example and default values. For example, in the case of *enumeration types* (e.g., gender ⟶ [MALE, FEMALE]), one of the elements is randomly selected as a parameter value. In the case of numeric parameters (e.g. size), a random number is generated within the specified range (e.g., between 1 to 10) in the API specification. Likewise, for the parameters whose values follow regular expressions (e.g., "[0-9]%" indicates a string that has a single-digit before a percent sign), random sequences are generated to fulfill the given pattern in the API specification (e.g., "8%").

(4) **Similar Parameters.** Having a large set of API specifications, example values can be found from similar parameters (sharing the same name and datatype). This can be possible by processing parameters of API repositories such as OpenAPI directory.

(5) **Named Entities.** Knowledge graphs provide information about various entities (e.g., cities, people, restaurants, books, authors). Examples of such knowledge graphs include for Freebase [31], DBpedia [32], Wikidata[33], and YAGO [34]. For a given entity type such as *"restaurant"* in the restaurant domain, these knowledge graphs might contain numerous entities (e.g., KFC, Domino's). Such knowledge bases can be used to sample values for a given parameter if the name of the parameter matches an entity type. In this paper, we use Wikidata to sample values for entity types. Wikidata is a knowledge graph which is populated by processing Wikimedia projects such as Wikipedia.

[11] An example illustrates what the value is supposed to be for a given parameter. But a default value is what the server uses if the client does not provide the value.

6 EXPERIMENTS & RESULTS

Before delving into the experiments, we briefly explain the training process in the case of using neural translation methods. We trained the neural models using the Adam optimizer [35] with an initial learning rate of 0.998, a dropout of 0.4 between recurrent layers (e.g., LSTM, BiLSTM), and a batch size of 512. It is worth noting that the hyper-parameters are initial configurations set based on the size of the dataset and values suggested in the literature, and finding optimized values requires further studies. Furthermore, in case of not using delexicalization, we also populate word embeddings of the model with GloVe [36].

In the time of translation, we used beam search with a beam size of 10 to obtain multiple translations for a given operation, and then the first translation with the same number of placeholders as the number of the parameters in the given operation is considered as its canonical template. Moreover, we replaced the generated *unknown* tokens with the source token that had the highest attention weight to avoid the out-of-vocabulary problem.

6.1 Translation Methods

We trained translation models using different sequence-to-sequence architectures and we also built a rule-based translator as described next. Given the size of the API2CAN dataset, we configured the models using two layers for both encoding and decoding parts at the most.

GRU. This model consists of two layers (each having 256 units) of Gated Recurrent Units (GRUs) [37] for both encoding and decoding layers using the attention mechanism [38].

Table 4: Excerpt of Transformation Rules

#		Resources Sequence	Transformation Rule
1	***Rule***	`GET /{c}/`	get list of {c.name}
	Example	`GET /customers`	get list of customers
2	***Rule***	`DELETE /{c}/`	delete all {c.name}
	Example	`DELETE /customers`	delete all customers
3	***Rule***	`GET /{c}/{s}/`	get the {$singular(c.name)$} with {s.name} being {s.name}
	Example	`GET /customers/{id}`	get the customer with id being <id>
4	***Rule***	`DELETE /{c}/{s}/`	delete the {$singular(c.name)$} with {s.name} being <{s.name}>
	Example	`DELETE /customers/{id}`	delete the customer with id being <id>
6	***Rule***	`PUT /{c}/{s}/`	replace the {$singular(c.name)$} with {s.name} being <{s.name}>
	Example	`PUT /customers/{id}`	replace the customer with id being <id>
7	***Rule***	`GET /{c}/{a}/`	get {a.name} {$singular(c.name)$}
	Example	`GET /customers/first`	get first customer
8	***Rule***	`GET /{c1}/{s}/{c2}/`	get the list of {c2.name} of the {$singular(c1.name)$} with {s.name} being {s.name}
	Example	`GET /customers/{id}/accounts`	get the list of accounts of the customer with id being <id>

LSTM. This model consists of two layers (each having 256 units) of two layers of LSTM for both encoding and decoding using the attention mechanism [38].

CNN. We also built a sequence-to-sequence model based on Convolutional Neural Network (CNN) as proposed in [39]. In particular, we used 3x3 convolutions (one layer of 256 units) with the attention mechanism [38].

BiLSTM-LSTM. This model consists of two layers (each having 256 units) of Bidirectional Long-Short Term Memory (BiLSTM) [40] for encoding, and two layers (each having 256 units) of Long-Short Term Memory (LSTM) [41] for the decoder using the attention mechanism [38].

Transformer. The Transformer architecture [42] has been shown to perform very strong in machine translation tasks [43, 44]. We used the Transformer model implemented by OpenNMT [45] using the same hyper-parameters as the original paper [42]. For an in-depth explanation of the model, we refer the interested reader to the original paper [42].

Rule-based (RB) Translator. Based on the concept of resource in REST APIs, we also built a rule-based translation system to translate operations to canonical templates (shown in Algorithm 2). First, the algorithm extracts the resources of a given operation based on the resource types extracted by the *Resource Tagger* algorithm (see Algorithm 1). Next, the algorithm iterates over an ordered set of *transformation rules* to transform the operation to a canonical template. A *transformation rule* is a hand-crafted Python function which is able to translate a specific HTTP method (e.g., GET) and sequence of resource types (e.g., a *collection* resource followed by a *singleton* resource) to a canonical template. We created 33 *transformation rules* by the time of writing this paper, some of which are listed in Table 4. In this table, `{c}`, `{s}`, and `{a}` stands for collection, singleton, and attribute controller respectively. And the $singular(.)$ function returns the singular form of a given name. For instance, in case of an operation like "`GET /customers`", given that the bot user requests a collection of customers, the provided transformer (rule number 1 in Table 4) is able to generate a canonical template as *"get the list of customers"*. Following Python function also presents the *transformation rule* implementation which is able to translate such operations (a single collection resource when the HTTP method is "GET"):

```
def transform(resources, verb):
 if verb != "GET" or len(resources) != 1:
    return
 if resources[0].type != "Collection":
    return
 collection = resources[0]
 return "get the list of {}".format(collection.name)
```

A transformer is written based on the assumption that a sequence of resource types has special meaning. For example, considering "`GET /customers/{id}/accounts`" and "`GET /users/{user_id}/aliases`", both operations share the same HTTP verbs and sequence of resource types (a singleton followed by a collection). In such cases, possible canonical templates are "*get accounts of a customer when its id is «id»*" and "*get aliases of a user when its user id is «user_id»*". Thus such a sequence of resource types can be converted to a rule like: *"get {collection} of a {singleton.collection} when its {singleton.name} is «{singleton.name}»"*; in which "{}" represents placeholders and *singleton.collection* represents the name of the collection for the given singleton resource (e.g., customers, users). Thus adding a new transformation rule would mean generalizing a specific sequence of resources types that is not considered in the existing translators. However, as discussed earlier, since many APIs do not conform to the RESTful principles, creating a comprehensive set of transformation rules is very challenging.

6.2 Canonical Utterance Generation

Quantitative Analysis. For each of the aforementioned NMT architectures, we trained models with and without using the

Algorithm 2: Rule-Based Translator

```
   Input: operation, transformation_rules written by experts
   Result: A canonical template
1  resources ⟵ ResourceTagger(operation);
2  foreach $t \in transformation\_rules$ do
3      canonical ⟵ t.transform(resources, operation.verb);
4      if $canonical \neq \phi$ then
5          param_clause ⟵ to_clause(operation.parameters) ;
6          canonical ⟵ canonical + " " + param_clause ;
7          return canonical;
8      end
9  end
10 return $\phi$
```

proposed *resource-based delexicalization* approach as described in Section 4.2. In these experiments, we did not tune any hyper parameters and trained the models on the training dataset. For each baseline, we saved the model after 10000 steps and used the model with the minimum perplexity based on the validation set to compare with other configurations. Table 5 presents the performance of each model in terms of machine translation metrics: bilingual evaluation understudy (BLEU) [46], Google's BLEU Score (GLEU) [47], and Character n-gram F-score (CHNF) [48].

In the case of using the RB-Translator, hand-crafted transformation rules are able to generate canonical templates for 26% of the operations. Creating such transformation rules is very challenging for lengthy operations as well as those not following RESTful principles. We did not include RB-Translators' performance in Table 5 because the results are not comparable to the rest. Our experiments indicate that RB-Translator performs reasonably well (BLEU=0.744, GLEU=0.746, and CHRF=0.850). However, the BiLSTM-LSTM model built on the proposed dataset using the resource-based delexicalization technique outperforms the RB-Translator (BLEU=0.876, GLEU=0.909, and CHRF=0.971), ignoring the operations which RB-Translator could not translate. As experiments indicate, *Delexicalized BiLSTM-LSTM* outperforms the rest of the translation systems, and resource-based delexicalization improves the performance of NMT systems by large.

Table 5: Translation Performance

Translation-Method	BLEU	GLEU	CHRF
Delexicalized BiLSTM-LSTM	**0.582**	**0.532**	**0.686**
Delexicalized Transformer	0.511	0.462	0.619
Delexicalized LSTM	0.503	0.470	0.652
Delexicalized CNN	0.507	0.458	0.601
Delexicalized GRU	0.481	0.450	0.623
BiLSTM-LSTM	0.318	0.266	0.421
Transformer	0.295	0.248	0.397
LSTM	0.278	0.226	0.381
CNN	0.271	0.220	0.379
GRU	0.251	0.198	0.347

Qualitative Analysis. Table 6 gives a few examples of canonical templates generated by the proposed translator (Delexicalized BiLSTM-LSTM). While the machine-translation metrics do not show very strong translation performance in Table 5, our manual inspections revealed that these metrics do not reflect the actual performance of the proposed translators. Therefore, we conducted another experiment to manually evaluated the translated operations. For this reason, we asked two experts to rate the generated canonical templates manually using a Likert scale (in a range of 1 to 5 with 5 showing the most appropriate canonical sentence). In the experiment, the experts were given pairs of generated canonical utterances and operations (including the description of the operation in the API specification). Next, they were asked to rate the generated canonical templates in a range of 1 to 5.

Figure 8 shows the Likert assessment for the best performing models in Table 5. Based on this experiment, canonical templates generated by RB-Translator are rated 4.47 out 5, and those of the delexicalized BiLSTM-LSTM are rated 4.06 out of 5 (by averaging the scores given by the annotators). The overall Kappa test showed a high agreement coefficient between the raters by Kappa being 0.86 [49]. Based on manual inspections, as also shown in Table 6, we observed that when APIs are designed based on the RESTful principles the delexicalized Delexicalized performs as good as RB-Translator.

Figure 8 also shows how the automatically generated dataset (*API2CAN*) represents their corresponding operations. Based on the rates given by the annotators, the dataset (training part) is also of decent quality while being noisy, indicating that the proposed set of heuristics for generating the dataset are well-defined. Given the promising quality of generated canonical templates, we concluded that the noises in the dataset can be ignored. However, yet it is desirable to manually clean the dataset.

Table 6: Examples of Generated Canonical Templates

	Sample
Operation	`GET /v2/taxonomies/`
Canonical	fetch all taxonomies
Operation	`PUT /api/v2/shop_accounts/{id}`
Canonical	update a shop account with id being <id>
Operation	`DELETE /api/v1/user/devices/{serial}`
Canonical	delete a device with serial being <serial>
Operation	`GET /user/ratings/query`
Canonical	get a list of ratings that match the query
Operation	`GET /v1/getLocations`
Canonical	get a list of locations
Operation	`POST /series/{id}/images/query`
Canonical	query the images of the series with id being <id>
Operation	`PUT /api /hotel /v0 /hotels /{hotelId} /rateplans/batch/$rates`
Canonical	set rates for rate plans of a hotel with hotel id being <hotelId>

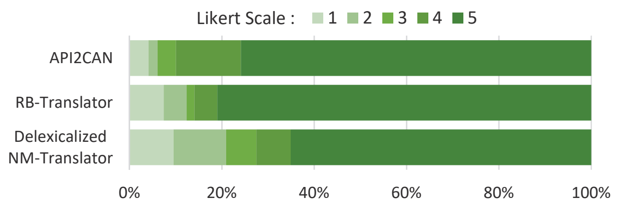

Figure 8: Assessment of Generated Canonical Templates

Error Analysis. Even though the proposed method outperforms the baselines, it still occasionally fails in generating high-quality canonical templates. Based on our investigations, there are three main sources of error in generating the canonical templates: (i) detecting resource types, (ii) translating APIs which do not conform to RESTful principles, and (iii) lengthy operations with many segments.

Detecting resource types requires natural language processing tools to detect parts of speech (POS) of a word (e.g., verb, noun, adjective), and to detect if a given noun is plural or singular (particularly for unknown words or phrases and uncountable nouns). However, these tools occasionally fail. Specifically, POS taggers are built for detecting parts of speech for words inside a sentence. Thus it is not surprising if they fail in detecting if a word like "rate" is a verb or noun in a given operation. For example, an operation like `GET /participation/rate` can indicate both "get the rate of participations" and "rate the participants". Another source of such issues is tokenization. It is common in APIs to concatenate words (e.g., whoami, addons, registrierkasseuuid, AddToIMDB). While it seems trivial for an individual to split these words, existing tools frequently fail. Such issues affect the process of detecting resources and consequently impact the generation of canonical templates negatively.

Unconventional API design (not conforming to RESTful principles) also extensively impacts the quality of generated canonical templates. Common drifts from RESTful principles includes using wrong HTTP verb (e.g., "`POST`" for retrieving information), using singular nouns for showing collections (e.g. `/customer`), adding non-resource parts to the path of the operation (e.g., adding *response format* like "json" in `/customers/json`. Since those API developers (who do not conform to design guidelines) follow their own thoughts instead of accepted rules, the automatic generation of canonical templates is challenging.

Lengthy operations (those with roughly more than 10 segments) naturally are rare in REST APIs. Such lengthy operations convey more complex intents than those with a lesser number of segments. As shown in Figure 6, unfortunately, such operations are also rare in the proposed dataset (*API2CAN*), impacting translation of lengthy operations.

6.3 Parameter Value Sampling

This section provides an analysis of parameters in the RESTful APIs and evaluates the proposed parameter sampling approach which is used for generating canonical utterances out of canonical templates. To this end, we processed API specifications which are indexed in OpenAPI Directory. Based on our analysis, the dataset contains 145971 parameters in total, which indicates that an operation has 8.5 parameters on average.

Figure 9 presents statistics of parameters in the whole list of API specifications in the OpenAPI Directory. As shown in the right-hand pie chart, most of the parameters are located in the payload (body) of APIs, followed by query and path parameters. Figure 9 also shows the percentages of parameter data types in the collection with *strings* being the most common type of parameters. About 1.5% of string parameters are defined by regular expressions, and 4.8% of them can be associated with an entity type[12]. String parameters are followed by integers, booleans, numbers, and enumerations. Moreover, some parameters are left without any type, or they are given general parameter types such as *"object"* without any schemes. These parameters are combined together in the left-hand pie chart in Figure 9 with a single label–*"others"*. Moreover, 28% of parameters are required parameters (not optional), 10.6% of parameters have not assigned any value in the API specifications, and 26% of all parameters are identifiers (e.g., id, UUID). Thus, sampling values is required only for less than 10.6% of parameters (those without any values). In particular, value sampling for string parameters requires more attention. That is because string parameters are widely used, and they are more difficult to automatically be assigned values in comparison to other types of parameters (e.g., integers, enumerations).

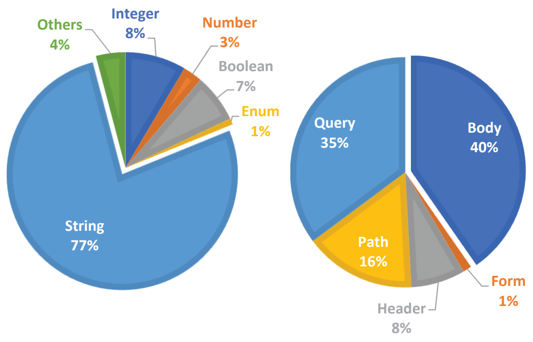

Figure 9: Parameter Type and Location Statistics

To evaluate how well the proposed method generates sample values for parameters, we conducted an experiment. Since generating sample values for data types such as numbers and enumerations is straightforward, we only considered string parameters in this experiment. To this end, we randomly selected 200 parameters and asked an expert to annotate if a sampled value is appropriate for the given value or not. The results indicate that 68 percent of sampled values are appropriate for given parameters. The main reason for inappropriate sampled values is noises in the API specifications. For instance, developers occasionally describe the parameters in the *example* part instead of the *description* part of the documentation. For instance, for a string parameter like "`customer_id`", the example part may be filled by "a valid customer id". Moreover, sometimes the same parameter name is used in different contexts for different purposes. For example, the parameter name like *"name"* which can be used for representing the name of a person, school, or any object.

7 CONCLUSION & FUTURE WORK

This paper aimed at addressing an important shortcoming in current approaches for acquiring canonical utterances. In this paper, we demonstrated that the generation of canonical utterances can be considered as a machine translation task. As such, our work also aimed at addressing an important challenge in training supervised neural machine translators, namely the lack

[12]We looked up the parameter name in Wikidata to find if there is associating entity type

of training data for translating operations to canonical templates. By processing a large set of API specifications and based on a set of heuristics, we build a dataset called *API2CAN*. However, deep-learning-based approaches require larger sets of training samples to train domain-independent models. Thus, by formalizing and defining resources in REST APIs, we proposed a delexicalization technique to convert an operation to a tagged sequence of resources to help sequence-to-sequence models to learn from such a dataset. In addition, we showed how parameter values can be sampled to feed placeholders in a canonical template and generate canonical utterances. We also gave a systematic analysis of web APIs and their parameters, indicating the importance of string parameters in automating the generation of canonical utterances.

In our future work, we will be working on improving the dataset (*API2CAN*). Moreover, given that fulfilling complex intents usually requires a combination of operations [8, 50], we will be working on compositions between operations. To achieve this, it is required to detect the relations between operations and generate canonical templates for complex tasks (e.g., tasks requiring conditional operations or compositions of multiple operations). In future work, we will target these problems, together with many other exciting opportunities as extensions to this work.

ABSTRACT

Graphs are ubiquitous and ever-present data structures that have a wide range of applications involving social networks, knowledge bases and biological interactions. The evolution of a graph in such scenarios can yield important insights about the nature and activities of the underlying network, which can then be utilized for applications such as news dissemination, network monitoring, and content curation. Capturing the continuous evolution of a graph can be achieved by long-standing sub-graph queries. Although, for many applications this can only be achieved by a set of queries, state-of-the-art approaches focus on a single query scenario. In this paper, we therefore introduce the notion of continuous multi-query processing over graph streams and discuss its application to a number of use cases. To this end, we designed and developed a novel algorithmic solution for efficient multi-query evaluation against a stream of graph updates and experimentally demonstrated its applicability. Our results against two baseline approaches using real-world, as well as synthetic datasets, confirm a two orders of magnitude improvement of the proposed solution.

1 INTRODUCTION

In recent years, graphs have emerged as prevalent data structures to model information networks in several domains such as social networks, knowledge bases, communication networks, biological networks and the World Wide Web. These graphs are *massive* in scale and *evolve* constantly due to frequent updates. For example, according to its latest quarterly update, Facebook has over 1.52B daily active users who generate over 500K posts/comments and four million likes every minute resulting in massive updates to the Facebook social graph.

To gain meaningful and up-to-date insights in such frequently updated graphs, it is essential to be able to monitor and detect continuous patterns of interest. There are several applications from a variety of domains that may benefit from such monitoring. In social networks, such applications may involve targeted advertising, spam detection [3, 40], and fake news propagation monitoring based on specific patterns [34]. Similarly, other applications like (i) protein interaction patterns in biological networks [37, 45], (ii) traffic monitoring in transportation networks, (iii) attack detection (e.g., distributed denial of service attacks in computer networks), (iv) question answering in knowledge graphs [2], and (v) reasoning over RDF graphs may also benefit from such pattern detection.

For the applications mentioned above it is necessary to express the required patterns as *continuous sub-graph queries* over (one or many) streams of graph updates and appropriately *notify* the subscribed users for any patterns that match their subscription. Detecting these query patterns is fundamentally a sub-graph isomorphism problem which is known to be NP-complete due to the exponential search space resulting from all possible sub-graphs [18, 33]. The typical solution to address this issue is to pre-materialize the necessary sub-graph views for the queries and perform exploratory joins [36]; an expensive operation even for a single query in a static setting.

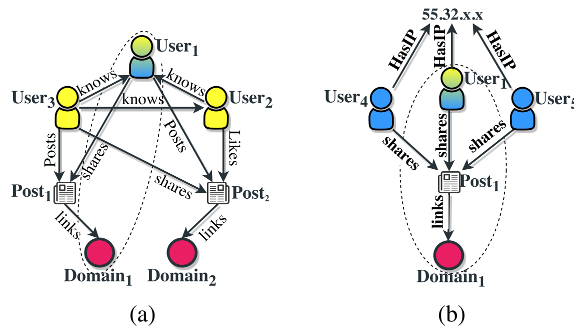

Figure 1: Spam detection: Users sharing and liking content with links to flagged domains. (a) A clique of users who know each other, and (b) Users sharing the same IP address.

These applications deal with graph streams in such a setup that is often essential to be able to support hundreds or thousands of continuous queries simultaneously. This leads to several challenges that require: (i) quickly detecting the affected queries for each update, (ii) maintaining a large number of materialized views, and (iii) avoiding the expensive join and explore approach for large sets of queries.

To better illustrate the remarks above, consider the application of spam detection in social networks. Fig. 1 shows an example of two graph patterns that may emerge from malicious user activities, i.e., users posting links to domains that have been flagged as fraudulent. Notice that malicious behavior could be caused either because a group of users that know each other share and like each other's posts containing content from a flagged domain (Fig. 1(a)), or because the group of users shared the same flagged post several times from the same IP (Fig. 1(b)). Even though these two queries are fundamentally different and produce different matching patterns, they share a common sub-graph pattern, i.e., "$\text{User1} \xrightarrow{\text{shares}} \text{Post1} \xrightarrow{\text{links}} \text{Domain1}$". If these two queries are evaluated independently, all the computations for processing the common pattern have to be executed twice. However, by identifying common patterns in query sets, we can amortize the costs of processing and answering them.

One simple approach to avoid processing all the (continuous) queries upon receiving a graph update is to index the query graphs using an inverted-index at the granularity of edges. While this approach may help us quickly detect all the affected queries for a given graph update, we still need to perform several exploratory joins to answer the affected queries. For example, in Fig. 1, we would need to join and explore the edges matching the pattern "User1 $\xrightarrow{\text{Shares}}$ Post1 and Post1 $\xrightarrow{\text{Links}}$ Domain1" upon each update to process the two queries. On the contrary, if we first identify the maximal sub-graph patterns shared among the queries instead, we can minimize the number of operations necessary to answer the queries. Therefore, a solution which groups queries based on their shared patterns would be expected to deliver significant performance gains. To the best of our knowledge, none of the existing works provide a solution that exploits common patterns for continuous multi-query answering.

In this paper, we address this gap by proposing a novel *algorithmic solution*, coined TRIC (TRIe-based Clustering) to index and cluster continuous graph queries. In TRIC, we first decompose queries into a set of directed paths such that each vertex in the query graph pattern belongs to at least one path (path covering problem [11]). However, obtaining such paths leads to redundant query edges and vertices in the paths; this is undesirable since it affects the performance of the query processing. Therefore, we are interested in finding paths which are shared among different queries, with minimal duplication of vertices. The paths obtained are then indexed using 'tries' that allow us to minimize query answering time by (i) quickly identifying the affected queries, (ii) sharing materialized views between common patterns, and (iii) efficiently ordering the joins between materialized views affected from the update. To this end, our *contributions* are:

- We formalize the problem of continuous multi-query answering over graph streams (Section 3).
- We propose a novel query graph clustering algorithm that is able to efficiently handle large numbers of continuous graph queries by resorting on (i) the decomposition of continuous query graphs to minimum covering paths and (ii) the utilization of tries for capturing the common parts of those paths (Section 4).
- Since no prior work in the literature has considered continuous multi-query answering in the context of graph streams, we designed and developed two algorithmic solutions that utilize inverted indexes for the graph query answering. Additionally, we deploy and extend Neo4j [43], a well-established graph database solution, to support our proposed paradigm. To this end, the proposed solutions will serve as baselines approaches during the experimental evaluation (Section 5).
- We experimentally evaluate the proposed solution using three different datasets from social networks, transportation, and biology domains, and compare the performance against the three baselines. In this context, we show that our solution can achieve up to two orders of magnitude improvement in query processing time (Section 6).

2 RELATED WORK

Structural graph pattern search using graph isomorphism has been studied in the literature before [18, 33]. In [17], the authors propose a solution that aims at reducing the search space for a single query graph. The solution identifies candidate regions in the graph that can contain query embeddings, while it is coupled with a neighborhood equivalence locating strategy to generate enumerations. In the same spirit [30] aims at reducing the search space in the graph by exploiting syntactic similarities present on vertex relationships. [31] considers the sub-graph isomorphism problem when multiple queries are answered simultaneously. However, these techniques are designed for static graphs and are not suitable for processing continuous graph queries on evolving graphs.

Continuous sub-graph matching has been considered in [41] but the authors assume a static set of sub-graphs to be matched against update events, use approximate methods that yield false positives, and small (evolving) graphs. An extension to this work considers the problem of uncertain graph streams [7], over wireless sensor networks and PPIs. The work in [15] considers a setup of continuous graph pattern matching over knowledge graph streams. The proposed solution utilizes finite automatons to represent and answer the continuous queries. However, this approach can support a handful of queries, since, each query is evaluated separately, while, it generates false positives due to the adopted sliding window technique. These solutions are not suitable for answering large number of continuous queries on graphs with high update rates.

There are a few publish/subscribe solutions on ontology graphs proposed in [29, 42], but they are limited to the RDF data model. Distributed pub/sub middleware for graphs has recently been proposed in [5], however, the main focus is on node constraints (attributes) while ignoring the graph structure.

The work in [9] provides an exact subgraph search algorithm that exploits the *temporal* characteristics of representative queries for online news or social media exploration. The algorithm exploits the structural and semantic characteristics of the graph through a specialized data structure. Where the authors consider continuous query answering with graph patterns over dynamic multi-relation graphs. In [36] the authors perform subgraph matching over a billion node graph by proposing graph exploration methods based on cloud technologies. While the aforementioned works are similar to the query evaluation scenario, the emphasis is on efficient search mechanisms, rather than continuous answering over streaming graphs.

In the graph streams domain; [28] proposes algorithms to identify correlated graphs from a graph stream. This differs from our setup since a sliding window that covers a number of batches of data is used, and the main focus is set on identifying subgraphs with high Pearson correlation coefficients. In [14], the authors propose continuous pattern detection in graph streams with snapshot isolation. However, this solution considers only isolated queries (i.e., one query at a time) and the patterns detected are approximate. Finally, in [13] the authors propose a solution over a distributed computational environment, while the solution operates under the assumption of a static and limited query set.

Finally, some of the techniques used for increasing the efficiency of the proposed algorithm employ standard data indexing practices from a variety of domains, although the assumed setup and target applications differ significantly: (i) the representation of materialized views bears similarities with techniques from centralized RDF query processing [24, 32, 39] and statement/property tables as in Jena1 and Jena2 [44], (ii) the problem of maintaining the materialized views of (graph) queries relates to incremental view maintenance [4, 8, 25, 47] in database and warehousing environments, (iii) while query decomposition and tree-based clustering is typical in a variety of domains and applications [31, 38].

In general, solutions like the proposed one on continuous subgraph pattern matching can be applied in a wide range of domains such as social networks, protein-protein interactions (PPI), cyber-security, knowledge graphs, road network monitoring, and co-authorship graphs. Social network graphs emerge naturally

Update stream S
$u_1 = (checksIn = (P_1, \text{plc}))$
$u_2 = (checksIn = (P_2, \text{plc}))$
$u_3 = (checksIn = (P_3, \text{plc}))$

Figure 2: (a) An update stream S and (b) the evolution of graph G after inserting $u_i \in S$.

from the evolving interactions and activities of the users, while applications such as advertising, recommendation systems, and information discovery aim at exploiting these interactions. Social network applications may benefit from continuous pattern matching, and can leverage on already observed patterns in content propagation [21, 22, 46] and influential user discovery [6, 9]. PPIs are data repositories [35, 37] that index proteins (graph vertices) and the interactions (graph edges) between them. PPI graphs are constantly updated due to additions and invalidations of interactions, while scientists manually query PPIs to discover new patterns. In such scenarios, subgraph matching could enhance information discovery through appropriate graphical user interface tools. In cyber-security, subgraph matching could be applied for network motoring, denial of service, and exfiltration attacks [20], while subgraph matching over road networks could capture traffic events, and taxi route pricing. Finally, in the domain of co-authorship graphs, users may utilize continuous query evaluation in services similar to Google Scholar Alerts, when requesting to be notified about newly published content.

3 DATA MODEL AND PROBLEM DEFINITION

In this section we outline the data (Section 3.1) and query model (Section 3.2) that our approach builds upon.

3.1 Graph Model

In this paper, we use attribute graphs [10] (Definition 3.1), as our data model, as they are used natively in a wide variety of applications, such as social network graphs, traffic network graphs, and citation graphs. Datasets in other data models can be mapped to attribute graphs in a straightforward manner so that our approach can be applied to them as well.

Definition 3.1. An *attribute graph* G is defined as a directed labeled multigraph:

$$G = (V, E, l_V, l_E, \Sigma_V, \Sigma_E)$$

where V is the set of vertices and E the set of edges. An edge $e \in E$ is an ordered pair of vertices $e : (s, t)$, where $s, t \in V$ represent source and target vertices. $l_V : V \longrightarrow \Sigma_V$ and $l_E : E \longrightarrow \Sigma_E$ are labeling functions assigning labels to vertices and edges from the label sets Σ_V and Σ_E.

For ease of presentation, we denote an edge e as $e = (s, t)$, where e, s and t are the labels of the edge($l_E(e)$), source vertex ($l_V(s)$) and target vertex ($l_V(t)$) respectively.

As our goal is to facilitate efficient continuous multi-query processing over graph streams, we also provide formal definitions for updates and graph streams (Definitions 3.2 and 3.3).

Definition 3.2. An update u_t on graph G is defined as an *addition* (e) of an edge e at time t. An addition leads to new edges between vertices and possibly the creation of new vertices.

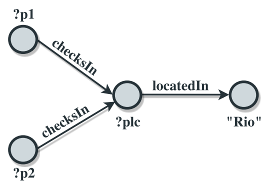

Figure 3: Example query graph pattern.

Definition 3.3. A *graph stream* $S = (u_1, u_2, \dots, u_t)$ of graph G is an *ordered sequence* of updates.

Fig. 2(a) presents an update stream S consisting of three graph updates u_1, u_2, and u_3 generated from social network events. While, Fig. 2 (b) shows the initial state of graph G and its evolution after inserting sequentially the three updates.

3.2 Query Model

For our query model we assume that users (or services operating on their behalf) are interested to learn when certain patterns emerge in an evolving graph. Definition 3.4 formalizes *query graph patterns* that define structural and attribute constraints on graphs.

Definition 3.4. A *query graph pattern* Q_i is defined as a directed labeled multigraph:

$$Q_i = (V_{Q_i}, E_{Q_i}, vars, l_V, l_E, \Sigma_V, \Sigma_E)$$

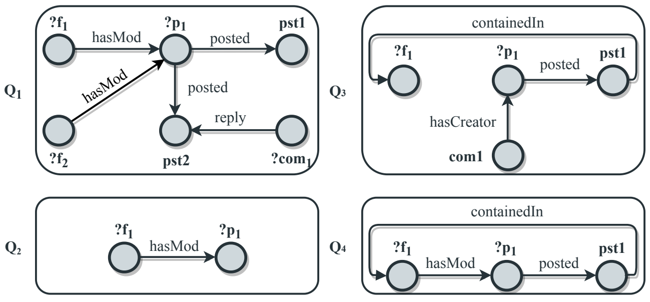
where V_{Q_i} is a set of vertices, E_{Q_i} a set of edges, and $vars$ a set of variables. $l_V : V \longrightarrow \{\Sigma_V \cup vars\}$ and $l_E : E \longrightarrow \Sigma_E$ are labeling functions assigning labels (and variables) to vertices and edges.

Let us consider an example where a user wants to be notified when his friends visit places nearby. Fig. 3 shows the corresponding query graph pattern that will result in a user notification when two people check in at the same place/location in Rio.

Based on the above definitions, let us now define the problem of *multi-query processing over graph streams*.

Problem Definition. Given a set of query graph patterns $Q_{DB} = \{Q_1, Q_2, \dots, Q_k\}$, an initial attribute graph G, and a graph stream S with continuous updates $u_t \in S$, the problem of *multi-query processing over graph streams* consists of continuously identifying all satisfied query graph patterns $Q_i \in Q_{DB}$ when applying incoming updates.

Query Set and Graph Modifications. A set of query graph patterns Q_{DB} is subject to modifications (i.e., additions and deletions). In this work, we focus on streamlining the query indexing phase, while developing techniques that allow processing each incoming query graph pattern separately, thus supporting continuous additions in Q_{DB}. In the same manner, a graph G is subject to edge additions and deletions, our main objective is to efficiently determine the queries satisfied by an edge addition. The proposed model does not require indexing the entire graph G and retains solely the necessary parts of G for the query answering. To this



(a)

Query ID	Set of Covering Paths
Q_1	$P_1 = \{?var \xrightarrow{hasMod} ?var \xrightarrow{posted}$ "$pst1$"$\}$ $P_2 = \{?var \xrightarrow{hasMod} ?var \xrightarrow{posted}$ "$pst2$"$\}$ $P_3 = \{?var \xrightarrow{reply}$ "$pst2$"$\}$
Q_2	$P_1 = \{?var \xrightarrow{hasMod} ?var\}$
Q_3	$P_1 = \{$"$com1$" $\xrightarrow{hasCreator} ?var \xrightarrow{posted}$ "$pst1$" $\xrightarrow{containedIn} ?var\}$
Q_4	$P_1 = \{?var \xrightarrow{hasMod} ?var \xrightarrow{posted}$ "$pst1$" $\xrightarrow{containedIn} ?var\}$

(b)

Figure 4: (a) Four query graph patterns that capture events generated inside a social network and (b) their covering paths.

end, we do not further discuss deletions on Q_{DB} and G, as we focus on providing high performance query answering algorithms.

4 TRIE-BASED CLUSTERING

To solve the problem defined in the previous section, we propose TRIC (TRIe-based Clustering). As motivated in Section 1, the *key idea* behind TRIC lies in the fact that query graph patterns overlap in their structural and attribute restrictions. After identifying and indexing these shared characteristics (Section 4.1), they can be exploited to batch-answer the indexed query set and in this way reduce query response time (Section 4.2).

4.1 Query Indexing Phase

TRIC indexes each query graph pattern Q_i by applying the following two steps:

1. Transforming the original query graph pattern Q_i into a set of path conjuncts, that cover all vertices and edges of Q_i, and when combined can effectively re-compose Q_i.
2. Indexing all paths in a trie-based structure along with unique query identifiers, while clustering all paths of all indexed queries by exploiting commonalities among them.

In the following, we present each step of the query indexing phase of Algorithm TRIC, give details about the data structures utilized and provide its pseudocode (Fig. 5).

$\underline{\mathcal{S}tep\ 1}$: **Extracting the Covering Paths.** In the first step of the query indexing process, Algorithm TRIC decomposes a query graph pattern Q_i and extracts a set of paths $CP(Q_i)$ (Fig. 5, line 1). This set of paths, covers all vertices $V \in Q_i$ and edges $E \in Q_i$. At first, we give the definition of a path and subsequently define and discuss the covering path set problem.

Definition 4.1. A *path* $P_i \in Q_i$ is defined as a list of vertices $P_i = \{v_1 \xrightarrow{e_1} v_2 \xrightarrow{e_2} \dots v_k \xrightarrow{e_k} v_{k+1}\}$ where $v_i \in Q_i$, such that two sequential vertices $v_i, v_{i+1} \in P_i$ have exactly one edge $e_i \in Q_i$ connecting them, i.e., $e_k = (v_k, v_{k+1})$.

Definition 4.2. The *covering paths* [1] *CP* of a query graph Q_i is defined as a set of paths $CP(Q_i) = \{P_1, P_2, \dots, P_k\}$ that cover all *vertices* and *edges* of Q_i. In more detail, we are interested in the least number of paths while ensuring that for every vertex $v_i \in Q_i$ there is at least one path P_j that contains v_i, i.e., $\forall i \exists j : v_i \in P_j$, $v_i \in Q_i$. In the same manner, for every edge $e_i \in Q_i$ there is at least one path P_j that contains e_i, i.e., $\forall i \exists j : e_i \in P_j$.

Obtaining the Set of Covering Paths. The problem of obtaining a set of paths that covers all vertices and edges is a graph optimization problem that has been studied in literature [1, 27]. In our approach, we choose to solve the problem by applying a greedy

```
       Input: Query $Q_i = (V_{Q_i}, E_{Q_i}, vars, l_V, l_E, \Sigma_V, \Sigma_E)$
       Output: $Q_{DB} \leftarrow Q_{DB} \cup Q_i$
Step 1 {  1  $Paths \leftarrow CP(Q_i)$; // Obtain the set of covering paths
Step 2 {  2  foreach $P_i \in Paths$ do // For each covering path $P_i$ of $Q_i$
          3      foreach trie $T_i$ with $root(T_i) = e_1 : e_1 \in P_i$ do
          4          $depthFirstSearch(T_i)$; // Traverse trie in DFS
                     // If there exists a trie that can store $P_i$
          5          if $\exists \{n_0 \rightarrow \dots n_i \rightarrow \dots n_k\} \subseteq P_i$ then
                         // Store the trie path positions
          6              $positions \leftarrow \{n_0 \rightarrow \dots n_i \rightarrow \dots n_k\}$;
                 // If all edges $e_i \in P_i$ cannot be indexed, create
                    additional trie nodes to index them
          7      if $positions \cap P_i \neq \emptyset$ then
          8          $create\_nodes(P_i \setminus positions)$;
          9      $last(positions) \leftarrow id(Q_i)$; // Store the query id
                 // Keep a reference to the last trie node
         10      $pathPositions \rightarrow pathPositions \cup last(positions)$;
                 // Store tries $T_i$ under which, edge $e_i$ is indexed
         11      foreach $e_i \in P_i$ do
         12          $edgeInd[e_i] \leftarrow T_i$;
             // Store the nodes that $Q_i$ was indexed under
         13  $queryInd[id(Q_i)] \leftarrow pathPositions$
```

Figure 5: Query indexing phase of Algorithm TRIC.

algorithm, as follows: For all vertices v_i in the query graph Q_i execute a depth-first walk until a leaf vertex (no outgoing edge) of the graph is reached, or there is no new vertex to visit. Subsequently, repeat this step until all vertices and edges of the query graph Q_i have been visited at least once and a list of paths has been obtained. Finally, for each path in the obtained list, check if it is a sub-path of an already discovered path, and remove it from the list of covering paths. The end result of this procedure yields the *set of covering paths*.

Example 4.3. In Fig. 4(a) we present four query graph patterns. These query graph patterns capture activities of users inside a social network. By applying Definition 4.2 on the four query graph patterns presented, Algorithm TRIC extracts four sets of covering paths, presented in Fig. 4(b).

Obtaining a set of paths serves two purposes: (a) it gives a less complex representation of the query graph that is easier to manage, index and cluster, as well as (b) it provides a streamlined approach on how to perform the materialization of the subgraphs that match a query graph pattern, i.e., the query answering during the evolution of the graph.

Materialization. Each edge e_i that is present in the query set has a materialized view that corresponds to its $matV[e_i]$. The materialized view of e_i stores all the updates u_i that contain e_i. In order to obtain the subgraphs that satisfy a query graph pattern Q_i all edges $e_i \in Q_i$ must have a non-empty materialized view (i.e., $matV \neq \emptyset$) and the materialized views should be joined as defined by the query graph pattern.

Figure 7: Materialized views of Q_1.

In essence, the query graph pattern determines the *execution plan* of the query. However, given that a query pattern in itself is a graph there is a high number of possible execution plans available. A path $P_i = \{v_1 \xrightarrow{e_1} v_2 \xrightarrow{e_2} \dots v_k\}$ serves as a model that defines the order in which the materialization should be performed. Thus, starting from the source vertex $v_1 \in P_i$ and joining all the materialized views from v_1 to the leaf vertex $v_k \in P_i : |P| = k$ yields all the subgraphs that satisfy the path P_i. After all paths P_i that belong in Q_i have been satisfied, a final join operation must be performed between all the paths. This join operation will produce the subgraphs that satisfy the query graph Q_i. To achieve this path joining set, additional information is kept about the intersection of the paths $P_i \in Q_i$. The intersection of two paths P_i and P_j are their common vertices.

Example 4.4. Fig. 7 presents some possible materialized views that correspond to the covering paths of query graph Q_1 (Fig. 4 (b)). In order to locate all subgraphs that satisfy the structural and attribute restrictions posed by paths P_1, P_2 and P_3 their materialized views should be calculated. More specifically, path $P_1 = \{?var \xrightarrow{hasMod} ?var \xrightarrow{posted}$ "$pst1$"$\}$, is formulated by two edges, edges $hasMod = (?var, ?var)$ and $posted = (?var, pst1)$, thus, their materialized views $matV[hasMod = (?var, ?var)]$ and $matV[posted = (?var, pst1)]$ must be joined. These two views contains all updates u_i that correspond to them, while the result of their join operation will be a new materialized view $matV[hasMod = (?var, ?var), posted = (?var, pst1)]$ as shown in Fig. 7. In a similar manner, the subgraphs that satisfy path P_2 are calculated, while P_3 that is formulated by a single edge does not require any join operations. Finally, in order to calculate the subgraphs that match Q_1 all materialized views that correspond to paths P_1, P_2 and P_3 must be joined.

$\underline{\mathcal{S}tep\ 2}$: **Indexing the Paths.** Algorithm TRIC proceeds into indexing all the paths, extracted in $\mathcal{S}tep$ 1, into a trie-based data structure. For each path $P_i \in CP(Q_i)$, TRIC examines the forest for trie roots that can index the first edge $e_1 \in P_i$ (Fig. 5, lines 3 − 6). To access the trie roots, TRIC utilizes a hash table (namely *rootInd*) that indexes the values of the root-nodes (keys) and the references to the root nodes (values). If such trie T_i is located, T_i is traversed in a *DFS* manner to determine in which sub-trie path P_i can be indexed (Fig. 5, line 4). Thus, TRIC traverses the forest to locate an existing trie-path $\{n_1 \rightarrow \dots n_i \rightarrow \dots n_k\}$ that can index the ordered set of edges $\{e_1, \dots, e_k\} \in P_i$. If the discovered trie-path can index P_i partially (Fig. 5, line 7), TRIC proceeds into creating a set of new nodes under n_k that can index the remaining edges (Fig. 5, line 8). Finally, the algorithm stores the identifier of Q_i at the last node of the trie path (Fig. 5, line 9).

Algorithm TRIC makes use of two additional data structures, namely *edgeInd* and *queryInd*. The former data structure is a hash table that stores each edge $e_i \in P_i$ (key) and a collection of trie roots T_i which index e_i as the hash table's value (Fig. 5, lines 11 − 12). Finally, TRIC utilizes a matrix *queryInd* that indexes the query identifier alongside the set of nodes under which its covering paths $P_i \in CP(Q_i)$ was indexed (Fig. 5, line 13).

Example 4.5. Fig. 6 presents an example of *rootInd*, *queryInd* and *edgeInd* of Algorithm TRIC when indexing the set of covering paths of Fig. 4 (b). Notice that TRIC indexes paths $P_1, P_2 \in Q_1$, path $P_1 \in Q_2$ and path $P_1 \in Q_4$ under the same trie T_1, thus, clustering together their common structural restrictions (all the aforementioned paths) and their attribute restrictions. Additionally, note that the *queryInd* data structure keeps references to the last node where each path $P_i \in Q_i$ is stored, e.g. for Q_1 it keeps a set of node positions $\{\&n_2, \&n_4, \&n_5\}$ that correspond to its original paths P_1, P_2 and P_3 respectively. Finally, *edgeInd* stores all the unique edges present in the path set of Fig. 4 (b), with references to the trie roots under which they are indexed, e.g. edge $posted = (?var, pst1)$ that is present in $P_1 \in Q_1$, $P_1 \in Q_3$ and $P_1 \in Q_4$, is indexed under both tries T_1 and T_3, thus this information is stored in set $\{\&T_1, \&T_3\}$.

The time complexity of Algorithm TRIC when indexing a path P_i, where $|P_i| = M$ edges and B the branching factor of the forest, is $\mathcal{O}(M * B)$, since TRIC uses a DFS strategy, with the maximum depth bound by the number of edges. Thus, for a new query graph pattern Q_i with N covering paths, the total time complexity is $\mathcal{O}(N * M * B)$. Finally, the space complexity of Algorithm TRIC when indexing a query Q_i is $\mathcal{O}(N * M)$, where M is the number of edges in a path and N the cardinality of Q_i's covering paths.

Variable Handling. A query graph pattern Q_i contains vertices that can either be literals (specific entities in the graph) identified by their label, or variables denoted as "?var". This approach alleviates restrictions posed by naming conventions and thus leverages on the common structural constraints of paths.

However, by substituting the variable vertices with the generic "?var" requires to keep information about the joining order of each edge $e_i \in P_i$, as well as, how each $P_i \in CP(Q_i)$ intersects with the

```
Input: Update $u_i = (e_i) : e_i = (s, t)$
Output: Locate matched queries
Step 1
1  $affectedTries \leftarrow edgeInd[e_i]$; // Get affected tries
2  foreach $T_i \in affectedTries$ do
3      foreach node $n_i \in T_i$ do // Traverse $T_i$ in DFS
4          if $edge(n_c) = e_i$ then // If current node indexes $e_i$
5              $fndPos \leftarrow n$ ; // Store the position
6              break ;              // Terminate the traversal
       // Update $matV$s of $fndPos$ and its children
7      $affectedQueries \leftarrow$ Trie Traversal & Materialization ($fndPos$)
8  foreach query $Q_i \in affectedQueries$ do
9      $results \leftarrow \emptyset$;
10     foreach $P_i \in Q_i$ do // For the covering paths of $Q_i$
11         $results \leftarrow results \bowtie matV[P_i]$;
12     if $results \neq \emptyset$ then
13         $mark\_Matched(Q_i)$;
```

Figure 8: Query answering phase ($\mathcal{S}tep$ 1) of Algorithm TRIC.

rest of the paths in $CP(Q_i)$. In order to calculate the subgraphs that satisfy each covering path $P_i \in CP(Q_i)$, each $matV[e_i] : e_i \in P_i$ must be joined. Each path P_i that is indexed under a trie path $\{n_1 \rightarrow \ldots n_i \rightarrow \ldots n_k\}$ maintains the original ordering of its edges and vertices, while the order under which each edge of a node n_i is connected with its children nodes ($chn(n_i)$), is determined as follows: the target vertex $t \in e_i$ (where e_i is indexed under n_i) is connected with the source node $s \in e_{i+1} : e_{i+1} \in chn(n_i)$ of the parent node n_i. Finally, for each covering path $P_i \in CP(Q_i)$ TRIC maintains information about the vertices that intersected in the original query graph pattern Q_i, while this information is utilized during the query answering phase.

4.2 Query Answering Phase

During the evolution of the graph, a constant stream of updates $S = (u_1, u_2, \ldots, u_k)$ arrives at the system. For each update $u_i \in S$ Algorithm TRIC performs the following steps:

1. Determines which tries are affected by update u_i and proceeds in examining them.
2. While traversing the affected tries, performs the materialization and prunes sub-tries that are not affected by u_i.

In the following, we describe each step of the query answering phase of Algorithm TRIC. The pseudocode for each step is provided in Figs. 8 and 10.

$\underline{\mathcal{S}tep\ 1}$: **Locate and Traverse Affected Tries.** When an update u_i arrives at the system, Algorithm TRIC utilizes the edge $e_i \in u_i$ to locate the tries that are affected by u_i. To achieve this, TRIC uses the hash table *edgeInd* to obtain the list of tries that contain e_i in their children set. Thus, Algorithm TRIC receives a list (*affectedTries*) that contains all the tries that were affected by u_i and must be examined (Fig. 8, line 1). Subsequently, Algorithm TRIC proceeds into examining each trie $T_i \in affectedTries$ by traversing each T_i in order to locate the node n_i that indexes edge $e_i \in u_i$. When node n_i is located, the algorithm proceeds in $\mathcal{S}tep2$ of the query answering process described below (Fig. 8, lines 3 – 7).

Example 4.6. Let us consider the data structures presented in Fig. 6, the materialized views in Fig. 9, and an update $u_1 = (posted = (p2, pst1))$ that arrives into the evolving graph (Fig. 9(a)). Algorithm TRIC prompts hash table *edgeInd* and obtains list $\{\&T_1, \&T_3\}$. Subsequently, TRIC will traverse tries T_1 and T_3. When traversing trie T_1 TRIC locates node n_2 that matches update $e_1 \in u_1$ and proceeds in $\mathcal{S}tep2$ (described below). Finally, when traversing T_3 TRIC will stop the traversal at root node n_6 as its materialized view is empty $matV[hasCreator = (pst1, ?var)] = \emptyset$ (Fig. 9 (b)), thus all sub-tries will yield empty materialized views.

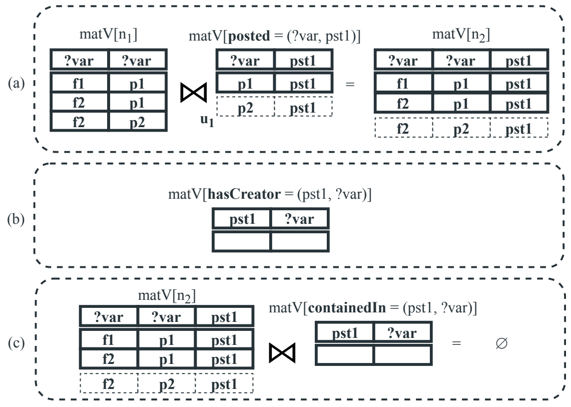

Figure 9: Updating materialized views.

```
Function: Trie Traversal & Materialization
Input: Node $n_i$
Output: Locate matched queries
// Update the current materialized view by joining the
   parent materialized view with the materialized view
   of the edge in node $n_i$
Step 2
1  $result \leftarrow matV[prnt(n_i)] \bowtie matV[edge(n_i)]$;
2  if $result = \emptyset$ then
3      return;
   // Store the query identifiers of node $n_i$
4  $affectedQueries \leftarrow affectedQueries \cup qIDs(n_i)$;
   // Recursively update the $matV$s of $n_i$'s children
5  foreach $n_c \in chn(n_i)$ do
6      Trie Traversal & Materialization ($n_c$);
7  return $affectedQueries$ ; // Return the affected $qIDs$
```

Figure 10: Query answering phase ($\mathcal{S}tep$ 2) of Algorithm TRIC.

$\underline{\mathcal{S}tep\ 2}$: **Trie Traversal and Materialization.** Intuitively, a trie path $\{n_0 \rightarrow \ldots n_i \rightarrow \ldots n_k\}$ represents a series of joined materialized views $matVs = \{matV_1, matV_2, \ldots, matV_k\}$. Each materialized view $matV_i \in matVs$ corresponds to a node n_i that stores edge e_i and the materialized view $matV_i$. The materialized view contains the results of the join operation between the $matV[e_i]$ and the materialized view of the parent node n_i ($matV(prnt(n_i))$), i.e., $matV_i = matV[prnt(n_i)] \bowtie matV[e_i]$. Thus, when an update u_i affects a node n_i in this "chain" of joins, n_i's and its children's ($chn(n_i)$) materialized views must be updated with u_i. Based on this TRIC searches for and locates node n_i inside T_i that is affected by u_i and updates n_i's sub-trie.

After locating node $n_i \in T_i$ that is affected by u_i, Algorithm TRIC continues the traversal of n_i's sub-trie and prunes the remaining sub-tries of T_i (Fig. 8, line 7). Subsequently, TRIC updates the materialized view of n_i by performing a join operation between its parent's node materialized view $matV[prnt(n_i)]$ and the update u_i, i.e., $results = matV[prnt(n_i)] \bowtie u_i$. Notice that Algorithm TRIC calculates the subgraphs formulated by the current update solely based on the update u_1 and does not perform a full join operation between $matV[prnt(n_i)]$ and $matV[edge(n_i)]$, the updated results are then stored in the corresponding $matV[n_i]$.

For each child node $n_j \in chn(n_i)$, TRIC updates its corresponding materialized view by joining its view $matV[n_j]$ that corresponds to the edge that it stores (given by $matV[edge(n_j)]$) with its parent node materialized view $matV[n_i]$ (Fig. 10, lines 1 – 7). If at any point the process of joining the materialized views returns an empty result set the specific sub-trie is pruned, while, the traversal continues in a different sub-trie of T_i (Fig. 10, lines $5-6$). Subsequently, for each trie node n_j in the trie traversal when there is a successful join operation among $matV[e_j] : e_j \in n_j$ and $matV[n_i]$, the query identifiers indexed under n_j are stored in *affectedQueries* list (Fig. 10, lines 4 and 7). Note that similarly to before, only the updated part of a materialized view is utilized as the parent's materialized view, an approach applied on database-management system [16].

Example 4.7. Let us consider the data structures presented in Fig. 6, Fig. 9, and an update $u_1 = (posted = (p2, pst1))$ that arrives into the evolving graph. After locating the affected trie node n_2 (described in Example 4.6) TRIC proceeds in updating the materialized view of n_2, i.e., $matV[n_2]$, by calculating the join operation between its parents materialized view, i.e., $matV[n_1]$ and the update u_1. Fig. 9, demonstrates the operations of joining $matV[n_2]$ with update u_1, the result of the operation is tuple $(f2, p2, pst1)$, which is added into $matV[n2]$, presented in Fig. 9(a). While the query identifiers of n_2 (i.e., Q_1) are indexed in *affectedQueries*. Finally, TRIC proceeds in updating the sub-trie of n_2, node n_3, where the updated tuple $(f2, p2, pst1)$ is joined with $matV[edge(n_3)]$ (i.e., $matV[containedIn = (pst1, ?var)]$). This operation yields an empty result (Fig. 9(c)), thus terminating the traversal.

Finally, to complete the filtering phase Algorithm TRIC iterates through the affected list of queries and performs the join operations among the paths that form a query, thus, yielding the final answer (Fig. 8, lines $8-13$).

The time complexity, of Algorithm TRIC when filtering an update u_i, is calculated as follows: The traversal complexity is $\mathcal{O}(T * (P_m * B))$, where T denotes the number of tries that contain $e_i \in u_i$, P_m denotes the size of the longest trie path, and B the branching factor. The time complexity of joining two materialized views $matV_1$ and $matV_2$, where $|matV_1| = N$ and $|matV_2| = M$, is $\mathcal{O}(N * M)$. Finally, the total time complexity is calculated as $\mathcal{O}((T * (P_m * B)) * (N * M))$.

Caching. During $\mathcal{S}tep$ 2, two materialized views are joined using a typical hash join operation with a build and a probe phase. In the build phase, a hash table for the smallest (in the number of tuples) table is constructed, while in the probe phase the largest table is scanned and the hash table is probed to perform the join. TRIC discards all the data structures and intermediate results after the join operation commences. In order to enhance this resource intensive operation, we cache and reuse the data structures generated during the build and probe phases as well as the intermediate results whenever possible. This approach constitutes an extension of our proposed solution (TRIC) and it is coined TRIC+.

4.3 Supporting richer models and languages

The proposed algorithm is easily extensible to more sophisticated data models and query languages; in this section, we briefly outline the necessary modifications to support graph deletions and updates, as well as more general types of graphs (e.g., property graphs).

Edge deletions may be handled by algorithms TRIC and TRIC+ by locating the affected paths, and traversing each path to locate the deleted edges; while visiting each edge, the materialized view that corresponds to that edge should be accessed and all affected tuples should be removed. Updates on the graph (e.g., on the label of an edge) may be modeled as an edge deletion followed by an edge addition operation. Finally, extending our solution for more general graph types, like property graphs, entails the addition of extra constraints within the nodes of the tries and the usage of a separate data structure to appropriately index these constraints. Then, query answering would include an extra phase for the determining the satisfaction of the additional constraints. Efficient execution of such extensions is an interesting topic for future research (see Section 7).

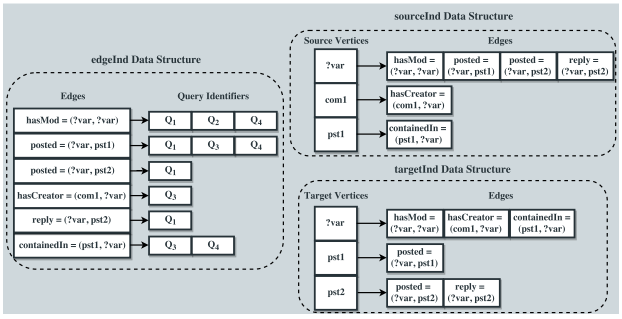

Figure 11: Index structures utilized by Algorithm INV.

5 ADVANCED BASELINES

Since no prior work in the literature considers the problem of continuous multi-query evaluation, we designed and implemented Algorithms INV and INC, two advanced baselines that utilize inverted index data structures. Finally, we provide a third baseline that is based on the well-established graph database Neo4j [43].

5.1 Algorithm INV

Algorithm INV (INVerted Index), utilizes inverted index data structures to index the query graph patterns. The inverted index data structure is able to capture and index common elements of the graph patterns at the edge level during indexing time. Subsequently, the inverted index is utilized during filtering time to determine which queries have been satisfied. In the following, we describe the query indexing and answering phase of INV.

The Query Indexing Phase of Algorithm INV, for each query graph pattern Q_i, is performed in two steps: (1) Transforming the original query graph pattern Q_i into a set of path conjuncts, that cover all vertices and edges of Q_i, and when combined can effectively re-compose Q_i, and finally, indexing those covering paths in a matrix along the unique query identifier, (2) Indexing all edges $e_i \in Q_i$ into an inverted index structure. In the following, we present each step of the query indexing phase of INV and give details about the data structures utilized.

$\underline{\mathcal{S}tep\ 1:}$ **Extracting the Covering Paths.** In the first step of the query indexing phase, Algorithm INV decomposes a query graph Q_i into a set of paths CP, a process described in detail in Section 4.1. Thus, given the query set presented in Fig. 4 (a), INV yields the same set of covering paths CP (Fig. 4 (b)). Finally, the covering path set CP is indexed into an array (*queryInd*) with the query identifier of Q_i.

$\underline{\mathcal{S}tep\ 2:}$ **Indexing the Query Graph.** Algorithm INV builds three inverted indexes, where it stores the structural and attribute constrains of the query graph pattern Q_i. Hash table *edgeInd* indexes all edges $e_i \in Q_{DB}$ (keys), and the respective query identifiers as values, hash table *sourceInd* indexes the source vertices of each edge (key), where the edges are indexed as values , and hash table *targetInd* that indexes the target vertices of each edge (key), where the edges are indexed as values. In Fig. 4(a) we present four query graph patterns, and in Fig. 11 the data structures of

INV when indexing those queries. Finally, INV applies the same techniques of handling variables as Algorithm TRIC (Section 4.1).

The Query Answering Phase of Algorithm INV, when a constant stream of updates $S = (u_1, u_2, \ldots, u_k)$ arrives at the system, is performed in three steps: (1) Determines which queries are affected by update u_i, (2) Prompts the inverted index data structure and determines which paths have been affected by update u_i, (3) Performs the materialization while querying the inverted index data structures. In the following, we describe each step of the query answering phase:

$\underline{\mathcal{S}tep\ 1}$: **Locate the Affected Queries.** When a new update u_i arrives at the system, Algorithm INV utilizes the edge $e_i \in u_i$ to locate the queries that are affected, by querying the hash table *edgeInd* to obtain the query identifier *qIDs* that contain e_i. Subsequently, the algorithm iterates through the list of *affectedQueries* and checks each query $Q_i \in qIDs$. For each query Q_i the algorithm checks $\forall e_i \in Q_i$ if $matV[e_i] \neq \emptyset$, i.e., each e_i should have a *non empty* materialized view. The check is performed by iterating through the edge list that is provided by *queryInd* and a hash table that keeps all materialized views present in the system. Intuitively, a query Q_i is candidate to match, as long as, all materialized views that correspond to its edges can be used in the query answering process.

$\underline{\mathcal{S}tep\ 2}$: **Locate the Affected Paths.** Algorithm INV proceeds to examine the inverted index structures *sourceInd* and *targetInd* by making use of $e_i \in u_i$. INV queries *sourceInd* and *targetInd* to determine which edges are affected by the update, by utilizing the source and target vertices of update u_i. INV examines each current edge e_c of the affected edge set and recursively visits all edges connected to e_c, which are determined by querying the *sourceInd* and *targetInd*. While examining the current edge e_c, INV checks if e_c is part of *affectedQueries*, if not, the examination of the specific path is pruned. For efficiency reasons, the examination is bound by the maximum length of a path present in *affectedQueries* which is calculated by utilizing the *queryInd* data structure.

$\underline{\mathcal{S}tep\ 3}$: **Path Examination and Materialization.** While INV examines the paths affected by update u_i ($\mathcal{S}tep$ 2), it performs the materialization on the currently examined path. INV searches through the paths formulated by the visits of edge sets determined by *targetInd* and *sourceInd*, and maintains a path $P_c = \{v_1 \xrightarrow{e_1} v_2 \xrightarrow{e_2} \ldots v_k \xrightarrow{e_k} v_{k+1}\}$ that corresponds to the edges already visited.

While, visiting each edge e_c, INV accesses the materialized view that corresponds to it (i.e., $matV[e_c]$) and updates the set of materialized views $matVs = \{matV_1, matV_2, \ldots, matV_k\}$ that correspond to the current path. For example, given an already visited path $P = \{v_1 \xrightarrow{e_1} v_2 \xrightarrow{e_2} v_3\}$ its materialized view $matV[P]$ will be generated, by $matV[P] = matV[e_1] \bowtie matV[e_2]$. When visiting the next edge e_n, a new path P' is generated and its materialized view $matV[P'] = matV[P] \bowtie matV[e_n]$ will be generated. If at any point, the process of joining the materialized views yields an empty result set the examination of the edge is terminated (pruning). This allows us to prune paths that are not going to satisfy any $Q_i \in affectedQueries$. If a path P_i yields a successful series of join operations (i.e., $matV[P_i] \neq \emptyset$), it is marked as matched.

Finally, to produce the final answer subgraphs Algorithm INV iterates through the affected list of queries $qIDs \in affectedQueries$ and performs the final join operation among all the paths that comprise the query.

Caching. In the spirit of TRIC+ (Section 4.2), we developed an extension of INV, namely INV+, that caches and reuses the calculated data structures of the hash join phase.

5.2 Algorithm INC

Based on Algorithm INV we developed an algorithmic extension, namely Algorithm INC. Algorithm INC utilizes the same inverted index data structures to index the covering paths, edges, source and target vertices as Algorithm INV, while the examination of a path affected during query answering remains similar. The key difference lies in executing the joining operations between the materialized views that correspond to edges belonging to a path. More specifically, when Algorithm INV executes a series of joins between the materialized views (that formulate a path) to determine which subgraphs match a path; it utilizes all tuples of each materialized view that participate in the joining process. On the other hand, Algorithm INC makes use of only the update u_i and thus reduces the number of tuples examined through out the joining process of the paths.

Caching. In the spirit of TRIC+ (Section 4.2), we developed an extension of INC, namely INC+, that caches and reuses the calculated data structures of the hash join phase.

5.3 Neo4j

To evaluate the efficiency of the proposed algorithm against a real-world approach, we implemented a solution based on the well-established graph database Neo4j [43]. In this approach, we extend Neo4j's native functionality with auxiliary data structures to efficiently store the query set. They are used during the answering phase to located affected queries and execute them on Neo4j.

The Query Indexing Phase. To address the continuous multi-query evaluation scenario, we designed main-memory data structures to facilitate indexing of query graph patterns. Initially, in the preprocessing phase, we convert each incoming query Q_i into Neo4j's native query language Cypher[1]. Subsequently, the query indexing phase of Neo4j commences as follows: (1) indexing each Cypher query in the *queryInd* data structure, and (2) indexing all edges $e_i \in Q_i$ in the *edgeInd* data structure where e_i is used as key, and a collection of query identifiers as values. The *queryInd* structure is defined as matrix, while the *edgeInd* is an inverted index, similarly to the data structures described in Section 5.1.

The Query Answering Phase. Each update that is received as part of an incoming stream of updates $S = (u_1, u_2, \ldots, u_k)$ is processed in the following steps: (1) an incoming update u_i is applied to Neo4j (2) the inverted index *edgeInd* is queried with $e_i \in u_i$, to determine which queries are affected, (3) all affected queries are retrieved from matrix *queryInd*, (4) the affected queries are executed.

To enhance performance, the following configurations are applied: (1) the graph database builds indexes on all labels of the schema allowing for faster look up times of nodes, (2) the execution of Cypher queries employs the *parameters syntax*[2] as it enables the execution planner of Neo4j to cache the query plans for future use, (3) the number of writes per transaction[3] in the database and the allocated memory were optimized based on the hardware configuration (see Section 6.1).

Figure 12: Query answering time for the SNB dataset.

6 EXPERIMENTAL EVALUATION

In this section, we present a series of experiments that compare the performance of the presented algorithms.

6.1 Experimental Setup

Data and Query Sets. For the experimental evaluation we used a synthetic and two real-world datasets.

The SNB Dataset. The first dataset we utilized is the LDBC Social Network Benchmark (*SNB*) [12]. *SNB* is a synthetic benchmark designed to accurately simulate the evolution of a social network through time (i.e, vertex and edge sets labels, event distribution etc). This evolution is modeled using activities that occur inside a social network (i.e. user account creation, friendship linking, content creation, user interactions etc). Based on the *SNB* generator we simulated the evolution of a graph consisting of user activities over a time period of 2 years. From this dataset we derived 3 query loads and configurations: (i) a set with a graph size of $|G_E| = 100K$ edges and $|G_V| = 57K$ vertices, (ii) a set with a graph size of $|G_E| = 1M$ edges and $|G_V| = 463K$ vertices, and (iii) a set with a graph size of $|G_E| = 10M$ edges and $|G_V| = 3.5M$.

The NYC Dataset. The second dataset we utilized is a real world set of taxi rides performed in New York City[4] (*TAXI*) in 2013 utilized in *DEBS 2015 Grand Challenge* [19]. *TAXI* contains more that $160M$ entries of taxi rides with information about the license, pickup and drop-off location, the trip distance, the date and duration of the trip, and the fare. We utilized the available data to generate a stream of updates that result in a graph of $|G_E| = 1M$ edges and $|G_V| = 280K$, accompanied by a set of $5K$ query graph patterns.

The BioGRID Dataset. The third dataset we utilized is BioGRID [35], a real world dataset that represents protein to protein interactions. This dataset is used as a stress test for our algorithms since it contains one type of edge (interacts) and vertex (protein), and thus every update affects the whole query database. We used BioGRID to generate a stream of updates that result in a graph size of $|G_E| = 1M$ edges and $|G_V| = 63K$ vertices, with a set of $5K$ query graph patterns.

Query Set Configuration. In order to construct the set of query graph patterns Q_{DB} we identified three distinct query classes that are typical in the relevant literature: chains, stars, and cycles [15, 26]. Each type of query graph pattern was chosen equiprobably during the generation of the query set. The baseline values for the query set are: (i) an average size ℓ of 5 edges/query graph pattern, a value derived from the query workloads presented in *SNB* [12], (ii) a query database $|Q_{DB}|$ size of $5K$ graph patterns, (iii) a factor that denotes the percentage of the query set Q_{DB} that will ultimately be satisfied, denoted as selectivity $\sigma = 25\%$, and (iv) a factor that denotes the percentage of overlap between the queries in the set, $o = 35\%$.

Metrics. In our evaluation, we present and discuss the filtering and indexing time of each algorithm, along with the total memory requirements.

Technical Configuration. All algorithms were implemented in Java 8 while for the materialization implementation the Stream API was employed. The Neo4j-based approach was implemented using the embedded version of Neo4j 3.4.7. Extensive experimentation evaluation concluded that a transactionsection 5.3 can perform up to $20K$ writes in the database without degrading Neo4j's performance, while in order to guarantee indexes are cached in main memory $55GB$ of main memory were allocated. A machine with Intel(R) Xeon(R) Processor E5-2650 at $2.00GHz$, $64GB$ RAM, and Ubuntu Linux 14.04 was used. The time shown in the graphs is wall-clock time and the results of each experiment are averaged over 10 runs to eliminate fluctuations in measurements.

6.2 Results for the SNB Dataset

In this section, we present the evaluation for the *SNB* benchmark and highlight the most significant findings.

Query Answering Time. Fig. 12(a) presents the results regarding the query answering time, i.e., the average time in milliseconds needed to determine which queries are satisfied by an incoming update, against a query set of $Q_{DB} = 5K$. Please notice that the y-axis is split due to the high differences in the performance of TRIC/TRIC+and its competitors. We observe that the answering time increases for all algorithms as the graph size increases. Algorithms TRIC/TRIC+ achieve the lowest answering times, suggesting better performance. Contrary, the competitors are more sensitive in graph size changes, with Algorithm INV performing the worst (highest query answering time). When comparing Algorithm TRIC to INV, INC and Neo4j the query answering time is improved by 99.15%, 98.14% and 91.86% respectively, while the improvement between INC and INV is 54.33%. Finally, comparing Algorithm TRIC+ to INV+, INC+ and Neo4j demonstrates a performance improvement of 99.62%, 99.17% and 96.74% respectively, while the difference of INC+ and INV+ is 54.6%.

The results (Fig. 12(a)) suggest that all solutions that implement caching are faster compared to the versions without it. In more detail, Algorithms TRIC+/INV+/INC+ are consistently faster than their non-caching counterparts, by 59.95%, 9.36% and 9.91% respectively. This is attributed to the fact that Algorithms TRIC/INV/INC, have to recalculate the probe and build structures required for the joining process, in contrast to Algorithms TRIC+/INV+/INC+ that store these structures and incrementally update them, thus providing better performance.

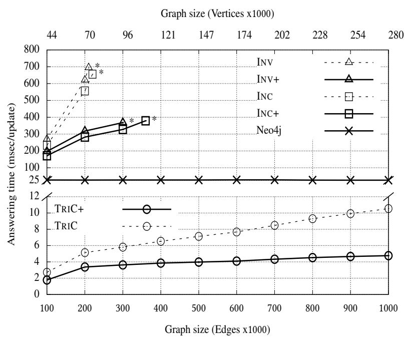
In Fig. 12(b) we present the results when varying the parameter σ, for 10%, 15%, 20%, 25% and 30% of a query set for $|Q_{DB}| = 5K$ and $|G_E| = 100K$. In this setup the algorithms are evaluated for a varying percentage of queries that match. A higher number of queries satisfied, increases the number of calculations performed by each algorithm. The results show that all algorithms behave in a similar manner as previously described. In more detail, Algorithm TRIC+ is the most efficient of all, and thus the fastest among the extensions that utilize caching, while TRIC is the most efficient solution among the solutions that do not employ a caching strategy. Finally, the percentage differences, between the algorithmic solutions remain the same as before in most cases.

Fig. 12(c) presents the results of the experimental evaluation when varying the size of the query database $|Q_{DB}|$. More specifically, we present the answering time per triple when $|Q_{DB}| = 1K$, $3K$ and $5K$, and $|G_E| = 100K$. Please notice the y-axis is in logarithmic scale. The results demonstrate that all algorithm's behavior is aligned with our previous observations. More specifically, Algorithms TRIC+ and TRIC exhibit the highest performance (i.e., lowest answering time), throughout the increase of $|Q_{DB}|$, and thus determine faster which queries of $|Q_{DB}|$ have matched given an update u_i. Similarly to the previous setups, the competitors have the lowest performance, while Algorithms INC and INC+ perform better compared to INV and INV+.

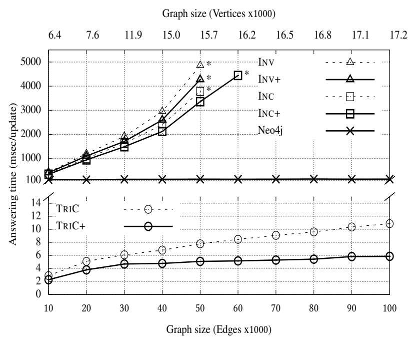
In Fig. 12(d) we give the results of the experimental evaluation when varying the average query size ℓ. More specifically, we present the answering time per triple when $\ell = 3$, 5, 7 and 9 of a query set for $|Q_{DB}| = 5K$ and $|G_E| = 100K$. We observe that the answering time increases for all algorithms as the average query length increases. More specifically, Algorithms TRIC+ and TRIC exhibit the highest performance (i.e., lowest answering time), throughout the increase of ℓs, and thus determine faster which queries have been satisfied. Similarly to the previous evaluation setups, the Algorithms INV/INV+/INC/INC+/Neo4j have the lowest performance, and increase significantly their answering time when ℓ increases, while Algorithms INC and INC+ perform better compared to INV, INV+ and Neo4j when $\ell = 9$.

Fig. 12(e) gives the results of the experimental evaluation when varying the parameter o, for 25%, 35%, 45%, 55% and 65% of a query set for $|Q_{DB}| = 5K$ and $|G_E| = 100K$. In this setup the algorithms are evaluated for varying percentage of query overlap. A higher number of query overlap, should decrease the number of calculations performed by algorithms designed to exploit commonalities among the query set. The results show that all algorithm behave in a similar manner as previously described, while AlgorithmsINV/INV+/INC/INC+ observe higher performance gains. Algorithm TRIC+ is the most efficient of all, and thus the fastest among the extensions that utilize caching techniques, while TRIC is the most efficient solution among the solutions that do not employ caching.

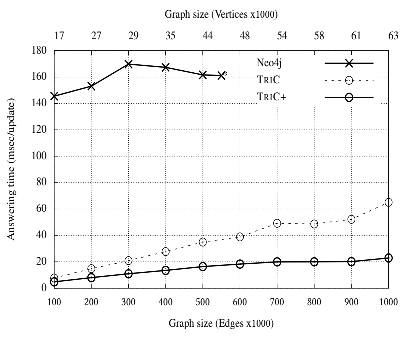
Fig. 12(f) presents the results regarding the query answering time, for all algorithms when indexing a query set of $|Q_{DB}| = 5K$ and a final graph of $|G_E| = 1M$ and $|G_V| = 463K$. Given the extremely slow performance of some algorithms we have set an *execution time threshold* of 24 hours, for all algorithms under evaluation, thus, when the threshold was crossed the evaluation was terminated. Algorithms TRIC/TRIC+ achieve the lowest answering times, suggesting better performance, while Algorithms INV/INV+/INC/INC+ are more sensitive in graph size changes and thus fail to terminate within the time threshold. More specifically, Algorithms INV/INV+ *time out* at $|G_E| = 210K$, while INC/INC+ *time out* at $|G_E| = 310K$ as denoted by the asterisks



(a) Influence of graph size.



(b) Influence of graph size.



(c) Influence of graph size.

Figure 14: Query answering time for (a) the *TAXI* dataset, and (b) & (c) the *BioGRID* dataset.

in the plot. When comparing TriC/TriC+ to Neo4j the query answering is improved by 77.01% and 92.86% respectively.

Fig. 13(a) presents the results regarding the query answering time, for Algorithms TriC, TriC+ and Neo4j when indexing a query set of $Q_{DB} = 5K$ and a final graph size of $|G_E| = 10M$ and $|G_V| = 3.5M$. Again, we have set an *execution time threshold* of 24 hours, for all the algorithms under evaluation. Algorithm TriC+ achieves the lowest answering times, suggesting better performance, while Algorithms TriC and Neo4j fail to terminate within the given time threshold. More specifically, Algorithm TriC *times out* at $|G_E| = 5.47M$, while Algorithm Neo4j times out at $|G_E| = 4.3M$ as denoted by the asterisks in the plot.

Overall, Algorithms TriC+ and TriC, the two solutions that utilize trie structures to capture and index the common structural and attribute restrictions of query graphs achieve the lowest query answering times, compared to Algorithms Inv/Inv+/Inc/Inc+ that employ no clustering techniques, as well as when compared with commercial solutions such as Neo4j. Adopting the incremental joining techniques (found in Algorithm TriC) into Algorithm Inc does not seem to significantly improve its performance when compared to Algorithm Inv. While, adopting caching techniques that store the data structures generated during the join operations, changes significantly the performance of Algorithm TriC+. Taking all the above into consideration, we conclude that the algorithms that utilize trie-based indexing achieve low query answering times compared to their competitors.

Indexing Time. Fig. 13(b) presents the indexing time in milliseconds required to insert $1K$ query graph patterns when the query database size increases. We observe that the time required to go from an empty query database to a query database of size $1K$ is higher compared to the time required for the next iterations. Please notice the y-axis is in logarithmic scale. This can be explained as follows, all algorithms utilize data structures that need to be initialized during the initial stages of query indexing phase, i.e. when inserting queries in an empty database, while as the queries share common restrictions less time is required for creating new entries in the data structures. Additionally, the time required to index a query graph pattern in the database does not vary significantly for all algorithms. Notice that query indexing time is not a critical performance parameter in the proposed paradigm, since the most important dimension is query answering time.

6.3 Results for the NYC and BioGRID Dataset

In this section, we present the evaluation for the *NYC* and *BioGRID* dataset and highlight the most significant findings.

The *NYC* Dataset. Fig. 14(a) presents the results from the evaluation of the algorithms for the *NYC* dataset. More specifically, we present the results regarding the query answering performance of all algorithms when $Q_{DB} = 5K$, $\ell = 5$, $o = 35\%$, $\sigma = 25\%$ and an execution time threshold of 24 hours. Please notice that the y-axis is split due to high differences in the performance of the algorithms. Algorithms Inv and Inv+ fail to terminate within the time threshold and *time out* at $|G_E| = 210K$ and $|G_E| = 300K$ respectively. Similarly, Algorithms Inc and Inc+ *time out* at $|G_E| = 220K$ and $360K$ respectively. When comparing Algorithms TriC and TriC+ to Neo4j the query answering is improved by 59.68% and 81.76% respectively. These results indicate that again an algorithmic solution that exploits and indexes together the common parts of query graphs (i.e., Algorithms TriC/TriC+) achieves significantly lower query answering time compared to approaches that do not apply any clustering techniques (i.e., AlgorithmsInv/Inv+Inc/Inc+/Neo4j).

The *BioGRID* Dataset. Figs. 14(b) and 14(c) present the results from the evaluation of the algorithms for the *BioGRID* dataset. In Fig. 14(b) we present the results regarding the query answering performance of the algorithms, when $Q_{DB} = 5K$, $\sigma = 25\%$ for a final graph size of $|G_E| = 100K$ and $|G_V| = 17.2K$. Additionally, we set an execution time threshold of 24 hours due to the high differences in the performance of the algorithms. The *BioGRID* dataset serves as a stress test for our algorithms, since it contains only one type of edge and vertex, thus each incoming update will affect (but not necessarily satisfy) the entire query database. To this end, Algorithms Inv/Inv+/Inc exceed the time threshold and time out at $|G_E| = 50K$, while Inc+ times out at $|G_E| = 60K$ as denoted by the asterisks in the plot. Finally, Fig. 14(c) presents the results for the *BioGRID* dataset for a final graph size of $|G_E| = 1M$ and $|G_V| = 63K$. We again observe that Algorithms TriC and TriC+ achieve the lowest answering time, while Neo4j exceeds the time threshold and times out at $|G_E| = 550K$. As it is demonstrated from the results yielded by the evaluation, Algorithms TriC and TriC+ are the most efficient of all; this is attributed to the fact that both algorithms create a combined representation of the query graph patterns that can efficiently be utilized during query answering time.

Comparing Memory Requirements. Fig. 13(c) presents the memory requirements of each algorithm, for the *SNB*, *NYC* and *BioGRID* datasets when indexing $|Q_{DB} = 5K|$ and a graph of $|G_E| = 100K$. We observe, that across all datasets, Algorithms TriC, Inv and Inc have the lowest main memory requirements, while, Algorithms TriC+, Inv+, Inc+ and Neo4j exhibit higher memory requirements. The marginally higher memory requirements of algorithms that employ a caching strategy, (i.e., Algorithms TRIC+/INV+/INC+) is attributed to the fact that all structures calculated during the materialization phase are kept in memory for future usage; this results in slightly higher memory requirements compared to algorithms that do not apply this caching technique (i.e., Algorithms TRIC/INV/INC). To this end, employing a caching strategy for all algorithms yields significant performance gains with minimal impact on main memory. Finally, Neo4j is a full fledged database management system, thus it occupies more memory to support the required specifications.

7 OUTLOOK

In this work, we proposed a new paradigm to efficiently capture the evolving nature of graphs through query graph patterns. We proposed a novel method that indexes and continuously evaluates queries over graph streams, by leveraging on the shared restrictions present in query sets. We also evaluated our solution using three different datasets from social networks, transportation and biological interactions domains, and demonstrated that our approach is up to two orders of magnitude faster when compared to typical join-and-explore inverted index solutions, and the well-established graph database Neo4j.

Our future research plans involve (i) further improving the algorithm performance by storing materializations within the trie to minimize trie traversal at query answering time and exploiting workload-driven statistics in the spirit of [23] and (ii) increasing the model expressiveness by implementing graph deletions, supporting more general graph types (e.g., property graphs), and introducing query classes that aim at clustering coefficient, shortest path, and betweenness centrality.

ABSTRACT

An evolving graph maintains the history of changes of graph topology and attribute values over time. Such a graph has a specific temporal and structural resolution. It is often useful to modify this resolution during analysis, for example, to consider communities rather than individual nodes, or to quantify changes at the level of days rather than hours.

We propose *attribute-based zoom* and *temporal window-based zoom* — two operators that support exploratory analysis of an evolving graph at different levels of resolution. We develop several alternative physical representations of an *evolving property graph* — a temporal generalization of a property graph — and detail how to implement the proposed zoom operators using dataflow operations. These different physical representations allow us to explore the trade-offs in temporal and structural locality with respect to the performance of the zoom operators. We implement the operators in Apache Spark, evaluate them on real evolving graph datasets, and demonstrate scalability to billion-edge graphs.

1 INTRODUCTION

Many social structures and systems can be represented as networks or graphs. The phenomena that are represented by these graphs can change over time, and therefore, many interesting questions about these graphs are related to their evolution rather than to their static state. Researchers study graph evolution rate and mechanisms [1, 9], the impact of specific events on further evolution [8, 39] and spatio-temporal patterns [27, 28], with most progress taking place in the last decade [24, 35, 37, 38, 40].

Our focus in this paper is on a temporal generalization of a property graph, called TGraph, which we recently introduced [37]. Figure 1 shows an example — an interaction network in which nodes represent people, and, for the students among them, include information about a school at which they are enrolled, while edges represent co-authorship. As in conventional property graphs [3], nodes and edges of a TGraph are associated with a set of key-value pairs that represent an assignment of values to attributes. In addition, TGraph associates a time interval (representing a set of discrete consecutive time points) with each state of a node or edge. For example, a `person` node *Ann* exists, and is enrolled at MIT, during the interval $T = [1, 7)$.

TGraph maintains the history of changes of graph topology and attribute values over time. It has a specific *temporal* and *structural resolution*, which users often want to modify for exploratory analysis, for example, to look at communities rather than individual nodes, or to quantify changes at the level of days rather than hours. In this paper we focus on two operators, aZoom^T and wZoom^T, that allow us to change the structural and temporal resolution of a TGraph, respectively. These operators are part of a compositional evolving graph algebra called TGA, which we presented in [37], that operates under *point semantics* [5].[1] A consequence of these semantics is that the TGraph must remain *temporally coalesced* — vertices and edges in the output of an operator must be associated with time periods of maximal length during which no change occurred.

Attribute-based zoom (aZoom^T). We may be interested in analyzing evolving graphs at different levels of *structural resolution*, to study properties and behavior of individual nodes, of communities, and of the graph as a whole. An operation that achieves this, known as *node creation*, is present in several conventional (non-temporal) graph query languages [14, 21, 32, 42]. Our focus is on a temporal generalization of this operation for graphs, called *temporal attribute-based zoom*, or aZoom^T for short.

Consider TGraph $\mathcal{G}_1$ in Figure 1, where school names are represented as values of the school property of person nodes. aZoom^T computes the TGraph in Figure 2, where schools become nodes (actors) rather than values.

aZoom^T is evaluated over a TGraph under *point semantics* and, specifically, under the principle of snapshot reducibility [5]: we evaluate the non-temporal variant of the operator over each state of the graph (also known as a "snapshot"), and then apply temporal coalescing [4] to represent each vertex or edge in the result with a single fact, corresponding to the longest interval during which no change occurred. aZoom^T is described in Section 2.2.

Temporal window-based zoom (wZoom^T). This operator changes the *temporal resolution* of a TGraph. This operation is important because it may not be known *a priori*, at the time when graph evolution is being recorded, at what time scale interesting trends can be observed. For example, changes in node centrality in a social network may be observable on the scale of weeks but not months. Understanding at what temporal resolution to consider network evolution is an integral part of exploratory analysis. Let us return to our running example in Figure 1, and assume that time points represent months of 2019. We may zoom out on $\mathcal{G}_1$ temporally, to 3-month windows, retaining nodes and edges in the result for a particular time window that were present in the input during all time points of the window. The result is presented in Figure 3, and described in more detail in Section 2.3.

Next, we explore different physical representations to answer the following questions: (i) How should we represent a TGraph to compute the result of aZoom^T and wZoom^T efficiently? Should we use a snapshot-based representation, storing graph evolution as a sequence of conventional graphs, that is easy to parallelize but lacks compactness, or should we leverage a more compact representation, as suggested by Figure 1? (ii) What representation should we use to efficiently execute *a sequence* of these operators? We address these questions, making the following contributions:

- We propose different physical representations of a TGraph and detail how to define aZoom^T and wZoom^T using dataflow operations for these representations (Section 3).

*This work was supported in part by NSF Grant No. 1916505.

[1]The focus of [37] is on defining the TGraph model and algebra, while this paper focuses on system and implementation aspects.

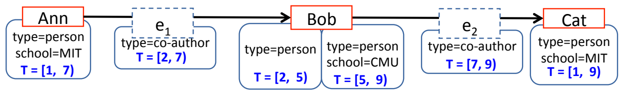

Figure 1: Evolving property graph (TGraph) $\mathcal{G}_1$.

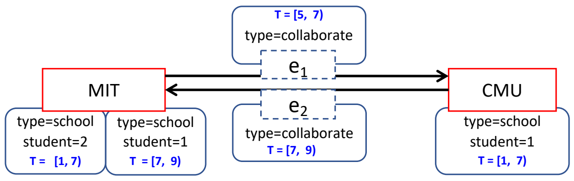

Figure 2: Result of aZoom^T over $\mathcal{G}_1$ (Figure 1). Semantically, this operation is executed over every snapshot of $\mathcal{G}_1$ to: (i) create `school` nodes for each value of the school property of `person` nodes in $\mathcal{G}_1$; (ii) count the number of persons enrolled at a school, set the value of the student property of the `school` node to that count; (iii) create edges of type `collaborate` between school nodes for which `co-author` edges were present in $\mathcal{G}_1$; and (iv) temporally coalesce the result across snapshots, due to point semantics.

- We describe how to efficiently implement aZoom^T and wZoom^T in Apache Spark (Section 4).
- We conduct an extensive experimental evaluation of aZoom^T and wZoom^T and demonstrate scalability to billion-edge graphs. We find that a physical representation that balances temporal and structural locality outperforms other representations in most cases (Section 5).

2 TGRAPH MODEL AND ZOOM OPERATORS

We provide the background on the evolving property graph model called TGraph, and define the operators aZoom^T and wZoom^T that take a valid TGraph as input, and output a TGraph.

2.1 Evolving property graphs

In [37] we proposed a logical model of an evolving graph called TGraph that represents a single graph (such as the Web, or a large collaboration network), and models the evolution of its topology, and vertex and edge properties. A TGraph is a directed multigraph: its nodes and edges have identity, and multiple edges may connect a given pair of nodes. Each entity (node and edge) has a required type label, and is associated with a (possibly empty) set of key-value pairs that represent its properties, each in the form of a property label (key) and a corresponding value. The set of properties for an entity is not fixed: it can be different among entities of the same type, and for the same entity over time.

We now recall the definition of TGraph from [37], simplifying it slightly. This definition extends the static property graph definition of Angles et al. [3] by associating periods of validity with graph nodes, edges, and their properties. Time is drawn from a linearly ordered discrete domain Ω^T.

Definition 2.1. A TGraph $\mathcal{G} = (V, E, L, \rho, \xi^T, \lambda^T)$ is a six-tuple:

- V is a finite set of *nodes* (or *vertices*), E is a finite set of *edges*, $V \cap E = \emptyset$, and L is a finite set of property labels;
- $\rho : E \longrightarrow (V \times V)$ is a total function that maps an edge to its source and destination nodes;
- $\xi^T : (V \cup E) \times \Omega^T \longrightarrow B$ is a total function that maps a node or an edge and time point to a Boolean, indicating existence of the node or edge at that time point; and
- $\lambda^T : (V \cup E) \times L \times \Omega^T \longrightarrow val$ is a partial function that maps a node or an edge, a property label, and a time point to a value of the property at that time point.

A valid TGraph conceptually corresponds to a sequence of valid conventional (non-temporal) graphs. This imposes the following conditions: (i) a condition on ξ^T that an edge can only exist at a time when both of the nodes it connects exist; and (ii) a condition on λ^T that a property can only take on a value at a time when the corresponding node or edge exists. Finally, we require that the property set of an entity **not** be empty at any time point when it exists. Practically, we require that each node and edge assign a value to a property called `type`.

Definition 2.1 associates graph nodes, edges and attribute values with *time points*. In the remainder of this paper, we will represent temporally adjacent time points by *intervals*, for syntactic compactness, as illustrated in Figure 1. Following the SQL:2011 standard, we use closed-open intervals, representing a discrete contiguous set of time points from Ω^T. This representation does not add expressiveness to a point-based representation, and is purely a syntactic device [10].

We now describe aZoom^T and wZoom^T in detail using our running example, and refer to [37] for a formal treatment.

2.2 Attribute-Based Zoom

Temporal attribute-based zoom, denoted aZoom^T, is a temporal generalization of the graph node creation operation [42]. Node creation over non-temporal graphs takes a graph pattern as input, and computes a new node for each occurrence of a match of the pattern in the input. To assign identity to new nodes, it is customary to extend this operation with a Skolem function f_s. aZoom^T will similarly create nodes in the output TGraph from disjoint groups of nodes in the input, such that nodes within a group agree on the values of all grouping attributes.

Conceptually, aZoom^T is executed over every snapshot of the input TGraph, and new nodes are assigned identity by a Skolem function f_s, which generates consistent assignments across time. In addition to creating new nodes, aZoom^T will also optionally compute values of node attributes using the aggregation function f_{agg}, including count, sum, min, max, average, and user-specified functions that are required to be commutative and associative. Next, aZoom^T computes edges as follows. Suppose that input nodes n and n' corresponds to output nodes g and g', respectively, and that edge e connects n to n'. Then, the output will contain the edge e, with g as its source and g' as its target. Essentially, the input edge is re-created in the output, and re-pointed.

Node creation, computation of node attribute values, and re-pointing of the edges, is executed over each snapshot of the input TGraph, under point semantics. As the final step, the result is then coalesced, associating a time interval of maximal length during which no change occurred with every newly-computed node and edge. We now illustrate aZoom^T with an example.

Example 2.2. Node *Ann* in Figure 1 is associated with a closed-open interval $T = [1, 7)$, signifying that the node existed in the graph for six consecutive time points with no change. *Bob* exists in the graph during $T = [2, 9)$, but with a change to its attributes at time 5, when `school=CMU` was added. School names are represented as values of the school property of person nodes.

We invoke aZoom^T to compute from $\mathcal{G}_1$ a TGraph where schools become nodes rather than values, as shown in Figure 2

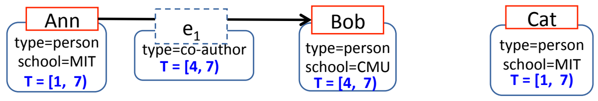

Figure 3: wZoom^T($\mathcal{G}_1$, window=3-months, nodes=all, edges=all, node.school=last(school)) over $\mathcal{G}_1$ (Figure 1).

with school nodes *MIT* and *CMU*. Note that the number of students at MIT changes over time: both *Ann* and *Cat* study there during $T = [1, 7)$, while only *Cat* studies there during $T = [7, 9)$. Note that both edge e_1 and e_2 have been redirected to newly created nodes and their validity period is updated to correct values based on when those were valid in the graph: While e_1 is valid during $T = [2, 7)$ in Figure 1, it is only valid during $T = [5, 7)$ in Figure 2, because *Bob* was not at CMU during $T = [2, 5)$.

2.3 Temporal Window-Based Zoom

The wZoom^T operator is analogous to *moving window temporal aggregation* in temporal relational algebra. This operator is inspired by stream aggregation of Li et al. [29] (adopted to graphs), and by generalized quantifiers [22].

The wZoom^T operator modifies validity periods of TGraph nodes and edges, by mapping different states of a node or an edge to a single representative state. This mapping is based on a specification of a temporal window, such as 2 months or 10 years. If the specified window is finer than the temporal resolution of the input TGraph, the operation has no effect. For example, applying wZoom^T with 1-month windows to a TGraph in which evolution is recorded across years will simply return the input TGraph. Note that, because wZoom^T is required to produce a valid TGraph as output, this operation does not support overlapping windows.

Window specification is of the form n $\{unit|\text{changes}\}$, where n is an integer, and *unit* is a time unit (e.g., 10 min, 3 years). Window specification generates a temporal relation W with the schema $(d \mid T)$, where each tuple associates a window number d with its period of validity T. We additionally require node and edge existence quantifiers {all|most|at least n|exists}, where n is a decimal representing the percentage of the time during which a node or an edge existed, relative to the duration of the window. Quantifiers are useful for observing different kinds of temporal evolution. For example, to observe strong connections over a volatile evolving graph we may include nodes that span the entire window (nodes=all), and edges that span a large portion of the window (edges=most). We refer to all and exists as universal and existential quantification, respectively.

A related point is that a given node or edge should exist at most once at any given time point, and so we must specify how conflicts in attribute values are resolved by wZoom^T. The answer to this question is determined by the window aggregation functions, which specify, for each attribute of a node or an edge, which of its values to accept as a representative for the given temporal window. We support the window aggregation functions first, last, and any (the default).

Example 2.3. Consider again TGraph $\mathcal{G}_1$ in Figure 1, and suppose that time points represent the months of 2018, and are divided into fiscal year quarters as follows: window $W1$: time points 1, 2, 3; $T = [1, 4)$, window $W2$: time points 4, 5, 6; $T = [4, 7)$, window $W3$: time points 7, 8, 9; $T = [7, 10)$. How might we quantify the state of $\mathcal{G}_1$ during each quarter, a 3-month temporal window?

Figure 3 shows the temporally coalesced results of zooming out to quarters over $\mathcal{G}_1$ with nodes=all and edges=all.

Ann is present in windows $W1$ and $W2$ in the input in Figure 1, and so is associated with $T = [1, 7)$ in the result for both universal and existential quantification. In contrast, *Bob* is present in the input for all of $W2$ but for only part of $W1$, and so is returned with $T = [4, 7)$ in the result for nodes=all, and with $T = [1, 7)$ for nodes=exists. Finally, *Cat* is present for all of $W1$ and $W2$, but for only part of $W3$ in the input (it is missing at time point 9), and so is associated with $T = [1, 7)$ in the output undernodes=all and with $T = [1, 10)$ under nodes=exists. Quantification is applied to edges analogously: e_1 is mapped to window $W2$ and e_2 is absent in the output in Figure 3, because there does not exist a quarter during which e_2 exists continuously in the input.

3 EVOLVING GRAPH REPRESENTATIONS AND DATAFLOW OPERATORS

In this section, we introduce several physical representations for a TGraph and detail how to define the zoom operations according to these representations. We express the zoom operators using general dataflow operations — directed acyclic graphs of operators resembling parallelizable second-order functions that execute user-defined first order functions. This is a popular programming model for distributed computations supported by systems such as Apache Spark [43] and Apache Flink [2].

We use the term *snapshot* to refer to a conventional (non-temporal) graph that represents the state of a TGraph during some interval in which no change occurred. Figure 4 shows the TGraph in our running example as a sequence of snapshots. When storing and accessing evolving graphs, we are concerned with preserving two kinds of locality: temporal and structural. Adopting the terminology of [19], with *structural locality*, neighboring vertices (resp. edges) of the same snapshot are laid out together, while with *temporal locality*, consecutive states of the same vertex (resp. edge) are laid out together. We develop four TGraph representations that differ in compactness and in the kind of locality (structural or temporal) they prioritize.

Representative Graphs (RG). RG represents a TGraph by a sequence of snapshots (conventional graphs), associating them with time intervals, see Figure 4 for an example. The snapshot sequence is by far the most common representation in the literature [15, 20, 24–26, 38, 40]. RG has the following schema:

```
TemporalGraph { interval: Interval,
                              snapshots: array(Snapshot) }
Snapshot { vertices: array(Vertex), edges: array(Edge) }
Interval { start: Date, end: Date }
Vertex { vid: long, type: string, attributes: dictionary }
Edge { eid: long, type: string, v1: Vertex, v2: Vertex,
       attributes: dictionary }
```

Note that vertices and edges of each snapshot store the attribute values for the interval represented by the snapshot. This representation is simple, and lends itself well to parallelizing operations in a distributed environment, as we can simply assign different snapshots to different workers. An advantage of RG is that it naturally preserves structural locality, and so is efficient for snapshot-based operations. An important drawback of RG is that it is not compact: in many real-world evolving graphs there is an 80% or larger overlap between consecutive snapshots [8].

Vertex Edge (VE). As illustrated in Figure 5, VE is a nested temporal relational representation of TGraph, with one relation storing vertices and the other edges, together with the corresponding

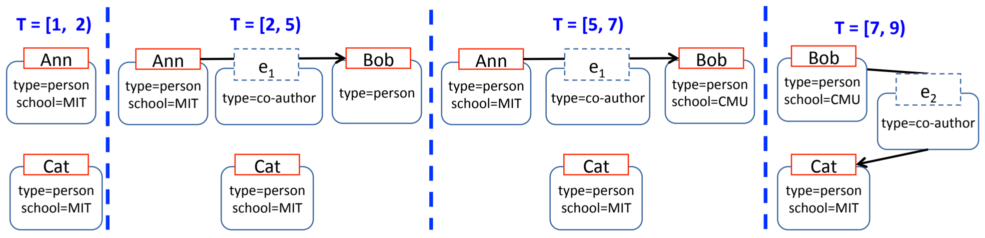

Figure 4: Representative-Graphs (RG): a "sequence of snapshots" representation of the TGraph $\mathcal{G}_1$ of Figure 1.

Vertices (V)

<u>v</u>	a	T
Ann	type=person, school=MIT	[1, 7)
Bob	type=person	[2, 5)
Bob	type=person, school=CMU	[5, 9)
Cat	type=person, school=MIT	[1, 9)

Edges (E)

<u>e</u>	v1	v2	a	T
e1	Ann	Bob	type=co-author	[2, 7)
e2	Bob	Cat	type=co-author	[7, 9)

Figure 5: Vertex-Edge (VE): nested relational representation of the TGraph $\mathcal{G}_1$ from Figure 1. The relations Vertices (V) and Edges (E) are temporally coalesced.

time intervals. Both relations are temporally coalesced, giving rise to a compact representation. VE stores all vertex properties together as a single nested attribute (and all edge properties analogously). VE has the following schema:

```
TemporalGraph { interval: Interval,
    vertices: array(Vertex),  edges: array(Edge) }
Interval { start: Date, end: Date }
Vertex { vid: long, type: string, interval: Interval,
        attributes: dictionary }
Edge { eid: long, type: string, vid1:long, vid2: long,
      interval: Interval, attributes: dictionary }
```

For edges, we store a unique edge identifier **eid**(long) to support multi-graphs, as well as the vertex identifiers **vid1**(long) and **vid2**(long) that are foreign keys referring to the vertex relation. The main advantage of VE's attribute representation is that it lends itself to schema evolution. A disadvantage is that different properties may have different evolution rates, and a change to a single property requires a new vertex or edge tuple. VE stores graph vertices and edges in unordered collections, and therefore does not maintain temporal locality by default in cases where the state of a vertex or edge changes. For example, two tuples for vertex *Bob* in Figure 5 may not be located consecutively, or even on the same worker, once the data is partitioned across a cluster. We can reconstruct temporal locality at runtime, by re-partitioning the data based on vertex or edge identifiers.

One Graph (OG), One Graph Columnar (OGC). These are two topologically compact representations. OG stores all vertices and edges once, in a single aggregated data structure, as shown in Figure 6. In OG, vertices and edges store the history of the evolution of their attributes as an array of key-value pairs, together with the corresponding validity periods. Figure 6 shows the OG representation for our example graph. Note that we have only one tuple for vertex *Bob*, which holds two sets of values for two corresponding validity periods T=[2,5) and T=[5,9). OG has the following schema:

```
TemporalGraph { interval: Interval,
    vertices: array(Vertex), edges: array(Edge) }
```

Vertices (V)

<u>v</u>	a
Ann	{ T=[1,7): type=person, school=MIT }
Bob	{ T=[2,5):type=person, T=[5,9):type=person, school=CMU }
Cat	{ T=[1,9): type=person, school=MIT }

Edges (E)

<u>e</u>	v1	v2	a
e1	Ann	Bob	{ T=[2,7): type=co-author }
e2	Bob	Cat	{ T=[7,9): type=co-author }

Figure 6: One Graph (OG): nested relational representation of the TGraph $\mathcal{G}_1$ from Figure 1. The relations Vertices (V) and Edges (E) are temporally coalesced.

```
Interval { start: Date, end: Date }
HistoryItem { interval: Interval, attributes: dictionary }
Vertex { vid: long, type: string,
                                history: array(HistoryItem) }
Edge { eid: long, type: string, v1: Vertex, v2: Vertex,
      history: array(HistoryItem) }
```

The schemas for OG and VE are similar in many ways. The main difference is that the interval and attribute dictionary in VE has been replaced with a **history** array that contains **HistoryItem**s. Each such history item stores an **interval** as the key and a dictionary of the corresponding **attributes**. The second difference is that OG contains a copy of the source and target vertex of each edge, instead of a foreign key to the vertex relation.

OGC, on the other hand, only stores the graph topology with validity periods as a graph, as shown in Figure 7. OGC has the following schema:

```
TemporalGraph { intervals: array(Interval),
             vertices: array(Vertex), edges: array(Edge) }
Interval { start: Date, end: Date }
Vertex { vid: long, type: string, intervals: Bitset }
Edge { eid: long, type: string, v1: Vertex,
      v2: Vertex, intervals: Bitset }
```

OGC is intended for topology-only attribute-less graphs, encoding the presence of a vertex or edge in each interval with a bitset. Both OG and OGC emphasize temporal locality, while also preserving structural locality, but lead to a much denser graphs than RG. This, in turn, makes parallelizing computation challenging.

In the remainder of this section, we describe how to define aZoom^T and wZoom^T in terms of dataflow operations according to our proposed representations.

3.1 Attribute-Based Zoom

We now describe aZoom^T for each TGraph representation. In the algorithms we present, V and E are overloaded to refer to the vertex and edge relations of a given snapshot (in the case of RG) or of the overall TGraph. In aZoom^T we use a Skolem function f_s to produce new vertex ids. f_s is a user-provided function that

Bitset (b): T={[1,2),[2,7),[7,9)}

Vertices (V)

v	b
Ann	[1, 1, 0]
Bob	[0, 1, 1]
Cat	[1, 1, 1]

Edges (E)

e	v1	v2	b
e1	Ann	Bob	[0, 1, 0]
e2	Bob	Cat	[0, 0, 1]

Figure 7: One Graph Column (OGC): nested relational representation of the TGraph $\mathcal{G}_1$ of Figure 1. Vertices (V) and Edges (E) are temporally coalesced. Bitsets represent validity during periods of T={[1,2),[2,7),[7,9)}.

takes the vertex id and all attributes as an input and produces a long identifier as output. We additionally apply the commutative and associative aggregation function f_{agg} to resolve cases where we have a series of vertices with identical identifiers but multiple values for the same attribute in the same snapshot. This is an important step that ensures that each snapshot in the result corresponds to a valid graph (see [36] for details).

RG. Recall thatRG maintains a collection of snapshots. We apply the same set of operations in an embarrassingly parallel manner to each snapshot, as there are no dependencies between them in this case (Algorithm 1). We iterate over each snapshot (lines 3-10) and return an RG (line 11) containing the aZoom^T result. We apply f_s to each vertex using a map (line 5) in order to compute a new identifier for each vertex. The copyWithVid function updates each vertex identifier while keeping other attributes unchanged. We then group vertices by id (line 7) and apply the aggregation function f_{agg} (line 8).

To redirect edges to the newly created vertices, we apply the function f_s to the vertices v1 and v2 of each edge in a map (line 9). The copyWithVids function updates the id of the vertices to the new identifiers. The edges contain a copy of their source and target vertices in RG, which obliviates the need for a join here.

Algorithm 1 aZoom^T over RG

```
Require: Skolem function $f_s : V \Rightarrow \mathbb{N}$; Aggregation function $f_{agg} : V \times V \Rightarrow V$
 1: $newSnapshots \leftarrow \emptyset$
 2:                                          ▷ Aggregate each snapshot
 3: for ($V$,E) in graph.snapshots do
 4:     $V' \leftarrow V$                          ▷ Update of vertex identifiers
 5:         .map{$v \Rightarrow v$.copyWithVid($f_s(v)$)}
 6:                           ▷ Vertex aggregation for identity-equivalence
 7:         .groupBy{$v \Rightarrow v.vid$}
 8:         .reduce{$(v_a, v_b) \Rightarrow f_{agg}(v_a, v_b)$}
                                      ▷ Edge redirection to new vertices
 9:     $E' \leftarrow E$.map{$e \Rightarrow e$.copyWithVids($f_s(e.v1), f_s(e.v2)$)}
10:     Add ($V'$, $E'$) to $newSnaphots$
11: return new TGraph $G(newSnapshots)$
```

VE. VE consists of two temporal relational tables for vertices and edges, which contain tuples for each vertex or edge history. Algorithm 2 details our implementation of aZoom^T for VE. We first calculate non-overlapping intervals (lines 2-5) based on the temporal splitter concept introduced in [11]. We join intervals and vertices (lines 7- 9), assign new identifiers (line 10), and enforce identity-equivalence in each interval with the aggregation function (line 12). Since VE edges only contain a foreign key to the corresponding vertices, we need to join the edges with their corresponding vertices for the edge redirection process (lines 14 and 15), before we can apply the f_s function to each corresponding vertex to redirect the edge (line 18).

Algorithm 2 aZoom^T over VE

```
Require: Skolem function $f_s : V \Rightarrow \mathbb{N}$; Aggregation function $f_{agg} : V \times V \Rightarrow V$
 1: $I \leftarrow V$       ▷ Non-overlapping intervals for each new vertex identifier
 2:     .map{$v \Rightarrow (f_s(v), v.interval)$}
 3:     .groupBy{$(vid, \_) \Rightarrow vid$}
 4:     .foldLeft(EmptyInterval)
 5:         {$(i, v) \Rightarrow$ mergeNonOverlapping($i$, $v.interval$)}
 6: $V' \leftarrow V$             ▷ Vertex aggregation for non-overlapping intervals
 7:     .join($I$).on{$(v, id) \Rightarrow v.id == i.vid$}
 8:     .flatMap{$(v, i) \Rightarrow$ verticesForIntervals($v$, $i$)}
 9:     .map{$(v, i) \Rightarrow$
10:         $v$.copyWithIdAndInterval($f_s(v)$, $i$) }
11:     .groupBy{$v \Rightarrow v.id$}
12:     .reduce{$(v_a, v_b) \Rightarrow f_{agg}(v_a, v_b)$}
13: $E' \leftarrow E$                        ▷ Edge redirection to new vertices
14:     .join($V$).on{$(e, v) \Rightarrow e.vid1 == v.id$}
15:     .join($V$).on{$((e, \_), v) \Rightarrow e.vid2 == v.id$}
16:     .map{$(e, v1, v2) \Rightarrow$
17:         $i \leftarrow$ recomputeInterval($e$, $v1$, $v2$)
18:         $e$.copyWithVidsAndInterval($f_s(v1), f_s(v2)$, $i$) }
    return new TGraph $G(V', E')$
```

OG. We implement aZoom^T for One Graph (OG) analogously to RG, with the difference that we compute over the entire TGraph rather than over each individual snapshot (Algorithm 3). We split each vertex in OG based on its history, and apply the f_s function to each element of the history array individually. We use a flatMap function on vertices combined with a map on the history elements of each vertex for this (lines 1-3). We again enforce identity-equivalence with our aggregation function (lines 4 and 5). The vertext computation portion of Algorithm 3 is illustrated in Figure fig:az-og. For edge redirection in OG, we split the edges by expanding the history of each corresponding vertex in that edge, as OG stores each edge only once. Next, we apply the Skolem function f_s to each element of the history (line 6-9).

Algorithm 3 aZoom^T over OG

```
Require: Skolem function $f_s : V \Rightarrow \mathbb{N}$; Aggregation function $f_{agg} : V \times V \Rightarrow V$
 1: $V' \leftarrow V$ .flatMap{$v \Rightarrow$
 2:     $v.history$.map{$(\_, attr) \Rightarrow$
 3:         $v$.copyWithIdAndAttributes($f_s(v.vid)$, $attr$) }}
 4: .groupBy{$v \Rightarrow v.vid$}
 5: .reduce{$(v_a, v_b) => f_{agg}(v_a, v_b)$}
 6: $E' \leftarrow E$ .map{$e \Rightarrow$
 7:     $h \leftarrow$ recompute_history($e$)
 8:     $e$.copyWithVidsAndHistory($f_s(e.v1.vid)$,
 9:         $f_s(e.v2.vid), h$)}
    return new TGraph $G(V', E')$
```

OGC does not represent attributes and so does not support aZoom^T.

3.2 Temporal Window-Based Zoom

As we did for aZoom^T, we express wZoom^T differently for each representation, with some common aspects. The first step is to

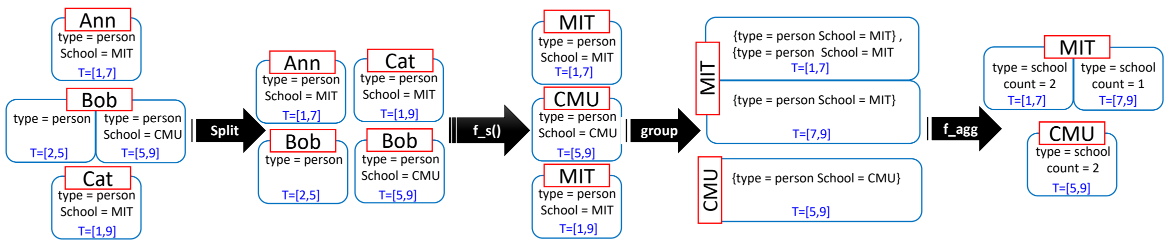

Figure 8: Illustration of the vertex computation portion of Algorithm 3, aZoom^T, over TGraph in Figure 6, with count as f_{agg}. The first two steps correspond to the call to flatMap on lines 1-3: splitting nodes based on their history array, and then calling the Skolem function f_s to generate ids for new nodes. In this example, f_s outputs the value of the school property. The next step groups vertices by id (line 4). The final step (line 5) applies the aggregation function count, storing the computed value as a vertex property.

compute the temporal window relation based on the window specification. We split the total graph lifetime temporally by applying the function computeNewIntervals to the graph. This function takes an interval as an input and returns a tuple containing the old and the recomputed interval.

A major difference to aZoom^T is that the TGraph must be coalesced *before* wZoom^T can be applied, in order to guarantee the correctness of the zoom operation. This is because aZoom^T executes over each snapshot (under snapshot reducibility), while the computation of wZoom^T is across snapshots. Consequently, if the input to wZoom^T is not coalesced, we cannot properly apply existence quantifiers and compute results of aggregation.

We additionally need to handle potential dangling edges for all representations in wZoom^T to ensure that every snapshot of the resulting TGraph is a valid graph, as specified in the condition over ξ^T in Definition 2.1. Recall that wZoom^T supports the quantifiers all, most, at least n, and exists, which can be translated to a threshold on the percentage of the time during which an entity (a vertex or an edge) existed, relative to the duration of the window: $t = 1$ for all, $t > 0.5$ for most, $t > 0$ for exists and $t > n$ for at least n. If an entity's existence meets the threshold, it will be retained in the result of the operation. A dangling edge check is only required if r_v is more restrictive than r_e, because a particular edges may pass the check, but one or more of the vertices it connects may not.

Algorithm 4 wZoom^T over RG

```
Require: resolve functions $f_v, f_e$; quantifiers $r_v, r_e$
 1:                                          ▷ Computation of new intervals
 2: $I' \leftarrow I.\mathbf{map}\{i \Rightarrow (i, \text{computeNewInterval}(i))\}$
 3:                                   ▷ Grouping of snapshots by new interval
 4: $S \leftarrow G.snapshots.\mathbf{join}(I')$
 5:     $.\mathbf{on}\{(s, interval) \Rightarrow s.i == interval.i\}$
 6:     $.\mathbf{groupBy}\{(s, interval) \Rightarrow interval.newInterval\}$
 7:                               ▷ Aggregation of vertices for new snapshots
 8: $V' \leftarrow S.\mathbf{flatMap}\{(i, snapshot) \Rightarrow$
 9:     $(i, snapshots.\text{map}\{s \Rightarrow s.vertices\})\}$
10:     $.\mathbf{groupBy}\{(i, v) \Rightarrow (i, v.id)\}$
11:     $.\mathbf{filter}\{(i, vertices) \Rightarrow \text{match\_threshold}(vertices, r_v)\}$
12:     $.\mathbf{reduceByKey}\{((v_a), (v_b)) \Rightarrow f_v(v_a, v_b)\}$
13:                                     ▷ Aggregate edges for new snapshots
14: $E' \leftarrow S.\mathbf{flatMap}\{(i, snapshot) \Rightarrow$
15:     $(i, snapshots.map\{s \Rightarrow s.edges\})\}$
16:     $.\mathbf{groupBy}\{(i, e) \Rightarrow (i, e.id)\}$
17:     $.\mathbf{filter}\{(i, edges) \Rightarrow \text{match\_threshold}(edges, r_e)\}$
18:     $.\mathbf{reduceByKey}\{((e_a), (e_b)) \Rightarrow f_e(e_a, e_b)\}$
                                              ▷ Recreate RG representation
19: $G' \leftarrow \text{merge}(I', V', E')$
```

RG implements wZoom^T as shown in Algorithm 4. We again use the computeNewInteval function to compute the new intervals based on the window specification (line 2). Next, we apply join, groupBy, and flatMap to map each vertex to one or more snapshots from the specification (lines 4-9). Then, vertices are grouped by their id within each new interval (line 10). Next, we filter vertices and edges based on the existence quantifier (line 11). We apply the math_threshold function to vertices with their respective thresholds (r) to filter vertices that do not meet the criteria of our quantifier. Finally, we apply the resolve function f_v to compute the new attribute values (line 12). We treat edges analogously (lines 14-18). At the end, we merge snapshots into a TGraph and remove dangling edges.

VE implements wZoom^T using Algorithm 5. Figure 9 illustrates this algorithm for vertex *Bob* from Figure 5. We first need to calculate the new intervals using computeNewInterval (lines 2-3). Then we join V with the intervals to align each vertex with each temporal window (lines 4-6) to split the vertices. Next, we group by interval and vertex (line 7), and filter vertices that do not pass the quantifier threshold (line 8). Finally, we resolve the vertices' final attributes (line 12). We apply the same operations to edges (lines 11-18). We remove dangling edges (given that $r_v > r_e$) with two semijoins (lines 17-19).

OG implements wZoom^T using Algorithm 6. Recall that in OG each vertex stores its interval information in a history array. We process each element of this array separately and rebuild the array afterwards (lines 1-4) for this process. We first invoke recomputeIntervals (line 2) to recompute the history array with updated intervals. Next, we leverage the aggregateAndFilterAttributes function (line 3) to group, filter and resolve vertices analogous to previous algorithms, and apply the same transformations to the edges as well (lines 5-8).

We again remove dangling edges with semijoins (lines 9-15). The only difference here is that joining edges with vertices is not enough, as we also need to update the history arrays. We achieve this with a map function which updates every edge history with the intersection of the edge history and the corresponding vertex history (lines 12 and 15) using the copyWithHistory function.

OGC implements wZoom^T similarly to OGC, but working with a bitset instead of a history array. Removing dangling edges in OGC is as simple as computing the logical and between the edge bitset and the corresponding vertex bitsets.

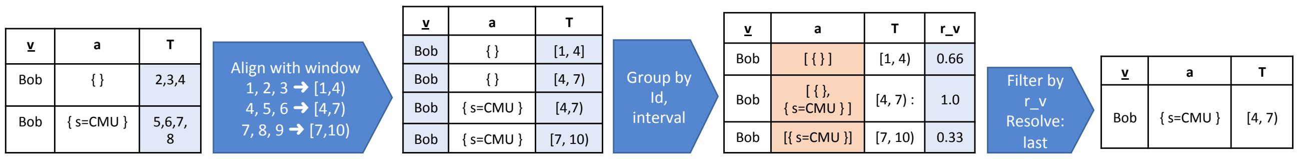

Figure 9: Illustration of Algorithm 5, wZoom^T, for vertex *Bob* in Figure 5, with window size 3 and last as f_v. The first step aligns each vertex with each temporal window (lines 4-6 of the algorithm). Next we create a single nested representation of each vertex per window and compute r_v, the fraction of the window during which the vertex was observed (line 7). Finally, we filter vertices by r_v and resolve their attribute values with f_v =last (lines 8, 9).

```

4 IMPLEMENTATION

We defined our zoom operators in Section 3 using general dataflow operations and UDFs that are implemented by a variety of popular systems. Apache Spark with GraphX [17] and Apache Flink with Gelly [7] are natural candidates for such workloads, as is Differential Dataflow [33]. We choose Apache Spark for our implementation due to its maturity and popularity.

Our implementation includes a TGraph API, several graph representations as discussed in Section 3, and several optimizations such as lazy coalescing. Our API supports chaining multiple operations together and switching between graph representations during query execution.

The VE representation is implemented directly over Spark's Resilient Distributed Datasets (RDDs) [43] while RG, OG and OGC leverage the GraphX library for static graphs [17]. We use the long datatype to represent node and edge identifiers to maintain interoperability with GraphX.

GraphX-specific implementation details. GraphX implements vertex-cut-based partitioning that reduces communication overhead [17] for certain aggregations on graphs. GraphX also provides an optimized implementation of a distributed triplet view, a concept originating from Resource Description Frameworks (RDF) [31]. The triplet view provides fast access to each edge and its corresponding source and destination vertex properties. The triplet view requires a materialized three-way join, which GraphX optimizes by implementing vertex-mirroring and a multicast join [17]. We leverage the implementation of the triplet view to efficiently access edges' vertex attributes in RG, OG and OGC. We implement RG as sequence of GraphX graphs, while OG and OGC are modeled as a single GraphX graph. GraphX mechanisms such as vertex-cut partitioning and the triplet view enabled us to implement graph operations more efficiently.

Data loading. The data is read from the Hadoop Distributed File System (HDFS). Our on-disk data layout uses Apache Parquet, a columnar data format for HDFS based on the Dremel project [34]. Apache Parquet does not have a mechanism for indexing, but it supports filter pushdown on any column by which the data is sorted on disk. We store and load vertices and edges as separate vertex and edge Parquet files. The default schema to store a graph on disk is similar to the VE schema described in Section 3. We load two of our representations (VE and RG) from this format. To apply a filter pushdown, the data on disk need to be sorted. For VE, we use the vertex/edge identifier as the first sort key, and the interval start time as the second key. Storing data in this way preserves temporal locality, and places the history of changes in a vertex or an edge together. Parquet does not support filter pushdown for datetime formats, hence we store time as UNIX timestamps (long).

We use a similar schema for RG, however, we sort vertices and edges by the interval start time first, and then by their vertex (resp. edge) identifier, to preserve structural locality. During our experiments we learned that RG can be loaded 30% faster using the structural locality instead of temporal locality (experiment omitted due to space constraints). While OG and OGC could be loaded in the same way as VE, we experimentally validated that it is significantly faster to pre-compute nested versions of the graphs with schemas described in Section 3, and then convert to OG or OGC during load time. A problem with this approach is that Parquet's filter pushdown will not work, since interval information is stored in a nested column. We resolve this issue by storing the first and last time a vertex/edge existed as a separate column on disk, and sorting on these columns.

We provide a GraphLoader utility that can initialize any of our physical representations from Apache Parquet files on HDFS or on local disk. This loader accepts a date range and filters the data through Parquet's filter pushdown. For datasets with a long evolution history, this optimization provides a substantial performance improvement (see [36]).

Coalescing. The coalesce primitive for merges adjacent and overlapping time periods for value-equivalent tuples. Several implementations have been suggested for the coalesce operation over temporal SQL relations [5]. In our implementation for VE, we use the partitioning method: grouping the vertex and the edge relation by key, then sorting by start time, and folding tuples within each group and checking pairs of adjacent tuples for value-equivalence. The effect of this operation is that a single tuple is produced for each period of maximum length during which no change occurred.

To further optimize performance, we coalesce lazily for sequences of two or more operations. Recall that aZoom^T computes in each snapshot, and so it does not require its input to be temporally coalesced to produce the correct output. In contrast, wZoom^T does require its input to be coalesced for correctness, because it computes across snapshots. This means that, in a sequence of aZoom^T and wZoom^T operators, the system does not need to temporally coalesce before invoking aZoom^T, but it must coalesce before invoking wZoom^T and at the end of the operator sequence, when the final result is produced.

5 EXPERIMENTAL EVALUATION

We conduct an experimental evaluation to study the performance of aZoom^T and wZoom^T. Our goal is to understand how different representations and their corresponding operator implementations perform for different datasets and workloads. We present three different categories of experiments: aZoom^T experiments (Section 5.1), wZoom^T experiments (Section 5.2), and experiments combining both operations (Section 5.3).

Cluster. All experiments are conducted on a 16-worker in-house Cloudera cluster, using Linux CentOS 14.04 and Spark v2.2. Each machine has 4 cores and 32 GB of RAM. Spark standalone cluster manager and Hadoop 2.6 were used. In each experiment, we report the mean runtime of three executions, each with a cold start. The runtime includes the setup time of submitting a job to the cluster manager, reading the data from disk, executing the operation, and materializing the results in memory. We set a 30-minute time-out for all experiments.

Datasets. We evaluate the performance on two real world datasets, WikiTalk and NGrams, and a family of synthetic datasets SNB, with different scale factors. All datasets are summarized in the table below, and differ in size, in the number and type of attributes, and in evolution rates, calculated as the average graph edit similarity [38] between consecutive snapshots (the edit similarity between snapshots i and j is the ratio of the number of common edges to the sum of the number edges: $2 * |E_i \cap E_j|/(|E_i| + |E_j|)$). In contrast to WikiTalk and NGrams, SNB is a growth-only graph, and so it shows a higher evolution rate.

	vertices	edges	snaps	ev. rate
WikiTalk	2.9M	10.7M	179	14.4
SNB:10	65K	1.9M	36	89
SNB:100	448K	20M	36	90
SNB:300	1.1M	59M	36	90
SNB:1000	3.3M	202M	36	91
NGrams:M	28M	606M	287	16.6
NGrams:L	48M	1.32B	328	18.2

WikiTalk is a real dataset that contains over 10 million messaging events (edges) among 3 million wiki-en users (vertices) at a 1-month resolution, from 2000 through 2016 [41]. Vertices have two attributes: `name` is a unique username for each account and `editCount` is the number of edits committed by the user (around 15K unique values). Edges have no attributes. WikiTalk is a very sparse dataset with short-lived edges and growth-only vertices: once added, a vertex persists for the lifetime of the graph and its attributes do not change.

NGrams is a real dataset that contains word co-occurrence pairs, with 88 million word vertices (3.2 unique words in all) and over 2.8 billion undirected co-occurrence edges. In our experiments we use two versions of this dataset: NGrams:L, with 328 yearly snapshots from 1520 through 1920, and NGrams:M, with 287 yearly snapshots from 1520 through 1870. NGrams is denser than WikiTalk; its vertices persist over time, while edges can appear and disappear. This dataset exhibits a linear relationship between the number of nodes and the number of edges.

The LDBC Social Network Benchmark (SNB) [12] is a synthetic graph generator that produces realistic networks with different types of entities and different attributes. We focus on SNB person entities (vertices) and on friendship relationships (edges), and generate datasets at four scale factors: SNB:10, SNB:100, SNB:300, and SNB:1000, with 36 monthly snapshots in each. SNB:1000 is the largest dataset that can be created without changing the generator source code. SNB does not generate a temporal benchmark but, since entities and relationships have timestamps, it can be viewed as a growth-only evolving graph. We use the vertices attribute `firstName` (5300 unique values in SNB:1000), edges have no attributes. The friendship network generated using SNB is growth-only graph, a graph where every vertex and edge is added once and never goes away.

5.1 Evaluation of aZoom^T

We now evaluate the performance of attribute-based zoom. Experiments are executed with RG, VE and OG, as described in Section 2, but not with OGC, which does not support aZoom^T.

Fixed number of groups, varying data size. Dataset size plays an important role in the performance of aZoom^T. We simulated different data sizes by using three datasets and varying the number of snapshots in each dataset. In this experiment and all other experiment in this section, we used aZoom^T with a hash function as the Skolem function f_S that generate new ids based on one of the attributes of the graph. In WikiTalk we group by

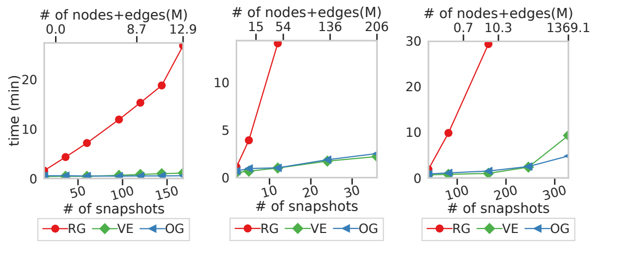

Figure 10: aZoom^T: The effect of dataset size on the runtime for each dataset. OG and VE perform on par, while RG quickly times out.

`username` (2.9M output groups), In NGrams— by `word` (3.2M output groups), and in SNB— by `firstName` (5,300 output groups).

Figure 10 shows the runtime of aZoom^T on different datasets. As expected, increasing the data size increases the execution time. OG is the best-performing representation, and VE is second-best. Both VE and OG exhibit sub-minute runtimes on WikiTalk: at most 0.54 min for OG and at most 1.09 min for VE (Figure 10a). The runtime of VE for SNB:1000 is at most 2.21 min for this graph with over 200M edges, where OG takes up to 2.53 minutes. (Figure 10b). Notably, OG scales well, even for NGrams, where OG computes in 4.8 min for 400 years worth of data and VE in 9.3, in a graph with 1.3 billion edges (Figure 10c). In contrast, RG is much slower than VE and OG, and it does not scale for the full SNB:1000 and NGrams:L dataset. It takes 26 minutes for WikiTalk, 14 minutes for 12 snapshots of SNB, timing out for anything larger and taking 29.55min to compute for 200 snapshots of NGrams, and timing out for 300 snapshots.

Fixed number of groups and graph size, varying number of snapshots. Another important factor in evolving property graphs that can impact operator performance is the number of snapshots (intervals during which no change occurred in the TGraph). We generate experimental datasets to measure this effect by merging consecutive snapshots of WikiTalk and NGrams:L, where we gradually decrease the number of intervals, while we keep the size of the dataset (in terms of the number of nodes and edges) fixed. For SNB:1000, we directly generate datasets with the desired number of snapshots. For WikiTalk, we select the last 160 months of history, and create graphs with between 2 and 160 snapshots. For NGrams, we select the last 320 years of the graph's history, and again generate datasets with between 2 and 320 snapshots. For SNB, we generate between 12 and 360 snapshots, corresponding to between 1 and 30 years worth of network evolution. Note that generating graphs in this way does neither change the number of nodes and edges, nor the group-by cardinality.

Figure 11 shows the runtime of aZoom^T as a function of the number of snapshots. OG and VE exhibit comparable performance for WikiTalk, executing in under 2 minutes, with OG being slightly more efficient. The trends are different in SNB: the runtime of aZoom^T on both OG and VE is near-constant, but VE is more efficient: 2.3 minutes for VE, compared to 2.9 minutes for OG. OG outperforms VE for NGrams; their runtime increases linearly with an increasing number of intervals.

The difference in performance across datasets is due to the nature of data evolution. WikiTalk and SNB only have one tuple per node, since attributes do not change over time, therefore an

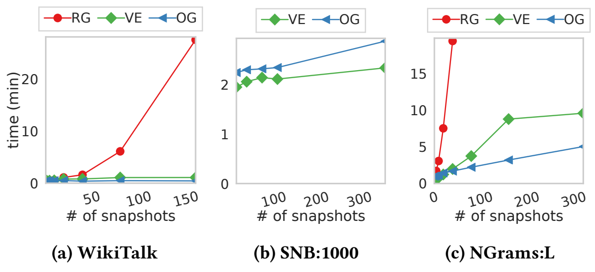

Figure 11: aZoom^T: Fixed dataset size and group-by cardinality, varying number of snapshots. The number of nodes and edges is fixed to the largest graph size, and the group-by cardinality is fixed to the natural group-by cardinality of each dataset.

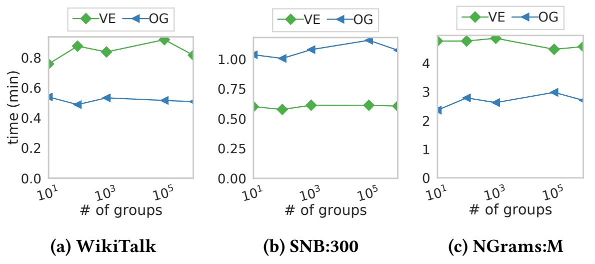

Figure 12: aZoom^T: Fixed dataset size and number of snapshots, with varying group-by cardinality.

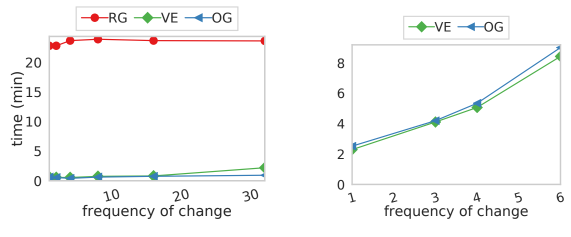
increase in the number of intervals does not change the number of tuples (which is not the case for NGrams). We observe that RG is the least efficient representation for this operation, except for the smallest number of intervals in WikiTalk, where all representations have roughly similar performance. The running time of RG grows linearly with the number of intervals, with a high slope. We timed out this experiment at 30 minutes per execution, and RG failed to complete for SNB and NGrams at 80 intervals.

Fixed size and number of snapshots, varying group-by cardinality. In this aZoom^T experiment, we investigate the effect of group-by cardinality — the number of new nodes being created by the aZoom^T operation, on performance. We work with the WikiTalk, SNB:300 and NGrams:300 datasets at their original temporal resolution. We vary the number of groups in the output by assigning a group identifier to each node in the input. Group identifiers are drawn uniformly at random from a given integer range. We varied the range to control group-by cardinality, setting it to 10, 100, 1,000, 100,000, and 1,000,000. Figure 12 shows the results of this experiment. We observe that the runtime of aZoom^T over OG, VE and RG is not affected by group-by cardinality. For visibility purpose, we did not include RG in Figure 12. On WikiTalk, RG showed an execution time of about 29 minutes for all the group-by cardinality values.

Frequency of change. In our final aZoom^T experiment, we study the effect of the frequency of change on performance. Therefore, we synthetically change vertex attributes values with a fixed frequency. While this intervention does not change the size of the graph in terms of the number of nodes and edges, it does change the storage requirements (e.g., the number of tuples for VE, or the length of the array in OG) for each vertex.



(a) WikiTalk (b) SNB:1000

Figure 13: aZoom^T: Fixed dataset size and number of snapshots, varying frequency of change of vertex attributes

Figure 13 shows the effect of the frequency of change on the performance for WikiTalk (Figure 13a) and SNB:1000 (Figure 13b). The size of each graph and the contained number of snapshots is fixed to the full dataset size. While the group-by cardinality does vary, the number of new groups is of the same order of magnitude as in the original graphs. We observe that the frequency of change has no effect on the performance of RG. This is because RG stores each vertex once per snapshot, irrespective of whether there was a change between consecutive snapshots. The runtime of aZoom^T on OG is higher when more changes occur. This is expected: Recall that OG stores attributes with their corresponding validity intervals in an array, and so a higher frequency of change results in longer arrays, which slows down operations on OG. VE stores each change as a new tuple,and a higher frequency of change results in more tuples, slowing down VE as well.

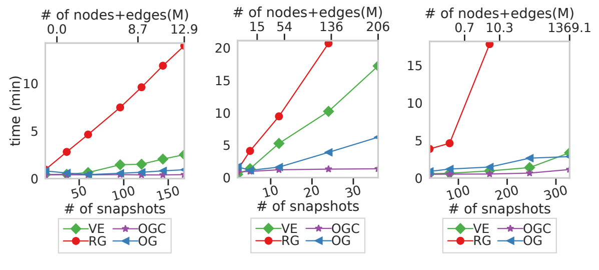
Summary. We studied the effects of data size, the number of snapshots, the frequency of attribute change, and the group-by cardinality (e.g., the number of newly-computed nodes) on the performance. We observed that OG is the best representation for aZoom^T, followed by VE. For our largest experimental datasets, with over 1.3 billion edges, aZoom^T can be executed in less than 5 minutes with OG. The dataset size (the total number of nodes and edges) affects operator performance on all datasets. The number of representative graphs (snapshots) has a small effect on VE and OG, and a significant effect on RG. We did not observe an effect of the group-by cardinality on the runtime in any representation. The frequency of change has a small effect on RG, but it affects VE and OG significantly.

5.2 Evaluation of wZoom^T

We now investigate the performance of wZoom^T. In all experiments, we load RG from disk enforcing structural locality, and VE enforcing temporal locality. For OG and OGC we load data from nested format described in Section 4.

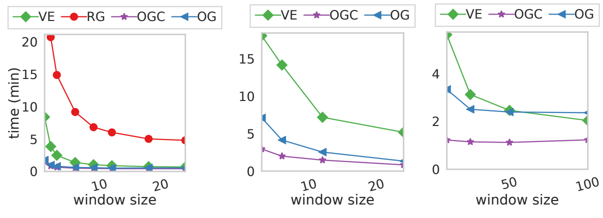
Fixed time window, changing data size. In this experiment, we fix the zoom window size to 3 snapshots for WikiTalk (grouping into up to 60 temporal windows) and SNB:1000 (grouping into up to 12 temporal windows), and 25 snapshots for NGrams:L (grouping into up to 16 temporal windows). We load different temporal slices of each graph and measure the execution time of wZoom^T. Figure 14 shows the results of this experiment. We applied "exists" quantifiers for both nodes and edges. We observed similar results for "all" quantifiers (except that they make wZoom^T slightly faster as fewer nodes and edges have to be kept in the result), which we omit for space reasons.

As expected, increasing the size of the graph increases the runtime on all representations. Our implementation based on



(a) WikiTalk (b) SNB:1000 (c) NGrams:L

Figure 14: wZoom^T: Fixed window size, changing data size, nodes=exists, edges=exists



(a) WikiTalk (b) SNB:1000 (c) NGrams:L

Figure 15: wZoom^T: Fixed data size and number of intervals with varying window size, nodes=all, edges=all. OG and OGC outperform other representations.

OGC is the clear winner for all datasets, taking 0.41 minutes for WikiTalk, 1.25 minutes for SNB and 1.12 minutes for NGrams. For WikiTalk and SNB, OG is the second winner while VE performs better for NGrams:L, particularly for larger TGraph sizes. Finally, RG performs worst for all datasets. The reason for VE's significant performance drop on SNB is window size. We look at the impact of window size on wZoom^T in the next section.

Fixed data size, varying temporal window size. In the previous experiment, we used a fixed zoom window size and increased the size of the graph. In this experiment, the size of the graph is fixed and we vary the size of the temporal window. Figure 15 shows the corresponding results. RG does not scale for temporal window-based zoom on large datasets, therefor we only report performance numbers for RG on WikiTalk. We observe that the performance of OG and OGC does not depend on the window size, while the operations on VE take longer to execute for smaller temporal windows. OGC is the winner among all datasets followed by OG; VE exhibits longer runtimes for smaller window sizes especially. This is because VE creates copies of each tuple in order to align them with the computed time windows. The smaller the window, the more tuples are created in the intermediate stage. This effect is more visible for WikiTalk and SNB because of their growth-only nature. In SNB, each vertex or edge exists from its start date to the life time of the graph, therefore VE needs to create a large amount of copies as each of those long intervals is split into intervals corresponding to the window size.

Summary. We studied the effect of data size and of temporal window size on performance. Our experiments showed that OGC performs best, followed by OG and VE. RG was the slowest representation in all cases. We also observed that smaller temporal window sizes (and thus more windows to compute) lead to longer execution time for RG and VE.

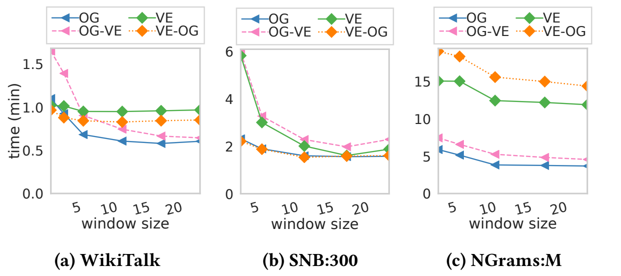


Figure 16: aZoom^T - wZoom^T combination and switching between memory representations. Fixed data size, group-by cardinality and number of intervals, varying the size of windows, node quantifier 'all', edge quantifier 'all'.

5.3 Operation Chaining

In this section we chain together aZoom^T to a wZoom^T and investigate whether switching between representations improves performance. Since OGC does not support attribute-based operation and due to the high memory usage and scalability issues of RG, we only run our experiments on VE and OG.

In the first experiment we run aZoom^T then wZoom^T with different windows sizes on WikiTalk, SNB:300 and NGrams:M. For aZoom^T on WikiTalk, we use edit count as the zoom attribute, for SNB we use first name, and for NGrams we use the word attribute. Figure 16 shows the results of this experiment. The x-axis lists window sizes for wZoom^T (in months for WikiTalk and SNB, and in years for NGrams), while the y-axis denotes the running time in minutes. Each line shows which representation is used. On WikiTalk, OG is the winner while OG-VE, VE-OG and VE are slightly slower. On SNB:300, VE-OG, and OG are fastest, and OG-VE is slowest, followed by VE.

In the previous section we saw that VE performs slightly better for aZoom^T on SNB, and OG performs significantly better for wZoom^T, so it makes sense for VE-OG and OG to show the best performance and for VE and OG-VE to show the worst. For NGrams, OG is the clear winner followed by OG-VE. The worst-performing combination here is VE-OG, followed by VE. On NGrams, OG performs significantly better for both aZoom^T and wZoom^T, and this can explain the results we are observing here.

In the next experiment we change the order of aZoom^T and wZoom^T. While this reordering does not always produce the same result, we can safely reorder the operations for WikiTalk and SNB, since no attributes change in these datasets, and so applying wZoom^T or aZoom^T first produces the same result with the "exist" quantifier for both vertices and edges.

Figure 17 shows the effect of group-by cardinality on wZoom^T - aZoom^T and aZoom^T - wZoom^T. In this experiments, we load the full graph for each dataset, project each node attribute to a random value based on group-by cardinality, and then perform the operations, with window size set to 6 months for WikiTalk and SNB, and 10 years for NGrams. We vary group-by cardinality from 10 to 1 million. We observe an increase in the execution time as the group-by cardinality increases, which we attribute to the fact that aZoom^T produces a larger intermediate graph for cases where we perform aZoom^T first. In contrast, we see no significant change in the execution time when wZoom^T is executed first. Interestingly, performing wZoom^T first in NGrams yields faster running time. Unlike in WikiTalk and SNB, vertices in NGrams are not growth-only, and they also span over a longer

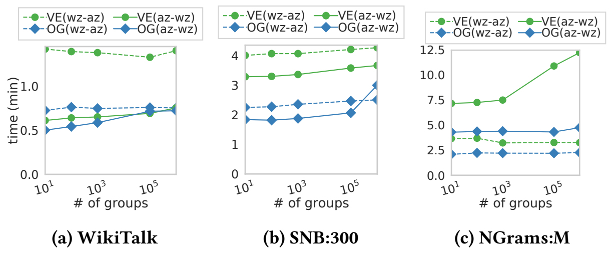

Figure 17: aZoom^T and wZoom^T performance for different group-by cardinalities with different zoom orders. Fixed data size and number of intervals. OG-based implementations perform best in most cases.

period of time. wZoom^T will reduce the number of snapshots and vertex tuples, which explains why wZoom^T - aZoom^T is faster than aZoom^T - wZoom^T.

Summary. We studied combining aZoom^T and wZoom^T for different combinations of parameters. Our experiments show that, while OG alone performs best in most cases, switching between representations does not significantly affect the running time. We also found that running aZoom^T before wZoom^T is fastest for growth-only datasets.

5.4 Summary

In this section, we first studied the effects of data size, the number of snapshots, the frequency of attribute change, and the group-by cardinality on the running time of aZoom^T. We observed that OG is the best performing representation for aZoom^T, followed by VE. We showed that representing the TGraph as a sequence of independent snapshots in RG results in the by far worst performance. The second part of this section focused on wZoom^T. We varied graph size and window size, and observed that OGC is the best-performing representation, followed by OG and VE. RG again exhibited the worst performance for wZoom^T. The last part of this section focused on combining aZoom^T and wZoom^T.

Overall, we found that OG, which balances temporal and structural locality, outperforms other representations in most cases.

6 RELATED WORK

Temporal models and languages in the relational literature are very mature (see, e.g., [10, 16, 23]). However, the same cannot be said for evolving graphs, where models differ in what time representation they adopt (point or interval), what top-level entities they model (graphs or sets of nodes and edges), whether they represent topology only or attributes or weights as well, and what types of evolution they support. Harary and Gupta [20] were, to the best of our knowledge, the first to informally propose to model graph evolution as a sequence of static graphs. This model has been predominant in the literature [15, 24–26, 38, 40], with various restrictions on the kinds of changes that can take place during graph evolution. In contrast to existing work, TGraph assigns periods of validity to nodes, edges and their properties, capturing evolution of graph topology and of node and edge attributes, and supports point-based semantics [37].

The attribute-based zoom operator is a temporal generalization of the node creation operator that is present in several conventional (non-temporal) graph query languages [42]. For example, StruQL outputs new nodes in a create clause, corresponding to the node creation operation with a Skolem function to create the object ids [13], while GOOD provides an abstraction operator that allows to create new nodes to represent multiple nodes based on shared properties [18]. To the best of our knowledge, a temporal generalization of this operator has not been considered except in our own prior work [37], and also has not been implemented in systems.

That said, the G* system supports SQL-style aggregation using the AggregateOperator per graph snapshot, supporting a limited version of summarization [26]. G* ingests evolving graph data one snapshot at a time, replicated across all machine without any compression, and is most similar to our RG. Our experiments showed that G* is not capable of loading graphs with a large number of intervals and does not scale for large size graphs [36]. We were not able to fully ingest any of our datasets used in Section 5 into G*. Chronograph, a system designed for temporal graph traversal [6], implements a version of temporal aggregation for the purpose of converting point-based to period-based semantics for edges, but not for nodes.

Temporal aggregation operators over relational data can be found in the literature, typically as an extension of non-temporal relational aggregation (see, e.g., example 10 in [11]). Li et al. proposed a general window aggregate for data streams [29] that can be applied to temporal relational data. Window aggregate semantics is based on a sliding window specification — a range and a slide — based on the desired data attribute that has a domain with a total order. The range specifies the width of the window e.g., 100 seconds or 100 rows, and the slide specifies how windows are formed. We are not aware of any proposal for an operator capable of changing the temporal resolution of evolving graphs, besides our own, introduced in [37], and no systems work on such an operator.

In our work we implement aZoom^T and wZoom^T operators in a dataflow system, and instantiate our ideas over Apache Spark [43], using the GraphX [17] library. We leverage the graph-specific optimizations provided by GraphX, as described in our implementation section, and incorporate temporal semantics into data representations and operators.

7 CONCLUSION

In this paper we proposed an implementation of two zoom operators — aZoom^T and wZoom^T — on evolving graphs. We detailed four physical representations — RG, VE, OG, and OGC, and described how to define the zoom operators using distributed dataflow operations, tailored to the corresponding data representation. We discussed how to efficiently implement the operators in Apache Spark with its GraphX library, and explained that our operator definitions could easily be implemented in other dataflow systems such as Apache Flink. In an extensive experimental evaluation on several real datasets with up to 1.3 billion edges, we explored the trade-offs in terms of temporal and structural locality with respect to zoom operator performance. We find that OG, which balances temporal and structural locality, outperforms the other representations in most cases.

In our future work we will extend our system to support additional operations on evolving graphs, such as Pregel-style analytics [30]. We will propose query optimization techinques for our workloads. Finally, we will design a query language with support for the proposed temporal zoom operators, among others.

Efficient Search for Multi-Scale Time Delay Correlations in Big Time Series Data

Nguyen Ho[†], Torben Bach Pedersen[†], Van Long Ho[†], Mai Vu[‡]
[†]Aalborg University, [‡] Tufts University

ABSTRACT

Very large time series are increasingly available from an ever wider range of IoT-enabled sensors deployed in different environments. Significant insights and values can be obtained from these time series through performing cross-domain analyses, one of which is analyzing time delay temporal correlations across different datasets. Most existing works in this area are either limited in the type of detected relations, e.g., linear relations alone, only working with a fixed temporal scale, or not considering time delay between time series. This paper presents our Time delaY COrrelation Search (TYCOS) approach which provides a powerful and robust solution with the following features: (1) TYCOS is based on the concept of mutual information (MI) from information theory, giving it a strong theoretical foundation to detect all types of relations including non-linear ones, (2) TYCOS is able to discover time delay correlations at multiple temporal scales, (3) TYCOS works in an efficient, bottom-up fashion, pruning non-interesting time intervals from the search by employing a novel MI-based noise theory, and (4) TYCOS is designed to efficiently minimize computational redundancy. A comprehensive experimental evaluation using synthetic and real-world datasets from the energy and smart city domains shows that TYCOS is able to find significant time delay correlations across different time intervals among big time series. The performance evaluation shows that TYCOS can scale to large datasets, and achieve an average speedup of 2 to 3 orders of magnitude compared to the baselines by using the proposed optimizations.

1 INTRODUCTION

Rapid advancements in IoT technology have enabled the collection of enormous amounts of time series data at unprecedented scale and speed. For example, a modern wind turbine has hundreds of sensors sampled at a high frequency, a smart building contains thousands of sensors sensing the surrounding environment, and an autonomic vehicle carries numerous vision sensors. All of them are collecting terabytes of data everyday. Analyzing these massive, heterogeneous and rich datasets can help uncover hidden patterns and extract new insights to support evidence-based decision making.

While time series analysis has been studied extensively in the past, its importance and value only continue to grow. One of the first steps to harness the enormous potential from modern big time series is to discover correlations among heterogeneous and cross-domain datasets. Consider for example the NYC Open Data [2] with more than 1,500 published datasets containing quantitative data from different domains, including weather and transportation, energy and environment etc. Cross-domain analysis among these datasets can reveal new insights about the city and its citizens, and thus aid policy makers in decision making. For instance, finding correlations between weather and transportation data can lead to the identification of individual weather events, such as the occurrence of a storm or a hurricane, which then helps explain an abnormal increase in the number of accidents. Data correlation is also useful in behavioral prediction and future planning. For example, illustrating that weather data (e.g., wind speed) is well-correlated with energy production can provide accurate prediction of the city's energy capacity at a specific time, thus allowing better resource planning. In the financial domain, data correlation can help forecast the price movement of related stocks, or predict the purchasing behavior of consumers, and thus assist investors in making real-time investment decisions. Not only is it useful in reasoning and predicting, data correlation can also be considered as one of the three building blocks to establish a causal relation [3], and thus can serve as a basis for constructing inference and learning models.

Despite its potential use, finding correlations in big time series is challenging. Not only does the very large volume of data raises significant challenges in terms of performance and scalability, their complex and noisy nature also presents difficulties in finding different types of correlation relations, or in the ability to deal with adaptive temporal scales. For example, stock prices or weather data exhibit non-linear relations, which cannot be captured by traditional correlation metrics such as Pearson Correlation Coefficient [23]. Besides, there is often a misconception that finding correlations and finding similarities in time series are the same task, where in fact, they are two different problems. Finding correlations is to look for statistical relationships in the data, whereas finding similarities means to find the optimal matching and/or alignment between time series sequences. Unlike the correlation-based approach, similarity metrics (which have positive values only) cannot distinguish between un-correlated and negatively correlated time series, both of which may have values close to 0. For example, consider a pair of time series (X, Y) generated by a sine function $y = sin(x)$. Here, $X \in (-\infty, \infty)$ represents a linearly increasing time series, while Y follows a sine function of X. In this example, X and Y do not exhibit any similarities among their values, but they do have an underlying relation. Such non-linear relations are common in areas such as signal processing, but cannot be detected using similarity measures. Thus, methods such as those used in Dynamic Time Warping [28] or MatrixProfile [31] have significant limitations in analyzing modern time series.

To make the problem even more challenging, cross-domain correlations might appear at different temporal scales. For example, correlations involving weather data might span over multiple temporal durations ranging from hours (e.g., during rain showers), to days, or even weeks (e.g., during a storm) depending on the weather events. Likewise, interactions between events might not always occur simultaneously. In practice, it is common to see events of one phenomenon influence other phenomena only after some delay of time. For instance, an increase of incidents caused by heavy rain can only be observed minutes or hours after the rain starts; or the impact of one rising stock on other stocks is visible only a few hours later. Given a heterogeneous set of time series data, there is a need to identify not only which datasets are correlated, but also when the correlations occur, and at what time delay.

Although correlation analysis has been researched extensively, current techniques are limited either in the type of detected relations, i.e., only linear ones, or the temporal scale and time delay in which they deal with. Most of the correlation works do not consider adaptive temporal scales as they assume correlations only exist for a fixed time period, e.g., [29], or ignore the time delay between variables of interest. There is no existing work that offers a holistic solution for searching window-based correlations, considering both multiple temporal scales and time delay, in modern big time series data.

This paper aims to address those challenges and limitations by introducing the Time delaY COrrelation Search (TYCOS) approach, making the following novel contributions: (1) We propose the first, to our knowledge, comprehensive solution for the multi-scale time delay correlation search problem that extracts significant correlations from big time series. (2) TYCOS is based on the concept of mutual information from information theory, giving it a strong theoretical foundation and the ability to discover various types of correlation relations, including linear and non-linear, monotonic and non-monotonic, functional and non-functional. (3) By combining the well-known Late Acceptance Hill Climbing (LAHC) search method with a window-based approach, TYCOS can automatically discover time delay correlations at multiple temporal scales, without requiring user inputs to specify the window sizes or the delay. (4) Based on mutual information properties, we propose a novel theory to identify noise in the data, enabling efficient pruning of non-interesting time intervals from the search, thus significantly reducing the search space and improving the search speed. (5) TYCOS is designed with efficient data structures to reuse the MI computation across a large number of windows, thus minimizing the computation redundancy. Moreover, TYCOS is scalable since it is designed in an efficient bottom-up fashion, making the method memory efficient and suitable for big datasets. And finally (6), we perform a comprehensive experimental evaluation using synthetic and real-world datasets from the energy and smart city domains, which shows that TYCOS is able to find interesting and important correlations among time series with high accuracy, can scale to large datasets, and achieves an average speedup of 2 to 3 orders of magnitude compared to the baselines.

2 RELATED WORK

Finding correlations among datasets is a fundamental step in data exploration. In the past, correlation analyses relied on traditional statistical metrics such as covariance or correlation coefficients to measure correlations [13, 15, 18, 19, 32]. However, these metrics are usually best for linear and/or monotonic dependencies. Recent studies had attempted to approach the problem from a high level. Sarma et al. [10] use the concept of *relatedness*, Pochampally et al. [24] use *joint precision* and *joint recall*, Alawini et al. [4] rely on the history and schema of datasets, Roy et al. [26] use the concept of *intervention*, to identify relations between datasets or data tables. Middelfart et al. [21] propose a bitmap-based approach to measure change relationships in a data cube. Chirigati et al. [7] propose a topology-based framework to identify spatio-temporal relationships in heterogeneous data corpuses. These studies, however, only focus on overall correlations. None of them consider correlations in time windows.

Surprisingly, very little effort has been made to design efficient solutions for time delay window-based correlations. Among them, Rakthanmanon et al. [25] design a Dynamic Time Warping-based technique (MASS) to quickly find the most similar subsequences in time series. Although considered to be the state of the art for subsequences matching, the technique does not have a mechanism to automatically search for correlated windows, but rather relies on a provided query. To improve MASS, Yeh et al. [31] designed the MatrixProfile framework to perform similarity joins between time series. However, as will be shown in Section 8.3, MASS and MatrixProfile cannot detect complex relations such as non-linear and non-functional ones. Other works, e.g., [8, 29] propose sliding window-based procedures to detect hidden correlations. However, they only focus on fixed size windows, not considering time delay, or using correlation coefficients as correlation measures, and thus, cannot find multi-scale time delay correlations and are limited in the types of relations they can detect. Our work in this paper overcomes those limitations. Since TYCOS uses MI as a correlation metric, it can discover all types of relationships. Furthermore, TYCOS works in a bottom-up fashion, and can thus automatically discover time delay correlations at multiple temporal scales.

Prior to this work, we investigated the use of MI in correlation discovery, and proposed AMIC [16, 17], a top-down approach to search for multi-scale correlations in big data. However, AMIC does not consider time delay correlations. Recently, we examine the power of LAHC in correlation search in a short paper [14]. The present paper significantly extends [14] by considering time delay correlations, and proposes a novel noise theory and MI computation technique to achieve better performance.

3 BACKGROUND

3.1 Mutual Information

MI is a statistical measure to quantify the shared information between two probability distributions. Given two discrete random variables X, Y with the corresponding probability mass functions (p.m.fs) $p(x)$, $p(y)$, and the joint distribution $p(x, y)$, the MI between X and Y is defined as

$$I(X;Y) = \sum_{y \in Y} \sum_{x \in X} p(x, y) \log \frac{p(x, y)}{p(x)p(y)} \tag{1}$$

Intuitively, $I(X;Y)$ represents the reduction of uncertainty of one variable (e.g., X) given the knowledge of another variable (e.g., Y) [9]. The larger $I(X;Y)$, the more information is shared between X and Y, and thus, the less uncertainty about one variable when knowing the other. The property that MI is equal to zero if and only if the considered variables are statistically independent, otherwise always positive if there exists any kind of dependency (e.g., linear and non-linear) [11], makes MI a versatile measure to capture correlations in noisy datasets which often exhibit a high degree of bias and abnormality, causing their relationships to often be arbitrary and non-linear.

Estimating mutual information: Eq. (1) is the theoretical definition of MI but is usually not used for computing MI, as it requires having the distributions of the underlying data which are often unknown in practice. To estimate MI from collected samples, we choose an estimation method proposed by Kraskov et al. [20] (hereafter called the *KSG* method) for several reasons: (1) The *KSG* method outperforms other estimators (e.g., histogram, kernel density estimation) in terms of computational efficiency and accuracy [22]; (2) The method uses $k-$nearest neighbor approximation and thus is data efficient, adaptive and has minimal bias [20]. These reasons make the *KSG* method particularly suitable for discovering temporal correlations in big and heterogeneous time series where the dependencies between different time series can be complex and might occur at multiple time scales.

The main idea of the *KSG* estimator is, instead of directly computing the joint and marginal probability distributions of the considered variables, it approximates the distributions by computing the densities of data points in nearby neighborhoods [20]. Specifically, *KSG* computes the probability distribution for the distance between each data point and its k^{th} nearest neighbor. For each data point, it searches for k nearest neighbor clusters (k is a pre-defined parameter) and computes the distance d_k to the k^{th}-neighbor. Then, the population density is estimated by counting the number of data points that fall within d_k. This leads to the computation of MI between two variables X and Y as [20]:

$$I(X;Y) = \psi(k) - 1/k - \langle \psi(n_x) + \psi(n_y) \rangle + \psi(n) \quad (2)$$

where ψ is the digamma function, k is the number of nearest neighbors, (n_x, n_y) are the number of marginal data points in each dimension falling within the distance d_k, n is the total number of data points and $\langle \cdot \rangle$ is the average function. The digamma function ψ is a monotonically increasing function. Thus, the larger n_x and n_y (i.e., more data points fall within the distance d_k), the lower $I(X;Y)$, and vice versa.

3.2 Late Acceptance Hill Climbing

Our correlation search algorithm is built based on LAHC [6] which we briefly introduce next. LAHC is an optimization technique attempting to find local optimal solutions for a given problem through iterative improvement. Given a target function f and a current solution S of f, LAHC tries to improve S by exploring potential candidates in the nearby neighborhood. If a better solution for f is found (according to some criteria), the current solution S is replaced by this new solution S_{new}, and the process is repeated until no further improvement can be made. LAHC is an extension of the classic Hill Climbing (HC) [27], but it differs from HC in its acceptance rule: a solution S_{new} is accepted if S_{new} is better than either the current solution S or a solution S_{old} found in the history. To do that, LAHC uses a fixed length array L_h to maintain a history of the most recently accepted solutions, and use L_h to justify the goodness of a candidate solution.

4 PROBLEM FORMULATION

Definition 4.1 *(Time series)* A time series $X_T = \{x_1, x_2, ..., x_n\}$ is a sequence of data values that measures the same phenomenon during an (observation) time period T, and is sorted in time order.

Note that the time period $T = [t_1, t_n]$ contains n time steps where each time step t_i has a recorded value $x_i \in X_T$, and t_1 and t_n denote the first, and the last time step of T. We say X_T has length n if X_T contains n data samples.

Definition 4.2 *(Time window)* A time window $w = [t_s, t_e]$ is a temporal sub-interval of T that records the events of X_T from time step t_s to time step t_e, and forms a (sub) time series $X_w = \{x_{t_s}, ..., x_{t_e}\} \subseteq X_T$.

We say w has size m, denoted as $|w| = m$, if w contains m time steps, and is equivalent to X_w containing m data samples.

Definition 4.3 *(Pair of time series)* A pair of two time series $(X_T, Y_T) = (\{x_1, x_2, ..., x_n\}, \{y_1, y_2, ..., y_n\})$ contains data collected from X_T and Y_T that measure two separate phenomena during the same observation period T. A tuple $(x_i, y_i) \in (X_T, Y_T)$ records the data values on X_T and Y_T at the same time step t_i.

Definition 4.4 *(Pair of time windows)* Let $w_X = [t_{x_s}, t_{x_e}]$, $w_Y = [t_{y_s}, t_{y_e}]$ be time windows of X_T and Y_T, respectively. Assume w_X and w_Y have the same length, i.e., $|w_X| = |w_Y|$. The pair of time windows $(w_X, w_Y) = ([t_{x_s}, t_{x_e}], [t_{y_s}, t_{y_e}])$ records the events of X_T from $[t_{x_s}, t_{x_e}]$, and of Y_T from $[t_{y_s}, t_{y_e}]$, and forms a pair of (sub) time series $(X_w, Y_w) = (\{x_{t_{x_s}}, ..., x_{t_{x_e}}\}, \{y_{t_{y_s}}, ..., y_{t_{y_e}}\}) \subseteq (X_T, Y_T)$.

Definition 4.5 *(Time delay window of a time series pair)* Let $(w_X, w_Y) = ([t_{x_s}, t_{x_e}], [t_{y_s}, t_{y_e}])$ be a pair of time windows like in Definition 4.4, and τ be an integer. The pair (w_X, w_Y) is called a time delay window of (X_T, Y_T) with the delay τ if $t_{y_s} - t_{x_s} = \tau$, and is denoted as $w_{X,Y+\tau} = ([t_s, t_e], \tau)$, where $t_s = t_{x_s}$ and $t_e = t_{x_e}$ are the start time and the end time of $w_{X,Y+\tau}$ on X_T, and τ is the time delay of w_Y w.r.t. w_X.

The window $w_{X,Y+\tau} = ([t_s, t_e], \tau)$ in Definition 4.5 defines a one-to-one mapping $f\colon w_X \mapsto_\tau w_Y$ that maps each event in w_X to the corresponding event in w_Y. The mapping is time correspondence, i.e., the event at the i^{th} time step of X_T in w_X is mapped to the event at the $(i+\tau)^{th}$ time step of Y_T in w_Y. Each window $w_{X,Y+\tau}$ is characterized by three parameters: the start time t_s, the end time t_e, and the time delay τ. The size of $w_{X,Y+\tau}$ equals to the size of w_X and w_Y, i.e., $|w_{X,Y}| = |w_X| = |w_Y|$.

A time delay window represents a shift (also called a "delay" or "lag") in time between two time series X_T and Y_T, and the value of τ indicates the shifted time units. Since τ can be equal to 0, or positive, or negative, the window $w_{X,Y+\tau} = ([t_s, t_e], \tau)$ is generalized for all time shifting scenarios. Semantically, if $\tau = 0$, then $w_{X,Y+\tau}$ does not have a time delay (or events of X_T in w_X and events of Y_T in w_Y occur at the same time). Whereas if $\tau > 0$, then w_Y is delayed τ time units from w_X (or events in w_Y occur τ time units after events in w_X). Similarly, if $\tau < 0$, w_X is delayed τ time units from w_Y. For brevity, in this paper, the two terms *time delay window* and *window* are used interchangeably.

Example 1. Consider a pair of time series (*Rain Precipitation (RP)*, *Injured Pedestrian (IP)*), and a time window $w_{RP,IP+30} = ([9.00\ am, 10.00\ am], 30\ mins])$. The window $w_{RP,IP+30}$ contains events of *RP* during $[9.00\ am, 10.00\ am]$, and maps them to events of *IP* occurring 30 minutes later, i.e., during the interval $[9.30\ am, 10.30\ am]$.

Fig. 1 illustrates 3 different scenarios of time window on (X_T, Y_T). Here, $w_1 = ([t_{s_1}, t_{e_1}], \tau_1 = 0])$ has no time delay, thus starts and ends at the same time on X_T and Y_T. Instead, the window $w_2 = ([t_{s_2}, t_{e_2}], \tau_2 > 0])$ has a time delay $\tau_2 > 0$, thus Y_T is shifted from X_T. The window $w_3 = ([t_{s_3}, t_{e_3}], \tau_3 < 0])$ has $\tau_3 < 0$, thus X_T is shifted from Y_T, similarly for w_4.

Definition 4.6 *(Mutual information of a window)* Let (X_T, Y_T) be a pair of time series, and $w_{X,Y+\tau}$ be a *time delay window* of (X_T, Y_T). The MI between X_T and Y_T within $w_{X,Y+\tau}$ is estimated using the *KSG* estimator as:

$$I_{w_{X,Y+\tau}} = I(X_w; Y_w) = \psi(k) - \frac{1}{k} - \frac{1}{m} \sum_{\substack{x_i \in X_w \\ y_j \in Y_w}} [\psi(n_{x_i}) + \psi(n_{y_j})] + \psi(m) \quad (3)$$

where m is the size of $w_{X,Y+\tau}$, and n_{x_i} and n_{y_j} are the number of data points falling within the k^{th}-nearest distances in each dimension d_x and d_y of point $(x_i, y_j) \in (X_w, Y_w)$.

Fig. 2 illustrates how to compute the MI of a window using *KSG* estimation. Consider a window $w_{X,Y+\tau}$ contains 7 data points

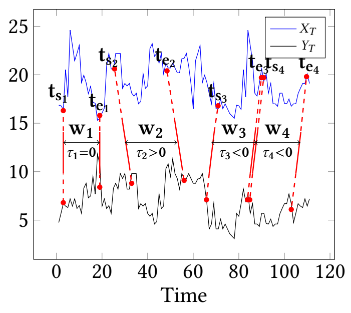

Figure 1: Time windows

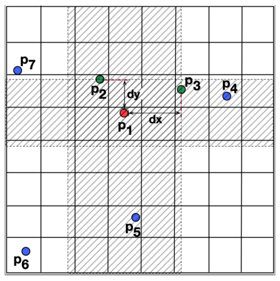

Figure 2: MI computation

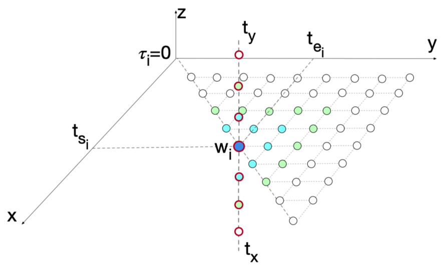

Figure 3: Search space of TYCOS

$\{p_1=(x_1,y_1),...,p_7=(x_7,y_7)\}$, with their positions projected into a two dimensional grid as in Fig. 2. Without loss of generality, we assume $\tau=0$ (events in X_w and Y_w occur at the same time step), the nearest neighbor parameter $k=2$, and the distance metric between neighbors is the *maximum norm*[1]. Under this setting, the 2 nearest neighbors of p_1 are p_2 and p_3 (in green), and the nearest distances from p_1 to its nearest neighbors in each dimension are dx and dy. The nearest distances allow the *KSG* estimator to form the marginal regions (in gray shade), from which the marginal counts are computed. In this case for point p_1, the marginal counts are n_{x_1}=3 (including p_2,p_3,p_5), and n_{y_1}=3 (including p_2,p_3,p_4). Similar steps are applied to other data points from p_2 to p_7. Finally, the marginal counts n_{x_i}, n_{y_i} are inserted into Eq. 3 to compute the MI of $w_{X,Y+\tau}$.

Definition 4.7 *(Correlated time delay window)* Let $w_{X,Y+\tau}$ be a *time delay window* of (X_T,Y_T), and $I_{w_{X,Y+\tau}}$ be the MI of $w_{X,Y+\tau}$. The two time series X_T and Y_T are said to be correlated within $w_{X,Y+\tau}$ iff $I_{w_{X,Y+\tau}} \geq \sigma$ where $\sigma > 0$ is a pre-defined correlation threshold.

Problem Statement: *Time delaY COrrelation Search (TYCOS). Let (X_T,Y_T) be a pair of time series measured during the time interval T, and $w_{X,Y+\tau}$ be a time delay window of (X_T,Y_T). Then TYCOS aims to find a set S of $w_{X,Y+\tau}$ such that $s_{\min} \leq |w_{X,Y+\tau}| \leq s_{\max} \wedge \tau \leq td_{\max} \wedge I_{w_{X,Y+\tau}} \geq \sigma \wedge \forall w_i, w_j \in S : w_i \nsubseteq w_j \wedge w_j \nsubseteq w_i$, where $|w_{X,Y+\tau}|$ denotes the size of $w_{X,Y+\tau}$, $s_{\min}$ and $s_{\max}$ are the minimum and maximum sizes that a window can have, $td_{\max}$ is the maximum time delay, and σ is the pre-defined correlation threshold.*

The goal of TYCOS is to find a set S of non-overlapping time delay windows that respect size and time delay constraints, and have their MI satisfying the pre-defined correlation threshold. As the size of each window is restricted in the range $[s_{\min}, s_{\max}]$, this implies that if correlations exist in the pair (X_T,Y_T), they will last at least for length $s_{\min}$, and at most for length $s_{\max}$. This assumption is meaningful especially when working with real datasets. For example, when searching for weather-related correlations, one could assume that correlations can only last for at most *several* weeks which correspond to the longest duration of a weather event. Furthermore, the time delay of a window is also assumed to be bounded by a maximum value $td_{\max}$ that represents the longest shifting duration between two time series. The value of $td_{\max}$ can be used to prevent spurious correlations. For example, a heavy rain cannot have an impact on the number of injured pedestrians one year later. Setting $td_{\max}$ value, for now, will rely on the expert's domain knowledge.

[1]L_∞: $d(p_i,p_j) = \| (d_x, d_y) \|_{\max} = \max(\| x_i - x_j \|, \| y_i - y_j \|)$

5 TYCOS: TIME DELAY CORRELATION SEARCH

5.1 Search Space and Time Complexity

The search space of TYCOS is represented by the number of *feasible* windows (*feasible* windows are those that respect the size and time delay constraints), illustrated in Fig. 3. Here, the x−axis represents the start time t_s, the y−axis represents the end time t_e, and the z−axis represents the time delay τ of a window. Each point in this 3−dimensional grid represents a window w_i identified by its start time index t_{s_i}, end time index t_{e_i}, time delay τ_i, and its MI I_{w_i}. Since the start time index t_{s_i} always has to be smaller than the end time index t_{e_i}, the *feasible* windows will reside only in half of the grid (Fig. 3).

LEMMA 1. *Let (X_T,Y_T) be a pair of two time series of length n, and $s_{\min}$, $s_{\max}$ be the minimum and maximum sizes of a window, $td_{\max}$ be the maximum time delay between X_T and Y_T. Then the size of TYCOS search space is $O(n^3)$.*

PROOF. To find all feasible windows, initially, a *Brute Force* search can start with a window $w_0 = ([t_{s_0}, t_{e_0}], \tau_0)$ at the minimum size $s_{\min}$ and the initial time delay $\tau_0 = 0$. For each start index t_{s_i}, it extends the end index t_{e_i}, creating a new and larger window $w_i^{'}$ until it reaches the maximum size $s_{\max}$. With one start index t_{s_i}, the number of windows created by extending the end index is: $s_{\max} - s_{\min} + 1$.

Furthermore, each window w_i has the possibility to shift $(2 * td_{\max})$ times (corresponding to *negative* and *positive* values of τ), creating $(2 * td_{\max})$ possible time delay windows. Finally, there are $(n - s_{\min} + 1)$ possible start indices t_{s_i}. Thus, the total number of feasible windows of TYCOS is:

$$(n - s_{\min} + 1) * (s_{\max} - s_{\min} + 1) * 2 * td_{\max} \sim n^3 \qquad (4)$$

if $s_{\max} \to n \wedge td_{\max} \to n \wedge s_{\min} \ll n$. □

LEMMA 2. *Let n be the length of (X_T,Y_T), and m be the average size of a window, then the worst-case time complexity of a Brute Force search for TYCOS on (X_T,Y_T) is $O(n^3m^2)$.*

PROOF. The complexity of TYCOS depends on the number of windows it needs to evaluate, and the time required to compute the MI of each window. The number of windows to be evaluated for TYCOS is $O(n^3)$, according to Lemma 1.

On the other hand, the MI is computed using the *KSG* estimator, in which the most expensive operator is the k-nearest neighbor (kNN) search. Therefore, the complexity of MI computation depends on the complexity of kNN search. Consider a window w_i of size m. A basic kNN algorithm applied to w_i will require $O(kdm)$ to find k nearest neighbors for one sample (d is the data dimensionality), and thus $O(kdm^2) \sim O(m^2)$ (if k and d are significantly smaller than m) for all samples in w_i [12]. Hence, the worst-case time complexity of a Brute Force search for TYCOS is $O(n^3m^2)$. However, if a more efficient data structure is used, such as k-d tree [5] or grid-based structure (for low dimensional data) [30], the expected-case *kNN* complexity is $O(kdm \log m) \sim O(m \log m)$, and thus, the expected-case Brute Force complexity is $O(n^3 m \log m)$. □

5.2 TYCOS$_{\textbf{LAHC}}$: A LAHC Based Approach

The time complexity of a Brute Force approach for TYCOS is computationally prohibitive in practice. For example, a pair of time series with *n=9,000* data points, $s_{\max} = 400$, $s_{\min} = 20$, and $td_{\max} = 20$ will create *136,870,440* windows. Our Brute Force search implemented in *C++* and run on a standard PC will take more than 12 hours to process all generated windows. In the next section, we propose a heuristic search method using LAHC to speed up the TYCOS process.

To improve the TYCOS process, we look at two angles for improvements: (1) reducing the search space, and (2) optimizing the MI computation. To reduce the search space, we adopt LAHC, and propose a novel MI-based theory to prune unpromising windows. To optimize the MI computation, we design efficient data structures so that we can reuse the computation across windows. The following sections discuss the intuition behind our approach and detail how LAHC can be applied to TYCOS. The MI-based theory and its applicability to TYCOS are introduced in Section 6. The efficient MI computation is described in Section 7.

5.2.1 The choice of LAHC. To explain the intuition behind the LAHC-based method, consider Fig. 4 that illustrates the MI value fluctuation across windows. Here, the $y-$axis represents the MI values of corresponding time windows on the $x-$axis. Given the correlation threshold σ (red line), the three windows which correspond to the three locally maximal points (in red) indicate highly correlated areas, and can be found by identifying the three peak (red) points in the search space. Since LAHC guarantees to achieve local optimal solutions, it becomes an ideal foundation for solving the TYCOS problem.

5.2.2 Apply LAHC to TYCOS. Indeed, finding correlations in time series means to find windows that maximize the MI. Thus, we consider the problem of searching for time delay correlations using LAHC, namely TYCOS$_{\textbf{LAHC}}$ (or TYCOS$_{\textbf{L}}$ in short), as a *maximization* problem. Specifically, the target function of TYCOS$_{\textbf{L}}$ is a *maximize* function, and our goal is to find windows where their MIs are locally maximal values that satisfy σ.

a) Search space navigation. We first illustrate how LAHC navigates through the search space of TYCOS in Fig. 5, with the three axes being the start time ($x-$axis), the end time ($y-$axis) and the time delay ($z-$axis) of a window. Assume $w_i = ([t_{s_i}, t_{e_i}], \tau_i)$ is the window where the search is currently at. Starting from w_i, if TYCOS$_{\textbf{L}}$ follows a rightwards trajectory on the $y-$axis, it moves the end time t_{e_i} of w_i forward in time, thus enlarging the window size. If it follows a leftwards trajectory on the $y-$axis, it moves the end time t_{e_i} backward in time, thus reducing the window size. Similarly, moving along the $x-$axis, TYCOS$_{\textbf{L}}$ can reduce or increase the start time t_{s_i}, therefore, extending or narrowing the size of w_i accordingly. On the $z-$axis, following the t_x direction, TYCOS$_{\textbf{L}}$ increases the shifting time of X_T w.r.t. Y_T. Following the t_y direction, TYCOS$_{\textbf{L}}$ will shift Y_T further from X_T. In both cases, it increases the time delay but keeps the same window size.

While exploring the search space in multiple directions, TYCOS$_{\textbf{L}}$ creates different windows by adjusting the indices of the current window. The generated windows are grouped into the same neighborhood if they share similar indices. The *neighborhood* concept is defined below.

Definition 5.1 *(δ-neighbor)* Let $w = ([t_s, t_e], \tau)$ be a window of (X_T, Y_T), and assume (X_T, Y_T) has length *n*. A window $w' = ([t_s', t_e'], \tau')$ is a *δ-neighbor* of w if $t_s' = t_s \pm \delta \lor t_e' = t_e \pm \delta \lor \tau' = \tau \pm \delta$, where δ is a pre-defined moving step such that $1 \le \delta \le n \land s_{\min} \le \left|w'\right| \le s_{\max} \land \tau' \le td_{\max}$.

A δ-neighbor window w' has at least one of its indices (i.e., $t_{s'}$, or $t_{e'}$, or τ') differing a δ step from the indices of w.

Definition 5.2 *(δ-neighborhood)* Let $w = ([t_s, t_e], \tau)$ be a window of (X_T, Y_T). A *δ-neighborhood* of w, denoted as N_δ, is formed by all *δ-neighbors* $w' = ([t_s', t_e'], \tau')$ of w.

The *neighborhood* concept is illustrated in Fig. 5. Consider the window w_i (in blue). The nearest $\delta-$neighborhood of w_i, called the $1-$neighborhood N_1, is the area formed by the 26 windows in blue color w_i^1 where $i = 1, ..., 26$. Each window in this neighborhood differs from w_i by *one* δ step, either by its start index, or its end index, or its time delay, or the combinations of them, or all. Going further, another neighborhood of w_i, called the $2-$neighborhood N_2, is the 50 windows in green color area. Each $\delta-$*neighborhood* forms an area where TYCOS$_{\textbf{L}}$ will iteratively look for potential candidates to improve w_i.

b) TYCOS$_{\textbf{L}}$ algorithm. We provide the outline of TYCOS$_{\textbf{L}}$ in Algorithm 1, and explain it in the following.

Consider a time series pair (X_T, Y_T), and let I_w be the target function to be maximized. To improve I_w, TYCOS$_{\textbf{L}}$ will start with an initial feasible solution, and explores its neighborhood to look for better solutions. Let $w = w_0$ where$|w_0| = s_{\min} \land \tau_0 = 0$ be an initial solution (Alg. 1, line 2). The goodness of w_0 is evaluated by computing $I(w_0)$ (line 3). Starting from w_0, TYCOS$_{\textbf{L}}$ will first explore its nearest neighborhood N_1, and search for a better solution than w_0 in this area. To do that, it creates all δ_1-neighbors of w_0 to form N_1. Then for each $w' \in N_1$, it computes $I(w')$ and selects the best neighbor *bestnb* which has the highest MI (lines 5 – 8). Next, it determines whether *bestnb* is a better solution than the current one w using the following policies:

- (*Policy 1*) If: $I_{bestnb} > I_w$ or $I_{bestnb} > I_{w_h}$ where $w_h \in L_h$, then: *bestnb* is a better solution than w and thus, w is replaced by *bestnb* (lines 10 – 12).
- (*Policy 2*) If: $I_{bestnb} \le I_w$ and $I_{bestnb} \le I_{w_h}$, then there is no better solution in the considered neighborhood, thus, no improvement can be made (lines 14 – 15).

In *Policy 1*, a better solution is found, the search moves to this new solution $w = bestnb$, and repeats the neighborhood exploration process on the new w. Note that since LAHC also uses a historical value w_h to justify a potential candidate solution, the newly selected solution *bestnb* might be better than w_h, but not necessarily better than the current solution w. This type of approximation creates some "randomness" in the search, which is helpful, for example, when the search needs to escape from plateau situations, i.e., when the search space is flat. In *Policy 2*, no better solution is found, then the *stopping conditions* are checked. If the *stopping conditions* are not yet satisfied, the search continues exploring larger neighborhoods. Otherwise, it stops and the value I_w at the stopping point is the locally maximal value. Finally, w is accepted and inserted into the result set S if $I_w \ge \sigma$ (lines 19 – 20).

When the *stopping conditions* are satisfied and TYCOS$_{\textbf{L}}$ stops, the time series pair might not be scanned entirely. In that case, TYCOS$_{\textbf{L}}$ restarts again on the remaining part of the data, looking

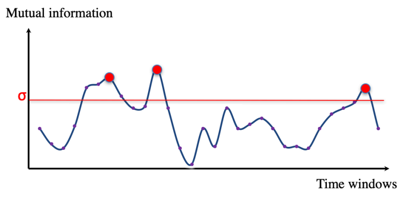

Figure 4: MI fluctuation

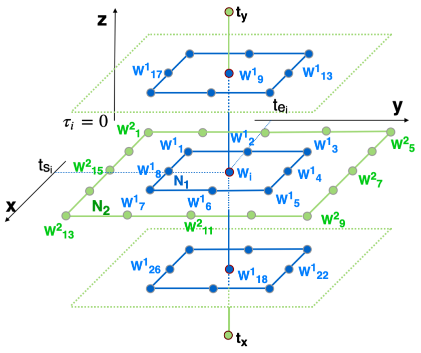

Figure 5: Explore neighborhood

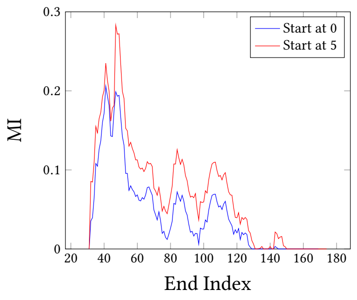

Figure 6: Changes of MI

for new local optimal solutions, until the entire time series are searched (line 21).

Stopping conditions: Ideally, TYCOS$_L$ will stop immediately when no better solution can be found in the considered neighborhood. However, to avoid situations where the occurrence of a temporary setback stops the search too early, an idle period is used to measure the number of non-improvements observed. The search will stop when the pre-defined max idle period $T_{maxIdle}$ is reached (line 4).

Initial solution: The initial window w_0 can be at the beginning, or at an arbitrary position in the time series. A good initial solution can help reach satisfying solutions faster, and vice versa. In Section 6, we rely on an MI-based theory to select a good initial solution, leading to a more promising exploration for the search.

The history list L_h: TYCOS$_L$ maintains a history L_h of the most recently accepted solutions and uses it to justify the goodness of a potential candidate. In our implementation, TYCOS$_L$ follows the *random* policy when selecting and updating an item in the history (line 9 and 16 – 18).

Algorithm 1 TYCOS$_L$: LAHC for TYCOS

```
    Input: $(X_T, Y_T)$: pair of time series
    Params: $\sigma, \varepsilon, s_{\min}, s_{\max}, td_{\max}$
    Output: $S$: a set of non-overlapping windows whose MI $\geq \sigma$
 1: while $(X_T, Y_T)$ is not scanned entirely do
 2:     Initial solution $w := w_0$ with $|w_0| = s_{\min} \wedge \tau_0 = 0$
 3:     Compute $I(w_0)$                        ▹ Evaluate the goodness of $w_0$
 4:     while $t_{idle} < T_{maxIdle}$ do
 5:         $N := Neighbors(w)$                 ▹ Identify the neighbors of $w$
 6:         for $w' \in N$ do
 7:             Compute $I(w')$                 ▹ Evaluate the goodness of $w'$
 8:         $bestnb := BestNeighbor(N)$         ▹ Select best neighbor in $N$
 9:         $w_h := random.get(L_h)$            ▹ Randomly select from $L_h$
10:         if $I_{bestnb} > I_{w_h}$ or $I_{bestnb} > I_w$ then
11:             $w := bestnb$                   ▹ Accept the candidate
12:             $t_{idle} := 0$                 ▹ Reset the idle time
13:         else
14:             $w := w$                        ▹ Reject the candidate
15:             $t_{idle} := t_{idle} + 1$      ▹ Increase the idle time
16:         if $I_w > I_{w_h}$ then             ▹ Update the history list
17:             $w_h := w$
18:             $I_{w_h} := I_w$
19:     if $I_w \geq \sigma$ then
20:         Insert $w$ to $S$
21:     $TYCOS_L(X'_T, Y'_T)$                   ▹ Restart TYCOS$_L$
22: return $S$
```

6 NOVEL NOISE THEORY TO IMPROVE TYCOS

6.1 Noise Identification

When TYCOS$_L$ performs the neighborhood exploration, conceptually, it is performing a depth-first search. Each neighbor window is considered as an expansion to a deeper level of the search tree, and the expansion only stops when the stopping conditions are met. During the expansion, some part of the data might be revisited multiple times, which can lead to redundant computation. To reduce potential redundancy, we explore several MI properties to establish principles that can help narrow the search space. Specifically, we seek the answer for the following research question: *"When should a certain part of data be completely removed from the search?".*

This research question concerns the removal of a data partition from the search without affecting its final outcomes. This is due to the fact that by repeatedly expanding the neighborhood, TYCOS$_L$ revisits a data partition multiple times, and in some cases, a particular data partition might be irrelevant to the search's objectives, i.e., including this particular data partition in the search process does not lead to promising results. If that data partition can be identified, it should not be included in future explorations of the search. The following example demonstrates this situation.

Consider the window w_i (blue point), and its neighborhood N_1 and N_2 in Fig. 5. In N_1 and N_2, neighbors that belong to the same exploration direction might contain overlapping data. For instance, $w^1_4 \in N_1$ is expanded from w_i by extending its end index by a δ_1 step, while $w^2_7 \in N_2$ is an extension of w^1_4 by enlarging w_i's end index a δ_2 step ($\delta_2 > \delta_1$). The process of extending one window to another window results in overlapping data that will be revisited multiple times in different exploration iterations.

On the other hand, consider Fig. 6 that plots the MI values of a time series pair with different start indices: the blue line starts at index 0, the red line starts at index 5, i.e., the data from 0 to 5 are not considered in the red line. From Fig. 6, it can be seen that by excluding the data range $[0-5]$ from the search, the MI values of subsequent windows increase and are larger than when including the considered range. This implies that the data range $[0-5]$ provides no information about the dependency between the times series pair, and thus can be considered as "noise" and eliminated from future exploration.

The above research question thus can be answered by establishing a "noise" identification principle. To do that, we rely on the following theorem to understand when a data partition can be considered as "noise" and should be eliminated.

Definition 6.1 (*Mixture distribution*) Let X and U be discrete random variables with the corresponding p.m.fs $p_X(x)$, $p_U(u)$. Let Z be a new random variable which is drawn from the same distribution as X with probability θ and from the same distribution as U with probability $1-\theta$ for a given $\theta \in [0,1]$. Then Z is said to have a mixture distribution between $p_X(x)$ and $p_U(u)$ with probability θ and is written as $Z = X \odot_\theta U$.

Theorem 6.1. *Let X, Y, U, V be discrete random variables and $p_X(x), p_Y(y), p_U(u)$, and $p_V(v)$ be their corresponding p.m.fs. Let*

$Z = X \odot_\theta U$ and $W = Y \odot_\eta V$ where $\odot$ denotes the mixture of two variables. Assume that, except for X and Y, other variables are pair-wise independent, i.e., $(U \perp V) \wedge (X \perp U) \wedge (X \perp V) \wedge (Y \perp U) \wedge (Y \perp V)$. Then $I(X;Y) \geq I(Z;W)$.

Proof. Z and W are the two mixed variables: $Z = X \odot_\theta U$ and $W = Y \odot_\eta V$. Then, for a value of x drawn according to $p_X(x)$ and a value of u drawn according to $p_U(u)$, we can write the probabilities for Z as follows:

$$p_Z(x) = P(Z = X)p_X(x) = \theta p_X(x) \tag{5}$$

$$p_Z(u) = P(Z = U)p_U(u) = (1-\theta)p_U(u) \tag{6}$$

Similarly, for $y \sim p_Y(y)$ and $v \sim p_V(v)$, we have:

$$p_W(y) = P(W = Y)p_Y(y) = \eta p_Y(y) \tag{7}$$

$$p_W(v) = P(W = V)p_V(v) = (1-\eta)p_V(v) \tag{8}$$

Then, we can write the following joint probabilities:

$$p_{Z,W}(x,y) = \theta\eta p_{X,Y}(x,y) \tag{9}$$

$$p_{Z,W}(x,v) = \theta(1-\eta)p_{X,V}(x,v) \tag{10}$$

$$p_{Z,W}(u,y) = (1-\theta)\eta p_{U,Y}(u,y) \tag{11}$$

$$p_{Z,W}(u,v) = (1-\theta)(1-\eta)p_{U,V}(u,v) \tag{12}$$

We have the MI between X and Y as

$$I(X;Y) = \sum_y \sum_x p_{X,Y}(x,y) \log \frac{p_{X,Y}(x,y)}{p_X(x)p_Y(y)} \tag{13}$$

And the MI between Z and W as

$$I(Z;W) = \sum_w \sum_z p_{Z,W}(z,w) \log \frac{p_{Z,W}(z,w)}{p_Z(z)p_W(w)} \tag{14}$$

Since Z can take the values in $\mathcal{R}_X$ if z is drawn from X, and in $\mathcal{R}_U$ if z is drawn from U (similarly for W), then from Eq. (14), it follows that:

$$\begin{aligned}
I(Z;W) = &\sum_{w\in\mathcal{R}_Y}\sum_{z\in\mathcal{R}_X} p_{Z,W}(x,y)\log\frac{p_{Z,W}(x,y)}{p_Z(x)p_W(y)} \\
&+ \sum_{w\in\mathcal{R}_Y}\sum_{z\in\mathcal{R}_U} p_{Z,W}(u,y)\log\frac{p_{Z,W}(u,y)}{p_Z(u)p_W(y)} \\
&+ \sum_{w\in\mathcal{R}_V}\sum_{z\in\mathcal{R}_X} p_{Z,W}(x,v)\log\frac{p_{Z,W}(x,v)}{p_Z(x)p_W(v)} \\
&+ \sum_{w\in\mathcal{R}_V}\sum_{z\in\mathcal{R}_U} p_{Z,W}(u,v)\log\frac{p_{Z,W}(u,v)}{p_Z(u)p_W(v)} \\
= &\sum_{y\in\mathcal{R}_Y}\sum_{x\in\mathcal{R}_X} \theta\eta p_{X,Y}(x,y)\log\frac{\theta\eta p_{X,Y}(x,y)}{\theta p_X(x)\eta p_Y(y)} \\
&+ \sum_{y\in\mathcal{R}_Y}\sum_{u\in\mathcal{R}_U} (1-\theta)\eta p_{U,Y}(u,y)\log\frac{(1-\theta)\eta p_{U,Y}(u,y)}{(1-\theta)p_U(u)\eta p_Y(y)} \\
&+ \sum_{v\in\mathcal{R}_V}\sum_{x\in\mathcal{R}_X} \theta(1-\eta) p_{X,V}(x,v)\log\frac{\theta(1-\eta) p_{X,V}(x,v)}{\theta p_X(x)(1-\eta) p_V(v)} \\
&+ \sum_{v\in\mathcal{R}_V}\sum_{u\in\mathcal{R}_U} (1-\theta)(1-\eta) p_{U,V}(u,v)\log\frac{(1-\theta)(1-\eta) p_{U,V}(u,v)}{(1-\theta)p_U(u)(1-\eta) p_V(v)}
\end{aligned} \tag{15}$$

Eq. (15) can be rewritten as

$$\begin{aligned}
I(Z;W) = &\ \theta\eta I(X;Y) + (1-\theta)\eta I(U;Y) \\
&+ \theta(1-\eta)I(X;V) + (1-\theta)(1-\eta)I(U;V)
\end{aligned} \tag{16}$$

Since we assume

$$(U \perp V) \wedge (X \perp U) \wedge (X \perp V) \wedge (Y \perp U) \wedge (Y \perp V)$$

This leads to

$$I(U;Y) = 0 \wedge I(X;V) = 0 \wedge I(U;V) = 0$$

Thus, Eq. (16) becomes

$$I(Z;W) = \theta\eta I(X;Y) \tag{17}$$

where $\theta \leq 1$ and $\eta \leq 1$, which leads to

$$I(X;Y) \geq I(Z;W)$$

□

Theorem 6.1 says that, if U and V are independent from each other and from X and Y, then adding them to X and Y will bring more uncertainty to (X, Y), in other words, they reduce the shared information $I(X;Y)$.

Definition 6.2 *(Consecutive windows)* Let $w_{X,Y+\tau} = ([t_s, t_e], \tau)$ and $w'_{X,Y+\tau'} = ([t_{s'}, t_{e'}], \tau')$ be the two time delay windows of (X_T, Y_T). Then $w_{X,Y+\tau}$ and $w'_{X,Y+\tau'}$ are consecutive iff $t_{s'} = t_e + 1 \wedge \tau = \tau'$.

From Definition 6.2, $w_{X,Y+\tau}$ and $w'_{X,Y+\tau'}$ are *consecutive* if they are next to each other and have the same shifting time, i.e., $w'_{X,Y+\tau'}$ starts right after the end time of $w_{X,Y+\tau}$. Since $w'_{X,Y+\tau'}$ follows $w_{X,Y+\tau}$, terminologically, we call $w_{X,Y+\tau}$ the *followed* window, and $w'_{X,Y+\tau'}$ the *following* window. Examples of *consecutive* windows are w_3 and w_4 in Fig. 1.

Definition 6.3 *(Concatenation operation $\odot$ of consecutive windows)* Let $w_{X,Y+\tau} = ([t_s, t_e], \tau)$ and $w'_{X,Y+\tau'} = ([t_{s'}, t_{e'}], \tau')$ be two consecutive windows of (X_T, Y_T). The concatenation between $w_{X,Y+\tau}$ and $w'_{X,Y+\tau'}$ is defined as: $w''_{X,Y+\tau} = w_{X,Y+\tau} \odot w'_{X,Y+\tau'} = ([t_s, t'_e], \tau)$. The concatenation operation joins two consecutive windows $w_{X,Y+\tau}$ and $w'_{X,Y+\tau'}$ into one bigger window $w''_{X,Y+\tau}$ which has its start time being the start time of the *followed* window, and its end time being the end time of the *following* window.

Based on the result of Theorem 6.1 and Definitions 6.2, 6.3, we define *noise* as follows.

Definition 6.4 *(Noise)* Let $w_{X,Y+\tau}$, $w'_{X,Y+\tau'}$ be two consecutive windows of (X_T, Y_T), $w''_{X,Y+\tau} = w_{X,Y+\tau} \odot w'_{X,Y+\tau'}$ be their concatenating window, and ε ($0 \leq \varepsilon < \sigma$) be a real number representing the *noise threshold*. Assume that $I_{w_{X,Y+\tau}} > 0$. Then $w'_{X,Y+\tau'}$ is called *noise* w.r.t. $w_{X,Y+\tau}$ iff $I_{w'_{X,Y+\tau'}} < \varepsilon \wedge I_{w''_{X,Y+\tau}} < I_{w_{X,Y+\tau}}$.

The noise principle says that if the MI of the *following* window $w'_{X,Y+\tau'}$ is less than the noise threshold, and the MI of the *followed* window $w_{X,Y+\tau}$ decreases after the concatenation, then the *following* window is *noise* w.r.t. the *followed* window.

6.2 Applying Noise Theory to Prune the Search Space

Based on the noise identification principle, we propose two improvements to be made in TYCOS$_\mathbf{L}$. We name TYCOS$_\mathbf{L}$ with noise theory applied as TYCOS$_\mathbf{LN}$.

6.2.1 *Initial noise pruning.*

Previously, we said that TYCOS$_\mathbf{L}$ can start out at the beginning of, or at an arbitrary location in the time series. This, however, can lead the search to an unpromising exploration area. For example, if the search starts out at the valleys in Fig. 4, it might take longer time to reach the top of the hill than if it starts somewhere on the edges. To avoid the

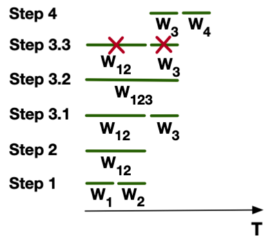

Figure 7: Initial window

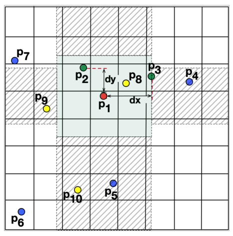

Figure 8: Efficient MI computation

"valley-trapped" situations, we use the noise theory to find a good starting point. The search is at a good starting point if the initial solution w_0 has $I_{w_0} \geq \varepsilon$ (the *noise threshold*). To find such a point, we first divide the time series into non-overlapping windows of the minimal size $s_{\min}$ with no time delay ($\tau = 0$), and then hierarchically combine them to form larger, and hopefully better windows. The combination stops when it finds a window w that has $I_w \geq \varepsilon$. Fig. 7 demonstrates this procedure.

In *Step 1*, initially the search starts with two minimal consecutive and non-overlapping windows w_1, w_2, and evaluates their goodness by computing I_{w_1}, I_{w_2}. In *Step 2*, it combines the *two* windows into a bigger one w_{12}, and computes $I_{w_{12}}$. Next, it compares the goodness of the 3 windows, and select the one that has the highest MI. Assuming that $\{I_{w_1}, I_{w_2}\} \leq I_{w_{12}} < \varepsilon$, then w_{12} is the one selected among the *three*. Since $I_{w_{12}}$ is still less than ε, it moves to *Step 3.1*, where a next minimal window w_3 is evaluated both separately (by computing I_{w_3}), and together with w_{12} (by computing $I_{w_{123}}$).

Assume that $I_{w_3} < \varepsilon$, and that by combining w_3 to w_{12}, it reduces the MI $I_{w_{12}}$, i.e., $I_{w_{123}} < I_{w_{12}} < \varepsilon$. According to Theorem 6.1, we can conclude that w_3 is noise w.r.t. w_{12}. Thus, the combination w_{123} does not lead to a promising result. The next window to be considered is w_4. However, w_{12} cannot be combined with w_4 without the presence of w_3, which we know is noise of w_{12}. Thus, the combination w_{1234} should not be formed, and w_{12} should also be eliminated from future consideration (*Step 3.3*). Next, in *Step 4*, w_3 is evaluated again in combination with w_4, and the procedure is repeated until it can find a window that has MI > ε. Once the starting point is determined, TYCOS**LN** begins its neighborhood exploration as described in Section 5.2.

6.2.2 Subsequent noise detection. The noise identification principle is also beneficial during the neighborhood exploration. We explain its applicability in Fig. 5. Assume w_i is the current window and w_4^1, w_7^2 are its neighbors when moving along the $y-$axis. In the first exploration, the neighbor w_4^1 is considered. Since w_4^1 is created by extending the end index of w_i by a δ_1-step, we have: $w_4^1 = w_i \odot w_{\delta_1}$ where w_{δ_1} is the extension to be concatenated with w_i. Assume that by applying our noise theory to w_i, w_{δ_1}, and w_4^1, we conclude that w_{δ_1} is noise w.r.t. w_i. In this case, it is not promising to further explore the neighborhoods of w_i along the $y-$axis in that direction. In the next exploration, TYCOS**LN** will omit w_7^2, as well as the entire forward direction along the $y-$axis.

Ensuring the completeness of TYCOS$_{\mathbf{LN}}$*:* When TYCOS**LN** stops at a locally optimal solution, it has followed the best path and explored to the deepest level of the current tree. This, however, does not guarantee that is the only path. In fact, we want to find the set of all windows that are above the correlation threshold. Thus, to ensure the completeness of the search, TYCOS**LN** is designed recursively so that once it stops at the locally optimal solution, it goes back to the previously found starting point and continues exploring other paths to find all feasible solutions.

Algorithm 2 reflects on how the noise theory is applied in TYCOS. In line 2, the noise theory is applied to find a good starting point. During the neighborhood exploration, the theory is applied again to prune the search space (line 5).

Algorithm 2 TYCOS**LN**: Apply noise theory to TYCOS**L**

```
    Input: $(X_T, Y_T)$: pair of time series
    Params: $\sigma$, $\varepsilon$, $s_{\min}$, $s_{\max}$, $td_{\max}$
    Output: $S$: a set of non-overlapping windows whose MI $\geq \sigma$
 1: while $(X_T, Y_T)$ is not scanned entirely do
 2:     Initial solution $w := InitialNoisePruning((X_T, Y_T), \varepsilon)$
 3:     Compute $I(w)$    ▷ Evaluate the goodness of the initial solution
 4:     while $t_{idle} < T_{maxIdle}$ do
 5:         $N := SubsequentNoiseDetection(w, \tau)$  ▷ Apply Theorem 6.1 to identify promising neighbors of $w$
 6:         $w := EvaluateCandidateSolution(w, N)$  ▷ Follow the steps 8-18 in Algorithm 1 to improve $w$
 7:     if $I_w \geq \sigma$ then
 8:         Insert $w$ to $S$
 9:     $TYCOS_{\mathbf{LN}}(X_T', Y_T')$                ▷ Restart TYCOS$_{\mathbf{LN}}$
10: return $S$
```

6.3 Setting the Correlation Threshold

6.3.1 Using normalized MI. Since MI is a measure of total dependence between variables, its magnitude represents the strength of the correlation. As the MI value is always non-negative, its lower bound is 0. However, the MI's upper bound varies and thus, it is difficult to set an appropriate correlation threshold using MI magnitude when data characteristics and their relationships are unknown. To overcome this challenge, we propose a robust method to set the correlation threshold based on the *normalized MI*:

$$0 \leq \tilde{I}_w = \frac{I_w}{H_w} \leq 1 \tag{18}$$

where I_w is the MI and H_w is the entropy of the window w.

In Eq. (18), the window entropy H_w represents the amount of uncertainty contained in the window w. Thus, $\tilde{I}_w$ represents the fraction of the window's uncertainty reduced by the shared information I_w. The larger $\tilde{I}_w$, the more information is shared between the window's variables, and thus the stronger correlation. The normalized MI $\tilde{I}_w$ is always scaled between [0, 1], and thus provides an easier way for users to set the threshold σ.

6.3.2 Using top-K filtering. Top-K maintains a list of K (K is a predefined parameter) windows that have the highest MI up to the current point. The top-K list represents the top correlated time-series windows, and can be used to set the value of σ. In this top-K filtering approach, σ starts with the MI value of the initial window w_0. As the search proceeds, the top-K list is filled, and σ gets updated by the minimum MI value in the list. Once the top-K list is full, it will get updated if there is a new window that has MI greater than the current value of σ. The element with the least MI value in the top-K list will be replaced by this new window, and σ is updated accordingly.

7 EFFICIENT MI COMPUTATION

In this section, we discuss the efficient MI computation (based on Eq. (2)) in TYCOS. Due to space limitations, the discussion will be brief and touch only important points.

Recall that while exploring its neighborhood, TYCOS might visit the same data partition multiple times. For example, while evaluating w_4^1 and w_7^2 in Fig. 5, TYCOS will repeatedly revisit w_i because w_4^1 and w_7^2 are extended from w_i. To minimize the redundancy, we design an efficient MI computation method so that computation of overlapping data can be reused across windows.

We observe that neighboring windows in each neighborhood N_i can differ from the current window w_i by only a small data partition w_{δ_i}, where w_{δ_i} is either removed from or added to w_i. For instance, in Fig. 5, w_8^1 differs from w_i by removing a w_{δ_1} data partition from w_i, whereas w_4^1 differs from w_i by adding a w_{δ_1} data partition to w_i. The removal of old data and the addition of new data can introduce different types of changes to the previous computation of w_i. These changes can be either changing the k-nearest neighbors or changing the marginal counts n_x, n_y of existing points. To track those changes, we introduce the *influenced region* and *influenced marginal region* concepts for each data point.

Definition 7.1 *(Influenced region (IR))* An *IR* of point $p_i = (x_i, y_i)$ is a square bounding box $R_i = (l_i, r_i, b_i, t_i)$, where l_i, r_i, b_i, t_i are its left-, right-, bottom-, and top-most indices, respectively, and are computed as $l_i = x_i - d$, $r_i = x_i + d$, $b_i = y_i - d$, $t_i = y_i + d$ where $d = \max(d_x, d_y)$.

Definition 7.2 *(Influenced marginal region (IMR))* The *IMRs* of point p_i are the marginal regions located within the nearest distance d_i in each dimension.

Fig. 8 illustrates these concepts. The *influenced region* of p_0 is the square colored in green, and the *influenced marginal regions* are those with gray shade in either dimension.

Lemma 3. *Given a window w_i and a data point $p \in w_i$, a new point o inserted into w_i will become the new k^{th}-neighbor of p iff o is within IR of p.*

Lemma 4. *Given a window w_i and a data point $p \in w_i$, an existing point o deleted from w_i will change the k nearest points of p iff o is within IR of p.*

Lemma 5. *Given a window w_i and a data point $p \in w_i$, a new point o inserted into w_i will increase the marginal count n_x (or n_y) of p iff o is within IMR_x (or IMR_y) of p.*

Lemma 6. *Given a window w_i and a data point $p \in w_i$, an existing point o deleted from w_i will reduce the marginal count n_x (or n_y) of p iff o is within IMR_x (or IMR_y) of p.*

Proof. Proofs of Lemmas 3, 4, 5, 6 are straightforward, thus omitted. □

Lemmas 3, 4, 5, 6 display unique properties of *IRs* and *IMRs*. An *IR* maintains an area where any point p_j either falling into or being removed from this region will change the k nearest points of p_i. In this case, a new k-nearest neighbors search is required for p_i. Instead, an *IMR* maintains an area where any point p_j either falling into or being removed from it will change the marginal counts of p_i. In this case, the marginalized neighbors of p_i have to be recounted.

Fig. 8 illustrates how changes are introduced and managed. For simplicity, we only discuss cases when new points are added into the previous computation. Changes introduced by removing points can be handled in a similar way. Assume that at time t_1, a new point p_8 is added to the current window and falls into the *IR* of p_1. The addition of p_8 changes the k^{th}-nearest neighbor of p_1, thus, triggers a new nearest neighbor search for p_1. At time t_2, a new point p_9 arrives and falls into the y-marginal influenced region of p_1, for which it will alter the marginal count n_y (but no new k-nearest neighbor search is required in this case). Similarly, a new point p_{10} will increase the marginal count n_x. In these cases, only a recount of n_x or n_y is performed.

As the result of our *efficient MI computation*, for each window, only a minimum search region (containing new points) and a minimum update region (containing points affected by added and removed points) require additional computation. The rest is reused, and thus minimizing the computational cost.

8 EXPERIMENTAL EVALUATION

We evaluate the effectiveness and efficiency of TYCOS using both synthetic and real-world datasets. Effectiveness measures the method qualitatively by assessing the quality of extracted windows, while efficiency measures the method quantitatively in terms of its performance and accuracy.

8.1 Baseline methods

Effectiveness evaluation: TYCOS is compared against four baseline methods. The first baseline is a traditional correlation metric: Pearson Correlation Coefficient (PCC) [23]. The second is the Fast Subsequence Search (MASS) algorithm [25], often used for subsequences matching in time series. The third is MatrixProfile [31], considered to be the state of the art method for similarity join between time series. The final baseline is the Adaptive Mutual Information-based Correlation (AMIC) [17] framework that follows a top-down approach to search for multi-scale temporal correlations in big time series.

Efficiency evaluation: TYCOS runtime is compared against the Brute Force and MatrixProfile (which uses different window lengths) methods. In addition, different variants of TYCOS, including LAHC-based TYCOS ($\text{TYCOS}_\mathbf{L}$), $\text{TYCOS}_\mathbf{L}$ with noise theory applied ($\text{TYCOS}_\mathbf{LN}$), $\text{TYCOS}_\mathbf{L}$ with the proposed efficient MI computation ($\text{TYCOS}_\mathbf{LM}$), and $\text{TYCOS}_\mathbf{L}$ with both noise theory and efficient MI computation ($\text{TYCOS}_\mathbf{LMN}$), are compared against each other to illustrate the effectiveness of the proposed noise theory and MI computation technique. We do not compare AMIC against TYCOS quantitatively, however, as AMIC does not consider time delay correlations, and thus, has a different search space. PCC and MASS are also not considered for efficiency evaluation because they lack mechanisms to automatically search for correlated windows.

8.2 Parameter setting for TYCOS

TYCOS requires setting 5 parameters: correlation threshold σ, noise threshold ε, minimum window size $s_{\min}$, maximum window size $s_{\max}$, and maximum time delay $td_{\max}$. Among these, σ, $s_{\min}$, $s_{\max}$, and $td_{\max}$ are user parameters, while ε is a hyper parameter.

The value of σ determines the strength of extracted correlations. The larger the σ, the stronger the correlations. In our experiments, we set the value of σ using the normalized MI (scaled between $[0, 1]$) introduced in Section 6.3. On the other hand, the values of $s_{\min}$, $s_{\max}$ and $td_{\max}$ are context dependent and is set based on domain knowledge. That is, given an application domain, it is usually intuitive how small/large a window could be and how long a time shift is possible. For example, when a user analyzes weather related data, he/she might decide that the longest duration of a weather event is *two weeks*, and thus set the size of $s_{\max}$ to *two weeks*. Similarly, a user can set $td_{\max}$ to *24 hours* by assuming that weather events have impacts on other events only within *a day* duration. Table 2 lists the values of σ, $s_{\min}$, $s_{\max}$ and $td_{\max}$ we use in each dataset.

For the hyper parameter ε, we set $\varepsilon = \frac{1}{4}\sigma$ in all experiments. This means that a window whose MI is less than 25% of the correlation threshold is considered unpromising to explore. The ratio $\varepsilon/\sigma = 0.25$ is chosen based on empirical studies we conduct

Table 1: **Identifying different types of correlation relations ($N(\mu, \sigma)$: normal distribution, $u \sim U(0, 1)$: uniform distribution)**

		$td = 0$ (No time delay)					$td = 150$ (With time delay)

Table 2: Parameters setting

Parameter	Energy datasets	Smart city datasets
Correlation threshold σ	0.3	0.2
Minimum window size $s_{\min}$	3 samples $\simeq$ 3 mins	3 samples $\simeq$ 15 mins
Maximum window size $s_{\max}$	10080 samples $\simeq$ 7 days	4032 samples $\simeq$ 14 days
Maximum time delay $td_{\max}$	2880 samples $\simeq$ 2 days	288 samples $\simeq$ 1 day

on different datasets, which consistently show that $\varepsilon/\sigma \simeq 0.25$ yields the best trade-off between accuracy and runtime gain. Section 8.5 shows this trade-off analysis, together with an analysis of the effects of σ, $s_{\max}$ and $td_{\max}$ on the performance of TYCOS.

8.3 Effectiveness evaluation

A) Evaluation on synthetic datasets: We generate synthetic datasets containing different types of relations, including both linear and non-linear, monotonic and non-monotonic, functional and non-functional functions. Then, we combine the generated relations into the same time series pair (the first time series is the values of x, the second time series is the values of $y = f(x)$). The individual relations are separated by independent data, and the time delays, td={0, 50, 100, 150} (samples), are added between x and y. Next, we apply TYCOS, and the baselines PCC, MASS, MatrixProfile and AMIC to the time series to verify whether the methods can detect the generated relations. A method detects a relation in a given pair of time series if it can locate a window w where (X_w, Y_w) corresponds to that relation. Table 1 shows the relations ($y = f(x)$ and u is added noise) recognized by the tested methods (the ✓ sign denotes an identified relation, and the × sign denotes an unidentified relation). The plots of the generated relations can be found in [17].

We see that when there is no time delay ($td = 0$), TYCOS and AMIC can detect all types of relations, while PCC, MASS, and MatrixProfile cannot detect non-linear and non-functional relations, e.g., a circle relation. When there is time delay ($td \neq 0$), PCC, MASS and AMIC cannot detect any relations, while MatrixProfile can detect only linear relations, unlike TYCOS which can detect all the tested relations.

B) Evaluation on real-world datasets: We evaluate TYCOS on two real-world data collections: smart energy [1] and smart city [2]. Using real-world applications, our goal is to make sense of extracted windows and learn insights from them. We describe the datasets, and the findings in the following.

The energy datasets [1]: measure energy usage from electrical devices in residential households in Maryland, USA during 07/2013-07/2014, and 02/2015-02/2016. There are 72 electrical plugs in total, and their consumptions are reported in minute and hour interval. We create pairwise time series from 72 plugs, and apply TYCOS and AMIC on each time series pair.

The smart city datasets: The NYC Open Data [2] contains more than 1,500 spatio-temporal datasets, providing rich information about NYC. For evaluation purposes, we consider two collections of data related to *weather* and *transportation.* Within *transportation*, we focus on the *Collision* dataset reporting the number of accidents in the city. The *Weather* dataset has 30 variables, recording weather condition in 5-minute and hour resolutions. The *Collision* dataset has 29 variables, recording incidents happened in minute resolution.

Summary of the results: On the energy datasets, TYCOS can extract correlations from more than 50 different time series pairs, while AMIC extracts fewer windows than TYCOS, and omits any correlations that have time delay. On smart city datasets, TYCOS is able to find correlations that could not be confirmed in [17] by AMIC. Due to space limitations, we cannot discuss all of them, but instead just show a few extracted correlations in Table 3 to illustrate our observations. In each column, the first number is the number of extracted windows, the second number is the time delay range, and the × sign denotes no windows can be extracted.

Table 3: Extracted correlations (h: hour, m: minute)

Correlations	TYCOS	AMIC
(C1) *Kitchen* vs. *Dish Washer*	80, [0-4h]	25, 0h
(C2) *Kitchen* vs. *Microwave*	21, [0-1h]	5, 0h
(C3) *Clothes Washer* vs. *Dryer*	39, [10-30m]	×
(C4) *Bathroom Light* vs. *Kitchen Light*	14, [1-5m]	×
(C5) *Kitchen Light* vs. *Microwave*	11, [0-2m]	4, 0m
(C6) *Children Room Light* vs. *Living Room Light*	8, [15-40m]	×
(C7) *Precipitation* vs. *Collisions*	28, [0.5-2h]	×
(C8) *Wind Speed* vs. *Collisions*	23, [0.25-1h]	×
(C9) *Precipitation* vs. *Pedestrian Injured*	16, [0.5-2h]	×
(C10) *Wind Speed* vs. *Motorist Killed*	12, [0.25-1h]	×

Interpretation of extracted windows: We interpret some of the correlations in Table 3 by comparing with the findings of [7, 17], and/or by plotting the data of extracted windows. Here, C1 presents a correlation between the energy usage of the *kitchen* and of the *dish washer*, with the time shift ranging from 0 to 4 hours. The extracted windows indicate frequent activities of kitchen from 16.00 to 19.00, and of dish washer from 21.00 to 23.00. C4 presents a correlation between the light upstairs in the bathroom, and the light downstairs in the kitchen, with an average time shift from 1 to 5 minutes. The correlation occurs frequently from 6.00 to 7.00. This pattern might hint that, either more than one person are living together so that when one is in the bathroom, the other goes to the kitchen; or that the same person wakes up in the early morning, goes to the bathroom and then comes to the kitchen. Interestingly, C5 can help provide extra information for C4. A correlation between the kitchen light and the microwave is identified, with a time shift between two devices is from 0 to 2 minutes, indicating the person might come to the kitchen to prepare breakfast. On smart city datasets, C7 and C8 present correlations between the increase of precipitation/ wind speed, and the number of collisions, with a time shift from 0.25 to 2 hours. In [17], AMIC could not confirm C7 and C8, because it does not consider the time delay between time series, and thus fail to capture correlations that are shifted in time. Furthermore, we found that precipitation has stronger impact on pedestrians

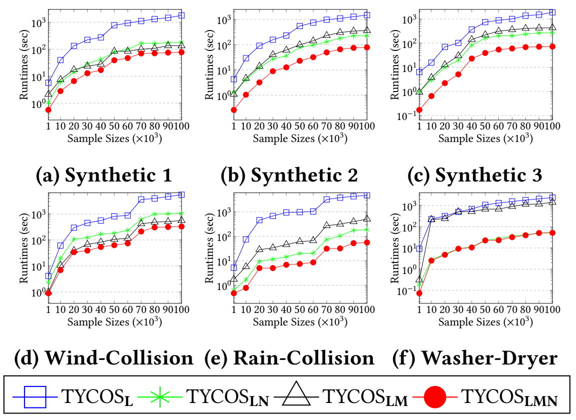

Figure 9: Runtime evaluation of TYCOS

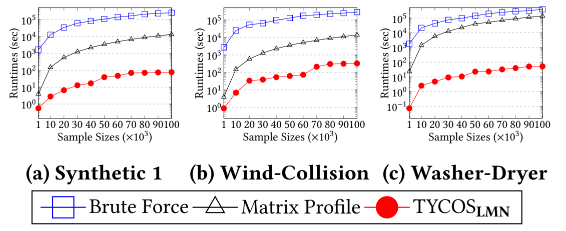

Figure 10: Brute Force, Matrix Profile, and TYCOS$_{\mathbf{LMN}}$

than on motorists or cyclists, while contrarily, wind has more impact on motorists and cyclists than pedestrians (C9, C10).

8.4 Efficiency evaluation

TYCOS performance is evaluated in terms of its runtime and accuracy. TYCOS is implemented in C++, and the experiments are run on a standard PC that has 2.7 GHz processor, 16 GB of RAM, and 512 GB of SSD.

A) Runtime evaluation: TYCOS runtime is evaluated by comparing its 4 different versions: TYCOS$_{\mathbf{L}}$, TYCOS$_{\mathbf{LN}}$, TYCOS$_{\mathbf{LM}}$, TYCOS$_{\mathbf{LMN}}$, and the Brute Force and MatrixProfile baselines. First, different TYCOS versions are compared against each other. The results on both synthetic and real-world data are shown in Fig. 9. The synthetic datasets, *Synthetic 1*, *Synthetic 2*, and *Synthetic 3*, are created by combining multiple relations from Table 1 into one time series pair. From Fig. 9 where the y-axis is in log scale, it can be seen that TYCOS$_{\mathbf{LMN}}$ achieves the best performance among all versions. Its speedup w.r.t. TYCOS$_{\mathbf{L}}$ ranges from 10 to 150 depending on data sizes. The average speedup is 20 on synthetic data, and 60 on real-world data. Furthermore, the noise theory and the efficient MI computation technique result in different speedups depending on data (there are situations where the noise theory is more efficient, and vice versa). The average speedup is 39 for the noise theory, and 32 for the efficient MI computation. However, applying both always yields better speedups than applying either of them.

Next, TYCOS with the best performance, TYCOS$_{\mathbf{LMN}}$, is compared against Brute Force and MatrixProfile. The results are shown in Fig. 10 (note log scale in the y-axis). We can see that TYCOS$_{\mathbf{LMN}}$ can achieve an average speedup of more than 3 orders of magnitude over Brute Force, and of more than 2 orders of magnitude over MatrixProfile, both of which are, however, exact.

B) Accuracy evaluation: To evaluate the accuracy of TYCOS, we compare the similarity of windows extracted from 3 versions: Brute Force, TYCOS$_{\mathbf{L}}$ and TYCOS$_{\mathbf{LN}}$. Note that the efficient MI computation technique does not change the accuracy of TYCOS$_{\mathbf{L}}$, thus, TYCOS$_{\mathbf{LM}}$ and TYCOS$_{\mathbf{LMN}}$ are not considered in this evaluation. Moreover, two windows are considered to be similar if they cover a similar range of indices. The comparison between

Table 4: Accuracy evaluation

	TYCOS$_{\mathbf{L}}$ vs. Brute Force		TYCOS$_{\mathbf{LN}}$ vs. TYCOS$_{\mathbf{L}}$	
Data Size	Synthetic Data	Real Data	Synthetic Data	Real Data

Brute Force and TYCOS$_{\mathbf{L}}$ evaluates how accurate the LAHC approach on the TYCOS problem is, while the comparison between TYCOS$_{\mathbf{L}}$ and TYCOS$_{\mathbf{LN}}$ validates the accuracy of the noise theory. Since Brute Force generates overlapped windows, the generated windows are aggregated and the overlapped windows are combined together. The same synthetic and real-world datasets as when evaluating the runtime are used in this experiments.

Table 4 shows the average accuracy of TYCOS$_{\mathbf{L}}$ w.r.t. Brute Force, and of TYCOS$_{\mathbf{LN}}$ w.r.t. TYCOS$_{\mathbf{L}}$. Depending on the data sizes, TYCOS$_{\mathbf{L}}$ extracts from 88% to 98% similar windows compared to Brute Force, while TYCOS$_{\mathbf{LN}}$ extracts windows that are from 90% to 100% similar to TYCOS$_{\mathbf{L}}$.

The quantitative evaluation proves that our proposed theory and technique are very effective in improving the search performance. They help achieve an average speedup of more than 3 orders of magnitude compared to the Brute Force method, while maintaining highly accurate results.

8.5 Effects of Parameters

We examine how the major parameters: ε, σ, $s_{\max}$, and $td_{\max}$, affect the performance of TYCOS. We do not consider $s_{\min}$ in this experiment because $s_{\min}$ has minimal impact on TYCOS results.

A) Noise threshold ε**:** First, we examine how different values of ε affect the accuracy and runtime, using both synthetic and real-world data in Fig. 11. We can see, as the ratio ε/σ increases, the runtime gain increases (Fig. 11b), but the error rate also increases (Fig. 11a, error rate is measured by the number of missing windows). This result is intuitive because as the ratio ε/σ increases, more of the TYCOS search space is pruned, leading to higher speedup and larger errors. Next, we perform a trade-off analysis between accuracy and runtime gain as a means for choosing a proper value of the noise threshold ε. In Fig. 12, the accuracy and the runtime gain of each tested dataset are plotted together, with the ratio ε/σ on the x-axis. On the two tested datasets, i.e., energy and smart city datasets, we found that, when $\varepsilon/\sigma \in [0.05, 0.3]$, TYCOS$_{\mathbf{LN}}$ maintains an error rate less than 5%, while reducing the runtime up to 50%, compared to TYCOS$_{\mathbf{L}}$. Thus, our experimental setting $\varepsilon = \frac{1}{4}\sigma$ proved to be effective and robust. This threshold can be adjusted according to user's preference for accuracy.

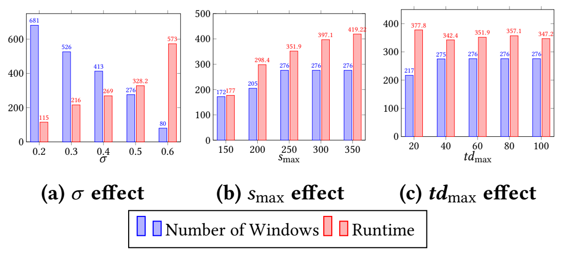
Figure 12: Trade-off analysis



(a) σ effect **(b) $s_{\max}$ effect** **(c) $td_{\max}$ effect**

Figure 13: Effect of σ, $s_{\max}$ and $td_{\max}$

B) Correlation threshold σ: We vary the values of σ to examine its effect, shown in Fig. 13a. We observe that, the correlations are stronger as σ increases, and thus, fewer windows are extracted. However, the runtime also increases because larger neighborhoods need to be explored to find strong correlations. For example, only 80 windows are extracted compared to 681 windows when σ increases from 0.2 to 0.6, while the runtime increases from 115 to 573 seconds.

C) Window size $s_{\max}$ and time delay $td_{\max}$: We examine how $s_{\max}$ and $td_{\max}$ affect TYCOS. We found that, although $s_{\max}$ and $td_{\max}$ are context dependent, the algorithm will converge after the two parameters reach certain values. When the convergence occurs, TYCOS extracts the same set of windows, while maintaining a similar runtime for $td_{\max}$, but an increasing runtime for $s_{\max}$. Fig. 13b and Fig. 13c illustrate this evaluation. Here, using the *(Snow, Collision)* datasets, TYCOS converges at $s_{\max} = 250$ and $td_{\max} = 60$, with 276 windows extracted when the convergence occurs. After the convergence, the runtime continues increasing as $s_{\max}$ goes beyond the value 250, while keeping similar values as $td_{\max}$ goes more than 60.

9 CONCLUSION AND FUTURE WORK

To our knowledge, TYCOS is the first comprehensive solution for the multi-scale time delay correlations search problem. TYCOS has the ability to extract all types of correlation relations, including both linear and non-linear, monotonic and non-monotonic, functional and non-functional ones. Our major contributions are: (1) integration of TYCOS and LAHC for multi-scale time delay correlations search, (2) the novel MI-based theory for noise identification, (3) the efficient MI computation technique to reduce computational redundancy. We perform an extensive evaluation on the effectiveness and efficiency of TYCOS, using both synthetic and real-world datasets. The evaluation shows that TYCOS can detect various types of relations in synthetic data, and find significant and interesting correlations in real-world data. The proposed noise theory and MI computation technique are also proved to be effective and improve the search performance by 2 to 3 orders of magnitude compared to the baselines. In future work, TYCOS can be extended to capture correlations across spatial dimensions. The result of this work can also provide a foundation for deeper data analysis, such as perform mining or infer causal effects from the extracted correlations.

ABSTRACT

Queries that can navigate large search spaces to identify complex objects of interest cannot be efficiently supported by traditional DBMSs. Searchlight is a recent system that aims to address this fundamental shortcoming by deeply yet transparently integrating Constraint Programming (CP) logic into the query engine of an array DBMS. This hybrid model enables exploration of large multi-dimensional data sets progressively and quickly.

Fast query execution is only one of the requirements of effective data-exploration support. Finding the right questions to ask is another notoriously challenging problem, given the users' lack of familiarity with the structure and contents of the underlying data sets, as well as the inherently fuzzy goals in many exploration-oriented tasks. To this end, in the context of Searchlight, we study the modification of initial query parameters at run-time. We describe how to dynamically refine (i.e., relax or tighten) the parameters of a query, based on the result cardinality desired by the user and the live query progress. This feature allows users to iterate over the datasets faster and without having to make accurate guesses on what parameters to use. Our experimental results show that the proposed techniques introduce little or no overhead while yielding considerable time savings compared to user-driven, manual query refinements. The result is a system that not only optimizes machine resource usage but also reduces user effort.

1 INTRODUCTION

Consider a researcher working with the MIMIC II dataset [1], which contains medical information for a number of ICU patients over a large period of time. Assume that she is studying historical ABP (Arterial Blood Pressure) signal readings and wants to identify time intervals that satisfy the following constraints:

- The length of the time interval can be from 8 to 16 seconds, and it can start at any point in time.
- The average signal amplitude must be within [150, 200] range for the interval.
- The maximum amplitude of the signal over the interval must exceed the maximum amplitude of the signal over its left and right neighborhoods by at least 80. The left (right) neighborhood is defined as an 8-second interval to the left (right) of the main interval.

This seemingly simple *search query* is difficult to express and even harder to optimize using traditional query languages and DBMSs [10]. Recent systems, such as Searchlight [10, 11], extends SciDB [2] with constraint-based search and optimization support, effectively integrating two mature technologies (DBMS and CP-based solver) to address queries that operate on large search spaces and over large data sets.

Now imagine that the user gets *zero* results after running the initial query, as illustrated in the top part of Figure 1. It turns out that the query was over-constrained! She then tries to guess the correct constraint parameters manually by *relaxing* the average amplitude constraint: now the average ABP amplitude must be within the [150, 250] range. When she runs this new query, she gets flooded with a large number of intervals, many of which overlap, as shown in the middle band of Figure 1. Since such a result can be overwhelming for her to parse and study, expecting that there might be more focused and "better" initial results she could work with, she then tries to *tighten* the interval to [150, 220]. After running the query again, she gets a reasonable number of results that she can explore in detail, as illustrated at the bottom of Figure 1.

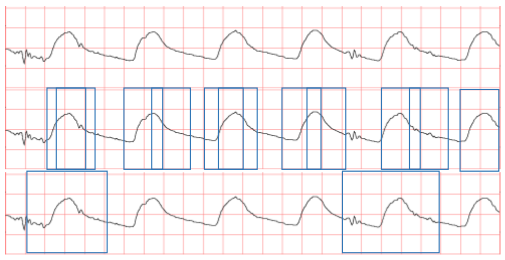

Figure 1: Exploring the ABP waveform data. *Top*: original query result. *Middle*: an over-relaxed query result. *Bottom*: final query result.

This scenario illustrates a number of problems:

- The user has to go through a series of guesses to identify a query that outputs a desirable number of results. This is often a frustrating and cumbersome process, especially if the user has limited knowledge about the data, which is often the case when exploring new data sets.
- The process of manual refinements (i.e., relaxation and tightening) might be quite complex even for seemingly

[*]This work was funded in part by NSF IIS-1526639.
[†]This work was done while the author was a PhD student at Brown University.

simple queries. In the earlier example, the user can modify the average amplitude constraint, or the two neighborhood constraints, or any combination of those, which collectively create an exponential number of possibilities.
- With manual refinements, no guarantees can be given for the final result. In general, users prefer to get results that are as close as possible to the original query parameters.

We address these problems in the context of Searchlight, which gives us an open DBMS platform to develop and test our solutions. At the same time, we emphasize that these problems would arise in any system supporting constraint-based queries and traditional solving technology. We also note that these issues are amplified when dealing with large datasets, as the query times can be larger and it becomes even more critical to perform such query iterations quickly and efficiently.

1.1 Motivation

A common initial step in data exploration is the identification of a small number of interesting cases that the user dives into for deeper study. In such cases, query refinements are applied to assure a target result cardinality to meet a "budget" constraint typically on user time or money. For example, a medical researcher may have the budget to run a survey on a specific number of patients with certain characteristics. A business may have a discount budget that is sufficient only to a specific number of customers within a given campaign. An advancement officer of a university may have a limited time to call a certain number of alumni on a given day. An astronomy researcher may have the time to study a limited number of celestial objects for a research project. In all these cases, the ability to have the system automatically tweak the query to produce a result set of a desirable size is very helpful.

Beyond these generic use scenarios, we have anecdotal evidence from a demonstration of waveform data exploration [11]. In this demo, the users were given the ability to fill in the parameters for template queries, such as signal amplitude, interval length, etc. However, since they had very limited knowledge about the presented dataset, their queries often output either too many results (sometimes thousands) or nothing at all. Both of the outcomes were frustrating, and the users had to go through a number of trial-and-error runs to identify a small set of results that is amenable to manual deeper inspection.

1.2 Query Refinement Approaches

Ideally, any system should perform any refinements automatically by detecting if the query needs to be modified during its evaluation without specific directives from the user. If there is a need for relaxing the query, it should choose the constraints and the degree of modification such that the final results are *closest* to the original constraint parameters according to the provided distance function. In the case of tightening, it should rank the results and output the top ones according to the specified ranking function. For performance optimization, it should reuse as much computation as possible to minimize the overhead from multiple searches. At the same time, if there is no need to modify the query, the automatic approach should not incur any significant overhead.

Query refinements have been studied in the context of relational DBMSs [4, 6–8, 12–18]. Similar approaches can be extended to array DBMSs (such as SciDB) as well. However, the query described in the example belongs to a different kind of *search* queries, which is the reason why an engine such as Searchlight that supported CP was used in the first place instead of the original array DBMS. As we argue in Section 6, existing methods cannot be easily applied to constraint-based search queries. These methods generally assume that either the result cardinality can be easily estimated for the query, or appropriate range-based indexes (e.g., B-trees or R-trees) exist over the objects of interest (which are time intervals for the example above), so that the search space of all possible objects could be traversed efficiently. Due to the ad-hoc nature of search queries, however, the result cardinality is hard to estimate. At the same time, since objects of interest are defined by the query itself, as part of the constraint specification, indexing becomes infeasible [10].

Another approach, possibly applicable to some simple search queries, would be to rewrite such queries in SQL and execute them on a relational (or array) engine, opening the possibility of using the existing query refinement techniques. However, previous research [9, 10] suggests that executing such search queries in a traditional engine, while possible, incurs significant performance penalties. More importantly, such conversion results in very complex SQL queries, for which the applicability of existing refinement methods would be quite limited.

1.3 Overview of Dynamic Query Refinement

In a nutshell, Searchlight uses Constraint Programming (CP) to perform the search over an in-memory *synopsis* of the original data. The solver dynamically builds the search tree, possibly pruning parts of the tree that cannot satisfy the constraints. We observe that the main reason the original query fails and, thus, produces an empty result is search pruning. If the query needs relaxation, only the previously pruned parts of the search space need to be revisited. Thus, we track these parts and later "replay" the search over them, if needed. The replaying is guided by a user-provided distance function — more promising replays are explored first. It is important to mention that this replay happens automatically, when we detect the absence of the desired number of results. At the same time, replaying is performed as part of the original query, thus removing the need to re-explore previously finished parts of the search space, resulting in considerable time savings. From the logical perspective, this approach can be seen as introducing an objective function and searching for results that minimize it. This results in a very natural extension of the traditional CP model that already supports objective function-based search. The only piece of information required from the user is the desired cardinality of the result k and, possibly, the distance function $d()$ [1]. Our approach guarantees to produce top-k results closest to the original constraints (i.e., minimizing $d()$).

Query tightening can be seen as a dual problem for query relaxation. Thus, the two work closely together. If the number of results at some point during the search exceeds the desired result cardinality, we switch the approach to query tightening, which essentially ranks all results according to the specified ranking function $r()$ [2]. The main idea behind our approach involves introducing a *dynamic* ranking constraint at that particular moment during the search that restricts the final result to top-k objects maximizing $r()$. As in the case of relaxation, it can logically be seen as introducing an objective function with the maximization

[1]We provide built-in distance functions by default.
[2]Some built-in ranking functions are provided by default as well.

goal. We call such a constraint dynamic since its parameters are constantly updating depending on the current result.

1.4 Contributions

Our main contributions are as follows:

- We introduce a novel distributed relaxation and tightening framework for search queries, which automatically detects the need for modifying the query at run-time and performs query refinements without the need for any user intervention. The user just needs to specify the target result cardinality and, optionally, the distance and ranking functions.
- The framework is general and applicable to different types of constraints. It works for any constraint of form $a \leq f_c() \leq b$, where $f_c()$ is an arbitrary expression, including User-Defined Functions (UDFs). It can be extended to other types of constraints, with the introduction of a meaningful distance and/or ranking measure. If desired, it can be even applied to other engines beyond Searchlight, provided they follow the CP execution model.
- Our implementation of this framework operates at the DBMS engine level and extends it in a natural way that is compatible with a generic CP model. Due to such a seamless integration, it does not interfere with the existing query processing, does not impact performance of queries that do not require relaxation/tightening, and leverages existing DBMS engine features.

We performed an extensive experimental evaluation over synthetic and real (MIMIC II) data, which we discuss in Section 5. Our results reveal tremendous time savings compared to manual refinements and very low overhead.

The rest of the paper is organized as follows. In Section 2 we describe Searchlight as the DBMS/CP platform we use to explore our solutions. Section 3 presents the formal model behind our relaxation/tightening framework. Section 4 describes design and implementation of our solutions. Section 5 presents the experimental evaluation Section 6 discusses the related work and Section 7 concludes the paper.

2 SEARCHLIGHT BACKGROUND

Searchlight is an extension of a traditional query processing engine for efficient execution of search queries. It introduces Constraint Programming (CP) methods to the query processing and operates *inside* the engine. The user submits a search query in form of a constraint program (decision variables and constraints over them).

Searchlight processes the query by creating a number of CP *Solvers* that perform the search on an in-memory *synopsis* of the original data. Since synopsis is a lossy compression of the original data, the CP-provided results (solutions) might contain false positives. Thus, the results need to be verified over the original data. This is done by another Searchlight component called *Validator*. The two components work concurrently to facilitate online answering. When Validator confirms a solution, it is immediately output, while false positives are filtered out. While Searchlight does not have the notion of a query plan, each execution can be imagined as a pipeline between two "operators": Solver and Validator. The Solver receives the query, outputs a stream of solutions (tuples) to the Validator, while the latter filters out false positives and outputs the final solutions to the user. Searchlight is implemented as part of the SciDB query engine and uses its infrastructure to distribute both search space and data across the cluster. Thus, Solvers and Validators exhibit both multi-node and multi-core parallelism. The details of query processing are out of scope of this paper, and the in-depth discussion can be found in the Searchlight paper [10].

There are no specific limitations on types of queries Searchlight can work with, since CP solvers are quite general. Users can use any of the constraints generally found in CP solvers. At the same time, most useful types of queries tend to use aggregate functions to assess regions in the data. For example, the query presented in the introduction section can be represented in Searchlight as follows:

- Decision variable x defines the start of the resulting interval. Its domain is the entire length of the recorded data, since the interval can start anywhere.
- Variable lx defines the length of the interval, $lx \in [8, 16]$.
- The amplitude constraint: $avg(x, x + lx, ABP) \in [150, 200]$, where $avg()$ is a built-in Searchlight aggregate. We will denote it c_1 for future reference.
- The left neighborhood constraint: $|max(x, x + lx, ABP) - max(x - 8, x, ABP)| \geq 80$. The right neighborhood is similar. We will denote them as c_2 and c_3 respectively.

When the Solver receives a CP specification similar to the above, it dynamically builds a *search tree* for the query. An example of such a tree for the query above can be seen in the left part of Figure 2. The nodes represent the current variable domains (search states), while edges represent Solver decisions that lead to the corresponding search states. Children's variable domains are subsets of the parent's ones, and leaves have the variables *bound* (i.e., the domains are scalars). The decision process (search heuristic) is tunable, can be selected and modified by the user [10]. The search process itself is performed in a traditional backtracking way. If, while building the tree, the Solver establishes a violation of query constraints (by relying on estimations from the synopsis), the entire corresponding sub-tree is pruned from the search (marked with the red "no" symbols in the figure), and is never built or visited. When a leaf of the tree is reached (i.e., the variables are bound to scalar values), the corresponding variable assignment (solution) is passed to the Validator.

3 QUERY REFINEMENT MODEL

In this section we discuss our relaxation/tightening framework. While described in the context of Searchlight, the model does not depend on its implementation details and is primarily driven by well established CP concepts. Throughout the paper, we use query "constraining" as a synonym for "tightening".

Each CP search query consists of a number of decision variables X and constraints C. Given such a query the search framework either outputs all results or proves there is none. However, if the user specifies the desired *cardinality* of the result k, the framework behaves differently depending on the outcome of the original query:

- The query outputs exactly k results. In this case the behavior stays the same.
- The query outputs a set of results $R = r, |R| < k$. In this case it is automatically modified to produce additional $k - |R|$ results. The additional results are guaranteed to minimize the specified $RD(r)$ function (discussed below). This is query relaxation.

- The query outputs $|R| > k$ results. In this case the framework effectively ranks the results based on the $RK(r)$ function (discussed below), and the query returns top-k results according to $RK(r)$. This is query constraining.

When relaxing or constraining a query, we consider only range-based constraints of form $a \le f(X) \le b$. The nature of $f()$ is not important. It might be an arbitrary algebraic expression containing User-Defined Functions (UDFs), built-in functions and variables from X. In our running example $f()$ is the $avg()$ function for constraint c_1 and the $max(x, x + lx) - max(x - 8, x)$ expression for c_2. We generally treat $f()$ as black boxes, but we assume the knowledge of values a', b' at every node of the search tree, such that $a' \le f(X) \le b'$ for all possible values of X at that node. This information is readily available as part of the search process and is used to make search decisions (for building the tree) and prune parts of the tree. In Searchlight a', b' are derived from the each node's variable domains by using the synopses to estimate constraint functions [10]. Thus, no modification to the query engine should be required in this regard. By default, we consider all range-based constraints for relaxation/constraining, but the user can exclude any of them from the process. We denote constraints considered for relaxation (constraining) as C^r (C^c). C^r does not necessarily equal C^c.

The relaxation and constraining processes are based on result ranking via separate relaxation and constraining ranking functions. In the two following sections we describe the default functions we use. Then we discuss the custom ranking functions requirements.

3.1 Query Relaxation Model

Assume a constraint $c \in C^r : a \le f_c(X) \le b$ and a result r such that $f_c(r) = t$. We define the relaxation distance $RD_c(r)$ as follows:

$$RD_c(r) = \begin{cases} 0 & \text{if } a \le t \le b \\ \frac{t-b}{max(f_c(X))-b} & \text{if } t > b \\ \frac{a-t}{a-min(f_c(X))} & \text{if } t < a \end{cases}$$

Then, the total relaxation distance $RD(r)$ is:

$$RD(r) = \max_{c \in C^r} w_c RD_c(r),$$

where $w_c \in [0, 1]$ are constraint weights, which can be defined by the user. By default, $w_c = 1$.

We selected the $RD()$ definition above just as a suitable *default*, aiming at providing reasonable out-of-box experience. As we discuss in Section 3.3, users can choose their own functions, provided they respect certain requirements. In general, p-norm is a logical choice when some distance between query points needs to be measured [4]. We chose max ($p = \infty$) to penalize results where some outlier constraints have large $RD_c()$ values. This allows us to limit the distances of final results. A weighted sum ($p = 1$) or Euclidean distance ($p = 2$) are other viable choices.

The denominators in $RD_c(r)$ require further explanation. In general, $f_c()$ from different constraints might have different scales. For example, one constraint might deal with ages (e.g., $f_{c_1}() \in [0, 150]$), while another with similarities (e.g., $f_{c_2}() \in [0, 1]$). That is why we perform [0, 1]-normalization of each $RD_c(r)$ by dividing it by the maximum possible difference in values. Min/max values for $f_c()$ can be usually derived from the obvious domain restrictions (e.g., age cannot exceed 150). We additionally allow users to specify the max/min values with the query, giving them more control over relaxation: we will not relax the corresponding constraints beyond the specified min/max values. We will use $RD_c(r)$ to denote the normalized distances, as well as the original ones, where appropriate.

In addition to $RD(r)$ for each result r we define $VC(r)$ as the number of constraints from C^r violated by r divided by $|C^r|$. Thus, $VC(r) \in [0, 1]$ is the normalized number of violated constraints. Then, we define the total relaxation penalty for r as:

$$RP(r) = \alpha RD(r) + (1 - \alpha)VC(r)$$

The $RP()$ allows users to prefer results with smaller number of violated constraints, which is especially important in cases when $RD(r)$ "looses" information about individual constraints (e.g., as in our choice of max). α controls the degree of the preference (the default is 0.5). We picked weighted sum as a suitable default, giving the user the choice between two criteria, $RD()$ and $VC()$. However, this default is not essential for the proposed framework. $RP()$ can be changed, and other criteria can be incorporated in the formulation, if required.

The model provides the following *relaxation guarantee*: if the user submits query Q with the cardinality requirement k, the query outputs at least k results r with the lowest $RP(r)$ values possible.

The definition above naturally incorporates queries in no need of relaxation, with $\ge k$ results. If r satisfies the original constraints, $RP(r) = 0$. Thus, the guarantee is automatically fulfilled. If the user chose to specify tight min/max bounds for some $f_c()$, we might not be able to find k results in case there are not enough results satisfying even *maximally* relaxed constraints (i.e., $\min f_c() \le f_c() \le \max f_c()$). This is because we effectively treat such $f_c()$ specification as a "hard" constraint.

Let us revisit the running MIMIC example. Assume the user wants $k = 3$ results and $C^r = \{c_1, c_2, c_3\}$. Additionally, $avg()$ and $max()$ values for the ABP signal lie within [50, 250]. Then a possible search might progress as follows:

(1) A result $r_1 = (180, 85, 85)$ is found (we write a result as a tuple of $f_i()$ values). Since it satisfies the constraints, $RP(r_1) = 0$ and it is output to the user.
(2) $r_2 = (190, 80, 90)$. Since, $RP(r_2) = 0$, it is output.
(3) Searchlight cannot find any more results, so it starts relaxing the query.
(4) $r_3 = (160, 70, 60)$ is found. It violates c_2 and c_3. For r_3: $RD_{c_1} = 0, RD_{c_2} = \frac{10}{80} = 0.125, RD_{c_3} = \frac{20}{80} = 0.25$. Thus, $RD(r_3) = 0.25$, and $RP(r_3) = \frac{1}{2}(0.25 + \frac{2}{3}) = 0.458$.
(5) $r_4 = (130, 80, 80)$ is found. For r_4: $RD_{c_1} = \frac{20}{100} = 0.2, RD_{c_2} = 0, RD_{c_3} = 0$. Thus, $RD(r_4) = 0.2$, and $RP(r_4) = \frac{1}{2}(0.2 + \frac{1}{3}) = 0.267$. Since $RP(r_4) < RP(r_3)$, r_3 is discarded, and r_4 is put into the result.

3.2 Query Constraining Model

The query performs constraining only when the number of results exceeds the k required by the user. That means during constraining each result r_i satisfies all constraints in C^c. For each function $f_c(X)$ from constraints in C^c the user can specify her preference in form of maximization or minimization of the function. For example, if some constraint's $f_c(X)$ is a property like the amplitude of a signal, the user might prefer large values of $f_c(X)$. On the other hand, if $f_c(x)$ is some spatial distance, the user might prefer smaller values. For each constraint $c \in C^c : c = a \le f_c(X) \le b$ and result $r : f_c(r) = t$ we define the ranking function $RK_c(r)$ as follows:

$$RK_c(r) = \begin{cases} \frac{b-t}{b-a} & \text{if } c \text{ is being maximized} \\ \frac{a-t}{b-a} & \text{if } c \text{ is being minimized} \end{cases}$$

Since r satisfies the constraints, $a \le t \le b$. As in the case of query relaxation, we normalize $RK_c()$ to $[0, 1]$ to account for the possibility of different scales for $f_c()$. If the interval is half-open, i.e., a or b is not specified, a suitable domain boundary for $f_c()$ can be used instead.

We define the full rank of result r as:

$$RK(r) = 1 - \sum_{c \in C^c} w_c RK_c(r),$$

where $w_c, 0 \le w_c \le 1 \wedge \sum_c w_c = 1$ represent the constraint weights to prioritize some constraints over others. By default, $w_c = \frac{1}{|C^c|}$. Note, $RK(r)$ assigns higher ranks to better results, which is more natural to the user. As in the case of $RD()$, any p-norm could be a reasonable choice for $RK()$. We saw the weighted sum providing meaningful results in practice. In addition, it allows us to demonstrate that the approach is flexible to the choice of distance functions.

Assuming these definitions, the model provides the following *constraining guarantee*: when the user submits query Q with the cardinality requirement k, if Q has at least k results r, the query outputs at most k results with highest $RK(r)$ possible. Note, if the query does not have at least k results, the relaxation will be performed instead.

Revisiting the running MIMIC example, let $C^c = \{c_1, c_2, c_3\}$, $w_{c_i} = \frac{1}{3}$. Let us assume the user prefers maximization for all constraints and wants a single result. Note, that f_{c_1} and f_{c_2} has the maximum value, 200, derived from the domain. The search might progress as follows:

(1) A result $r_1 = (160, 100, 100)$ is found. Its rank is $RK(r_1) = 1 - \frac{1}{3}(\frac{40}{50} + \frac{100}{120} + \frac{100}{120}) = 0.178$.
(2) A result $r_2 = (150, 80, 85)$ is found. Its $RK(r_2) = 0.014$. Since $RK(r_2) < RK(r_1)$, r_2 is discarded.
(3) The next result is $r_3 = (190, 120, 120)$. Its $RK(r_3) = 0.289$. Since $RK(r_3) > RK(r_1)$, r_1 is discarded, and r_3 becomes the new top-1.

In addition to the scalar ranking approach just described we support another popular vector-based ranking called *skyline* [3]. In that case the query simply outputs non-dominated results, where a result is a vector of values of $f_c(), c \in C^c$ (as in the example above). By definition, V dominates W, iff $\forall i : v_i \ge w_i \wedge \exists i : v_i > w_i$. The meaning of $>$ for each $f_c()$ is defined by the user's minimization/maximization preference, as in the scalar case. For skyline, however, we cannot guarantee that the number of results will not exceed k, since non-dominated vectors are not comparable.

3.3 Approach Customization

In addition to the default penalty and ranking functions discussed above, the user can add their own custom functions. The functions may be called by the query engine during the search at any search tree node, where some variables may still be unbound. This means the custom $RP()/RK()$ functions must be able to output the penalty/rank interval for all possible solutions contained in the corresponding sub-tree. Our implementation provides the user with the current variable domains and synopsis-based intervals for all constraint functions at any node. This information should be enough to compute the required bounds.

The functions must conform to the certain requirements to ensure the relaxation/constraining guarantees and proper performance. For a custom RP returning ranges $[lp, hp]$, the requirements are:

- $RP() \ge 0$, with larger values corresponding to worse relaxation. All results satisfying the original query must have $RP() = 0$.
- $lp = hp$ at solutions (leaves) of the tree, since the variables are bound there.
- $RP()$ cannot underestimate lp, which means it cannot be greater than the minimum of penalties for all possible solutions at the corresponding sub-tree.

The requirements for the RK functions are similar, with the only differences that $RK()$ assigns larger values to better candidates and, thus, should not underestimate hp. The user can define her own dominance measure for the skyline ranking as well. The corresponding function is periodically called over the current top-k results to determine if any of the current sub-tree solutions might enter the top-k.

In principle, customization can go beyond static ranking function. *Dynamic* functions is an interesting extension, where the ranking functions may change depending on the results already found, e.g., the user might want to prefer "diversity" among the relaxed results so that their relaxation distances differ by at least the specified amount. This can be accomplished by introducing new constraints depending on the results already discovered. Other dynamic modifications might be possible as well, depending on the user's preference. Studying such richer functionality is left for future work.

4 QUERY RELAXATION AND CONSTRAINING

In this section we describe the implementation of the relaxation/constraining model. Our approach is general and can be applied to other CP-based engines.

In general, a CP solver dynamically builds and traverses the search tree. The dynamic nature of the search process allows for modification of existing constraints and the addition of new ones. Thus, if a query does not produce enough results satisfying the original constraints, we can revisit some parts of the search tree with modified (relaxed) constraints. If a query produces too many results, we can introduce new dynamic constraints to prune results having smaller ranks than the already found ones.

The efficiency of the relaxation and constraining heavily relies on effective pruning. We exploit the following cases:

- During the main search at the Solver. This is the most effective point. It allows us to prune parts of the search tree with possibly large number of candidates and avoid unnecessary validations later.
- Just before validating the candidate at the Validator. This is effective in case Validators lag behind the Solvers, and their candidate queues grow large. In that case new ranking/penalty information about the current result might allow us to perform additional pruning and avoid expensive I/O.
- After validating the candidate at the Validator. Even if the candidate passes the validation over the real data, it is necessary to check them again with the up-to-date penalty/ranking values. However, this is is done only for correctness, with no performance benefits. These checks do not require any additional I/O.

4.1 Query Relaxation

A CP solver dynamically builds the search tree and validates query constraints at every node of the tree. A node either satisfies the constraints or *fails*. Successful nodes eventually lead to leaves, which produce candidate solutions. When the search is finished, if we have not found k results (the user's desired cardinality), we start revisiting parts of the search tree with modified, relaxed constraints. We do not have to revisit successful search nodes, since these nodes satisfied the *original* constraints and cannot yield any new solutions. Previously failed search nodes, on the other hand, could lead to new candidates satisfying the *relaxed* constraints. We call this process *fail replaying*.

When we encounter a failed search node, we prune the node as usual. However, we also record the current search state of the node:

- Current decision variable domains. This information is crucial when the fail is replayed later to resume the search from this exact point without revisiting any extraneous search nodes.
- The ranges $[a', b']$ for every function $f_c(), c \in C^r$. As we discussed in Section 3, these are available as part of the normal search process.

After this information has been obtained, we compute the best (*BRP*) and worst (*WRP*) relaxation penalties possible for the saved failed node (i.e., for the solutions in its sub-tree). For the built-in *RP* function this is straightforward from the definition. The custom function, as discussed in Section 3.3, must compute these values itself. After the relaxation penalties are computed, the fail is inserted in the priority queue ranked by the *BRP*.

If during the search at least k results are found, we just stop recording the fails. At the same time the constraining mechanism turns on, which we discuss further in Section 4.3. If the main search completes with less than k results, the relaxation is needed. We start replaying fails from the priority queue (i.e., minimizing *BRP*). To replay a fail, we do the following:

(1) A new CP search is initiated with the decision variables assigned the domains recorded at the fail. This can be seen as traveling back in time to the moment just before the fail.
(2) Each violated constraint is modified: $a \leq f_c() \leq b \rightarrow a' \leq f_c() \leq b'$, where $[a', b']$ is the recorded interval. This guarantees the search will not fail again when resumed.

The new search is handled exactly the same as the original one. Thus, it might fail again, at other search nodes further in the search tree. One example is when a previously valid constraint becomes violated due to more accurate synopsis estimations (those tend to become better closer to leaves). Such *repeated* fails are caught as the original ones and might be replayed later. During replays we explore only previously untouched parts of the search tree. No search nodes are ever revisited, which improves performance and guarantees the absence of duplicate results.

The discussed replay mechanism can be seen as naïve, since it does not allow any additional pruning at the search level. When we replay a fail, we relax previously failed constraints maximally, so they cannot fail again. Thus, we just relax constraints until the search reaches the leaves. The new candidates, however, do not necessarily belong to the best-k results. To improve the efficacy of pruning we take into account the Maximum Relaxation Penalty (*MRP*) among the already found results.

$MRP \in [0, 1]$ effectively defines the worst penalty a result can have to belong to the best-k, and it constantly changes during the execution. Let us first assume the built-in *RP* function. While the number of results found is less than k, the $MRP = 1$. When at least k results have been found, *MRP* might decrease. We modify the process as follows:

- When a fail is recorded, its *BRP* is compared with *MRP*. If $BRP > MRP$, the fail is discarded completely, since its search sub-tree cannot provide any useful candidates (i.e., with $RP(r) \leq MRP$).
- When a fail is selected for replaying, its recorded intervals $[a', b']$ are tightened according to the current *MRP* to improve pruning, since the constraints will be relaxed as minimally as possible. In addition, we repeat the *BRP* and *MRP* comparison, since *MRP* might have changed.

Let us discuss the interval tightening in more detail. Assume the built-in *RP*() function discussed in Section 3.1 with $\alpha \neq 0$. If $\alpha = 0$, the relaxation distance does not influence *RP*(), so no tightening is possible. Otherwise, to qualify for the result, all candidate solutions r must have $RP(r) \leq MRP$. Since $RP(r) = \alpha RD(r) + (1 - \alpha)VC(r)$,

$$RD(r) \leq \frac{MRP - (1 - \alpha)VC(r)}{\alpha}.$$

Let us revisit the example from Section 3.1 and illustrate the above algorithm with Figure 2. In this figure the search nodes are rectangles with the synopsis values for the c_1 and c_2 functions (we do not show c_3). The search encounters two fails. The first one in the search order is the lower one, for which both c_1 and c_2 are violated, since $110 < 150$ and $60 < 80$. Its $BRP = \frac{1}{2}(max(\frac{40}{100}, \frac{20}{80})) + \frac{1}{2}\frac{2}{3} = 0.53$. The fail is recorded into the table. Then the search encounters the upper fail, for which only c_2 is violated. Its $BRP = \frac{1}{2}(\frac{20}{80}) + \frac{1}{2}\frac{1}{3} = 0.29$. Assume $MRP = 0.5$ at some point during the relaxation, and the next fail is being taken from the table. According to the formula above, $RD(r) \leq 0.33$. Thus, the $[10, 60]$ is tightened to $[80 - 0.33 * 80, 60] = [53, 60]$, which is used as the relaxed c_2.

For the custom *RP*() function we cannot apply the same logic for tightening intervals, since the custom *RP*() is effectively a black box. In this case the constraints are relaxed to the $[a', b']$ intervals. However, at each search node we call the custom *RP*() function to check against the *MRP*. If the search node does not pass the check, we fail the node and prune the sub-tree completely.

After the search tree with relaxed constraints reaches a leaf, the corresponding solution is submitted to the Validator in the same way as in the original search. Validator is aware of the relaxation and validates the relaxed candidate accordingly, by taking into account the current *MRP* value. As we discussed in the beginning of Section 4, it performs two checks: one before and one after the validation. At the first one it compares the candidate's *BRP*(r) value (supplied by the Solver) with the current *MRP* and discards the candidate if $BRP(r) > MRP$. Otherwise, it performs the validation as usual with *all* constraints relaxed maximally with respect to *MRP*. Relaxing all constraints here is required for correctness, since even if some constraints fail during validation, the solution's penalty might still be below the *MRP*, and it will qualify for the result. That is why the second check is required after the validation.

It is the responsibility of the Validator to update the *MRP* value, since it produces the final result. If a new result decreases *MRP*, the Validator broadcasts the change to all instances in the cluster, so *MRP* is (asynchronously) updated for all Solvers/Validators

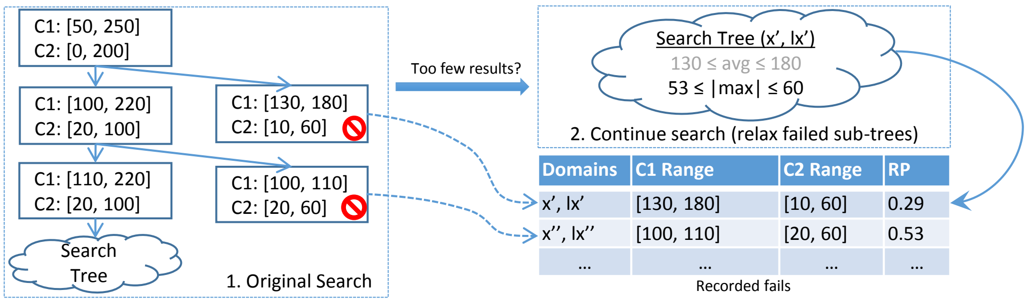

Figure 2: Example of fail recording and replaying for the running MIMIC query.

participating in the query. No special changes to the distributed query processing is required beyond that.

The correctness of the the model's relaxation guarantee is due to the correctness of the CP search itself. While the search process itself uses heuristics to guide the process, the pruning is performed in the provable way, without eliminating any valid results. Constraints modification during the search process is guided by the *MRP*, which is maintained based on the currently discovered results, so subsequent relaxation results will not be eliminated. As far as the complexity of the approach goes, it is equivalent to the complexity of the underlying CP search problem, since the relaxation is performed as in terms of CP.

4.2 Query Relaxation Optimizations

We now discuss a number of useful optimizations for query relaxation. These do not modify the main algorithm, but offer performance gains in common situations.

Computing functions at fails. When we catch a fail, we save the $[a', b']$ intervals for functions $f_c(), c \in C^r$. However, if the search fails at a search node, it does not necessarily mean all constraints have been verified yet. The fail might happen at the first violated constraint, in which case the subsequent constraints are not touched at all. This implies some $f_c()$ values might be unknown. For example, in our running MIMIC example, if c_1 fails, c_2, c_3 are not verified, and min/max ABP values are not computed.

In such cases we can force the computation via the Searchlight API to obtain $[a', b']$ ranges for the remaining constraints. However, $f_c()$ might be relatively expensive, and the cumulative overhead of the fail recording might become quite large. We perform the computation in a lazy way instead, when the fail is replayed. There are compelling reasons behind the lazy evaluation. First of all, if the query does not require any relaxation (i.e., it discovers at least k results) or the fail does not pass the *MRP* check later, the fail and its intervals will not be needed at all. Thus, the total completion time might improve. Second, delays for interactive results might decrease, as we do not pay the full price of computing $f_c()$ immediately, but later, when really needed.

This does not require any significant changes to the engine. Lazy evaluated functions' values are recorded as unknown, and the constraints are considered as non-violated. During the replay, Searchlight automatically estimates unknown values and checks the constraints.

Partial relaxation at replays. When we replay fails, we relax the violated constraints according to the saved $[a', b']$ intervals (tightened with respect to the *MRP* value). However, even the tightened intervals might be quite wide, resulting in poor pruning. This is especially true for fails happening closer to the root of the tree. To avoid over-relaxation, we do not relax the violated constraints all the way, but rather use a percentage of the relaxation interval — a parameter called Replay Relaxation Distance ($0 \le RRD \le 1$). If, for example, a constraint $f_c() \le 10$ needs to be relaxed to $f_c() \le 20$, and $RRD = 0.3$, we relax the constraint to $f_c() \le 10 + (20 - 10) \times 0.3 = 13$. The parameter exposes a trade-off. On the one hand, the relaxation becomes more conservative, avoiding potential performance drops. Too much tightening, however, might result in an increased number of fails and the cost of maintenance. On the other hand, loosing the relaxation decreases the number of replays, but might result in increased cost of the search itself. Our experiments showed that the cost of the search usually considerably outweighs the cost of the maintenance, and decreasing the value of *RRD* might considerably speed-up some queries without slowing down the others. This parameter does not change the result and is purely performance-related.

Saving function states at fails. When recording a fail, we store enough information to replay the fail later. However, some $f_c()$ functions might have additional information computed. For example, *max*() might store support coordinates for its $[a', b']$ range, which might allow us to avoid recomputing the function at other nodes of the tree. We extended the Searchlight API with the ability to serialize such information and save it when recording a fail. During the replay this information is restored. The optimization provides significant performance benefits in the presence of a large number of fails with expensive functions.

Sorting the Validator queue on ***BRP*****.** When candidate solutions are received by a Validator, they are put into its FIFO queue, which does not take candidate *BRP* values into account. However, candidates with better *BRP* values might have a better chance of belonging to the final result. They also might help to decrease the *MRP* faster, which improves pruning at Solvers. Thus, we decided to use a priority queue ranked by *BRP* at the validators instead. While a priority queue is generally more expensive than FIFO, in practice performance benefits resulting from better pruning outweigh the queue maintenance costs, as supported by our experiments.

Speculative Relaxation. Before relaxing a query, we executed the *original* query until completion. Only then the recorded fails are replayed if needed. If the user does not mind intermediate results, relaxation can start when first fails are encountered. We call this *speculative relaxation* and provide it as an option.

Speculative relaxation is done by additional CP solvers replaying fails concurrently with the main execution. This is done only when the Validators are idle, so that relaxed candidates do not interfere with the main search. Speculative Solvers still consume

CPU resources, which might slow down the main Solvers and increase query result latency for the user. At the same time, they might provide *relaxed* results much faster. The best use-case for speculation is probably when the user has little insight about the data, and expects an original query to fail.

4.3 Query Constraining

Query constraining deals with the problem of many results. That means it does not need to examine fails, since it is only interested in the results satisfying the *original* constraints, which failed sub-trees cannot contain. After the query begins execution, we consider only the query relaxation and tracks the fails. If the query produces at least k results, it turns off the relaxation, stops tracking fails and starts constraining the query to prune inferior results. The pruning is based on ranking supplied by the built-in or custom function, as described in Section 3.2. Effective pruning allows us to avoid discovering and ranking each result of the original query by eliminating entire parts of the search tree that cannot contain better results than already discovered.

Recall that we explore three possible points of pruning. The first one is Solver-based, at the search tree. When at least k results are found, Searchlight computes the Minimum result RanK (*MRK*) — the minimum rank $RK()$ among all the k results found so far. This is similar to the query relaxation's *MRP*. For a new result to belong to the top-k results its rank *RK* must exceed *MRK*. Similar to query relaxation, for each search sub-tree we compute *BRK* — the Best possible RanK, which is the maximum *RK* among all solutions that might be found in the sub-tree. This can be easily done by using Searchlight-provided synopsis estimations for constraint functions. If the *BRK* value for the sub-tree falls below *MRK*, it is pruned, since no results from that sub-tree can enter the top-k. The check is done by introducing a new *dynamic* constraint into the search: $BRK(r) \geq MRK$. The constraint is dynamic, since *MRK* is updated during the search, with new information coming from both local and remote Searchlight instances. It results in progressively better values for *BRK*, and, thus, better results. At the same time the pruning becomes progressively tighter, resulting in better performance. The *MRK* updates are performed by Validators, as in the case of *MRP*, since Validators produce final results. The cost of checking the dynamic constraint is negligent. We ensure it is done after the original constraints have been checked at the node, so all $f_c()$ functions have been already computed. Computing *BRK* itself just involves a small number of arithmetic operations.

Let us revisit the example from Section 3.2 with the same C^c and parameters. Let us assume at some search node $c_1 \in [100, 190], c_2, c_3 \in [100, 200]$. Then, for the sub-tree $BRK = 1 - \frac{1}{3}(\frac{10}{50} + 0) = 0.933$. If, for example, $MRK = 0.8$, the search will continue for the sub-tree. However, if at some node in the sub-tree $c_1 \in [100, 180], c_2, c_3 \in [100, 150]$, the *BRK* becomes $\frac{1}{3}(\frac{20}{50} + 2\frac{50}{120}) = 0.589 < MRK$. Thus, the sub-tree is pruned.

When a leaf of the search tree is reached, the corresponding candidate is sent to the Validator, which does checks similar to the query relaxation, but without relaxing any constraints. It takes into account the $BRK(r)$ value of the candidate and updates the global *MRk* (if r enters the top-k).

Skyline computation (see Section 3.2) is done similarly to the scalar query constraining. It is implemented by introducing another dynamic constraint for the result. However, instead of checking the scalar *MRK* value at every node, the constraint compares the estimated $f_c()$ intervals with the current skyline. If the sub-tree is dominated by the skyline, it is pruned. Otherwise, we keep traversing the tree and passes the candidates to the Validator.

The same correctness and complexity argument as for the relaxation applies to the constraining as well, since it is performed as CP search.

5 EXPERIMENTAL RESULTS

We performed an extensive experimental evaluation of the proposed techniques. The main part of the evaluation consisted of measuring the benefits of using our approach against the only alternative available to the user — manual relaxation/constraining. Additionally, we wanted to make sure these features do not bring any significant overhead to the existing query processing. Another important part of the evaluation was to measure the benefits of our optimizations from Section 4.2. Note that existing query refinement solutions are designed for traditional database systems running SQL over relational data, and are not readily applicable to constraint-based search queries over multidimensional data, which we study here. Finally, a head-to-head comparison of Searchlight with a pure DBMS approach is available elsewhere [10] for both synthetic and a real-world data sets. The same paper [10] also argues about the prohibitive complexity of formulating CP queries in relational terms.

We measure the benefit of our approach in terms of query latency. While the quality of the final results might be another measure, such a measure would be governed by the user via the ranking/penalty functions and, thus, can be considered as immutable for our purposes.

Performing a user study would be important to measure the usability of our approach. Such a study would allow us to measure user satisfaction with the quality of the refined results and to more accurately account for time savings for the user. This works was primarily directed at the design and implementation part of the framework. It also lacks a GUI component, as well as a realistic workload to perform a meaningful user study. We leave a user study for future work.

All experiments were performed on a four-instance Searchlight Amazon AWS cluster. The cluster consisted of c4.xlarge machines running Debian 8.6 (kernel 3.16) with 7.5GB of memory. We used two data sets. The first one was a synthetic data set from the original Searchlight paper, 100GB total size. The second data set was a part of the MIMIC II [1] waveform data for the Arterial Blood Pressure (ABP) signal. The data set size was 100GB as well. These data set are representative of general Searchlight workloads: the synthetic one introduces areas of varying function amplitudes, while the MIMIC provides real-world distribution. On a side note, the data sets choice plays secondary importance to the queries, since our approach relies on the efficacy of the *general* Searchlight search process and should work for all data sets that can be handled efficiently by Searchlight.

We used a variety of queries to perform the experimental evaluation. However, to provide concise and meaningful presentation, we discuss different aspects of our approach with the help of two characteristic queries for each data set. By default, we assumed the user's cardinality requirement of 10 results. The queries were as follows:

- **S-SEL** (from Synthetic SELective) is an empty-result query for the synthetic data set. Being maximally relaxed it becomes a non-empty, but very selective query.

- **S-LOS** (from Synthetic LOoSe) outputs empty result initially. However, the maximally relaxed version is very loose, outputs a very large number of results, and does not allow the search process to perform much pruning.
- **M-SEL/LOS** (from Mimic SELective/LOoSe). This are the MIMIC versions of the queries above

Semantically, the M-SEL/LOS correspond to the running example from Section 2, They contain exactly the same variables and constraints, but different parameters (domains and thresholds). Thus, we do not repeat the query constraints here. S-SEL/LOS have the same constraints (function amplitude and neighborhoods), but with synthetic attributes from the generated data. So queries basically look for certain "spikes" in the data, where a spike is determined by comparing the resulting intervals with the neighborhood.

The main idea behind choosing selective and loose types of queries is the observation that a selective query allows the user to perform manual relaxation without significant performance penalties. The user just have to relax the constraints maximally, and the query still finishes in a reasonable amount of time. The user then can choose the best 10 results. A loose query, however, being maximally relaxed outputs an avalanche of results, which results in significant latency. Such over-relaxation might be quite costly in practice. Since the user cannot easily predict the selectivity beforehand, the system should be able to handle both types of queries automatically.

We used the maximally relaxed versions of the queries above to measure the performance of the query constraining, since they output more than 10 results. As in the case of relaxation, the selective queries' results can be ranked manually. For the loose query this is infeasible.

5.1 Query Relaxation

We measured the benefits of the automatic relaxation over the manual approach, in which the user would be forced to guess the correct query, possibly in several iterations. This manual relaxation scenario is the only alternative available to the users and exactly the case we want to avoid in practice, hence it was important to compare it with our solution. The manual approach was performed using Searchlight as well, so the search engine remained the same. We will often refer to the automatic approach as just Searchlight. We studied the following scenarios:

- **USER-3**. This is a common user scenario. The original query gives an empty answer. Then the user relaxes it in a cautious way, several times, and gets the required number of results on the second try. Thus, she comes through 3 iterations (hence, the name). In practice the number of iterations might be much larger, due to a large number of relaxation possibilities, but three iterations was enough to demonstrate our point.
- **USER-2**. In this scenario the user guesses the query correctly from the first try, for the total of 2 iterations. Note, this scenario is quite infeasible in practice, and can be seen as an oracle-based approach, in which the user immediately knows the correct relaxation. This approach establishes an important baseline.
- **USER-MAX**. This is the scenario in which the user just relaxes the query maximally after the original query fails. Depending on the query, this might perform like the oracle approach above (e.g., for selective queries) or just start outputting a large stream of results without any means of pruning (for loose ones). In the latter case the user would have to stop the query and guess further, since such queries might easily take hours to finish.

First, we provide query completion times for the selective queries S-SEL and M-SEL under different scenarios described above. The results are illustrated in Table 1, where the "SL" column corresponds to the automatic Searchlight relaxation approach discussed in the paper. For the USER-2 scenario in the parenthesis we specify the completion time of the second, correctly relaxed, query. For these queries the USER-2 and -MAX scenarios are basically equivalent since there is no much penalty in relaxing the query maximally.

Table 1: S/M-SEL query completion times (secs) for query relaxation.

Query	SL	USER-3	USER-2	USER-MAX
S-SEL	97	327	210 (120)	216
M-SEL	150	544	380 (240)	380

As can be seen, even comparing with the USER-2 approach Searchlight provided considerable performance gains. They come from two sources:

- Searchlight does not need to re-explore the already traversed parts of the search tree. After the main search is finished, it can concentrate only on the previously unexplored (i.e., failed) parts. This is in contrast with any of the manual approaches, which have to start every query iteration from scratch.
- When relaxing the query, Searchlight is able to provide additional pruning based on the best results found so far. While for selective queries it is not necessarily the game changer, it has a much more pronounceable effect for loose queries, which we show later.

We also measured the time it took Searchlight to obtain the first result. For the S-SEL queries it took Searchlight 42 seconds in the SL approach versus 91s seconds for the USER-2 (the best) approach. The corresponding times for the M-SEL query were 45 and 198 seconds. We saw similar trends across all queries we ran. The results come as no surprise, since Searchlight is able to start the relaxation right away without restarting queries with new parameters.

When it came to the overhead of the query relaxation approach itself, it did not exceed 5 seconds for the synthetic and 3 seconds for the MIMIC queries. This overhead mainly came from assessing and recording the fails.

Table 2 provides the corresponding results for the loose queries. For the "Max" case, we stopped the query after 1 hour (hence the > symbol in the table), since this was enough to demonstrate our point.

Table 2: S/M-LOS query completion times (secs) for query relaxation.

Query	SL	USER-3	USER-2	USER-MAX
S-LOS	105	314	208 (106)	>3600
M-LOS	91	177	118 (83)	>3600

This experiment shows the same trend as for the selective queries with a single exception: the USER-MAX and USER-2 behaved differently. When the user relaxed the query maximally, it ran for a very long period of time (we stopped it after 1 hour) due to the very large number of results. In practice, the user cannot just stop the query and rank the currently found results, since she is not guaranteed to find the top-k among them. However, Searchlight guarantees correct top-k results. Since the maximal relaxation is out of the question, without Searchlight the user would have to continue the guessing game of scenario USER-3 but with potentially more iterations and longer times.

Searchlight outputs the first result in 92 and 45 seconds for S-LOS and M-LOS, respectively. The corresponding times for the USER-2 were 108 and 77 seconds. This is the same trend as we discussed for the selective queries. The auto relaxation overhead remained at comparably low levels: 15 seconds for S-LOS and 1 second for M-LOS.

The next experiment measured the overhead of the auto relaxation for the queries that do not need it. We wanted to explore the possibility of keeping the relaxation always on, without the user turning the knob. For this experiment we ran the second query from USER-2 with the relaxation turned on. The results are given in Table 3.

Table 3: Query completion times (secs) for queries not needing relaxations.

Relax	S-LOS	M-LOS	S-SEL	M-SEL
Off	106	83	120	240
On	116	98	127	290

As can be seen, turning on the auto-relaxation does not have any significant impact on the query completion times. The notable exception is M-LOS query, for which Searchlight submitted a lot of relaxed candidates to the Validator before 10 results were actually found. However, this overhead was the largest we saw for a large number of queries we ran. Even with such an overhead the auto-method would be quite helpful for the user, since the relaxed candidates are output to her as useful feedback. At the same time, the time to first result did not change significantly for all queries, which means the interactivity was not hampered, and the overhead was limited to the total completion time.

5.2 Query Constraining

In the absence of automatic query constraining, the only option is to run the query until completion and then rank results at the client. While this might work for queries with small number of results, it is very inefficient for queries returning a lot of them. In addition, the manual approach misses significant pruning opportunities. Our main results are shown in Table 4. "Off" means no constraining, which is equivalent to the manual approach; "Rank" means scalar ranking automatic constraining, and "Skyline" — vector domination constraining. Both approaches were described in Section 3.2. By default we specify times in seconds, and we use 'h' and 'm' symbols to denote hours and minutes.

Table 4: Query completion times (secs) for query constraining.

Method	S-LOS	M-LOS	S-SEL	M-SEL	M-SEL'
Off	2h 8m	2h 24m	120	240	263
Rank	60	154	29	139	135
Skyline	314	13m	93	269	218

The loose S/M-LOS queries could not even finish in a reasonable time. These queries actually were outputting results with very low latency during the execution. However, since constraints were loose, they created an avalanche of such results without the ability to prune. To guarantee the top-10 results the user would have to stop the query and constrain it by hand, possibly in several iterations.

At the same time, for the same queries Searchlight provided considerable performance gains, coming from pruning both at Solvers and Validators, as we described in Section 4.3. This was especially evident for the rank-based constraining. The skyline constraining was less effective, with respect to the query completion time. However, comparing with the manual "Off" approach, the performance benefits were considerable. The reduced efficacy can be attributed to the nature of skyline — it is harder to prune interval-based search nodes at Solvers and candidates at Validators.

The selective queries S-SEL and M-SEL allowed us to measure the constraining benefits for the queries for which the client-based filtering is a viable alternative due to their reasonable completion time. In most cases our approach resulted in considerable gains. The M-SEL query is somewhat of an exception, for which the skyline approach performed worse than the "Off" approach. This can be attributed mostly to some overhead from the skyline based checks during pruning (without any benefits) and slightly different rebalancing of the candidates between Validators. The last column of the table (M-SEL') provides results for another selective MIMIC query. It can be seen that both rank and skyline auto approaches provided significant improvements for query completion times, so the M-SEL case should not be considered a trend for selective queries.

When it comes to the overhead of the automatic approach, it is kept at the minimum. Actually, it is smaller than that for the query relaxation since it does not need any maintenance similar to tracking of failed search nodes. As for the Solver- and Validator-level checks, they are quite cheap for the rank-based constraining, being in-memory algebraic comparisons. For skyline-based constraining the checks are somewhat more expensive, and they must be active all the time, from the beginning of the query. However, the checks can be done quite efficiently using the variety of existing methods for skyline computation. This problem is well-researched, for example, for relational skylines. The overhead in this case is basically the cost of computation, which cannot be avoided for such a non-trivial constraint.

5.3 Query Relaxation Optimizations

In this section we describe experiments to measure the performance of the relaxation optimizations from Section 4.2.

Computing functions at fails. In this experiment we measured the difference between the two different strategies to compute functions $f_c()$ when catching fails. The first strategy, "Full", corresponds to fully evaluating all functions at the failed node. The "Lazy" corresponds to the lazy evaluation. Both strategies were described in Section 4.2.

The results are presented in Table 5 where the parenthesis times specify the times to first result, which is a reasonable measure of interactivity. While times to the first result might seem large, they include the completion time of the *original* query, which found no results at all. The optimization provided benefits for more expensive synthetic queries. At the same time it did not result in any overhead for all queries. We also ran additional experiments for more expensive MIMIC queries, for which we took the same M-SEL/LOS queries and increased their cardinality requirements from 10 to 200 results. We saw the significant benefits at the fail recording stage: for some queries the fail tracking overhead decreased from 30 to 15 seconds.

Table 5: Query completion and first result times (secs) for fail recording methods.

Method	S-LOS	M-LOS	S-SEL	M-SEL
Full	120(100)	81(45)	112(46)	149(45)
Lazy	105(90)	91(45)	97(42)	150(45)

Saving UDF states at fail recording. In this experiment we measured the impact of saving additional UDF information when recording fails. In contrast with the previous optimization, which just lazily postpones computation of some UDFs, this optimization allows us to avoid re-computation of some UDFs completely. The results are presented in Table 6 for query completion and first-result times (the latter is given in parenthesis).

Table 6: Query completion and first-result times (secs) for the UDF saving optimization.

UDF saving	S-LOS	M-LOS	S-SEL	M-SEL
On	105(90)	91(45)	97(42)	150(45)
Off	113(111)	104(70)	97(40)	154(46)

The optimization was especially beneficial for the loose queries. For the selective queries the benefits were not pronounced due to the structure of those queries. The replays were relatively cheap, involving less re-computation. As in the previous case, this optimization did not result in any overhead as well, at the same time allowing better performance in many cases. The memory footprint for the saved states depends on the functions. Standard aggregate functions use about 80 bytes per save for the two-dimensional data set (16 bytes for the range itself plus 64 bytes for the support coordinates for the min and max values).

Speculative execution. As can be seen from the experiments, the time to the first result is often quite large. This is a logical result for empty-result queries, since Searchlight first finishes the main, non-relaxed, query and only then tries to relax it. We support speculative relaxation as a means to start the relaxation sooner. The corresponding query completion and first result times are presented in Table 7.

Table 7: Query completion and first result times (secs) for speculative relaxation.

Speculation	S-LOS	M-LOS	S-SEL	M-SEL
On	128(7)	90(45)	115 (2)	152(47)
Off	105(90)	91(45)	97(42)	150(45)

As can be seen from the results in many cases speculative execution significantly improved times to the first result. We could not find suitable queries to demonstrate the same trend for the MIMIC queries. While the speculative Solver for those queries replayed some of the fails, they resulted in a small number of non-perspective candidates. As we discussed in Section 4.2, speculative Solvers are restricted to fails found by main Solvers so far.

As expected, the speculative relaxation has its own overhead coming from the consumption of CPU resources by the speculative Solver. For some queries the increase in the completion time was significant. We decided to run an additional experiment (not shown here), with one additional CPU thread available. As expected, the times for the speculative relaxation turned on and off were the same, which suggests the overhead is CPU related and cannot be trivially extinguished. Basically, the decision of trading off some completion time to faster interactive results is up to the user.

Partial relaxation during replays. This optimization addresses the issue of over-relaxing the query at a fail replay, when early fails might be relaxed in a very loose way because of loose estimations. As we discussed in Section 4.2, the *RRD* parameter ($0 \leq RRD \leq 1$), allows us to perform the relaxation in a more controlled way by enforcing tighter relaxation. The results of changing this parameter for the loose queries are presented in Table 8. We did not see any significant effect of the parameter to first result times.

Table 8: Query completion times (secs) for different *RRD* values.

Query *RRD*	0.1	0.3	0.5	0.7	1.0
S-LOS	106	105	106	106	106
M-LOS	87	91	112	145	54m

As can be seen from the table, the optimization resulted in gains only for some queries (we saw gains for other MIMIC queries as well). M-LOS query, for instance, fails almost immediately, and replaying its early fails with maximal relaxation effectively results in traversing most of the search tree. For S-LOS, on the other hand, search fails are relatively deep in the search tree, so maximal relaxation does not cause significant increase in the number of visited search nodes. In general, the benefits of the optimization depend on the nature of the search tree, which in turn depends on the query. At the same time, it does not introduce any overhead, which allows us to keep it always on. We saw a slightly elevated number of fail recordings and replays, but not significant enough to cause any drop in performance.

Additional experiments with the fail and candidate queues. We extended the Validator to sort the candidates on the *BRP* value. This in general might allow the Validator to identify better relaxed results faster, which in turn results in better *MRP* values and more effective pruning. We performed the experiment over a number of queries with different cardinality requirements to vary the number of candidates at runtime. For some queries, we saw 8-12% improvement in total completion times and no major impact on the first results.

We also measured the benefits of our fail-based approach presented in the paper against simply continuing the search "through" the fail. The latter would still involve relaxing constraints, but no fail recording (and later replaying) would be made — the search would be immediately resumed from the point of failing. One reason to do that would be to simplify the approach and decrease the memory overhead. However, we claim it would result in a sub-optimal approach, where the *utility* of the fails is not taken into consideration. Our experiments supported this claim. When we replayed the fails in the order they were encountered, simulating the immediate search resume, we did not see any improvements in the completion or first result times. Moreover, for some queries the completion times increased up to several orders of magnitude. For example, for S-LOS the time increased from 105 seconds to 56 minutes. We believe these results emphasize the necessity of a utility-based approach.

6 RELATED WORK

Query relaxation [12, 14–16] deals with the empty-answer and too-few-answers query problems by relaxing the original query constraints. The past work on query refinement can be studied under two broad categories. The first includes relaxation based on some statistics readily available in the database. For example, the Stretch-and-Shrink (SnS) framework [14] uses query cardinality estimations via precomputed samples and then uses the estimations to find relaxed ranges for each range-based query constraint independently. The framework heavily relies on fast cardinality estimations. Multiple estimations might have to be made at every step of the interactive refinement. Another framework [4] uses histograms to produce cardinality estimations and derive proper constraint ranges for the query. The results presented to the user are ranked based on the distance (e.g., Euclidean) from the original constraint ranges. There is also the possibility of using probabilistic [15] and machine learning [16] frameworks to produce relaxations. These methods, however, still rely on statistics to provide probabilistic estimations for the relaxation decision or the learning stage to understand the rules hidden inside the data. On the other hand, Searchlight targets queries for which the cardinality is not known beforehand. It would be also hard to estimate properly due to a large search space and possible complexity of query constraints. The results are also not known, and might be expensive to find, which makes the learning stage or probabilistic estimations infeasible.

The other category includes methods that use indexes to relax constraints. One such approach [12] is to relax join and selection predicates, and obtain the relaxation *skyline*. These methods have limited applicability for Searchlight, since results cannot be indexed beforehand. Also Searchlight generally works with regions (subsets) instead of single tuples, and the search space itself depends on the query constraints. Additionally, query constraints might be more complex than ranges, potentially referencing data outside of regions (e.g., the neighborhood constraints in the query from the Introduction). This makes R-trees (or other traditional index trees) generally ineffective for traversal and pruning.

The too-many-results problem creates the dual problem of *contracting* the query. These methods [4, 14] generally use precomputed statistics to make fast cardinality estimations and find suitable ranges for query constraints. The corresponding frameworks usually handle both relaxation and contraction at the same time. Another approach is to get rid of excessive answers by ranking and outputting only the best few. The "best" can be based on a scalar ranking function (top-k queries) or vector domination (skyline [5] queries). These methods commonly rely on traditional precomputed structures, such as views [6, 8] and R-trees [17, 18]. The view-based approaches require advance knowledge of at least a part of the workload to materialize proper views. The R-tree approaches traverse the tree and perform MBR-based pruning. If such structures are not readily available, the only option is to perform a sequential scan and either build the required structures or do the processing during the scan (e.g., sorting [3, 7], batch computation [3] or building structures optimized for particular queries [17]). For Searchlight, no indexes are available beforehand, thus we performed a comprehensive search. This might seem similar to the sequential scan-based approaches, however, as we argued, the nature of the constraint-based queries is different and, thus, requires novel approaches.

7 CONCLUSION

Fast query execution is necessary but not sufficient for effective interactive data exploration. Users often go through multiple query iterations to identify a reasonable set of results that matches their goals. It is thus critical for the underlying system to aid the users, optimizing for human labor, time and attention, to maximize user productivity.

We introduce dynamic and automatic refinement of constraint-based search queries, based on user-specified target result cardinalities. When relaxing a query, we guarantee optimal results according to user-specified distance functions. When constraining, we output the top results according to a ranking function. Unlike previous solutions, our approach does not require any pre-computed indexes nor does it require result cardinality estimations, which might be extremely hard to obtain accurately for queries with complex constraints. Our approach instead alters the constraints during the run-time. Our techniques naturally fit in and can effectively leverage the common features of CP platforms and DBMSs. Furthermore, our approach can explore more promising parts of the search space first, which considerably improves pruning and, consequently, provides better interactivity and query completion times.

Our approach provides significant performance benefits in comparison with the tedious and inefficient manual approach. At the same time, it incurs negligible performance overhead, even for queries that end up not needing any refinements.

ABSTRACT

CPU has been identified as the energy bottleneck for database systems and existing approaches only allow database systems to trade the performance for energy. However, our work show that cutting down the energy cost of database systems without losing the CPU performance is feasible. We first develop a measurement methodology to accurately evaluate the energy cost of different CPU micro-operations. Then three popular database systems with different setups and data sizes are used as benchmarks to explore the energy distribution on CPU micro-operations. Our experimental results show that L1 data cache (L1D cache) consumes 39%-67% of total CPU energy and it is definitely the energy bottleneck of database systems. This finding inspires us a novel idea on building energy-efficient database systems with customized CPU architecture that features low L1D cache energy cost. A proof-of-concept system is developed to evaluate this idea and the experimental results show that our solution can not only achieve 60% of peak energy saving but also gain further performance improvement.

1 INTRODUCTION

As the infrastructure of the data center, database system has been limited by the energy wall. The energy cost of powering the database server is not only rapidly approaching the machine acquisition cost[24], but the energy wall also limits the scalability of database server. CPU[13, 19, 25], main memory[23] and disk[24] may become the energy bottleneck due to different computer architectures and database types. In this paper, we focus on the energy profiling of typical relational database systems on the x86_64 architecture with local disk, and many evidences have confirmed that CPU consumes more power than other major components in our scenario[13, 19, 25].

According to whether the workload is running or not, the CPU energy cost may be classified into Busy-CPU energy cost and Idle-CPU energy cost. The Idle-CPU energy cost has been reported to reduce from 50% to 18%[19]. Undoubtedly, the Busy-CPU energy cost as the dominant part attracts a lot of research work. For example, both academia and industry have expended a great deal of effort in energy-oriented query optimization[21, 28, 29] and the external energy knobs based approaches[13, 19, 21, 23]. The basic idea is building the cost model based on the Busy-CPU energy cost to choose the energy-optimized query plan or set the appropriate CPU voltage and frequency according to the database load status. These methods consider CPU as a black box and the energy cost is reduced by trading the performance, such as a 43%-80% performance loss[21, 28].

Actually, there are many different micro-operations inside the CPU and they expect different energy costs. Existing black-box optimization methods cannot take advantage of micro energy cost characteristics of database workloads so they often lead to significant performance loss to meet the energy saving demand.

Energy-efficient database systems expect that the CPU architecture can significantly cut down the Busy-CPU energy cost. To achieve this object, an in-depth breakdown of Busy-CPU energy cost is indispensable. It cannot only help us identify the energy bottleneck on CPU, but it is also the basic work to design a novel customized CPU architecture for energy-efficient database machine. Breakdown analysis of Busy-CPU energy cost will help to answer some important questions such as what is the microscopic distribution of Busy-CPU energy cost and how different database implementations and settings affect this distribution.

In this paper, we design micro-benchmarks to breakdown the Busy-CPU energy cost of typical read query workloads, and enable the energy-efficient database system on the customized CPU architecture. Unless otherwise specified, the query will refer to read query. It is very difficult to achieve an accurate breakdown of energy cost on a real database system. The micro-operations which can be monitored are so many e.g., about 514 events inside our CPU that we cannot evaluate the energy cost for every micro-operation. To isolate the energy cost of an individual micro-operation, we need to overcome many mutual related factors, such as the compiler optimization and architectural features. In addition, to enable energy-efficient database systems, we have investigated many CPU architectures and updated the kernels of both operator system and database system to make them support the customized CPU architecture well. Finally, we present a clear energy cost distribution pattern of database systems and give a proof-of-concept system to cut down the energy cost without losing the performance. The major contributions are as follows.

- A micro analysis based accurate energy breakdown method is proposed for the Busy-CPU energy cost with typical query workloads.
- The energy bottleneck L1D cache is identified based on extensive experiments on three typical database systems.
- The L1D energy-efficient CPU architecture design is proposed and the experimental results show that 60% of peak energy saving can be achieved with further performance improvement.

The rest of the paper is organized as follows. Section 2 presents our evaluation approach and the energy cost of micro-operations. Section 3 profiles the energy cost of database systems along with a detailed analysis. Section 4 presents our proof-of-concept system design, optimization approach and evaluation results. Section 5 analyzes the energy cost preference of some typical scenarios. Section 6 describes the related work. Section 7 summaries our work and presents directions for future work.

2 MICRO ANALYSIS METHOD FOR BUSY-CPU ENERGY

In this section, we will present our methodology on how to break down the Busy-CPU energy cost into the energy cost of different micro-operations for queries in relational database systems.

Corresponding author is Xiaofeng Meng.

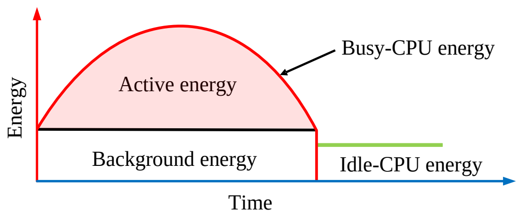

Figure 1: Example of energy cost along the workload running.

2.1 Key Idea

Depending on whether the CPU is on operational states or idle states, we name the total energy cost as Busy-CPU energy cost and Idle-CPU energy cost, shown in Figure 1. When fixing the CPU frequency and voltage, we further divide Busy-CPU energy cost into the Active energy cost and the Background energy cost, defined as

$$Busy\text{-}CPU\ \ energy = Active\ \ energy + Background\ \ energy.$$

When running a workload, the Active energy is the real cost used for the calculation and data movement and the Background energy is the fixed cost to activate the hardware. Obviously, the Active energy cost can reveal the power usage of a workload so that it is our profiling target.

We first formalize the Active energy cost as the sum of the energy cost of micro-operations. Next, we mainly solve three issues. (1) We have to identify which micro-operations to be profiled. The query workloads are typically data-intensive. This motivates us to pay an attention to the data movement related micro-operations, such as the cache load. When we know the executed counts of these micro-operations and the energy cost driving them once, we can actually evaluate their energy cost. (2) How to quantify the energy cost of an individual micro-operation. We construct many micro-benchmarks, each of which shows a simple performance behavior issued by the specific micro-operations. Then, we also build energy models to map the energy cost of micro-benchmarks into the energy cost of an individual micro-operation. (3) How to verify the accuracy of the energy cost of an individual micro-operation. We have to construct the other micro-benchmarks which have the clear and complex performance behaviors. We can identify the difference between the estimated energy cost and the measurement value to take the verification. We will give a detailed introduction focusing on the above three issues.

2.2 Problem Formalization

We denote the analyzed micro-operation set as MS and then formalize the Active energy cost E_{active} for the workload w as

$$E_{active}(w) = E_{other}(w) + \sum_{m \in MS} E_m(w), \tag{1}$$

where $E_m(w) = N_m(w) \times \Delta E_m$ is the energy cost of the micro-operation m. ΔE_m is the energy cost driving the micro-operation m once and N_m is the count executing the micro-operation m and E_{other} is the unisolated energy cost, including the calculation, L1I cache and TLB, etc. According to Eq. (1), we have to solve the ΔE_m and N_m. Noting that our energy breakdown model is based on the stable voltage and CPU frequency. The dynamic voltage and frequency scaling (DVFS) will cause fluctuations on ΔE_m, so we disable DVFS during the testing. However, we can also evaluate the impact of different voltages and CPU frequencies. To solve Eq. (1), we must construct the set MS and evaluate the ΔE_m of every micro-operation in MS.

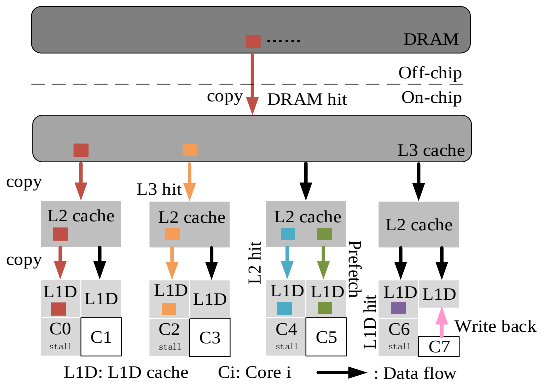

Figure 2: Example of data movement on the modern CPU architecture. The CPU core in the white box is busy and it in the gray box is stall.

2.3 Energy Breakdown Representation

Generally speaking, the query workload is usually data-intensive, so that we tend to choose data movement related micro-operations to characterize the energy cost. For the modern CPU architecture, the data is frequently moved between main memory and registers. In order to cross the memory wall, the CPU (e.g., Intel i7-4790 in our experiment) contains a three-level cache memory sub-system, shown in Figure 2. The closer the cache memory is to the CPU core, the smaller, faster and more energy-efficient it will be. We describe three ways of data movement that have the great impact on query workloads.

Regular data fetching. If the data is not in registers, the load instruction will fetch the data of the cache line size (e.g., 64 Bytes) and the CPU core could stall to wait for the data return. Noting that if instructions are uncorrelated with each other, speculation and out-of-order execution can disable the pipeline bubble. In addition, data fetching follows a step-by-step replication strategy. The CPU will first fetch data from L1D cache. If L1D cache hits (L1D hit), the data will be loaded into the register, like Core 6 in Figure 2. Otherwise, the CPU will go to the next level cache to search for data, called as L1D cache miss (L1D miss). Specifically, when L1D cache misses, L2 cache starts to search for data. There are also two cases: hit and miss. If L2 cache hits, the data will be copied to L1D cache first, and then copied to the register, like Core 4 in Figure 2. Similarly, L3 hit and DRAM hit are like Core 2 and Core 0 in Figure 2. Although the step-by-step replication strategy can provide the good data locality, the data movement leads to much energy cost.

Data prefetching. In order to improve the CPU performance, the data prefetching technique is used to predict the data usage under the background and fetch it without the pipeline bubble, like Core 5 in Figure 2. So, the data prefetching will also cause the data movement behavior. Four prefetching techniques are provided in Intel i7-4790[3]. Two are implemented through L1D hardware prefetcher to replicate the data into L1D cache in advance. Unfortunately, they cannot support the performance counter in Intel i7-4790. The two other types of prefetches that can be generated by the L2 hardware prefetcher – prefetches into the L2 cache (L2 prefetching) or prefetches into the L3 cache (L3 prefetching). Their behaviors can be monitored by the performance counter. In our paper, the data prefetching only means the L2 hardware prefetcher.

Write-back. Although the query is the read-only workload, lots of temporary data, e.g., local variables, have to be created and updated. The store operation always updates the data into L1D cache within 1 cycle. Because the local variables do not need to be eventually persisted so that they are rarely written to the lower level memory due to the write-back strategy. For example, L1D cache store hit rate is 99.86% in our experiment. So, we also evaluate the store operation which writes the data into L1D cache.

Based on the above analysis, we define the micro-operation set MS as

$$MS = \{L1D, Reg2L1D, L2, L3, mem, pf, stall\}$$

for the query workload. $\forall m \in \{L1D, L2, L3, mem\}$ is that a load operation reads the data from m to the next higher level memory. For example, $m = L2$ means to load the data from L2 cache to L1D cache. $Reg2L1D$ means that the store operation writes the data from the register to L1D cache. We combine two different types of prefetches generated by the L2 hardware prefetcher together as a micro-operation pf meaning to prefetch data. The micro-operation $stall$ is the stall event due to memory access. Recalling the Eq. (1), we next evaluate N_m and ΔE_m.

The energy breakdown of update/write queries is a totally different problem from the read queries. We need to know how to write the data into main memory. It may involve more micro-operations about writing. We do not discuss it in depth in this paper.

2.4 Micro-Operation Counting

The modern processors have built-in performance monitor unit (PMU) to record the performance related events. We can use Linux Perf[5] or ocperf[6] to get them from PMU to evaluate the micro-operation count N_m. For $\forall m \in \{L1D, L2, L3, pf\}$, it is worth noting that N_m is the sum of both the hit count and the miss count due to the step-by-step replication strategy. N_{pf} involves the L2 prefetching count N_{pf}^{L2} and the L3 prefetching count N_{pf}^{L3}. Especially, N_{mem} is the miss count of L3 cache. $N_{Reg2L1D}$ is the hit count when writing the data into L1D cache. N_{stall} is the stall cycle count due to the data load.

2.5 Energy Evaluation of Micro-Operation

To quantify ΔE_m, we design a set of micro-benchmarks which can achieve the specific performance behavior, such as only accessing L1D cache, etc. Finally, we can use the Active energy cost of micro-benchmarks to evaluate the ΔE_m of different micro-operations.

2.5.1 Micro-Benchmark Design. Isolating memory access to only follow a specific performance behavior is a challenging task in modern processors. The design of the micro-benchmark methodology is inspired by the recent work[22]. The out-of-order execution, speculation execution and data prefetching have worked well in hiding memory latencies but at the same time make the energy cost benchmarking for an individual instruction difficult. In addition, the treading switching, DVFS and the compiler optimization could affect the evaluation accuracy. In order to accurately evaluate ΔE_m, we make a lot of effort on it. First, our micro-benchmarks should minimize the effect of CPU architectural optimization. Second, we must configure the appropriate runtime environment to reduce the error, shown in Section 2.5.3. Third, we must review the assembly code which is generated by the compiler to disable some compiler flags who will change the performance behavior. Our micro-benchmarks follow two design frameworks to skip out of the architectural optimization.

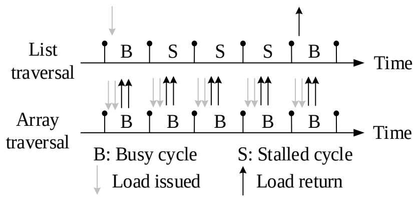

Figure 3: CPU execution behaviors when list traversal and array traversal only load data from L1D cache.

List traversal. We allocate a size of memory as an array Arr of pointers. The size of each item is 64 Bytes (i.e., cache line size) which can be processed by a load operation. We link every item as the list. Then, we traverse the list many times. Through the correct implementation, we can ensure that micro-benchmarks only load data from the specific memory layer. In this way, the energy cost of each micro-benchmark can be broken down into the energy cost of the specific micro-operations and stall cycle.

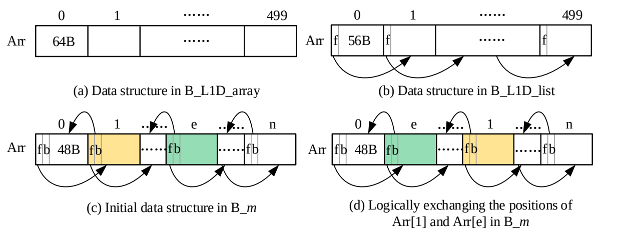
The list structure can make sure the data items have the back-and-forth dependency. Due to the access dependency, in the premise of disabling the perfetching the CPU does not know the address of the next data item until the previous item is finished. An example is shown in Figure 3. We assume the data in L1D cache and a L1D load requires 4 cycles from issue to return. Due to the unknown address of next data item, the pipeline is forced to break, leading to 1 load cycle and 3 stall cycles, i.e., L1D load energy and stall energy. The link traversal can disable the out-of-order execution and the pipeline to minimize the energy cost measurement error incurred by CPU architectural optimization.

Array traversal. The energy cost of stall cycle cannot be separated by list traversal. So, we design the array traversal framework. In it, the micro-benchmark allocates a size of memory as an array Arr (also 64 Bytes per data item), and then sequentially traverses it many times. Under some special conditions, CPU architectural optimization can make micro-benchmarks only load data from the specific memory layer without stall cycles.

As well known, the data item in array is completely independent and supports random access because the CPU knows the address of all data items before traversing. The load of next data does not have to wait for the finish of the previous data item. As shown in Figure 3, although a L1D load still requires 4 cycles, 3 stall cycles can be hidden due to the continuous pipeline. In addition, the Dual-Issue technique of Intel i7-4790 can issue two load instructions per cycle without stall.

2.5.2 Micro-Benchmark Set. For evaluating ΔE_m ($\forall m \in MS$), we build a micro-benchmark set MBS including 6 micro-benchmarks to show the specific performance behaviors as follows.

B_L1D_array. This micro-benchmark is used to evaluate ΔE_{L1D}, only accessing L1D cache without stall cycles. As shown in Algorithm 1, it follows the array traversal framework and allocates memory size smaller than or equal to the size of L1D cache. As shown in Figure 4a, if $S_{mem} = 32KB$ (i.e., L1D cache size in i7-4790), the Arr size is 500 and the size of each item is 64 Bytes. T is usually set into a huge value, such as 1 billion, to maintain



Arr
64B
(a) Data structure in B_L1D_array
56B
(b) Data structure in B_L1D_list
48B
(c) Initial data structure in B_m
(d) Logically exchanging the positions of Arr[1] and Arr[e] in B_m

Figure 4: Examples of data structures in different micro-benchmarks. B_m represents B_L2, B_L3 and B_mem. Pointer f points the next data item and pointer b points the previous data item.

a stable memory access pattern. A large T also applies to Algorithm 2-4. For balancing the performance, it can also be reduced moderately. So, all the data easily fit the L1D cache, so there will not be any miss after initial set of loads. Noting that we unroll the *Arr* and traverse it instead of loop traversal, it will avoid the effects of loop control statements as much as possible. By this programming optimization, 98.6% instructions are the desired load instructions.

Algorithm 1 B_L1D_array

```
Input: $S_{mem}$: allocated memory size; $T$: loop times;
1: allocate $S_{mem}$ memory size as an array $Arr$ with $\frac{S_{mem}}{64}$ items;
2: for iter $i$ in range $T$ do
3:     traverse $Arr$ through unrolling $\frac{S_{mem}}{64}$ times;
4: end for
```

B_L1D_list. The energy cost of this micro-benchmark mainly involves the load operation from L1D cache and the CPU stall. As shown in Algorithm 2, it follows the list traversal framework and allocates memory size smaller than or equal to the size of L1D cache, such as still 32KB. We also give an example to show such data structure in Figure 4b.

Algorithm 2 B_L1D_list

```
Input: $S_{mem}$: allocated memory size; $T$: loop times;
1: allocate $S_{mem}$ memory size as an array $Arr$ with $\frac{S_{mem}}{64}$ items;
2: partition each item into a pointer f (the first 8 Bytes) and the
   last 56 Bytes of data;
3: for iter $j$ in range $\frac{S_{mem}}{64} - 1$ do
4:     $Arr[j].f = \&Arr[j+1]$;
5: end for
6: for iter $i$ in range $T$ do
7:     use pointer f to traverse $Arr$ and unroll $\frac{S_{mem}}{64}$ times;
8: end for
```

B_L2, B_L3 and B_mem. They will be used to evaluate ΔE_m ($\forall m \in \{L2, L3, mem\}$). As shown in Algorithm 3, they follow the list traversal framework and only access the specific memory layers. When only accessing the memory layer m, the allocated memory size should be as close as possible to the sum of the m size and sizes of its higher caches to ensure that the majority of data is in m. Using B_L2 as an example, the allocated memory size should be close to 288KB (32KB L1D cache and 256KB L2 cache). Similar setup methods can be extended to B_L3 and B_mem. Noting that we do not use the linked list structure similar to B_L1D_list, the sequential load along physical position means the simple access pattern, which is easily employed by the modern CPU to improve the performance. However, it has the serious impact on profiling. For example, when setting $S_{mem} = 260KB$ for Algorithm 2, the L1D hit rate is 55%, so that there is no guarantee that only L2 cache is accessed. Thus, we randomize the access order (logical position) and generate jump access on a large span to break the data locality, as shown in Figure 4d. Because the low memory layer is far larger than the high memory layer, the data will usually miss in the high memory layer.

Algorithm 3 B_L2, B_L3 and B_mem

```
Input: $S_{mem}$: allocated memory size; $T$: loop times; $\varepsilon_{span}$: span
   threshold of two given data items;
1: allocate $S_{mem}$ memory size as an array $Arr$ with $\frac{S_{mem}}{64}$ items;
2: partition each item into a pointer f (the first 8 Bytes), and
   pointer b (the second 8 Bytes) and the last 48 Bytes of data;
3: for iter $j$ in range $\frac{S_{mem}}{64} - 1$ do
4:     $Arr[j].f = \&Arr[j+1]$;
5:     $Arr[j].b = \&Arr[j-1]$ $(j-1>0)$;
6: end for
7: for iter $z$ in range $\frac{S_{mem}}{64} - 1$ do
8: //avoid frequent exchange of logical neighbors when $e$ is
   always the same value.
9:     randomly pick $e \in [1, \frac{S_{mem}}{64} - 2]$ to satisfy $|z-e| > \varepsilon_{span}$
   and $Arr[e]$ is not the logical neighbor of $Arr[z]$;
10:    exchange the logical positions of $Arr[z]$ and $Arr[e]$;
11: end for
12: for iter $i$ in range $T$ do
13:    use pointer f to traverse $Arr$ and unroll $\frac{S_{mem}}{64}$ times;
14: end for
```

B_Reg2L1D. The energy cost of this micro-benchmark mainly involves the store operation from registers and the L1D cache. As shown in Algorithm 4, it only accesses the same variable repeatedly, but it is effective to ensure that the CPU only execute the store operation. This benchmark always access the same variable, the CPU can find it in registers, instead of reading it from L1D cache every time. In addition, the allocated memory size is large enough, so that the CPU has to perform multiple store operations to complete the assignment. Due to temporary variable assignment, the vast majority of store operations only involve L1D cache.

Algorithm 4 B_Reg2L1D

```
Input: $T$: loop times; $ut$: unrolling times;
1: allocate 64 Bytes of memory size as a variable $A$;
2: for iter $i$ in range $T$ do
3:     execute $p = A$ through unrolling $ut$ times; //variable
   assignment
4: end for
```

Our micro-benchmark set can achieve the specific performance behavior. Noting that it may be not the only way, but it has been enough accurate to help us profile the energy cost of database systems.

2.5.3 Runtime Configuration. The accurate execution of our micro-benchmarks depends on some runtime configurations to overcome the measurement error.

Compiler optimization. In order to minimize the impact of unnecessary instructions, our micro-benchmark set is compiled with an optimization level of -O3. The necessary temporary variables are added with a *volatile* modifier, such as a temporary pointer variable for linked list pointer tracking, which can cancel the compiler's active optimization to avoid the microscopic behavior changing.

Thread switching. In order to prevent the thread attached by the micro-benchmark from being switched between different idle CPUs during execution, the micro-benchmark will be fixed on a specific logic core to run.

DVFS knobs. EIST (Enhanced Intel SpeedStep Technology), an Intel DVFS implementation, changes CPU frequency and voltage to balance energy cost and performance. The energy cost of micro-components will increase with the improvement of CPU frequency and voltage. Because our micro-benchmarks are effective under the stable frequency and voltage, EIST technique will incur the measurement error of energy cost. We turn off these options and execute our micro-benchmarks under the given frequency and voltage according to our experimental requirement.

Prefetcher. The data prefetching could lead to the unexpected load instructions into our micro-benchmarks. So, the hardware prefetcher will be turned off by modifying MSR registers when running our micro-benchmarks. It will be turned on when evaluating the energy cost of query workloads.

Through running our micro-benchmarks, we can isolate the specific micro-operations and reduce most of measuring errors. It will lead to an easy solution to ΔE_m in next section.

2.5.4 Energy Model to Evaluate ΔE_m. We construct a series of energy models to map the energy cost of the micro-benchmark into ΔE_m. For any micro-benchmark $mb \in MBS$, we define the Active energy cost of mb as $E(mb)$ which will be given in next section. Here, we assume that $E(mb)$ is known to give the solution of ΔE_m.

Through running B_L1D_array which only loads data from L1D cache, we can solve the ΔE_{L1D} as

$$\Delta E_{L1D} = \frac{E(B\_L1D\_array)}{N_{L1D}}.$$

Recalling that N_{L1D} is the count loading data from L1D cache in Section 2.4. Similarly, when running B_L1D_list, we can solve the ΔE_{stall} as

$$\Delta E_{stall} = \frac{E(B\_L1D\_list) - E_{L1D}}{N_{stall}}.$$

For the micro-operations $x, y \in C = \{L1D, L2, L3, mem\}$, if the micro-operation x loads data from the higher memory layer than y, we denote $x > y$. When running the micro-benchmark B_L2, B_L3 and B_mem, respectively, we can solve the ΔE_m as

$$\Delta E_m = \frac{E(B\_m) - \sum_{i>m}^{i \in C} \Delta E_i N_i - E_{stall}}{N_m}. \tag{2}$$

Due to the step-by-step replication strategy, loading data from the low memory layer must also lead to a load operation from the higher memory layer. So, the load energy cost of the higher memory layer needs to be eliminated in Eq. (2). When running B_Reg2L1D, we can solve the $\Delta E_{Reg2L1D}$ as

$$\Delta E_{Reg2L1D} = \frac{E(B\_Reg2L1D)}{N_{Reg2L1D}}.$$

Prefetching energy. In term of the energy cost, the data prefetching and the regular data fetching are similar. we follow the assumption that the energy is mainly consumed in moving data from a specific memory layer to a higher layer [18] and set $\Delta E_{pf}^{L2} = \Delta E_{L3}$ and $\Delta E_{pf}^{L3} = \Delta E_{mem}$. ΔE_{pf}^{L2} is the energy cost of an individual L2 prefetching from L3 cache and ΔE_{pf}^{L3} is the energy cost of an individual L3 prefetching from main memory[4].

2.5.5 Verification Method of ΔE_m. For verifying the accuracy of ΔE_m, we propose a verification micro-benchmark set $VMBS$ derived from MBS, where each micro-benchmark shows a more complex performance behavior.

Micro-benchmarks in $VMBS$ essentially perform a series of data movement operations and data calculation operations to simulate the real workload. We first construct two micro-benchmarks B_add and B_nop. They only loop the known number of add and nop instructions to evaluate the ΔE_{add} and ΔE_{nop}. Next, we add the *add* and *nop* instructions into the micro-benchmarks in MBS to finally construct $VMBS$ including 7 micro-benchmarks shown in Table 3. For example, B_L1D_list_nop is to add the *nop* instruction into B_L1D_list.

When running a micro-benchmark $v \in VMBS$, Eq. (1) is used to solve the estimated Active energy cost $\overline{E}_{active}(v)$ where we set the $E_{other}(v) = \Delta E_{add} N_{add}(v) + \Delta E_{nop} N_{nop}(v)$. We measure the real $E_{active}(v)$ and define the accuracy as

$$acc(v) = 1 - \frac{|\overline{E}_{active}(v) - E_{active}(v)|}{E_{active}(v)},$$

where $acc < 0$, set $acc = 0$. If the acc is closer to 1, the estimated energy cost is closer to the real energy cost, showing that the ΔE_m got by our approach is accurate.

Through the above effort, we have got all of ΔE_m ($m \in MS$). Next, we introduce how to measure the Active energy.

2.6 Active Energy Evaluation

Our experiments run on the server with an Intel i7-4790 processor (L1D cache size is 32KB, L2 cache size is 256KB and L3 cache size is 8MB), 32GB DDR3-1600 main memory and a 500GB SATA hard drive. Our processor is popular to enable that our results are representative. The operator system is Ubuntu 14.04 including Linux Perf, ocperf and RAPL (Running Average Power Limit)[10].

We leverage RAPL to measure the energy cost. RAPL counters are highly accurate on x86_64 and allow us to separately measure the energy cost of the core domain $E(core)$, the package domain $E(package)$ (including the core, L3 cache and memory controller) and the main memory domain $E(memory)$. We can run an only-blocked program (e.g., sleep 1) to use its RAPL's measurement values as the Background energy cost of three different domains per second when disabling idle states (i.e., C-states[7]). For workloads which do not access L3 cache and main memory, we observe the $E(core)$ as the Busy-CPU energy cost, such as B_L1D_list and B_L1D_array. For the workloads which do not access main memory, we observe the $E(package)$ as the Busy-CPU energy cost. For other workloads, we observe $E(package) + E(memory)$ as the Busy-CPU energy cost. E_{active} is Busy-CPU energy cost minus the corresponding Background energy cost.

2.7 Selection of CPU Frequency and Voltage

Our micro-benchmarks set is usually used to evaluate ΔE_m under the fixed CPU frequency and voltage. However, the real workloads widely run with the EIST knob turned on to balance the performance and energy. So, in this section we will profile the performance of TPCH query workloads when turning on EIST

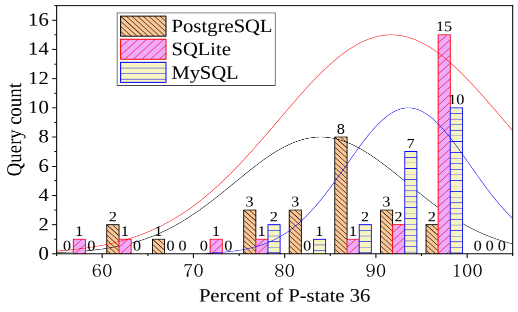


Figure 5: Query count distribution bars and the fitting distribution curves based on the percent of P-state 36.

Table 1: Runtime behaviors of micro-benchmarks

Micro-benchmarks	BLI	L1D miss%	L2 miss%	L3 miss%	IPC
B_L1D_list	98.9	0.01	-	-	0.26
B_L1D_array	99.5	0.01	-	-	2.02
B_L2	98.5	99.93	0.02	-	0.09
B_L3	98.6	98.68	99.98	0.01	0.03
B_mem	97.8	98.86	99.88	97.45	0.005
B_Reg2L1D	99.98	0.02	-	-	1.01
B_add	98.4	-	-	-	2.01
B_nop	99.87	-	-	-	3.99

Table 2: Energy cost of micro-operations at different CPU frequencies and voltages

P-state	36 (3.6GHz)	24 (2.4GHz)	12 (1.2GHz)
Micro-operations	Energy cost (nJ)		
ΔE_{L1D}	1.30	0.90 ↓	0.60 ↓
ΔE_{L2}	4.37	3.25 ↓	1.64 ↓
ΔE_{L3}, ΔE_{pf}^{L2}	6.64	5.91 ↓	5.33 ↓
ΔE_{mem}, ΔE_{pf}^{L3}	103.1	99.1 ↓	99.04 ↓
$\Delta E_{Reg2L1D}$	2.42	1.60 ↓	1.10 ↓
ΔE_{stall}	1.72	1.07 ↓	0.80 ↓
ΔE_{add}	1.03	-	-
ΔE_{nop}	0.65	-	-

to identify their preference for CPU frequency and voltage. That can help us evaluate a more reasonable ΔE_m.

EIST usually sets the CPU into different states to save energy[1], including C-states and P-states[7]. C-states are idle states {C0, C1, C2, ...}. C0 means the CPU non-idle and others mean that the CPU enters an idle state with different energy-saving levels. C0 can be further subdivided into different P-states. So, P-states can be called as operational states. Each P-state also has a different energy-saving level. We focus on P-states due to the profiling of Active energy cost. In truth, a P-state is both a frequency and voltage operating point. For the high CPU load, a high-performance P-state might be set, and vice versa. Intel i7-4790 includes 29 candidate P-states. CPU frequency of each P-state differs by 100MHz.

[1]The modern processor frequency can be separated into (1) core frequency involving ALU, L1 cache, L2 cache and etc, and (2) uncore frequency involving L3 cache, memory controller and etc. In this paper, the CPU frequency means core frequency. The uncore frequency in Intel i7-4790 will dynamically match the CPU frequencies.

Table 3: Energy cost of verification micro-benchmarks and the accuracy

Verification micro-benchmarks	$\bar{E}_{active}$ (J)	E_{active} (J)	*acc*%
B_L1D_list_nop	129.34	122.04	94.36
B_L1D_array_add	169.85	150.71	88.73
B_L2_nop	122.01	125.57	97.08
B_L3_add	215.37	224.16	96.07
B_mem_nop	396	345.37	87.22
B_L1D_list_L2	168.29	158.26	94.01
B_L1D_list_nop_add	193.06	186.94	96.83

The highest P-state is 36 (3.6GHz CPU frequency) and the lowest is 8 (800MHz CPU frequency).

In this experiment, we turn on the EIST knob and set the P-state range from 8 to 36. Our purpose is to analyze the P-state preference of query workloads. We use 22 TPCH queries [8] to benchmark PostgreSQL, SQLite and MySQL with baseline configuration and baseline data size (more detailed instructions in Section 3) and sample the runtime P-state per 100 milliseconds. According to the percent of P-state 36, Figure 5 shows query count distributions of three database systems. We find that most of queries tend to run at P-state 36, due to the high CPU load (average 96% CPU usage). So, we will fix the CPU at P-state 36 in the following trunk experiment. We also evaluate the impact of other P-states on our results in Section 3.5.

2.8 Results of Micro-Benchmarks

We turn off these knobs which will lead to measurement errors shown in Section 2.5.3, fix the CPU at P-state 36 and specify all workloads to run on the core CPU0. For B_L1D_list, B_L1D_array and B_Reg2L1D, we allocate the memory size as 31KB; for B_L2, allocate 260KB; for B_L3, allocate 6MB and for B_mem allocate 60MB. These setups ensure that our micro-benchmarks only fetch data from the single memory layer under an acceptable latency.

Performance behaviors of micro-benchmarks. As shown in Table 1, BLI (Body-Loop Instruction%) is the percentage of the desired instructions in the main loop and IPC (Instruction Per Clock) is the number of instructions per cycle. For BLI, 98.9% instructions of B_L1D_list is to load data from L1D cache. For other micro-benchmarks, this metric also has a good performance, showing that our micro-benchmarks have little noise instructions. In addition, our micro-benchmarks can provide the specific performance behavior. For B_L1D_list, L1D miss rate is only 0.01%, showing that it always only accesses the L1D cache. Even for B_mem, it can still skip out of cache memory and load data from main memory with a hit rate 97.45%. Especially, IPC shows the CPU stall status. For B_L1D_array, IPC is 2.02 showing that CPU is always busy and no stall. However, IPC=0.26 for B_L1D_list shows that 4 cycles are required to execute a load operation. For B_Reg2L1D, IPC is 1.01 and the number of L1D store instructions are 98.37% of all instructions, showing that CPU always executes 1 store instruction per cycle. These results reveal that our benchmarks can work properly with specific performance behaviors.

Evaluation of ΔE_m. According to E_{active} of micro benchmarks and energy models in Section 2.5.4, we give the energy cost of micro-operations in Table 2. The unit of energy cost is Nanojoule. For the load operation the data is closer to the CPU causing the energy cost to be lower. Especially for ΔE_{L1D}, it is

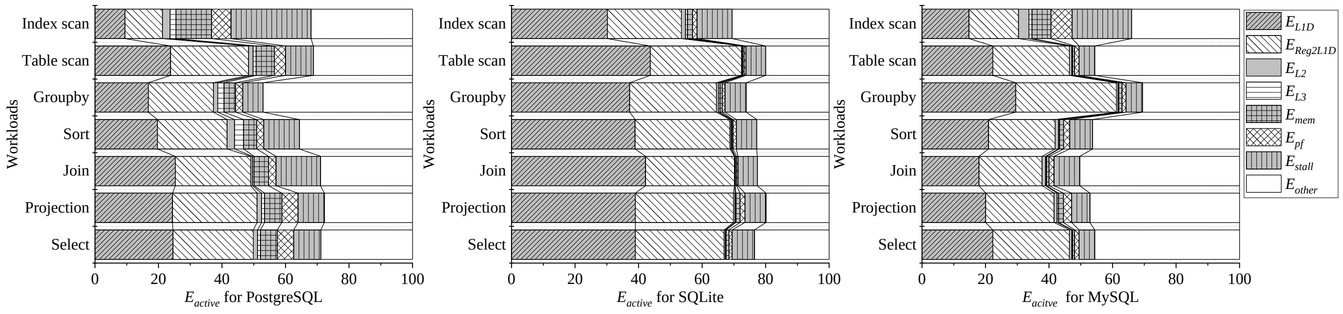

Figure 6: Active energy cost breakdown of the basic query operations for three different database systems.

the lowest than other load operations. Oppositely, loading from the main memory will get a high energy cost penalty. Actually, it explains that why improving cache hit rate can improve both the performance and energy-efficiency.

Verification of ΔE_m. We use the verification method in Section 2.5.5 to evaluate the accuracy of ΔE_m. In Table 3, we give the real Active energy cost and the estimated Active energy cost and the accuracy. The unit of energy cost is Joule. The average accuracy is 93.47%. Even for the most complex B_mem_nop, the accuracy is still high. It shows that ΔE_m proposed by us is accurate enough to break down the energy cost of real workloads.

3 ENERGY COST DISTRIBUTION OF QUERIES

In this section, we use ΔE_m to break down the energy cost of query workloads implemented on the real database systems. We use the PostgreSQL-9.5.2, SQLite-3.14.2 and MySQL-8.0.13 as our analysis targets. We will deeply analyze the energy cost of 7 basic query operations and 22 queries in TPCH[8] with different data sizes and knob settings. We will compare the energy cost breakdown of queries with the typical CPU-bound workloads. In addition, we also show the impact of different P-states on the energy cost breakdown.

To avoid the random error, we disable the result display by updating the database kernels and run the workloads 100 times (10 times for long-running workloads). Finally, the average energy cost is got. We turn on the hardware prefetchers, specify all workloads to run on the core CPU0 and fix the CPU into P-state 36. In addition, the percent of the Background energy cost is 47.2%-51.7% of Busy-CPU energy cost in our experiments. Our main findings are summarized as follows.

- 77.7%-89.2% of Busy-CPU energy cost can be broken down into the energy cost of data movement and the Background energy cost. The energy cost of data movement (7 micro-operations in *MS*) is 55%-76.4% of Active energy cost.
- $E_{L1D} + E_{Reg2L1D}$ is 39%-67% of Active energy cost, identified as the energy bottleneck. This phenomenon does not appear in the typical CPU-bound workloads. In addition, it is little affected by the data size, the database setting and CPU frequency and voltage.
- The sequential scanning in query workloads is the major reason that leads to this energy cost pattern.

3.1 Experimental setup

We take our experiments with 100MB (baseline), 500MB and 1GB data. In addition, each database system has many configurable knobs. We investigate them and tune two important knobs that also have similar roles in three database systems. In Table 4, we give three kinds of database settings to limit the memory usage. The resource size provided to three database systems at each setting is approximate. The `small` setting looks stringent and the `large` setting is relaxed.

Table 4: Knob settings for three database systems

Database systems	Knobs	Small	Baseline	Large
PostgreSQL	Shared_buffers	8MB	128MB	1024MB
	Work_mem	4MB	64MB	512MB
SQLite	Cache_size	2000	16000	65000
	Page_size	4KB	8KB	16KB
MySQL[1]	Inbuffer_size	8MB	128MB	1024MB
	Inpage_size	4KB	8KB	16KB

3.2 Energy Cost of Basic Query Operations

We profile the energy cost of 7 basic query operations with the baseline data size on the baseline setting. 77.7%-89.2% Busy-CPU energy cost can be broken down into the energy cost of data movement and the Background energy cost, showing that our energy breakdown approach can work well on database systems. Figure 6 gives the breakdown of E_{active}. The energy cost of data movement is 68.1% for PostgreSQL, 76.4% for SQLite and 56.8% for MySQL, becoming dominant. For the three database systems, the energy cost distribution is similar, and much energy is consumed in L1D cache load/store. $E_{L1D} + E_{Reg2L1D}$ is 41.6% for PostgreSQL, 66.6% for SQLite and 43.4% for MySQL. So, we can think that this phenomenon could be general for most of relational database systems.

L1D cache load. Actually, we can easily explain why the percent of E_{L1D} is high. In the database systems, almost all of the query operations is based on sequential scan. Even if segmentation or paging strategies are used to manage data, each data block is big enough to fit the CPU cache to ensure a good data locality. So, the modern CPU architecture can ensure most of data to be loaded at L1D cache when sequentially scanning. For example, L1D hit rate of 7 basic query operations is 97.74% and IPC of the complex `join` operator is 1.85, showing good data locality.

L1D cache store. In addition, the reason why the energy cost of L1D cache store is high is because the query workload will generate many temporary data, such as temporary storage of intermediate data and output stream. These temporary data are

[1]For MySQL knobs, `inbuffer_size` is short for `innodb_buffer_pool_size` and `inpage_size` is short for `innodb_page_size`.

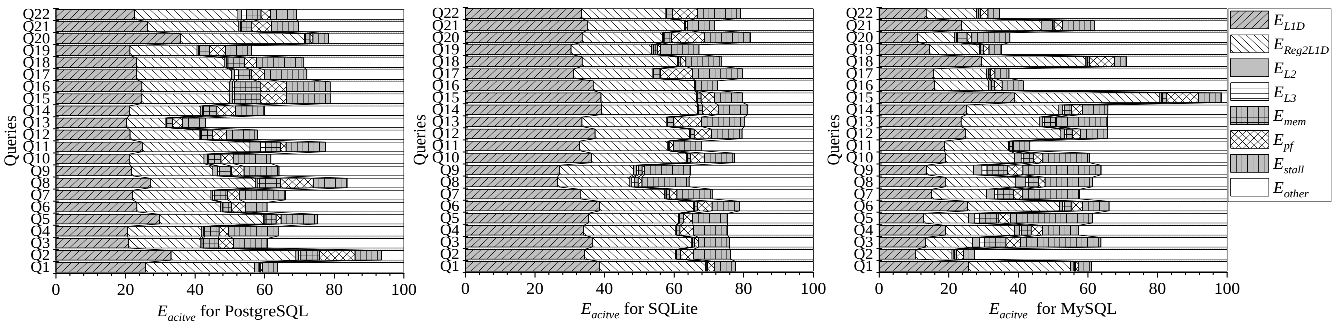

Figure 7: Active energy cost breakdown of TPCH for three different database systems.

written in L1D cache but they little have to be persisted due to the write-back strategy. In our experiment, the store operations are frequently issued by 7 basic query operations, being about 66% of the load operations but 99.86% of them occur at L1D cache.

In summary, although the implementation of three database systems has impact on the energy cost distribution, L1D cache load/store is still their energy bottleneck. In addition, the query workload is read-only operation, but the energy cost of temporary data write is still high.

3.3 Energy Cost of TPCH

We profile the energy cost of TPCH with the baseline data size on the baseline setting. 79.2%-88.7% Busy-CPU energy cost can be broken down. As shown in Figure 7, the energy cost of data movement is 65% for PostgreSQL, 75% for SQLite and 55% for MySQL. In addition, the energy cost distributions of three database systems are similar. The percent of E_{L1D} + $E_{Reg2L1D}$ is so attractive, 46.8% for PostgreSQL, 60% for SQLite and 38.6% for MySQL. The phenomenon is like it in basic query operations because complex queries are the combination of basic operations.

Sequential scanning. For SQLite, the percent of E_{L1D} + $E_{Reg2L1D}$ is higher than that of two other database systems either in the TPCH or the basic query operations because SQLite tends to the sequential scanning. Actually, the energy cost of sequential scanning prefers to L1D cache. We take an example to illustrate the relationship between sequential scanning and the energy cost of L1D cache. As shown in Figure 6, the difference of both index scan and table scan is scan table using the index (B tree) or not. Obviously, index scan utilizes the pointer chasing to reorganize data causing the relatively weak data locality. Table scan tends to the sequential scanning. Without exception, the percent of E_{L1D} + $E_{Reg2L1D}$ reduces and the percent of E_{stall} increases for index scan compared with table scan.

Similarly, SQlite as the mobile database is usually used to manage the small-scale data so that it does not involve many complex optimization strategies, such as the hash join. The main data access method is sequential scanning. It is reasonable because the hardware optimization is more important than software optimization for the small-scale data. The sequential scanning is easily sped up by the hardware optimization, such as speculation and out-of-order execution. It will lead to the less stall cycles. For SQLite, the present of E_{stall} is 12% lower than two other database systems, showing the good performance of sequential scanning. For optimizing performance on large-scale data, we think that both PostgreSQL and MySQL may construct the complex data structure and reorganize the data, such as the compact buffer management. These optimizations can improve the performance, e.g., average 3.31× faster than SQlite in our experiment. However, they will introduce the extra calculations, and they also hinder hardware optimization due to the weak data locality, leading to the low percent of E_{L1D} + $E_{Reg2L1D}$.

Impact of data size. We evaluate the energy cost distributions of three database systems with different data sizes (100MB, 500MB and 1GB) on the baseline setup. As shown Figure 8, we only illustrate the average energy cost result of 22 queries in TPCH as a vector due to the space limitation and PG is short for PostgreSQL. As the data size increases, the energy cost distributions of three database systems have not changed significantly. We also analyze the energy cost change of every query and find that E_{stall} of 14% queries is improved by 2× when increasing the data size. The large data size may lead to frequent swapping in and out of data pages and CPU stall. In general, the L1D cache load/store is still the energy bottleneck which is hardly affected by the data size.

Impact of different settings. As shown in Figure 9, we also compare the impact of different database settings being from Table 4. For MySQL, E_{stall} is reduced when the *large* setting provides more memory to fit data pages but PostgreSQL and SQLite are not sensitive to different settings. It still suggests that different settings have little impact on the energy cost distribution.

In summary, sequential scanning is the basic behavior of query workloads. For different database system implementations, the dependency of sequential scanning affects the energy allocation for L1D cache. Data size and database settings do not lead to substantial changes in this energy cost distribution. So, our findings could be general for query workloads of database systems.

3.4 Comparison to CPU-Bound Workloads

With the optimization of database systems and the performance improvement of the disk, the database system has tended to be CPU-bound from disk-bound. For example, CPU usage is 96% and IPC=1.9 showing a busy CPU, when running TPCH in our experiment. In this section, we compare the energy cost distributions of query workloads with the energy cost distributions of typical CPU-bound workloads. As shown in Figure 10, we evaluate the energy cost of 9 workloads in the classic CPU benchmark CPU2006-v99[2], involving the compression, compiling and simulation workloads, etc. Not like the query workloads, the energy cost distributions of typical CPU-bound workloads are not similar to each other. For three database systems, the percent of E_{L1D} + $E_{Reg2L1D}$ of 76% queries is greater than 40%, but the percent is only 11% for CPU2006. For some extreme CPU2006 workloads (Mcf and Libquantum), E_{L1D} + $E_{Reg2L1D}$ is so low at only 5.6%, but this behavior does not occur in query workloads.

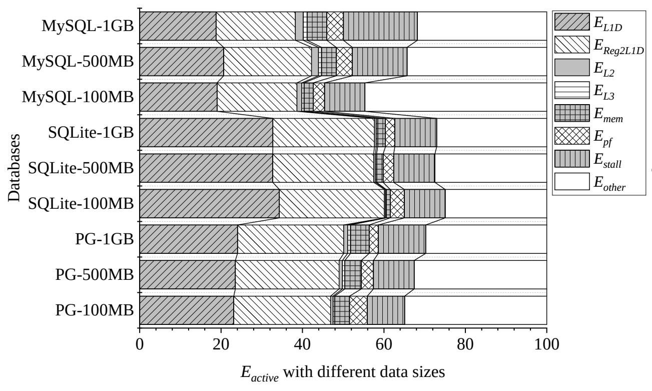

Figure 8: Impact of data size.

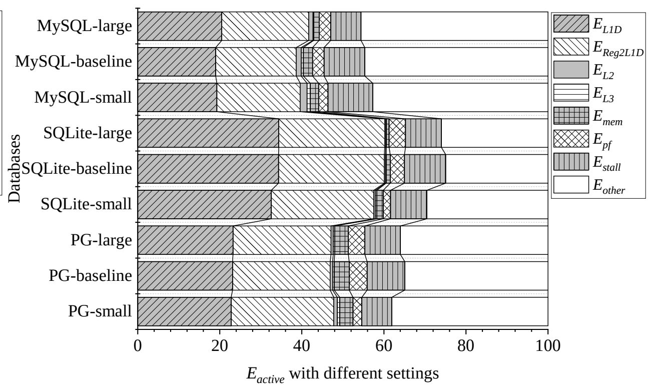

Figure 9: Impact of database setting.

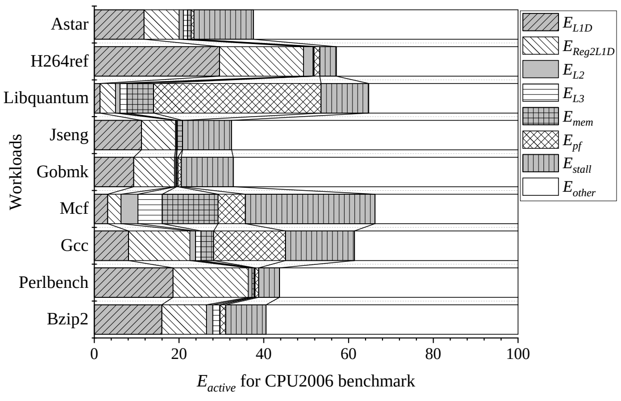

Figure 10: Energy cost breakdown of CPU2006.

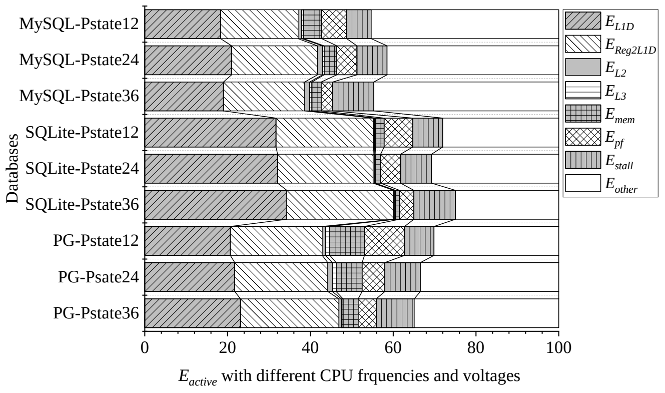

Figure 11: Impact of CPU frequencies and voltages.

In summary, we think that the energy cost pattern of query workloads is totally different from the typical CPU-bound workloads and it could be unique to query workloads.

3.5 Impact of CPU Frequency and Voltage

In the real scenario, the EIST knob is usually turned on, so that we in this section explore the impact of different CPU frequencies and voltages on the energy cost breakdown. We select two other P-states: P-state 24 and P-state 12 to first evaluate energy cost of micro-operations and then break down energy cost of three databases under baseline knob settings and baseline data size.

As shown in Table 2, the energy cost of micro-operations under low P-states will definitely reduce. The closer the micro-operation is to the CPU core, the more significantly the energy cost decreases. For example, ΔE_{L1D} reduces by 53.8% from P-state 36 to P-state 12, but 3.9% for ΔE_{mem}.

As shown in Figure 11, we compare the energy cost breakdown of three databases at different P-states. In our experiment, E_{active} decreases by 32%±2% at P-state 24 and 51%±1% at P-state 12, but the energy cost breakdown has little impact due to the lower energy cost of micro-operations. In detail, because ΔE_{mem} has little change at different P-states, the percent of both E_{mem} and E_{pf} (involving main memory accessing) have a significant improvement at P-state 12, about 2× and 2.2 × compared with P-state 36. However, the absolute impact is still little. Actually, different P-states cannot change the query runtime characteristics, so that the L1D cache load/store hit rate is still high, only leading to the slight reduction of the percent of $E_{L1D} + E_{Reg2L1D}$ at low P-states. For example, the percent of $E_{L1D} + E_{Reg2L1D}$ at P-state 12 only decreases by 4%-8.6% for three databases, compared with it at P-state 36. Our result shows that the L1D cache load/store operations are still the energy cost bottleneck at different CPU frequencies and voltages.

In essence, this experiment reveals the energy cost profiling for typical query runtime characteristics at different CPU frequencies and voltages. For other query scenarios, the CPU could not always be at the high P-state when turning on the EIST knob, such as real-time query workloads. However, their runtime characteristics should be similar to those shown in this paper. So, we think that this energy cost bottleneck could be general for many query scenarios even if turning on the EIST knob.

In summary, the low CPU frequency and voltage will lead to the low energy cost of micro-operations, but the L1D cache load/store operations are still the energy cost bottleneck.

4 PROOF-OF-CONCEPT SYSTEM

In the section, we will discuss the customized CPU architecture design which can enable the energy-efficient database systems. The optimization and evaluation on SQLite will be given.

4.1 L1D Energy-Efficient CPU Architecture

L1D cache load/store is the energy bottleneck, but their optimization is difficult on typical x86_64 architecture because L1D cache has the lowest energy cost than other memory layers.

For database systems, a good energy-efficient CPU architecture should provide the lower energy cost L1D cache (i.e., Arch

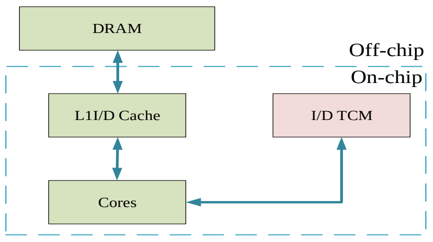

Figure 12: ARM1176JZF-S architecture as an L1D energy-efficient CPU architecture.

1) or provide a piece of the low energy cost memory at the same speed as L1D cache (i.e., Arch 2). For Arch 1, users can transparently migrate the database systems on it. For Arch 2, users need to update the kernel of database systems to decide what data to put into the low energy cost memory. We investigate many CPU architectures and only find the architecture similar to Arch 2. As shown in Figure 12, ARM1176JZF-S[1] supports 16KB L1D cache, 32KB DTCM (Data Tightly Coupled Memory) and 256MB main memory. TCM is the programmable on-chip memory which is as fast as L1 cache but its energy cost is lower than L1 cache. So, ARM1176JZF-S could be as an L1D energy-efficient CPU architecture. In this section, we will use the DTCM load instead of the L1D cache load to reduce Busy-CPU energy cost.

4.2 System-Level Co-Design

We will optimize SQLite because, as a mobile database it can work well on ARM architecture, but the optimization is still difficult. First, although Linux supports many hardware environments, it cannot be directly compiled in this ARM environment. The ARM hardware environments are so diverse that Linux can only identify some mainstream architectures and it does not support ARM1176JZF-S well. We have to modify and update Linux kernel to make it support TCM, Linux perf and cross compiling. Second, we have to implement the TCM driver and API enabling that TCM can be accessed in user space. It took us about 2 months to build an available runtime environment. For SQLite, our optimization strategies are as follows.

Database buffer. We allocate 16KB DTCM for database buffer, which will be dynamically managed by SQLite.

Special variables. We use the Linux perf to profile the SQLite's runtime and find that about 70% L1D cache load operations are issued by the `sqlite3VdbeExec()` function to execute the query plan. This phenomenon in x86_64 architecture is similar to it in ARM architecture. We allocate 4KB DTCM and put some key structures of `sqlite3VdbeExec()` in it, such as query plan (`Vdbe`), meta data (`Vdbe->db`), cursor (`Vdbe->apCsr` and `Vdbe->apCsr->aOffset`), head address of heap space (`Vdbe->aOp` and `Vdbe->aMem`), etc.

B tree. Every table in SQLite is organized as a B tree. The primary key or row ID will be the key of B tree. So, the top layers of B tree will be frequently read. Based on this, we allocate 12KB DTCM to put the root and first few layers of B-tree of current tables into DTCM. We divide DTCM memory evenly according to the number of tables being queried. In this way, we can ensure that more B tree data of small tables are loaded into DTCM.

Noting that our strategies are for L1D cache load operation. The energy cost optimization of L1D cache store operation is more difficult. We do not discuss it in this paper.

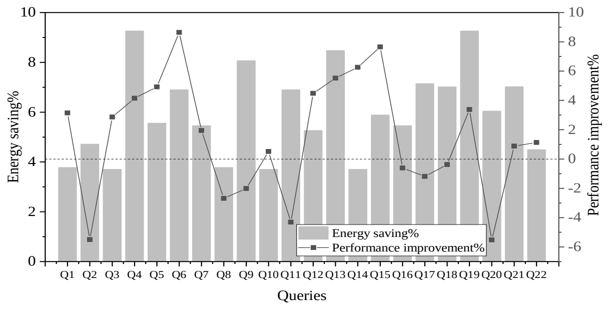

Figure 13: Energy saving and performance improvement for SQLite using DTCM or not on ARM1176JZF-S.

4.3 Evaluation Results

ARM does not support RAPL, so that we use the external power meter to measure the energy cost. We first design a micro benchmark B_DTCM_array, which only loads data from DTCM. It is similar to Algorithm 1 but allocates memory from DTCM, instead of main memory. Compared with B_L1D_array, the energy cost of B_DTCM_array can reduce by 10% with no performance loss. Therefore, 10% will be as the peak energy saving of DTCM in our experimental environment.

In Figure 13, we show the energy saving and performance improvement of the optimized SQLite. Noting that we compare whether SQLite uses DTCM on ARM, not SQLite on Intel CPU or ARM CPU. We use 10MB TPCH data and the `small` setting to take our experiment. Our optimization makes SQLite save average 6% energy and improve average 1.5% performance. It means that our approach can achieve 60% of the peak energy saving. The dominant factor is that accessing the hot data in DTCM can bypass the L1D cache leading to L1D cache energy saving. In addition, the performance of 64% queries can be further improved due to the avoidance of hot data misses. For the non-optimized SQLite, 25% L1D miss rate in ARM1176JZF-S could cause the hot data to swap in and out the L1D cache from main memory. However, DTCM has the fixed physical address, so that the hot data in DTCM is not loaded from main memory.

Advantages. Limited to the hardware implementation, 6% energy saving in our experiments may seem to be less, but our approach has three advantages as follows. First, compared with the existing approaches, our approaches can save energy with no performance reduction. It is advantageous for energy-strict real-time tasks, such as UPS-powered data centers and databases in smart phones. Second, our approach is orthogonal to existing approaches. Our approach tends to save energy from the view of CPU architecture, so that it can work together with application-level energy optimization approaches, such as energy-oriented query optimization and DVFS-based approaches. Third, our approach is depend on the implementation of TCM. So, these results in our paper only suggest that our approach can achieve 60% of the peak energy saving, and do not mean the final energy-saving potential. The existing work shows that the optimized TCM has got 40% energy saving compared with L1D cache[9]. If integrating such an optimized TCM into ARM1176JZF-S, our approach should get a maximum 24% energy saving.

In summary, our optimized SQLite can achieve 60% of the peak energy saving. It can also achieve 1.5% performance improvement due to the avoidance of hot data misses.

Table 5: Energy cost bottleneck of B_mem at different CPU frequencies and voltages

P-state	36 (3.6GHz)	24 (2.4GHz)	12 (1.2GHz)
Micro-operations	Energy cost (J) / Percent%		
E_{mem}	295.4 (16.6%)	284.2 (29.8%)	284.6 (47.4%)
E_{stall}	**1416.1 (79.8%)**	**630.6 (66.2%)**	**310.1 (51.6%)**
E_{active}	1772.5 (100%)	952.9 (100%)	600.5 (100%)

5 POTENTIAL OPTIMIZATIONS

Based on the Busy-CPU energy breakdown results, we also find some additional interesting energy cost phenomena in Figure 6 and 7 that suggests other optimization approaches.

In index-intensive scenario, especially for index scan of PostgreSQL and MySQL, the percent of both E_{mem} and E_{pf} becomes prominent, also causing a high E_{stall}. Similar phenomenon can also be seen in PostgreSQL's basic query operations compared with them of two other database systems. In addition, as the data size increases, the main memory access is also more frequent, especially for MySQL. They imply a memory-bound tendency. In this section, we will focus on the energy cost optimization of memory-bound workloads. Actually, we think that improving main memory performance or radically lowering CPU frequency and voltage are efficient ways to save energy.

To explain our idea, we first profile the energy cost of a typical memory-bound workload under different CPU frequencies and voltages. The micro-benchmark B_mem is a typical memory-bound workload and we break down its energy cost shown in Table 5. Interestingly, such a slight change to ΔE_{mem} does not imply that the low P-state will cause the energy cost to increase for memory-bound workloads, although the elapsed time may be increased. Actually, B_mem's performance bottleneck is main memory, the energy cost bottleneck is the CPU (E_{stall}, not E_{mem}). This result suggests that the energy cost bottleneck is in the CPU, even if for non-CPU bound workloads. So, the ultra-linear decrease in E_{stall} causes a reduction in E_{active} with slight performance loss. For example, B_mem only trades 7% performance loss for 46% E_{active} saving when lowering P-state from 36 to 24. The energy-efficiency ($\frac{Perf}{Energy}$)[14] is improved by 70%. In addition, EIST cannot work well on memory-bound workloads. When turning on the EIST knob, the percent of P-state 36 is 98.6% due to the high CPU load (99.8% CPU usage), implying failure of dynamic energy saving.

Actually, for memory-bound query scenarios, an energy-saving chance is to reduce E_{stall}. Improving main memory performance tends to reduce N_{stall} or radically lowering CPU frequency and voltage tends to reduce ΔE_{stall}. We take a preliminary experiment on PostgreSQL's index scan to confirm the second approach. When lowering P-state from 36 to 24, PostgreSQL's index scan only trades 20% performance loss for 27% E_{active} saving, showing that the energy-efficiency is improved by 10%. However, our strategy is not trivial. PostgreSQL's table scan, a CPU-bound workload, has to trade 30% performance loss for 28% E_{active} saving, i.e., the energy-efficiency is reduced by 3%. So, a customized DVFS approach is expected for memory-bound query scenarios. It should analyze the query plan, such as index-intensive or not, and monitor the main memory access to employ a more radical DVFS strategy.

The percent of MySQL's E_{other} is higher than that of two other databases, especially for basic query operations, so that energy-efficient calculation components or instruction-related components, e.g., instruction TCM (ITCM), should be considered.

6 RELATED WORK

Energy characterization and optimization in database systems is the basic work to design an energy-efficient database systems. There are extensive researches on this topic from different aspects, including (1) macro energy cost breakdown, (2) trade-off based energy optimization and (3) employing TCM. However, we take a micro analysis of the Busy-CPU energy cost of database systems and then provide a customized CPU architecture to enable the energy-efficient database systems.

Macro energy cost breakdown. The energy-efficient database design is systematically reported in [14]. From then on, the researchers had made much effort to make sense of its energy bottleneck. Research work focuses on the breakdown of the energy cost of the major resources, i.e., the CPU, main memory and disk, on various of system architectures. For the classic x86_64 architecture with local disk, the CPU is identified as the energy cost for disk-based database systems[19, 25] and in-memory database systems[13]. For the architecture of ARM+RDRAM (Rambus DRAM), the main memory is identified as the bottleneck[23]. For the system with the remote disk array, the disk is the energy bottleneck[24]. These above conclusions are difficult to explain whether the power is consumed by the database system or by the hardware itself because the measurement of the total energy cost contains the Background energy cost and Idle-CPU energy. Our work divides the Busy-CPU energy cost into the Active energy cost and the Background energy cost, and only profile the Active energy cost which is consumed by database systems. In addition, the existing work focuses on the macro energy breakdown of major resources. However, the main drawback is that they cannot give the clear optimization suggestions on hardware architecture due to the lack of the fine-grained information. We study the micro energy analysis inside CPU and have the ability to make sense of microscopic energy cost distribution. It is helpful to design the CPU architecture for energy-efficient database systems.

Trade-off based energy optimization. For the x86_64 architecture, the CPU has been identified as the energy bottleneck for database systems. Because the energy cost distribution inside the CPU is unknown, the existing work sees the CPU as an inseparable whole to design the energy-oriented query optimizer or tune the external DVFS knobs. Inspired by the performance-oriented query optimizer, PET [28, 29] as an energy-aware query optimization constructs a cost model to choose the low-energy query plans under a DBA-specified energy/performance trade-off level. QED [21] uses query aggregation to leverage common components of queries to reduce energy cost. These query optimization techniques are used to gracefully trade response time for energy. DVFS knobs can be configured by users to trade the voltage and CPU frequency for energy. It provides the chance to optimize the energy. PVC[21] and sweet spots[13] attempt all of combinations between the voltage and CPU frequency for a specific workload to choose one combination which can minimize the energy cost. Their drawback is hard to apply to all queries. Other approaches leverage feedback-control loops to dynamically set DVFS knobs using the load profile and can obey a query latency limit as a soft constraint. Based on this idea, lots of work has achieved the adaptive energy control for various of databases, such as the disk-based transaction-oriented DBMS [20, 26, 30] and data-oriented in-memory DBMS [19]. In order to get a good energy-saving effect, these techniques expect a relaxed run-time constraint, so that they in essence trade the performance for the energy. Through our micro analysis of the Busy-CPU energy cost, we have found the micro-operation level energy bottleneck. With the help of the L1D cache energy-efficient CPU architecture, we can cut down the energy cost of database systems with slight performance improvement.

Employing TCM. TCM as on-chip memory is usually used for performance improvement by combining the micro performance feature of applications, such as digital signal processing[12], MapReduce framework[16] and embedded multi-media[15]. However, we attempt to use TCM to reduce the energy cost, combining the micro energy feature of database systems. The main idea of our optimization is to put the hot data into TCM to save the energy. The similar idea for TCM has appeared. They at compile-time analyze a given piece of program, identify the hot data and put them into TCM at runtime to reduce the energy cost of data movement, such as a SPM management framework for nest-loop[17], a data program relationship graph for global and stack variables[27] and heap data[11]. Facing the complex database systems, these program-level optimization methods under specific premises may not work. Actually, our optimization is system-level. We profile the runtime behavior of database system, review its source code and elaborately identify the hot data. Although the optimized SQLite is only a proof-of-concept system, it confirms that our method is feasible. Providing the customized CPU architecture is a possible way to enable energy-efficient database systems.

7 SUMMARY & FUTURE WORK

In this paper, we propose a novel idea to reduce the energy cost based on profiling the energy cost of CPU micro-operations for databases systems. Our approach can break down the majority of Busy-CPU energy cost and isolate the accurate energy cost of data movement. The CPU energy breakdown method exposes that L1D cache load/store is the energy bottleneck of database systems. The finding supposes that we may achieve energy efficiency by adopting a customized CPU architecture with lower L1D energy cost. TCM can meet this requirement well and an optimized system-level co-design solution for SQLite is implemented to evaluate the proposed idea. The experimental result of the proof-of-concept system shows that our method can achieve 60% of the peak energy saving with further performance improvement.

In future, we will try to profile the energy cost of other typical database systems, such as NoSQL systems to identify their energy distribution feature on CPU and check if our method can be employed into more type of database systems.

ABSTRACT

Distributed database systems partition the data across multiple nodes to improve the concurrency, which leads to higher throughput performance. Traditional concurrency control algorithms aim at producing an execution history equivalent to any serial history of transaction execution. Hence an agreement on the final serial history is required for concurrent transaction execution. Traditional agreement protocols such as Two-Phase-Commit (2PC) are typically used but act as a significant bottleneck when processing distributed transactions that access many partitions. 2PC requires extensive coordination among the participating nodes to commit a transaction.

Unlike traditional techniques, deterministic concurrency control techniques aim for producing an execution history that obeys a pre-determined transaction ordering. Recent proposals for deterministic transaction processing demonstrate high potential for improving the system throughput, which had led to their successful commercial adoption. However, these proposals do not efficiently utilize and exploit modern computing resources and are limited by design to conservative execution.

In this paper, we propose a novel distributed queue-oriented transaction processing paradigm that fundamentally re-thinks how deterministic transaction processing is performed. The proposed paradigm supports multiple execution paradigms, multiple isolation levels, and is amenable to efficient resource utilization. We employ the principles of our proposed paradigm to build Q-Store, which is the first to support speculative execution and exploits intra-transaction parallelism efficiently among proposed deterministic and distributed transaction processing systems. We perform extensive evaluation against both deterministic and non-deterministic transaction processing protocols and demonstrate up to two orders of magnitude of improved performance.

1 INTRODUCTION

Distributed transaction processing is challenging due to the inherent overheads of costly commit protocols like *2-Phase-Commit* (2PC) [13]. Even for use cases such as in-memory databases and stored-procedure-based transactions, 2PC is either used (e.g., [24, 25, 46]) or avoided by eliminating the processing of multi-partitioned transactions (e.g., [27, 28]). Note that 2PC by itself does not ensure serializable transaction processing, and it requires a distributed concurrency control protocol to guarantee serializability. Traditional concurrency control protocols may abort active distributed transactions non-deterministically to

ensure serializable transaction processing. When such abort decisions are coupled with 2PC, the cost of the distributed transaction processing is further increased because of the overhead of rollbacks and restarts.

Deterministic databases [12, 40] reduce the cost of committing distributed transactions by imposing a single order on executing a batch of transactions prior to actual execution. By ensuring the same pre-execution ordering, deterministic database systems eliminate the need to abort transactions for violating serializability guarantees (in optimistic concurrency control), avoiding deadlocks (in pessimistic concurrency control), or node crash failures.

Unfortunately, the state-of-the-art designs of distributed deterministic databases suffer from other inefficiencies. We identify three of these inefficiencies that limit their performance and scalability. First, they rely on single-threaded pre-execution sequencing and scheduling mechanisms which cannot exploit multi-core computing architectures and limit vertical throughput scalability [20]. Second, they mostly support a conservative (non-speculative) form of transaction execution. One exception is the work by Jones et al. [24], which performs speculative-execution only for multi-partition transactions but limits the concurrency for single-partition transactions (a property inherited from H-Store's design). Third, they follow a thread-to-transaction assignment which limits intra-transaction parallelism [34, 35].

In this paper, we propose a novel transaction processing paradigm of *queuing-oriented processing*, and describe Q-Store. Q-Store is built on the principles of queue-oriented paradigm, which provides a unified abstraction for processing distributed transactions deterministically and does not suffer from the inefficiencies such as lower utilization of cores. Furthermore, it admits multiple execution paradigms (i.e., *speculative* or *conservative*) and multiple isolation levels (i.e., serializable isolation or read-committed isolation) seamlessly, unlike existing proposals of the deterministic database. It is important to note that several existing non-deterministic database systems already support multiple forms of isolation levels (e.g., [22, 30, 33, 37, 38]).

Our *queue-oriented* transaction processing paradigm can efficiently utilize the parallelism available with commodity multi-core machines by maximizing the number of threads doing useful work. Q-Store processes batches of transactions in two multi-threaded yet deterministic phases of *planning and execution*, as shown in the right side of Figure 1. Each phase utilizes all available computing resources efficiently, which improves the system's throughput significantly. The planning phase is carried out by multiple *planning-threads*, delivering maximum CPU utilization. Planning-threads generate queues of transaction operations that require minimal coordination among *execution-threads*. These queues are executed by execution-threads that are assigned to different cores to maximize cache efficiency. Each execution-thread is assigned one or more queues for execution. In other words, these queues constitute a schedule for executing transnational operations of a batch of transactions. Any coordination among execution-threads is performed via efficient and distributed lock-free data structures. In particular, we make the following contribution, in this paper.

- We propose a novel queue-oriented transaction processing paradigm that facilitates distributed transaction processing and unifies local and remote transaction processing in a single paradigm based on pre-determined priorities of queues. Our proposed paradigm supports multiple execution paradigms and multiple isolation levels and leads to implementation of efficient transaction processing protocol (Section 3).
- We present a formalization of our proposed paradigm and prove that it produces serializable histories to guarantee serializable isolation. We also formally show how our paradigm can support read-committed isolation seamlessly (Section 4).
- We design and build Q-Store, which is a distributed transaction processing system that relies on the principles of our proposed queue-oriented paradigm (Section 5).
- We present the results of an extensive evaluation of Q-Store. In our evaluation, we compare Q-Store against non-deterministic and deterministic transaction processing protocols using workloads from standard macro-benchmarks such as YCSB and TPC-C. We perform our evaluation using a single code-base, which allows us to conduct an apple-to-apple comparison against 5 transaction processing protocols. Our experiments demonstrate that Q-Store out-performs state-of-the-art deterministic distributed transaction processing protocols by up to 22.1×. Against non-deterministic distributed transaction processing protocols, Q-Store achieves up to two orders of magnitude better throughput (Section 6).

2 BACKGROUND

In this section, we give an overview of Calvin [40] as a representative for deterministic databases. As far as we know, Calvin is regarded as the state-of-the-art distributed deterministic transaction processing protocol, and has been commercialized [12]. Other deterministic transaction processing protocols are either designed for non-distributed environments (e.g., [9, 11, 35]) or a variation that improves parts of Calvin's protocol while re-using the remaining parts as-is (e.g., [44]). These proposals are covered in Section 7 in more details. We also briefly describe the transaction model used by Q-Store which adopts the same transaction model used by [35], which is in sharp contrast from Calvin's transaction model.

2.1 Transaction Processing in Calvin

This section gives a brief description of how Calvin works based on [40]. The basic processing flow requires 3 phases: a sequencing phase, a scheduling phase, and an execution phase with 5 sub-phases. Figure 1 (left), illustrate these phases.

Each node, in Calvin, runs a single sequencer thread, a single scheduler thread, and one or more worker threads. The sequencer thread forms batches of sequenced transactions. It uses a time-based demarcation of batches. Batches formed by different nodes are processed by scheduler threads in strict round-robin fashion. Scheduler threads use deterministic locking to schedule transactions that require the full knowledge of the read/write sets of transactions, which is similar to *Conservative 2PL* [8]. Unlike Conservative 2PL, Calvin ensures that conflicting transactions are deterministically processed according to their sequence number in the sequencing batch. For example, let t_a and t_b denote two conflicting transactions (i.e., cannot be scheduled to execute concurrently), and $seq(t)$ denote the sequence number of transaction t as determined by the sequencer thread. If $seq(t_a) < seq(t_b)$, then Calvin ensures that t_a is scheduled before t_b. Once locks on all the records are acquired by the scheduler thread, the transaction is ready for execution, and it is given to a worker thread for execution.

As Calvin is a distributed database system, each worker thread executes an assigned transaction in the following phases:

Phase 1 - Read/write set analysis: This phase is used to determine the set of nodes that are participating in the transaction. For this set, nodes that are executing at least one write operation are marked as active participants.

Phase 2 - Perform local read operations: This phase is performed by all participants if records are available locally.

Phase 3 - Serve remote read operations: Multicast records to active participants. This phase is the last phase performed by non-active participants. At this point, they can declare the transaction as completed and move to the next transaction.

Phase 4 - Collect remote read operations: This phase is performed by active participants only, and they need to wait for remote records before moving to the next phase. Hence, worker threads can postpone the active transaction (while waiting) and resume another transaction that is ready for execution.

Phase 5 - Execute transaction logic and perform local write operations: This phase is also performed only by active participants.

Discussion. The original Calvin paper by Thomson et al. [40] does not clearly describe how a transaction is committed (or aborted). However, by looking into the code-base of one of the implementations of Calvin from [20], which we ported to our test-bed, we discovered that the basic idea goes as follows.

The sequencer determines the participant nodes of every sequenced transaction by performing **Phase 1** from above. When a participant node completes its work on a transaction, it sends a one-way acknowledgment (ACK) message to the sequencer of the transaction. When the sequencer collects all ACK messages from all participants, it commits the transaction and sends a response message to the client of the transaction. Worker threads (that execute transactions) can re-use read/write set analysis performed by the sequencer thread to avoid needless computation.

2.2 Q-Store's Transaction Model

We adopt the same transaction model used by [35]. In this model, a transaction is broken into fragments. A fragment can perform

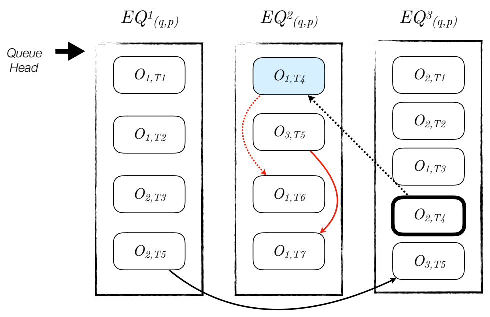

Figure 2: An example illustrating transaction dependencies in Q-Store. Execution-queues (EQs) are planned by planning-thread $PT_{(q,p)}$

Figure 3: System Architecture

multiple operations on the same record, such as read, modify, and write operations. A fragment can cause the transaction to abort, and in this case, we refer to such fragments as abortable fragments.

Furthermore, there are can be dependencies among fragments. In Figure 2, we illustrate these dependencies. There are 7 planned transactions in 3 execution-queues. Fragments are denoted as O_{i,T_j} where i denotes the fragment index in transaction T_j. We describe the notations in detail in Section 4.

Data dependencies exist when an operation in a fragment requires a value that is read by another fragment of the same transaction (solid black arrow between O_{2,T_5} and O_{3,T_5}).

Conflict dependencies exist between fragments from different transactions that access the same record, and the dependee fragment performs a write operation (solid red arrow between O_{3,T_5} and O_{1,T_7}).

Two kinds of commit dependencies exist between fragments. The first kind is concerned with fragments of the same transaction. In this case, a commit dependency exists between two fragments of the same transaction if the dependee is an *abortable* fragment (dotted black arrow between O_{2,T_4} and O_{1,T_4}). In this example, O_{2,T_4} is an abortable fragment. The second kind of commit dependencies, which we refer to as *speculation dependencies*, exist between fragments of different transactions. Tracking them is required when using the speculative execution paradigm. A speculation dependency exists between the two fragments when the dependent fragment reads speculatively uncommitted data written by the dependee fragment (dotted red arrow between O_{1,T_4} and O_{1,T_6}).

Discussion. It is worth noting that speculation dependencies are a realization of conflict dependencies. Tracking speculation dependencies is needed to ensure correct transaction execution with speculative execution. Note that, in Q-Store, conflict dependencies are not explicitly tracked during planning. It is possible to capture these during planning, but that would introduce additional overhead to the planning phase, which is undesirable.

3 TRANSACTION PROCESSING IN Q-STORE

In this section, we describe the novel and unique features of Q-Store. As far as we know, Q-Store is the first distributed deterministic transaction processing system to provide following features.

Efficient two-phase distributed processing model. In Figure 1, we show the critical differences between Calvin's processing model and Q-Store' processing model. On the left side (Calvin) of Figure 1, the total number of phases required to process a batch of transactions is 3 with the execution phase requiring 5 sub-phases. Note that the sequencing and the scheduling phases in Calvin are single-threaded. On the right side, Q-Store processes a batch of transactions in two multi-threaded phases of planning and execution. The execution phase does not include any sub-phases. Q-Store reduces the number of phases compared to Calvin (See Figure 1). Furthermore, Q-Store uses all available cores efficiently. All available threads work on the planning of a batch, then all of them work on execution.

Multi-paradigm execution. The design of Q-Store admits multiple execution paradigm. The processing of a batch of transactions can be speculative or conservative. Transaction isolation can be serializable or read-committed.

Queue-oriented processing. The planning phase in Q-Store abstracts the logical semantics of a transaction into prioritized queues of transaction fragments. Queues provide ordering for conflict fragments that seamlessly resolve conflict dependencies among fragments of different transactions. Therefore, threads during execution only deal with the other dependencies. Furthermore, queues can be implemented efficiently to ensure efficient execution and communication.

3.1 Queue-oriented Architecture

In Figure 3, we illustrate an example architecture of Q-Store, which consists of three server nodes. A client may send transactions that require access to multiple partitions, which we call multi-partition transactions. A client selects one of the server nodes for a given transaction and sends the transaction to the selected server. The role of the selected server is to coordinate the execution of the received transaction. Note that a server can be selected during the client session establishment, which allows mechanisms for load-balancing. Mechanisms for load-balancing include client-side libraries and middle-ware-based mechanisms. These details are beyond the scope of this paper.

Also in Figure 3, each node maintains a set of local *client transaction queues.* There is one client transaction queue per planner-thread to avoid contention. Planner-threads create fragments from transactions and capture dependencies, and create queues of fragments for each execution thread. Each planner-thread also updates the *Batch Meta-data* distributed data structure. The Batch Meta-data stores information about fragment dependencies, and execution-queues progress status. It is a globally shared lock-free distributed data structure that is used to facilitate minimal coordination among execution threads. In Figure 3, yellow arrows depict communication patterns during the planning-phase

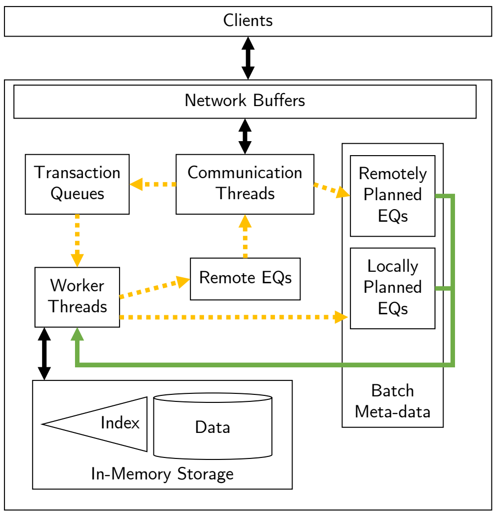

Figure 4: Server Node Architecture

while green arrows depict communication patterns during the execution-phase.

Zooming into a single node, Figure 4, we illustrate the major components of a server node. Similar to Figure 3, yellow and green arrows, depict communication during planning-phase and execution-phase, respectively.

Each server employs a set of threads to complete various tasks. We can broadly categorize threads into two sets: (i) *communication threads*, and (ii) *worker threads*. Q-Store employs communication threads to handle message transmission and reception among the servers and clients. They are also responsible for handling messages between server components and network buffers. They store client transactions in transaction queues, send and receive remote execution-queues (EQs), and apply updates to the batch meta-data.

Each worker thread may participate in either one or two phases: *planning* and *execution* (e.g., we can have dedicated worker threads for each phase). Hence depending on the phase, we refer to these worker threads as either *planning-threads* or *execution-threads*. We use $\mathbb{P}$ to represent the set of planning-threads and $\mathbb{E}$ to represent the set of execution-threads. The planning-threads take a set of transactions and generate *plans* to execute these transactions. The execution-threads execute transactions according to these plans.

3.2 Priorities in Q-Store

In Q-Store, we use the notion of priorities to impose order at various levels granularity. The concept of priority captures the ordering of queues and transaction fragments elegantly. Execution-threads need to respect these priorities to ensure the correct ordering of conflicting transactions. We have three different levels of granularity from the perspective of execution.

We formalize the notion of priorities by representing our distributed system as a set $\mathbb{S}$, which is the set of server nodes. We assign each server S_q a priority q, that is,

$$\mathbb{S} := \{S_1,\ S_2, ..., S_q\},\ \text{where}\ q \geq 1$$

Q-Store requires each server to associate a priority p with each of its planning-threads. Note that the planning-thread priority p differs from the server priority q. As each planning-thread also inherits the priority of its server, so each planning-thread has two associated priorities. Hence, we use the $P_{q,p}$ representation for a planning thread with priority p.

$$\mathbb{P}_q := \{P_{q,1},\ P_{q,2}, ...,\ P_{q,p}\},\ \text{where}\ q, p \geq 1 \quad (1)$$

Planning-threads create execution-queues for transactions and tag them with their priorities. The execution-queues created by a planning-thread constitute schedules of transaction fragments of the set of transactions processed by the planning-thread. Execution-threads execute fragments according to planned schedules while respecting the priorities of execution-queues in addition to checking and resolving dependencies among fragments.

3.3 Logging and Recovery

Q-Store like other deterministic transaction processing systems (e.g., [25, 40]) assumes a deterministic stored procedure based transaction model [1]. Within this model, all inputs of a transaction are available before this transaction can start execution. Therefore, the input of a batch of transactions is logged before they are delivered to execution-threads. Periodic check-pointing of the database state is used to reduce the time required for recovery in case of a failure. In this paper, we mainly focus on transaction execution as we can rely on the same techniques for logging and recovery as [25, 40].

4 FORMALIZING Q-STORE

We now formalize the planning and execution phases of Q-Store. Later in this section, we also prove that Q-Store transaction processing protocol produces serializable histories.

4.1 Planning Transactions

As stated earlier in the previous section, the set of planning-threads $\mathbb{P}_q$ at a server inherit its priority q, and each planning-thread $P_{q,p}$ in the set $\mathbb{P}_q$ has another priority p to prioritize planning-threads of the same server. In general, planning-threads may use any mechanism to create execution-queues as long as they ensure that conflicting operations are placed in the same queue. For example, a *range*-based partitioning of the *record-identifiers* can be used, which ensures that operations accessing the same record are placed in the same execution queue. However, a placement strategy that minimizes the dependencies among execution-queues can yield better performance. More sophisticated approaches based on some cost model are also possible as long as the planning times are minimized and do not introduce significant overhead to the processing latency. The study of such strategies is out of the scope of this paper.

We denote the set of these execution-queues as $\mathbb{Q}_{q,p}$ and individual execution-queue as $Q^i_{q,p}$.

$$\mathbb{Q}_{q,p} := \{Q^1_{q,p},\ Q^2_{q,p}, ..., Q^i_{q,p}\},\ \text{where}\ i \geq 1 \quad (2)$$

In Q-Store, each planning-thread processes a batch of transactions and places its fragments in its respective execution-queues. Hence, each i^{th} execution-queue $Q^i_{q,p}$ contains a set of operations that access the records belonging to that sub-partition, which implies that fragments from two execution-queues created by the same planning-thread have operations, access records in different sub-partitions, and any conflicting fragments (i.e., access the same records) are placed in the same execution-queue.

Q-Store's planning-threads try to balance the load and create execution-queues equal to the number of execution-threads in the system. Such planning is done to keep execution-threads from being idle. More formally:

$$\forall\, P_{q,p}, \in \mathbb{P}_q,\ |\mathbb{Q}_{q,p}| \geq |\mathbb{E}| \tag{3}$$

However, it is undesirable in practice to have the number of execution-queues much larger than the number of execution-threads because it can lead to performance degradation due to low-level issues (e.g., cache-locality).

Each transaction can perform multiple operations. These operations can be grouped into fragments if they are accessing the same record. Otherwise, a fragment has a single operation. We denote the set of fragments in a transaction T as O_T. For presentation simplicity, let us assume that each fragment $O_{k,T}$ in set O_T can be either a read (R) or a write (W).

$$O_T := \{O_{1,T},\ O_{2,T}, ..., O_{k,T}\}$$

A planning-thread may distribute the fragments of a given transaction across multiple execution-queues. Q-Store needs to impose an order to the transactions that are being planned. This order can be as simple as the order imposed by the *client-transaction-queue*. A transaction and its fragments inherit the priorities of its planning-thread.

Hence, we can identify the order of a transaction T using a triple (i, p, q), where q is the priority of the server, p is the priority of the planning thread, and i can be the order imposed by the client-transaction-queue.

$$\forall\, i, j,\ i < j \rightarrow T_{(j,p,q)} \xrightarrow{\text{follows}} T_{(i,p,q)} \tag{4}$$

Equation 4 shows that as $T_{(i,p,q)}$ has a smaller identifier (i) than $T_{(j,p,q)}$, so it must have been placed in the client-transaction-queue before $T_{(j,p,q)}$.

Since transactions may have operations accessing remote partitions, planning-threads similarly create remote execution-queues to be executed at remote nodes. Note that our notation of an execution-queue $Q^i_{q,p}$ identifies the priority q of a remote server, which guides the execution phase. Therefore, queue execution at remote nodes is also deterministic.

When the planning-threads have collectively processed a set of transactions, they mark the resulting batch of execution-queues (local and remote) as ready for execution and deliver them to (local and remote) execution threads.

4.2 Speculatively Executing Transactions

The execution phase is performed by a set of execution-threads. Each server consists of a set of execution-threads $\mathbb{E}$.

$$\mathbb{E} := \{E_1, E_2, ..., E_j\},\ \text{where } j \geq 1$$

We require all the execution-threads to adhere to the following condition strictly:
`Condition`: *For each record, operations belonging to higher priority execution-queues must always be executed before executing any lower priority operations.*

$$\begin{gathered}\forall\, Q_m \in \mathbb{Q}_{q,p},\ \forall\, Q_n \in \mathbb{Q}_{s,t},\ \forall\, O_i \in Q_m,\ \forall\, O_j \in Q_n \\ \mid (q > s)\ \vee\ ((q = s)\ \wedge\ (p > t)) \rightarrow O_j \xrightarrow{\text{follows}} O_i\end{gathered} \tag{5}$$

This condition ensures that the order of executed operations follows a single order within and across servers. In other words, Q-Store requires execution-threads $\mathbb{E}$ to process the operations from those execution-queues, which have the highest priority among all the servers and planning-threads. However, Q-Store does allow the execution-queues produced by a single planner thread to be executed in parallel because they have the same priority.

Execution-threads process fragments from the execution-queues speculatively such that fragments are allowed to read uncommitted data (speculating that it would commit at a later time). Q-Store tracks these speculative actions and captures corresponding speculation dependencies (Section 2.2).

When a violation of an integrity constraint causes a transaction to abort, other fragments of the same transaction that have updated records must rollback as well. The other fragments may have uncommitted updates that have been read by fragments belonging to other transactions. In this case, dependent fragments and their respective transactions must rollback, causing a cascade of aborts through the batch.

4.3 Conservatively Executing Transactions

Q-Store also seamlessly supports a conservative execution, which introduces stalls when processing queues, but has the advantage of avoiding cascading aborts. In Q-Store, a transaction is aborted when the transaction logic induces an abort (e.g., for violating an integrity constraint). By design, non-deterministic aborts (e.g., for ensuring deadlock-free execution) do not exist in Q-Store.

Looking back at our example illustrating transaction dependencies from Section 2.2, Fragment O_{1,T_4} depends on O_{2,T_4} which is abortable. In conservative execution, the execution-thread executing $EQ^2_{q,p}$ stalls until the dependency is resolved. The event of resolving the dependency indicates that O_{2,T_4} is not going to abort. Therefore, any records updated by fragment O_{1,T_4} are safe for any read operations by subsequent fragments in the execution-queue.

Fragments are marked by planning-threads to ensure that execution-threads know when to wait and stall the processing of an execution-queue. When execution-threads encounter a marked fragment, they stall waiting for its commit dependencies to be resolved. Execution-threads can work on other execution-queues if they need to stall due to unresolved commit dependencies. Therefore, we are still exploiting parallelism by allowing other fragments to execute. If an integrity constraint violation happens, then, only one transaction is aborted and rollbacked.

4.4 Serializability

We now prove the serializability guarantees of Q-Store's transaction processing model.

THEOREM 4.1. Q-Store*'s distributed transaction processing is serializable.*

PROOF. One principle of our queue-oriented paradigm is to treat local and remote execution-queues in the same way. Therefore, the fact that an execution-queue is remote or local is an orthogonal concept.

Let us assume that Q-Store produces a non-serializable history, which means that there exist 4 transaction fragments that are executed in an incorrect order. Let these fragments be as follows: $O_{i,T_n}, O_{j,T_n}, O_{k,T_m}$ and O_{l,T_m}. Here O_{i,T_n} conflicts with O_{k,T_m} and O_{j,T_n} conflicts with O_{l,T_m}. Further, let $n < m$ in the client transaction queue, which means that a planner plans T_n before T_m. A non-serializable history means that at one execution-queue O_{i,T_n} is executed before O_{k,T_m} while O_{k,T_m} is executed before O_{i,T_n} at another execution node. More formally,

$$\exists Q_a, Q_b \text{ s.t. } \{O_{i,T_n}, O_{k,T_m}\} \in Q_a \wedge \{O_{j,T_n}, O_{l,T_m}\} \in Q_b \tag{6}$$

Furthermore, the following constraint captures one possible non-serializable history for the transaction fragments.

$$O_{k,T_m} \xrightarrow{\text{follows}} O_{i,T_n} \land O_{j,T_n} \xrightarrow{\text{follows}} O_{l,T_m} \tag{7}$$

The other non-serializable history is captured by:

$$O_{i,T_n} \xrightarrow{\text{follows}} O_{k,T_m} \land O_{l,T_m} \xrightarrow{\text{follows}} O_{j,T_n} \tag{8}$$

Either Q_a or Q_b has fragments from T_m ordered before T_n, which contradicts the fact that the planner of Q_a and Q_b planned T_n before T_m.

□

4.5 Read-committed Isolation

Not only that, Q-Store supports multiple execution paradigms but also multiple isolation levels seamlessly using the queue-oriented paradigm. Supporting read-committed isolation requires planning-threads to produce an additional set of execution-queues $Q'^{j}_{q,p}$ such that they only contain read-only transaction fragments as shown in Eq. 9. Read-only transaction fragments do not perform any write operations.

$$\begin{aligned} &\forall\, P_{q,p}, \in \mathbb{P}_q, \mathbb{Q}_{q,p} := \{Q^1_{q,p},\ Q^2_{q,p}, ..., Q^i_{q,p}\} \\ &\cup \{Q'^1_{q,p},\ Q'^2_{q,p}, ..., Q'^j_{q,p}\},\ \text{where } i \geq 1, j \geq 1 \end{aligned} \tag{9}$$

Furthermore, Q-Store employs a copy-on-write technique that creates a private copy of the updated records. Using these two simple techniques, Q-Store can support read-committed isolation seamlessly.

4.6 Discussion

The performance of speculative execution is dependent on the workload. Two properties of the workload can degrade the performance of speculative execution. The activation of logic-induced aborts which leads to the cascading aborts phenomena. The conservative execution solves this issue at the cost of more coordination among execution-threads.

For either of the execution paradigms, there is another workload property that impacts their performance negatively. The existence of a large number of data dependencies among fragments (see Section 2.2) in the planned workload limits the concurrency because it forces additional coordination among threads to resolve these data dependencies.

In Q-Store, mitigating the impact of data dependencies require more intelligent planning. Planning-threads can minimize the data dependencies among execution-queues. However, solving the minimization problem cannot introduce significant latency. Furthermore, because the database is partitioned, this can only work for local execution-queues. Planning-threads can intelligently move read-only fragments to a special set of execution-queues that allow resolving data-dependencies before executing dependent fragments. The implementation of these optimization remains as future work.

Limitations Advantages and disadvantages of deterministic transaction processing are discussed in the literature [36]. The key limitation of deterministic transaction processing is that the knowledge of the full read/write sets is required. One approach is to run the transaction without committing its write-set to compute the full read/write sets [40]. In general, this approach does not guarantee the finality of the read/write set when running the transaction. Another approach is to partially execute the transaction over multiple batches instead of a single batch. The study of these approach is beyond the scope of this paper.

5 IMPLEMENTATION

We now present some key details for our implementation of Q-Store. In our implementation of Q-Store, we model various components of Q-Store as a set of producers and consumers. As stated in Section 3, Q-Store includes a set of communication-threads. These threads perform two tasks: (i) consuming messages from the network and storing them in respective queues, and (ii) consuming messages from the worker-threads and pushing those on to the network. The task of consuming messages from the network involves reconstructing the raw buffers into appropriate message types so that other threads can interpret them.

In Q-Store, we partition the database using a range-partitioning scheme. At each server, we allocate an equal number of worker threads that assume the roles of both the planning-threads and execution-threads but only one role at a time. This scheme simplifies both the planning and execution phases as computing the number of sub-partitions across the whole cluster requires no additional communication.

When an input thread receives a client transaction, it places the transaction into a client-transaction-queue associated with one of the planning-threads, in a round-robin fashion. We allocate one client-transaction-queue for each planning-thread. This approach eliminates contention among the planning-threads to fetch the next transaction.

Q-Store employs a *count-based batch demarcation* mechanism which requires Planning-threads to create batches of transactions containing a specific number of transactions. However, *time-based implementations* for defining batches are also possible (e.g., a batch is created every 5 milliseconds).

Our Q-Store's implementation requires minimal low-level synchronization among all the threads in the system. Communication threads and worker threads utilize lock-free data structures to interact. For instance, if a worker thread is currently acting as a planning-thread, then as soon as it has processed the required number of transactions for the next batch and created its execution-queues, it starts acting as an execution-thread and checks for any available execution-queue to process. When it has executed all the required execution-queues, then it resumes the role of a planning-thread.

Batch Meta-data Q-Store requires execution-threads to process both the local execution-queues and remote execution-queues. This requirement implies there is a need to store locally generated execution-queues and incoming remote execution-queues. We employ a distributed lock-free data-structure, which we refer to as the *Batch meta-data* (illustrated in Figures 3 and 4), to store these execution-queues as well as any relevant meta-data needed to fulfill transactions dependencies. The implementation of dependencies uses a count to represent the number of dependencies to be resolved. When a dependency is resolved, we use atomic operations to decrement the dependency count. The communication-threads push the incoming remote execution-queues directly to the batch meta-data, which makes these queues available for execution. In this case, communication-threads are acting as virtual planning-threads. Execution-threads access this batch meta-data to fetch any available remote execution-queues. Moreover, the batch meta-data also stores the incoming acknowledgment messages (ACK), which an execution-thread transmits after processing a remote execution-queue, and the commit protocol uses them.

Commitment Protocol Q-Store's design allows us to support two light-weight commitment protocols. We can commit a transaction as soon as its last operation has been processed when using conservative execution. Alternatively, we can defer the commitment of all the transactions to the end of the batch when using speculative execution.

Note that the former approach requires additional implementation complexity to ensure that committed transactions do not read uncommitted updated from aborted transactions. The latter approach could cause a non-trivial increase in the latency at the client because all transactions are committed at the end. However, the latter approach also helps the system to amortize the cost of the commit protocol over a batch of transactions [7].

One of the key advantages of employing deterministic transaction processing protocols is that non-deterministic aborts are no longer possible (e.g., aborts induced by concurrency control algorithms). Therefore, there no need to rely on *costly commit protocols*, such as 2PC.

For speculative execution in Q-Store, the commit protocol commits the whole batch after all the execution-queues are processed. On completing the execution of an execution-queue, the worker thread sends an ACK message notifying the planner's node about it. When the planner's node receives the ACK message, it updates the batch meta-data associated with the remote execution-queue. Further, Q-Store requires the local execution-threads to directly update the batch meta-data. When all the local execution-queues are executed and remote execution-queues are acknowledged, the planner node starts the commit stage for the planned transactions.

To commit a particular transaction, we check if all of its fragments' dependencies are resolved. If so, the transaction is committed. Otherwise, the transaction needs to be aborted, and the rollback process is started. During rollback, the speculative dependency path is walked, and dependent transactions are aborted. Note that, in the conservative execution, there are no speculative dependencies, and there are no cascading aborts.

6 EVALUATION

In this section, we present an extensive evaluation of Q-Store. We implement our techniques in ExpoDB [18, 19, 35]. We compare the performance of Q-Store's speculative execution with the following concurrency control techniques. The conservative execution's performance evaluation and analysis remain future work.

- NO-WAIT: A representative of pessimistic protocols. A two-phase locking (2PL) variant that aborts a transaction if a lock cannot be acquired [3].
- TIMESTAMP: A basic time-ordering protocol [3] that is a representative of time-ordering concurrency control protocols.
- MVCC: An optimistic concurrency control protocol that relies on maintaining multiple versions of the accessed records. We select MVCC as representative of multi-version concurrency control protocols.
- MaaT: An optimistic concurrency control protocol [29] that is a representative of optimistic concurrency control protocols.
- Calvin: A deterministic transaction processing protocol [40].

We use a range-based partitioning instead of the original hash-based partitioning used by [20].

Cluster Setup We use a total of 32 Amazon EC2 instances for all experiments (16 server nodes and 16 client nodes). The instance type *c5.2xlarge*, which has 16GB of RAM and 8 vCPUs.

Table 1: Workload configurations parameters. Default values are in parenthesis.

Parameter Name	Possible Parameter Values
Common parameters:	
% of multi-partition txns.	1%, 5%, 10%, 20%, (50%), 80%, 100%
YCSB Workloads:	
Zipfian's theta	(0.0), 0.4, 0.8, 0.9, 0.99
% of write operations	0%, 5%, 20%, (50%), 80%, 95%
Operations/txn.	2, 4, 8, 12, (16)
Partitions accessed/txn.	2, 4, (8), 12, 16
Server nodes counts	2, 4, 8, (16)
Batch sizes	$5K$, $10K$, $20K$, $40K$, ($80K$), $160K$, $320K$
TPC-C Workloads:	
% of Payment txn.	0%, 50%, 100%

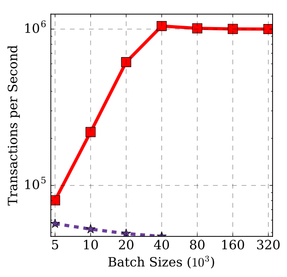
We use Ubuntu 16.04 (xenial), GCC 5.4, Jemalloc 4.5.0 [2, 23] and compile our code with -O2 compiler optimization flag. We pin threads to cores to reduce the variance from the operating system scheduling and the effect of the caching system. Each dedicates 4 threads as worker threads, and 4 as communication threads. For Calvin, 2 out of the 4 worker threads are dedicated to sequencing and scheduling tasks. Each client node maintains a load of $10K$ active concurrent transactions.

Workloads We use two common macro-benchmarks for our evaluation. The first one is YCSB [5]. YCSB is representative of web applications used by YAHOO. The YCSB benchmark is modified to have transactional capabilities by including multiple operations per transaction. Each operation can be either a `READ` or a `READ-MODIFY-WRITE` operation. The benchmark consists of a single table that is partitioned across server nodes, and each node hosts 16 million records. The benchmark can be configured to capture various workload characteristics.

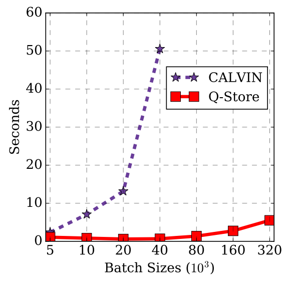
We also experiment with workloads based on the industry-standard TPC-C [41]. The TPC-C benchmark simulates a wholesale order processing system. There are 9 tables and 5 transaction types in this benchmark. All tables are partitioned across server nodes, where a partition can host one or more warehouses. Similar to previous studies in the literature[20, 45], we focus on the two main transaction profiles (`NewOrder` and `Payment`) out of the five transaction profiles, which correspond to 88% of the default TPC-C workload mix [41].

We report the average of 3 trials where each experiment trial runs for 120 seconds, and we ignore the measurements of the first 60 seconds, as it is used as a warm-up period. All reported measurements are observed by the client-side; thus, they are reflective of practical settings. Table 1, shows the various configuration parameters we used in our evaluation. Unless mentioned otherwise, we employ the default values.

Our experimental evaluation focuses on answering the following questions: (1) How does batch size affects the performance of batch-based distributed transaction processing systems (e.g., Calvin and Q-Store)? How do these systems handle high-volume workloads with large batches of concurrent multi-partition transactions? How do the following workload characteristics impact the performance of distributed transaction processing protocols: (a) the contention induced by data access skew; the percentage of multi-partition transactions in the workload; (b) the percentage of update operations in each transaction; (c) the transaction size (i.e., the number of operation per transaction); (d) the number of partitions accessed per transaction, and; (e) the transaction profiles? (3) How do these transaction protocols scale with respect to the number of nodes in the cluster?



(a) Throughput



(b) 99th Percentile Latency

Figure 5: Impact of varying batch sizes on the system throughput and 99th percentile latency of deterministic systems.

6.1 YCSB Experiments

The YCSB benchmark is versatile, and we use it to answer many of the questions related to sensitivity factors. We start by studying the impact of batch sizes for protocols that rely on batching.

Impact of Batch Sizes Using the YCSB benchmark, we first study the impact of batch size on protocols that rely on batching, such as Calvin and Q-Store. The current implementation of Q-Store uses a count-based batch demarcation mechanism. On the other hand, the original Calvin implementation uses a time-based mechanism. For this set of experiments to be meaningful, we modified Calvin to use a count-based batch demarcation mechanism and make it stand on the same ground as Q-Store. We use the default parameters and varying the batch size from 5K to 320K. The results are shown in Figure 5. Compared to Calvin, Q-Store scales very well as we increase the batch size up to $80K$.

Moreover, Calvin's throughput is very low because both the sequencing layer and the scheduling layer are single-threaded per node. With a large number of transactions per batch, those layers act as a bottleneck for the system. These results also show that Q-Store's architecture can utilize computing and network resources more efficiently. Beyond $80K$, the throughput of Q-Store plateaus as transaction processing becomes CPU-bound, and the latency starts to increase because worker threads take more time to process large batches. Calvin cannot handle large batches as transaction latency values exceed the experiment period. Remarkably, at $40K$ batches, Q-Store demonstrates an improvement of 22.1× the throughput of Calvin and an order of magnitude lower latency.

The most significant insight for Q-Store is that for large deployments (e.g., here, we have a total of 64 worker threads distributed over 16 server nodes), we need more work per thread to ensure efficient transaction processing and to hide the latency. Q-Store can handle large batches of concurrent transactions while keeping the latency low.

The presented results indicate that Q-Store is efficient in terms of performing useful work locally. The bottleneck is in the communication protocol, which is expected because the network is slower than local communication.

In the remaining experiments, we use the original time-based batch demarcation mechanism for Calvin and use their reported parameter of $5ms$ [20]. We observe that with $5ms$ time-based batch demarcation, Calvin produces batches of size 160 per node approximately.

Variable Contention In this set of experiments (Figure 6), we vary the Zipfian skew factor θ from 0.0 (uniform) to 0.99 (extremely skewed). As θ approaches 1.0, the data access becomes more skewed within a partition, but the partitions are chosen uniformly per transaction. In other words, each partition receives uniform access, but the record access within the partition is skewed. It is possible to use a Zipfian distribution for partitions as well, but that would not measure the performance of how each node is dealing with skewness. Further, in such a case, mostly one node is active while the remaining nodes are idle most of the time. We use a 50% multi-partition workload such that the 16 operations in a transaction randomly access exactly 8 partitions.

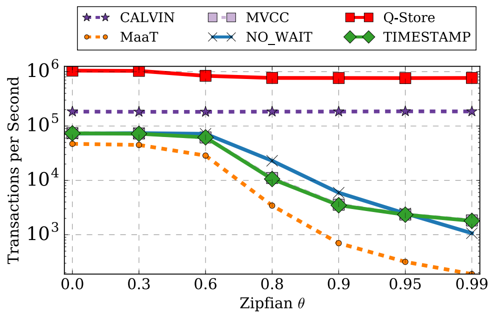


Figure 6: Impact of varying the data access skewness parameter θ of the Zipfian distribution on systems throughput (log scale).

Both Calvin and Q-Store perform better because they both avoid the cost of the two-phase commit protocol (2PC). However, Q-Store achieves up to 6× better throughput. The first reason for that is queue-oriented execution and communication. Q-Store sends a queue of ordered operations that belong to several concurrent transactions to remote nodes. Thus, Q-Store ensures a more efficient communication.

Since different threads execute queues in parallel, Q-Store exploits intra-transaction parallelism (both within a node and across nodes) better than Calvin. For Calvin, the level of contention does not affect its performance because the bottleneck is in the sequencing and scheduling layer. Note that Q-Store's throughput degrades slightly under high-contention (i.e., beyond $\theta = 0.6$) due to the imbalance in the size of execution queues.

The throughputs for non-deterministic protocols are low because they require a costly 2PC protocol for committing each transaction. As the contention increases, the abort rates also increases, which lowers their performance even more. When transactions abort, they are retried using a random back-off period. Under high-contention, transactions may abort multiple times, which effectively increases the latency per transaction, which lowers the throughput. Remarkably, Q-Store achieves nearly two orders of magnitude better system throughput under high-contention in comparison to non-deterministic protocols.

Varying multi-partition transactions rate Now, we focus on the impact of multi-partition transactions in the workload. We vary the percentage of multi-partition transactions in the workload from 0% (single-partition transactions only) to 100% (multi-partition transactions). We fix the values of other parameters to the default values. The results shown in Figure 7 are for low contention (i.e., $\theta = 0.0$). Note that in comparison to Figure 6, there is no noticeable difference in the throughputs of the protocols with single-partition transaction workloads, except for Calvin.

Non-deterministic protocols do not need to perform 2PC, which allows them to avoid 2PC's cost. When the rate of multi-partition transactions increases, non-deterministic protocols incur the overhead of 2PC to ensure serializable execution, and

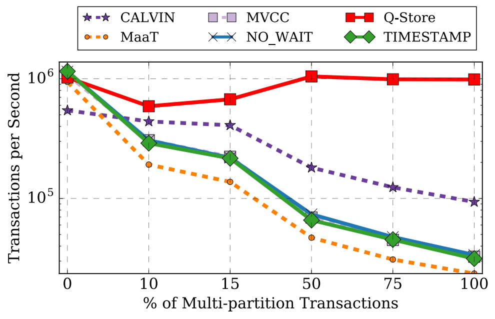

Figure 7: Impact of varying the percentage of multi-partitions transactions in the workload on the system's throughput.

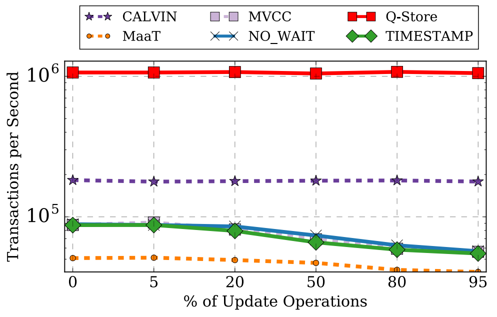

Figure 8: Impact of varying the percentage of update operations in the workload on the system's throughput.

thus, their throughput decreases. Thus, our results validate previously published results (e.g., [20]), which illustrate the poor performance of non-deterministic protocols.

Despite the deterministic nature of Calvin, its throughput also decreases as the rate of multi-partition transaction increases. Calvin needs to send a given transaction to all participants and waits for their responses before scheduling the next conflicting transaction. This approach increases the communication overhead per transaction and negatively affects the performance of Calvin. Unlike Calvin, Q-Store is not sensitive to multi-partition transactions. In addition to avoiding 2PC overhead, it has minimal communication overhead. Q-Store communicates only a minimal number of execution queues between partitions, which contain scheduled operations of several transactions. Thus, it effectively reduces the communication overhead per transaction. Q-Store outperforms Calvin's throughput by up to 10.6×.

Vary the percentage of update operations In the following experiments, we study the impact of the percentage of the update operations on the transaction processing performance. In previous experiments, we used a value of 50%, which means that 8 out of 16 operations are updating the database in each transaction. To study this factor, we vary the percentage of update operations from 0% (read-only operations) to 95%. We fix the remaining parameters to their default values. Note that increasing the rate of update operations increases the contention on records (e.g., exclusive locks induce record contention).

Figure 8 shows the result of varying the percentage of update operations. The results show that neither Q-Store nor Calvin are sensitive to this factor. Calvin employs deterministic locking to avoid aborting transactions unnecessarily while Q-Store executes operations according to their order in a given queue.

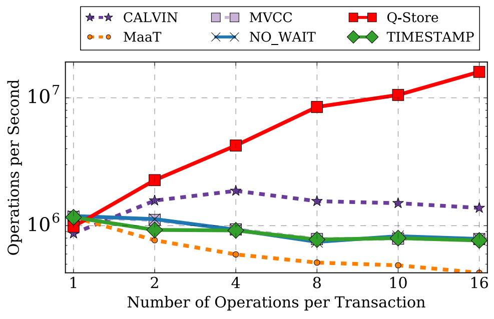

Figure 9: The impact of varying the number of operation per transaction on system's throughput. We force each operation access a different partition. This results is for low contention $\theta = 0.0$.

In other words, for Q-Store there is no difference between the *read* or *update* operations as Q-Store executes each operation in-order, which eliminates any sensitivity to this factor. With non-deterministic protocols, we observe that the abort-rate increases as the contention increases due to more update operations in the workload. For NO-WAIT, MaaT, TIMESTAMP, and MVCC, the abort-rates are up to 41%, 19%, 7%, and 6%, respectively, at 95% update rate.

When a transaction is read-only, there is no need to perform 2PC, but participants still need to communicate messages to finalize the running transaction. As the transaction involves more update operations, the overhead of 2PC protocol becomes more substantial, which negatively affects the performance of non-deterministic protocols that rely on 2PC as their atomic commitment protocol. Notably, Q-Store shows an improvement in its system's throughput by up to 5.9× and 17.1× over Calvin and MVCC (the next best non-deterministic protocol), respectively.

Vary the number of operations per transaction Now, we experiment with varying the number of operations per transaction. We set the percentage of multi-partition transactions to 50%, and force each transaction to access the same number of partitions as its number of operations. For example, if a transaction has 4 operations, the number of partitioned accessed by that transaction is also 4. However, each partition has the same probability of access by any operation, and we do not force operations to be remote.

This experiment aims to capture execution and communication overheads as transactions become larger. For non-deterministic protocols, as the number of operations increases, the cost of 2PC increases because it is more likely that more nodes need to participate in the commitment protocol. Calvin performs better than other non-deterministic protocols, but its performance does not scale with larger transactions. Q-Store, on the other hand, scales well as the number of operations per transaction increases. With 16 operations per transaction, Q-Store's performance reaches a remarkable throughput of nearly 16 million operations per second. These numbers are 12× and 20× better than those for Calvin and NO-WAIT, respectively, as shown in Figure 9. These gains are due to the proposed efficient queue-oriented execution and communication. For Q-Store, the number of queues communicated is constant (but their sizes may vary) while the other protocols exchange messages for remote operations, which increases the overall communication overhead.

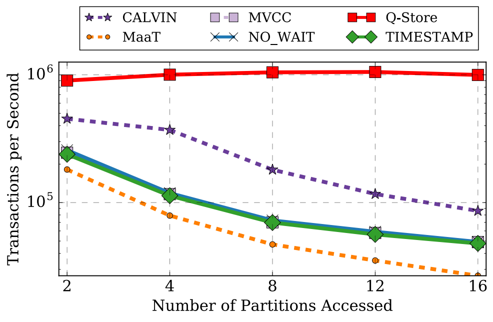

Figure 10: The impact of varying the number of partitions accessed by each transaction on the system's throughput.

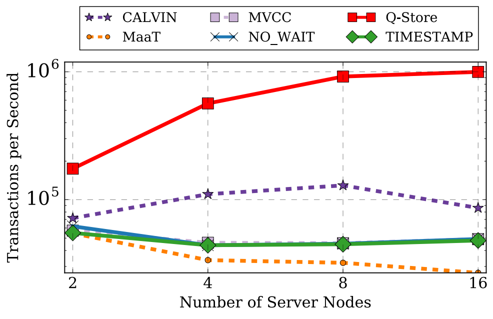

Figure 11: Throughput scalability results while varying the number of server nodes.

Vary partitions per transaction In Figure 10, we show the results for varying the number of partitions accessed by transactions having 16 operations. We use uniform data access, which leads to a low contention workload. By having uniform data access, the effect of contention is negligible, which can help us to examine the communication costs. As we increase the number of partitions accessed by a transaction, the overhead of committing this transaction increases because the commitment involves agreement of more participants per transaction. This issue is mainly a problem for non-deterministic protocols as the participants need to agree on the order for operations. As the number of participants increases, more coordination is required to commit each transaction.

While Calvin eliminates the overhead of 2PC, it still suffers from increasing the number of partitions accessed per transaction. The reasons for that are: (i) it needs to send the transactions to more participants, and (ii) it needs to wait for acknowledgments from more participants before declaring a transaction as committed. This communication overhead increases as the number of partitions accessed increases. In contrast, Q-Store demonstrates its insensitivity to this factor and achieves a throughput of around a million transactions per second despite the increase in the number of partitions accessed per transaction. Since the workload is uniform, the number of partitions accessed affects only the sizes of remote execution queues, and there is no increase in the number of communicated execution queues.

Scalability For all previous experiments, we have used 16 servers. In this set of experiments, we vary the number of nodes to evaluate the scalability. We set the percentage of multi-partition transactions to 50%, and force each transaction to access all available partitions. Figure 11, shows that Q-Store scales well as the number of server nodes increases in the cluster, achieving over

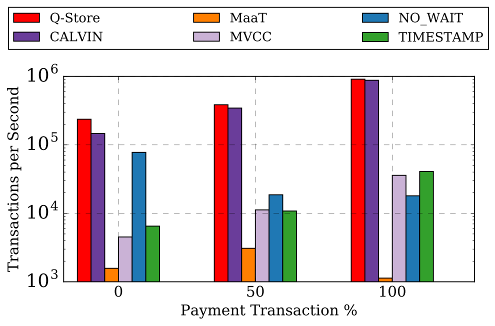

Figure 12: The impact of different TPC-C transaction mixes on the system's throughput. 15% **multi-partition transactions is used.**

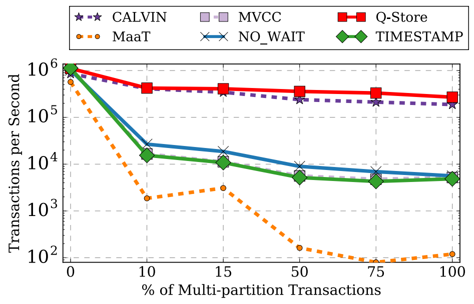

Figure 13: Varying the percentage of multi-partition transaction with equal ratios of Payment and NewOrder transactions.

1 million transactions per second at 16 server nodes. Other approaches do not scale due to the overhead of multi-partition transactions. Calvin's performance cannot scale because of the single-threaded pre-execution phases, while non-deterministic protocols do not scale due to the increased overhead of 2PC.

6.2 TPC-C Experiments

We also evaluate Q-Store with workloads based on the industry-standard TPC-C benchmark. For this set of experiments, we use a total of 16 server nodes, with 4 warehouses per server. Hence, the total number of warehouses is 64. We use three workloads: 100% NewOrder-transaction workload, 50% Payment and 50% NewOrder transactions workload mix, and finally 100% Payment-transaction workload. We use the standard rate of 15% of the payment transactions coming from remote customers as the multi-partition transaction rate, for all the transactions in the workloads. We also restrict the number of partitions accessed to *two* even for NewOrder transactions.

The results are shown in Figure 12. Both deterministic systems Calvin and Q-Store significantly outperform other algorithms by a significant margin due to their use of 2PC. Q-Store outperforms Calvin by up to 1.8×. Remarkably, Q-Store outperforms NO-WAIT, which is the best performing non-deterministic protocol, by up to 55.2×. NO-WAIT suffers from high abort rates due to contended warehouse records (to avoid deadlocks) and the overhead of 2PC for multi-partition transactions. On the other hand, Q-Store eliminates the overhead of 2PC and execution-induced aborts.

The second set of experiments that use TPC-C workloads study the effects of multi-partition transaction rates (Figure 13). The transaction profiles in TPC-C are more complicated than their YCSB counterparts. It involves data dependencies among operations, which can reduce the performance of Q-Store. For example, in the NewOrder transaction, many operations require the new value of the OrderId, which is updated by the same transaction. Our current implementation creates an execution-queue per warehouse, which serializes all operations accessing records belonging to a given warehouse. Despite this unfavorable data partitioning scheme, Q-Store's throughput still outperforms Calvin's throughput. [1]

7 RELATED WORK

Research on distributed transaction processing systems started several decades ago. One of the key challenges in distributed transaction processing is managing the execution of concurrent transactions such that they produce serializable execution histories. Bernstein and Goodman [3] give a comprehensive overview of distributed concurrency control techniques. In this section, we cover some of the recently proposed distributed transaction processing systems and transaction processing techniques that are mostly related to Q-Store. We categorize them as follows.

Non-deterministic Transaction Processing When a transaction updates multiple partitions of the distributed database, there is a need for a commit protocol to ensure that the updates are consistent across all the partitions because nodes may arrive at distinct order of execution for the transaction operations. As a result, aborts may occur non-deterministically. The two-phase commit protocol is typically used to resolve this problem, but naive implementations of 2PC suffer from costly overheads, which negatively impact the system performance. Therefore, many optimizations for 2PC have been proposed (e.g., [26, 29, 31, 39]) while preserving the non-deterministic nature of execution. However, due to this non-determinism, these systems suffer from execution-induced aborts and cannot eliminate the overhead of 2PC [1]. In contrast to these approaches, Q-Store processes transactions deterministically and eliminates the overhead of 2PC and non-deterministic aborts during execution.

Eliminating Multi-partition Transactions Some proposed approaches avoid the cost of 2PC by avoiding the need to process multi-partition transactions. For example, G-store [6] allows applications to declare arbitrary groups of records and moves these groups to a single node to avoid the overhead of processing multi-partition transactions. In a similar spirit, LEAP [27] avoids the cost of 2PC by moving records accessed by a given transaction to a single node at run-time implicitly. Q-Store, on the other hand, embraces multi-partition transactions, and deterministically orders operations into execution-queues; thus avoiding the need for a 2PC protocol.

Deterministic Transaction Processing Deterministic approaches to transaction processing showed great potential in the academic research literature and even had commercial offerings, e.g., [12, 42]. For single-partitioned workloads, H-Store[25] uses single-threaded serial execution per partition. For workloads having multi-partition transactions, H-Store provides limited concurrency by employing a coarse-grained locking mechanism that locks all the partitions prior to the start of a transaction. Jones et al. [24] studies the application of speculative concurrency control to multi-partition transactions in H-Store, which allows transactions to read uncommitted updates of transactions that are performing distributed commitment protocol. Unlike H-Store, Q-Store does not lock partitions to produce a serializable execution for operations of multi-partition transactions. Instead, Q-Store creates execution-queues that capture the serializable order of conflicting operations, and it assigns these execution-queues to worker threads. After that, each worker thread executes its assigned execution-queues according to the pre-determined priority of execution-queues, which allows Q-Store to maintain its high performance despite the multi-partition workloads.

In Gargamel [4], a single dedicated load-balancing node pre-serializes (using static analysis) possibly conflicting transactions before their execution. The load-balancing node can easily become the bottleneck for the system. Unlike Gargamel, Q-Store is centered around the notion of priority and exploits multiple nodes for planning.

Calvin [40, 44] uses determinism to eliminate the cost of two-phase-commit protocol when processing distributed transactions. T-Part [44] relies on the same system architecture of Calvin, but its scheduling layer constructs transaction dependency graphs to reduce the stalling of worker threads. There are fundamental architectural differences between Calvin and Q-Store. The planning phase performs the same functionality as the two-step (sequencing and scheduling) pre-processing phases, but *in parallel*, and the execution phase of Q-Store does not rely on any locking mechanism and employs a queue-oriented (speculative and conservative) processing design. Additionally, in contrast to Calvin, which assigns a transaction to a worker thread for processing, Q-Store assigns an execution-queue to a worker. Because of this thread-to-transaction mapping, Calvin cannot exploit intra-transaction parallelism opportunities within a single node.

Intra-transaction Parallelism Most transaction processing systems perform a thread-to-transaction assignment, which makes these systems unable to exploit intra-transaction parallelism efficiently. Several research studies proposed techniques for exploiting this kind of parallelism in centralized environments (e.g., [10, 34, 35, 43]). Q-Store goes beyond these proposals and exploits intra-transaction parallelism within and across nodes in the context of distributed transaction processing.

8 CONCLUSIONS AND FUTURE WORK

We presented Q-Store, which efficiently processes distributed multi-partition transactions via queue-oriented priority-based execution model. We present a formalization of our system and describe its design and implementation. We perform an extensive evaluation of Q-Store using different workloads from standard benchmarks (that is, YCSB and TPC-C). We demonstrate that Q-Store, consistently and significantly achieves higher performance than existing non-deterministic and deterministic distributed transaction processing systems. We experimentally demonstrate that Q-Store out-performs the state-of-the-art deterministic distributed transaction processing protocol by up to $22.1\times$ with YCSB workloads. Against non-deterministic distributed transaction processing protocols, Q-Store achieves up to two orders of magnitude better throughput with YCSB workloads, and up to $55\times$ with TPC-C workloads.

There are renewed research interests in byzantine fault-tolerance for transaction processing [14–17, 21, 32]. In future, we plan to support byzantine fault-tolerance for database transactions in Q-Store. On the one hand, blockchain transactions are deterministic, which aligns with the kind of transactions that Q-Store's supports. On the other hand, it is very challenging to design and implement

[1] For TPC-C like workloads, unlike Calvin, Q-Store's performance can be further optimized by further splitting execution-queues and exploit parallelism instead of serializing operations per warehouse. However, such optimization is beyond the scope of this paper, and we leave it to future work.

efficient, Byzantine fault-tolerant protocols. We believe that the design principles behind Q-Store can lead to efficient Byzantine fault-tolerant protocols, as very few blockchain proposals look at optimizing execution.

ABSTRACT

Time series anomaly detection is an important task, with applications in a broad variety of domains. Many approaches have been proposed in recent years, but often they require that the length of the anomalies be known in advance and provided as an input parameter. This limits the practicality of the algorithms, as such information is often unknown in advance, or anomalies with different lengths might co-exist in the data. To address this limitation, previously, a linear time anomaly detection algorithm based on grammar induction has been proposed. While the algorithm can find variable-length patterns, it still requires preselecting values for at least two parameters at the discretization step. How to choose these parameter values properly is still an open problem. In this paper, we introduce a grammar-induction-based anomaly detection method utilizing ensemble learning. Instead of using a particular choice of parameter values for anomaly detection, the method generates the final result based on a set of results obtained using different parameter values. We demonstrate that the proposed ensemble approach can outperform existing grammar-induction-based approaches with different criteria for selection of parameter values. We also show that the proposed approach can achieve performance similar to that of the state-of-the-art distance-based anomaly detection algorithm.

1 INTRODUCTION

Time series anomaly detection is an important task, with applications in a broad variety of domains. Many approaches have been proposed in recent years, but often they require that the length of the anomalies be known in advance and provided as an input parameter. Recently, this limitation has been addressed by introducing a time series anomaly detection approach that is based on grammar induction and has a linear time complexity with respect to the data size (the time series length).

Typically, the grammar-induction-based anomaly detection follows a four-step process. In the first step, the input time series is converted into a discrete sequence of symbols via a sliding window; this discretization depends on two parameters. In the second step, grammar induction (e.g., via the Sequitur algorithm [15]) is applied to the discrete sequence to quickly identify grammar rules that are repeating strings of symbols. The third step maps the repeating strings back to the time series subsequences that the strings represent. Finally, a meta time series named *rule density curve* is computed, which records the frequency of grammar rules at each point and is used to detect and rank the anomalies. Specifically, it is assumed that anomalies correspond to rarely occurring strings and hence are indicated by minima of the rule density curve.

While the grammar-induction-based algorithm can find variable-length patterns, it still requires preselecting values for at least two parameters at the discretization step. These two discretization parameters are the number of segments (i.e., the length of a word, also called PAA size which will be explained later), and the alphabet size. How to choose the parameter values properly is still an open problem, especially in an unsupervised setting where no training data are available.

Figure 1 presents an example that illustrates the challenge of choosing proper parameter values, even with the knowledge of ground truth information that allows us to evaluate the quality of anomalies detected. Figure 1.top shows a snippet of dishwasher electricity usage time series. An anomalous cycle that has an unusual short power usage period is highlighted in red. We ran the algorithm with different parameter value combinations, and the results are shown in Figure 1.bottom. According to the figure, the best parameter value combination (indicated by the arrow) is significantly different from the second best combination. Moreover, we see that parameter values that are close to the optimal values actually perform badly. As a result, guessing the "best" parameter values can be very tricky.

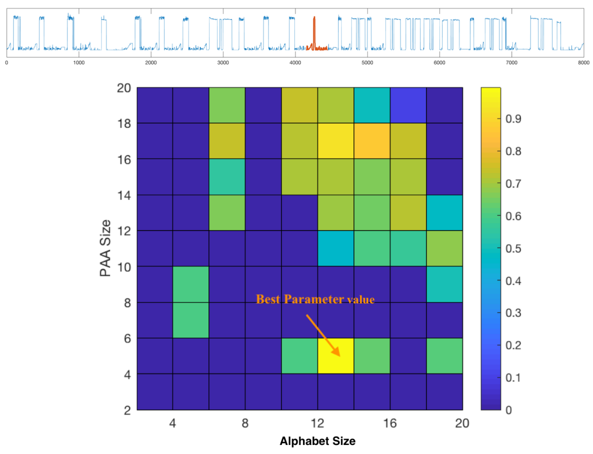

Figure 1: (top) A snippet of dishwasher electricity usage time series. An anomalous cycle is highlighted in red. (bottom) Performance of the grammar-induction-based algorithm with different discretization parameter values in the task of detecting the anomalous subsequence.

To overcome the challenge mentioned above, in this paper, we introduce a robust version of the grammar-induction-based anomaly detection method, which utilizes ensemble learning. Intuitively, instead of using a single combination of parameter values, the method generates the final result based on a set of results obtained using different parameter values. We design an approach that combines the results returned by each ensemble member corresponding to a different combination of parameter values. Furthermore, in the discretization step, we use an approach to compute multi-resolution words to efficiently represent time series subsequences. This approach can dramatically reduce the cost of discretization and increase the scalability of the proposed work.

The contribution of this paper is summarized as follows:

- The proposed ensemble grammar induction can achieve better performance than the grammar induction with a single combination of parameter values.
- The proposed ensemble grammar induction is particularly suitable for unsupervised anomaly detection, where no training set is available to perform a grid search for the best parameter values.
- The proposed approach has a linear time complexity with respect to the data size and can achieve performance comparable to that of the state-of-the-art distance-based approach that has a quadratic time complexity.
- We adapt a fast algorithm to discretize subsequences, which reduces the cost of repeated computation.
- We demonstrate that the ensemble approach can be applied to find meaningful anomalies in real-world application.

The rest of the paper is organized as follows. Section 2 describes related work. Section 3 presents definitions and notations used in the paper. The process used for discretization and numerosity reduction is described in Section 4. The grammar-induction-based anomaly detection is presented in Section 5. The ensemble approach is introduced in Section 6. The experimental results are shown in Section 7, and conclusions are summarized in Section 8.

2 RELATED WORK

First, we describe the state-of-the-art time series anomaly detection approach. Keogh et al. [9] introduced a concept named *time series discord*, which is the subsequence that has the largest one–nearest-neighbor (1-NN) distance, hence it represents the most unusual subsequence in the time series. The authors introduced an algorithm named HOTSAX to effectively detect the time series discord. Recently, a series of matrix-profile-based approaches, STOMP [23] and STAMP [21], have been introduced for fast computation of 1-NN distances for every subsequence. It has been shown that compared with the original method, STOMP and STAMP can achieve more stable and generally better performance. However, all these methods have a quadratic time complexity with respect to the data size, and the accuracy is sensitive to the length of the discord that has to be specified in advance as an input parameter [20].

In previous work, we proposed a series of approximate time series pattern discovery algorithms called GrammarViz based on grammar induction [10, 19, 20]. The idea is that by learning a context-free grammar from a discrete sequence of symbols that approximates the original time series, one can identify the repeating strings. Recently, in [18], we have extended the idea of grammar-induction-based anomaly detection by introducing the concept of rule density curve, which is a meta time series that records the frequency of grammar rules (repeating strings) at each point of the original time series. Since anomalies correspond to rarely occurring strings, they are indicated by minima of the rule density curve. It has been shown that this approach can achieve competitive performance compared to the state-of-the-art while having linear time complexity. However, the algorithm requires the user to preselect values of two important parameters, and the performance can be greatly affected by these values.

Several ensemble algorithms have been proposed for unsupervised anomaly detection [17, 22]. Most of them use the average performance as the ground truth and select a very small number of detectors to approximate the average performance. All these approaches are introduced for point-based anomaly detection. How to use them for detecting anomalous subsequences is still unclear. Besides, since subsequences extracted from a time series via a sliding window are highly overlapped, the detector used in these approaches [1] cannot resolve this problem.

Other works [2, 4, 8] also focus on anomaly detection; however, these techniques often focus on detecting anomalies in event logs (discrete or mixed data type time series) and the lengths of the anomalies are often very short.

3 NOTATIONS AND PROBLEM DEFINITION

We first describe the fundamental definitions related to time series and grammar induction. We then formulate the problem of time series anomaly detection.

3.1 Notations and Definitions

We start with the definitions related to time series:

Time series $T = t_1, \ldots, t_m$ is a set of observations ordered by time.

Subsequence $T_{p,q}$ of a time series T is a subsequence of elements in T starting from position p and ending at position q, of length $n = q - p + 1$. Typically, $n \ll m$, and $1 \le p \le m - n + 1$.

Subsequences can be extracted from time series via a sliding window. In many applications, we are interested in finding unusual "shapes." Therefore, anomaly discovery result is more meaningful when the method can maintain offset- and amplitude-invariance during the anomaly detection process. This can be achieved by normalizing all subsequences prior to applying an anomaly detection algorithm. **z-normalization** is a procedure that normalizes the mean and standard deviation of a subsequence to zero and one, respectively.

Since the proposed anomaly detection approach is based on grammar induction, we next introduce the definitions related to grammar induction using a toy example shown in Figure 2. Intuitively, grammar induction is a process that induces a hierarchical grammar structure from a **token sequence** S, which is a sequence of discrete tokens (words). In the example, S consists of nine two-letter tokens. The hierarchical grammar structure is represented by a set of **grammar rules**. Each grammar rule represents a repeating string of token segments in S. In the example, two rules R_1 and R_2 represent the repeating token segments *ab*, *bc* and *cc*, *cc*, respectively. Following the terminology used in previous work [15, 20], each grammar rule is also called a **non-terminal** and each token stored in the token sequence is called a **terminal**.

Using the set of grammar rules, the original token sequence S is represented by the compressed sequence R_0. Since compressibility is a measure of regularity (and hence incompressibility is a measure of anomalousness), the compressed sequence plays an important role in motif (repeated patterns) discovery and anomaly detection.

R_2
$S = ab, bc, aa, cc, cc, ab, bc, cc, cc$
Grammar Rules:
$R_0 \rightarrow R_1, aa, R_2, R_1, R_2$
$R_1 \rightarrow ab, bc$
$R_2 \rightarrow cc, cc$

Figure 2: Example of grammar induction applied to a token sequence.

Clearly, the grammar induction approach cannot be directly used for real-valued time series. To use it, we need first to approximate the original time series by a discretized token sequence. We describe the time series discretization process in detail in Section 4.

3.2 Problem of Anomaly Detection

Based on the definitions above, we can formulate the problem of anomaly detection. In this work, we follow the previous anomaly detection framework GrammarViz [20], and determine a hierarchical grammar structure for a time series, through the processes of time series discretization and grammar induction. The anomaly candidates are subsequences that cannot be compressed by induced grammar rules.

To illustrate the basic idea behind this process of anomaly detection, we use another toy example of a simple token sequence:

$$S = aa, bb, cc, xx, aa, bb, cc. \tag{1}$$

The grammar structure induced from S is shown in Table 1. We see that S contains a repeating pattern, aa, bb, cc, represented by the grammar rule R1. The token xx, however, does not appear in any grammar rules (i.e., it is incompressible). It is not hard to see that token xx is *structurally* dissimilar from the rest of the sequence. In the grammar-induction-based time series anomaly detection framework, the subsequence that xx represents is considered an anomaly candidate.

Table 1: Example of grammar rules induced from token sequence S of Eq. (1)

Grammar rules	Expanded sequence
$R_0 \rightarrow R_1, xx, R_1$	$aa, bb, cc, xx, aa, bb, cc$
$R_1 \rightarrow aa, bb, cc$	aa, bb, cc

4 DISCRETIZATION AND NUMEROSITY REDUCTION

Time series discretization [12] is a common step in many time series data mining tasks, including anomaly detection [5, 9]. Since grammar induction requires discrete input, it is necessary to approximate the time series by a token sequence first. In general, discretization offers several advantages including noise removal, dimensionality reduction, and improved efficiency.

In this section, we first describe the algorithm called *Symbolic Aggregate approXimation* (SAX) [12], a widely used time series discretization technique. We then describe *numerosity reduction*, a procedure that removes repeating consecutive tokens to form a more compact token representation of a time series [11, 20].

4.1 Symbolic Aggregate approXimation

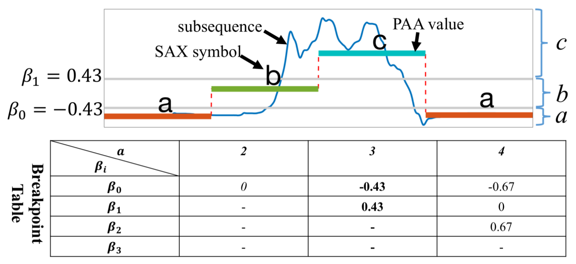
In this section, we describe SAX [12], a popular technique used to discretize univariate time series.

SAX consists of two steps. At the first step, the *Piecewise Aggregate Approximation* (PAA) is used to convert a normalized subsequence of length n from a time series T into a representation of a lower dimension $w < n$ (w is called PAA size). Specifically, the subsequence is divided into w equal-sized windows, and the average value of the elements within each window is computed. In other words, the PAA coefficients vector [12] is a w-dimensional vector that consists of the average values from w equal-sized segments of the input subsequence. PAA coefficients are an approximate representation of the original subsequence.

At the second step, the PAA coefficients vector is mapped to w symbols from an alphabet of size a, according to a breakpoint table [12], defined such that the regions are approximately equal-probable under the Gaussian distribution. This maximizes the chances that the symbols occur with an approximately equal probability. These w symbols form a SAX word.

Figure 3 illustrates the SAX process for an example subsequence (shown as the blue curve). The bold flat lines represent the values of PAA coefficients computed from their respective segments in the subsequence. The breakpoint table with a from 2 to 4 is also shown in the figure. Since we set $a = 3$ in this example, two breakpoints in the second column of the table are used to generate three regions: $(-\infty, -0.43)$, $[-0.43, 0.43)$, $[0.43, \infty)$. The PAA coefficients falling into these three regions are mapped to symbols a, b, and c, respectively. In this example, the SAX word $abca$ is formed to approximate the original subsequence.

This description shows how SAX is applied to a given subsequence. In order to discretize the entire time series, SAX is usually applied via a sliding window of length n.



a / β_i	2	3	4
β_0	0	**-0.43**	-0.67
β_1	-	**0.43**	0
β_2	-	-	0.67
β_3	-	-	-

Figure 3: Example of the SAX process, with $a = 3$ and $w = 4$, which approximates the original subsequence by the word *abca*.

4.2 Numerosity Reduction

In practice, since neighboring subsequences are only off by one point, the neighboring tokens generated by SAX are often identical to each other. This phenomenon, however, will result in an overwhelming number of grammar rules that represent trivial matches, and this redundancy will significantly affect both the scalability and the quality of results. To avoid this problem, a *numerosity reduction* step is added to further compress the token sequence. Specifically, whenever there is a sequence of one token repeating consecutively multiple times, numerosity reduction will output only the first occurrence of the token along with its offset.

For example, a token sequence

$$S = ba, ba, ba, dc, dc, aa, ac, ac \tag{2}$$

can be compressed to

$$S_{\text{NR}} = ba_1, dc_4, aa_6, ac_7, \tag{3}$$

where the subscripts indicate the positions in the original uncompressed token sequence. S_{NR} contains all information needed to retrieve the original token sequence.

5 GRAMMAR INDUCTION

In this section, we first describe Sequitur [15], a grammar induction algorithm with a linear time complexity. We then describe the process of computing the rule density curve and ranking anomalies.

5.1 Sequitur

Sequitur is a linear-time greedy algorithm to induce a context-free grammar structure from a discrete token sequence.

Sequitur maintains a list of grammar rules and a table of digrams based on the input sequence. A digram is a pair of consecutive tokens (terminals or non-terminals) in the sequence. Two principles, digram uniqueness and rule utility, are applied to constrain the rules during grammar induction. Digram uniqueness requires that digrams stored in the digram table should be unique. Rule utility requires that rules that only appear once should be removed to minimize the size of grammar.

To illustrate how Sequitur works, consider an example token sequence generated by SAX with parameters $w = 2, a = 3, n = 16$, after the numerosity reduction step:

$$S_{\text{NR}} = ab_1, bc_8, aa_{15}, cc_{21}, ca_{25}, ab_{29}, bc_{34}, aa_{40}. \tag{4}$$

A step-by-step grammar induction process is shown in Table 2. From Step 1 to Step 6, since neither digram uniqueness nor rule utility is violated, the algorithm simply reads the first six tokens and adds digrams into the digram table, respectively. In Step 7, the algorithm finds that the digram $\{ab, bc\}$ occurs in the digram table twice. Therefore, in Step 8, the algorithm forms a new rule, $R_1 \rightarrow ab, bc$. The new non-terminal symbol R_1 is generated to replace all occurrences of $\{ab, bc\}$, and the digram table is updated to maintain the uniqueness of digrams by removing $\{ab, bc\}$ and adding $\{R_1, aa\}$ and $\{ca, R_1\}$. Similarly, in Step 9, the digram $\{R_1, aa\}$ appears twice and therefore is replaced, in Step 10, by a new rule R_2. After the digram table is updated in Step 10, the algorithm finds that the rule R_1 only appears once. Therefore, in Step 11, R_1 is expanded to satisfy rule utility.

After processing the entire token sequence, the original token sequence is compressed into $R_0 \rightarrow R_2, cc, ca, R_2$ and the string cc, ca is identified as an anomaly candidate since it cannot be compressed.

5.2 Rule Density Curve

We next describe the construction of the rule density curve [20]. Simply stated, a rule density curve is a meta time series, in which each value is equal to the number of grammar rules that "cover" the respective time point. For anomaly detection, we are interested in the intervals for which the rule densities are the lowest. These intervals correspond to subsequences (more precisely, the SAX strings that represent these subsequences) that rarely appear in grammar rules, and hence are potentially anomalous. For the example sequence shown in Table 2, the time series points corresponding to the token subsequence cc, ca will have a count of zero since cc, ca does not appear in any grammar rules.

To construct the rule density curve, we map each instance of a rule back to the subsequence index based on the index recorded in the numerosity reduction step, and then we keep track of the number of rules that cover each time point.

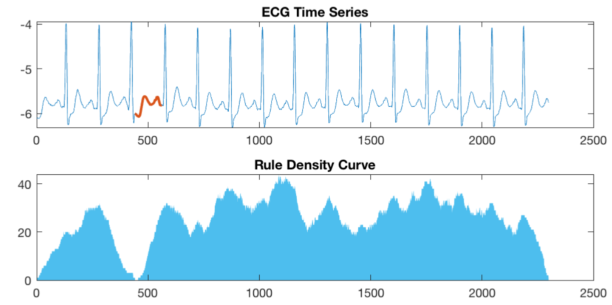


Figure 4: An example of the rule density curve generated for an ECG time series.

Once the rule density curve is constructed, we can locate the potentially anomalous subsequences by finding the local minima of the curve and ranking them based on their respective rule density values.

An example is shown in Figure 4. Figure 4.top shows an electrocardiogram (ECG) time series and Figure 4.bottom shows the rule density curve computed from this time series. An anomaly candidate, highlighted in red in Figure 4.top, corresponds to the minimum of the rule density curve. According to [20], this location corresponds to an anomalous premature heart beat.

5.3 Challenges of Parameter Selection

Although the grammar-induction-based approach described above has been successfully used in time series data mining problems [7, 20], it has two drawbacks that can strongly affect the quality of patterns found. First, approximation errors are inevitably introduced due to the information loss at the discretization step. For example, two subsequences represented by the same SAX word may actually be dissimilar and have a large distance. Second, Sequitur is a greedy algorithm which cannot guarantee the globally optimal result. Therefore, the grammar rules learned may not perfectly reflect the repeating and anomalous patterns in the time series. In summary, a single run of grammar induction with fixed parameter values may simply not be enough to detect high quality anomalies.

In this paper, in order to mitigate the limitations of the existing grammar-induction-based anomaly detection framework while still maintaining high efficiency, we introduce an ensemble approach to generate a rule density curve based on multiple runs with different parameter values.

Table 2: Example of Sequitur inducing grammar from token sequence S_{NR} of Eq. (4)

Step	Grammar rules	Digrams
1.	$S \rightarrow ab_1$	
2.	$S \rightarrow ab_1, bc_8$	$\{ab, bc\}$
3.	$S \rightarrow ab_1, bc_8, aa_{15}$	$\{ab, bc\}, \{bc, aa\}$
4.	$S \rightarrow ab_1, bc_8, aa_{15}, cc_{21}$	$\{ab, bc\}, \{bc, aa\}, \{aa, cc\}$
5.	$S \rightarrow ab_1, bc_8, aa_{15}, cc_{21}, ca_{25}$	$\{ab, bc\}, \{bc, aa\}, \{aa, cc\}, \{cc, ca\}$
6.	$S \rightarrow ab_1, bc_8, aa_{15}, cc_{21}, ca_{25}, ab_{29}$	$\{ab, bc\}, \{bc, aa\}, \{aa, cc\}, \{cc, ca\}, \{ca, ab\}$
7.	$S \rightarrow \boldsymbol{ab_1, bc_8}, aa_{15}, cc_{21}, ca_{25}, \boldsymbol{ab_{29}, bc_{34}}$	$\boldsymbol{\{ab, bc\}}, \{bc, aa\}, \{aa, cc\}, \{cc, ca\}, \{ca, ab\}, \boldsymbol{\{ab, bc\}}$
8.	$S \rightarrow R_1, aa_{15}, cc_{21}, ca_{25}, R_1$ $R_1 \rightarrow ab, bc$	$\{R_1, aa\}, \{bc, aa\}, \{aa, cc\}, \{cc, ca\}, \{ca, ab\}, \{ca, R_1\}$ $\{ab, bc\}$
9.	$S \rightarrow \boldsymbol{R_1, aa_{15}}, cc_{21}, ca_{25}, \boldsymbol{R_1, aa_{40}}$ $R_1 \rightarrow ab, bc$	$\boldsymbol{\{R_1, aa\}}, \{bc, aa\}, \{aa, cc\}, \{cc, ca\}, \{ca, ab\}, \{ca, R_1\}, \boldsymbol{\{R_1, aa\}}$ $\{ab, bc\}$
10.	$S \rightarrow R_2, cc_{21}, ca_{25}, R_2$ $\boldsymbol{R_1 \rightarrow ab, bc}$ $R_2 \rightarrow R_1, aa$	$\{R_2, cc\}, \{cc, ca\}, \{ca, R_2\}$ $\{ab, bc\}$ $\boldsymbol{\{R1, aa\}}$
11.	$S \rightarrow R_2, cc_{21}, ca_{25}, R_2$ $R_2 \rightarrow ab, bc, aa$	$\{R_2, cc_{21}\}, \{cc, ca\}, \{cc_{21}, R_2\}$ $\{ab, bc\}, \{bc, aa\}$

6 ENSEMBLE GRAMMAR INDUCTION

In this section, we introduce the proposed ensemble-based grammar induction approach.

6.1 Ensemble Rule Density Curve

The algorithm that generates the ensemble rule density curve from a set of multiple grammar induction runs is shown in Algorithm 1. First, we generate N rule density curves using values for PAA size w and alphabet size a randomly chosen from intervals $[2, w_{\max}]$ and $[2, a_{\max}]$, respectively (Lines 4–6). Second, we remove low-quality curves based on their standard deviations (Lines 7–10). Third, we normalize each remaining curve to the same scale (Line 11). Finally, we combine the results from all normalized curves by computing the median (Line 14).

Algorithm 1: Ensemble Rule Density Curve

```
1:  Input: time series $T$, sliding window length $n$, ensemble
    size $N$, maximum PAA size $w_{\max}$, maximum alphabet
    size $a_{\max}$, ensemble selectivity $\tau$
2:  Output: ensemble rule density curve $d_e$
3:  $\mathcal{D}$ =[] {Compute $N$ rule density curves with random
    parameter values and compute the standard deviation
    for each of them}
4:  for $i = 1$ to $N$ do
        {Randomly generate parameter values; any $w, a$
    combination is used only once}
5:    $w, a$ = GenerateRandomParam($w_{\max}, a_{\max}$)
6:    $d_i$ = GrammarInduction($T, n, w, a$)
7:    $s_i$ = ComputeStd($d_i$);
8:  end for
9:  index = ArgSort($s$) {Sort the standard deviations in
    descending order}
10: for $i = 1$ to $\tau N$ do {Keep $\tau$% of the density curves and
    normalize each of them}
11:   $d_{\text{norm}} = d_{\text{index}[i]} / \max(d_{\text{index}[i]})$
12:   $\mathcal{D}$.add($d_{\text{norm}}$)
13: end for
14: $d_e$ = ComputeMedian($\mathcal{D}$) {Compute the median for all
    normalized rule density curves}
15: return $d_e$
```

6.1.1 Removing Low-Quality Rule Density Curves.

Not all rule density curves provide reliable information about anomalies. Intuitively, low-quality curves correspond to situations where a grammar rule set has a similar frequency everywhere, and they should be removed from the ensemble to improve the effectiveness of anomaly detection. Towards this end, the algorithm computes the standard deviation for each of the generated rule density curves (Line 8). We then rank the curves based on the standard deviation in descending order and only keep the top τ% of the curves to form the ensemble set $\mathcal{D}$.

An example that illustrates the quality variation among different rule density curves is shown in Figure 5. All four curves in Figure 5 are generated from the ECG time series shown in Figure 4.top. The first two curves colored in blue are the top-2 curves based on the ranking by the standard deviation. The last two curves colored in red are the bottom-2 curves based on this ranking. As seen from the figure, it is very hard to determine the anomaly location from the bottom-2 curves. In contrast, the top-2 curves reveal the anomaly location clearly. This example demonstrates that using the rule density curves with higher standard deviations can help identify anomalies and potentially reduce the number of false positives.

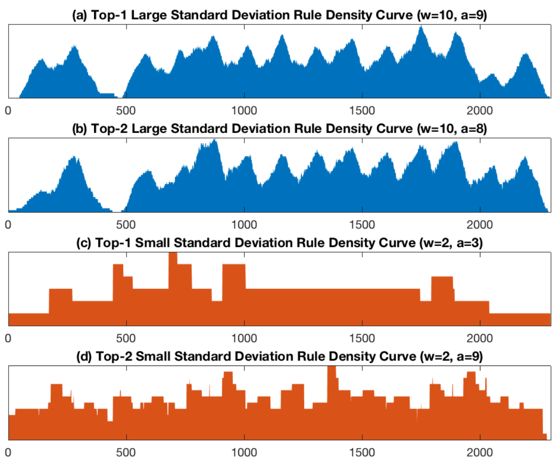

Figure 5: Examples of rule density curves generated from the ECG time series with different parameter values.

6.1.2 *Normalizing Rule Density Curves.*

Intuitively, each rule density curve may have a different scale. For example, using a coarse discretization resolution (i.e., small PAA size and alphabet size) tends to result in a large average frequency of grammar rules since it is more likely to find a match due to a smaller dictionary size. Conversely, using a fine discretization resolution (i.e., large PAA size and alphabet size) tends to result in a small average frequency of grammar rules. Consequently, without a normalization process, some anomaly detectors may undeservedly dominate the decision.

To avoid this problem, we normalize each of the rule density curves in the ensemble set, so that each point of the curve falls in the range [0, 1]. It is worth noting that we do not use min-max normalization because we want to preserve the significance of the locations where the rule density is zero.

6.1.3 *Combining Rule Density Curves.*

At the final step, we compute an ensemble rule density curve d_e based on all normalized curves kept in the set. In this paper, the specific way in which we combine all rule density curves in the ensemble is by computing the median value at each time point. Once the ensemble rule density curve is generated, the algorithm ranks the anomaly candidates through the same process as described in Sec. 5.2.

6.2 Multi-resolution SAX Word Computation

Since the ensemble approach requires computing different SAX words (corresponding to different parameter values) for the same subsequence, it is important to increase the efficiency of the discretization process. Therefore, in this subsection, we describe a fast way to compute multi-resolution SAX words [6].

6.2.1 *Fast Computation of SAX Words with Different Values of w.*

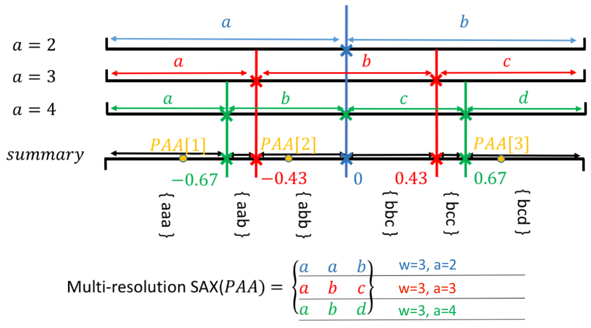
We first describe a fast way to compute the PAA coefficients [16]. First, two vectors of statistical features for a time series T are pre-computed: $\text{ESum}_x(x) = \sum_{i=1}^{x} t_i$ and $\text{ESum}_{xx}(x) = \sum_{i=1}^{x} t_i^2$. Given a subsequence $T_{p,q}$ of length n, the SAX representation can be computed by Algorithm 2. In this algorithm, the mean and variance of $T_{p,q}$ are computed in constant time (Lines 3–5). The cost of computing the PAA coefficients (Lines 6–8) is $O(w)$ for a single resolution, which is faster than the trivial approach whose computation cost is $O(n)$ ($w < n$).

Algorithm 2: Fast Compute PAA (FastPAA)

```
1: **Input**: subsequence $T_{p,q}$, $\text{Esum}_x$,$\text{Esum}_{xx}$, PAA size $w$
2: **Output**: PAA representation $A$
3: $E_x = \text{Esum}_x(q) - \text{Esum}_x(p)$
4: $E_{xx} = \text{Esum}_{xx}(q) - \text{Esum}_{xx}(p)$
5: $n = q - p + 1$, $\mu = E_x/n$, $\sigma = \sqrt{(E_{xx} - E_x^2/n)/(n-1)}$
6: **for** every PAA segment **do**
7:     $A_i = \left(\frac{\text{Esum}_x(A_{i,e}) - \text{Esum}_x(A_{i,s})}{n/w} - \mu\right)/\sigma$ {$A_{i,s}$ and $A_{i,e}$ are the start and end points of the $i$th PAA segment}
8: **end for**
9: **return** $A$
```

6.2.2 *Fast Computation of SAX Words with Different Values of a.*

To efficiently compute SAX words with multiple resolutions, we adapt an algorithm we introduced in a previous work [6]. Specifically, given a maximum alphabet size $a_{\max}$, to fast compute SAX words with different alphabet sizes, we first gather breakpoint tables of all alphabet size values used in the ensemble. For each interval between any two breakpoints, a symbol sequence containing corresponding symbols up to $a_{\max}$ resolution is recorded. We represent any PAA coefficient belonging to the interval by the pre-computed symbol sequence.



$$\text{Multi-resolution SAX}(PAA) = \begin{Bmatrix} a & a & b \\ a & b & c \\ a & b & d \end{Bmatrix}$$

Figure 6: Fast computation of multi-resolution SAX.

An example with alphabet sizes from 2 to 4 is shown in Figure 6. In the figure, the set of breakpoints for all alphabet sizes from 2 to 4 (labeled by '×' in each line) are projected to the line denoted as "summary." All distinct breakpoints with a from 2 to 4 in the breakpoint table (Fig. 3.bottom) create 6 intervals, and each interval stores a sequence of symbols. The i^{th} position in such a sequence stores the corresponding symbol for alphabet size $a = i + 1$. For example, the 3 PAA coefficients that fall in intervals $(-\infty, -0.63]$, $(-0.43, 0]$ and $(0.63, \infty)$ (denoted by yellow dots) are mapped to symbol sequences *aaa*, *abb*, and *bcd*, respectively. A symbol matrix is then created by concatenating such symbol sequences (bottom of Figure 6). The i^{th} row of the symbol matrix represents a SAX word generated with alphabet size $i + 1$. For example, the first row *aab* is the SAX word generated for $a = 2$. To construct the matrix of SAX words with all alphabet sizes, for each PAA coefficient, we only need to perform at most 3 comparisons to determine the interval via binary search, which is the same as generating fixed-resolution SAX. By using binary search to determine which interval the PAA coefficient belongs to, we can find its SAX representations in all resolutions from $a = 2$ to $a = a_{\max}$ with a time complexity of $O(2\log(a_{\max}))$. When $a_{\max} = 20$, the cost of computing all resolutions is similar to computing a fixed resolution.

6.2.3 *Overall Improvement.*

The time complexity of computing SAX words with multiple resolutions in a straightforward manner (without acceleration) is $O(nw_{\max}a_{\max} + w_{\max}^2 a_{\max}^2)$. In contrast, with the proposed acceleration, the computation cost is $O(w_{\max}^2 \log(a_{\max}))$, which is a significant improvement.

7 EXPERIMENTAL EVALUATION

We perform a series of numerical experiments to evaluate the accuracy and speed of ensemble grammar induction applied to time series anomaly detection. In all experiments, unless noted otherwise, the parameter values are: $a_{\max} = 10$, $w_{\max} = 10$, $N = 50$, and $\tau = 40\%$. All the experiments are conducted on a 16 GB RAM laptop with quad core processor of 2.5 GHz. We first show the performance on real-world time series. We then evaluate the impact of parameter sets used in the ensemble. Finally, we analyze the scalability of the algorithm and conduct a case study on an electric load time series.

Table 3: Properties of datasets used for experimental evaluation

Dataset	Time Series Length	Segment Length	Data Type
TwoLeadECG	1772	82	ECG
ECGFiveDay	2772	132	ECG
GunPoint	3150	150	Motion
Wafer	3150	150	Sensor
Trace	5775	275	Sensor
StarLightCurve	21504	1024	Sensor

Table 4: Performance evaluation results (average Score)

Dataset	Proposed Approach	GI-Random	GI-Fix	GI-Select	Discord
TwoLeadECG	0.3951	0.2873	0.0629	0.1663	**0.4931**
ECGFiveDay	0.3903	0.2988	0.2671	0.105	**0.4794**
GunPoint	**0.4728**	0.3715	0.2411	0.056	0.4
Wafer	**0.3179**	0.2126	0.1382	0.248	0.309
Trace	**0.5718**	0.2022	0.3601	0.3408	0.2816

StarLightCurve	1.0	0.96	0.76	1.0	1.0

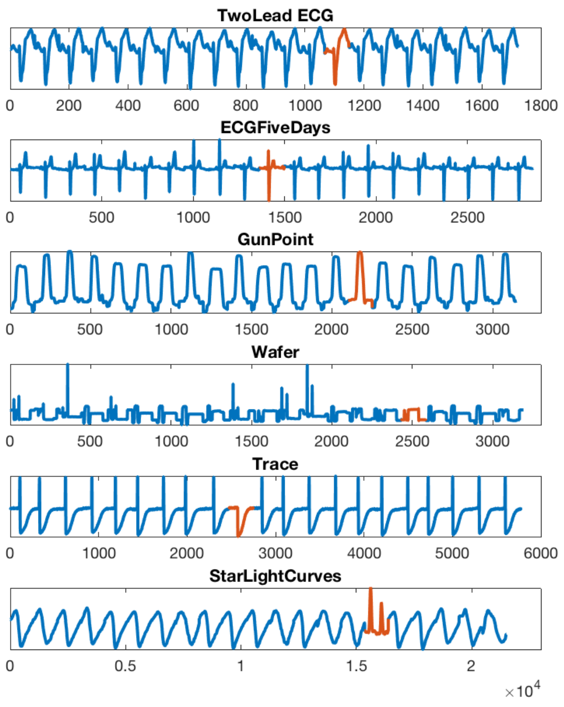

Figure 7: Examples of the test time series generated from six real-world and synthetic time series datasets. In each time series, the segment that belongs to a different class is highlighted in red.

7.1 Performance Evaluation in Comparison to Baseline Methods

Since it is difficult to find annotated time series for anomaly detection, to evaluate our proposed method, we compile our own data using several real-world and synthetic time series datasets from the UCR Time Series Classification Archive [3].

7.1.1 Datasets. We chose six time series datasets with diverse characteristics from the archive. The properties of the data are shown in Table 3. The datasets originate from different application domains including medicine (ECG), 3D motion tracking (GunPoint), manufacturing (Wafer), synthetic sensor data (Trace) and astronomy (StarLightCurve), with different instance lengths (ranging from 82 to more than 1000).

The instances are labeled with class information. For each dataset, we treat all instances that belong to the first class as "normal" data, and all the remaining instances that belong to other classes as "anomalous." We first generate a normal time series by concatenating 20 randomly selected normal instances. Then an anomalous instance is randomly selected and planted into the generated normal time series at a random position between 40% and 80% of the series. In this manner, we generate 25 time series for each of the six datasets. One example of the generated time series for each of the six datasets are shown in Figure 7, with planted anomalous instances highlighted in red. All methods being compared are run to locate the planted anomalous instance in each time series, with sliding window length n equal to the instance length.

7.1.2 Performance Evaluation. Each of the tested methods returns top-3 ranked anomaly candidates (which are required to not overlap with each other) for each time series. We evaluate the performance of each method by quantifying the overlap between the discovered anomalies and the ground truth (the planted anomaly). Specifically, for each anomaly candidate, we compute a quantity called Score, defined as:

$$\text{Score} = 1 - \min\left(1, \frac{|\text{PredictLocation} - \text{GTLocation}|}{\text{GTLength}}\right), \quad (5)$$

where PredictLocation is the location of the anomaly candidate, while GTLocation and GTLength are the location and length of the planted anomalous instance. The maximum value, Score = 1, is obtained when PredictLocation exactly matches the ground truth. The better the overlap between the anomaly candidate and the ground truth, the higher the Score. If the anomaly candidate does not overlap with the ground truth at all, then Score = 0.

For each method and each time series, we only use the maximum Score achieved among the three anomaly candidates. For each method, we record the average Score value computed over the set of 25 time series generated per dataset; the average Score values are reported in Table 4. We also record the quantity called HitRate, which is the fraction of the anomaly candidates that overlap with the ground truth (i.e., satisfy the condition Score > 0); the HitRate values are reported in Table 5. Finally, we record the number of times the ensemble grammar induction method wins/ties/loses against a baseline method; these results are reported in Table 6.

7.1.3 Baselines. The proposed ensemble-based method is compared against four different baseline methods, which are described below.

- **Grammar Induction with Random Parameter Values** (GI-Random): The grammar-induction-based anomaly detection approach with randomly selected parameter values w and a. The ranges from which w and a are chosen are the same as in the ensemble-based approach..

- **Grammar Induction with Fixed Generic Parameter Values** (GI-Fix): The grammar-induction-based anomaly detection approach with fixed parameter values $w = 4$ and $a = 4$. These are popular parameter values that can be used in most of datasets as reported in [20].
- **Grammar Induction with Selected Parameter Values** (GI-Select): The grammar-induction-based anomaly detection approach with w and a values selected via an optimization procedure described in [19], using 10% of the normal time series. The ranges from which w and a are chosen are the same as in the ensemble-based approach.
- **Time Series Discord** (Discord): The state-of-the-art approach that computes the one–nearest-neighbor (1-NN) distance for every subsequence in the time series; the subsequences with the largest 1-NN distances are labeled as anomalies. In the experiments, we use the latest Matrix-Profile-based implementation of this approach [23] to compute the 1-NN distances.

7.1.4 Results. The overall performance results measured by the average Score and HitRate are shown in Tables 4 and 5, respectively.

According to Table 4, the proposed approach achieves the highest average Score values in four out of six datasets, and the second-highest average Score values in two of the datasets. Compared with GI-Random, GI-Fix, and GI-Select, the proposed approach achieves higher average Score values in all six datasets. Compared with Discord, the proposed approach achieves a higher average Score value in four out of six datasets (GunPoint, Wafer, Trace and StarLightCurve). In two datasets (ECGFiveDays and TwoLeadECG), Discord outperforms the proposed approach.

According to Table 5, the proposed approach achieves the highest HitRate values (alone or shared) in five out of six datasets, and the second-highest HitRate value in one of the datasets. These results are consistent with those in Table 4 and indicate that the proposed approach can successfully locate an anomalous subsequence that strongly overlaps with the ground truth.

In addition, Figure 10 shows a detailed comparison summary of the proposed approach against all baselines. Each of the six rows corresponds to one of the datasets, and each of the four columns corresponds to one of the baselines. In each plot, a blue dot located at the point (x, y) denotes a pair of Score values (ensemble Score, baseline Score), computed from Eq. (5) for one of the 25 generated time series. A dot located in the lower triangle (highlighted in pink) of the plot corresponds to a win of the proposed approach (ensemble Score > baseline Score); a point located in the upper triangle corresponds to a loss (ensemble Score < baseline Score), and a point located on the diagonal corresponds to a tie (ensemble Score = baseline Score). The numbers of wins, ties, and losses of the proposed method against the baselines are shown in Table 6.

According to Figure 10, the proposed approach outperforms GI-Random, GI-Fix, and GI-Select. Moreover, in most of the tested datasets, the proposed method often detects ground truth anomalies that are completely missed by these variations of the grammar-induction-based approach (i.e., the respective baseline Score values are zero), while the opposite outcomes (ensemble Score values are zero) are quite rare. Compared with Discord, the proposed approach achieves similar performance. Moreover, in most of the tested datasets, cases where the ensemble-based approach discovers ground truth anomalies missed by Discord are more common than the opposite ones.

According to Table 6, compared with GI-Random, GI-Fix, and GI-Select, the proposed method wins in more than half of the time series in most datasets. Compared with Discord, the results are similar to those measured by Score and HitRate. Specifically, the proposed approach has more wins than losses in three datasets (GunPoint, Wafer, and Trace), loses more often than wins in two ECG datasets, and is in a virtual dead heat with Discord in the StarLightCurves dataset.

In summary, the experiments indicate that using an ensemble of parameter values can significantly improve the performance of the grammar-induction-based approach, compared to the variations of the method where a single combination of parameter values is selected. Also, the proposed method can achieve a competitive performance compared with the state-of-the-art discord approach. Importantly, while the latter has a quadratic time complexity, the former preserves a linear time complexity and hence is much more feasible for anomaly detection in large-scale data.

7.2 Effects of Parameter Value Ranges

In this subsection, we first evaluate how the ensemble grammar induction approach performs for different parameter value ranges determined by $w_{\max}$ and $a_{\max}$. Specifically, we evaluate the performance on the same time series that were used in Sec. 7.1. As the baseline for comparison, we use the best of the GI-Random, GI-Fix, and GI-Select methods for each dataset. We report the number of wins/ties/loses vs. the baseline for all tested parameter value ranges. We then evaluate how values of three hyper parameters — ensemble size N, ensemble selectivity τ, and sliding window length n — affect the result. In these experiments, we evaluate the performance based on Score and HitRate.

7.2.1 Effect of $w_{\max}$ and $a_{\max}$. We first test the proposed approach with values of $w_{\max}$ and $a_{\max}$ equal to each other and varying from 5 to 20. The results are shown in Table 7. According to the results, the smallest ranges ($w_{\max} = a_{\max} = 5$) lead to the worst performance. A possible explanation is that the ranges are too small to generate a sufficient number of high-quality rule density curves. The performance significantly improves for $w_{\max} = a_{\max} = 15$. However, increasing the range values beyond 15 is not useful; furthermore, in two datasets (TwoLeadECG and StarLightCurve) the performance slightly deteriorates when the ranges go up to 20, and in the GunPoint dataset the performance actually peaks for $w_{\max} = a_{\max} = 10$. The lack of performance improvement (or even some deterioration) at range values larger than 15 indicates that long and high-resolution SAX words may capture too much noise in data and, as a result, produce low-quality rule density curves. Nevertheless, the ensemble-based method still outperforms other approaches that rely on a single combination of parameter values.

7.2.2 Effect of $w_{\max}$. We also test the proposed approach with values of $w_{\max}$ varying from 5 to 20 and fixed $a_{\max} = 10$. The results are shown in Table 8. Once again, we observe that when the range is too small ($w_{\max} = 5$), the performance is the worst. The performance significantly improves for larger values of $w_{\max}$, with the peak-performance value depending on the dataset.

7.2.3 Effect of $a_{\max}$. In this experiment, we test the proposed approach with values of $a_{\max}$ varying from 5 to 20 and fixed $w_{\max} = 10$. The results are shown in Table 9. For $a_{\max} = 5$, the performance is subpar for the ECGFiveDays, GunPoint, and

Table 6: Wins/ties/losses of ensemble grammar induction against all baselines

$a_{\max} = 15$, $w_{\max} = 10$	11/6/8	13/6/6	13/4/8	8/8/9	16/0/9	15/0/10
$a_{\max} = 20$, $w_{\max} = 10$	11/4/10	14/5/6	13/4/8	9/9/7	15/0/10	12/1/12

Trace datasets, and it is terrible for the StarLightCurve dataset (as a rule, this dataset exhibits the worst performance when one or both range values are small). However, $a_{\max} = 5$ actually results in the best performance for the Wafer dataset. For most datasets, the $a_{\max}$ values of 10, 15, and 20 produce very similar results.

The last two experiments indicate that having a larger range for w is more important than for a, which may indicate that a variation in the PAA size has a larger effect on the performance of the algorithm than a variation in the alphabet size, and hence w is a more important parameter to choose, in general.

Table 10: Performance (average Score) vs. N

Dataset	$N = 5$	$N = 10$	$N = 25$	$N = 50$
TwoLeadECG	0.3424	0.3488	0.3912	0.3951

Trace	0.4767	0.5789	0.5994	0.5718
StarLightCurve	0.8244	0.7593	0.8676	0.9369

Table 11: Performance (HitRate) vs. N

Dataset	$N = 5$	$N = 10$	$N = 25$	$N = 50$
TwoLeadECG	0.52	0.6	0.72	0.72
ECGFiveDays	0.68	0.72	0.76	0.8
GunPoint	0.56	0.76	0.68	0.68
Wafer	0.44	0.64	0.6	0.72
Trace	0.76	0.96	0.96	0.96
StarLightCurve	1.0	1.0	1.0	1.0

7.2.4 Effect of Ensemble Size. We next evaluate the proposed method with the ensemble size N varying from 5 to 50 (recall that all other experiments used the fixed value $N = 50$). The average Score and HitRate of the proposed method for different ensemble sizes are shown in Tables 10 and 11, respectively.

We observe that the performance for a small ensemble size ($N = 5$) is worse than for a larger ensemble size ($N = 25$ or $N = 50$) for all datasets. In general, the Score and HitRate values increase as N grows, but these increases saturate when the ensemble size is large enough (e.g., when $N \geq 25$). The results indicate that selecting $N \geq 25$ may be suitable for most cases.

We also observe that the Score values are, in general, rather low for all methods, for most datasets except StarLightCurve. This could be due to the fact that the Score is normalized by the ground truth length (cf. Eq. (5)). However, the planted anomaly may only have a small section that differs from the "normal" data, and that may be what the algorithms detect. In such case, treating the entire planted instance as anomalous would indeed lower the Score. This explanation is later validated by the results in Table 13, which show that a shorter sliding window length results in higher Score values in some cases. Nevertheless, this is why we also use the HitRate, which is independent of the ground truth length, as an alternate measure.

7.2.5 Effects of Ensemble Selectivity. Next, we evaluate the proposed method with ensemble selectivity τ varying from 5% to 100%. In this experiment, the evaluation of the average Score value (which is computed over 25 time series) is repeated 20 times for each dataset and τ value. We then compute the mean and standard deviation over the set of 20 average Score values. The results are shown in Table 12. We observe that better performance is typically achieved for smaller τ values (e.g., from 5% for ECGFiveDays and Trace datasets to 20% for GunPoint and StarLightCurve datasets), while the standard deviation is typically smaller for τ values of 20% or 40%. Therefore, we recommend choosing τ around 20% since it combines a relatively high level of performance with a relatively small variance of results.

7.2.6 Effects of Sliding Window Length. In this experiment, we investigate how the proposed method performs when the sliding window length n is less than the ground truth anomaly

Table 12: Mean and standard deviation over 20 average Score values, vs. τ

Dataset	τ = 5%	τ = 10%	τ = 20%	τ = 40%	τ = 80%	τ = 100%

length (denoted as n_a). Specifically, we test five different sliding window lengths equal to 60%, 70%, 80%, 90% and 100% of n_a. The average Score and HitRate values are shown in Tables 13 and 14, respectively. According to the results, while there exists some variation in the performance, the dependence on n is not significant, and the proposed method robustly outperforms the existing grammar-induction-based approaches in most cases.

7.3 Scalability

We evaluate the scalability of the proposed ensemble-based approach by applying it to a 160,000 length random walk (RW) time series, ECG data [18] and electroencephalogram (EEG) data [13]. We compare the computation times for the proposed method and for the state-of-the-art discord discovery approach. In the experiment, we use STOMP [23], the latest Matrix-Profile-based algorithm, to detect discords. It has been shown that STOMP is both faster and more robust to different types of data compared to the original discord discovery method HOTSAX [9].

The scalability, evaluated as the computation time versus the time series length, is shown in Figure 8. We see that, as the time series length increases, the computation time grows significantly slower for the proposed method than for STOMP. At the largest time series length, the proposed approach is about one order of magnitude faster than STOMP, for all three types of time series data. We also find that the computation times for both approaches are roughly independent of the sliding window length.

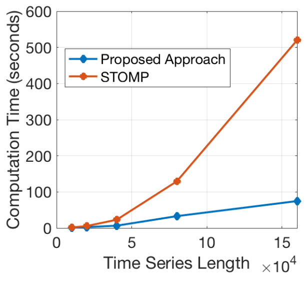
(b) ECG time series



(c) EEG time series

Figure 8: Scalability: Computation time vs. time series length.

7.4 Case Study: Anomaly Detection in Electric Power Usage Time Series

Interpreting the time dependence of electric power usage has many potential applications [21]. In this section, we show that the ensemble grammar induction method can find anomalies in large-scale electric power usage time series. We use 100 days of the fridge-freezer power usage data provided in [14], to evaluate the performance of the proposed method. The entire time series, which consists of approximately 600,000 points, is shown in Figure 9(a), and the first 20,000 points are shown in Figure 9(b). We run the proposed method with the sliding window length of 900, which is about the duration of one cycle (shown in red box in Figure 9(b)). The computation time is about one minute. Figures 9(c) and 9(d) show the two top-ranked anomaly candidates detected by the proposed method.

We see that the top-1 anomaly represents a cycle whose shape is unusual compared to the typical cycles shown in Figure 9(b). The top-2 anomaly represents an unusual event that contains normal cycles and short spikes. The two anomalies represent different, unusual power usage patterns. Since this time series is very long, and the anomalies have different lengths, using the state-of-the-art discord discovery approach would be time consuming. In contrast, the proposed method provides an efficient way to detect anomalies.

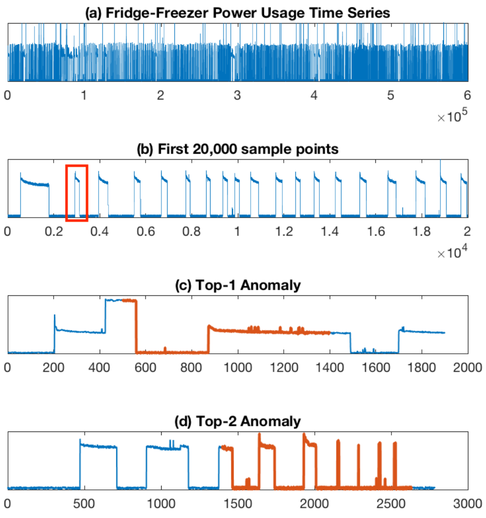


Figure 9: A 600,000 length fridge-freezer power usage time series, and two top-ranked anomalies detected in this series by ensemble grammar induction.

7.5 Detecting Multiple Anomalies

We also investigate the effectiveness of the proposed approach in detecting multiple anomalies in time series. In this experiment, we use the StarlightCurve dataset to generate 10 time series. Each of these time series is of length 43008 and contains two randomly selected and placed anomalies of length 1024. We evaluate the performance by the number of ground truth anomalies detected (a ground truth anomaly is considered detected if it overlaps with at least one of the top-3 ranked anomaly candidates). The proposed method performed well as it successfully identified both anomalies in nine time series and one of the two anomalies in one time series.

8 CONCLUSION

In this paper, we introduce a robust grammar-induction-based anomaly detection approach utilizing ensemble learning. Instead of using a particular combination of parameter values for anomaly detection, the proposed method generates the final result based on a set of results obtained using different parameter values. The experiments performed on datasets with known ground truth show that the proposed ensemble approach can outperform existing grammar-induction-based approaches with different criteria for selection of parameter values. We also show that the proposed approach, which has a linear time complexity with respect to the data size, can achieve performance similar to that of the state-of-the-art distance-based anomaly detection approach that has a quadratic time complexity.

Incremental Based Top-k Similarity Search Framework for Interactive-Data-Analysis Sessions

Oded Elbaz, Tova Milo, and Amit Somech

Tel Aviv University, Israel

ABSTRACT

Interactive Data Analysis (IDA) is a core knowledge-discovery process, in which data scientists explore datasets by issuing a sequence of data analysis actions (e.g. filter, aggregation, visualization), referred to as a session. Since IDA is a challenging task, special recommendation systems were devised in previous work, aimed to assist users in choosing the next analysis action to perform at each point in the session. Such systems often record previous IDA sessions and utilize them to generate next-action recommendations. To do so, a compound, dedicated session-similarity measure is employed to find the top-k sessions most similar to the session of the current user. Clearly, the efficiency of the top-k similarity search is critical to retain interactive response times. However, optimizing this search is challenging due to the non-metric nature of the session similarity measure.

To address this problem we exploit a key property of IDA, which is that the user session progresses *incrementally*, with the top-k similarity search performed, by the recommender system, *at each step*. We devise efficient top-k algorithms that harness the incremental nature of the problem to speed up the similarity search, employing a novel, effective *filter-and-refine* method. Our experiments demonstrate the efficiency of our solution, obtaining a running-time speedup of over 180X compared to a sequential similarity search.

1 INTRODUCTION

Interactive Data Analysis (IDA) is an important procedure in any process of data-driven discovery. It is ubiquitously performed by data scientists and analysts who interact with their data "hands-on" by iteratively applying analysis actions (e.g. filtering, aggregations, visualizations) and manually examining the results. This is primarily done to understand the nature of the data and extract knowledge from it, yet is also fundamental for particular data scientific tasks such as data wrangling and cleaning, feature selection and engineering, and explaining decision models.

However, since IDA is long known as a complex and difficult task, extensive research has been devoted to the development of *recommendation systems* that assist users in choosing an appropriate next-action to perform at each point in an IDA session. Many of these IDA recommendation systems [2, 15, 16, 26, 43] rely on a *similarity comparison* between users' sequences of analysis actions (denoted *sessions*). They follow the assumption that if two session *prefixes* are similar, their *continuation* is likely to also be similar. Hence, they utilize a repository of prior analysis sessions (of the same or other users): Given an *ongoing* user's session, such systems first retrieve the top-k most similar session prefixes from the repository, then examine their continuation and use the gathered information to form a possible next-action recommendation [2, 15, 16, 43]. Since these recommender systems are *interactive*, the efficiency of the top-k session similarity search is critical. However, most previous work focuses on the *quality* and *applicability* of the produced IDA recommendations, rather than on their *scalability* and running time *performance*.

Our goal in this paper is thus to devise efficient, scalable algorithms for this particular top-k similarity search problem, a significant computational bottleneck in many IDA recommender systems. Specifically, we focus our attention on a dedicated similarity measure for analysis sessions [3], which we denote by *SW-SIM*. In a comprehensive user study [3], *SW-SIM* was compared, quality wise, against several alternative similarity measures, and was found to be the most suitable for the context of data analysis sessions. Consequently, it has been adopted by multiple IDA recommender systems and applications, e.g., [2, 4, 30, 41, 44]. *SW-SIM* is an extension of the well-known Smith-Waterman algorithm [35] for local sequence alignment. Intuitively, given a similarity metric for individual analysis-actions (e.g. filter, aggregation, visualization), *SW-SIM* compares two sessions s, s' by *aligning* them, i.e. matching similar action pairs using an *alignment matrix*. The measure allows for (yet penalizes) gaps in the alignment, and gives a higher weight to the more recent actions in the session, since they are expected to have higher relevance on the current user's intent.

Given a current user session and a sessions repository, a naive top-k search may be done by sequentially iterating over all sessions in the repository, computing the *SW-SIM* similarity score of the current session w.r.t. each of their prefixes, then selecting the top-k prefixes with the highest score. This simple algorithm, however, is prohibitively time consuming: **Our experiments show that even when employed on a medium size repository of 10K sessions, the naive sequential search takes more than 17 seconds to complete**. This is excessively high for a real-time response.

To optimize it, two key challenges must be addressed:

1. A single similarity comparison of two sessions is expensive to begin with. Computing *SW-SIM* requires to construct an alignment matrix, which results in a high computation time (quadratic in the mean session length).

2. Employing existing optimizations is highly non-trivial. Since *SW-SIM* is a non-metric similarity measure, existing optimizations for similarity search e.g. [8, 33, 37] are inadequate. Furthermore, because analysis sessions are compound sequences of complex analysis actions, they do not have a numeric vector representation, which is a requirement by other top-k optimization works [33].(See Section 2 for an elaborated discussion.)

A key observation underlying our work is that the user session progresses *incrementally* with the top-k similarity search performed by the IDA recommender system *at each step*. We exploit this property to address the two challenges mentioned above: Our first, rather direct optimization, speeds up the processing of a *single* similarity comparison between two sessions by utilizing previous-step computations. Our second, more sophisticated optimization, tackles the *top-k search* by employing a novel filter-and-refine technique. It employs lower and upper bounds stemming from the incremental growth of the sessions accompanied by a dedicated index structure. Our experiments demonstrate that **using our optimizations, a speedup of more than 180X is obtained compared to a non-optimized sequential search**. Importantly, this is done while retaining a perfect accuracy of results, since our algorithms are exact.

We next explicitly state our assumptions and focus, then summarize our contributions and paper organization.

Paper Focus and Assumptions.
1. Although the particular IDA settings may vary, many IDA recommender systems rely on a top-k prefixes search. IDA settings may vary between systems, in terms of, e.g., the type of allowed analysis actions, structure of the data, user expertise, etc. However, the incremental, session-like nature of the process characterizes most IDA settings. Our paper is thus aimed at solving a computational bottleneck in a growing number of IDA-dedicated recommendation systems [2, 15, 16, 26, 43] that rely on finding the top-k most similar session prefixes in order to generate recommendations. Our solution is generic, suitable for a wide range of IDA platforms, regardless of their particular settings.
2. *SW-SIM* is currently the most-suitable measure for IDA sessions similarity. A multitude of definitions exist for measuring the similarity between two arbitrary sequences, such as *Dynamic Time Warping* for time series and *Smith-Waterman* for DNA sequences. In the context of data analysis sessions, *SW-SIM* is considered the most comprehensive and suitable (See [3] for a comparative study).
3. The focus of this paper is on performance and scalability, rather than on the quality of the produced recommendations. Different IDA recommender systems may use the selected top-k sessions in different ways in order to generate recommendations, possibly using additional information such as the data properties, user profiles, etc. But in all of them - response time optimization of the top-k search is clearly a critical issue. We therefore focus on performance and scalability rather than discussing the quality of the recommendations produced. For the latter, we refer the reader to works e.g. [2, 15, 16, 26, 43] in which the focus is on the quality of recommendations produced.

Technical Contributions & Paper Organization.
Section 3: We provide a simple, generic model for representing IDA sessions, and describe the alignment-based session similarity notion. Based on this model, we develop a formal definition for the incremental top-k similarity search problem.
Section 4: We describe an optimization for the incremental construction of a session alignment matrix and means to derive prefixes similarity scores from it.
Section 5: We present a novel threshold-based algorithm for the incremental top-k search, which utilizes effective similarity lower and upper bounds, also stemming from the incremental nature of the search problem.
Section 6: We demonstrate the efficiency of our solution via extensive experiments on artificial and real-life session repositories.

We begin by reviewing related work (Section 2), and finally present our conclusions and limitations in Section 7.

2 RELATED WORK

There is vast literature on sequences similarity, alignment, and top-k search. We survey works in numerous application domains, explaining why existing optimizations are inadequate for the context of IDA.
Bioinformatics-based optimizations for sequence alignment. Local alignment techniques are known to be extremely useful in the bioinformatics domain for tasks such as DNA and protein sequencing [22, 25, 39]. In this application domain, alignment is often performed between a query sequence and an extremely long *reference* string (e.g. a DNA genome), often from a fixed, small size alphabet (comprises, e.g., six nucleotides). Consequently, biology-driven optimizations such as [14, 18, 28, 40] exploit this particular property (small alphabet size) in order to index the large reference string. These solutions typically use a prefix/suffix tree or hash tables mapping small, common substrings to their location in the reference string. In contrast, in our context the “alphabet" (namely the analysis-actions space) is unbounded and, as explained in the next section, there is a predefined notion of distance between letters (analysis actions in our context). Such solutions, therefore, cannot be directly employed in our case.
Edit Distance and Dynamic Time Warping (DTW). Edit distance and DTW are popular alignment-based measures that are used in numerous application domains such as textual auto-correction, speech recognition and the comparison of time series. However, as noted in [3], these measures lack important properties for the context of IDA sessions. Classical edit-distance, which originated from the comparison of textual strings, assumes that letters are either *identical* or *mismatched*, which is inadequate for the context of IDA. This is because the alphabet, containing individual actions, is much larger and more complex. Also, the compound similarity of individual “letters” (actions) should be taken into consideration. DTW, on the other hand, does support the employment of a designated distance metric for the sequences' objects, yet is not compatible with the notion of *gaps* [32]. Also, both measures do not support the important time-discount feature [3], which allows giving a higher weight to the more recent actions in the session. Optimization works for these measures are typically based on specific properties of the measures or application domain [19, 38].
General solutions for similarity search in a non-metric space. *SW-SIM* is a non-metric similarity measure, thus many optimizations that rely on the *triangle inequality* property (e.g.,[8, 27]) cannot be used here. Other solutions for non-metric spaces, e.g. [6, 7, 19, 34], assume that the sequences' objects are numeric vectors (e.g. as in Minkowski distance, Cosine distance), as opposed to sequences of abstract objects (analysis actions in our case). But even ignoring this, employing any such solutions in our context requires indexing each session prefix, which may be prohibitively large (typically by an order of magnitude compared to the number of sessions). Existing solutions for optimized top-k search supporting arbitrary, non-metric similarity measure are Constant Shift Embedding (CSE) [31] and NM-Tree [34]. We examine these solutions in our experimental evaluation (Section 6.2) and show that our algorithm is consistently superior, obtaining a performance improvement of at least two orders of magnitude.
Incremental keyword query autocompletion. Incremental computation is used for optimization in a variety of database applications, e.g., interactive association-rules and sequence mining [29], but most notably for incremental text autocompletion [10, 17, 24]. the latter solutions efficiently perform a *top-k keyword*

similarity search at each key stroke of the user (using string edit distance). However, such solutions also exploit the rather small alphabet size and use a trie-index, a dedicated prefix tree for strings. As explained above, in our case the "alphabet" (i.e., the analysis-actions space) is complex and unbounded. Last, [21] and [20] suggest algorithms for incrementally computing the *string edit distance* of Ax and B (where x is an additional character) in $O(|A| + |B|)$ by using the distance matrix computed for A and B. We employ similar principles for our single-pair incremental alignment computation (Section 4), yet, importantly, augment them with novel techniques for efficient top-k similarity search.
Similarity search of scientific/business workflows. Similarity search has also been considered in the context of workflows [12, 23, 36] in two main contexts - searching for workflow *specifications*, and searching for workflow *traces*. They employ, however, a different notions of similarity focusing mainly on the structure/nesting of the workflow-specification components (different from the the unstructured, free-form nature of IDA sessions). Also, to our knowledge, these works do not address the *incremental* nature of the top-k similarity search problem, that is more typical for IDA sessions than for workflows.

3 PRELIMINARIES

We start by providing basic definitions for IDA, then define the incremental top-k similarity search problem.

Interactive Analysis Sessions. In the process of IDA, users investigate datasets via an interactive user interface which allows them to formulate and issue analysis actions (e.g., filter, grouping, aggregation, visualization, mining) and to examine their results. Formally, we assume an infinite domain[1] of analysis actions Q and model an analysis session as a sequence of actions $s = \langle q_1, q_2, \ldots, q_n \rangle | q_i \in Q$. We use $s[i]$ to denote the i'th action in s (q_i) and s_i to denote the session's *prefix* up to q_i, i.e. $s_i = \langle q_1, q_2, \ldots, q_i \rangle$. Therefore, $s = s_n$, and s_0 is the empty session. An ongoing user session, denoted u, is built incrementally. At time t the user issues an action q_t, then analyzes its results and decides whether to issue a next action q_{t+1} or to terminate the session. The session (prefix) u_t at time t thus consists of the actions $\langle q_1, \ldots, q_t \rangle$, where the following actions in the session, i.e., $q_{t+1}, ..q_n$ are not yet known.

In this work we consider the case of comparing the similarity of the user session u to other sessions (and parts thereof) in a given repository, denoted S, containing prior analysis sessions performed by the same or other users. To formally define sessions similarity, let us first consider the similarity of individual analysis actions, then generalize to sessions.

Individual Actions Similarity. Given a *distance metric* for individual analysis actions $\Delta : Q \times Q \rightarrow [0, 1]$ over the actions domain, the *action similarity function* $\sigma(q_1, q_2)$ is the complement function defined by $\sigma(q_1, q_2) = 1 - \Delta(q_1, q_2)$ for all q_1, q_2 in Q. Several distance/similarity measures for many kinds of analysis actions, e.g. for SQL and OLAP queries visualizations, and web-based analysis actions have been proposed in the literature (e.g. [3, 16, 26]) and our framework can employ any of them as long as the corresponding measure defines a metric space.

Session Similarity. As mentioned in Section 2, there are several ways to lift the similarity of individual elements into similarity of sequences [11]. To assess which measure is the most suitable

[1]The domain is practically infinite since some action types, e.g. "filter", may have an unbounded number of possible parameter assignments.

		a	b	c	A	B
	0	0	0	0	0	0

(b) Session ψ

Figure 1: Alignment Matrices for u_4 = "$ABAB$"

for comparing analysis sessions, the authors of [3] formulated desiderata for an ideal session similarity measure, based on an in-depth user study:

- It should take the actions' *order of execution* into consideration, i.e. two sessions are similar if they contain a *similar* set of actions, performed in a *similar order*.
- "Gaps" (i.e subsequences of non-matching actions) should be allowed yet penalized.
- Long matching subsequences should be better rewarded than shorter matching subsequences.
- Recent actions in the sessions are more relevant than old ones.

They conclude that the only measure respecting all of the above mentioned desiderata is the *Smith-Waterman similarity measure* [35], a popular measure for local sequence alignment, and propose an extension suitable for the context of analysis actions, denoted *SW-SIM* in our work. We next describe the measure.

The similarity score of two sessions is defined recursively, on increasingly growing prefixes, with the base of the recursion being the empty prefix. At each point, the similarity of the pair of actions at the end of the prefixes is considered, and the best option, score-wise, is chosen. The two actions may either be matched, in which case an award proportional to their similarity is added to the accumulated score for their preceding prefixes, or, alternatively, one of the actions is skipped over. In this case a linear *gap penalty* $0 \le \delta \le 1$ is deducted from the accumulated score. To reflect the fact that the matching/skipping of older actions is less important than that of recent ones, rewards/penalties are multiplied by a decay factor $0 \le \beta \le 1$ with an exponent reflecting how distant the actions are from the sessions' end. More formally, the sessions similarity is defined using an *alignment matrix.*

Definition 3.1 (Alignment Matrix, Similarity Score). Given sessions s, s' of lengths n, m resp., their alignment matrix $A_{s,s'} \in \mathbb{R}^{(n+1)\times(m+1)}$ is recursively defined as follows. For $0 \le i \le n$, $0 \le j \le m$:

$$A_{s,s'}[i,j] = \begin{cases} 0, \text{ if } i = 0 \lor j = 0, \text{ else:} \\ max \begin{cases} A_{s,s'}[i-1, j-1] + \sigma(s[i], s'[j])\beta^{(n-i)+(m-j)} \\ A_{s,s'}[i, j-1] - \delta\beta^{(n-i)+(m-j)} \\ A_{s,s'}[i-1, j] - \delta\beta^{(n-i)+(m-j)} \\ 0 \end{cases} \end{cases}$$

The similarity score between s and s' is defined as:

$$Sim(s, s') := A_{s,s'}[n, m]$$

Note that even though the distance between *individual actions* forms a metric space, as noted in the introduction, *SW-SIM* does not induce a metric on IDA sessions.

The optimal values for the decay factor β and the gap penalty δ are typically chosen by the system administrator using an extrinsic evaluation, as explained in Section 6.1.

The following example illustrates the definition.

Example 3.2. For simplicity, assume that the action space is represented by the English letters, both uppercase and lowercase, and assume the following action similarity for any two distinct uppercase letters X,Y and their corresponding lowercase versions x,y.

$$\sigma(\cdot,\cdot) := \begin{cases} \sigma(X,X) = 1 \\ \sigma(x,x) = 1 \\ \sigma(x,X) = \sigma(X,x) = 0.5 \\ \sigma(x,y) = \sigma(X,Y) = 0.1 \\ \sigma(X,y) = \sigma(y,X) = 0 \end{cases}$$

Identical letters are maximally similar, and two instances of the same letter, but in different case (upper/lower), are 0.5 similar. Different letters but of the same case are 0.1 similar. Let u_4 ="ABAB" be the current user session, and consider two repository sessions ϕ ="abcAB" and ψ ="ABabc". Intuitively, according to the desiderata above, we expect ϕ to be more similar to u_4 than ψ, as their most recent suffix ("AB") is identical. This is reflected also in the alignment matrices of ϕ and ψ, depicted in Figure 1a and Figure 1b (resp.), when setting the gap penalty $\delta = 0.1$ and decay factor $\beta = 0.9$. The bottom-right cell in each matrix reflects the alignment score of the two sessions. The highlighted cells describes the alignment "trace", namely the cells chosen (among the three options in alignment formula) when advancing to the next step in the final score computation. Specifically, when the highlighted trace moves vertically/horizontally we have a gap, and when it moves diagonally the corresponding actions are matched. As we can see, the similarity score $Sim(u_4, \phi)$ is higher than $Sim(u_4, \psi)$.

Our definition of *SW-SIM* follows that of [3, 35] with a minor adaptation to our context. First, we define the similarity score as the *bottom-right* cell of the alignment matrix, as opposed to the *maximal* cell value in [3, 35]. This is because we focus on measuring the similarity of the current session to all *session prefixes* in the repository[2]. Second, we apply a decay factor to both actions matches and gaps, as opposed to only matches in [3], since their significance decreases as the session advances. Also, note that [3] suggests dynamically setting the decay factor and gap penalty, which are both constants in our case. As we shall see, the use of constant parameter values facilitates effective optimization via computation factorization.

Problem Definition. To assist the user in choosing an appropriate next-action, IDA recommender systems search the repository S to identify session prefixes that are most similar to u_t - the current, ongoing user session at time t. The continuation of the retrieved sessions is then processed by the recommender systems and used to derive a next-action recommendation for u_t.[3]

Let $\mathcal{P}refix(S)$ be the set consisting of all session prefixes in repository S, i.e. $\mathcal{P}refix(S) = \{s_i \mid s \in S, 1 \le i \le |s|\}$. Since the user session $u = \langle q_1, q_2, ...\rangle$ is built incrementally, at each step $t = 1, \ldots, |u|$ we are given u_t and wish to identify its top-k most similar session prefixes in the repository.

[2]This is done by IDA recommendation systems in order to process the continuation of matching session-prefixes to next-action recommendations.
[3]Other information is often used as well, e.g. the *interestingness* or *frequency* of the actions to be recommended, the user profile, etc.

u \ φ		a	ab	abc	abcA	abcAB

(b) u, ψ

Figure 2: Similarity vectors for u_4 and u_5

Definition 3.3 (Incremental Top-k Similarity Search). Given a user session u_t at time t and a sessions repository S, the set $top_k(u_t, S) \subseteq \mathcal{P}refix(S)$ consists of k session prefixes s.t. $\forall s \in top_k(u_t, S), \forall s' \in \mathcal{P}refix(S) \backslash top_k(u_t, S) : Sim(u_t, s) \ge Sim(u_t, s')$. The incremental search problem is to compute, at each $t = 1, \ldots, |u|$, the set $top_k(u_t, S)$.

For simplicity, we assume that in the course of a user session u, the repository S is unchanged. In Section 5.5 we discuss the minor changes required in our framework to support the case of a dynamic repository where sessions are incremented or added.

Last, note that while session prefixes may be long and contain "historical" actions of less importance, *SW-SIM* (as explained above) favors *recent*, later actions over old ones. Also, it is easy to show that in *SW-SIM*, the similarity of a prefix $s_i = \langle q_1, q_2, ...q_i\rangle$ is always higher (or equal) than the similarity of any shorter *sub-session* of s ending in q_i.

4 INCREMENTAL SIMILARITY COMPUTATION

We first optimize the similarity calculations between the current user session u and all prefixes of a *single* repository session s. Rather than computing the alignment matrix from scratch for each prefix of s, we show that: (1) it is sufficient to compute one alignment matrix between two sessions, then use it to simultaneously derive *all prefixes similarity scores*, and (2) the alignment matrix $A_{u_t,s}$ at time t can be efficiently constructed by reusing the previous matrix $A_{u_{t-1},s}$ computed at time $t-1$.

Given a current user session u_t and a repository session s of size $|s|$, we define a *similarity vector*, $\vec{Sim}(u_t, s)$ containing the similarity score of u_t and each prefix of s, i.e.,

$$\vec{Sim}(u_t, s) = [Sim(u_t, s_0), Sim(u_t, s_1), \ldots, Sim(u_t, s_{|s|})]$$

We use $\vec{Sim}(u_t, s)[j]$, where $j = 1 \ldots |S|$, to denote the j element in the vector. The similarity vector $\vec{Sim}(u_t, s)$ can be derived from the alignment matrix $A_{u_t,s}$ using the following observation:

Observation 4.1. *Given an alignment matrix $A_{u_t,s}$*

$$\forall 0 \le j \le |s| : \vec{Sim}(u_t, s)[j] = \frac{A_{u_t,s}[t,j]}{\beta^{|s|-j}}$$

Namely, the similarity score of u_t and prefix s_j is derived from their corresponding element in the alignment matrix, $A_{u_t,s}[t,j]$, by readjusting the decay factor β. The proof is derived from the more general observation that for arbitrary prefixes s_i and s'_j of session s and s':

$$A_{s_i,s'_j}[i,j] = \frac{A_{s,s'}[i,j]}{\beta^{(|s|-i)+(|s'|-j)}} \qquad (1)$$

Example 4.2. To continue with our running example, the similarity vectors $\vec{Sim}(u_4, \phi)$ and $\vec{Sim}(u_4, \psi)$ are given in the first row of the tables in Figure 2a, and Figure 2b, resp. According to Observation 4.1, an element in the similarity vector, e.g. $\vec{Sim}(u_4, \phi)[3]$, may be computed directly from the corresponding cell in the alignment matrix of u_4 and ϕ: $\vec{Sim}(u_4, \phi)[3] = \frac{A_{u_4,\phi}[4,3]}{\beta^2} = \frac{0.58}{0.81} = 0.71$.

Further exploiting the incremental nature of the problem, we next show how to efficiently construct a similarity vector $\vec{Sim}(u_t, s)$ at time t, from that computed at time $t-1$, thereby avoiding explicitly building the entire alignment matrix. To do so, we generalize the dynamic programming construction of the alignment matrix (Definition 3.1). Vector entries at time t are computed by reusing entries in the previous similarity vector $\vec{Sim}(u_{t-1}, s)$, computed at time $t-1$ (see the colored parts of the formula in Proposition 4.3).

Proposition 4.3. *For every repository session s, user session u and time t > 1,*

$$\vec{Sim}(u_t, s)[j] = \begin{cases} 0, \text{ if } j = 0, \text{ else:} \\ max \begin{cases} \vec{Sim}(u_{t-1}, s)[j-1]\,\beta^2 + \sigma(u_t[t], s[j]) \\ \vec{Sim}(u_t, s)[j-1]\beta - \delta \\ \vec{Sim}(u_{t-1}, s)[j]\,\beta - \delta \\ 0 \end{cases} \end{cases}$$

The proof is obtained by employing Equation 1 on each case of the conditional definition.

Example 4.4. Continuing with our example, assume that the user now issues a new action "c", i.e. at $t = 5$, u_5 = "*ABABc*". The new similarity vectors $\vec{Sim}(u_5, \phi)$ and $\vec{Sim}(u_5, \psi)$, are depicted in the bottom row of Figures 2a and 2b, resp. As before, the similarity scores $Sim(u_5, \phi)$ and $Sim(u_5, \psi)$, appear in the right-most cell of the vectors. Using Proposition 4.3 we can derive each value in the new vectors from the previous corresponding similarity vectors at time $t = 4$. For example, the fourth element in $\vec{Sim}(u_5, \psi)$ is given by:

$$\vec{Sim}(u_5, \psi)[4] = max \begin{cases} \vec{Sim}(u_4, \psi)[3]\beta^2 + \sigma(\text{“c”}, \text{“b”}) \\ \vec{Sim}(u_5, \psi)[3]\beta - \delta \\ \vec{Sim}(u_4, \psi)[4]\beta - \delta \end{cases}$$

$$= max(1.45, 1.22, 1.78) = 1.78$$

Let us analyze the reduction in time complexity resulting from these two simple optimizations. Let $|\widehat{s}|$ be the average session size and λ the complexity of computing similarity for individual actions. The expected time complexity of computing the similarity vector $\vec{Sim}(u_t, s)$ by construcitng all ($|\widehat{s}|$) allignemnt matrices is $O(|\widehat{s}|^3\lambda)$. Employing Observation 4.1 allows us to compute the same vector by constructing only one alignment matrix, in $O(|\widehat{s}|^2\lambda)$. Further employing Proposition 4.3 reduces the expected time to $O(|\widehat{s}|\lambda)$ since only $|s|$ action similarity calculations are required, between $u_t[t]$ (the new action in u_t) and all actions of s.

5 INCREMENTAL TOP-K ALGORITHMS

We are now ready to address the incremental top-k problem - given an ongoing user session u, retrieve the set $top_k(u_t, S)$ of similar prefixes at each time $t = 1, \ldots, |u|$. We first present a simple algorithm, denoted I-TopK, that iterates over the repository S and computes the similarity vector for each session. We then show how a much faster variant, denoted T-TopK, is obtained by employing a novel, incremental-based *filter-and-refine* approach.

Algorithm 1 T-TopK(u_t, S, k)

```
    Input: $u_t$ - current user session,
           $S$ - session repository,
           $k$ - size of the top-k set.
    Output: $top_k(u_t, S)$ - a set of top-k most similar session
            prefixes to $u_t$.
 1: $top \leftarrow MaxHeap(k)$
 2: if t == 1 then
 3:     Use I-TopK to obtain $top_k(u_t, S)$
 4: else
 5:     Compute $inf^t$, the lower-bound similarity threshold
 6:     $C \leftarrow \{s | s \in S \wedge sup^t(s) \geq inf^t\}$
 7:     for session $s \in C$ do
 8:         $m \leftarrow$ latest time $t' < t$ that $\vec{Sim}(u_{t'}, s)$ was computed.
 9:         for ($i = m + 1; i \leq t; i++$) do
10:             Compute $\vec{Sim}(u_i, s)$ using Proposition 4.3
11:         for ($j = 1; j \leq |s|; j++$) do
12:             $top.push(\vec{Sim}(u_t, s)[j], s_j)$
13:         if $|top| == k$ then
14:             $C \leftarrow C \setminus \{s | sup^t(s) < minScore(top)\}$
15: return $top$
```

5.1 Iterative Top-k Algorithm (I-TopK)

Algorithm I-TopK takes the following as input: the current session u_t, the sessions repository S, and the desired size k of the top-k set. It iterates over the repository, computing the similarity vector $\vec{Sim}(u_t, s)$ for each $s \in S$ by employing Proposition 4.3, i.e. by using the similarity vector $\vec{Sim}(u_{t-1}, s)$ calculated at the previous iteration ($t-1$). The top-k similarity scores (along with their corresponding prefixes) are maintained in a max-heap of size k, which will contain the exact set $top_k(u_t, S)$ of the top-k most similar prefixes to u_t at the end the loop.

The time complexity of I-TopK is $O(|S||\widehat{s}|\lambda)$, since it iterates over a session repository of size $|S|$ and computes a similarity vector in $O(|\widehat{s}|\lambda)$. The max-heap is maintained in a negligible cost of $O(log\ k)$, as we assume that $k << |S|$. As for space complexity, I-TopK requires storing the previous similarity vectors computed at $t-1$, therefore it requires $O(|S||\widehat{s}|)$ space, where $|\widehat{s}|$ is the average session size.

5.2 Threshold-Based Algorithm (T-TopK)

The T-TopK algorithm follows a *filter-and-refine* paradigm, s.t. in the *filter* step, repository sessions are pruned according to an *overestimation* of their similarity scores. Then, during the *refinement* step, the similarity vectors are computed only for candidate sessions passing the filter step. Importantly, T-TopK is guaranteed to be exact since the *filter* step always *overestimates* the true similarity scores and *underestimates* the filter thresholds. The novelty and efficiency of the algorithm stem from exploiting the incremental nature of the search problem.

We first describe the outline of the T-TopK algorithm, then in Sections 5.3 we present the techniques used for its *filter* step, i.e., the efficient calculation of the similarity lower and upper bounds.

T-TopK Algorithm Outline. Algorithm 1 depicts the outline of the T-TopK algorithm. For a given user session u_t, a sessions repository S and a number k, the prefixes set $top_k(u_t, S)$ is retrieved in the following manner. First, if u_t contains only one action, the I-TopK algorithm will be used, since we have no previous prefix to rely on. Otherwise we employ a *filter-and-refine* process as follows.

Filter Step. We first find candidate sessions that are likely to contain prefixes in the top-k set $top_k(u_t, S)$:

(1) Form a global similarity threshold. We first compute an initial lower bound threshold, denoted inf^t, for the similarity score of a prefix to be a member of $top_k(u_t, S)$. The threshold inf^t *underestimates* the true minimal similarity score (Line 5).

(2) Compute a similarity upper-bound for each session. We then form a similarity upper-bound for each session s, denoted $sup^t(s)$, that overestimates the maximal similarity of a prefix in s to the current user session u_t.

The algorithm then filters the repository S by retrieving all sessions having similarity upper-bounds greater than inf^t (Line 6). Importantly, since the lower bound is *underestimated* and the upper bounds are *overestimated* - no false negatives can occur. In Section 5.3 we describe how the similarity lower and upper bounds are defined and efficiently calculated.

Refinement Step. We employ a *refinement* step over the candidate sessions and calculate the exact similarity scores using their *similarity-vectors.* Recall that to efficiently construct a similarity vector (Proposition 4.3) at time t, we need to have the vector of time $t-1$. However, we may not have calculated a similarity vector at $t-1$ if a session was pruned in the filter step. Thus, for each such candidate session we reconstruct, if necessary, its previous vectors from time $< t$ (We discuss below how this computation can be performed in user idle-times, allowing T-TopK a further speed-up), then compute the current similarity vector $\vec{Sim}(u_t, s)$ (Lines 9- 10).

Last, we iteratively push each element in the similarity vector into a max-heap *top* of size k (Lines 11- 12), and further prune candidate sessions if their upper bound is lower than the minimum score in *top* (Lines 13-14). Finally, the max-heap *top* holds the set $top_k(u_t, S)$, containing the top-k most similar prefixes to u_t.

Offline computation in user idle-times. User idle-times occur between two consecutive actions - while the user examines the results of her current action, before executing the next one (which typically takes several seconds). Our algorithm utilizes such idle-times, to compute similarity vectors skipped at previous iterations *offline*, so that they are already available when needed in the top-k search.

Correctness of the T-TopK algorithm. We next sketch the correctness proof, showing that the T-TopK algorithm is correct, i.e., always retrieves the *exact* set of top-k most similar session prefixes:

Let *top* denote the output of the algorithm. We need to show that $top_k(u_t, S) = top$. We will consider $t > 1$ (the case of t=1 is trivial). First, we show that for an arbitrary prefix s_j of a repository session s, $s_j \in top_k(u_t, S) \rightarrow s_j \in top$. If $s \in top_k(u_t, S)$ then $Sim(u_t, s) \geq inf^t$ (as inf^t is the similarity lower bound). Hence, for the upper bound $sup^t(s)$ of session s we can easily see that $sup^t(s) \geq inf^t$, thus $s \in C$, i.e. s is retrieved and processed as a candidate session. The proof for the case that $s_j \in top_k(u_t, S) \leftarrow s_j \in top$ follows similar lines.

To complete the picture we still need to explain how (1) the similarity lower bound inf^t, and (2) the upper bounds $sup^t(s)$ are computed and compared.

5.3 Incremental-Based Similarity Bounds

We first explain how the similarity lower and upper bounds are defined, then describe how the candidate sessions are efficiently retrieved.

5.3.1 Similarity Threshold (Lower Bound).

The threshold inf^t forms a lower-bound (underestimated) for the similarity score of a prefix to be a member of $top_k(u_t, S)$. Intuitively, we use the sessions in the (already computed) top-k set of time $t-1$ as a potential representative for the top-k set of time t, and define our threshold w.r.t. them. Let $S^{t-1}_{top} \subseteq S$ denote the set of sessions with prefixes in $top_k(u_{t-1}, S)$. The similarity threshold is defined by:

$$inf^t = minScore(top_k(u_t, S^{t-1}_{top}))$$

As the size of S^{t-1}_{top} is at most k, inf^t is computed efficiently.

The proof that inf^t always underestimates the exact lower-bound can be immediately obtained from the simple observation that:

$$\forall S' \subseteq S, minScore(top_k(u_t, S')) \leq minScore(top_k(u_t, S'))$$

In particular, the observation holds for $S' = S^{t-1}_{top}$.

Nevertheless, we show that inf^t cannot be too far from the *exact* threshold at t-1, using the following observation:

Observation 5.1. $minScore(top_k(u_{t-1}, S))\beta - \delta \leq inf^t$

This stems from the fact that the lowest possible inf^t is obtained when the last query in u_t is not aligned in *any* of the sessions in S^{t-1}_{top} (hence a gap penalty is absorbed).

Example 5.2. Assume that $k = 1$ (i.e. we are interested in the top-1 similar prefixes), and consider the sessions u, ϕ, ψ from our running example. Considering the similarity vectors at $t = 4$ (detailed in Example 4.2), the most similar prefix is ϕ_5 and thus $top_1(u_4, \{\phi, \psi\}) = \{\phi_5\}$. Consequently, its corresponding session is in the set $S^4_{top} = \{\phi\}$. For computing the threshold $inf^5 = minScore(top_1(u_5, S^4_{top}))$, we construct the similarity vector $\vec{Sim}(u_5, \phi)$ (bottom row in Figure 2a), and take the maximal score among its elements, thus $inf^5 = 1.95$.

5.3.2 Upper-Bounding Similarity Scores.

Let $\widehat{sup}^t(s) = max_{1 \leq j \leq |s|} Sim(u_t, s_j)$ denote the *tight*, exact upper bound for the similarity score of all prefixes in s. Recall that for sessions in S^{t-1}_{top}, we already computed their similarity vectors when computed the lower bound inf^t, therefore their tight bound is already at hand. Nevertheless, for the rest of the sessions, i.e. $s \in S \setminus S^{t-1}_{top}$, we show that the incremental nature of the computation can be used to form $sup^t(s)$, an effective over-approximation to $\widehat{sup}^t(s)$. An important observation is that we are only interested in upper-bounding the scores of sessions containing at least one prefix with a similarity scores higher than inf^t (otherwise it can be safely pruned). We therefore define a *proper* similarity upper bound as follows:

Definition 5.3 (Proper upper bound). $sup^t(s)$ *is a proper upper bound w.r.t.* u_t *and* S*, if for every session* s *having some prefix* s_j *where* $Sim(u_t, s_j) > inf^t$*, we have that* $sup^t(s) \geq \widehat{sup}^t(s)$.

A second important observation, is that unless the last action in u_t, denoted q_t, is aligned to an action in $s \in S \setminus S^{t-1}_{top}$, s can be safely pruned.

Observation 5.4. *For a session $s \in S \setminus S^{t-1}_{top}$, if when computing $Sim(u_t, s)$ the action q_t is not matched with any of s's actions, then for every prefix s_j of s, $Sim(u_t, s_j) \leq inf^t$.*

This is because if q_t is not matched with an action in s_j it absorbs a gap penalty, i.e., $Sim(u_t, s_j) = Sim(u_{t-1}, s_j)\beta - \delta$ (Proposition 4.3). On the other hand, since $s_j \notin top_k(u_{t-1}, S)$ we know that $Sim(u_{t-1}, s_j) \leq minScore(top_k(u_{t-1}, S))$. Then, using Observation 5.1 we can see that $Sim(u_t, s_j)$ can never exceed inf^t.

Consequently, in the analysis below we ignore sessions where q_t is not matched with any of s's actions, and for brevity, unless stated otherwise, whenever we refer to a session s we mean one in $S \setminus S^{t-1}_{top}$ where q_t has a match.

We next provide two ways to overestimate $\widehat{sup}^t(s)$. In our efficient implementation of the filter procedure for candidate session retrieval (to be detailed in the next subsection), we use the first bound to quickly prune irrelevant sessions, then use the second one for further pruning the candidates set.

First bound (B_1). The following observation shows that we can bound $\widehat{sup}^t(s)$ from above using the top-k set of the previous iteration and the maximal similarity of the session's individual actions to the new action q_t.

Observation 5.5.

$$\widehat{sup}^t(s) \leq minScore(top_k(u_{t-1}, S))\beta^2 + max_{q\in s}\{\sigma(q_t, q)\}$$

Intuitively, this is because for every prefix not in $top_k(u_{t-1}, S)$, the similarity to u_{t-1} is smaller than $minScore(top_k(u_{t-1}, S))$. Consequently, even if the newly added action q_t is matched to the most similar action in s, by the definition of the similarity measure, the cumulative score cannot be greater than the prefix similarity (multiplied by the decay factor, following the arrival of a new action) plus the similarity of the best match (Proof omitted). We therefore use the following as our first upper-bound:

$$B_1(s) = minScore(top_k(u_{t-1}, S))\beta^2 + max_{q\in s}\{\sigma(q_t, q)\}$$

Note that since $top_k(u_{t-1}, S)$ is already computed, to calculate the bound we only need the similarity of q_t and the actions in s. As individual actions do reside in a metric space (unlike sessions/prefixes), we show in Section 5.4 how this is done efficiently.

Second bound (B_2). An alternative, less intuitive upper-bound for $\widehat{sup}^t(s)$ is achieved by dividing u_t into three disjoint subsequences w.r.t. a session s, and separately bounding the similarity to each part: (a) the segment of u_t that was already compared to s in previous iterations, denoted u_τ (b) the segment containing only the last added action q_t, and (c) the segment in between these two. By adding up the bounds for each segment we obtain a bound for the whole sequence:

Proposition 5.6.

$$\widehat{sup}^t(s) \leq max_{1\leq j\leq |s|}\{\vec{sim}_{u_\tau,s}[j]\}\beta^{2(t-\tau)} + \frac{\beta^{2(t-\tau)} - \beta^2}{\beta^2 - 1} + \\ + max_{q\in s}\{\sigma(u_t[t], q)\}$$

The latter proposition holds for $\beta < 1$[4].

Proof Sketch. We prove by induction. We denote $s_\tau := max_{1\leq j\leq |s|}\{\vec{sim}_{u_\tau,s}[j]\}$. The base case is when $t = \tau + 1$. We can easily show that:

$$\widehat{sup}^{\tau+1}(s) \leq s_\tau\beta^2 + max_{q\in s}\{\sigma(u_t[t], q)\}$$

We know that:

$$\widehat{sup}^{t+1}(s) \leq \widehat{sup}^t(s)\beta^2 + max_{q\in s}\{\sigma(u_{t+1}[t+1], q)\} \quad (2)$$

Assuming the inequality holds for t, we can bound $\widehat{sup}^t(s)\beta^2$:

$$\widehat{sup}^t(s)\beta^2 \leq \beta^2(s_\tau\beta^{2(t-\tau)} + \frac{\beta^{2(t-\tau)} - \beta^2}{\beta^2 - 1} + max_{q\in s}\{\sigma(u_t[t], q)\})$$

Since $max_{q\in s}\{\sigma(u_t[t], q)\} \leq 1$ we have:

$$\widehat{sup}^t(s)\beta^2 \leq s_\tau\beta^{2(t+1-\tau)} + \frac{\beta^{2(t+1-\tau)} - \beta^4 + \beta^2(\beta^2 - 1)}{\beta^2 - 1}$$

We can use the latter expression in (2) to obtain:

$$\widehat{sup}^{t+1}(s) \leq s_\tau\beta^{2(t+1-\tau)} + \frac{\beta^{2(t+1-\tau)} - \beta^2}{\beta^2 - 1} + max_{q\in s}\{\sigma(u_{t+1}[t+1], q)\}$$

Hence the inequality holds for $t + 1$ □

Importantly, note that this bound requires no action-similarity computations besides those already performed for B_1, and that all other values are either predefined constants or already computed in previous iterations. The proper upper bound $sup^t(s)$ is defined as the minimum of the two bounds: $sup^t(s) = min(B_1(s), B_2(s))$

5.4 Efficient Retrieval of Candidate Sessions

As mentioned above, we use the first bound B_1 to quickly identify relevant sessions, then compute the full bound only for the retrieved sessions, for further pruning. We use the following observation, which follows immediately from Observation 5.5.

Observation 5.7. *For $sup^t(s)$ to be not smaller than inf^t, s must contain some action q s.t.*

$$\sigma(q_t, q) \geq inf^t - minScore(top_k(u_{t-1}, S))\beta^2$$

To identify sessions that contain such actions, we employ an index structure that uses the fact that the action similarity measure defines a *metric space* (See Section 3). Specifically, in our implementation we use a *metric-tree* [8] - a popular index structure that harnesses the triangle inequality property of a metric space to facilitate a fast similarity search.

Sessions selection via the actions metric-tree. Individual actions are stored in a metric tree, with pointers from each action to the session it appears in[5]. From Observation 5.7 and our definition of the action distance notion, it follows that all sessions that satisfy the bound B_1 must contain some action q s.t.:

$$\Delta(q_t, q) \leq 1 - inf^t + minScore(top_k(u_{t-1}, S))\beta^2$$

We thus use the metric tree for a fast retrieval of all such actions q, and follow their associated pointers to identify the relevant sessions. Now we only need to compute Bound B_2 for the retrieved sessions to select those with upper bound greater than inf^t.

Example 5.8. For our running example, at $t = 5$ we retrieve candidate sessions via the metric tree, w.r.t. the lower bound 1.95 (computed as in Example 5.2). Recall that our goal is to retrieve sessions having an action q s.t. $\Delta(q_5, q) \leq 1 - inf^5 + minScore(top_1(u_4, \{\phi, \psi\}))\beta^2$, namely actions similar to q_5 = "c" with distance no more than $1 - 1.95 + 2.28 * 0.81 = 0.897$. Only

[4]For the case of $\beta = 1$, the middle part in the compound expression is defined to be 0

[5]The distance function used is the complement of our predefined action similarity function, i.e. $\Delta(q, q') = 1 - \sigma(q, q')$

the letters “C” and “c” meet this constraint, therefore sessions ψ (that contains “c”) is retrieved and added to the initial candidate sessions set. Then, the upper bound for ψ is given by $sup^5(\psi) = min(\{B_1(\psi), B_2(\psi)\}) = min(2.84, 3.09) = 2.84$ (full computation omitted), which is greater than the lower bound 1.95, therefore the final set of candidate sessions is $\{\psi\}$.

5.5 Analysis of Pruning Effectiveness

Intuitively, the effectiveness of T-TopK is dependent on (1) the *amount of reduction* in the examined candidate sessions, on which the exact similarity scores are calculated, as well as on (2) the *cost of retrieving* the candidate sessions.

First, let us assess the expected time complexity of T-TopK. Let $|\widehat{C}|$ be the expected number of candidate sessions meeting the bounds (we assume $|\widehat{C}| >> k$), and let $\widehat{\tau}$ be the expected number of missing similarity vectors that need to be computed for each candidate session. Also, denote by α the cost of the metric-tree search. Thus the average time complexity of T-TopK is given by $O(\alpha + \lambda|\widehat{C}|\widehat{\tau}|\widehat{s}|)$.

The parameters $|\widehat{s}|$ (mean session size) and λ (cost of individual action similarity operation) are not controllable nor affected by the implementation of the T-TopK algorithm. We therefore analyze the performance of T-TopK according to the following parameters: α - the cost of the actions metric tree search, $|\widehat{C}|$ - the expected number of candidate sessions, and $\widehat{\tau}$ the expected number of missing vectors per candidate session.

Cost of searching the actions metric tree (α). Recall that the individual actions metric tree is used to efficiently retrieve all repository sessions that satisfy Bound B_1. Based on the cost model for metric trees proposed in [9], α is given by: $\sum_{l=1}^{L} \lambda M_{l+1} F(\widehat{r_l} + r_q)$, where: $F(x)$ is the action-distance probability distribution (i.e., the probability that the distance of two arbitrary actions $\leq x$), L is the number of levels in the tree, and M_l is the number of nodes in level l of the tree, $\widehat{r_l}$ is the mean *covering radius* of nodes at level l, and r_q is the search range (in our case, $r_q = 1 - inf^t + minScore(top_k(u_{t-1}, S))\beta^2$). Also note that M_{L+1} is the total number of individual actions stored in the metric tree. Based on this cost model, we can see that (1) naturally, increasing the size of the actions domain and the cost of action-distance computation increases α. (2) More importantly, decreasing the range r_q decreases α. The latter is greatly affected by the lower bound inf^t and the upper bound $B1$, as described next.

Expected number of candidate sessions ($|\widehat{C}|$). The number of candidate sessions directly stems from the number of sessions that satisfy both bounds $B1$ and $B2$. Intuitively, $|\widehat{C}|$ depends on three factors: (1) *How high is the lower-bound.* Naturally, the *higher* the lower-bound inf^t is, the *less* the repository sessions may surpass it. The lower bound inf^t, computed by $minScore(top_k(u_t, S_{top}^{t-1}))$ is higher, if the least similar prefix in the top-k set, computed over the sessions in S_{top}^{t-1}, is of high similarity to u_t. In turn, this holds if the probability that q_t, the newly added action to u_t will be similar enough to actions contained in the sessions of S_{top}^{t-1}, and also on the *exact* similarity threshold computed at t-1 (higher is better). (2) *How low are the upper bounds.* Similarly, *lower* upper-bounds reduce the chance that repository sessions can surpass the lower bound. Both upper bounds are lower when the decay factor β is lower (this directly stems from Observation 5.5 and Proposition 5.6). Also, for both upper bounds, if the probability that q_t is aligned to an action in $s \in S \setminus S_{top}^{t-1}$ is lower - so are the upper bounds. (3) *The underlying session similarity probability distribution* - intuitively, how many sessions, on expectation, may contain prefixes with high similarity to u_t - sufficient to satisfy Bounds $B1$ and $B2$. Naturally, if many sessions are likely to have prefixes similar to u_t, more candidates will be retrieved.

Expected number of missing similarity vectors $\widehat{\tau}$. A higher number of missing similarity vectors decreases the performance of $T - TopK$. It may happen if a session did not make it to the candidates set C for several consecutive iterations, yet is suddenly considered at time t. However, recall that many of these missing vectors may be effectively computed in user idle times. We also show in Section 6.3 that even idle-times shorter than the minimal human reaction time (250ms) are sufficient to compute a significant portion of the missing vectors.

In summary, the effectiveness of the pruning is dependent on multiple, intertwined factors that stem both from the underlying structure of the analysis sessions (and actions) as well as the problem parameters (such as the gap penalty δ and the size of k). In our experimental evaluation (See Section 6) we have empirically examined the effect of various such parameters on the performance of T-TopK. Besides using a real-life session repository, we used a multitude artificially crafted repositories, each with different underlying structure, as well as different settings of the search problem. We show that in almost all such configurations, T-TopK is highly efficient in comparison to I-TopK and surpasses other baseline algorithms by 2-3 orders of magnitude.

Additional Remarks. We conclude with two remarks. First, considering the space complexity of T-TopK - on top of storing the similarity vectors there is an additional cost induced by maintaining the metric tree. However, assuming that the metric tree is balanced, the overall space complexity of the algorithm is thus $O(|S||\widehat{s}|)$, which is the same as for I-TopK. In Section 6 we show that the additional cost induced by the metric tree is marginal, even when the session repository contains over $1.5M$ individual actions.

Last, note that in practical settings the repository is dynamic, i.e., new sessions are added and existing ones are incremented. T-TopK can be easily adapted to this setting, as newly added or incremented repository sessions merely induce more *missing similarity vectors.* Recall from Section 5.2 that missing vectors can be computed during *user idle-times* (between her consecutive actions) thereby minimizing the effect on computation time.

6 EXPERIMENTAL STUDY

As mentioned above, since the speedup achieved by our optimizations may be affected by the underlying structure of the session repositories, one would ideally like to evaluate their performance on a *multitude* of real-life session repositories with different characteristics.

However, the only publicly available repository (to our knowledge) of real-life analysis sessions is rather small [1]. Therefore, we first performed experimental evaluations on a variety of artificially crafted session repositories, each having different internal characteristics that may effect the performance of our solutions. Then, we used the session repository of [1] to verify that the same performance trends hold on real life sessions as well.

Last, let us recall that our experiments focus on running-time performance. For an evaluation of the quality of recommendations generated based on *SW-SIM* we refer the reader to, e.g., [2, 3].

In what comes next, we describe the experimental setup and the construction method for the artificial repositories in Section 6.1, then show the performance of our solution compared to numerous baseline approaches in Section 6.2. Last, we examine the scalability and performance trends w.r.t. numerous parameters of the search problem and session repositories (Section 6.3).

6.1 Experimental Datasets & Setup

Artificial Session Repositories Construction. In the absence of real-life session repositories that are large enough and publicly available, we constructed a multitude of artificial repositories, each with different underlying characteristics that may affect the performance of our solution. Each repository was constructed by first building an action (metric-) space with certain, configurable properties, then constructing repository sessions by drawing actions from this space (also w.r.t. a configurable setting). The controllable parameters and the ranges we use are depicted in Table 1.

Generating the individual action space. Recall that our algorithms model analysis actions as abstract objects in a given metric space. We represent here actions as points in an N-dimensional Euclidean space, with the Euclidean distance as the distance metric. To obtain values in $[0, 1]$ range, each element is restricted to the range $[0, \frac{1}{\sqrt{N}}]$. We the simulate a controlled degree of similarity between actions as follows: first draw a (controllable) number of action points uniformly at random (u.a.r.), to serve as cluster centers, then generate additional actions around each center using a (multi-variant) normal distribution, with the cluster-center as mean. In our experiments we varied the number N of action-space dimensions, the number of action clusters, and their radius (standard deviation), obtaining different degrees of underlying action-similarity in the repository session.

Generating repository sessions. The sessions repository is constructed in an analogous manner. We first generate a set of "seed" sessions, then use them to generate sessions with varying degrees of similarity to the seed. For each session (seed or other) we draw its length from a given normal distribution. To construct a seed-session we select (u.a.r) a sequence of actions of the given length. The rest of the repository sessions are constructed based on one of the seed-sessions. To further control the similarity of an arbitrary session s to its corresponding seed, we set a fraction p of "random" actions in s. Namely, $p \cdot l$ actions in s are randomly drawn (u.a.r) from the entire action space. The rest $(1-p)\cdot l$ actions in s are chosen from the same action-clusters as the actions in the corresponding seed session. Intuitively, setting a high value of p of "random" actions significantly decreases the potential of two sessions to be similar.

In the experiments below we used multiple repository configurations, as depicted in Table 1.

REACT-IDA Session Repository. We used the only publicly available repository (to our knowledge) of real-life sessions [1], collected as part of the experimental evaluation of an existing IDA recommender system [26]. The user sessions were performed by 56 analysts who used a web-based IDA interface in order to explore four different datasets from the cyber-security domain. The repository contains 1100 distinct actions. The average session length is 8.5 actions, and the median user idle-time is 40 seconds.

Action Similarity. Recall that both algorithms require a measure for action similarity. When using the real-life repository, we employed the similarity measure of the IDA recommender system [26] whose analysis UI was used to record the sessions.[6] For the artificial repositories, where the actions reside in a multi-dimensional metric-space, we used Euclidean distance.

Parameter	Min	Max	Default
Problem Parameters			
Decay Factor β	0.1	1	0.9
Gap Penalty δ	0.05	1	0.1
Output Size k	4	24	12
Controlled Repository Parameters			
Action Dim.	5	500	25
#Action Clusters	3K	24K	6K

Session len.	$\mathcal{N}(4, 3^2)$	$\mathcal{N}(32, 12^2)$	$\mathcal{N}(16, 3^2)$

Table 1: Problem & Repository Parameters

Default Parameters Selection. The search problem parameters (namely, the decay factor β, the gap penalty δ, and the size of k) may affect the performance of our solution. However, to capture the real-life setting where the algorithms are embedded in actual IDA recommender systems, the default values are set to optimize the *quality* of the *SW-SIM* measure, rather than the performance of our optimizations. To do so, we embedded *SW-SIM* as the top-k search component in the IDA next-step recommender system [26] (code available in [1]), and performed the hyper-parameters selection routine as described in [26]. Briefly, this is done by executing a grid search for the systems' parameters (including the top-k problem parameters), and selecting the configuration that allows the recommender system to achieve the highest qualitative performance (as determined in a predictive accuracy evaluation).

As for the artificial repository construction, intermediate values were chosen as default values, as stated in Table 1. Nevertheless, in Section 6.3 we examine the effect of varying each problem/repository parameter on the running time performance of our solution.

Hardware and Software Specifications. We implemented the algorithms presented in the previous sections in *Java 8*, using Guava (https://github.com/google/guava) for the max-heap. For the metric-tree we used an M-tree [8] Java implementation (https://github.com/erdavila/M-Tree), employing *Minimum Sum of Radii* split policy (See [8]), and a maximum node capacity of 20 objects. All experiments were conducted over *Intel Core i7-4790, 3.6GHz* machine (4 dual cores), equipped with 8GB RAM.

6.2 Baseline Comparison

We compared the performance of the T-TopK algorithm to the following baseline algorithms, each computing the exact set $top_k(u_t, S)$ according to the alignment based similarity measure (Definition 3.1). Among these, we show the results of the following baselines: (1) **Naive Sequential Search (NSS)** that retrieves the set of similar prefixes by iteratively comparing u_t to each prefix of each repository session in S using a direct implementation of Definition 3.1 with no further optimizations, then selects

[6]The similarity notion considers both the action syntax and (a signature of) the results. (See [26]).

Baseline	REACT-IDA (1.1K actions)		Repo-10 (160K actions)		Repo-100 (1.6M actions)	
	Time (ms)	#ops	Time (ms)	#ops	Time (s)	#ops
NM-Tree	42.3	27.5K	18,503	12.3M	186	123M
CSE	55	36.6K	18,224	12.1M	183	121M
NSS	51.9	35K	17,204	11.5M	170	123M
OSS	7.6	5.1K	3,242	1.36M	32	13.6M
I-TopK	1	1.1K	237	160K	2.4	1.6M
T-TopK	**0.5**	**641**	**59**	**39K**	**0.9**	**722K**

Table 2: Baseline Comparison. We compared various baseline algorithms in terms of running times and the number of similarity operations

the top-k similar prefixes. (2) **Optimized Sequential Search (OSS)**, which employs the first optimization described in Section 4, instead of computing the alignment matrix for each prefix. Namely, it iterates over all sessions in $s \in S$, constructs a single alignment matrix $A_{u_t,s}$, and uses Observation 4.1 to derive the similarity scores of u_t and each prefix of s. (3) **I-TopK**, the iterative algorithm depicted in Section 5.1 which employs both of the optimizations in Section 4. (4) **T-TopK**, the optimized algorithm described in Sections 5.2-5.4. (5) **Constant Shift Embedding (CSE)[31]** and (6) **NM-Tree [34]**, are general purpose solutions for top-k search in a non-metric space. Both use *metrization* techniques: CSE use a simple solution that increments each distance score by a predefined constant, so the triangle inequality is enforced. Then, all session prefixes in S are stored in a *metric tree* (w.r.t. the new metric space). When given the ongoing session u_t, the metric tree is traversed, using the new metric to obtain the exact set of top-k similar prefixes. NM-tree uses a more sophisticated similarity-preserving transformation on the original (non-metric) distance measure, then employs an extension of the metric tree to index and query the transformed metric space.

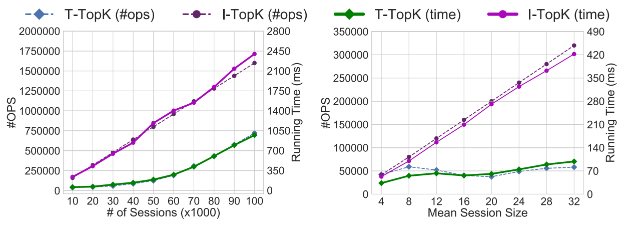
Finally, recall from Section 2 that optimization techniques dedicated to other similarity measures (e.g., DTW, Global Sequence Alignment) are inadequate for *SW-SIM*, therefore could not serve as baselines. Also, approximation-based solutions were omitted as well since this work concerns with the case of exact computation of the similarity scores.

Evaluation Process. We evaluated all baselines using a multitude of configurations for the top-k search problem (i.e. the constants β, δ of the similarity measure, and k), on various configurations of artificial repositories.

The evaluation process is as follows. Given a session repository S, in each trial we draw a random session prefix as u_t, then employ each baseline to retrieve $top_k(u_t, S)$. We performed 100 trials for each repository, capturing the average execution time and memory consumption, and the average number of action similarity operations performed in each run.

Results. Table 2 presents a representative sample of the results, showing the average running time and the number of action similarity operations (denoted #ops) obtained by each baseline. The comparison is presented for the REACT-IDA repository (Containing 1.1K actions) as well as Repo-10 and Repo-100, which are two artificial session repositories (with the default configuration stated in Table 1) containing 10K and 100K sessions (resp., 160K and 1.6M actions).

First, for both Repo-10 and Repo-100, the performance of *NM-Tree* and *CSE* is almost on-par with NSS (the naive sequential search). This could be due to the fact that transforming the non-metric space may induce high overlap between the metric-tree nodes, therefore the search deteriorates to sequential search plus additional overhead induced by the metric tree (See [34]). Second, note that OSS improves running times by $5X$ (and #ops by $9X$)



(a) Repository Size **(b) Mean Session len.**

Figure 3: Effect of Scale Parameters

over NSS due to its efficient use of Observation 4.1. However, a more significant improvement of $15X$ in running times (and $9X$ in terms of #ops) is achieved by I-TopK which utilizes the incremental computation. **Finally, an additional 2-4X speedup is obtained by T-TopK, resulting in an overall improvement of 189X to 291X over the NSS baseline**.

The performance trends on the REACT-IDA repository (comprising the smaller collection of real-life sessions) are similar, with some minor variation. We can first see that NM-Tree performs slightly better than NSS and CSE. This is due to the underlying structure of the dataset that allows the NM-Tree to perform (and store) the distance-preserving transformations more efficiently.

However, both our optimized algorithms perform significantly better, with T-TopK dominating. Interestingly, while the REACT-IDA is fairly small, the pruning-based optimizations of T-TopK are still highly effective. T-TopK retains a $2X$ speedup compared to I-TopK, and significantly outperforms the other baselines.

Next, we present a performance comparison of the algorithms when employed on a multitude of different repositories and with different problem parameters, as well as an examination of the computation segments in T-TopK. Since in all configurations, the performance of T-TopK was significantly better (by at least an order of magnitude) than the baseline algorithms, we omit them from presentation and use only I-TopK as a baseline.

6.3 Scalability & Parameters Effect

We next analyze the performance of the T-TopK Algorithm compared to I-TopK, by varying the problem parameters as well as the repository parameters, one at a time, while keeping the rest at their default values (As in Table 1). We measured both the running times, number of action similarity operations (#*ops*), and memory consumption.

Scalability Parameters. Figure 3a depicts the performance of the algorithms when increasing the number of sessions in the repository. For both algorithms we can see a rather linear increase in running times (correspondingly, #*ops* however the two plots overlap), but T-TopK shows a significant speed up of 3X (on average) over I-TopK. Moreover, as we can see in Figure 3b, when the mean *session length* increases, T-TopK performance stays stable compared to a linear increase for I-TopK. This demonstrates that

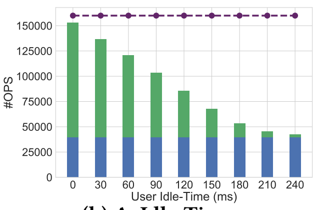
(g) A: % Random Actions



(h) A: Idle-Time

Figure 4: Parameters Effect on REACT-IDA (R) and Artificial (A) Datasets

the effectiveness of the threshold-based approach further grows for longer sessions. As for memory consumption, the maximal usage for T-TopK did not exceed $74MB$ even for a repository as big as 100K sessions (1.6M individual actions), which is negligible in practice. We therefore do not further discuss memory consumption in the next experiments.

Problem Parameters. Recall that the problem parameters are the gap penalty δ, the decay factor β and the output set size k. We examine their effect on the performance, when varying each parameter, and keeping the rest at their default values. To gain a better insight on the computation of T-TopK, we break the total *#ops* performed into three computational segments: (1) forming the initial similarity lower bound, (2) the metric-tree search, and (3) computing similarity vectors for candidate sessions. The corresponding running time trends are similar, therefore omitted from the figures below. Also, as Segment (3) is negligibly small when using the default idle-time, we further restrict the default user idle-time to 150ms, which naturally stresses T-TopK. The performance of I-TopK in terms of #ops is represented by a dotted flat line since it is not dependent on the problem parameters.

We observe that increasing each of the problem parameters results in a minor increase in #ops for T-TopK. Figure 4a and Figure 4c show the effect of the decay factor β and the output size k on performance, when the algorithms are employed on the REACT-IDA repository, and Figure 4d shows the effect of the gap penalty δ on the default artificial repository (the effect of δ on the REACT-IDA repository was marginal, therefore the figure is omitted). The increase in performance is expected, since the values of the problem parameters play a part in the lower/upper bound computations: (1) The decay factor β affects the upper bound, therefore lower values induce more restrictive candidate selection, and thereby better performance. (2) Increasing the output size k causes a decrease in the lower bound threshold inf^t, thus more candidate sessions are examined.

To gain a deeper insight on the performance w.r.t. the computation segments, we examine in Figure 4b, the number of sessions retrieved in the metric-tree search results (i.e. sessions satisfying bound B_1) and the number of sessions among them that also meet bound B_2 (hence satisfy the upper bound), for varying β values. We can see that the first set grows with β (hence the cost of Segment 2 increases), but many sessions are pruned via bound B_2 (thus the cost of Segment 3 does not increase).

Repository Parameters. As is the case for most top-k search optimizations and dedicated data structures, the underlying structure of the data points may impact the performance of the T-TopK algorithm (note that the incremental similarity optimizations presented in Section 4 are not affected by such parameters).

Therefore, to properly evaluate the effectiveness of T-TopK we constructed a multitude of artificial repositories (as described above), each with a different underlying structure that stems from a particular repository-parameters configuration. We varied each construction parameter and examined its effect on the performance of T-TopK (keeping the rest of the parameters at their default configuration). Figures 4e, 4f and 4g depict the performance of T-TopK compared to I-TopK when varying the amount of individual action clusters, percentage of "seed sessions", and the percentage of random actions in a session, respectively. Intuitively, increasing the values of each of these parameters inflict more "randomness" on the underlying structure of the data points (sessions), therefore the mean similarity score of two arbitrary sessions decreases. In turn, lower similarity scores imply smaller lower bounds, therefore more candidate sessions are examined. With the exception of one case, in all observed settings, even when increasing these parameters, T-TopK was still effective, outperforming I-TopK. The only setting where I-TopK outperformed T-TopK was when setting a high ($> 60\%$) percentage of random actions in the repository sessions, which significantly decreases the average session similarity score (Importantly, further increasing this parameter had a negligible effect on performance). However, as we show next, given slightly higher user idle-times, (which is a very reasonable assumption) T-TopK still outperforms I-TopK, even when the percentage of random actions is high, as the computation segment of calculating similarity vectors (in green) is significantly diminished.

User Idle-Times. We measured how the mean user idle-time affects the performance of T-TopK. Such idle time between consecutive actions of the same user often takes several seconds. Figure 4h depicts the performance when varying the expected time ranges from 0 to 0.24 seconds. Interestingly, even the latter, which is lower than the minimal human reaction time to a visual stimulus, was already sufficient to compute all missing vectors offline. As expected, T-TopK improves when the idle-time increases, and when all missing vectors are computed offline - T-TopK obtains almost a 3X speedup over I-TopK.

7 CONCLUSION

In this work, we show (for the first time, to our knowledge) that by utilizing the progressive nature of IDA sessions, a major running-time speedup (of over $180X$) can be obtained, compared to current solutions for top-k similarity search of analysis sessions. Our solution allows IDA recommendation systems to effectively rely on much larger session repositories while retaining interactive response times.

However, the scope of our work is limited in two main aspects: First, our solution is dedicated to the *SW-SIM* similarity measure for analysis sessions. While considered a very comprehensive, useful measure, some IDA recommendation systems use different session similarity measures. Nevertheless, we believe that the core principles of our solution may be applicable (with some tweaking and adaptations) to other similarity measures - even outside the scope of IDA, (e.g. scientific/business workflows, prescriptive analytics, mashups [5, 13, 42]).

Second, as common in many filter-and-refine based frameworks, the efficiency of the pruning techniques used by the T-TopK algorithm may be affected by underlying characteristics of the session repository, as well as the parameters of the search problem. In the absence of large enough, publicly available real-life IDA workloads, our experimental evaluation is performed, primarily, over a multitude of carefully crafted artificial repositories, each with different characteristics. Although we have shown that similar performance trends occur on the real-life session repository as well (the only one that is publicly available), it is still left to demonstrate the performance speedup on other real-life IDA workloads (when such become publicly available). Nevertheless, recall that the efficiency of the single-alignment optimizations, and the computation of the similarity vectors (as presented in Section 4), is independent of the session repository or problem parameters - and even these alone still provide a significant speedup of $40 - 80X$ compared to the currently available solutions.

pgFMU: Integrating Data Management with Physical System Modelling

ABSTRACT

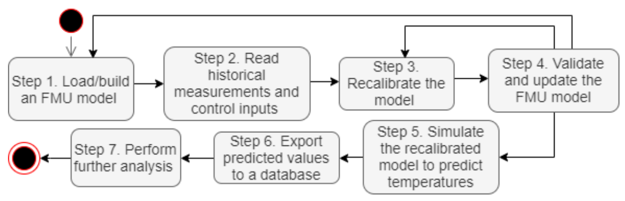
By expressing physical laws and control strategies, interoperable physical system models such as Functional Mock-up Units (FMUs) are playing a major role in designing, simulating, and evaluating complex (cyber-)physical systems. However, existing FMU simulation software environments require significant user/developer effort when such models need to be tightly integrated with actual data from a database and/or model simulation results need to be stored in a database, e.g., as a part of larger user analytical workflows. Hence, users encounter substantial complexity and overhead when using such physical models to solve analytical problems based on real data. To address this issue, this paper proposes pgFMU - an extension to the relational database management system PostgreSQL for integrating and conveniently using FMU-based physical models inside a database environment. pgFMU reduces the complexity in specifying (and executing) analytical workflows based on such simulation models (requiring on average 22x fewer code lines) while maintaining improved overall execution performance (up to 8.43x faster for multi-instance scenarios) due to the optimization techniques and integration between database and an FMU library. With pgFMU, cyber-physical data scientists are able to develop a typical FMU workflow up to 11.74x faster than using the standard FMU software stack. When combined with an existing in-DBMS analytics tool, pgFMU can increase the accuracy of Machine Learning models by up to 21.1%.

1 INTRODUCTION

Cyber-physical system experts, cyber-physical data scientists, and cyber-physical developers often need to analyze, predict, and simulate physical systems. For this purpose, *physical system models* are often used to capture time-dependent behaviour and dynamics of such systems [1]. They offer powerful, rigorous, and cost-effective means to characterize and reason about such systems, without the need to build, interact, and/or interfere with such systems. Physical system models (*physical models* for short) are well supported by a number of physical system modelling software tools and environments. However, each such modelling environment often uses a specialized form and format of a physical model with limited possibilities to utilize such models across different tools and environments. To mitigate this problem, *Functional Mock-up Interface (FMI)* [2] has emerged as a de-facto standard [3] to facilitate physical model exchange and co-simulation across a large number of modelling tools. In FMI, physical models are compiled into a standard representation, denoted as *functional mock-up units* (FMUs). FMUs reflect real physical systems composed of physical and digital components interacting in complex ways according to a set of pre-defined control strategies and physical laws. FMUs allow accurately defining system behaviour even in the physical states that are not observable in the real world, unlike what is required by traditional AI/ML models (e.g., artificial neural networks). Due to these advantages, FMUs continue gaining popularity in relevant physical modeling communities [5]. FMI has already been broadly adopted and supported by 130+ software tools, including well-known simulation environments Simulink (Matlab) [4] and EnergyPlus [6] (80.000+ downloads), as well as JModelica [8]/Open Modelica [10] (more than 20 companies and 30 universities in the consortium) with 1600+ model components and 1350+ functions from many domains available in a standard library alone.

Despite comprehensive physical modelling support, existing FMI-based simulation environments and tools offer poor database (DB) integration and lack built-in support for conveniently including physical models into user-defined analytical workflows. Thus, user data (e.g., model parameters, measurements, control inputs) cannot be conveniently supplied to the model from a DB and model results cannot be effectively used in larger analytical workflows (e.g., those encompassing multiple simulations) while offering convenient declarative approaches to manage such physical models within a common data management and physical modelling environment. Without these capabilities, model-driven analytical tasks become complicated and slow in terms of both development time and execution, and less usable for users working with, e.g., prescriptive analytics applications [12]).

As a running example, consider a prediction problem from the energy field. The aim is to predict and analyze indoor temperatures inside a house that is heated by an electric heat pump (HP) under different heating scenarios (e.g., *no heating*, *heating at max power*). For this task, a physical model represented as an FMU needs to be calibrated and simulated using measurements and weather data stored in the database. Predictions need to be stored in the database, for further analysis and visualization. In this case, as shown in Figure 1, the user has to pick relevant FMU-compliant software tools (e.g., JModelica [8] or Python [7] + PyFMI [14] + ModestPy [3]) and then use these tools to (1) load a pre-generated FMU file or manually build an FMU file from a model specification file, (2) read historical measurements and (future) control inputs from a database, (3) recalibrate the model (e.g, using ModestPy) in case the model cannot ensure the good fit with the historical measurements, (4) validate the model against real measurements, and update the model and/or parameters values, (5) simulate the updated model to generate temperature predictions for different scenarios (e.g, using PyFMI), (6) export predicted values back to the database, and (7) perform further analysis utilizing a DBMS. This imposes limitations for the user in terms of number of software tools and libraries to use, and in terms of the overall complexity and ability to effectively utilize physical models in larger analytical workflows where both simulation and optimization are required. In this and similar user workflows, interleaved data exchange between a database and a



Step 1. Load/build an FMU model
Step 2. Read historical measurements and control inputs
Step 3. Recalibrate the model
Step 4. Validate and update the FMU model
Step 5. Simulate the recalibrated model to predict temperatures
Step 6. Export predicted values to a database
Step 7. Perform further analysis

Figure 1: Running example workflow

modelling tool makes the workflows difficult to specify and evaluate, leading to significant implementation complexity, developer and performance overheads. This calls for new solutions offering more tight integration between a database and a modeling tool.

This paper proposes pgFMU – an extension to the PostgreSQL [9] DBMS to address these issues. pgFMU is a SQL-based model- and data management environment that brings benefits to cyber-physical data scientists and cyber-physical software developers. pgFMU facilitates FMU model storage, simulation, and parameter estimation tasks by effectively integrating FMI inside PostgreSQL. For this purpose, pgFMU offers a number of User-Defined Functions (UDFs) accessible by simple SQL queries for each necessary operation. As such, our extension exhibits the following advantages: (1) increased user productivity (on average 11.74x faster for user-defined workflows in terms of development time) due to the usage of a single integrated system for FMU-specific use cases, (2) reduced system complexity (22x fewer code lines), (3) increased performance due to the reduction in I/O operations and optimization for multi-instance workflows (up to 8.43x faster), (4) reduced number of error-prone actions by minimizing the number of software systems and tools a data scientist is required to work with, and 5) when used in combination with traditional Machine Learning models, pgFMU can increase model accuracy by up to 21.1%. These are supported by the results of our experiments which are based on the real-world use cases. Lastly, pgFMU is an open-source project and can be found on GitHub[1].

The rest of the paper is organized as follows: Section 2 elaborates on solving the aforementioned use case using traditional stack, Section 3 discusses the related work Section 4 highlights technical challenges of integrating FMUs inside a FMS, Section 5 discusses how pgFMU tackles model storage and specification, Section 6 presents our pgFMU-based approach for parameter estimation, Section 7 discusses the model simulation, Section 8 presents the experimental evaluation, and Section 9 concludes the paper and suggests future research directions.

2 RUNNING EXAMPLE

In this section, we follow Figure 1 and elaborate on the steps of solving the exemplified case of predicting indoor temperatures of a house. This example illustrates a typical process, steps, and software packages a cyber-physical data scientist would adopt to address this specific and similar problems based on FMU models.

Load / build an FMU model. A Functional Mockup Unit (FMU) is a .zip file consisting of a number of XML files, model and underlying solver implementation C-language files and/or their binary compilations for execution on different hardware platforms. The XML files describe model variables and parameters, attributes, default stop time, tolerance, etc., to be used, mostly, by FMU libraries and software tools and not the end-user. The cyber-physical data scientist can either download a pre-compiled FMU file from the (third-party) system modellers, or build an FMU file manually using a modelling tool, e.g., Open Modelica [10]. The latter option requires domain knowledge and modeling skills to mathematically capture all instantaneous thermal energy losses (and gains), intensities, and their balance within the building (e.g., windows, walls). For this problem, at time $t_k, k = 1 \ldots n$, temperature dynamics of the house can be captured by a generic *linear time invariant state space* model (1) (adapted from [11]):

$$\begin{aligned} x(t_{k+1}) &= F(x(t_k), u(t_k), \theta(t), t) \\ y(t_k) &= H(x(t_k), u(t_k), \theta(t), t), \end{aligned} \tag{1}$$

where $x(t_0) = x_0$ is the initial state, F is a linear or non-linear function, $F : \Re^n \times \Re^m \times \Re^p \times \Re \to \Re^n$, $x(\cdot) \in \mathbb{R}^n$ is the state variable vector, $u(\cdot) \in \mathbb{R}^m$ is the model input vector, $\Theta(\cdot) \in \mathbb{R}^p$ is the parameter vector, $y(\cdot) \in \mathbb{R}^O$ is the model output vector, and $H : \Re^n \times \Re^m \times \Re^p \times \Re \to \Re^O$ is the output function.

This model often needs to be translated into a representation required by a specific modelling tool, e.g., the Modelica [13] program shown in Figure 2. There, u is the *input variable* – heat pump power rating settings in the range [0 ... 1], corresponding to [0 .. 100%] of HP power operation; x is the *state variable* – indoor temperatures; y is the *output variable* – energy consumed by a heat pump. The parameters are represented by A, B, C, D, and E; $A = \left(-\frac{1}{R \cdot Cp}\right)$, $B = \left(\frac{P \cdot \eta}{Cp}\right)$, $C = P$, $D = 0$, $E = \left(\frac{\theta_a}{R \cdot Cp}\right)$, where $Cp = 1.5kWh/^{\circ}C$ is the thermal capacitance (the amount of energy needed to heat up by 1 $^{\circ}C$ within 1 hour); $R = 1.5^{\circ}C/kW$ is the thermal resistance; $P = 7.8kW$ is the rated electrical power of the heat pump; $\eta = 2.65$ is the performance coefficient (the ratio between energy usage of the heat pump and the output heat energy); $\theta_a = -10^{\circ}C$ is the outdoor temperature.

Read historical measurements and control inputs. Modelling tools often have poor support for database integration and require model parameters and inputs to be provided in a predefined format, usually a text file. If model inputs are stored in a database, the users are required to either manually export them to use it within the modelling software, or to download and familiarize themselves with often complex library functionality (e.g. Matlab Database Explorer app [4] or *psycopg2* [16] Python package). Yet, storing the measurements in a database has a number of advantages while handling the concurrent I/O operations such as managing the information from the multiple sensors and serving end-user applications. Lastly, the user is required to retrieve the control inputs from the FMU, and manually match them with the input data series obtained from the measurements.

Recalibrate the model. Values of one or more model parameters (e.g., A, B, E in Figure 2) are often either not known, or tuned for another physical system. This may result in poor model predictions, or erroneous decisions. *Parameter estimation* (or model calibration) is the operation of fitting model parameters to actual measurements, such that simulated model states and

[1]https://github.com/OlgaRyb/pgFMU.git

outputs acceptably match measured system states and outputs. In our problem, the unknown model parameter values are A, B and E (see Figure 2), and the sum of squared errors between the measured and simulated indoor temperatures is to be minimized.

Parameter estimation can be performed, for instance, using the ModestPy Python package [3] and its built-in function `Estimation`. In this situation, `Estimation` requires a path to the working directory, a path to the FMU model file, input measurements, known values of the parameters, values to be estimated, and a dataset with real measurements to calibrate upon. All these formal parameters need to be specified explicitly by the user. Additionally, in case the user needs to further use the updated model, parameters update is required to be done manually by calling a specific function from the *PyFMI* [14] package.

Often, a set of relevant parameters to be estimated has to be identified by the user. This operation demands an extensive domain knowledge, or assistance of the external domain expert. As an alternative, the user can use the functionality of *PyFMI* Python package to retrieve the relevant parameters of an FMU model. However, the list of retrieved parameters always needs to be accompanied by often complex filtering. For example, by default the *PyFMI* fetches the full list of parameters, including the parameters related to the built-in solver internally connected with the FMU model. Such parameters are not relevant for the parameter estimation operation, therefore, should be filtered out.

Validate and update the FMU model. Once parameter estimation is performed, the model needs to be validated before it can be used for subsequent predictions, e.g., using cross-validation. In case the model cannot generate predictions with sufficient accuracy, the model has to be either re-calibrated (e.g., with a different set of parameters) or further refined or replaced (i.e., using another FMU). In our case, validation should be performed using user-defined Python scripts.

Simulate the recalibrated model to predict temperatures. Next, we need to generate predictions by simulating the calibrated FMU model based on the desired input (HP power rating setting in the range [0 ... 1]/heating scenario). During simulation, model outputs and states are computed based on the provided inputs (and previous states), as seen in Figure 3. To simulate the model in this workflow, the user need to write a (Python) program (e.g. using the *PyFMI*) to load the *.fmu* file, read input data, map data to the form required by the simulation library (e.g. using *numpy* and *pandas* [15]), simulate the model (*PyFMI*), and insert simulation results back in the database (*psycopg2*).

Export predicted values to a database. For further analysis and visualization, the user needs to export data either directly to a database or first to a text file and then import the text file into a database using the respective SQL command.

Perform further analysis. Stored predicted indoor temperatures may further be used for subsequent visualization, analysis, optimization, and/or decision support. However, if predictions

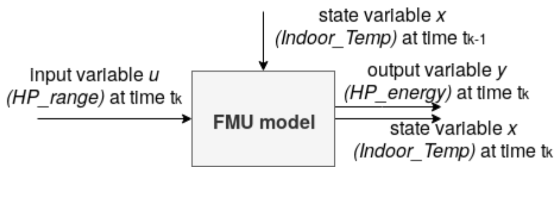

Figure 3: Simplified simulation FMU schematic of the HP system

under different model inputs are required, or by using different models, this overall process needs to be repeated. When predictions with multiple FMU model need to be performed, the cyber-physical data scientist faces additional complexity of managing all these models, their parameters values, and predictions. As seen in Table 1, for this particular example, the data scientist would have to perform 7 steps utilizing 6 different Python packages and writing 88 lines of code. The necessity to utilize multiple software packages makes development time-consuming and error-prone. At the same time, the usage of different programming interfaces makes such tasks difficult to perform, manage, and customize. FMU integration inside a DBMS, as in pgFMU, results in an order of magnitude reduction in the code (as seen in last table column).

3 RELATED WORK

FMU model simulation is widely supported by over 130 tools and packages, most of them being commercial ones. Among open-source projects are OpenModelica[10], PyFMI [14], and FMI Library as a part of JModelica[8]. However, even while providing GUI (e.g., OpenModelica), these tools do not have the solid support for the import and export of data from/to a DBMS. For example, OpenModelica requires an intermediary text file to be created as an input to the simulation engine; this text file should follow a strict format to be able to continue the simulation.

Another well-known environment for FMU simulation and parameter estimation is JModelica [8]. JModelica offers a Python interface, and serves the user with a number of functions required for a broad range of simulation- and optimization-related tasks. Another advantage of JModelica is package orchestration: even though some packages (e.g. PyFMI or Assimulo [20]) are claimed to be independent of other software, individual package management still remains a challenge. Nonetheless, JModelica does not provide yet a direct database input support, so the users are required to use extra packages (e.g. psycopg2).

At the same time, attempts were made to develop in-DBMS analytics: SAS [21] in collaboration with Teradata suggested the integration of DBMS with predictive modelling (including regression analysis and time series analytics); Tiresias [22] - a PostgreSQL-based system that supports "how-to" queries for defining and integrated evaluation of constrained optimization problems, and SolveDB - an extensible DBMS for SQL-based optimization problems [23]. The existing DBMSes offer only limited analytical support, such as in-DBMS linear optimization and, to

Table 2: Comparison between in-DBMS analytics tools and pgFMU

some extent, forecasting and simulation. To our best knowledge, no systems have until now supported in-DBMS storage, analysis, simulation, and calibration of the FMI-compliant models.

There exists a number of tools that incorporate traditional Machine Learning (ML) models into a DBMS, e.g., the hugely popular MADlib [27] and the recently released Microsoft (MS) SQL Server ML Services [28]. Table 2 shows a comparison of pgFMU with these systems. As we can see, neither MADlib, nor Microsoft SQL Server ML Services support physical system models (like FMUs), unlike pgFMU. MADlib follows the same integration approach as pgFMU by offering a set of UDFs specialized for ML. MS SQL Server ML Services provides a single T-SQL stored procedure for executing external Python and R scripts for ML, which is considerably less user-friendly as two languages (SQL + Python/R) are involved. While the UDFs of pgFMU can be installed as a DBMS extension, pgFMU can be used as a complement to existing ML tools, e.g., MADlib, which we demonstrate in Section 8.

4 CHALLENGES OF INTEGRATING FMUS INSIDE A DBMS

In the next section, we highlight 3 essential technical challenges of integrating FMUs inside a DBMS:

Challenge 1. Language Integration Challenge: *How to integrate and expose FMUs in database queries?* The challenge is to offer effective new SQL constructs, so that FMUs and FMU instances can be created, analyzed, manipulated, and used effectively together with existing SQL constructs.

Challenge 2. FMU Meta-data Challenge. *How to optimally take advantage of FMU meta-data to semi-automate task specification and data mapping?* Traditionally, the specification of FMU tasks and mapping between (discrete) data stored in a database and the FMU variables is manual and very verbose, but there is a huge opportunity to take advantage of the meta-data stored as a part of a FMU to automate such specifications.

Challenge 3. FMU Performance Challenge. *How to increase system performance when a (generic) FMU needs to be instantiated and used many times?* Individual tasks within FMU workflows (e.g., Figure 1) often require the same FMU to be instantiated and simulated many times. When model parameters and inputs change only marginally, FMU computations/results of FMU simulation can be reused to increase overall performance. The next sections elaborate on how pgFMU addresses these challenges.

5 MODEL SPECIFICATION, STORAGE, AND MANIPULATION

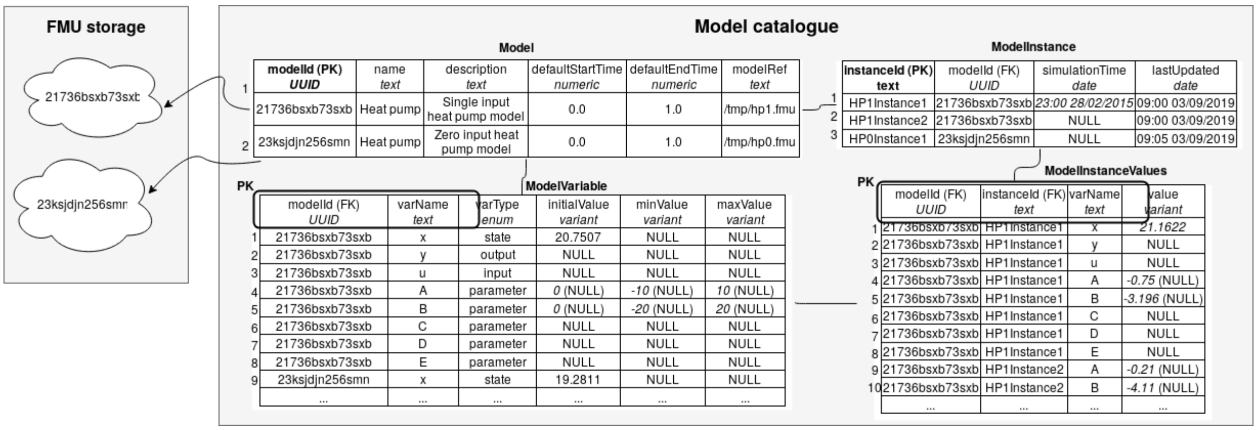
pgFMU aims to facilitate arbitrary user-specified FMU-based workflows by enabling creation, storage, and manipulation of FMU models (e.g., in terms of model parameters to be estimated) in a DBMS through user-specified SQL queries. This leads to Challenge 1: Language Integration Challenge (Section 4). Here, pgFMU takes a "session-like" approach where FMU instances are managed and used by explicitly calling commands in a particular order for FMU creation, deletion, etc. For this, pgFMU employs the same approach as MADlib [27] and offers a set of easy-to-use User-Defined Functions (UDFs) that support the full range of model management operations. pgFMU packs and offers these UDFs as a PostgreSQL extension, for ease-of-use and installation. Thus, FMU-specific functionality of pgFMU can be used with, e.g., the functionality of MADlib, for combined machine learning and physical simulations, as shown later. In this section, we describe in detail the new DBMS constructs / UDFs for model specification and storage, explain how they work, and show how users can take advantage of them when working with FMU models.

In pgFMU, a user can create an instance of an FMU model by using the function (UDF) *fmu_create (modelRef, [instanceId])* $\mapsto$ *instanceId*. As input, the function takes a mandatory textual argument *modelRef*, that represents either a path to a pre-compiled FMU (.fmu) file, a Modelica (.mo) file, or inline Modelica model code. If *modelRef* is a Modelica argument, it will be automatically compiled into an FMU file. The function returns a textual model instance identifier *instanceId*, which uniquely identifies the model instance in the subsequent model management function calls. The model instance identifier can be set manually by the user by supplying *instanceId* as an optional argument.

As explained in Section 4, FMU meta-data can be used to semi-automate task specification and data mapping (Challenge 2). For this, pgFMU reads meta-data from the user-defined FMUs once during FMU load and stores it in a *model catalogue* in a database. Thus, pgFMU automatically detects simulation parameters (start/stop timestamp, time step), variable causalities (e.g., *input*, *output*, *parameter*) and data types (e.g., *float*, *integer*, *string*), automatically configures simulation, and performs implicit data conversions when needed. The user can manually override the detected parameters. As seen in Figure 4, the model catalogue consists of four basic tables: *Model*, *ModelVariable*, *ModelInstance*, and *ModelInstanceValues*. *Model* captures the essential model attributes. FMU models are identified with a Universally Unique Identifier (UUID) [25] - a 128-bit string for unique object identification. All loaded models are stored in the *FMU storage* (non-volatile memory). *ModelVariable* describes the model variables: the variable name, variable type, and the initial, minimum, and maximum values. The combination of *ModelId* and *varName* attributes serves as the primary key. *initialValue*, *minValue*, and *maxValue* have the *variant* [24] type - a specialized PostgreSQL data type that allows storing any data type in a column, while keeping track of the original data type. *ModelInstance* stores the information about model instances. It uses *instanceId* as the primary key, and *modelId* as a foreign key. In this way, multiple instances of the same parent model can be stored. *ModelInstanceValues* stores the model instance variable values. Here, the combination of *modelId, instanceId*, and *varName* is a primary key. Lastly, we show some fields in all four tables decoded in regular and italic font. Here, the italic indicates the changes occurred after executing a query example (e.g., *fmu_parest*, Section 6). The initial field value is decoded with regular font.

A user can create an instance of the heat pump model (see Section 2) using the following intuitive SQL query in pgFMU:

```sql
SELECT fmu_create('/tmp/hp1.fmu', 'HP1Instance1');
```



Model

	modelId (PK) *UUID*	name *text*	description *text*	defaultStartTime *numeric*	defaultEndTime *numeric*	modelRef *text*
1	21736bsxb73sxb	Heat pump	Single input heat pump model	0.0	1.0	/tmp/hp1.fmu
2	23ksjdjn256smn	Heat pump	Zero input heat pump model	0.0	1.0	/tmp/hp0.fmu

ModelInstance

	instanceId (PK) **text**	modelId (FK) *UUID*	simulationTime *date*	lastUpdated *date*
1	HP1Instance1	21736bsxb73sxb	*23:00 28/02/2015*	09:00 03/09/2019
2	HP1Instance2	21736bsxb73sxb	NULL	09:00 03/09/2019
3	HP0Instance1	23ksjdjn256smn	NULL	09:05 03/09/2019

ModelVariable

	modelId (FK) *UUID*	varName *text*	varType *enum*	initialValue *variant*	minValue *variant*	maxValue *variant*
1	21736bsxb73sxb	x	state	20.7507	NULL	NULL
2	21736bsxb73sxb	y	output	NULL	NULL	NULL
3	21736bsxb73sxb	u	input	NULL	NULL	NULL
4	21736bsxb73sxb	A	parameter	*0* (NULL)	*-10* (NULL)	*10* (NULL)
5	21736bsxb73sxb	B	parameter	*0* (NULL)	*-20* (NULL)	*20* (NULL)
6	21736bsxb73sxb	C	parameter	NULL	NULL	NULL
7	21736bsxb73sxb	D	parameter	NULL	NULL	NULL
8	21736bsxb73sxb	E	parameter	NULL	NULL	NULL
9	23ksjdjn256smn	x	state	19.2811	NULL	NULL
	...	...	...	...	...	...

ModelInstanceValues

	modelId (FK) *UUID*	instanceId (FK) *text*	varName *text*	value *variant*
1	21736bsxb73sxb	HP1Instance1	x	*21.1622*
2	21736bsxb73sxb	HP1Instance1	y	NULL
3	21736bsxb73sxb	HP1Instance1	u	NULL
4	21736bsxb73sxb	HP1Instance1	A	*-0.75* (NULL)
5	21736bsxb73sxb	HP1Instance1	B	*-3.196* (NULL)
6	21736bsxb73sxb	HP1Instance1	C	NULL
7	21736bsxb73sxb	HP1Instance1	D	NULL
8	21736bsxb73sxb	HP1Instance1	E	NULL
9	21736bsxb73sxb	HP1Instance2	A	*-0.21* (NULL)
10	21736bsxb73sxb	HP1Instance2	B	*-4.11* (NULL)
	...	...	...	...

Figure 4: pgFMU model catalogue (filled with example data values)

The result of query execution is shown in Row 1 in *Model*, Row 1 in *ModelInstance*, Rows 1-8 in *ModelVariable* and *ModelInstance-Values*, and the object *21736bsxb73sxb* in *FMU storage*. Similarly, the user can use *fmu_create* to interact with Modelica model files:

```sql
SELECT fmu_create ('HP0Instance1', '/tmp/model.mo');
SELECT fmu_create('HP0Instance1', 'model heatpump
    output Real x, ..., y = C*x + D*u;end heatpump;');
```

The result of executing either of these calls corresponds to Row 2 in *Model*, Row 3 in *ModelInstance*, Row 9 in *ModelVariable*, and the object *23ksjdjn256smn* in *FMU storage*. The user can also create a copy of the model instance by using *fmu_copy (instanceId, [InstanceId2])* ↦ *instanceId2* (e.g., when managing many heat pumps of the same type); it takes the initial instance *instanceId* as input, and outputs the copy of this instance with the new instance identifier *InstanceId2* (user-defined or pgFMU-generated). The code snippet below illustrates the usage of *fmu_copy* (leading to changes in Row 2 in *ModelInstance* and Rows 9, 10 in *ModelInstanceValues*):

```sql
SELECT fmu_copy ( 'HP1Instance1', 'HP1Instance2');
```

In pgFMU, the initial copy of the FMU file is reused when either creating a new instance of the same FMU model (Row 2 in *ModelInstance*), copying a model instance, or changing a model state in the database environment. Once loaded (see Figure 4, *FMU storage*), an FMU model is used for all further operations; in this way, we avoid the creation and load of superfluous FMU model files, and we control and manipulate model instances while minimizing memory and computational resources. Algorithm 1 presents the logic behind *fmu_create*.

Furthermore, pgFMU provides a number of utility functions to analyse and manipulate the model instance variable values. For example, the function *fmu_variables (instanceId)* ↦ *(instanceId, varName, varType, initialValue, minValue, maxValue)* returns the details of all variables and parameters of the supplied model instance *instanceId*. The result includes the variables' initial, minimum, and maximum values, which can also be retrieved using the function *fmu_get(instanceId, varName)* ↦ *(initialValue, minValue, maxValue)*. In addition, a user can set the initial, maximum and minimum values of *HP1Instance1 A* and *B* model instance parameters using *fmu_set_initial(instanceId, varName, initialValue)* ↦ *instanceId*, *fmu_set_minimum (instanceId, varName, minValue)* ↦ *instanceId*, and *fmu_set_maximum (instanceId, varName, maxValue)* ↦ *instanceId* (Row 4 in *ModelVariable*, italic font):

```sql
SELECT fmu_set_initial('HP1Instance1', 'A', 0);
SELECT fmu_set_minimum('HP1Instance1', 'A', -10);
SELECT fmu_set_maximum('HP1Instance1', 'A', 10);
```

Furthermore, a user can retrieve all "HP1Instance1" model variables that serve, for example, as model parameters using the following query (the query output is shown in Table 3):

```sql
SELECT * FROM fmu_variables('HP1Instance1') AS f WHERE
f.varType = 'parameter'
```

The model instance can be brought back to its initial state using *fmu_reset (instanceId)* ↦ *instanceId* (see Rows 4, 5 in *ModelVariable*, and Rows 4, 5, 9, 10; the regular font indicates the initial values for the specific model instance). The user can delete either a specific model instance using *fmu_delete_instance (instanceId)*, or an entire FMU model using *fmu_delete_model (modelId)*. In the

Algorithm 1: fmu_create

```
Input:
    Stored model representation: modelRef;
    Optional: Unique model instance identifier [instanceId];
Output:
    Model instance identifier instanceId;
 1: if modelRef = .fmu file then
 2:     fmuModel ← Construct a model object using PyFMI
        function load_fmu(modelRef);
 3: else
 4:     if modelRef = .mo file or inline Modelica model
        specification then
 5:         fmuModel ← Construct a model object using PyFMI
            function compile_fmu(modelRef);
 6:     end if
 7: end if
 8: if instanceId is not given then
 9:     instanceId ← pgFMU-generated instanceId;
10: end if
11: Store the FMU model file in FMU storage;
12: Retrieve model variable names varName, types varType and
    values value by means of PyFMI function
    fmuModel.get_model_variables;
13: Insert the related sets of records into Model, ModelVariable,
    ModelInstances, ModelInstancesValues;
14: Return instanceId;
```

Table 3: *fmu_variables* example query output

instanceId	varName	varType	initial-Value	min-Value	max-Value
HP1Instance1	A	parameter	0	-10	10
HP1Instance1	B	parameter	0	-20	20
...	...	...	...	...	...

latter case, all model instances associated with this FMU model will be automatically removed from the database.

6 MODEL PARAMETER ESTIMATION

Model parameter estimation is a key functionality in pgFMU. Model instance parameters in pgFMU can be estimated using *fmu_parest (instanceIds, input_sqls, [pars])* $\mapsto$ *estimationErrors*. It takes a list of model instances *instanceIds* as input, updates the model instances with updated parameter values, and returns the list of estimation errors for each model instance *estimationErrors* (Root Mean Square Errors (RMSEs) by default). The user must also specify a list of SQL queries (*input_sqls*, one SQL query for each model instance) that produce the data to use in the parameter estimation, i.e., model training input and output variable pairs at different time instances. By default, the function estimates all model parameters. Optionally, the user can override this list by supplying a list of specific parameter names *pars*.

For example, the user can estimate the model parameters "A" and "B", and then store the updated model instance in the model catalogue using the following query (output is shown in Rows 4 and 5 in *ModelInstanceValues*, italic font):

```sql
SELECT fmu_parest('{HP1Instance1}', '{SELECT * FROM
    measurements}', '{A, B}')
```

fmu_parest() adopts the functionality of the ModestPy [3] Python package, which uses multiple optimization runs of the Global (denoted as G) and the Local (denoted as LaG) Search algorithms on different subsets of inputs to ensure result optimality even in the case of non-convex problems (later Figure 5 will illustrate the intuition behind this). In pgFMU, we use the ModestPy genetic algorithm implementation as G, and gradient-based method implemented by scikit-learn as LaG.

fmu_parest is designed to reduce the required amount of computation when parameters of multiple FMU instances need to be estimated (Challenge 3). Therefore, it automatically detects the number of model instances supplied and uses different algorithms when estimating parameters of a single model instance (SI scenario) or multiple instances (MI scenario).

Single instance parameter estimation Algorithm 2 provides implementation details for *fmu_parest* within the SI scenario. *fmu_parest* not only estimates the parameters of the FMU model instances, but also validates and updates the model instance with the new parameter values.

Multi-instance optimization In many scenarios, a user has a number of instances of the same model, e.g., 20 instances (*HP1Instance1*, *HP1Instance2*,.., *HP1Instance20*) of the heat pump model *HP1* corresponding to 20 different houses located in the same neighbourhood. In this case, pgFMU can apply its MI optimization when estimating parameters for multiple instances.

For example, the user can estimate the parameters "A" and "B" of *HP1Instance1* and *HP1Instance2* using the following query (leading to Rows 4, 5, 9, and 10 in *ModelInstanceValues*, italic font):

Algorithm 2: fmu_parest_SI

```
Input:
    Unique model instance identifier: instanceId;
    Query to retrieve measured data: input_sql;
    Optional: List of parameters [pars];
Output:
    estimationError;
1: Result set measurements ← Execute input_sql;
2: uuid ← Retrieve FMU model UUID from ModelInstance
   table identified by instanceId;
3: if pars is not given then
4:     pars ← Retrieve parameter variables from ModelVariable
       table identified by uuid;
5: end if
6: Retrieve the input variable values from the result set
   measurements;
7: parsEstimated, estimationError ← Run G & LaG for
   pars;
8: Update ModelInstanceValues with parsEstimated;
9: Return estimationError;
```

```sql
SELECT fmu_parest('{HP1Instance1, HP1Instance2}', '{
    SELECT * FROM measurements, SELECT * FROM
    measurements2}', '{A, B}')
```

Figure 5 illustrates the logic behind the MI optimization of *fmu_parest*. This optimization occurs in two stages. During the first stage, we estimate the parameters of *HP1Instance1* (solid blue line). In most cases, only the lower and upper bounds of each model parameter are known, and such bounds are usually defined by real-world physical constraints (e.g., HP performance coefficient cannot be negative). We set the initial parameter values to random numbers between the lower and the upper bounds mentioned above. Then, we follow the steps described in Algorithm 2, i.e., firstly, we run Global Search (G) to reduce the search space. Here, *1_G*, *2_G*, and *3_G* (filled circles) indicate the G iterations for *HP1Instance1*. After finding a good place in the search space, Local Search after Global (LaG) finetunes the parameter values to find optimal ones. We denote LaG iterations as *1_LaG*, *2_LaG*, and *3_LaG* (empty circles). *3_LaG* (exemplified by Rows 4, 5 in *ModelInstanceValues*) is the optimal parameter values of *HP1Instance1*.

The next stage is to perform parameter estimation for *HP1Instance2* (red dashed line). First, we check that the model instances belong to the same parent FMU. Next, we check whether the condition for the MI optimization invocation holds, i.e., we only

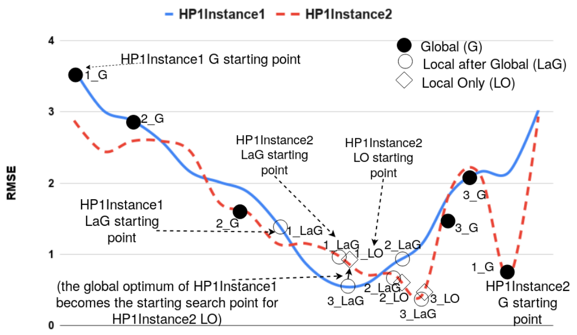


Figure 5: *fmu_parest* MI optimization

invoke the MI optimization after ensuring similarity (by calculating the L2 norm) between the input (and output) measurements of *HP1Instance1* and *HP1Instance2*. L2 norm (or the Euclidean norm) is one of the simplest and widely known, but still accurate and robust metrics for measuring the similarity between time series [26]. It is important to check the similarity between model instances time series to make sure the optimal solutions for these model instances lie within the same neighbourhood (see Figure 5). In case the difference between measurement time series is greater than a threshold, we do not invoke the MI optimization, and instead, run Algorithm 2 (a combination of G+LaG) for every instance. The *1_G*, *2_G*, and *3_G* points (filled circles) indicate the G iterations, while *1_LaG*, *2_LaG*, and *3_LaG* (empty circles) illustrate the LaG iterations. *3_LaG* would, in this case, be the optimal parameter values of *HP1Instance2*.

If the measured time series are sufficiently similar, i.e., the difference between them is less than *threshold*, we invoke the MI optimization. This means the optimal parameters values of *HP1Instance1* (solid blue line, *3_LaG*) become the initial parameter values of *HP1Instance2* (red dashed line, *1_LO*). In this way, we run Local Only Search (LO) (which is essentially the same algorithm as LaG, but with different initial parameter values) to obtain optimum parameter values of *HP1Instance2*, as its solution lies within the neighbourhood of the best solution of *HP1Instance1*. The points *1_LO*, *2_LO*, and *3_LO* (diamonds) are converging to those found by LaG. *3_LO* (exemplified by Rows 9, 10 in *ModelInstanceValues*) is the optimum parameter values of *HP1Instance2*. Algorithm 3 describes MI optimization for n model instances.

In pgFMU, the MI optimization significantly speeds up parameter estimation for multiple model instances. This speed-up is possible because G is much more expensive than LaG (see Section 8), and instead of G+LaG only LO is run. pgFMU provides the gradient-based Local Search algorithm with the good initial parameter values. In [3] authors emphasize, that "the initial global search would not be needed if the approximate initial values of parameters were known. In such a case the gradient-based methods would easily outperform GA [genetic algorithm]". As it will be shown later in Section 8, this statement holds. It should also be noted that the quality of the solution is dependent on the internal ModestPy algorithms. Within pgFMU, we adapt and enhance the functionality of ModestPy to best capture user preferences, streamline parameter estimation, and facilitate user interaction. The empirical evaluation of the MI parameter estimation shows identical accuracy with and without MI optimization.

7 MODEL SIMULATION

Users can simulate models by utilizing the function *fmu_simulate (instanceId, [input_sql], [time_from], [time_to])* $\mapsto$ *(simulationTime, instanceId, varName, values)*, which performs simulation on the supplied model instance and returns simulation results as a table of a timestamp, a model instance identifier, a variable name, and the variable's simulated value. By default, the simulation results for all state and output variables are returned. It is also possible to supply a time series of model input variable values by specifying an SQL query *input_sql*. If desired, the user can also specify a time window for simulation using the *time_from* and *time_to* parameters; otherwise, the start and end time will be determined by *defaultStartTime* and *defaultEndTime*. The system raises an error, e.g., if insufficient model input time series or an incomplete simulation time interval is provided.

Algorithm 3: fmu_parest_MI

```
Input:
    List of unique model instance identifiers: instanceIds;
    List of queries to retrieve measured data: input_sqls;
    Optional: List of parameters [pars], float [threshold].
Output:
    List of estimationErrors;
 1: if pars is not given then
 2:     pars ← Retrieve parameter variables from ModelVariable
        table identified by InstanceIds;
 3: end if
 4: for i = 0 to length (instanceIds)-1 do
 5:     Result set measurements[i] ← Execute input_sql[i];
 6:     parsEstimated[0], estimationError[0] ← Run
        fmu_parest_SI for instanceIds[0];
 7:     for i = 1 to length (instanceIds)-1 do
 8:         if modelId[0] ! = modelId[i] then
 9:             Run fmu_parest_SI for instanceIds[i];
10:         else
11:             $\delta$ = L2 norm of measurements[i] from
                measurements[0];
12:             if $\delta \geq$ threshold then
13:                 Run fmu_parest_SI for instanceIds[i];
14:             else
15:                 Update all the initial parameter values of
                    instanceIds[i] to parsEstimated[0];
16:                 parsEstimated[i], estimationError[i] ←
                    Run LO for instanceIds[i];
17:             end if
18:         end if
19:     end for
20:     Update ModelInstanceValues with parsEstimated;
21: end for
22: Return estimationErrors;
```

Table 4: *fmu_simulate* example query output

simulationTime	instanceId	varName	value
08:00 28/02/2015	HP1Instance1	x	20.7507
08:30 28/02/2015	HP1Instance1	y	0.0041
...	...	...	...

For example, the user can simulate the model by supplying model input values from the table *measurements* (Table 6) using the following query (also updating *ModelInstanceValues*, Row 1 and *ModelInstance*, Row 1, values in italic):

```sql
SELECT simulationTime, instanceId, varName, value
FROM fmu_simulate('HP1Instance1','SELECT * FROM
    measurements') WHERE varName IN ('y', 'x');
```

Table 4 shows the output of this query. If needed, the user can filter values of the desired columns using the standard WHERE clause predicates. We note that returning variable values as separate columns is not possible due to PostgreSQL limitations. In PostgreSQL, UDFs require fixed output schemas; flexible schemas are not supported in a convenient and easy-to-use way.

If multi-instance simulations are needed, the user can call a standard LATERAL join:

```sql
SELECT * FROM generate_series(1, 100) AS id,
LATERAL fmu_simulate('HP1Instance' || id::text ,
'SELECT * FROM measurements') AS f
```

Using *fmu_simulate*, model simulation is performed in two stages. In the first stage, an input object required for model simulation is created according to the FMU meta-data. This object consists of a set of input time series, automatically transformed for each input variable by taking into account their data types and variabilities (Challenge 2). In the second stage, an underlying model instance is simulated within the time interval (user-specified or from the model catalogue) while feeding the simulation algorithm with an input object. The simulation results are then emitted as a table (Table 4). Algorithm 4 depicts the logic behind *fmu_simulate*.

The UDFs described in Sections 5, 6, and 7 can be combined to solve specific problems. For instance, the example regarding HP temperature prediction can be specified using a single query (producing the same results and updates as *fmu_create, fmu_parest*, and *fmu_simulate* example queries from Sections 5, 6, and 7):

```
SELECT time, value
FROM fmu_simulate (fmu_parest {fmu_create
 ('HP1Instance1', 'C:\temp\hp1.fmu')},
'{SELECT * FROM measurements}', '{A, B}'),
'SELECT time, 'u' AS varName, value
 FROM generate_series('''2015-01-01'''::timestamp,
'''2015-01-02'''::timestamp, '''1 hour'''::
interval) AS time WHERE varName = 'x'
```

In addition, there are few important points. Firstly, all pgFMU UDFs are independent of each other and can be used in any order. Similar to other modelling software, e.g., Matlab and JModelica,

```
Algorithm 4: fmu_simulate
Input:
    Unique model instance identifier: instanceId;
    Optional: Query to retrieve measured data: [input_sql],

```

the user is only requested to create the in-DBMS instance of an FMU model. pgFMU provides full flexibility when configuring user workflows: if parameter estimation is not required, the user can simulate the model right away, or change the order of actions and perform model simulation followed by parameter estimation. Next, in pgFMU, we eliminate explicit I/O operations (e.g. historical measurements import, or simulation results export from a third-party software into DBMS) as all the computations are done "in-place" inside DBMS. This affects the essential operations (parameter estimation, model simulation) due to the data-driven nature of these operations. Furthermore, when operating many instances of the same model, we eliminate the necessity to load the same FMU file multiple times. We store one single FMU model, and operate with in-DBMS model instances. These instances share the essential information about the initial FMU through model catalogue, and can be considered as sufficient substitutes of FMUs. pgFMU is also able to operate several in-memory FMU model files at a time. Lastly, as we use prepared SQL queries, we avoid the repeated reevaluation of database queries for measurements retrieval.

8 EXPERIMENTAL EVALUATION

In this section, we evaluate pgFMU in real-world circumstances. Firstly, we describe our experimental setup. Then, we present the results of the evaluation with regard to model quality, performance, and usability.

8.1 Experimental Setup

As a baseline, we follow a traditional workflow for model storage, calibration, simulation, and validation, and perform the steps described in Figure 1. We consider two scenarios: *single instance (SI) scenario* and *multi-instance (MI) scenario*. In the SI scenario, we execute parameter estimation and simulation using a single model instance only. In the MI scenario, we execute parameter estimation and simulation for many model instances.

Three main system configurations are compared: (1) workflow execution within a Python IDE (referred as *Python*), (2) workflow execution using the non-optimized version of pgFMU (referred as *pgFMU-*), and (3) workflow execution using the optimized version of pgFMU (referred as *pgFMU+*). *Python* is based on the usage of standard Python packages. In *pgFMU-* configuration we use the pgFMU system with no multi-instance optimization activated, and *pgFMU+* takes advantage of the MI optimization. All three configurations are evaluated using Ubuntu 17.1 OS on a Lenovo ThinkPad with a four-core Intel i7 processor, and 8 GB of DDR3 main memory. For parameter estimation within pgFMU, we utilize genetic algorithm (GA) for Global Search and sequential quadratic programming (SQP) for Local Search. The study argues [3] that this combination of algorithms produces optimal results in terms of accuracy and performance. For GA, we use default settings with a fixed randomly derived seed. For SQP, the default settings were used as well. More information about default parameters settings is available on the library homepage.

Generalizability was one of the main criteria for choosing the test models. The models should represent real-world physical systems with varying numbers of inputs and outputs, and different physical meaning of model parameters. We follow a workflow process identical to the one outlined in Figure 1, i.e., we estimate the unknown parameters of the model (model parameter estimation), validate the model with regard to the real input measurements (model validation), and simulate the model to predict the values of the model state variable (model simulation). We have chosen three different FMU models, each of them representing a real-world physical system. These models are denoted *HP0, HP1*, and *Classroom*, respectively. *HP1* corresponds to the running example model described in Section 2. *HP0* is a modification of *HP1* with zero inputs, such that we keep the heat pump power at a constant rate. *Classroom* is a thermal network model [17] represented by a classroom in a 8500 m^2 university building at the SDU Campus Odense (Odense, DK). Table 5 summarizes the inputs, outputs and parameters of the three models. For experimental evaluation within the MI scenario, we construct 100 synthetic datasets for each FMU model. We multiply the original dataset time series values with a constant $delta$ from the numerical range $\delta \in \{0.8, \ldots, 1.2\}$, meaning we amplify or decrease the numerical values by up to 20% while ensuring the same data distribution as the original datasets. In Section 6 we explain the reasoning behind such numerical range of δ. We also ensure that the datasets respect the physical constraints of the real-world systems.

8.2 Model quality

In this subsection, we compare and evaluate model quality for *Python*, *pgFMU-*, and *pgFMU+*. We perform parameter estimation and model simulation within the *SI scenario* and *MI scenario*.

SI scenario. Within *Python*, parameter estimation is performed using the ModestPy package, whereas *pgFMU-* and *pgFMU+* utilize the *fmu_parest* UDF. *HP1* was calibrated using the NIST dataset [18]. *HP0* was calibrated using the same dataset with u being kept at a constant rate of 1.38%. For both models, we estimate the parameters based on the hourly aggregated data from February 1-21, while using February 22-28 for validation. The *Classroom* model was calibrated using measurements data from University building O44 in Odense, DK. Table 6 shows an excerpt of the datasets for all three models. We compare parameter values and error value for *HP0, HP1* and *Classroom* for *Python*, *pgFMU-*, and *pgFMU+*. Table 7 shows this comparison. To evaluate the quality of the model, we use the RMSE metric. RMSE and Mean Absolute Error (MAE) are two commonly used metrics for model evaluation. However, a study [19] argues that RMSE is more appropriate to be used when unfavourable conditions should be given a higher weight, i.e., RMSE penalizes large errors stricter than MAE. In our case, we want to distinguish every occurrence when a model fails to secure a good fit with the measured data, therefore, we choose RMSE for model quality evaluation.

For *HP0* (Table 7), the model parameter values have converged to the same values within *Python*, *pgFMU-* and *pgFMU+*. The RMSEs when performing parameter estimation for *Python*, *pgFMU-*, and *pgFMU+* are near identical (the relative difference is only 0.013%). For *HP1*, the RMSEs in all three configurations are exactly the same, and for *Classroom* the relative difference is at most 0.018%. We consider these differences negligible. Thus, *pgFMU-* and *pgFMU+* handles single model workflow computations with the same accuracy as *Python*. The identical accuracy for all three configurations is achieved through the usage of the same Python ModestPy library; however, both *pgFMU-* and *pgFMU+* use a modified version of ModestPy to provide generalizability and handle all types of FMU models, and perform data binding and pre-processing steps discussed in Section 2.

MI scenario. For the MI scenario, we compare RMSE values for 100 instances of each model (*HP0, HP1* and *Classroom*) side-by-side. Each model instance is supplied with a synthetic dataset based on the measured data. For *Classroom*, the RMSE values for all three configurations are matching, resulting in the same average RMSE values (1.61°*C*). For *HP1*, RMSE values differ a bit more, but are still very close, with either *Python*, *pgFMU-*, or *pgFMU+* as the better one. The average RMSE values yield in 2.03°*C* for all three configurations. Thus, the model quality is also the same here. We observe a similar behaviour for *HP0*, where for *pgFMU-* and *Python* the average RMSE is 0.68°*C*, while *pgFMU+* estimates the model parameters with 0.66°*C* average accuracy.

When enabling MI optimization, one must remember the conditions for this feature to produce acceptable results. By default, parameter estimation is performed using Algorithm 2 (Section 6), unless the user alters the threshold value. In our case, we have set the threshold to 20% (Section 8.1) based on the series of experiments reflected in Figure 6. In this Figure, the x-axis represents dataset dissimilarity in terms of L2 norm distances, the y-axis encodes the corresponding RMSE values, and the secondary y-axis shows the execution time of G+LaG and LO. RMSE is represented using the same unit as the dependent variable (for *HP1*, the indoor temperature in °*C*). The Figure shows that the execution time of G+LaG is significantly larger than LO. We see that G takes approximately 90% of the execution time (considering that LaG and LO are the same algorithms, with different initial parameter values). The Figure shows that there is no difference in G+LaG and LO RMSEs until maximum dissimilarity reached approximately 30%; after this, the difference grows linearly. This is because the optimal solution for *instanceId[0]* used as initial parameter values for the remaining models *instanceId[1], ..., instanceId[n-1]* (see Algorithm 3) was not able to provide satisfactory results. Further, the choice of a threshold value is always contextually dependent, and a user has to decide about the acceptable RMSE values.

Combining pgFMU and MADlib. To improve model quality, pgFMU can be used in combination with other in-DBMS analytics tools, e.g., MADlib. If in our *Classroom* model the number of occupants in the room is unknown, we can use MADlib to predict occupancy, e.g., using the ARIMA model and the following query to train the model:

```sql
SELECT arima_train(
'occupants', -- Source table
'occupants_output', -- Output table
'time', -- Timestamp column
'value'); -- Timeseries column
```

In this experiment, we used the original dataset to train the model and perform the prediction. We divided the dataset into training (80%) and validation (20%) sets. We created two model instances: without occupancy information, and with occupancy values predicted by the MADlib ARIMA model. Then, we simulated the two models, and compared model RMSEs. The *Classroom* model

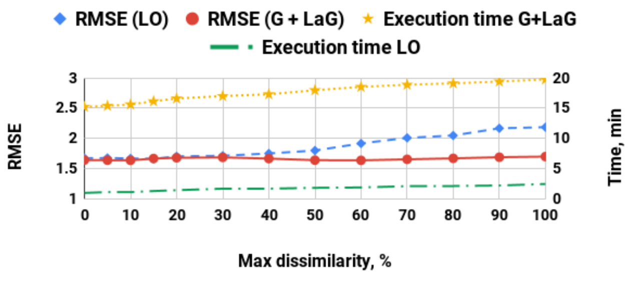

Figure 6: Avg. RMSE & execution time overhead of LO & G+LaG for datasets of different dissimilarity (HP1 model)

Table 5: FMU models

ModelID	Measurements dataset	Inputs	Outputs	Parameters
HP0	NIST Engineering Lab's Net-Zero Energy Residential Test Facility	No inputs	HP power consumption *y*, Indoor temperature *x* (state variable).	Thermal capacitance *Cp*, thermal resistance *R*.
HP1	NIST Engineering Lab's Net-Zero Energy Residential Test Facility	HP power rating setting in the range [0 .. 100%] *u*	HP power consumption *y*, Indoor temperature *x* (state variable).	Thermal capacitance *Cp*, thermal resistance *R*.
Classroom	Data from the classroom in the test facility in Odense, DK	Solar radiation *solrad*, outdoor temperature *tout*, number of occupants *occ*, damper position *dpos*, radiation valve position *vpos*.	Indoor temperature *t* (state variable)	Solar heat gain coeff. *shgc*, zone thermal mass factor *tmass*, ext. wall thermal resistance *RExt*, occupant heat generation effectiveness *occheff*.

Table 6: Dataset for *HP0, HP1* (top), *Classroom* (bottom)

No	Timestamp	x	y	u
1	2015/02/01 00:00	20.7507	0	0

...	...	...	...	...	...	...	...

with the occupancy values predicted by MADlib ARIMA showed up to 21.1% increased accuracy in terms of RMSE.

Reversely, pgFMU can be used to improve the quality of traditional ML models. In the next experiment, we used the indoor temperatures of the *Classroom* computed using pgFMU to increase the accuracy of the logistic regression model that identifies the position (open/closed) of the ventilation damper *dpos*. When we include indoor temperature *t* into the feature vector of the model, this yields 5.9% increased model accuracy.

8.3 Performance evaluation

In this subsection, we look into the performance comparison of *Python*, *pgFMU-*, and *pgFMU+* for *HP0, HP1*, and *Classroom* within SI and MI scenarios.

Single instance scenario. To evaluate pgFMU performance within the SI scenario, we compare the execution time for all three models. Table 8 shows this comparison. For all the models, we do not observe a significant difference in execution time between *Python*, *pgFMU-* and *pgFMU+* (for *HP0*, *Python* is faster by 0.14%, for *HP1* and *Classroom pgFMU-* and *pgFMU+* perform better by 0.10%, and 0.12%, respectively). We conclude that within *Python*, *pgFMU-*, and *pgFMU+* the performance is practically identical, as expected. However, in Table 8 we see that model calibration takes more than 99% of execution time. This imposes limitations when estimating the parameters of multiple model instances.

Table 7: SI scenario, model calibration comparison

	Python		*pgFMU-, pgFMU+*	
	Param. values	RMSE	Param. values	RMSE
HP0	Cp: 1.53	0.7701	Cp: 1.53	0.7702
	R: 1.51		R: 1.51	
HP1	Cp: 1.49	0.5445	Cp: 1.49	0.5445
	R: 1.481		R: 1.481	
Classroom	RExt: 4	1.6445	RExt: 4	1.6442
	occheff: 1.478		occheff: 1.478	
	shgc: 3.246		shgc: 3.246	
	tmass: 50		tmass: 50	

MI scenario. For the MI scenario, we use *Python*, *pgFMU-* and *pgFMU+*, and scale the number of model instances to 100 for each FMU model. We match the synthetic dataset with each FMU model instance. Figure 7 shows the execution time for *Python*, *pgFMU-*, and *pgFMU+* for *HP0, HP1* and *Classroom.* The execution workflow of storing, calibrating, simulating, and validating 100 *HP0* model instances takes 1083.7 min (18.06 hours) for *Python*, 1073.7 min (17.9 hours) for *pgFMU-*, and 204.2 min (3.4 hours) for *pgFMU+*. As we can see, *pgFMU+* outperforms *Python* and *pgFMU-* by 5.31x. The execution workflow of storing, calibrating, simulating, and validating 100 *HP1* model instances takes 1329.63 min (22.16 hours) for *Python*, 1319.48 min (21.97 hours) for *pgFMU-*, and 241.47 min (4.02 hours) for *pgFMU+*. In this case, *pgFMU+* outperforms *Python* and *pgFMU-* by 5.51x. We observe an even larger difference in workflow execution time for 100 *Classroom* model instances. It takes 1380.68 min (23.01 hours) for *Python*, 1370.95 min (22.85 hours) for *pgFMU-*, and 163.6 min (2.73 hours) for *pgFMU+*; *pgFMU+* is faster by 8.43x.

As we can see, the execution time grows linearly with more model instances, but the growth rate is different for different models. The common pattern for all three models is that *Python* and *pgFMU-* exhibit a similar growth rate. For *pgFMU+*, the execution time also grows linearly, but slower compared to *Python* and *pgFMU-*. This means *pgFMU+* performs user-defined workflows based on the FMU model calibration and simulation on average 6.42x faster. Such gains in the runtime are achieved through a number of optimization steps described in Sections 6 and 7.

8.4 Usability

We conducted usability tests to evaluate how the functionality of pgFMU reflects user needs. We asked a group of 6 PhD-candidates and 24 master students from four different universities in Denmark, Poland, Spain, and Belgium to individually perform the task of *HP1* and *Classroom* model calibration and simulation. All the participants were asked to complete the SI workflow based on Figure 1 using *Python* and *pgFMU.* The execution of the MI workflow was optional. During the usability testing, we recorded the issues with both configurations, and observed the learning curve of the participants as they progressed with the task. All participants were timed.

Table 8: Configurations comparison, SI scenario

ID	Operation	execution time, s					
		HP0		HP1		Classroom	
		Python	pgFMU±	Python	pgFMU±	Python	pgFMU±
1	Load FMU	0.02	0.025	0.02	0.021	0.03	0.03
2	Read historical measurements & control inputs	0.02	0.021	0.03	0.031	0.04	0.041
3	(Re)calibrate the model	842.99	844.18	834.68	833.88	830.2	829.16
4	Validate and update FMU model	0.01	-	0.01	-	0.01	-
5	Simulate FMU model	0.16	0.214	0.2	0.22	0.35	0.44
6	Export predicted values to a DBMS	0.06	-	0.06	-	0.05	-
	Total	**843.26**	**844.44**	**835**	**834.15**	**830.68**	**829.67**

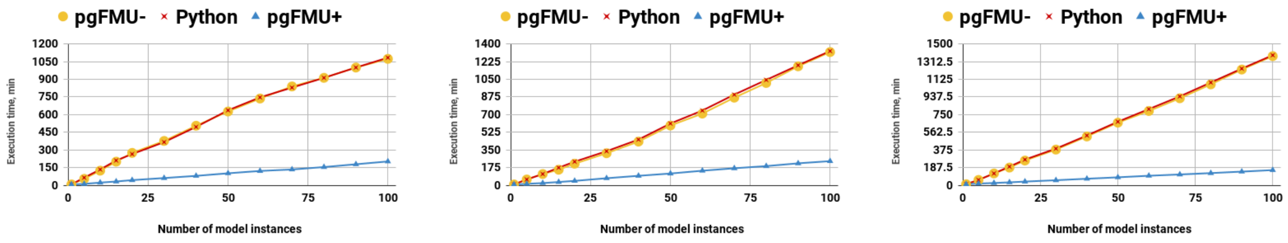

Figure 7: *HP0, HP1, Classroom* (from the left to the right) parameter estimation execution time

In the beginning, the users were asked to answer a pre-assessment questionnaire aimed at identifying their knowledge about physical systems modelling. By using the scale from 1(very little) to 5(very much), the participants answered the following questions:

Q1. How familiar are you with energy systems and physical system modelling?
Q2. How familiar are you with model simulation and calibration?
Q3. How familiar are you with model simulation software?
Q4. How comfortable are you with using Python IDE(s)?
Q5. How comfortable are you with using SQL?

Based on the participants' answers, they did not consider themselves experts in the energy domain (Q1). Only 2 people estimated the familiarity with energy systems as "very much". For Q1, Q2 and Q3, the majority (27 out of 30 for Q1 and Q2, 26 out of 30 for Q3) ranked their knowledge in energy systems, model simulation and calibration processes, and model simulation software as "very little" or "little". When speaking about programming environments, 25 out of 30 students knew "much" or "very much" about the SQL, with only 14 out of 30 giving the same score to the Python. We concluded that graduate and post-graduate students possessed more knowledge about SQL, and felt more comfortable with using SQL-based functions rather than Python packages.

For this session, we set the time limit to 3 hours. The participants tested the *pgFMU* functionality first, then the *Python.* All participants but one were able to finalize the task within the defined time range. Figure 8 illustrates the time distribution for every user performing the steps described in Figure 1 for *HP1* and *Classroom* models. With pgFMU it took under 20 minutes for all participants to become familiar with the syntax, and complete the task. The minimum learning time for pgFMU was reported to be 9.6 minutes, and the maximum was 17.6 minutes, respectively. On average, with pgFMU the participants finished the task (excluding the runtime) 11.74x faster than with *Python.*

The main criticism regarding the suggested setup was the necessity to use multiple Python packages, and the inability to

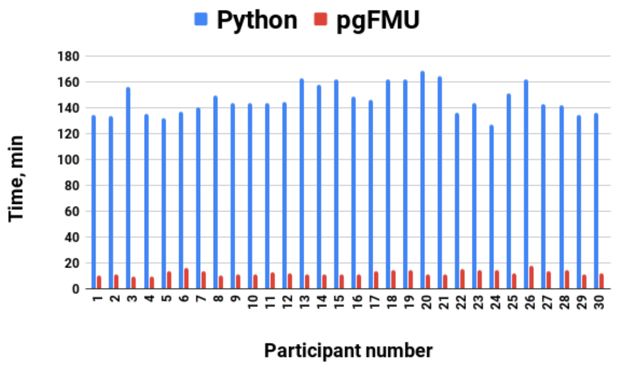

Figure 8: Users learning and development time (combined)

perform all the tasks with a single programming package/tool. The whole workflow was described as "intuitive" and "easy to understand", but the need to use different libraries was characterized as "confusing" and "unsettling". One of the participants reported that both PyFMI and ModestPy packages in their documentation use domain-specific language which was difficult to grasp. Table 9 shows highlighted feedback that the participants expressed about the strengths and weaknesses of both systems.

At the end, all users were asked to answer a post-assessment questionnaire aimed at identifying participants' opinion regarding the functionality of *Python* and *pgFMU.* By using the scale from 1(very unsatisfactory) to 5(very satisfactory), the participants were asked to answer the following questions :

Q1. How was it to retrieve information about model variables?
Q2. How was it to set model parameters?
Q3. How was it to calibrate the model?
Q4. How was it to simulate the model?
Q5. How was your satisfaction with systems' functionality?

Table 9: Strengths and weaknesses of *Python* and *pgFMU*

Strong points of *Python*	Strong points of *pgFMU*
“Better to debug, analyze"; “More functionality”; “Control over program flow”; “Data visualization option”;	"Data and model in one place"; "Easy to run and understand"; "Simplicity, no need to use or import external tools"; "Familiar SQL syntax";
Weak points of *Python*	Weak points of *pgFMU*
"A lot of unknown new modules and packages"; "No one ready package to do everything"; "A lot of code to set up configuration, some functions not intuitive"; "You need practise[*sic*] to understand";	"Not so much configuring available"; "I don’t see any significant [*weak points*] besides maybe installation of the package on postgres [*PostgreSQL*];" "Specific database implementation";

The questionnaire results show a clear advantage of using *pgFMU* over *Python*. When performing the workflow depicted in Figure 1, *pgFMU* scores better when retrieving (3.7 out of 5 for pgFMU vs 3.1 out of 5 for Python) or setting the model variables (3.83 out of 5 vs 3.26 out of 5 respectively), calibrating (3.66 out of 5 vs 3.1 out of 5 respectively) and simulating the model. In particular, the model simulation functionality of *pgFMU* was commended, scoring 4.17 out of 5 (for the same operation, *Python* scored only 3.53 out of 5). *pgFMU* outperforms *Python* in terms of overall participants’ satisfaction, scoring 4.2 and 3.6 out of 5, respectively.

Lastly, *pgFMU* requires substantially fewer lines of code than does *Python*; Table 1 shows this comparison. In addition, *pgFMU* does not require any customization, meaning it is capable of working with any number of model inputs, outputs and parameters without UDF adjustment for every specific model or use case. On the contrary, *Python* requires the user to manually retrieve and match model inputs with measurements data.

9 CONCLUSION AND FUTURE WORK

This paper presents pgFMU - the first DBMS extension to support storage, simulation, calibration, and validation of physical system models defined as Functional Mock-up Units (FMUs) within a single DBMS environment. This extension is developed for cyber-physical data scientists and cyber-physical software developers. For such users, pgFMU provides a set of powerful User-Defined Functions (UDFs) invoked by traditional SQL queries. The UDFs are designed as stand-alone functions within pgFMU, and can be used in a user-defined sequence. Furthermore, pgFMU provides efficient functionality to store, simulate an arbitrary number of FMU model instances, and estimate the parameters of such instances. The aforementioned properties all contribute to supporting FMU model simulation and parameter estimation tasks within a DBMS environment. Due to its in-DBMS implementation, pgFMU demonstrates increased performance (up to 8.43x, and on average 6.42x faster for multi-instance workflows) for data-dependent workflows and improves user productivity (11.74x times faster in terms of development time). Moreover, it can increase Machine Learning model accuracy by up to 21.1% when used in combination with existing in-DBMS analytics tools, e.g., MADlib.

pgFMU has been tested by the entry level cyber-physical data scientists. The usability testing showed positive results, reporting the development time more than an order of magnitude lower than the traditional approach. As reported by the participants, pgFMU was capable of addressing the major point of dissatisfaction, namely the variety of software packages and libraries the user is obliged to use, and the domain-specific nature of such packages. pgFMU simplifies the overall analytical procedure, and minimizes the efforts required to specify and calibrate a particular model; the users are able to perform the necessary operations with approximately 22x fewer code lines. pgFMU was also reported to provide a more intuitive way of scripting and a better data organisation.

Future work will continue the development of functionality to support in-DBMS FMU-based dynamic optimization. This includes the adoption of various model predictive control means, covering the optimization of control inputs. Additionally, we will look into FMU integration challenges in the Big Data setting, including just-in-time (JIT) FMU compilation to optimize user queries, and scheduling FMU execution on multi-core multi-node environments.

ABSTRACT

The emergence of mobile apps (e.g., location-based services, geo-social networks, ride-sharing) led to the collection of vast amounts of trajectory data that greatly benefit the understanding of individual mobility. One problem of particular interest is next-location prediction, which facilitates location-based advertising, point-of-interest recommendation, traffic optimization, etc. However, using individual trajectories to build prediction models introduces serious privacy concerns, since exact whereabouts of users can disclose sensitive information such as their health status or lifestyle choices. Several research efforts focused on privacy-preserving next-location prediction, but they have serious limitations: some use outdated privacy models (e.g., k-anonymity), while others employ learning models with limited expressivity (e.g., matrix factorization). More recent approaches (e.g., DP-SGD) integrate the powerful differential privacy model with neural networks, but they provide only generic and difficult-to-tune methods that do not perform well on location data, which is inherently skewed and sparse.

We propose a technique that builds upon DP-SGD, but adapts it for the requirements of next-location prediction. We focus on user-level privacy, a strong privacy guarantee that protects users regardless of how much data they contribute. Central to our approach is the use of the skip-gram model, and its negative sampling technique. Our work is the first to propose differentially-private learning with skip-grams. In addition, we devise data grouping techniques within the skip-gram framework that pool together trajectories from multiple users in order to accelerate learning and improve model accuracy. Experiments conducted on real datasets demonstrate that our approach significantly boosts prediction accuracy compared to existing DP-SGD techniques.

1 INTRODUCTION

The last decade witnessed a rapid development in mobile devices capabilities, accompanied by the emergence of numerous locations-centric applications, such as point-of-interest (POI) search, geo-social networks, ride-sharing services, etc. As a result, vast amounts of rich trajectory data have become available. Coupled with recent advances in machine learning, these data can benefit numerous application domains, such as traffic analysis, location-based recommendations, homeland security, etc.

Mobile users share their coordinates with service providers (e.g., Google Maps) in exchange for receiving services customized to their location. The service providers analyze the data and create powerful machine learning models. Subsequently, these models can be *(i)* placed on user devices to improve the quality of location-centric services; *(ii)* shared with business affiliates interested in expanding their customer base; or *(iii)* offered in a Machine-Learning-as-a-Service (MLaaS) infrastructure to produce business-critical outcomes and actionable insights (e.g., traffic optimization). Figure 1 illustrates these cases. Given historical trajectories, several approaches exploit recent results in neural networks to produce state-of-the-art POI recommender systems [10, 35, 58]. Even though individual trajectory data are not disclosed directly, the model itself retains significant amounts of specific movement details, which in turn may leak sensitive information about an individual's health status, political orientation, entertainment preferences, etc. The problem is exacerbated by the use of neural networks, which have the tendency to overfit the data, leading to unintended memorization of rare sequences which act as quasi-identifiers of their owners [9, 13]. Hence, significant privacy risks arise if individual location data are used in the learning process without any protection.

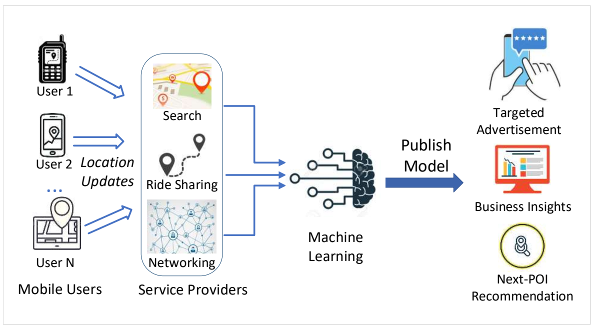

Figure 1: System Model

The research literature identified several fundamental privacy threats that arise when performing machine learning on large collections of individuals' data. One such attack is *membership inference* [25, 52] where an adversary who has access to the model and some information about a targeted individual, can learn whether the target's data was used to train the model. Another attack called *model inversion* [56] makes it possible to infer sensitive points in a trajectory (e.g., a user's favorite bar) from non-sensitive ones (e.g., a user's office). Within the MLaaS setting—where a third party is allowed to only query the model—this implies extracting the training data using only the model's predictions [20].

Iterative procedures such as stochastic gradient descent (SGD) [7] are often used in training deep learning models. Due to the repeated accesses to the data, they raise additional challenges when employing existing privacy techniques. In order to prevent the inference of private information from the training data, recent approaches rely on the powerful *differential privacy (DP)* model [14]. Sequential querying using differentially private mechanisms degrades the overall privacy level. The recent work in [2] provides a tight-bound analysis of the composition of the Gaussian Mechanism for differential privacy under iterative training procedures, enabling the utility of a deep learning model to remain high [39], while preventing the exposure of the training data [6, 27]. While integrating differential privacy techniques into training procedures like stochastic gradient descent is relatively straightforward, computing a tight bound of the privacy loss over multiple iterations is extremely challenging (see Section 6 for a summary of results).

The seminal work in [2] provided *record-level* privacy for a simple feed-forward neural network trained in a centralized manner. The approach provides protection only when each individual contributes a single data item (e.g., a single trajectory). When an individual may contribute multiple data items, a more strict protection level is required, called *user-level* privacy. McMahan et. al. [39] showed that one can achieve *user-level* privacy protection in a federated setting for simple learning tasks. However, ensuring good utility of the trained model for datasets with various characteristics remains a challenge. McMahan et. al. [39] remove skewness in their inputs by pruning each user's data to a threshold, thus discounting the problems of training neural models on inherently sparse location datasets, usually having density around 0.1% [60]. Existing work on privacy-preserving deep learning either assume large and dense datasets, or are evaluated only on dummy datasets [21] that are replicated to a desired size using techniques such as [38]. Such techniques overlook the difficulty of training models on smaller or sparse datasets, which often prevent models from converging [40]. Moreover, they require extensive hyperparameter tuning to achieve good accuracy, and the rough guidelines offered to tune these parameters [37] do not extend to more complex neural architectures, or to datasets different from those used in their work.

We propose a technique that can accurately perform learning on trajectory data. Specifically, we focus on next-location prediction, which is a fundamental and valuable task in location-centric applications. The central idea behind our approach is the use of the skip-gram model [41, 43]. One important property of skip-grams is that they handle well sparse data. At the same time, the use of skip-grams for trajectory data increases the dimensionality of intermediate layers in the neural network. This creates a difficult challenge in the context of privacy-preserving learning, because it increases data sensitivity, and requires a large amount of noise to be introduced, therefore decreasing accuracy.

To address this challenge, we capitalize on the *negative sampling (NS)* technique that can be used in conjunction with skip-grams. NS turns out to be extremely valuable in private gradient descent computation, because it helps reduce the gradient update norms, and thus boosts the ratio of the useful signal compared to the noise introduced by differential privacy. In addition, we introduce a data grouping mechanism that makes learning more effective by combining multiple users into a single bucket, and then training the model per bucket. Grouping has a dual effect: on the positive side, it increases the information diversity in each bucket, improving learning outcomes; on the negative side, it heightens the adverse effect of the introduced Gaussian noise. We study closely this trade-off, and investigate the effect of grouping factors in practice.

Our specific contributions are:

(1) We propose a private learning technique for sparse location data using skip-grams in conjunction with DP-SGD. To our knowledge, this is the first approach to combine skip-grams with DP to build a private ML model. Although our analysis and evaluation focus on location data, we believe that DP-compliant skip-grams can also benefit other scenarios that involve sparse data.
(2) We address the high-dimensionality challenge introduced by skip-grams through the careful use of *negative sampling*, which helps reduce the norm of gradient descent updates, and as a result preserves a good signal-to-noise ratio when perturbing gradients according to the Gaussian mechanism of DP. In addition, we group together data from multiple users into buckets, and run the ML process with each bucket as input. By increasing the diversity of the ML input, we are able to significantly boost learning accuracy.
(3) We perform an extensive experimental evaluation on real-world location check-in data. Our results demonstrate that training a differentially private skip-gram for next-location recommendation clearly outperforms existing approaches for DP-compliant learning. We also perform a thorough empirical exploration of the system parameters to understand in-depth the behavior of the proposed learning model. Our findings show that DP-compliant skip-grams are a powerful and robust approach for location data, and some of the trends that we uncovered can also extend to other types of sparse data, beyond locations.

The rest of the paper is organized as follows: we provide background information in Section 2. Section 3 introduces the system architecture, followed by the details of our private location recommendation technique in Section 4. We perform an extensive experimental evaluation in Section 5. We survey related work in Section 6, followed by conclusions in Section 7.

2 BACKGROUND

2.1 Differential Privacy

Differential Privacy (DP) [17] represents the de-facto standard in protecting individual data. It provides a rigorous mathematical framework with formal protection guarantees, and is the model of choice when releasing aggregate results derived from sensitive data. The type of analyses supported by DP range from simple count or sum queries, to the training of machine learning models. A popular DP flavor that is frequently used in gradient descent due to its refined composition theorems is (ε, δ)-differential privacy. Given non-negative numbers (ε, δ), a randomized algorithm $\mathcal{M}$ satisfies (ε, δ)-differential privacy iff for all datasets D and D' differing in at most one element, and for all $E \subseteq \text{Range}(\mathcal{M})$, the following holds:

$$Pr[\mathcal{M}(D) \in E] \leq e^{\varepsilon} Pr[\mathcal{M}(D') \in E] + \delta \tag{1}$$

The amount of protection provided by DP increases as ε and δ approach 0. Dwork et al. [17] recommend setting δ to be smaller than $1/n$ for a dataset of cardinality n. The parameter ε is called *privacy budget*.

Datasets D and D' that differ in a single element are said to be *neighboring*, or *sibling*. When the adjacency between the datasets is defined with respect to a single data record, then the DP formulation provides *record-level* privacy guarantees. The amount of protection can be extended to account for cases when a single individual contributes multiple data records. In this case, the sibling relationship is defined by allowing D and D' to differ only in the records provided by a single individual. This is a stronger privacy guarantee, called *user-level* privacy.

To achieve (ε, δ)-DP, the result obtained by evaluating a function (e.g., a query) f on the input data must be perturbed by adding noise sampled from a random variable Z. The amount of noise required to ensure the mechanism $\mathcal{M}(D) = f(D) + Z$ satisfies a given privacy guarantee depends on how sensitive the function f is to changes in the input, and the specific distribution chosen for Z. The Gaussian mechanism (GM) [16] is tuned to the sensitivity S_f computed according to the global ℓ_2-norm as $S_f = \sup_{D \simeq D'} ||f(D) - f(D')||_2$ for every pair of sibling datasets D, D' . GM adds zero-mean Gaussian noise calibrated to the function's sensitivity as follows:

Theorem 2.1. *For a query $f : D \rightarrow \mathbb{R}$, a mechanism $\mathcal{M}$ that returns $f(D) + Z$, where $Z \sim \mathcal{N}(0, \sigma^2 S_f^2)$ guarantees (ε, δ)-DP if $\sigma^2\varepsilon^2 \geq 2ln(1.25/\delta)$ and $\varepsilon \in [0, 1]$ (see [17] for the proof).*

The *composability* property of DP helps evaluate the effect on privacy when multiple functions are applied to the data (e.g., multiple computation steps). Each step is said to consume a certain amount of privacy budget, and the way the budget is *allocated* across multiple steps can significantly influence data utility.

2.2 Neural Networks

Modern machine learning (ML) models leverage the vast expressive power of artificial neural networks to dramatically improve learning capabilities. Convolutional networks have shown exceptional performance in processing images and video [30]. Recurrent networks can effectively model sequential data such as text, speech and DNA sequences [12, 28]. A neural network is composed of one or more interconnected multilayer stacks, most of which compute non-linear input-output mappings. These layers transform the representation at one level (starting with the raw input) into a representation at a higher, more abstract level. The key to improving inference accuracy with a neural net is to continually modify its internal adjustable parameters.

Stochastic gradient descent (SGD) is the canonical optimization algorithm for training a wide range of ML models, including neural networks. It is an iterative procedure which performs parameter updates for each training example x_i and label y_i. Learning the parameters of a neural network is a nonlinear optimization problem. At each iteration, a batch of data is randomly sampled from the training set. The error between the model's prediction and the training labels, also called *loss*, is computed after each iteration. The loss is then differentiated with respect to the model's parameters, where the derivatives (or gradients) capture their contribution to the error. A *back-propagation* step distributes this error back through the network to change its internal parameters that are used to compute the representation in each layer from the representation in the previous layer. Each internal parameter of the model θ is brought closer to predicting the correct label as follows:

$$\theta = \theta - \eta \cdot \nabla_\theta \mathcal{J}(\theta; x^{(i)}; y^{(i)})$$

where η is the *learning rate* hyper-parameter and $\mathcal{J}$ is the loss function. Iteratively recomputing gradients and applying them to update the model's parameters is referred to as *descent*, and this operation is performed until the model's performance is satisfactory.

2.3 Differentially Private-SGD (DP-SGD)

Introduced in [1], DP-SGD integrates (ε, δ)-DP with neural networks. It modifies traditional SGD in that after calculating the changes in its internal parameters, it obfuscates the gradient values with noise sampled from the Gaussian distribution.

Table 1: Summary of Notations

Notation	Definition
U, P	Sets of users and check-in locations, respectively
N, L	Cardinalities of sets U and P, respectively
U_u	Historical record of user u's check-ins
dim	Dimension of location embedding space
b, η	Batch size and learning rate, respectively
q	User sampling probability per step
m	Expected user sample size per step
ε, δ	Privacy parameters of Gaussian mechanism
σ	Noise scale
λ	Data grouping factor
$\mathcal{H}$	Set of training buckets
C	Per-layer clipping norm

DP-SGD averages together multiple gradient updates induced by training-data examples, *clips* (i.e., truncates) each gradient update to a specified maximum ℓ_2-norm, and adds Gaussian random noise to their averaged value. Clipping each gradient bounds the influence of each training-data example on the model. Accordingly, the sensitivity of the average query can be adjusted as desired, and due to the added noise tuned to the sensitivity of the query, differential privacy is ensured in each iteration. Typically, repeatedly executing a query results in sharp degradation of the privacy protection, as more information is leaked by multiple usages of private iterations. The *moments accountant* technique [1] computes the privacy loss resulting from the composition of Gaussian mechanisms under random sampling. It tracks the moments of the privacy loss variable in each step of the descent, and provides a much tighter upper bound on privacy budget consumption than the standard composition theorem [17].

3 SYSTEM ARCHITECTURE

In Section 3.1 we define the problem statement. We outline the learning model architecture in Section 3.2 and we show how it is utilized in Section 3.3. Table 1 summarizes notations used throughout the paper.

3.1 Problem Statement

Data Representation. The input to our learning model consists of check-in data from a set of N users $U = \{u_1, u_2, ..., u_N\}$. The set of L check-in locations (e.g., points of interest) is denoted as $P = \{l_1, l_2, ..., l_L\}$. Each user $u \in U$ has a historical record of check-ins denoted as $U_u = \{c_1, c_2, ...\}$, where each element c_i is a triplet $\langle u, l, t\rangle$ comprised of user identifier, location and time.

Learning Objective. The objective of our model is to predict the location that a given user u will check into next, given a time-ordered sequence of previous check-ins of the user. The past check-ins can represent the user's current trajectory or his entire check-in history. For each scenario, we describe the usage of the model in Section 3.3. In an initial step, we employ an unsupervised learning method, specifically the skip-gram model [43], to learn the latent distributional context [50] of user movements over the set P of possible check-in locations. A latent representation of every location in a reduced-dimension vector space is the intermediate output. Next, we determine for each user

u its inclination to visit a particular location l by measuring how similar l is in the latent vector space to the locations previously visited by u.

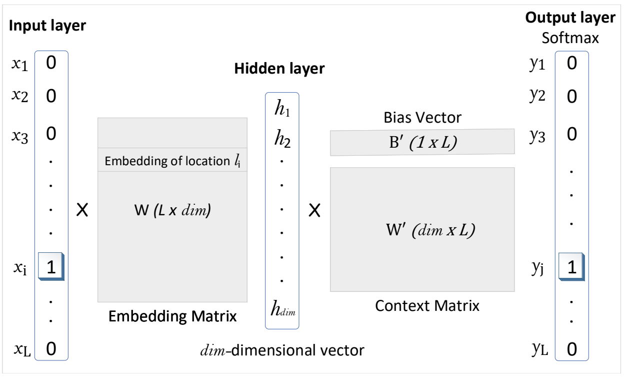

Figure 2: Architecture of the location-recommendation model

3.2 Learning Model

The skip-gram negative sampling (SGNS) model [41, 43] was initially proposed to learn word embeddings from sentences. However, several recent efforts [10, 35, 58] show that the model is also appropriate for location recommendation tasks. Specifically, the model is used to learn location embeddings from user movement sequences, where each location corresponds to a word, and a user's check-in history to a sentence.

Given the set of check-ins of a user, we treat the consecutively visited locations as a trajectory that reflects her visit patterns. A data pre-processing step is required to make the data format compatible with the input of a neural network: every location in P is tokenized to a word in a vocabulary of size $L = |P|$. Given a *target* location check-in c, a symmetric window of win context locations to the left and win to the right is created to output multiple pairs of target and context locations as training samples. The assumption is that if a model can distinguish between actual pairs of target and context words from random noise, then good location vectors will be learned.

Figure 2 illustrates the neural network used in our solution. The model parameters consist of three tensors $\theta = \{W, W', B'\}$ and two hyper-parameters representing the embedding dimensions dim and the negative samples drawn neg. Consider a target-context location pair (l_x, l_y). First, both locations are one-hot encoded into binary vectors $\vec{x}$ and $\vec{y}$ of size L. The multiplication of $\vec{x}$ with embedding matrix W produces the embedding vector for the input location l_x (i.e., the i^{th} row of matrix W). $W \times x$ represents the mapping of input location x to a vector $\vec{h}$ in an dim-dimensional space. Next, for each positive sample (i.e., true target/context pair), a neg number of negative samples are drawn. The context location vector $\vec{y}$ along with the negative samples are passed through a different weight matrix W' and bias vector B'. Finally, a sampled softmax loss function is applied to calculate the prediction error. At a high level (we refer the reader to [49] for a detailed look), the parameters are modified such that the input word (and the corresponding embedding) is tugged closer to its neighbors (i.e., paired context locations), and tugged away from the negative samples. As a result, during back-propagation, only $neg + 1$ vectors in W or W' are updated instead of entire matrices. In the original work [41, 43], negative sampling was devised to improve computational efficiency, as updating the entire model in each iteration can be quite costly. In private learning, it also plays an important role in controlling the adverse affects of noisy training.

We remark here that techniques such as Noise Contrastive Estimation [23] and Negative Sampling use a non-uniform distribution for drawing the samples—for example, by decreasing the sampling weight for the frequent classes—whereas, we use a sampled softmax function with a uniform sampling distribution. This is a necessity for preserving privacy, since estimating the frequency distribution of locations from user-submitted data will cause privacy leakage. Lastly, the embedded vectors are normalized to unit length for efficient use in downstream applications. On top of improving performance [32, 55], normalizing the vectors assists similarity calculation by making cosine similarity and dot-product equivalent.

We detail the privacy-preserving learning model in Section 4. In the remainder of this section, we show how the model, once computed in a privacy-preserving fashion, can be utilized.

3.3 Model Utilization

We provide an overview of how our proposed privacy-preserving next-location prediction model is utilized. Once our privacy-preserving learning technique is executed, the resulting model can be shared with consumers, since the users who contributed the data used in the training are protected according to the semantic model of DP. While the utilization of our model is orthogonal to our proposal, we include it in this section in order to provide a complete, end-to-end description of our solution's functionality.

A typical use of our model is for a mobile user to download[1] it to her device, provide her location history as input, and receive a next-location recommendation. Alternatively, a service provider who already has the locations of its subscribers, will perform the same process to provide a next-location suggestion to a customer. We emphasize that, the model utilization itself does not pose any privacy issues. In both cases above, neither the input, nor the output to the model are shared, so there is no privacy concern. The only time we need to be concerned about privacy is when *training* the model, since a large amount of trajectories from numerous users is required for that task.

Consider a user who has recent check-ins ζ in a relatively short time period (e.g., last few hours). This set of locations forms the basis for recommending to the user the next location to visit. The normalized embedded matrix W in the fully-trained model encodes the latent feature vector of all locations. For each location check-in $l_i \in \zeta$, the embedding vectors $w(l_i)$ are extracted and stacked on top of each other. More precisely, to obtain the embedding vector $w(l_i)$, the binary vector of l_i is multiplied with W (similar to the first step of the training process). This process is equivalent to extracting the dim-dimensional row corresponding to location l_i. Then, the average of elements across dimensions of the stacked vectors is computed to produce a representation $\mathcal{F}(\zeta)$ of the recent check-ins of the user. Finally, cosine similarity scores are computed as the dot-product of the vector $\mathcal{F}(\zeta)$ to the embedding vector of each location in the universe L. We rank all locations by their scores and select the top-K locations as the potential recommendations for the user.

In the case when the user has no recent check-ins, the representation $\mathcal{F}()$ can be computed over her movement profile

[1]To reduce communication costs, only the embedding matrix is deployed.

comprising of historical check-ins. Other methods include training an additional model to learn latent feature vectors of each user from her preferences and locations visited. As in [19, 58], a user's feature representation can be used to determine her inclination to visit a particular location. However, modeling each user with such personalized representations, while at the same time preserving *user*-level privacy, is a fundamentally harder problem (in terms of both system design and privacy framework), and is left as future work.

When the model is deployed at an untrusted location-based service provider (LBS), additional privacy concerns must be addressed. In this case, the mobile user must protect the set ζ (or $\mathcal{F}(\zeta)$) *locally*. Techniques such as geo-indistinguishability [3] can be applied to protect the check-in history (discussed in Section 6). For example, the check-in coordinates can be obfuscated to prevent adversaries from pinpointing the user to a certain location with high probability. Addressing these vulnerabilities in the MLaaS setting is orthogonal to the scope of this paper.

4 PRIVATE LOCATION PREDICTION (PLP)

Section 4.1 presents in detail our proposed approach for private next-location prediction. Section 4.2 provides a privacy analysis of our solution.

4.1 Private Location Prediction (PLP)

PLP is a customized solution to location recommendation. It learns latent factor representations of locations while controlling the influence of each user's trajectory data to the training process. Bounding the contribution of a *single* data record in the SGD computation has been proposed in previous work [2, 53]. We make several extensions and contribute data grouping techniques to boost model performance. Even while combining data of multiple users, we guarantee user-level privacy (such as in [21, 39]). By grouping data records of multiple users, we benefit from cross-user learning to improve model performance.

Algorithm 1 depicts the procedure of this learning process. Model hyperparameters labeled batch size β, learning rate η and loss function $\mathcal{J}$ are related to gradient descent optimization, whereas hyperparameters labeled grouping factor λ, sampling probability q, gradient clipping norm bound C, noise scale σ and privacy parameters ε, δ are introduced to create an efficient and privacy-preserving system. We briefly describe each component in isolation before coupling them together to illustrate the big picture.

User Sampling. Given a sampling probability $q = m/N$, each element of the user set is subjected to an independent Bernoulli trial which determines whether the element becomes part of the sample. As a consequence, the size of sampled set of users U_{sample} is equal to m only in expectation. This is a necessary step in correctly accounting for the privacy loss via the moments accountant [2].

Data Grouping. Data grouping is essentially a pre-processing technique that significantly boosts model performance. It has a dual purpose. The first is to reduce the effects of skewness and sparsity inherent to location data, where the frequency of check-ins of users at locations follows the Zipf's law [11]. The second is to provide cross-user learning to smooth updates in the model parameters produced by the function in lines 15-22. The underlying intuition is simple: to ensure good performance of the context model, each update of a training step must contribute to the final result. By combining the profiles of multiples users

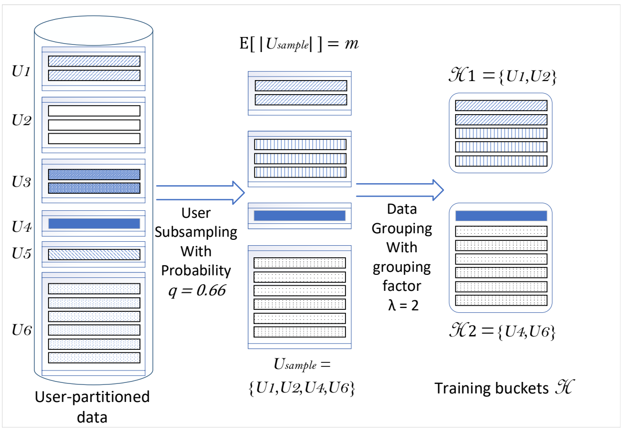

Figure 3: Data sampling and grouping

we also reduce minor observation errors that may be produced from specific data points in a user's profile.

Our data grouping technique agglomerates the data of multiple users into buckets $\mathcal{H}$. Given a grouping factor λ, users (and their entire data) are randomly assigned to buckets such that each bucket contains λ users. This operation is encapsulated in the *groupData*$(\cdot)$ function in line 6. As a separate method, we also tried equal frequency grouping, where a global pass over the record count of each user is used to produce buckets such that each contains approximately the same number of records (while ensuring that the data records of each user are not split into multiple buckets). However, we noticed no statistically significant benefit in model accuracy from equal frequency grouping than with a random grouping. Accordingly, we use the latter in the rest of the work.

Figure 3 illustrates the data sampling and grouping process (corresponding to lines 5-6) for a sampling probability of 0.66 and $\lambda = 2$. Grouped data in each bucket is organized as a single array for processing by gradient descent optimization. Recall from Section 3.2 that a symmetric moving window is applied to create training examples, after the array is read by the *generateBatches*() function (in line 17). A number β of target-context location pairs are placed in each batch.

In brief, at each step of PLP, we sample a random subset of users (line 5), combine the data of multiple users into buckets (line 6), compute a gradient update with bounded ℓ_2 norm from each bucket (lines 7-8), add noise to the sum of the clipped gradients (line 9), take their approximate average, and finally update the model by adding this approximation (line 10). Alongside, a privacy ledger is maintained to keep track of the privacy budget spent in each iteration by recording the values of σ and C (lines 3 and 11). This tracker has the added benefit of allowing privacy accounting at any step of the training process. Given a value of δ and the recorded ledger, the moments accountant can compute the overall privacy cost in terms of ε. This functionality is provided by the cumulative_budget_spent() function in line 12, which implements the moments accountant from [2].

Privacy Mechanism. The gradient values computed in line 20 do not have an a-priori bound. This complicates the application of the Gaussian Mechanism (GM), which is generally tuned to the sensitivity of the performed query. In this particular use case, we employ a Gaussian sum query in line 9, the results of which are then averaged using a fixed-denominator estimator. To bound the sensitivity of this query, a maximum sensitivity of C is enforced

Algorithm 1 Algorithm for Private Location Prediction with user-level privacy.

```
Input: loss function $\mathcal{J}(\theta)$, grouping factor $\lambda$, learning rate $\eta$, sampling probability $q = m/N$, gradient norm bound $C$, batch size $\beta$, privacy parameters $\varepsilon, \delta$
1:  procedure TrainPrivateLocationEmbedding
2:      Initialize: Model $\theta_0 = \{W, W', B'\}$,
3:              Privacy Accounting ledger $\mathcal{A}(\delta, q)$
4:      for each step $t = 1, \ldots$ do
5:          $U_{sample} \leftarrow$ a random sample of $m_t$ users
6:          Initialize buckets $\mathcal{H} \leftarrow groupData(U_{sample}, \lambda)$
7:          for each data bucket $d_h \in \mathcal{H}$ do
8:              $\bar{g}_h \leftarrow$ ModelUpdateFromBucket$(\theta_t, d_h)$
9:          $\widehat{g}_t = \frac{1}{|\mathcal{H}|}(\sum_{h \in \mathcal{H}} \bar{g}_h + \mathcal{N}(0, \sigma^2 C^2 I))$      ▷ Noise.
10:         $\theta_{t+1} = \theta_t + \widehat{g}_t$      ▷ Model Update.
11:         $\mathcal{A}$.track_budget$(C, \sigma)$
12:         if $\mathcal{A}$.cumulative_budget_spent() $\geq \varepsilon$ then:
13:             return $\theta_{t-1}$
14:
15: function ModelUpdateFromBucket$(\theta_t, d_h)$
16:     $\Phi \leftarrow \theta_t$
17:     $\mathcal{B} \leftarrow generateBatches(d_h, \beta)$
18:     for each $b \in \mathcal{B}$ do
19:         $\Phi \leftarrow \Phi - \eta \frac{1}{|b|} \sum_{(x_i, y_i) \in b} \nabla_{\Phi} \mathcal{J}(\Phi, x_i, y_i)$
20:     $g_h = \Phi - \theta_t$
21:     $\bar{g}_h = g_h / \max(1, \frac{\|g_h\|_2}{C})$      ▷ Gradient Norm Clipping.
22:     return $\bar{g}_h$
```

on every gradient computed on bucket h as follows (equivalent to line 21):

$$||\bar{g}_h||_2 = \begin{cases} ||g_h||_2 & \text{for } ||g_h||_2 \leq C \\ C & \text{for } ||g_h||_2 > C. \end{cases}$$

Gradient clipping places a strict limit on the maximum contribution—in terms of its ℓ_2 norm—of the gradient computed on a bucket. Formally, $||\bar{g}_h||_2 \leq C$. The sensitivity of the scaled gradient updates with respect to the summing operation is thus upper bounded by C. Finally, dividing the GM's output by the number of buckets $|\mathcal{H}|$ yields an approximation of the true average of the buckets' updates.

We note that increasing the number of users in each bucket increases the valuable information in each gradient update. At the same time, the noise introduced by the Gaussian mechanism is scaled to the sensitivity of each bucket's update (i.e., C). If too few buckets are utilized, this distortion may exceed a limit, meaning that too much information output by the summing operation is destroyed by the added noise. This will impede any learning progress. We treat the grouping factor λ as a hyper-parameter and tune it.

In a multi-layer neural network such as the one described in our work, each tensor can be set to a different clipping threshold. However, we employ the *per-layer clipping* approach of [37], where given an overall clipping magnitude C, each tensor is clipped to $C/\sqrt{|\theta|}$. In the skip-gram model, $\theta_0 = \{W, W', B'\}$, hence $|\theta| = 3$, so we clip the ℓ_2-norm of each tensor to $C/\sqrt{3}$. However, the effect of clipping on the three tensors is rather different due to the difference in their dimensionality. Context matrix W' is clipped to the same degree as bias vector B', despite the fact that they have dimensions $(L \times dim)$ and $(1 \times L)$, respectively. While the dimensionality of the embedding matrix W is $(L \times dim)$, only a fraction of the weights—proportional to *neg*, instead of L—are considered for clipping due to the sampling of *neg* number of negative examples in the sampled softmax function. Simply put, $||W||_2$ is proportional to *neg* and when carefully tuned, the clipping parameter is large enough that nearly all updates are smaller than the clip value of $C/\sqrt{|\theta|}$, improving the signal-to-noise ratio over iterative computations. We discuss the effect of this parameter in controlling the distortion of Gaussian noise in Section 5.

4.2 Privacy Analysis

Recall that, our proposed system provides *user-level* differential privacy to individuals who contribute their check-in history to the training data. This ensures that all individuals are protected, regardless of how much data they contribute (i.e., even if the length of the check-in history varies significantly across users). Let U_k denote the data of a single user. The sensitivity of the Gaussian Sum Query (GSQ) function w.r.t. to neighboring datasets that differ in the records of a single user is defined as

$$S_{GSQ} = \max_{\{U_{sample}, U_k\}} ||GSQ(U_{sample} \cup U_k) - GSQ(U_{sample})||_2$$

In Algorithm 1, GSQ is executed over the bucket gradients, which complicates the analysis of the privacy properties of the algorithm. We consider two distinct scenarios where a user's data may be assigned to: (i) exactly one bucket; or (ii) more than one bucket. We define ω as the *data split factor*, meaning that a user's data may be placed in at most ω buckets.

Case 1 [$\omega = 1$]. This represents the scenario where multiple (up to λ) users' data may be present in a single bucket, but a single user's data may be allocated to at most one bucket. Figure 4(a) depicts this case, which is assumed by default in Algorithm 1. This is a sufficient condition to ensure that the per-user contribution to a bucket's gradient update is tightly bounded. Formally, there exists a unique $d_h \in \mathcal{H}$ s.t. $U_k \subseteq d_h$. In addition, when the ℓ_2 norm of the gradient $||\bar{g}_h||_2$ computed on a data-bucket d_h is upper-bounded by the clipping factor C, we get

$$S_{GSQ} \leq \max_{\{\mathcal{H}, d_h\}} ||GSQ(\mathcal{H} \cup d_h) - GSQ(\mathcal{H})||_2 \leq C$$

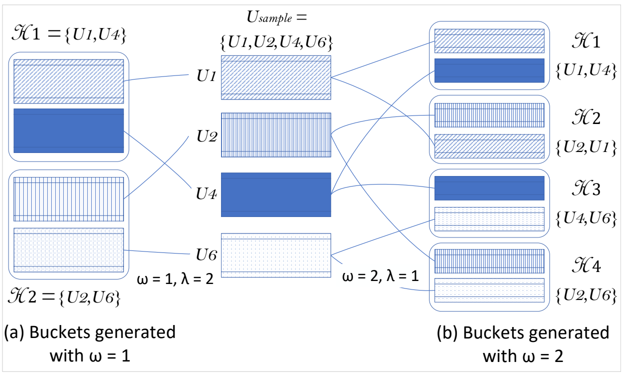
An informal proof that this approach satisfies (ε, δ)-DP is as follows: The sensitivity of the gaussian sum query $GSQ = \sum_{h \in \mathcal{H}} \bar{g}_h$ is bounded as $S_{GSQ} \leq C$, if for all buckets we have $||\bar{g}_h||_2 \leq C$. By extension, if a sampled user (and his location visits) can be assigned to exactly one bucket, *sibling* datasets that differ in the data of a single user can change the output of GSQ by at most C. Therefore, Gaussian Noise drawn from $\mathcal{N}(0, \sigma^2 C^2 I)$ guarantees user-level (ε, δ)-DP.

Case 2 [$\omega > 1$]. If the data of a single user is split over multiple buckets, then it is possible that even after scaling the bucket gradients to C, the sensitivity of the Gaussian sum query is no longer C w.r.t. to user-neighboring datasets. Figure 4(b) illustrates an example with $\omega = 2$. A similar split strategy (proposed in [38]) is used in the empirical evaluation of [21], wherein a small dataset is scaled up to amplify privacy accounting. However, the authors fail to regulate their noise scale to reflect the altered data sensitivity or alternatively recompute the achieved privacy guarantee. We show that when the data of a user U_k is split across multiple buckets, the sensitivity of the query increases to

ω. Assuming that $|\mathcal{H}| \leq |U_{sample}|$, we can write,

$$\omega = \max_{\{U_k \in U_{sample}\}} |\{d_h : d_h \in \mathcal{H} \text{ and } d_h \cap U_k \neq \emptyset\}|$$

meaning that the data of a user can influence the gradients of at most ω buckets. Accordingly, if for all buckets $||\bar{g}_h||_2 \leq C$, a single user can change the output of *GSQ* by at most ωC. Therefore, to guarantee user-level (ε, δ)-DP, Gaussian Noise must be drawn from $\mathcal{N}(0, \sigma^2\omega^2C^2I)$.



$\mathcal{H}1 = \{U1,U4\}$

ω = 2, λ = 1
$\mathcal{H}1$ $\{U1,U4\}$
$\mathcal{H}2$ $\{U2,U1\}$
$\mathcal{H}3$ $\{U4,U6\}$
$\mathcal{H}4$ $\{U2,U6\}$
(a) Buckets generated with ω = 1
(b) Buckets generated with ω = 2

Figure 4: Sensitivity of Gaussian Sum Query over U_{sample} users: (a) $\omega = 1$, a single user's data is placed in exactly one bucket; (b) $\omega = 2$, a single user's data is split across two buckets. Since gradients computed over the generated buckets $\mathcal{H}_1, ..., \mathcal{H}_4$, are bounded by C, a user can contribute at most $2C$ to the computed sum.

We remark here that values of $\omega > 1$ produced no positive effect in our evaluation. We experimented with $\omega = 2$ by splitting a user's data to exactly two random buckets. We found that the signal-to-noise ratio is adversely affected, since the marginally improved signal from the split data is offset by the now quadrupled (proportional to ω^2) noise variance. In the rest of the work, we set ω to 1.

5 EXPERIMENTS

Section 5.1 provides the details of the experimental testbed. Section 5.2 focuses on the evaluation of the proposed technique in comparison with the state-of-the-art DP-SGD approach. In Section 5.3 we evaluate in detail our approach when varying system parameters, and provide insights into hyper-parameter tuning.

5.1 Experimental Settings

Dataset. We use a real dataset collected from the operation of a prominent geo-social network, namely *Foursquare* [59]. The data consist of a set of user check-ins. Every check-in is described by a record comprising of user identifier, the latitude and longitude of the check-in, and the identifier of the POI location. In order to simulate a realistic environment of a city and its suburbs, we focus on check-ins within a single urban area, namely Tokyo, Japan. In particular, we consider a large geographical region covering a 35×25km^2 area bounded to the South and North by latitudes 35.554, 35.759, and to the West and East by longitudes 139.496, 139.905. We filter out the users with fewer than ten check-ins, as well as the locations visited by fewer than two users (such filtering is commonly performed in the location recommendation literature [33, 61]). The remainder of the data contains a total of 739, 828 check-ins from 4, 602 unique users over 5, 069 locations during a time period of 22 months from April 2012 to January 2014.

Implementation. All algorithms were implemented in Python on a Ubuntu Linux 18.04 LTS operating system. The experiments were executed on an Intel Xeon Platinum 8164 CPU, with 64GB RAM. All data and intermediate structures (e.g., neural network parameters, gradients) are stored in main memory. The proposed neural model is built using Google's Tensorflow library [1]. To account for the privacy budget consumption of the complex iterative mechanism used in learning, we use the privacy accounting method from [54], which allows for a tight composition of privacy-preserving steps. At each step of the computation, we calculate the (ε, δ) tuple from moment bounds, according to the moments accountant procedure introduced in [37].

Evaluation Metric. To evaluate the performance of location recommendation, we adopt the "leave-one-out" approach, which has been widely used in the recommender systems literature [10, 19, 26, 35, 57, 58]. This metric simulates the behavior of a user looking for the next location to visit. Given a time-ordered user check-in sequence, recommendation models utilize the first $(t - 1)$ location visits as an input and predict the t^{th} location as the recommended location. The recommendation quality is measured by *Hit-Rate (HR)*. *HR@k* is a recall-based metric, measuring whether the test location is in the top-k locations of the recommendation list. The outcome of the evaluation is binary: 1 if the test location is included in the output set of the recommender, and 0 otherwise. In the rest of the section, we use the terms *prediction accuracy* and *HR@k* interchangeably.

Model Training. Our testing and validation sets consist of location visits of users who are not part of the training set. Since we do not train models to learn user specific representations (such as in [10, 35, 58]), this is an accurate representation of real-life model utilization at a user's device. Validation and testing sets are created in a similar fashion. First, a randomly selected set of 100 users and their corresponding check-ins are removed from the dataset. From these, time ordered sequences of trajectories are generated. Each individual trajectory does not exceed a total duration of six hours (following the work in [10, 34]). The remaining 4402 users and their check-ins represent the training dataset for learning the parameters of the proposed model.

To train the model, we utilize Adam [29], a widely adopted optimization algorithm for deep neural network models that has specific properties to mitigate disadvantages of traditional SGD, such as its difficulty in escaping from saddle points, or extensive tuning of its learning rate parameter. We implement the optimizer in a differentially private manner by tracking an exponential moving average of the noisy gradient and the squared noisy gradient, as illustrated in [24]. We found that tuning the initial learning rate and decay scheme for Adam only affects the learning in the very first few steps. Typically, Adam does not require extensive tuning [29] and a learning rate between 0.001 to 0.1 is most often appropriate. In our experiments, we found that a learning rate value $\eta \in [0.02, 0.07]$ produces similar results, so we set it to 0.06 for all our runs.

Parameter Settings. We select the training hyper-parameters of the skip-gram model via a cross validation grid search. Figure 5 depicts the validation accuracy over 200 data epochs using the non-private learning approach. We plot the validation Hit-Rate for $k = 5$, 10 and 20 candidates, respectively. We look for those models that reach the highest accuracy. The embedding dimension *dim* is set to 50. While a larger number of hidden units allows more predictive power, the accuracy improvement reaches a plateau when the embedding dimension is in the range [50, 150]. In non-private training, it is preferable to use more units, whereas for private learning a larger model increases the sensitivity of the gradient. We keep our model at the lower end of the *dim* range to keep the number of internal parameters of the models low. The batch size is set to $b = 32$, and the context window parameter $win = 2$ (for a total window size of 5). These parameters are also consistent with those utilized in previous work [10, 58]. Varying the number of negative examples sampled (denoted by *neg*) marginally affects the non-private model, whereas with private learning we find that it directly controls the sensitivity of the private sum query (in Section 5.3 we show experiments on how to tune it). The default value for negative samples is $neg = 16$.

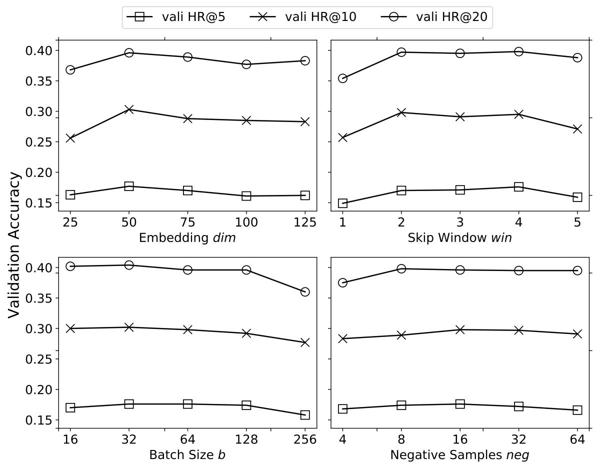

Figure 5: Non-private model hyperparameter tuning

For the privacy parameters, we fix the value of $\delta = 2 \times 10^{-4} < 1/N$ as recommended in previous work on differentially-private machine learning [2, 39]. For a given value of δ, the privacy budget ε affects the amount of steps we can train until we exceed that budget threshold. We set the default value of the hyper-parameters to $q = 0.06$, $\sigma = 2.5$, $C = 0.5$, $\lambda = 4$ (please see Table 1 for a summary of notations). Recall that, the sampling ratio of each lot is $q = m/N$, so each epoch consists of $1/q$ steps.

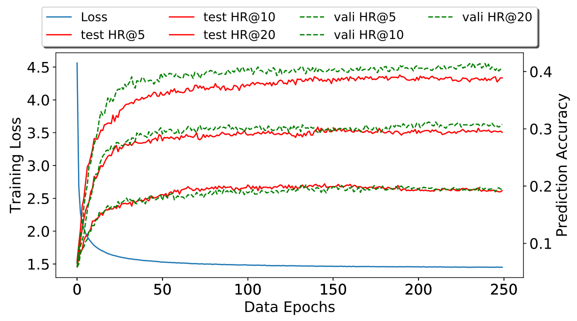

Figure 6: Non-private model performance

5.2 Comparison with Baseline

We evaluate the performance of our proposed approach in comparison with two baselines: *(i)* a non-private learning approach using SGD, and *(ii)* the state-of-the-art user-level DP-SGD approach from [2, 39].

First, we evaluate the non-private location prediction model described in Section 3.2. Figure 6 illustrates the validation and testing Hit-Rate at $k = 5$, 10 and 20. The model generalizes well to the test set, and there appears to be no evidence of overfitting up to 250 data epochs. The presented results are competitive with existing approaches in [35, 58], suggesting that the model hyper-parameters are suitable to capture the underlying semantics of mobility patterns. The best testing accuracy of the non-private model for the *HR*@10 setting is 29.5%.

Throughout our evaluation we found that, when the model is trained in a differentially private manner, there is only a small difference between the model's accuracy on the training and the test sets. This is consistent with both the theoretical argument that differentially private training generalizes well [5, 15], and the empirical evidence in previous studies [2, 39]. For brevity of presentation, in the rest of this section we only show *HR*@10 evaluation results (similar trends were recorded for *HR*@5 and *HR*@20).

Next, we evaluate our proposed Private Location Prediction (PLP) approach in comparison with DP-SGD [2], which is summarized in Section 2. We adapt the model to work on user-partitioned data, so that it guarantees user-level privacy. The improvements of PLP over DP-SGD passed the paired t-test with significance value $p < 0.01$.

Figure 7 plots the prediction accuracy of the privately trained models for varying levels of privacy ε. For each ε value, we consider two settings each for sampling probability $q = 0.06$ (upper left) and $q = 0.10$ (bottom right). We set $\sigma = 1.5$. We compare PLP against the baseline DP-SGD for two values of the grouping factor λ. As expected, a general trend we observed is that providing more privacy budget allows the models to train to a higher accuracy. However, for the baseline approach, the convergence of the model is thwarted because the model update computed on the data of a single user contributes a limited *signal*, which is often offset by the introduced Gaussian noise. On the other hand, the results show that by incorporating data grouping in its design, PLP is able to ameliorate the data sparsity problem inherent to location datasets. The gain is more pronounced when the grouping factor increases (i.e., higher λ).

Next, we measure the effect of sampling probability q on accuracy. From the theoretical model [2], we know that q directly affects the amount of privacy budget utilized in each iteration (q is also called "privacy amplification factor"). A lower sampling rate includes less data in each iteration, hence the amount of budget consumed in each step is decreased. Our results in Figure 8 confirm this trend. We vary the rate of user sampling q from 4% to 12%. For all runs, we fixed the budget allowance at $\varepsilon = 2$. For a higher sampling probability, the privacy budget is consumed faster, hence the count of total training steps is smaller, leading to lower accuracy. Our proposed PLP method clearly outperforms DP-SGD, whose accuracy drops sharply with an increase in q. We note that, due to the proposed grouping strategy, PLP is more robust to changes in sampling rate, as its accuracy degrades gracefully. In general, a larger bucket cardinality leads to better accuracy, except for the lowest considered sampling rate, where the small fraction of records included in the computation at each

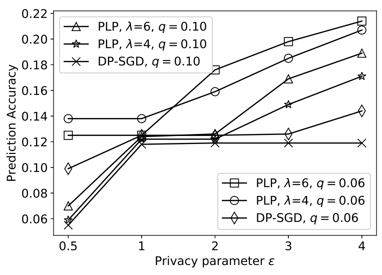

Figure 7: PLP vs DP-SGD: varying privacy budget ε

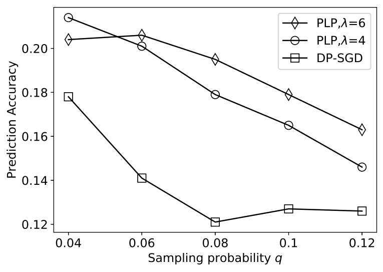

Figure 8: PLP vs DP-SGD: varying sampling ratio q

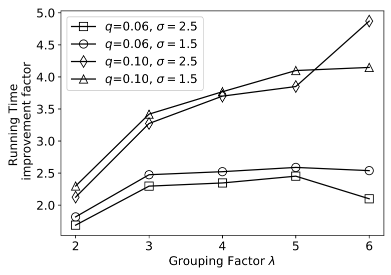

Figure 9: Running time, varying grouping factor λ

step prevents buckets from reaching a significant diversity in their composition.

Finally, we provide a result on the runtime improvements offered by PLP. The y-axis in Figure 9 depicts the multiplicative factor by which PLP is faster that DP-SGD. We show results for two values of q, and for each we present the runtime with two values of noise scale. Linearly scaling the grouping factor has two opposing effects: on the one hand, fewer buckets implies that equally few bucket gradients need to be computed and averaged. On the other hand, as each bucket gets assigned more users, it takes longer to compute each bucket gradient. When fewer users are sampled (i.e., $q = 0.06$) the latter effect begins to dominate for $\lambda > 5$, whereas for $\lambda \in [2, 5]$, the computational efficiency scales from 1.6× to 2.5×. In the setting where sampling rate is higher, at $q = 0.10$, the runtime improvements scale monotonically, to over 4.8× for $\lambda = 6$. These results are consistently observed even with a different number of total iterations (as a larger σ allows more iterations).

In summary, our results so far show that PLP clearly outperforms the existing state-of-the-art DP-SGD. Furthermore, its accuracy was observed to reach values as high as 24%, which is quite reasonable compared to the maximum of 29.5% reached by the non-private learning approach. In the rest of the evaluation, we no longer consider DP-SGD, and we focus on tuning the parameters of the proposed PLP technique.

5.3 Hyper-parameter Tuning

The objective of tuning model hyper-parameters is to obtain a good balance of accuracy and computational overhead of learning. We focus on the following parameters, which we observed throughout the experiments to have a significant influence: grouping factor λ, noise scale σ, the magnitude of ℓ_2 clipping norm, and the number of negative samples *neg*.

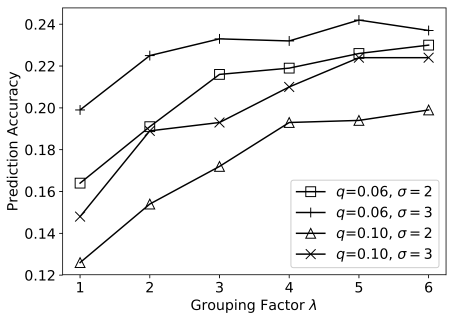

Figure 10: Effect of varying λ

Effect of Grouping factor λ. Figure 10 shows the influence on accuracy of grouping factor λ. We consider two distinct settings each of sampling parameter q and noise scale σ (for a total of four lines in the graph). To limit sensitivity, we clip the gradient norm of each tensor to a maximum l_2 norm of 0.5. Choosing the grouping factor must balance two conflicting objectives: on the one hand, assigning the data of multiple users to the same bucket improves the signal in each bucket gradient, by improving the data diversity within the bucket. On the other hand, the Gaussian noise must be scaled to the sensitivity of a bucket gradient, and a larger bucket size results to fewer buckets, which in turn increases the effect of added noise. Our results confirm this trade-off: initially, when λ increases there is a pronounced increase in accuracy. After a certain point, the accuracy levels off, and reaches a plateau around the value of $\lambda = 5$. When the grouping factor is increased further (not shown in the graph), the accuracy starts decreasing, because there is no significant gain in per-bucket diversity, whereas the relative noise-to-signal ratio keeps increasing.

Effect of Noise Scale σ. The noise scale parameter σ directly controls the noise added in each step. A larger σ leads to more noise, but at the same time it decreases the budget consumption per step, which in turn allows the execution of more learning steps. Figure 11 depicts the model accuracy for varying settings of noise scale. The results presented correspond to two settings each of sampling rate and privacy budget (for a total of four lines). We observe that for the lower-range of σ values, the accuracy is rather poor, especially for smaller settings of privacy budget ε. This is explained by the fact that too little noise is added per step, and the privacy consumption per step is high. As a result, only a small number of steps can be executed before the privacy budget is exhausted, leading to insufficient learning. For larger ε settings, the effect is less pronounced, because there is sufficient budget to allow more steps, even when the noise scale is low.

Conversely, a larger σ allows more steps to be executed, so the best accuracy is obtained for the largest $\sigma = 3.0$ setting. However, we also note that the accuracy levels off towards that setting. For larger σ values (not showed in the graph), we observed that the noise magnitude is too high, and even if budget is slowly exhausted, the training loss in each learning step is excessively high, preventing the model from converging, and leading to very low accuracy. We conclude that the choice of noise scale must be carefully considered relative to the total privacy budget, such that a sufficient number of steps are allowed to execute, while at the same time the loss function value per step is not excessive.

The total number of executed steps also influences the computational overhead of learning. If execution time is a concern, one may want to reduce the number of steps by reducing σ, in an attempt to accelerate the learning (intuitively, since less noise is added at each step, the model will converge faster). This approach is still subject to ensuring that a sufficient number of steps are executed, as neural networks need to perform several complete passes over the dataset.

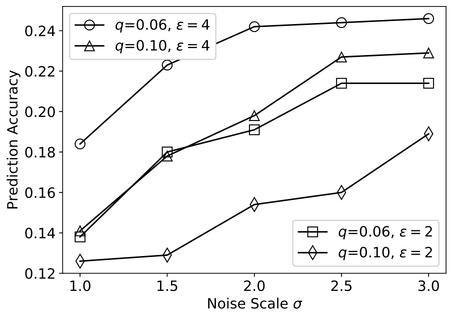

Figure 11: Effect of varying σ

Effect of Clipping norm C. We vary the clipping bound of every tensor in the model $\theta_0 = \{W, W', B'\}$. The value C represents the magnitude of per-tensor clipping, which is set to be equal for every tensor in the model. Clipping more aggressively decreases sensitivity, which in turn leads to a lower privacy budget consumption per step, and allows additional learning iterations to be executed. Conversely, setting the threshold too low also limits the amount of learning that the model can achieve per step. Figure 12 plots the obtained results for several combinations of sampling probability and grouping factor.

We observe that the for the range of values considered, the decrease in sensitivity has a more pronounced impact, and as a result the smaller clipping bounds lead to better accuracy. Of course, one cannot set the clipping bound arbitrarily low, as that will significantly curtail learning. Another factor to consider is the nature of the data, and the effect on gradient values. If the norm of the resulting tensors following gradient computation is high, then a low clipping threshold will destroy the information and prevent learning. In our case, we were able to keep the gradient norm low by using negative sampling, which in turn allowed us to obtain good accuracy for that setting. In cases where this is not possible, it is recommended to increase the clipping threshold value.

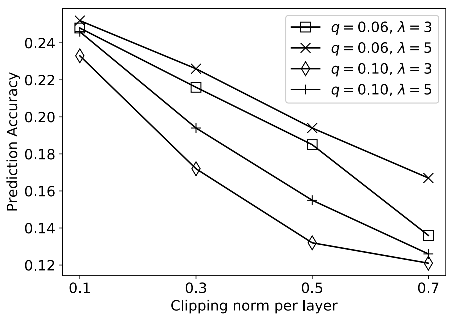

Figure 12: Effect of varying ℓ_2 clipping norm

Effect of Negative samples *neg*. In our final experiment, we investigate the effect on accuracy of negative sampling, which is an important factor in the training success of a skip-gram model. We plot the model accuracy for various values of negative sampling in Figure 13. The number of negative samples *neg* controls the total fraction of weights that are updated for each training sample, and as a side effect it helps keeping the gradient norm low. We can observe a clear 'U'-shaped dependency, reaching a maximum at $neg = 16$. The observed trend is the result of two conflicting factors: if the number of negative samples is too low, training is slowed down, due to the fact that only a small part of the layers are updated per step. Conversely, if too many samples are drawn, then the correspondingly many parameters that need to be updated lead to a large norm. Gradient clipping has an aggressive effect, and as a result, the amount of information that can be learned in each update is obliterated by the noise.

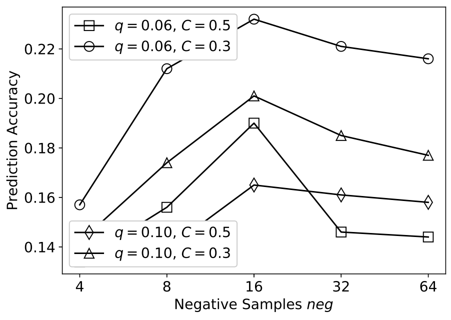

Figure 13: Effect of varying *neg*

6 RELATED WORK

Location recommendation. The problems of location recommendation and prediction have received significant attention in the last decade. Recommending a location to visit to a user necessitates modeling human mobility for the sequential prediction task. Markov Chain (MC) based methods, Matrix Factorization (MF) techniques, and Neural Network models (NN) are the schemes of choice for this objective. MC-based methods utilize a per-user transition matrix comprised of location-location transition probabilities computed from the historical record of check-ins [62]. The m^{th}-order Markov chains emit the probability of the user visiting the next location based on the latest m visited locations. Private location recommendation over Markov Chains is studied in [63]. Aggregate counts of check-ins in discretized regions are published as differentially private statistics. However, due to the sparsity in check-in behavior and the general-purpose privacy mechanisms, their method can only extend to coarse spatial decompositions (e.g., grids having larger than $5km^2$ cells). Factorizing Personalized Markov Chains (FPMC) [47] extend MC by factorizing this transition matrix for the collaborative filtering task. Matrices containing implicit user feedback on locations can also be exploited for location recommendation via weighted matrix factorization [33]. Private Matrix Factorization has been explored in [36, 51], but we are not aware of any proposal for their application to the problem we are considering. Neural Networks have become a powerful tool in recommender applications due to their flexibility, expressive power and non-linearity. Recurrent Neural Networks (RNN) can model sequential data effectively, especially language sentences [42]. Recurrent nets have also been adapted for location sequences [34, 64]. However, RNNs assume that temporal dependency changes monotonically with the position in a sequence. This is often a poor assumption in sparse location data. As a result, the state-of-art [10, 19, 35, 58] employs the skip-gram model [43] to learn the distributional context of users check-in behavior. Extensions incorporate temporal [19, 35, 61], textual [10] and other contextual features [58]. However, none of these studies provide any privacy features, which is the crux of our work.

Differential Privacy (DP) and Neural Networks. A recent focus in the differential privacy literature is to reason about cumulative privacy loss over multiple private computations given the values of ε used in each individual computation [8, 18, 44, 54]. A fundamental tool used in this task is privacy amplification via sampling [4], wherein the privacy guarantees of a private mechanism are amplified when the mechanism is applied to a small random subsample of records from a given dataset. Abadi et. al. [2] provide an amplification result for the Gaussian output perturbation mechanisms under Poisson subsampling. Their technique, called moments accountant, is based on the moment generating function of the privacy loss random variable. Other privacy definitions that lend themselves to tighter composition include Rényi Differential Privacy [44] and zero-Concentrated Differential Privacy [8], and their application to private learning with data subsampling ([54],[31] respectively). However, these privacy models are relatively new and the distinctions in privacy guarantees at the user-end remain to be investigated. In practice, (ε, δ)-differential privacy is the de-facto privacy standard [21, 39].

Location Privacy We overview literature that focuses on preventing the location based service provider (the adversary) from inferring a mobile user's location in the online setting. Spatial k-anonymity (SKA) [22] generalizes the specific position of the querying user to a region that encloses at least k users. The resulting anonymity set bounds the adversary's probability of identifying the query user to at most $1/k$. However, this syntactic notion of privacy can be easily circumvented when the data are *sparse*, i.e., the distribution of the number of location visits of an average user over the universe of POIs is long-tailed. Moreover, check-ins in sparse regions are especially vulnerable to an adversary with background knowledge, significantly increasing the probability that de-anonymization succeeds [45]. Another source of leakage is when the querying user moves, disconnecting himself from the anonymity set. DP can be used in the context of publishing statistics over datasets of locations or trajectories collected from mobile users. The Local Differential Privacy paradigm is well suited for this purpose, and its application to location data is explored in [46]. The Randomized Response mechanism is used to report, in addition to users actual locations, a large number of erroneous locations. Recommendation models that utilize these statistics can at best leverage spatial proximity queries [48] or apply to coarse spatial decompositions [46], and are incapable of cross-user learning such as in the case of the skip-gram model. Lastly, adapting the powerful guarantees of DP to protecting exact location coordinates, Geo-indistinguishability (GeoInd) [3] relaxes the DP definition to the euclidean space. It is the privacy framework of choice for obfuscating user check-ins in the absence of a trusted data curator.

Note that, SKA and GeoInd rely on obfuscating individual location records that make up the larger dataset, making them suitable only for applications that utilize spatial proximity queries (e.g., a user that sends noisy coordinates to obtain points of interest in her vicinity). Utilizing these methods to publish data for training ML models is not viable, since adding noise to the coordinates wipes out any contextual information on the POI visited (beginning with the POI identifier). Moreover, since the same user may have numerous check-in records in a longitudinal location dataset, data publishing with the common techniques suffers from serious privacy leakages. *User-level correlations* (e.g., multiple checkins of a user that are closely related) severely increase the possibility of de-anonymization in the case of SKA. Likewise, in the case of GeoInd, the cumulative privacy loss variable calculated via a standard composition theorem exceeds reasonable privacy levels.

7 CONCLUSIONS

We proposed a new approach for differentially-private next-location prediction using the skip-gram model. To the best of our knowledge, ours is the first technique that deploys DP-SGD for skip-grams. We made use of negative sampling to reduce the norms of gradient updates when dealing with high-dimensional internal neural network layers, and provided a data grouping technique that can improve the signal-to-noise ratio and allows for effective private learning. Our extensive experiments show that the proposed technique outperforms the state-of-the-art, and they also provide insights into how to tune system parameters.

Although our results focus on location data, we believe that our findings can be extended to other types of sparse data. In future work, we plan to test the viability of our approach for other learning tasks. Furthermore, we plan to investigate flexible privacy budget allocation strategies across different stages of the learning process, such that accuracy is further improved. Finally, we will study more sophisticated data grouping approaches that make informed decisions on which users to place together in the same bucket. Since such decisions are data dependent, a careful trade-off must be considered between the budget consumed performing the grouping and the remaining budget used for learning, such that prediction accuracy is maximized.

ABSTRACT

We study the problem of explaining differences between two snapshots of the same database table including record insertions, deletions and in particular record updates. Unlike existing alternatives, our solution induces transformation functions and does not require knowledge of the correct alignment between the record sets. This allows profiling snapshots of tables with unspecified or modified primary keys. In such a problem setting, there are always multiple explanations for the differences. Our goal is to find the simplest explanation. We propose to measure the complexity of explanations on the basis of minimum description length in order to formulate the task as an optimization problem. We show that the problem is NP-hard and propose a heuristic search algorithm to solve practical problem instances. We implement a prototype called Affidavit to assess the explanatory qualities of our approach in experiments based on different real-world data sets. We show that it can scale to both a large number of records and attributes and is able to reliably provide correct explanations under practical levels of modifications.

1 INTRODUCTION

When the content of a database table is frequently changing, it is difficult to find and understand the differences manually. For this reason, a large number of tools has been developed with the goal of supporting database administrators in situations like these [1, 7–9, 24]. Most of them cannot only identify deleted and inserted records but also highlight changes of individual attribute values of records that exist in both snapshots. However, the existing solutions share a big limitation. They require knowledge of the correct record alignment, usually derived from primary key attributes. In certain use cases though, immutability of primary keys is not a valid assumption. Our research is motivated by a use case of an industry project that aims to understand database updates caused by proprietary software updates. We found existing solutions not well suited because keys of the same records sometimes get reassigned during the update.

Figure 1 serves as a running example for such a problem instance. It shows two table snapshots $\mathcal{S}_1$ and $\mathcal{T}_1$ whose uncolored records have been deleted and inserted respectively. Equally colored records resemble a correctly aligned pair of records in which the record from $\mathcal{T}_1$ was derived from the record in $\mathcal{S}_1$ with the transformations specified below the table.

Snapshots $\mathcal{S}_1$ and $\mathcal{T}_1$ could belong to a company's ERP system whose database was transformed as part of an update to a newer software revision. While the attribute value changes were likely done to meet a new data format specification, the deletions and insertions constitute changes of the table content or noise from continued use of both databases between transformation and snapshotting. The company might be interested in an explanation for the changes because the conversion script is unavailable, proprietary or legacy code that is difficult to understand. A direct benefit of reverse-engineering the transformation is that, additional full system conversions can be avoided if more data needs to be transformed later on, reducing both costs and downtime.

Other application domains include data integration, e.g. duplicate detection when integrating multiple sources with redundant records in the target schema, as well as analysis of changes of third-party data sources without access to the transaction log.

What makes the running example interesting, are the changes to the composite primary key {*ID1, ID2, Date*} that make it necessary to identify other suitable attributes for record linking. *ID2* looks very promising because it is part of the primary key and has perfect discriminability and coverage [3]: The provenance of every single target record is reduced to exactly one source record. However, the correct alignment shows that these characteristics can be highly misleading. *ID2* in $\mathcal{T}_1$ was most likely filled using a skolem function [2] as part of an auto-increment policy. Linking with *Date* is another promising option, yet it would fail to explain the provenance of the three records *T13, T14, T15* in which *'99991231'* in *Date* was replaced by *'20180701'*. On the other hand, once the correct transformation function for Val has been learned, it would be very helpful for aligning the records without missing out on these three pairs. Learning this function without the alignment is difficult though.

Intuitively, we can expect at least *some* attributes to be unchanged in practice and use them to partially resolve the alignment problem. For example, *Type* and *Org* suggest an alignment of records *S11* and *T13*. The division function of *Val* implied by the input-output example *'65'* $\mapsto$ *'0.065'* generalizes to other alignment clusters, too, often resolving them.

Extending snapshot comparison with record linking and function synthesis creates a challenging duality. Scalable unsupervised record linking methods need domain knowledge on how to use the attributes to cluster records into blocks that are small enough for detailed similarity comparisons. In the case of attributes whose values have been systematically changed, algorithms that induce string transformations from examples are needed to learn how to use the attribute for blocking. However, the records need to be aligned already to produce the required input-output examples. Hence, these two sub-problems affect each other and cannot be solved independently.

The core of our contribution is an unsupervised search algorithm that iteratively learns which attributes have likely been changed and induces the corresponding value transformation functions. The resulting solution can deal with transformed or unspecified primary keys and produces more than a report of the differences. It yields an explanation that can be used to transform additional, unseen records of the source table because it generalizes the value changes instead of only listing them.

Target table $\mathcal{T}_1$

$$\mathcal{F}^{\mathcal{E}_1} = \left(\begin{array}{lllllll} f^{\mathcal{E}_1}_{ID1}: & \{S01 \mapsto T07, & S02 \mapsto T02, & S03 \mapsto T06, & S05 \mapsto T04, & S06 \mapsto T03, & S07 \mapsto T09, \quad S08 \mapsto T10, \\ & S09 \mapsto T08, & S11 \mapsto T13, & S12 \mapsto T14, & S13 \mapsto T15, & S15 \mapsto T11 & S17 \mapsto T12\}, \\ & \{0000 \mapsto 0006, & 0001 \mapsto 0001, & 0002 \mapsto 0005, & 0004 \mapsto 0003, & 0005 \mapsto 0002, & 0006 \mapsto 0008, \\ f^{\mathcal{E}_1}_{ID2}: & 0007 \mapsto 0009, & 0008 \mapsto 0007, & 0010 \mapsto 0012, & 0011 \mapsto 0013, & 0012 \mapsto 0014, & 0014 \mapsto 0010, \\ & 0016 \mapsto 0011\}, & f^{\mathcal{E}_1}_{Date}: & \text{‘9999123’}x & \mapsto \text{‘2018070’}x, & \textit{otherwise} & x \mapsto x, \\ f^{\mathcal{E}_1}_{Type}: & x \mapsto x, & f^{\mathcal{E}_1}_{Val}: & x \mapsto x\ /\ 1000, & f^{\mathcal{E}_1}_{Unit}: & x \mapsto \text{'k \$'}, & f^{\mathcal{E}_1}_{Org}: \quad x \mapsto x \end{array} \right)$$

Figure 1: Problem Instance $\mathcal{I}_1 = (\mathcal{S}_1, \mathcal{T}_1, \mathcal{A}_1, \mathcal{F}_1)$ that shows the content of two snapshots of the same table. Primary key attributes are bolded. The attribute functions specified in $\mathcal{F}^{\mathcal{E}_1}$ are part of a possible explanation $\mathcal{E}_1$ for the changes that uses the colored records in $\mathcal{S}_1$ to create the records of the same color in $\mathcal{T}_1$. Note that the alignment of the colored records is also given by $f^{\mathcal{E}_1}_{ID1}$. Uncolored records are records which $\mathcal{E}_1$ explains as deleted and inserted respectively.

2 RELATED WORK

The problem presented in this work extends the classic task of reporting differences of table snapshots in two dimensions: record linking and function synthesis. Handling both efficiently at once is not as trivial as combining the best solutions of both fields. It is not even straight-forward how to apply the respective state-of-the-art techniques at all in this context due to their requirements. Our contribution is an exploration of the intersection of the two problems. It is not our goal to improve the state-of-the-art in either of these fields. Instead, we aim to solve them in the context of a comparison tool that requires minimal user effort to make it practical to profile database snapshots with hundreds of tables.

Table Comparison Tools In the industry, there is a high demand for database analysis software which resulted in a large number of both free and commercial solutions for the comparison of relational database tables. Exploring this market, we found, among others, options such as ApexSQL Data Diff [1], Replicator [8], Redgate SQL Data Compare [24], Devart Data Compare [9] or SQL Delta [7]. However, to the best of our knowledge, they can only be used on tables for which a primary key is specified and none of the available products is able to cope with changes of the primary key attributes as it is common standard to use them to link the records for comparison. If they do include functionality to link records in a different way, it requires manual effort by the user, for example by explicitly defining linkage rules. Furthermore, while most of the products are able to export executable SQL scripts that implement the transformation of the data, they do not generalize well to unknown records because the value changes are explicitly stated per record and there is no learning of systematic transformation functions on the level of attributes. As a consequence, the generated reports lack an explanation of the changes in case a systematic pattern exists.

Record Linking Record linking has been frequently studied in academic research and is also known as record, entity or instance matching, identity resolution or deduplication [5]. There are several solutions available that implement both supervised and unsupervised algorithms for linking structured data, for example Magellan [17] inlcuding DeepMatcher [20], JedAI [21], dedupe [4], SILK [16], or WInte.R [18].

In a supervised setting, a set of annotated examples is given. Each example corresponds to a record described in two different representations that usually share some attributes but not necessarily the whole schema. While powerful, we do not consider techniques centered around supervision as users typically use comparison tools as a first attempt to understand changes in large amounts of data without investing manual annotation effort.

JedAI is a suite of unsupervised algorithms that do not require an annotated training dataset to link records. It contains methods for data cleaning, blocking and matching that can be configured by a user to guide the matching process. JedAI offers a rather generic approach where it is not required to define attribute-specific similarity functions. However, the lack of annotated examples means, the user needs to choose a suitable configuration of the different algorithms manually. This depends on the individual data and requires domain knowledge. Our solution is unsupervised without user guidance by using a universally applicable cost function to search for good linking criteria.

A major difference to both supervised and unsupervised approaches, is that we aim to learn transformation functions that transform records from one representation to the other. At the same time, this yields a strong criterion for the task of separating deleted or inserted records from transformed data. Most record linking algorithms however, link records purely based on a fuzzy notion of similarity. They are designed to support use cases in which no transformation function might exist, e.g. linking data from different sources.

Induction of Transformation Functions Learning string manipulations from input-output examples is a research field that has real-world applications in widespread tasks such as data preparation and spreadsheet manipulation. This is exemplified by several works of Gulwani et al. [12–14, 23] that laid the foundations for different add-ins of Microsoft Excel and Azure, marketed under the names QuickCode and FlashFill. FlashMeta [23] on the other hand, is a framework into which the authors were able to cast several different instances of the problem by separating the induction algorithm from the domain-specific language of the transformations.

The language of transformation functions that can be induced by these algorithms spans a subset of regular expressions that includes loops and conditionals. These kinds of transformations are more expressive but have many more parameters than the function families we consider in this work. As it is usually impossible to learn all function parameters from a single input-output example, a set of examples is used to unambiguously induce a specific function. Typically, a user is supposed to give a handful of examples.

Unfortunately, the authors in [26] found that current methods do not scale well to a large number of examples which led them to develop an iterative algorithm that re-uses intermediate search results from previous examples. The third-party scala re-implementation of FlashFill [19] that we were able to try was indeed too slow to be used on large tables as its induction time was in the range of seconds for a single example. On the other hand, there is no mention in [26] of how it deals with mislabeled or noisy examples, leading us to belief that it is not well suited for such scenarios. While in our setting one can reasonably expect to be able to provide a set of input-output examples that includes some correct ones, the examples can be extremely noisy due to record deletions and insertions as well as the unknown alignment of records. This makes it difficult to use state-of-the-art techniques that support complex transformations if the goal is to scale to large tables.

An alternative to induction for learning transformation functions, is the retrieval of a fitting transformation from a corpus. TDE [15] follows such an approach with $50K$ functions crawled from Github and Stackoverflow and recently showed substantially better performance than induction-based systems.

3 PROBLEM STATEMENT

Given two table snapshots with unaligned records, our goal is to explain the differences with a set of operations that transform the source snapshot to the target snapshot. Allowed operations are record insertions, deletions and transformation functions on an attribute level, for example to express a primary key mapping.

Definition 3.1. **(Problem Instance)** A *problem instance* $\mathcal{I} = (\mathcal{S}, \mathcal{T}, \mathcal{A}, \mathcal{F})$ is a set of source ($\mathcal{S}$) and target ($\mathcal{T}$) records given as value tuples under the same schema $\mathcal{A}$ which is a tuple of d attributes. $\mathcal{F} \supset \{id\}$ contains candidate transformation functions.

We will describe $\mathcal{F}$ implicitly with meta functions (see Table 1) used to solve a problem instance, such as prefixing or integer addition. $\mathcal{F}$ contains all their instantiations (i.e. parameter choices) that transform at least one source value to a target value of the same attribute, e.g. $x \mapsto x + 5$. We do not define a problem instance directly by meta functions because the space of possible explanations depends on the concrete instantiations (see Def. 4.1).

The definition of all other symbols is to be understood in relation to one specific, fixed problem instance. It should be clear from the context which problem instance they refer to.

Definition 3.2. **(Explanation)** An *explanation* is a tuple $\mathcal{E} = (\mathcal{S}^{\mathcal{E}-}, \mathcal{T}^{\mathcal{E}+}, \mathcal{F}^{\mathcal{E}})$ of source records labeled as deleted ($\mathcal{S}^{\mathcal{E}-} \in \mathcal{S}$), target records labeled as inserted ($\mathcal{T}^{\mathcal{E}+} \in \mathcal{T}$) and a tuple $\mathcal{F}^{\mathcal{E}} = (f^{\mathcal{E}}_{a_1}, \ldots, f^{\mathcal{E}}_{a_d})$ of attribute functions from $\mathcal{F}$.

Definition 3.3. **(Core)** $\mathcal{S}^{\mathcal{E}} := \mathcal{S} \setminus \mathcal{S}^{\mathcal{E}-}$ is called the *core* of an explanation $\mathcal{E}$.

The core contains all source records which are not labeled as deleted. It is used to produce the target records which are not labeled as inserted.

Definition 3.4. **(Core Image)** The result $\mathcal{T}^{\mathcal{E}}$ of applying the attribute functions of $\mathcal{F}^{\mathcal{E}}$ to the core $\mathcal{S}^{\mathcal{E}}$ is called *core image*:

$$\begin{aligned} \mathcal{T}^{\mathcal{E}} := \mathcal{F}^{\mathcal{E}}(\mathcal{S}^{\mathcal{E}}) \quad &:= \Pi_{f^{\mathcal{E}}_{a_1}, \ldots, f^{\mathcal{E}}_{a_d}}(\mathcal{S}^{\mathcal{E}}), \text{ and so for } s \in \mathcal{S}^{\mathcal{E}}: \\ \mathcal{F}^{\mathcal{E}}(s) \quad &= \left(f^{\mathcal{E}}_{a_1}(\Pi_{a_1}(s)), \ldots, f^{\mathcal{E}}_{a_d}(\Pi_{a_d}(s))\right). \end{aligned}$$

We are only interested in explanations that state the origin of every single target record, either as the result of transforming a source record or as an insertion. Moreover, we demand that each target record provenance is unambiguous by enforcing $\mathcal{F}^{\mathcal{E}}$ to be a bijection between $\mathcal{S}^{\mathcal{E}}$ and $\mathcal{T}^{\mathcal{E}}$.

Definition 3.5. **(Validity)** An explanation $\mathcal{E}$ is called *valid* if $\mathcal{T}^{\mathcal{E}+} = \mathcal{T} \setminus \mathcal{T}^{\mathcal{E}}$ and $|\mathcal{S}^{\mathcal{E}}| = |\mathcal{T}^{\mathcal{E}}|$. The set of valid explanations for a problem instance $\mathcal{I}$ is denoted by $\mathcal{E}^{\mathcal{I}}$.

From now on, when we talk about explanations, we implicitly mean valid explanations.

PROPOSITION 3.6. *Given a problem instance $\mathcal{I}$ and attribute functions $\mathcal{F}^{\mathcal{E}}$, a valid explanation $\mathcal{E}$ can be constructed from $\mathcal{F}^{\mathcal{E}}$ by appropriately choosing $\mathcal{S}^{\mathcal{E}-}$ and $\mathcal{T}^{\mathcal{E}+}$.*

PROOF. Let $\mathcal{S}^{\mathcal{E}} = \{s \mid s \in \mathcal{S} \text{ and } \mathcal{F}^{\mathcal{E}}(s) \in \mathcal{T}\}$. If multiple core records are transformed into the same target record, remove all but one such record from $\mathcal{S}^{\mathcal{E}}$. This yields $\mathcal{T}^{\mathcal{E}} = \mathcal{F}^{\mathcal{E}}(\mathcal{S}^{\mathcal{E}})$ (Definition 3.4) with $|\mathcal{S}^{\mathcal{E}}| = |\mathcal{T}^{\mathcal{E}}|$. Finally, construct $\mathcal{S}^{\mathcal{E}-} = \mathcal{S} \setminus \mathcal{S}^{\mathcal{E}}$ (Definition 3.3) and $\mathcal{T}^{\mathcal{E}+} = \mathcal{T} \setminus \mathcal{T}^{\mathcal{E}}$ (Definition 3.5). □

We use Figure 1 to elaborate on these definitions. It visualizes some problem instance $\mathcal{I}_1$ with $\mathcal{S}_1$, $\mathcal{T}_1$, $\mathcal{A}_1$ as depicted by the two tables. $\mathcal{F}_1$ could be defined implicitly by the following meta functions which have a varying number of parameters: identity, constant value, division, prefix replacement and value mappings (see Table 1).

The record coloring visualizes a possible explanation $\mathcal{E}_1$. The colored target records are producible from the source records of the same color using the specified attribute functions. $\mathcal{E}_1$ has the following formal components:

$$\begin{aligned} \mathcal{S}^{\mathcal{E}_1 -} &= \left\{ s \in \mathcal{S}_1 \mid \Pi_{\mathrm{ID1}}(s) \in \{\mathrm{S10}, \mathrm{S04}, \mathrm{S14}, \mathrm{S16}\} \right\} \\ \mathcal{T}^{\mathcal{E}_1 +} &= \left\{ t \in \mathcal{T}_1 \mid \Pi_{\mathrm{ID1}}(t) \in \{\mathrm{T01}, \mathrm{T05}, \mathrm{T16}\} \right\} \\ \mathcal{F}^{\mathcal{E}_1} &= \textit{as shown below the tables in Figure 1} \end{aligned}$$

For instance, applying its attribute functions to the first source record (S01) produces the seventh target record (T07):

$$\begin{aligned} &\mathcal{F}^{\mathcal{E}_1}((\mathrm{S01}, 0000, 20130416, \mathrm{A}, 80000, \mathrm{USD}, \mathrm{IBM})) \\ =\ &\big(f^{\mathcal{E}_1}_{ID1}(\mathrm{S01}), f^{\mathcal{E}_1}_{ID2}(0000), f^{\mathcal{E}_1}_{Date}(20130416), f^{\mathcal{E}_1}_{Type}(\mathrm{A}), \\ &\ f^{\mathcal{E}_1}_{Val}(80000), f^{\mathcal{E}_1}_{Unit}(\mathrm{USD}), f^{\mathcal{E}_1}_{Org}(\mathrm{IBM})\big) \\ =\ &(\mathrm{T07}, 0006, 20130416, \mathrm{A}, 80, \mathrm{k}\ \$, \mathrm{IBM}) \end{aligned}$$

$\mathcal{E}_1$ is a valid explanation because every target record is either producible from exactly one core record or is included in $\mathcal{T}^{\mathcal{E}_1 +}$.

3.1 Explanation Quality

The example above can be used to demonstrate that, even if systematic operations are used to change a table, it is in general impossible to be sure about the correct explanation given two snapshots. Besides $\mathcal{E}_1$, there are many more valid explanations using the same meta functions. For instance, the twelfth target record (T12) could also be created from the sixteenth (S16) source record instead of the seventeenth (S17). A second valid explanation $\mathcal{E}_2$ could therefore be constructed by adjusting the set of core records and replacing two value mappings in $f^{\mathcal{E}_1}_{ID1}$ and $f^{\mathcal{E}_1}_{ID2}$. This would not affect the brevity of the explanation. However, we would also have to replace $f^{\mathcal{E}_1}_{Date}$ with a function that additionally maps *20160807* to *20161231*. For this, we could not instantiate a simple meta function anymore and we would need a value mapping. As it would have more parameters than a prefix replacement, explanation $\mathcal{E}_2$ is less intuitive than $\mathcal{E}_1$.

Our formal definition of an explanation's quality is motivated by [11] in which the cost of a schema mapping induced from data instances is measured by the number of variables and constants in its minimum repair. Schema mapping repairs are defined as first-order formulas that state exceptions to the schema mapping to make it fit the given data example. The corresponding concept in our problem are records outside of the core whose origin can not be explained with the induced functions. The central task becomes the balancing of the size of the core with the complexity of the functions which does not have a straight-forward solution. We decide to loosely follow the concept of minimum description length [25] and prefer explanations that maximally compress the problem instance. Specifically, we evaluate the description length of our input data $\mathcal{S}$ and $\mathcal{T}$ under an explanation and ignore the contribution of inputs $\mathcal{A}$ and $\mathcal{F}$ as their description length is independent of the choice of $\mathcal{E}$.

Proposition 3.7. *$\mathcal{S}$ and $\mathcal{T}$ are implicitly described by a valid explanation $\mathcal{E} = (\mathcal{S}^{\mathcal{E}-}, \mathcal{T}^{\mathcal{E}+}, \mathcal{F}^{\mathcal{E}})$ and its core $\mathcal{S}^{\mathcal{E}}$.*

Proof. $\mathcal{S} = (\mathcal{S} \setminus \mathcal{S}^{\mathcal{E}-}) \cup \mathcal{S}^{\mathcal{E}-} \overset{(Def.\ 3.3)}{=} \mathcal{S}^{\mathcal{E}} \cup \mathcal{S}^{\mathcal{E}-}$,

$$\mathcal{T} \overset{(Def.\ 3.5)}{=} \mathcal{T}^{\mathcal{E}+} \cup \mathcal{T}^{\mathcal{E}} \overset{(Def.\ 3.4)}{=} \mathcal{T}^{\mathcal{E}+} \cup \mathcal{F}^{\mathcal{E}}(\mathcal{S}^{\mathcal{E}}) \qquad \square$$

Note that every source record is described exactly once (in the two disjoint sets $\mathcal{S}^{\mathcal{E}}$ and $\mathcal{S}^{\mathcal{E}-}$) and the choice of $\mathcal{E}$ only affects the distribution of the source records to these two sets. However, from the records in $\mathcal{T}$, only those contained in $\mathcal{T}^{\mathcal{E}+}$ need to be described. Therefore, an explanation compresses inputs $\mathcal{S}$ and $\mathcal{T}$ if its attribute functions $\mathcal{F}^{\mathcal{E}}$ can be described shorter than the core image $\mathcal{T}^{\mathcal{E}}$ which are the records from $\mathcal{S}$ and $\mathcal{T}$ that can be reconstructed from $\mathcal{E}$ and $\mathcal{S}^{\mathcal{E}}$. For this reason, we optimize the description lengths of $\mathcal{T}^{\mathcal{E}+}$ and $\mathcal{F}^{\mathcal{E}}$ but not $\mathcal{S}^{\mathcal{E}-}$ or $\mathcal{S}^{\mathcal{E}}$.

To measure the description length of the records in $\mathcal{T}^{\mathcal{E}+}$ by strictly following the definition of minimum description length, we would need to determine the minimum number of bits needed to represent $\mathcal{T}^{\mathcal{E}+}$. We decide to loosen this requirement both for semantic and practical reasons. In the context of this work, it is sufficient to count the number of data values that appear in the formal description of an explanation.

Definition 3.8. The description length of the record set $\mathcal{T}^{\mathcal{E}+}$ is defined by $\mathcal{L}(\mathcal{T}^{\mathcal{E}+}) := |\mathcal{A}| \cdot |\mathcal{T}^{\mathcal{E}+}|$.

Concerning the description length of an explanation's attribute functions, it is difficult to find a general definition that captures the brevity of a function's signature. We decide to use the smallest number of parameters that are needed to instantiate the function from a meta function, which again is a count of data values. It shall be denoted by $\psi(f)$.

Definition 3.9. The description length of an explanation's attribute functions $\mathcal{F}^{\mathcal{E}}$ is defined by $\mathcal{L}(\mathcal{F}^{\mathcal{E}}) := \sum_{a \in \mathcal{A}} \psi(f^{\mathcal{E}}_a)$.

Definition 3.10. **(Costs of Explanations)** The costs $c(\mathcal{E})$ of an explanation are defined by $c(\mathcal{E}) := 2\alpha\mathcal{L}(\mathcal{T}^{\mathcal{E}+}) + 2(1-\alpha)\mathcal{L}(\mathcal{F}^{\mathcal{E}})$.

Parameter $\alpha \in [0, 1]$ can be used to prioritize one of the components. For example, in the standard setting $\alpha = 0.5$, explanation $\mathcal{E}_1$ of Figure 1 has costs $c(\mathcal{E}_1) = \mathcal{L}(\mathcal{T}^{\mathcal{E}_1 +}) + \mathcal{L}(\mathcal{F}^{\mathcal{E}_1}) = 7|\mathcal{T}^{\mathcal{E}_1 +}| + \sum_{a \in \mathcal{A}} \psi(f^{\mathcal{E}}_a) = (7 \cdot 3) + (13 \cdot 2 + 13 \cdot 2 + 2 + 0 + 1 + 1 + 0) = 21 + 56 = 77$.

Our cost definition captures two desirable qualities of an explanation. The first term rewards explanations that use a large core to produce a big subset of the records in $\mathcal{T}$. Therefore, explanations that successfully align many records are preferred. The second term promotes simple explanations, as complicated attribute functions with many parameters, such as value mappings, are penalized for their lengthy description.

We can now formally express the requirements of an optimal solution for a problem instance.

Definition 3.11. **(Optimal Solution)** Given a problem instance $\mathcal{I}$, the set of optimal solutions is defined by $\mathcal{E}^* := \underset{\mathcal{E} \in \mathcal{E}^{\mathcal{I}}}{argmin}\ c(\mathcal{E})$.
We call the problem of finding such an optimal solution Explain-Table-Delta.

In practice, $\mathcal{E}^*$ is unlikely to contain more than one optimal explanation. In some problem instances though, multiple source records can be used to produce the same target record and more than one provenance leads to an explanation with optimal costs. Note that $\mathcal{E}^{\mathcal{I}} \neq \emptyset$ as $\mathcal{E}_{\emptyset} = (\mathcal{S}, \mathcal{T}, \{id\}^d)$ is a trivial explanation for every problem instance $\mathcal{I}$ that can always be given. It lists all source records as deleted and all target records as inserted. For example, on $\mathcal{I}_1$ and $\alpha = 0.5$, this explanation has costs $|\mathcal{A}_1| \cdot |\mathcal{T}_1| = 7 \cdot 16 = 112$.

3.2 Problem Complexity

Theorem 3.12. ***(NP-Hardness)*** *The problem Explain-Table-Delta is NP-hard for $\alpha > 0$.*

$\mathbf{c_i}$	#	v_1	v_2	v_3	v_4
$\mathbf{v_1 \vee v_2 \vee \overline{v_3}}$	c1	1	1	0	-
$\mathbf{\overline{v_1} \vee v_4}$	c2	0	-	-	1
$\mathbf{v_3}$	c3	-	-	1	-

Source records $\mathcal{S}$

c1	0	0	0	-	$\mathbf{v_1 \vee v_2 \vee \overline{v_3}}$
c1	0	1	0	-	
c1	0	1	1	-	
c1	1	0	0	-	
c1	1	1	0	-	
c1	1	0	1	-	
c1	1	1	1	-	
c2	0	-	-	0	$\mathbf{\overline{v_1} \vee v_4}$
c2	0	-	-	1	
c2	1	-	-	1	
c3	-	-	1	-	$\mathbf{v_3}$

Target records $\mathcal{T}$

Figure 2: Reduction of an example 3-sat instance $c = (v_1 \vee v_2 \vee \overline{v_3}) \wedge (\overline{v_1} \vee v_4) \wedge v_3$ to a problem instance of Explain-Table-Delta with 3 source and 11 target records.

Proof. *Via polynomial-time reduction from 3-sat.*
Figure 2 shows an example reduction. Let $c = \bigwedge_{i=1}^{n} c_i$ be an instance of 3-sat with clauses c_i over variables from a set $\mathcal{V} = \{v_1, ..., v_d\}$. Then, we can create a problem instance $\mathcal{I} = (\mathcal{S}, \mathcal{T}, \mathcal{A}, \mathcal{F})$ for which the optimal solution specifies a model of c if c is satisfiable. For this, we set $\mathcal{A} := (\#, v_1, ..., v_d)$. We let $\mathcal{F}$ contain only two possible attribute functions, *id* ($x \mapsto x$) and *boolean negation* ($x \mapsto \overline{x}$). The latter shall swap the truth values {'0', '1'} and otherwise behave like *id*.

We construct $\mathcal{S}$ to have n records. For each clause c_i, $\mathcal{S}$ contains a record s_i such that $\Pi_{\#}(s_i) = \text{'c'} \circ i$ and

$$\Pi_{v_j}(s_i) = \begin{cases} \text{'1'}, & v_j \text{ positive in } c_i \\ \text{'0'}, & v_j \text{ negative in } c_i \\ \text{'-'}, & v_j \text{ not in } c_i. \end{cases}$$

$\mathcal{T}$ is constructed to contain a maximum of $7n$ records. For a clause c_i with k literals, the $2^k - 1$ different models over the variables in c_i are used to define one target record each. Let m_k be such a model for clause c_i. Then, the corresponding target record $t_{i,k}$ has $\Pi_{\#}(t_{i,k}) = \text{'c'} \circ i$. and

$$\Pi_{v_j}(t_{i,k}) = \begin{cases} \text{'1'}, & v_j \text{ positive in } c_i \text{ and } v_j \text{ true in } m_k \text{ or} \\ & v_j \text{ negative in } c_i \text{ and } v_j \text{ false in } m_k \\ \text{'0'}, & v_j \text{ positive in } c_i \text{ and } v_j \text{ false in } m_k \text{ or} \\ & v_j \text{ negative in } c_i \text{ and } v_j \text{ true in } m_k \\ \text{'-'}, & v_j \text{ not in } c_i. \end{cases}$$

The description length $\mathcal{L}(\mathcal{F}^{\mathcal{E}})$ is 0 for every explanation as the two possible functions *id* and *boolean negation* have no parameters that need to be instantiated. Consequently, for $\alpha > 0$, the costs of explanations for $\mathcal{I}$ are solely determined by $|\mathcal{T}^{\mathcal{E}+}|$.

Note that any explanation $\mathcal{E}$ can only produce exactly one target record from the source record of clause c_i because of the functionality of $\mathcal{F}^{\mathcal{E}}$. Because of attribute #, this target record needs to belong to a model of c_i, independent of the choice of $f^{\mathcal{E}}_{\#}$. For the same reason, a target record describing a model of clause c_i can only be produced by the source record corresponding to clause c_i. This means that for a fixed clause c_i, it is impossible to produce more than one target record that describes a model of c_i. Hence, each clause c_i for which $\mathcal{E}$ produces a target record from the corresponding source record reduces $|\mathcal{T}^{\mathcal{E}+}|$ by 1. An optimal solution is one that fulfills this criterion on the most clauses.

Lastly, note that $\mathcal{F}^{\mathcal{E}}$ describes an interpretation over the variables in $\mathcal{V}$. A variable $v_i \in \mathcal{V}$ in this interpretation is *true* if $f^{\mathcal{E}}_{v_i} = id$ and *false* if $f^{\mathcal{E}}_{v_i} =$ *boolean negation*. Applying $\mathcal{F}^{\mathcal{E}}$ to the source record of clause c_i produces a record that contains the truth values of all variables occuring in c_i under this interpretation. If the resulting record is a target record, the interpretation satisfies the clause as target records of c_i describe models. We can conclude that if the 3-sat instance c is satisfiable, an optimal solution $\mathcal{E}^*_0$ for the corresponding Explain-Table-Delta problem is able to produce a target record for every single clause by letting $\mathcal{F}^{\mathcal{E}^*_0}$ describe a model of c. Therefore, given the optimal solution $\mathcal{E}^*_0$, $|\mathcal{S}^{\mathcal{E}^*_0 -}| = 0$ can be used to check if c is satisfiable and if it is, a model can be extracted from $\mathcal{F}^{\mathcal{E}^*_0}$. □

4 AFFIDAVIT

In this section, we describe the components of the search algorithm presented as Algorithm 1 to solve practical instances of Explain-Table-Delta. We implement it in a prototype that is called Affidavit[1] (Algorithm For Function-Inducing Delta Analysis Via Integration of Tables). For a given problem instance, it produces an explanation that serves as an affidavit to declare that, to the best of its knowledge, the specified modifications were used to generate the target from the source table.

Thanks to Proposition 3.6, the task of finding explanations can be reduced to a search for attribute functions. Consequently, Explain-Table-Delta can be understood as a constraint satisfaction problem. If the set of possible attribute functions is finite, a brute-force solution could enumerate and assess all possible attribute function tuples by treating each attribute as a variable with domain $\mathcal{F}$. Clearly, this approach does not scale and works poorly in practice because meta functions like value mappings cause $\mathcal{F}$ to grow exponentially with the size of the data.

We propose a best-first search instead, which starts from a set of empty or partial function assignments and efficiently navigates towards a full assignment with good quality. A transition in the search space corresponds to deciding on the function of an attribute. Each of the assignments of a search state acts as a constraint on the possible alignment of source and target records. The more attribute functions have been assigned, the more it becomes clear which records belong together under these assumptions, making it easier to decide on functions for the remaining attributes. A bad function choice eventually leads to high costs because it results in a small core or complicated functions for the remaining attributes. The search is guided by estimations of the final explanation costs of partial function assignments.

4.1 Preliminaries

Definition 4.1. **(Search Space)** Given $\mathcal{I}$ with $|\mathcal{A}| = d$, the *search space* is defined by $\mathcal{H}^{\mathcal{I}} := \{(h_1, ..., h_d) \mid h_i \in \{*, \diamond\} \cup \mathcal{F}\}$.

This means, a search state $\mathcal{H} \in \mathcal{H}^{\mathcal{I}}$ is a d-tuple whose component h_i assigns either $*$, $\diamond$ or some function f from $\mathcal{F}$ to attribute a_i. In the case of $*$, the function of a_i is still undecided. A $\diamond$ means that Affidavit has identified the attribute as one for which a value mapping is best suited. It will be resolved at the very end of the search when the alignment is maximally determined.

Definition 4.2. **(End State)** $\mathcal{H}$ is called *end state* if the function of each attribute is determined, i.e. if $\{a_i \in \mathcal{A} \mid h_i \in \{*, \diamond\}\} = \emptyset$.

    return $\mathcal{H}^{ext}$
```

Given a search state $\mathcal{H}$, its function assignments can be used as criteria for standard blocking [10] to group source and target records together.

Definition 4.3. **(Blocking Index)** The *blocking index* of a source or target record r under a search state $\mathcal{H}$ is determined by the projection $\xi^{\mathcal{H}}$ to those attributes whose functions are already determined. In the case of source records, the attribute functions are applied during projection:

$$\xi^{\mathcal{H}} := r \mapsto \begin{cases} \Pi_{\{h_i(a_i) \mid h_i \notin \{*, \diamond\}\}} & (r) \quad \text{if } r \in \mathcal{S} \\ \Pi_{\{a_i \mid h_i \notin \{*, \diamond\}\}} & (r) \quad \text{if } r \in \mathcal{T}. \end{cases}$$

$\Xi^{\mathcal{H}}$ denotes the set of all blocking indices:

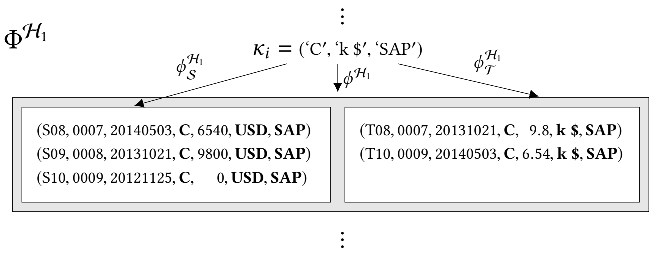
$$\Xi^{\mathcal{H}} := \{\xi^{\mathcal{H}}(s) \mid s \in \mathcal{S}\} \cup \{\xi^{\mathcal{H}}(t) \mid t \in \mathcal{T}\}.$$

To address source records, target records and the block belonging to an index κ, we define:

$$\phi^{\mathcal{H}}_{\mathcal{S}} := \kappa \mapsto \{s \in \mathcal{S} \mid \xi^{\mathcal{H}}(s) = \kappa\}$$
$$\phi^{\mathcal{H}}_{\mathcal{T}} := \kappa \mapsto \{t \in \mathcal{T} \mid \xi^{\mathcal{H}}(t) = \kappa\}$$
$$\phi^{\mathcal{H}} := \kappa \mapsto \left(\phi^{\mathcal{H}}_{\mathcal{S}}(\kappa), \phi^{\mathcal{H}}_{\mathcal{T}}(\kappa)\right).$$

Definition 4.4. **(Blocking Result)** The *blocking result* under search state $\mathcal{H}$ is the set of all blocks $\Phi^{\mathcal{H}} := \{\phi^{\mathcal{H}}(\kappa) \mid \kappa \in \Xi^{\mathcal{H}}\}$.

Figure 3 visualizes parts of an example blocking result.



$\Phi^{\mathcal{H}_1}$
κ_i = ('C', 'k \$', 'SAP')

Figure 3: A block with index κ_i within blocking result $\Phi^{\mathcal{H}_1}$ of search state $\mathcal{H}_1 := (*, *, *, id, *, x \to$ 'k \$', $id)$ on $\mathcal{I}_1$.

4.2 Initialization Strategy

A natural choice for the set of start states $\mathcal{H}^0$ of the search is $\mathcal{H}^\emptyset = \{(*, ..., *)\}$ in which all assignments are empty. While it begins the search without any wrong assumptions and can in theory lead to any explanation, it comes with a drawback. Without any assumption on how to link the records, producing input-output examples to learn the first function is very difficult.

A second natural way of beginning the search comes to mind which dampens this issue. Given the assumption that there is at least one attribute which has not been changed, the search can be started from the set

$$\mathcal{H}^{id} := \{(id, ..., *), (*, id, *, ..., *), ..., (*, ..., id)\}.$$

We prefer it to $\mathcal{H}^\emptyset$ as this assumption should be valid for nearly all practical use cases.

Furthermore, we find overlap scores another reasonable choice to determine a start state. It can drastically improve the runtime by beginning the search from a state in which most of the attributes have already been assigned. The idea is to independently assume for each attribute that it has not been changed and use it to link source and target records that have the same value on this attribute. Giving a score of 1 per attribute on which two records are identical, the score of each pair denotes their similarity in terms of an attribute overlap. Assuming that k unchanged attributes exist, the score of correctly aligned record pairs will be at least k and it is very likely that among the pairs with the highest overlap score, their large overlap will stem mainly from these attributes. We take advantage of this by using the target record with the highest overlap for each source record to build the most likely a-priory alignment over all source records. Sorting the attributes by how often their values overlap on these pairs, we use the k' most frequently overlapping ones to build a set $\mathcal{A}^{id}$. Our choice of k' is determined by the most frequent overlap score among these pairs. This leads to the set of start states

$$\mathcal{H}^s := \{(h_1, \ldots, h_d)\} \text{ with } h_i = \begin{cases} id & \text{if } a_i \in \mathcal{A}^{id} \\ * & \text{otherwise.} \end{cases}$$

To compute record overlaps without a quadratic comparison of all records, we calculate it only for record pairs that share at least one value. Very frequent attribute values that are shared by nearly every record generate an enormous amount of alignment pairs. Therefore, we ignore value overlaps in which the number of resulting pairs would be above a configurable threshold. This limits the a-priori matching to pairs that share at least one value that is not too frequent.

4.3 Extending Search States

AFFIDAVIT discovers potential attribute functions from the blocking result $\Phi^{\mathcal{H}}$ of a search state $\mathcal{H}$ as described in Section 4.4. The resulting functions are used to extend $\mathcal{H}$ by assigning an induced function to the corresponding attribute.

To extend a state $\mathcal{H}$, we first decide on a set of attributes $\mathcal{A}'$ for which functions are induced. The decision is based on an estimation of the indeterminacy of the undecided attributes of $\mathcal{H}$. We estimate it for an attribute by computing its maximum number of distinct source values over all blocks that have both target and source records. This corresponds to an upper bound for the number of source values that need to be considered as the origin of a target value. $\mathcal{A}'$ consists of the β most determined attributes from this estimation. In the next step, we create extensions of $\mathcal{H}$ with the β most promising function candidates of each attribute in $\mathcal{A}'$. The branching factor β is configurable to limit the number of extensions that are produced.

For each $a \in \mathcal{A}'$, we compare its resulting extensions to $\mathcal{H}_g$ which is an extension of $\mathcal{H}$ on a with a map function constructed from a random alignment of all records that respects $\Phi^{\mathcal{H}}$. We build it by mapping each source value to the target value with the highest co-occurrence in the random record alignment. If $\mathcal{H}_g$ has the lowest costs, we store a in the set $\mathcal{A}^{\diamond}$ and reject the attribute's extensions, otherwise we keep all extensions with costs lower than those of $\mathcal{H}_g$. If the function of a in the optimal solution is a value mapping, there typically is no other function type that can be instantiated to a good function candidate for that attribute. This is why, once their indeterminacy is low, this check allows the detection of attributes for which map functions are likely needed.

If we did not keep any extension from the β most determined attributes, we try the next most determined one until we have found at least one extension or we have come to the conclusion that all undecided attributes should receive a map function. In the latter case, we mark all attributes from $\mathcal{A}^{\diamond}$ with $\diamond$ and finalize the state by replacing one $\diamond$ after another. The replacement is a greedy value mapping from the random alignment, just like $\mathcal{H}_g$. We re-sample a new random alignment after each $\diamond$ is replaced in order to have the next map respect the previous assignment.

Figure 4 demonstrates how AFFIDAVIT finds the optimal solution on $\mathcal{I}_1$ starting from $\mathcal{H}^0 = \mathcal{H}^{id}$. The number in square brackets indicates the order in which the states are expanded. $\mathcal{A}'$ is implicitly given by the origin of the arrows. Greyed out arrows lead to extensions that are not added to the queue because no induced function was better than a greedy map ($\diamond$), the queue was full with better states (†, see Section 4.6) or because of duplicate detection.

4.4 Inducing Functions

4.4.1 Supported Meta Functions. Our framework supports any meta function whose parameters are learnable from one input-output example. An example for such a meta function is the conversion of a date attribute. An input-output example such as *'Sep 31 2019'* $\mapsto$ *'20190931'* contains enough information to learn to split the source value by white spaces to extract month, day and year (in that order) and express the date in '*yyyymmdd*' format. Note that there can still be input-output examples of that function such as *'Oct 10 2019'* $\mapsto$ *'20191010'* for which the function instantiation is not unambiguous. It would not be clear from this example if the target format is '*yyyymmdd*' or '*yyyyddmm*'. However, one could simply generate both candidate functions or learn the function from a different input-output example. On the other hand, any linear function of the form $x \mapsto mx + c$ needs at least two input-output examples to learn its parameters m and c. After one example, the number of possible meta function instantiations is still infinitely large. There is no single example that would be enough to induce the function and it is impossible too, to generate all possible candidate functions from one example.

To transform values of an attribute that was the target of a function type that is not supported, Affidavit tries to learn the full value mapping. This way it can still produce explanations with a correct record alignment, even if a more concise function can not be learned. As a mapping with more than one entry needs an input-output example for every value it transforms, value mappings are not learned during the search like other functions. Instead, they are learned at the very end when the record alignment is maximally defined by regular functions.

4.4.2 Inducing Function Candidates. To induce functions for an attribute, AFFIDAVIT uses noisy input-output examples that it samples from blocks that have both source and target records inside them. It does this by randomly selecting up to k distinct target records from these blocks and trying for each one to produce its attribute value from the value of any source record in the same block. We do so by instantiating functions from the meta functions. For example, if target record *T08* from Figure 3 was sampled to learn functions for Val, the following functions could be induced: $x \mapsto x - 6530.2$ (from *'6540'*), $x \mapsto \frac{x}{1000}$ (from *'9800'*), $x \mapsto x + 9.8$ (from *'0'*), $x \mapsto$ *'9.8'* (from any source value).

The set of induced functions over the sampled target records is filtered to include only functions that have been generated a statistically significant amount of time. The idea behind this, is that the function of the optimal solution would be generated each time we sample a target record from the core image of the optimal solution. However, it is only generated from examples in which the effect of the optimal function is actually visible. How often it gets generated, depends on the fraction θ of records with this property in relation to the number of target records. For example, the optimal function might be the one that removes trailing zeroes if there are any but it would not be generated from correct examples without trailing zeroes in the source value.

We regard the sampling of a target record as Bernoulli experiment with success chance θ. Assuming $|\mathcal{T}| >> k$, we treat each experiment as independent, such that the number of records X from which the best function would be generated is a random variable that follows a Binomial distribution with success chance θ and sample size k. We set k to the smallest integer for which $p(X \geq 5) \geq \rho$. Both the estimated fraction θ and the confidence level ρ are configurable parameters. Choosing a larger θ speeds up the algorithm but risks that functions of the optimal solution will not be sampled if θ underestimates the amount of noise in the target records or the rarity of the function's effect. A function that was generated n times, is filtered if $p(X = n) < \rho$. If θ is set lower than the actual fraction, the function of the optimal solution will be found with a probability of a least ρ.

4.4.3 *Ranking Function Candidates.*

In the next step, we determine the best β candidate functions for each attribute. This time, the fact that some functions are not induced from all value pairs which they cover, prevents us from simply ranking the candidates by how often they were generated. While the function from the optimal solution is very likely to be contained in the candidate set after filtering, it is not necessarily the one that was generated most often.

A complete evaluation would consist in traversing all blocks and applying every function candidate to the block's source record values in order to compare the resulting histogram with the block's target values. As this can be very expensive, we use sampling to estimate the fraction of records that each function would align. This time, we sample k' distinct source records and to penalize functions that map too many source values to the same target value, we evaluate on the level of blocks that contain them instead of the individual records. In each block of a sampled source record, we apply all function candidates to every source record value of the block to create a value histogram each in which every resulting value has a frequency equal to the sum of the frequencies of all source values from which it was created. For example, $x \mapsto \frac{x}{1000}$ on block κ_i from Figure 3 results in the histogram $\{1 \times \textit{`6.54'}, 1 \times \textit{`9.8'}, 1 \times \textit{`0'}\}$, while $x \mapsto \textit{`9.8'}$ produces $\{3 \times \textit{`9.8'}\}$. For each function candidate of an attribute, we compute the overlap of the resulting histogram and the target value histogram of the block ($\{1 \times \textit{`9.8'}, 1 \times \textit{`6.54'}\}$ for $\kappa_i$) by summing up the minimum of the frequency of each value present in both histograms. On block $\kappa_i$, $x \mapsto \frac{x}{1000}$ would have an overlap of 2, whereas $x \mapsto \textit{`9.8'}$ has an overlap of 1. We rank the candidate functions in descending order by the size of their total overlap minus their description length to determine the best β candidates.

We choose the smallest integer k' for which it holds that if we use $p = \theta$ in Cochran's formula [6] for determining sample sizes:

$$k' \geq \frac{z^2 \cdot p \cdot (1-p)}{e^2}.$$

For this, we choose $z = 1.96$ and $e = 0.05$ which yields a confidence of 95% that the overlap on the sampled blocks is within ±5% of the overlap over all blocks. If $\Phi^{\mathcal{H}}$ is already very fine-grained with many blocks, this results in a huge speed-up over an evaluation over all blocks. If $\Phi^{\mathcal{H}}$ is still very vague with few blocks, we usually evaluate on many more source records than we sample because we fully evaluate the blocks in which they are contained. This makes the sampling actually less risky than the guarantees of the formula imply.

4.5 Evaluating Search States

The cost function from Definition 3.10 is defined for explanations which can only be constructed from end states. However, during the search, it is necessary to assess the quality of partial search states. In this section, we describe how we extend this definition to partial search states (and end states) in a coherent way to arrive at the cost function used by Affidavit.

The cost component $\mathcal{L}(\mathcal{F}^{\mathcal{E}})$ that measures the description length of an explanation's attribute functions has an obvious counterpart for search states:

$$c_f(\mathcal{H}) := \sum_{h_i, h_i \notin \{*, \diamond\}} \psi(h_i).$$

The value of $\mathcal{L}(\mathcal{T}^{\mathcal{E}+})$ however, depends on $|\mathcal{T}^{\mathcal{E}+}|$ which is not yet determined by a partial search state $\mathcal{H}$. A lower bound is given by the record set for which it is already clear from the partial function assignments of $\mathcal{H}$ that no source record will be aligned with it in any end state to which this search state can lead. Any record in a block without source records is such a record.

On the other hand, the blocks that do have source records can still be used to improve this lower bound. Because a valid explanation's attribute function tuple is a bijection, the number of those records can be estimated from the blocking result of $\mathcal{H}$ from the blocks which have more target than source records:

$$c_t(\mathcal{H}) := \sum_{\kappa \in \Xi^{\mathcal{H}} | \, |\phi_{\mathcal{T}}^{\mathcal{H}}(\kappa)| > |\phi_{\mathcal{S}}^{\mathcal{H}}(\kappa)|} |\phi_{\mathcal{T}}^{\mathcal{H}}(\kappa)| - |\phi_{\mathcal{S}}^{\mathcal{H}}(\kappa)|.$$

Moreover, there is an alternative way of computing $|\mathcal{T}^{\mathcal{E}+}|$ that can be useful to estimate costs during search.

Corollary 4.5. *Let* $\Delta = |\mathcal{S}| - |\mathcal{T}|$. *The validity properties can be leveraged to compute* $|\mathcal{T}^{\mathcal{E}+}|$ *in terms of* $|\mathcal{S}^{\mathcal{E}-}|$ *and* Δ.

Proof. $|\mathcal{T}^{\mathcal{E}+}| \overset{(Def.\ 3.5)}{=} |\mathcal{T}| - |\mathcal{T}^{\mathcal{E}}| = (|\mathcal{T}| + \Delta) - \Delta - |\mathcal{T}^{\mathcal{E}}|$

$= |\mathcal{S}| - \Delta - |\mathcal{T}^{\mathcal{E}}| \overset{(Def.\ 3.5)}{=} |\mathcal{S}| - \Delta - |\mathcal{S}^{\mathcal{E}}|$

$= (|\mathcal{S}| - |\mathcal{S}^{\mathcal{E}}|) - \Delta \overset{(Def.\ 3.3)}{=} |\mathcal{S}^{\mathcal{E}-}| - \Delta$ □

Just like $|\mathcal{T}^{\mathcal{E}+}|$, $|\mathcal{S}^{\mathcal{E}-}|$ cannot be completely calculated for a partial search state $\mathcal{H}$. However, as before we can compute a lower bound by using the blocking result of $\mathcal{H}$:

$$c_s(\mathcal{H}) := \sum_{\kappa \in \Xi^{\mathcal{H}} | \, |\phi_{\mathcal{S}}^{\mathcal{H}}(\kappa)| > |\phi_{\mathcal{T}}^{\mathcal{H}}(\kappa)|} |\phi_{\mathcal{S}}^{\mathcal{H}}(\kappa)| - |\phi_{\mathcal{T}}^{\mathcal{H}}(\kappa)|$$

Definition 4.6. **Costs of Search States** The cost of a search state $\mathcal{H}$ is defined by

$$c(\mathcal{H}) := 2\alpha \cdot c_f(\mathcal{H}) + 2(\alpha - 1) \cdot \max(c_t(\mathcal{H}), c_s(\mathcal{H}) - \Delta).$$

It depends on both the problem instance and the search state which lower bound underestimates less.

4.6 Queue

The best-first search tends to spend most of its time visiting search states with few assignments which is most pronounced when starting the search from $\mathcal{H}_\emptyset$ or $\mathcal{H}_{id}$. This stems from the fact that costs monotonically increase when a function is added to an undecided attribute. What makes this behavior problematic, is the fact that there are exponentially many search states from which one can reach an end state. For instance, there are $2^{|\mathcal{A}|}$ states in the search lattice on a path from $\mathcal{H}_\emptyset = (*, \ldots, *)$ to the end state $\mathcal{H}_{id} = (id, \ldots, id)$. Even with duplicate elimination, unless $\mathcal{H}_{id}$ aligns all records, a complete search would possibly try exponentially many subsets of *id* assignments to check if the remaining attributes can have other functions assigned that result in a better explanation. This behavior cripples performance as the number of attributes grows.

Fortunately, apart from (direct as well as indirect) parents of the optimal solution, it is in practice very unlikely to find many different search states that are at least as good as the optimal solution and will therefore be extracted before it. The likelihood of finding a search state with this property strongly decreases with the number of assignments of a state. For instance, setting *ID1* to *id* in $\mathcal{I}_1$ is an assignment that makes the state $(*, *, id, *, *, *, *)$ look promising at first and even still after extending it to $(*, *, id, *, *, x \mapsto \text{'}k\ \$\text{'}, *)$. These states align a lot of records with relatively cheap functions. This is why they are extracted first in Figure 4. However, the costs of states that result in an incorrect record alignment eventually increases fast when assigning functions to the remaining attributes. In this case, costly value mappings are neededÃű on attributes that could be transformed with a simple operation under the correct alignment. In addition, if the same source value is aligned with multiple different target values (which is more likely under a wrong alignment), the number of aligned records will drop even when using value mappings. For an increasing number of assignments, this makes it more and more unlikely to find states with *ID1* set to *id* that have lower costs than the optimal solution.

Therefore, we decide to use a modified priority queue that is bounded to hold $max(1, \varrho - i + 1)$ search states at the same time on the i-th level of the lattice, i.e. the level on which states have i attributes assigned. If a level is full, it only accepts a new state if it is not worse than all states on the same level. If an inserted state is accepted, it drops the worst state on the same level to make space. Polling the queue still returns the state with the lowest costs independent of the level. In case of equal costs, it returns states with a higher number of assignments first. Heuristically, it is quite unlikely in practice to skip the optimal solution due to this limitation. The most important decisions of the search happen at the early levels. While the cost of search states with only one or a few assignments might still be underestimated, a handful of assignments is in practical problem instances usually enough to identify the best foundation for inducing the remaining attribute functions.

5 EVALUATION

To evaluate Affidavit, we have implemented the meta functions described in Table 1 which include basic string and number transformations. The experiments are meant to demonstrate the core functionality and scalability of the framework. In practice, one might encounter problem instances with functions not supported by our prototype. However, we decided to evaluate on self-created problem instances based on these meta functions because this gives us certainty about the correct transformations and alignment as well as control over the degree of change and noise. This way, we can judge the given explanations in-depth. Furthermore, we can evaluate on the same table multiple times with different transformations, giving a more trust-worthy result. We describe our synthetic transformation of real-world datasets in Section 5.1 and the evaluation protocol in Section 5.2. In Section 5.3, we report about the quality of the produced explanations. Finally, we evaluate in Section 5.4 how our algorithm scales with the number of records and attributes of a problem instance.

Name	Operation	Parameters
Identity	$x \mapsto x$	–
Uppercasing	$x \mapsto \textsc{Uppercase}(x)$	–
Constant Value	$x \mapsto c$	c
Addition (Numeric)	$x \mapsto x + y$	y
Division (Numeric)	$x \mapsto x/y$	y
Front Masking	$.\{\lvert m \rvert\} \circ x \mapsto m \circ x$	m
Front Char Trimming	$[c]^* \circ x \mapsto x$	c
Prefixing	$x \mapsto y \circ x$	y
Prefix Replacement	$y \circ x \mapsto z \circ x$	y, z
Value Mappings	$x \mapsto \begin{cases} y_1 & \text{if } x = x_1 \\ \dots & \\ y_n & \text{if } x = x_n \end{cases}$	$x_1, \dots, x_n,$ $y_1, \dots, y_n$

Table 1: Meta functions implemented in Affidavit. The inverse variants of these functions are also supported, e.g. suffixing in addition to prefixing. String concatenation is denoted by $\circ$.

5.1 Datasets

We perform our experiments on the datasets[2] described in more detail in [22] which have already been used to evaluate algorithms for detecting functional dependencies. They cover a wide range of topics (e.g., flight routes, chess game logs, web log data, etc.) and feature different structural properties, both in terms of the number of attributes (5 to 223) and records (100 to 250000).

For each dataset used in [22], we create ten problem instances in three settings of varying difficulty. Each problem instance is the result of choosing some records of the table as core, transforming it with randomly sampled functions and using the remaining records as noise for the source and target snapshots. A setting consists of two parameters τ and η. The transformation percentage τ denotes the likelihood to sample a function different from *id* for an attribute. This means, it can happen that every attribute gets transformed. In this case, we reject the sampling and generate another one. To sample a function for an attribute that is to be transformed, we randomly instantiate a function from the meta functions described in Table 1. We make sure to generate functions that fit the domain of the attribute, e.g. we do not use uppercasing on numerical attributes. In the case of value mappings, we instantiate it as a random permutation of the source values. These are potentially the hardest transformations to learn due to the high number of parameters and can easily lead to a wrong alignment when confused with *id*. The noise percentage η refers to the fraction of source and target records that are outside the core of the generated problem instance.

To create two table snaphots from a dataset, we first determine the source and target noise by randomly selecting two record subsets. We choose the size of the noise sets such that these records make up a fraction η each of the resulting snapshots. The number of records in the resulting snapshots decreases to a fraction $\frac{1}{\eta+1}$ of the dataset as the noise records are distributed over both snapshots. The rest of the dataset records resembles the core of our reference explanation. We create the core image by applying the sampled transformations to the corresponding attributes of these core records. We also apply the sampled transformations

[2]https://hpi.de/naumann/projects/repeatability/data-profiling/fds.html

to the target noise as its data format should be similar to the core image records. Finally, we add the the source and target noise to the core and core image, respectively.

In addition to the random attribute transformations, we augment each dataset with a new attribute that contains a set of running integers to simulate a simple primary key. We use the same integers in both snapshots in two different permutations. The resulting attribute results in a wrong record alignment if it is used for blocking and is supposed to challenge AFFIDAVIT's ability to deal with transformed primary key attributes. If the dataset already has attributes in which the fraction of distinct attribute values is larger than 0.7, we remove these attributes for our experiments as it might make the alignment too easy when that attribute is not transformed. In Table 2, $|\mathcal{A}|$ denotes the resulting number of attributes after these modifications. Dataset attributes that are completely empty prior to the transformations are ignored as well and do not count towards this number.

5.2 Evaluation Protocol

On each problem instance, we evaluate AFFIDAVIT with two different configurations on a unix system with 24 cores at 2.6 GHz and 200GB memory. The first configuration uses $\mathcal{H}^0 = \mathcal{H}^s$ (start states) determined with a maximum block size of 100000 for the overlap matching, $\beta = 1$ (branching factor) and $\varrho = 1$ (queue width). The second configuration uses $\mathcal{H}^0 = \mathcal{H}^{id}$, $\beta = 2$ and $\varrho = 5$. Both configurations were run with $\alpha = 0.5$, $\theta = 0.1$ (core size estimation) and $\rho = 0.95$ (confidence).

We have chosen two configurations of AFFIDAVIT that resemble different approaches of tackling the problem. Using overlap sampling to begin the search from a promising start state follows the spirit of unsupervised record linking and assumes that similarities in the data can be leveraged a-priori to align the records with sufficient accuracy for the induction of transformation functions. The intention of this approach is a reduction of runtime compared to a more exhaustive search. As such, we chose to push further into that direction by limiting both branching factor and queue width to see how well one can induce the remaining functions when starting from an a-priori alignment. The resulting configuration corresponds to a greedy search that induces one attribute after another without backtracking. We compare this configuration with a search that begins with the set of start states $\mathcal{H}^{id}$ in which each state corresponds to the assumption that one particular attribute was not changed. We use parameters that allow the search to traverse a larger part of the search lattice as this setting is supposed to be more robust in exchange for runtime.

Table 2 describes the macro average over the ten problem instances per dataset per setting with four numbers comprised of runtime t, relative core size Δ_{core}, relative costs Δ_{costs} and accuracy *acc*. The latter three numbers are computed by comparing the resulting explanation $\mathcal{E}_{res}$ to the reference explanation $\mathcal{E}_{ref}$ that correctly describes the attribute functions and separation of core and noise records that were used to create the problem instance. For example, $\Delta_{core} = 0.8$ means that $\mathcal{E}_{res}$ aligned 20% less records than $\mathcal{E}_{ref}$ and $\Delta_{costs} = 0.99$ says that the cost $c(\mathcal{E}_{res})$ was 1% lower (better) than $c(\mathcal{E}_{ref})$. Accuracy is calculated by applying the learned functions $\mathcal{F}^{\mathcal{E}_{res}}$ to each core record $r \in \mathcal{S}^{\mathcal{E}_{ref}}$ and comparing it with the correct transformation $\mathcal{F}^{\mathcal{E}_{ref}}(r)$. For computing accuracy, we ignore the artificial primary key attribute that we added and measure it as the fraction of cells in $\mathcal{S}^{\mathcal{E}_{ref}}$ that are correctly translated this way.

5.3 Result Quality

The results presented in Table 2 show that $\mathcal{H}^{id}$ performs very well in the setting ($\eta = 0.3, \tau = 0.3$) as it learned to correctly translate the core in every run, with minor deviations only in the *balance* and *nursery* datasets. This is a hint that AFFIDAVIT can be used with this setting out-of-the-box to produce high quality explanations for problem instances with a reasonable amount of noise and transformations. However, we see a definite decline in accuracy on some datasets in the setting ($\eta = 0.7, \tau = 0.7$). We attribute it mainly to the high noise, as we can see on *balance*, *chess* and *nursery* that AFFIDAVIT was able to produce explanations cheaper than the reference, aligning a larger number of records by including noise in the core. This shows that our search is effective at minimizing costs but that our cost definition does not reliably lead to the correct explanation when the majority of the records are noise. Consequently, this effect is more pronounced in tables with few attributes. Nevertheless, we see on some datasets that AFFIDAVIT can still correctly learn transformations when the majority of attributes has been changed. This holds especially for tables with a large number of attributes which supports our claim that at least a handful of unchanged attributes is needed to correctly bootstrap the alignment in the beginning of the search – but not necessarily more.

As expected, we find most of the runtimes of $\mathcal{H}^s$ to be significantly lower. The performance in terms of accuracy is mostly comparable to that of $\mathcal{H}^{id}$ which shows that our use of overlap sampling is a promising way to start the search. However, we can see obvious gaps in performance on datasets such as *chess*, *letter* or *nursery*. We manually investigated this and found out that $\mathcal{H}^s$ begins the search assuming that the artificial primary key attribute was unchanged. As highlighted by $\Delta_{core} = 0$, this leads to a trivial explanation because AFFIDAVIT was not able to find functions for the remaining attributes to support anything but an empty core. The reason for this behavior is the fact that these tables contain only attributes with very few distinct values in relation to the number of records. As such, the maximum block size is exceeded when producing records pairs based on overlapping attribute values. The exception is the maximally distinct attribute of running integers which leads to a wrong a-priori alignment. Increasing the maximum block size to the point where a correct start state is found, we found the initial matching already took longer than the total runtime of the more exhaustive configuration. This shows that there are problem instances for which the search from $\mathcal{H}^{id}$ is preferable because it is independent of record similarity and can correct wrong decisions by backtracking.

5.4 Scalability

AFFIDAVIT was designed with the goal of scaling to large problem instances. In the context of database tables, this means that the runtime should increase at most linearly with both a growing number of records and attributes.

5.4.1 *Row Scalability.* We begin by experimentally measuring the scalabilty of AFFIDAVIT to tables with a large number of records. For this, we run the $\mathcal{H}^{id}$ configuration on scaled versions of a ($\eta = 0.3, \tau = 0.3$) problem instance of *flight-500k* which comes from the same source as *flight-1k* but by default has 500000 records and 20 attributes. To scale the problem instance to $x\%$ of the original size, we use $x\%$ of the core records as well as $x\%$ of the source and target noise. We then create the corresponding core image from the scaled core. The sampled transformations

				$\eta = 0.3, \tau = 0.3$				$\eta = 0.5, \tau = 0.5$				$\eta = 0.7, \tau = 0.7$

Table 2: Experimental results of two Affidavit configurations $\mathcal{H}^s$ and $\mathcal{H}^{id}$ on problem instances of varying difficulty.

stay the same. However, we remove value mapping entries defined over attribute values that do not exist anymore in the scaled version. Otherwise the costs of the reference explanation would be unnecessarily high. The resulting run times in Figure 5 confirm that Affidavit scales linearly in the number of records. Moreover, it was able to produce the reference explanation in every run on these problem instances.

5.4.2 Attribute Scalability. Attribute scalability is difficult to assess experimentally because removing attributes from a problem instance can completely alter the difficulty. However, because of the modified priority queue, we can give a rough theoretical upper-bound in ϱ for the worst-case complexity that suggests linear scalability in the number of attributes. For a fixed ϱ, Affidavit begins the search with ϱ search states with one assignment each. Ignoring duplicate elimination, in the absolute worst-case, each of these search states and its (direct and indirect) children are visited in depth-first order. Assuming $\varrho < |\mathcal{A}|$, this results in visiting level ϱ with $O(\varrho!)$ states that are each followed by $|\mathcal{A}| - \varrho$ extensions to produce a full assignment which gives $|\mathcal{A}|O(\varrho!) - \varrho O(\varrho!)$ total extensions. In the case of $\mathcal{H}^0 = \mathcal{H}^{\emptyset}$, this number is at most one larger, for $\mathcal{H}^0 = \mathcal{H}^s$ it is smaller.

Technically, there are operations inside each extension that are not constant in the number of attributes, leading to a polynomial complexity. However, during the extension of a state, the runtime is dominated by the induction of functions for a fixed attribute. As the number of attributes for which this is performed is bounded by β, a linear runtime increase with a growing number of attributes should be the result in practice. The normalized runtimes in Figure 6 support this expectation. The resulting data is very noisy though for a low number of attributes which can be explained by the fact that individual differences in difficulty of the datasets have a proportionally bigger impact on the runtime than the difference in the already low number of attributes.

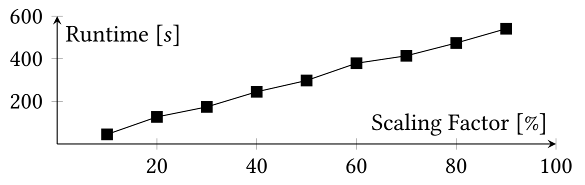

Figure 5: Runtimes on a ($\eta = 0.3, \tau = 0.3$) problem instance of *flight-500k* scaled to different numbers of records.

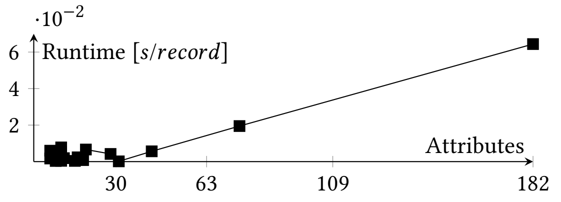

Figure 6: Runtimes of $\mathcal{H}^{id}$ taken from Table 2 for the setting ($\eta = 0.3, \tau = 0.3$) normalized by the number of records of each dataset in relation to the number of its attributes.

6 CONCLUSIONS AND FUTURE WORK

Motivated from an industrial use case in the domain of data exchange, we found a lack of solutions for reverse-engineering updates of relational tables without knowledge of the record alignment. In particular, this pertains snapshots of tables with unspecified or modified primary keys. The resulting task requires record linking and function induction at the same time. To the best of our knowledge, we presented the first theoretical framework that explores both problems at once. As there are no straight-forward criteria that define the best solution, we suggested to measure the quality of a solution on the basis of minimum description length. While we could prove that the resulting optimization problem is NP-hard, we proposed an algorithm based on a best-first search to solve practical instances of the problem. We implemented a prototype of our algorithm called Affidavit and evaluated it on several problem instances of varying difficulty based on real-world datasets. The results confirmed that Affidavit scales linearly with the number of records and attributes. Moreover, we have identified a parameter configuration that can be used out-of-the-box to reliably produce correct explanations under practical levels of noise and transformations of the data. As our algorithm is completely unsupervised, this setting can be used to compare snapshots of databases with many tables without prior linking or labeling of the data by hand.

In practical problem instances, the meta functions implemented so far, would likely not be versatile enough to explain all data transformations. In its current form, Affidavit is most usable by administrators with domain knowledge about which meta functions commonly occur in their domain. They are able to customize Affidavit by adding further meta functions via implementation of a small Java interface. In Future Work, the prototype could be updated to support a richer set of functions by default. For instance, we recently added support for date conversions. Furthermore, it would be interesting to integrate a function corpus like it was done in TDE [15] instead of manually extending the supported functions.

Future work could also investigate a problem variant without knowledge of the schema alignment. Consequently, table modifications like attribute renaming, merging or splitting could be supported. We think the insights and methods of this work would be valuable for such a task as well.

ABSTRACT

Despite the emergence of *probabilistic logic programming* (PLP) languages for data driven applications, there are currently no debugging tools based on provenance for PLP programs. In this paper, we propose a novel provenance model and system, called P3 (Provenance for Probabilistic logic Programs) for analyzing PLP programs. P3 enables four types of provenance queries: traditional explanation queries, queries for finding the set of most important derivations within an approximate error, top-K most influential queries, and modification queries that enable us to modify tuple probabilities with fewest modifications to program or input data. We apply these queries into real-world scenarios and present theoretical analysis and practical algorithms for such queries. We have developed a prototype of P3, and our evaluation on real-world data demonstrates that the system can support a wide-range of provenance queries with explainable results. Moreover, the system maintains provenance and execute queries efficiently with low overhead.

1 INTRODUCTION

In many data intensive applications, there has been a paradigm shift towards probabilistic and statistical reasoning. In some cases, it is in support of programs that rely on probability distributions. Probabilistic reasoning is used as a basis to trade off performance and accuracy, when collecting and aggregating readings from sensors. In other cases, probabilistic reasoning is dictated by use of external libraries, typically involving programs that rely on outputs of machine learning libraries which are intrinsically probabilistic.

Consequently, over the past few years, there is an emergence of *probabilistic logic programming* (PLP) languages. Many of these languages use database-style declarative conjunctive rules that are loosely based on Datalog semantics with extensions to handle probability. These include SLP [21], Datalog$_P$ [7], PRISM [28], ICL [23], ProbLog [24]. A common thread across these systems is that they allow both data and rules to be probabilistic, and are based on Sato's distribution semantics [27] among possible worlds under a given probability distribution. These languages cover the bulk of PLP languages in use today.

In addition, some PLP languages are used as machine learning models, such as Markov Logic Networks (MLN) [26] and Probabilistic Soft Logic (PSL) [3]. These PLP programs are combined with probabilistic graphical models (PGM), or converted to weighted Boolean formulas [6], for inference and learning. Beyond these languages, BAYONET [9], which introduces their own flavor of probabilistic network programming language.

Despite the proliferation of declarative PLP languages, there are currently no tools that enable us to debug and analyze programs. Given the declarative feature, a natural question to ask is whether *data provenance* [11] can be used for debugging these declarative data-driven systems. However, prior provenance work falls short in enabling debugging capabilities for PLP programs because they are geared primarily towards traditional relational databases. The most obvious candidate is provenance in probabilistic databases [25]. However, these systems do not work for PLP programs, given that only tuples are labeled with independent probabilities while the operators in SQL remain deterministic. This is unlike PLP programs where the rules (and hence the operators used for executing these rules) are probabilistic. Consequently, systems that support provenance in probabilistic databases do not work on queries or programs with uncertainty built into the algorithm rather than the underlying data.

In this paper, we present a model and system called P3 (Provenance for Probabilistic logic Programs). P3 enables a novel form of provenance, which we term *probabilistic provenance*. P3 is aimed at the first class of declarative PLP programs described above. All of these languages consist of programs that are a union of weighted conjunctive rules with recursion (without negation), and adhere to the possible world semantics. A representative example of this language that we use throughout our paper is ProbLog, although the approach can be generalized to similar languages. In ProbLog, tuples and rules are labeled with probabilities. ProbLog-like languages encompasses a wide range of PLP programs that involve reasoning with uncertainty over data. To the best of our knowledge, our work is the first one providing a comprehensive case study on using probabilistic provenance for PLP analysis.

By allowing PLP programs to be analyzable using probabilistic provenance, P3 enables a whole series of novel provenance queries not previously possible, including (1) showing the derivation graphs that explain tuples and their probability values; (2) finding the set of most important derivations for a derived tuple based on its provenance; (3) finding the top-K most influential variables (including base tuples and rules) for a derived tuple based on its provenance; and (4) supporting modification queries, where we can answer how to modify variables' probabilities to efficiently change the derived tuple probability to a target score with small cost.

The key contributions of this paper are as follows:

- **Probabilistic provenance model.** We propose a provenance based approach to reason PLP programs with semantics similar to ProbLog. Provenance is maintained through both graph-based representation (provenance graph) and algebraic representation (provenance polynomials).
- **Probabilistic provenance queries.** We demonstrate how the provenance model can enable provenance queries to answer explanation, derivation, influence and modification questions about derived tuples. We further demonstrate how these queries can generate meaningful results in the presence of cycles in recursive rules.
- **Implementation and evaluation.** We have implemented P3, and evaluated the system over use cases based on real-world data. Through our use cases, we also demonstrate how P3 can help debug and fix errors in ProgLog programs. Our results demonstrate that P3 can enable a range of novel provenance queries with low overhead at maintenance and query time.

2 BACKGROUND

Given our choice of ProbLog as a representative example, we first provide an introduction to the salient features of the language. ProbLog's syntax is based on Datalog, with the main difference being that all base tuple clauses and rule clauses are labeled with probabilities. A ProbLog program specifies a probability distribution over all possible non-probabilistic subprograms of the ProbLog program. The semantics of ProbLog is defined by the success probability of a query, which is the probability that the queried tuple succeeds among these subprograms.

```
rid p1: H() :- B1(),B2(),...,Bn().
tid p2: B1().
```

Figure 1: ProbLog syntax

Figure 1 summarizes the ProbLog syntax. There are two types of clauses: a weighted conjunctive rule (first line in Figure 1 where `H()` means the rule head, and `B1(),B2(),..., Bn()` are relations in the rule body), and a probabilistic base tuple (second line in Figure 1). Each conjunctive rule has a `rid`, labeled with a probability (p1 in Figure 1) of being true. Each base tuple has a `tid`, labeled with a probability score of existence (p2 in Figure 1).

2.1 Running Example

As a running example used throughout the paper, we consider the `Acquaintance` ProbLog program shown in Figure 2. The program computes all pairs of people who may know each other.

```
r1 0.8: know(P1,P2) :-
        live(P1,C), live(P2,C), P1!=P2.
r2 0.4: know(P1,P2) :-
        like(P1,L), like(P2,L), P1!=P2.
r3 0.2: know(P1,P3) :-
        know(P1,P2), know(P2,P3), P1!=P3.
t1 1.0: live("Steve","DC").
t2 1.0: live("Elena","DC").
t3 1.0: live("Mary","NYC").
t4 0.4: like("Steve","Veggies").
t5 0.6: like("Elena","Veggies").
t6 1.0: know("Ben","Steve").
```

Figure 2: `Acquaintance` ProbLog rules and base tuples

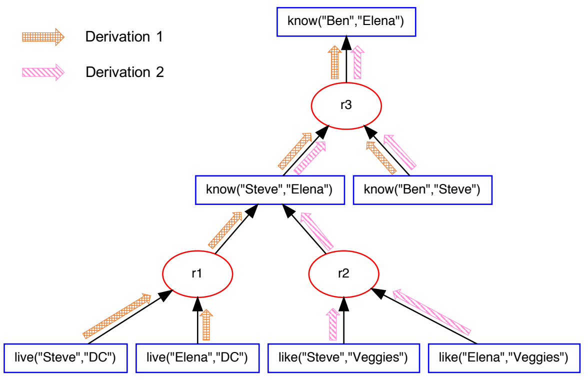

Figure 3: Provenance graph of `know("Ben","Elena")` with annotated derivations

In the `Acquaintance` program, people who live in the same place (`r1`) or like the same item (`r2`) may know each other with some probability. The `Acquaintance` relationship can also be transitive with some probability (`r3`). Given the program in Figure 2, our P3 system demonstrates how we can derive more `Acquaintance` relations based on existing relations. For example, we can infer whether `know("Ben","Elena")` can be derived by querying the tuple, and also derive the probability that Ben knows Elena.

Beyond inferring probability values, P3 will enable the following classes of queries:

- **Probability explanations.** Figure 3 is a provenance graph which explains how `know("Ben","Elena")` is derived. There are two derivations in Figure 3, annotated by two types of arrows. They share some paths to derive the tuple. We can use provenance queries to answer which derivation contributes more to the tuple probability.
- **Change modification.** After getting the probability score of `know("Ben","Elena")`, we may be dissatisfied with its score, and would like to increase or decrease it, either by changing base tuple values or rule weights. To minimize disruption, we would like make the fewest possible changes. A provenance query may be used to find out the variable that influences the derivation of `know("Ben", "Elena")` most, so that if we would like to modify its probability values with the fewest number of variable changes, we can start with the most influential variables. Likewise, we can also use provenance queries to determine the fewest number of modifications to rules.

2.2 ProbLog Semantics

As is shown in Figure 1, each clause c_i (whether a base tuple or rule) is labeled with a probability p_i. These probabilities are mutually independent. A ProbLog program $T = \{p_1 : c_1, \cdots, p_n : c_n\}$ defines a probability distribution over logic programs $L \subseteq L_T = \{c_1, \cdots, c_n\}$ as follows:

$$P(L|T) = \prod_{c_i \in L} p_i \prod_{c_i \in L_T \setminus L} (1 - p_i) \quad (1)$$

where L denotes one non-probabilistic subprogram, also called one possible world. The success probability $P(q|T)$ of a query q in a ProbLog program T is defined as:

$$P(q|L) = \begin{cases} 1, & \exists\theta : L \models q\theta \\ 0, & \text{otherwise} \end{cases} \quad (2)$$

$$P(q, L|T) = P(q|L) \cdot P(L|T) \tag{3}$$

$$P(q|T) = \sum_{L \subseteq L_T} P(q, L|T) \tag{4}$$

The success probability of query q corresponds to the probability that the query q has a proof, given the probability distribution over logic programs. As mentioned in [24], the success probability of a ProbLog query can be computed as the probability of a Boolean monotone DNF (Disjunctive Normal Form) formula of binary variables being true, which is an NP-hard problem [29]. The DNF formula is obtained by SLD-resolution [8], and then represented by binary decision diagrams (BDDs) [4] in order to compute its probability efficiently.

The reason we choose ProbLog semantics to be the focused of this paper is as follows:

- Sato's distribution semantics or possible worlds semantics [5] is widely used in probabilistic databases, where the base tuple score has a meaningful semantics - probability. In ProbLog, the rule weight also means the probability that the rule is true.
- Provenance in probabilistic databases is intuitively easy to be extended in ProbLog's syntax and semantics.
- Alternative PLP languages (such as PRISM, ICL, SLP, and Datalog$_P$) that adhere to the Sato's distribution semantics impose extra constraints such as mutual exclusion constraint for rule bodies of the same rule head, and do not allow for recursion. However, ProbLog is more general and expressive, and it supports recursive rules which is necessary in network data applications. Hence, provenance support for ProbLog naturally carries forward to these alternative languages.

Note that while we focus on ProbLog, given ProbLog's generality, the concepts that we introduce in this paper can be generally applied to any declarative probabilistic programs that are based on union of conjunctive rules.

3 PROVENANCE MODEL

In this section, we introduce the provenance model used in P3. Traditionally, provenance can have both graph representation (provenance graph) and algebraic representation (provenance polynomials). P3 provides both types of representations, and as we will see later, different representations support different types of provenance queries.

3.1 Provenance Graph

Given a ProbLog-like PLP program, we model its provenance as a directed graph $G(V, E)$, which describes the data dependencies (see Figure 3 as an example).

The vertex set V in G consists of tuple vertices and rule execution vertices. An oval denotes a rule execution vertex, and a rectangle denotes a tuple vertex. We also annotate the associated probability for each tuple vertex and rule execution vertex. For a concise graph representation, we omit the probability values in the example provenance graph, but they are maintained as an associated attribute and can be queried.

The edge set E consists of unidirectional edges that represent data dependencies between tuple vertices and rule execution vertices. An edge is always pointing from a tuple vertex t to a rule execution vertex r, or from a rule execution vertex r to a tuple vertex t. The former indicates t is an input of r, and the latter means t is derived through r. The provenance graph G shows the complete derivation history of teh PLP program. For a queried tuple q (derivable from the PLP program), it provenance is the a subgraph of G rooted by q's corresponding tuple vertex.

For PLP programs containing recursive rules, it may generate cycles during the derivations. A cycle appears when a derived tuple can also be an input tuple in one of its own derivations. However, we prove that the cycles in the graph can be removed without affecting computing the success probability of the queried tuple q (See Section 3.3 for details).

Figure 3 shows a simple provenance graph for `Acquaintance` example. Intuitively, we can find two derivations of tuple `know("Ben","Elena")` in the graph. `know("Ben","Elena")` is derived through rule `r3` when both `know("Ben","Steve")` and `know("Steve","Elena")` are true. Then there are two ways to derive `know("Steve","Elena")`: through `r1` or through `r2`. The two derivations also share some paths.

3.2 Provenance Maintenance

The provenance maintenance for PLP shares similarities with that of ExSPAN engine [31]: we perform an automatic rule rewrite of the PLP program to create and maintain provenance information at runtime as a side-computation along with the evaluation of the original PLP program. During this process, our system naturally maintains provenance as a graph: the *direct* dependencies of the tuple and rule executions (i.e., the edges in the provenance graph) are captured and stored in relational tables.

More concretely, each rule `rid p H() :- B1(),...,Bn().` is rewritten into three rules at compile time [1]:

```
H() :- B1(),...,Bn().
prov(H(),p,rid) :- B1(),...,Bn().
rule(rid,(B1(),...,Bn())) :- B1(),...,Bn().
```

The first rule performs the original tuple derivation; the second rule records the dependency between the rule execution and its input tuples (i.e., `B1(), ..., Bn()`); the final rule records that the derived tuple `H()` has a derivation from this particular rule execution. In addition, we further identify rules labeled with probabilities and associate the rule execution vertices with their corresponding probabilities. For example, consider rule `r1` in Figure 2, its execution results in two dependencies (captured in the `prov` and `rule` table respectively): $\texttt{know(P1,P2)}\xleftarrow{0.8}\texttt{r1}$ and $\texttt{r1}\leftarrow\texttt{(live(P1,C), live(P2,C))}$. These are reflected in Derivation 1 in Figure 3.

The maintenance of provenance only adds a reasonable constant cost for each rule evaluation, and is expected to have limited impacted on the scalability of the program or application.

3.3 Provenance Querying

With the captured direct dependencies (i.e., the edges in the provenance graph), we can extract the complete provenance of a queried tuple y by recursively traversing the graph: starting from y, we traverse the graph by following the edges until we reach base tuples. The returned provenance is presented in a pre-determined representation. Generally, the graph traversal allows us to extract any provenance representation defined as a provenance semiring [11].

Provenance polynomials. In this paper, provenance polynomial is adopted as the basis for answering more complex queries (such as identifying the most influential base tuples, etc), for

[1]For performance considerations, additional optimization is adopted in the actual implementation to ensure that the rule body, which is the same for all the three rules, only needs to be evaluated once.

its close connection to probability calculation. The provenance polynomial for a queried tuple q in ProbLog is a Boolean formula $\lambda(q)$, where each literal denotes one individual tuple or rule. The literals are Boolean variables and each has some probability of being true. There are two binary operators "$\cdot$" and "+" in $\lambda(q)$. Specifically, "$\cdot$" denotes conjunctive use of multiple tuple or rules for the derivation of a derived tuple, and "+" denotes union of alternative derivations for the same derived tuple.

For example, if tuple q is derived from a conjunctive rule r_1 which takes tuple t_1 and t_2 as input, then the provenance polynomial of this derivation is $r_1 \cdot t_1 \cdot t_2$. Suppose that q has another derivation from rule r_2 which takes tuple t_3 and t_4 as input, then the complete provenance polynomial $\lambda(q)$ is $r_1 \cdot t_1 \cdot t_2 + r_2 \cdot t_3 \cdot t_4$.

Consider the `Acquaintance` example (see Figure 2), the provenance polynomial of the derived tuple `know("Ben","Elena")` is r_3 · `know("Ben","Steve")` · `know("Steve","Elena")`, where `know("Steve","Elena")` is a derived tuple that can be further expanded. The complete provenance polynomial of tuple `know("Ben","Elena")` is the following:

r_3 · `know("Ben","Steve")` ·
(r_1 · `live("Steve","DC")` · `live("Elena","DC")` +
r_2 · `like("Steve","Veggie")` · `like("Elena","Veggie")`)

This provenance polynomial represents the two derivations of `know("Ben","Elena")`.

Success probability of provenance polynomial. Noting that this example provenance polynomial consists of only base tuple literals and rule literals, we can, at least in theory, compute the success probability of the provenance polynomial. We simply treat the provenance polynomial as a formula of random variables; we can then calculate its success probability by plugging in the probabilities of the base tuples and the rules, which are provided as input to a ProbLog program. More formally,

$$\mathbf{P}[\lambda(q)] = \mathbf{E}[\widetilde{\lambda}(q)] \tag{5}$$

where $\widetilde{\lambda}$ denotes the arithmetization form of λ. $\mathbf{P}[]$ denotes success probability, and $\mathbf{E}[]$ denotes expectation.

However, computing the success probability of an arbitrary provenance polynomial is an NP-hard problem [29]. For instance, the success probability of formula $a+b$ is not the sum of the probability of a and the probability of b because of Inclusion–Exclusion principle. Therefore, in practice, we use Monte-Carlo sampling [14] approach to estimate the probability value.

Handling cycles. For a ProbLog program containing recursive rules, a cycle may appear in the provenance graph where a derived tuple can also be an input tuple for one of its own derivation. This raises issues when we retrieve provenance polynomials from the provenance graph – the provenance polynomials may potentially be arbitrarily long (by infinitely expanding the graph traversal through cycles) or contain literals that correspond to derived tuples (by stopping the graph traversal at these derived tuples). This would greatly affect the calculation of the success probability of the provenance polynomial.

However, we show that any such cycles can be removed from the provenance graph without affecting the success probability of the provenance polynomial. Generally, if the queried tuple q has cycles in its provenance graph, its provenance can be written as a polynomial in the following form:

$$\lambda(q) = (P_E + P_I) \cdot \lambda(q) + P'_E + P'_I \tag{6}$$

where P_E and P'_E each denotes a polynomial that only contains base tuples and rule literals. P_I and P'_I each denotes a polynomial containing other derived tuple literals (e.g., the provenance graph contains other cycles that do not involve q). The polynomial $(P_E + P_I) \cdot \lambda(q)$ indicates that some derivations of q depend on the existence of q itself.

Given the existence of cycles, q has infinitely many derivations: some derivations can traverse around a cycle multiple times. We define a series of formula that progressively include derivations with multiple-round cycles:

$\lambda^0(q)$ includes derivations containing no cycles. We have

$$\lambda^0(q) = P'_E + P'_I \tag{7}$$

$\lambda^1(q)$ includes derivations containing at-most-one-round cycles, that is, it includes all derivations in $\lambda^0(q)$ but also derivations containing exact one-round cycles. We have

$$\begin{aligned}
\mathbf{P}[\,\lambda^1(q)\,] &= \mathbf{P}[\,(P_E + P_I) \cdot \lambda^0(q) + P'_E + P'_I\,] && (8)\\
&= \mathbf{P}[\,(P_E + P_I) \cdot (P'_E + P'_I) + P'_E + P'_I\,] && (9)\\
&= \mathbf{P}[\,(1 + P_E + P_I) \cdot (P'_E + P'_I)\,] && (10)\\
&= \mathbf{P}[\,P'_E + P'_I\,] \text{ (Absorption Law)} && (11)
\end{aligned}$$

Thus, we have $\mathbf{P}[\,\lambda^0(q)\,] = \mathbf{P}[\,\lambda^1(q)\,]$. Likewise, we have $\mathbf{P}[\,\lambda^0(q)\,] = \mathbf{P}[\,\lambda^1(q)\,] = \mathbf{P}[\,\lambda^2(q)\,] = \cdots = \mathbf{P}[\,\lambda^\infty(q)\,] = \mathbf{P}[\,P'_E + P'_I\,]$. Therefore, if we are only concerned about calculating its success probability, we can simplify provenance polynomial for q as:

$$\lambda(q) = P'_E + P'_I \tag{12}$$

Furthermore, to simplify P'_I, if any derived tuple q_k in P'_I that has cycles in its derivation graph, we can replace $\lambda(q_k)$ with $\lambda^0(q_k)$. Then we have

$$\lambda(q) = P'_E + P'_I \mid (\,\forall \lambda(q_k), \lambda(q_k) = \lambda^0(q_k)\,) \tag{13}$$

In cases where $\lambda^0(q_k)$ also includes $\lambda(q)$, we can replace $\lambda(q)$ with $P'_E + P'_I \mid (\forall \lambda(q_k), \lambda(q_k) = \lambda^0(q_k))$ in $\lambda^0(q_k)$, and then remove $\lambda^0(q_k)$ following the same process (Equation (6) to Equation (12)). Recursively, the final provenance polynomial for q consists of only base tuple literals and rule literals.

4 REASONING PLP WITH PROVENANCE

The provenance of a queried tuple can be used in a variety of ways to reason a PLP program. For instance, users may want to know how a tuple is derived (Explanation Query), which derivation contributes most to achieving the probability of the derived tuple (Derivation Query), which base tuple has the most influence on the derivation of the queried tuple (Influence Query), and how to change the base tuples to achieve a given target value (Modification Query). These questions can help users reason and debug a PLP program. A summary of the provenance query types discussed in this paper is shown in Table 1.

4.1 Explanation Query

An *Explanation Query* returns the complete derivations of the queried tuple. The success probability of the queried tuple as well as any intermediate derived tuples can be computed efficiently using Monte-Carlo simulation. Consider the `Acquaintance` program (see Figure 2), an example Explanation Query is:

Query 1: Show the derivations of the derived tuple `know("Ben","Elena")`.

By querying the provenance of `know("Ben","Elena")`, we get provenance polynomial λ(`know("Ben","Elena")`) =

Table 1: Summary of provenance query types

Query Type	Operation
Explanation Query	Illustrate the derivations graph of the queried tuple for explanation
Derivation Query	Find the set of most important derivations of the queried tuple given some approximation error
Influence Query	Show the (top-K) most influential variables (base tuples and rules) of the queried tuple
Modification Query	Modify the variables to achieve a target probability value with minimal change

r_3 · `know("Ben","Steve")` ·
(r_1 · `live("Steve","DC")` · `live("Elena","DC")` +
r_2 · `like("Steve","Veggie")` · `like("Elena","Veggie")`)

Its success probability $\mathbf{P}[\,\lambda($`know("Ben","Elena")`$)\,] = 0.18$, meaning there is a 18% probability `Ben` knows `Elena`. The provenance polynomial also corresponds to the visual provenance graph shown in Figure 3 and explained in Section 3.1: tuple `know("Ben","Elena")` has two derivations that share parts of their paths.

4.2 Derivation Query

Sometimes, the complete explanation can be too long or too complex for users to (intuitively) understand; instead, users may be interested in a more compact explanation that still retains a *close-enough* success probability. For example, in the `Acquaintance` scenario, suppose two person `Alice` and `Bob` share many common hobbies (and thus may know each other from the same hobby groups). But if `Alice`'s and `Bob`'s addresses show that they are next-door neighbors, then this serves as a strong explanation for why `Alice` knows `Bob`; it easily trumps the share-similar-hobbies explanation which can be long and tedious.

More generally, after computing the success probability of a queried tuple, it is intuitive to ask: (a) which derivations contributed most to the success probability? (b) can we find a small set of important derivations to achieve an approximate probability? The *Derivation Query* is used to answer these types of questions. Formally, given a provenance polynomial λ, the Derivation Query returns a *sufficient provenance* λ^S:

$$|\,\mathbf{P}[\,\lambda\,] - \mathbf{P}[\,\lambda^S\,]\,| \le \epsilon \qquad (14)$$

where λ^S consists of a subset of the monomials in λ, and ϵ is a user-specified error limit. As an example, consider the `Acquaintance` program. An example Derivation Query is:

Query 2: What are the most important derivations of `know("Ben","Elena")`, assuming an error limit of ϵ?

The original provenance polynomial is given by Query 1, which consists of two monomials, corresponding to the two derivations of `know("Ben","Elena")`. The returned sufficient provenance varies with the value of ϵ: When ϵ is set to 0.001, the sufficient provenance remains the same, as removing either of the monomials would yield a success probability change greater than ϵ. After we increase ϵ to 0.01, the returned sufficient provenance λ^S(`know("Ben","Elena")`) =
r_3 · `know("Ben","Steve")` ·
r_1 · `live("Steve","DC")` · `live("Elena","DC")`
It removes one derivation and presents the most important derivation: The fact that `Steve` and `Elena` live in the same city contributes more to the derivation of `know("Steven","Elena")` (and then, in turn, the derivation of `know("Ben","Elena")`, since rule `r1` has a significantly higher probability than `r2`.

Compute sufficient provenance. For a queried tuple q, each monomial in the provenance DNF formula $\lambda(q)$ corresponds to one derivation path of q. The probability of each monomial is computed by multiplying all the probabilities of literals in the monomial. So it is easy to find the most important derivation of q. However, the probability of λ is not the sum of the probability of each monomial in λ, since these monomials can be correlated. In fact, finding the smallest sufficient provenance of λ, i.e., the $\epsilon-$approximate polynomial with the minimal number of monomials, is NP-hard [25].

A naïve way to compute sufficient provenance is to sort the monomials in the provenance polynomial according to their probabilities in a descending order. We can then progressively remove monomials that have the lowest probabilities, until the error limit ϵ is reached. This doesn't guarantee the smallest sufficient provenance but it provides an approximation. In our evaluation in Section 6, this naïve approach performs surprisingly well.

Alternatively, prior work [25] on approximate lineage for probabilistic databases proposed an algorithm to efficiently find an ϵ-approximation of provenance polynomial. Our system extends it for PLP programs. Briefly, the algorithm finds a sufficient provenance of a $k-$literal polynomial λ in the following steps:

- **Step 1.** It first finds an arbitrary match of λ: A match of λ consists of a set of *independent* monomials in λ. Since these monomials are independent, the success probability of the match can be efficiently computed.
- **Step 2.** If the match is already an $\epsilon-$approximation of λ, then the match is returned as the final result.
- **Step 3.** Otherwise, the monomials in λ are partitioned into groups, where the monomials in each group share at least one literal. Therefore, each group can be rewritten into the form $l \cdot (m_1 + m_2 + ... + m_k)$, where l is the literal shared by all monomials in the group.
- **Step 4.** The algorithm can then recursively find the sufficient provenance for $m_1 + m_2 + ... + m_k$, which is a $(k\text{-}1)-$literal polynomial. The algorithm is guaranteed to terminate at 1-literal polynomial.

Although this algorithm is more efficient than the naïve approach, it relies heavily on the choices of the match (in Step 1) and the groups (in Step 3). In some cases, it provides little reduction in the size of the provenance polynomial.

4.3 Influence Query

In addition to derivations of a queried tuple, users may also be interested in the influence of each literal on the queried tuple. An *Influence Query* returns the most influential literals (i.e., rule weight or base tuple probability) of a given derived tuple.

Intuitively, the influence of a literal x_i on a provenance polynomial λ measures the impact on the success probability of λ when the value of x_i changes. For example, a counterfactual base literal would have a large influence, because setting it to be false would invalidate the derived tuple. We adopt the definition proposed in a prior work [13]: Consider λ as a multiple-variable function, the influence of x_i is the partial derivative $\frac{\partial \lambda}{\partial x_i}$.

Definition 4.1. **Literal influence [13].** The influence of a literal x_i on the provenance polynomial λ, denoted $\text{Inf}_{x_i}(\lambda)$, is:

$$\text{Inf}_{x_i}(\lambda) = \frac{\partial \lambda}{\partial x_i} = \mathbf{P}[\lambda|_{x_i=1}] - \mathbf{P}[\lambda|_{x_i=0}] = \mathbf{E}[\widetilde{\lambda}|_{x_i=1} - \widetilde{\lambda}|_{x_i=0}] \quad (15)$$

where $\widetilde{\lambda}$ denotes the arithmetization form of λ. $\mathbf{P}[]$ denotes probability, and $\mathbf{E}[]$ denotes expectation. $\mathbf{P}[\lambda] = \mathbf{E}[\widetilde{\lambda}]$.

Based on this definition, P3 can answer Influence Query efficiently by using Monte-Carlo sampling approach to estimate $\mathbf{E}[\widetilde{\lambda}|_{x_i=1} - \widetilde{\lambda}|_{x_i=0}]$. Consider the `Acquaintance` program. An example Influence Query is:

Query 3: What are the most influential literals to the success probability of `know("Ben","Elena")`?

Table 2: Results of Influence Query

Variable	Influence Value
r_3	0.896
r_1	0.2
t_6	0.1792

Table 2 lists the top-3 most influential literal. It shows that rule `r3` is the most influential. It makes intuitive sense: Rule `r3` is the critical recursive rule that allows for the generation of multi-hop `know` relationships, including the case for `Ben` and `Elena` who know each other through their direct relationships with `Steve`.

4.4 Modification Query

For a queried tuple, our system can answer which derivations contribute most, and which individual variables are the most influential ones. Users may further explore how to effectively modify the base variables to adjust the queried tuple's success probability, for example, when the success probability of the queried tuple is suspiciously low (or high). The *Modification Query* aims to answer this type of question. We use the results from the Influence Query as a basis to answer Modification Queries.

Based on Equation (5), we can easily get

$$\mathbf{P}[\lambda_t] = \text{Inf}_{x_i}(\lambda) \cdot p(x_i) + \mathbf{P}[\lambda|_{x_i=0}] \quad (16)$$

It means that for any variable x_i, the success probability of the derived tuple is positively correlated to $p(x_i)$, and the positive coefficient is the influence value of x_i. Equation (16) effectively considers $\mathbf{P}[\lambda]$ as a function of $p(x_i)$.

Query 4: Given a target success probability of the queried tuple, how should we modify the base literals to achieve the targe with minimal cost?

Here, we consider the cost is defined as:

$$\text{Cost} = \sum_i |\Delta p(x_i)| \quad (17)$$

which is the summation of the probability change of each modified literal. To find a good solution for Query 5, We follow a heuristic-based greedy algorithm. The algorithm selects the most influential variable, and change its value to reach the target probability. Sometimes, even changing the most influential variable to the maximum value of 1 (or minimum value of 0) is still not enough. In this case, we continue to find the most influential variable in the remaining variables, until the target probability is reached. The most influential variable in each iteration corresponds to the highest slope to change, so the total cost of modification of variables is minimized. The strategy returned by this heuristic-based algorithm is not guaranteed to be an optimal solution of minimal cost, but, by leveraging the result of Influence Query, it works well empirically.

Take the `Acquaintance` program as an example. The original success probability of `know("Ben","Elena")` is 0.18. If we hope to modify the value to be above 0.5, the answer returned by P3 is that we should change variable r_3 to 0.56. The total cost of the change is 0.36. Further evaluation of the effectiveness of the heuristic-based algorithm is elaborated in Section 5.2.

5 CASE STUDY

The `Acquaintance` program is a simple example to illustrate how provenance is utilized to reason the evaluation results of ProbLog programs. In this section, we present two case studies to showcase how users can benefit from P3's practical reasoning capabilities. Performance evaluations will follow in the next section.

Visual Question Answering. Our first use case describes a scenario from multi-modal learning in the machine learning community, called Visual Question Answering (VQA). The learning task is to answer user's questions regarding a presented photo, e.g., identifying a (partially blocked) object in the photo. In this scenario, we use provenance to provide some insights from human-explainable perspective, e.g., to identify the most influential features that lead to the learning result.

Mutual Trust in Social Network. Our second use case is similar to the `Acquaintance` example, which, at the core, computes probabilistic recursive rules. In this scenario, we use sampled data from real-world trust network, and computes pair-wise mutual trust between each pair of peers in the network. We use provenance to identify critical *direct* trust relationships.

5.1 Visual Question Answering

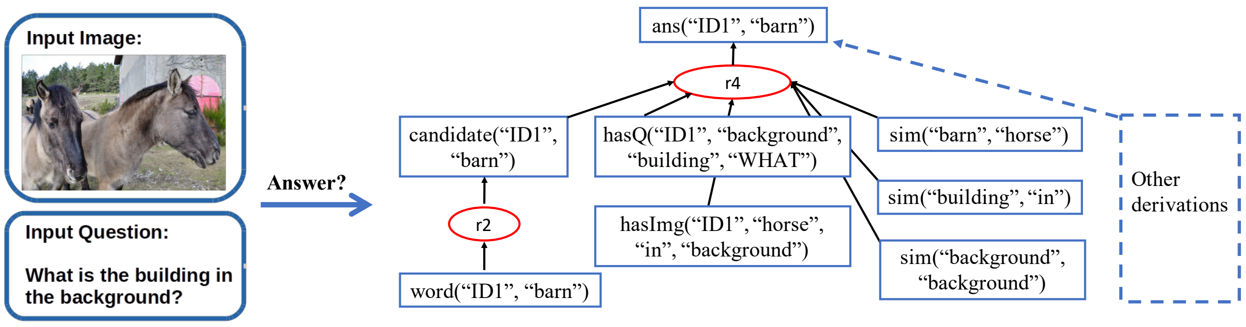
This use case involves supporting the Visual Question Answering (VQA) [2] task using a probabilistic logic program. In VQA, the system answers a natural language question about an image. This task comgines natural language, image processing, and logical reasoning. Prior work on PSL based VQA program [1] can decompose and reason VQA task in terms of logic rules, but lacks the ability to explain the derivation procedure for the answer. Here, we rewrite the VQA-PSL program in ProbLog syntax, and provides provenance queries to explain VQA answers.

The input of this use case is a set of tuples parsed from both the image (`hasImg` relation) and the question (`hasQ` relation) with some probability. The similarity between words are also base tuples (`sim` relation). The input also includes `word` relation tuples. It is the set of answers with prior confidence scores as probability. The scores can come from some sources, e.g. a dictionary with word frequency.

The VQA-PSL program [1] is written into an equivalent VQA ProbLog program shown in Figure 5. Each rule is associated with a weight probability, which can be assigned any reasonable values. The four rules in Figure 5 explain how the final answers (`ans` relation) can be derived step-by-step combining image information, question parsing information, and words similarity knowledge.

In Figure 5, rule `r1` extends the `hasImg` relation by replacing items with their synonyms (but with a diminishing score). For example, `hasImg(V,"apple","in","background")` can be extended to `hasImg(V,"fruit","in","background")`, as `apple` is similar to `fruit` (indicated by `sim("apple","fruit")`).

Rule `r2` states that a word in the dictionary automatically becomes a candidate answer. However, it may then be out-weighted



Input Image:
Input Question:
What is the building in the background?
Answer?
ans("ID1", "barn")
r4
candidate("ID1", "barn")
hasQ("ID1", "background", "building", "WHAT")
sim("barn", "horse")
sim("building", "in")
sim("background", "background")
hasImg("ID1", "horse", "in", "background")
r2
word("ID1", "barn")
Other derivations

Figure 4: Abstract provenance graph of `ans("ID1","barn")`. The complete most important derivation is shown.

by results generated by rule `r3` which further considers how the candidate answer is correlated with user's question and the objects appeared in the photo.

Finally, rule `r4` takes all the candidate answers and evaluates their correlation with the question and the objects in the photo. Stronger correlation will have higher scores. Note that we assigned equal weight to all words in the dictionary such that the predicted result is unbiased.

```
r1 w1:hasImgAns(V,Z,X1,R1,Y1) :-
      word(V,Z), hasImg(V,X1,R1,Y1),
      sim(Z,X1), sim(Z,Y1).
r2 w2:candidate(V,Z) :- word(V,Z).
r3 w3:candidate(V,Z) :- word(V,Z),
      hasQ(V,X,R,Y), hasImgAns(V,Z,X1,R1,Y1),
      sim(R,R1), sim(Y,Y1), sim(X,X1).
r4 w4:ans(V,Z) :- candidate(V,Z),
      hasQ(V,X,R,"WHAT"), hasImg(V,Z1,R1,X1),
      sim(Z,Z1), sim(R,R1), sim(X,X1).
```

Figure 5: VQA ProbLog program

Given an image and a question shown in Figure 4, the input tuples can be obtained using a image captioning system and natural language processing system. The word similarity inputs are obtained from Word2Vec library. The evaluation of the ProbLog program returns the tuple `ans("ID1","barn")` as the the result with the highest confidence, meaning that the building in the presented photo (identified by "ID1") is determined as a barn. We query the provenance of `ans("ID1","barn")` to check whether the returned provenance can give meaningful explanations.

Query 1A: Show the derivations of `ans("ID1", "barn")`. Since the provenance graph for the queried tuple has many branches, to enhance readability, we only display a condensed graph shown in Figure 4 instead of the complete fine-grained provenance graph. The actual complete graph can be generated by our system if the user hopes to take a closer look at it.

In Figure 4, we show the most important derivation to `ans("ID1", "barn")`, and leave out other derivations. In the most important derivation, word "barn" is selected as a candidate (rule `r2`) given that "barn" is included in the dictionary. Besides, "barn" is strongly correlated to the horse appeared in the photo, adding some other words similarity relation, `ans("ID1", "barn")` is derived through rule `r4`. There are other derivations that can also derive `ans("ID1", "barn")`, but they contribute less to the final probability of `ans("ID1", "barn")`.

Query 1B: Show the most influential base tuple to `ans("ID1", "barn")`. Our next query concerns the base tuple that influences the final learning result the most. In other words, we would like to understand which factor would affect

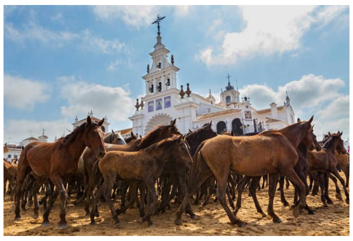


Figure 6: Image of horses in front of a church

the predicted result the most if its value was changed. We performed the influence query on the returned provenance result, then identified that the base tuple `word("ID1","barn")` is the most influential one. This is reasonable, however, less interesting as it is simply stating the obvious truth that a word must be considered as a potential answer to affect the result. As the program mainly depended on the information from `hasImg()` and `sim()` for prediction, we decided to find the most influential tuples in these two relations respectively.

We further identified the base tuple `hasImg("ID1", "horse", "in", "background")` as the most influential one in `hasImg()`. Its influence value was approximately 0.005. Effectively, this result states that the building being identified as a barn is largely influenced by the fact that there is a horse in the background. In `sim()`, the most influential tuple was `sim("barn", "horse")` with 0.03 influence value. Again, it confirmed that horse was the key factor that would affect the result the most. Both tuples coincided with human intuition while supporting the feasibility of our approach as well.

Query 1C: Show the most influential base tuple after making modifications to the input image. Our next query demonstrates the use of provenance queries for debugging. Intuitively, we expected that `ans("ID1","church")` would have the highest probability if we replaced the horses in the photo with a cross. We replaced `hasImg("ID1","horse","in","background")` with `hasImg("ID1","cross","in","background")` to mimic the modified photo aforementioned. However, the result was not as what we expected. We observed that `ans("ID1","barn")` still appeared in the evaluation result with the highest probability value. For debugging purposes, we ran the query on Figure 6 and captured the image information shown in Table 3.

We then updated the word similarity using Word2Vec. However, `ans("ID1","barn")` was still predicted as the most probable answer (i.e., the answer with the high probability). Demonstrating the generality of our approach, we use the previous queries to debug this issue. First, we ran the Derivation Query to show the most important derivations of `ans("ID1", "barn")` and `ans("ID1", "church")`. We found out that "barn" had

Table 3: Captured image information

Information	Prob.
`horse color brown`	1
`horse in field`	0.88
`cloud in sky`	0.85
`building with roof`	0.5
`cross on building`	1

very high similarities with other objects in the image ("cross": 0.30, "horse": 0.35, "cloud": 0.33), while "church" had much lower values ("cross": 0.09, "horse": 0.19, "cloud": 0.01). Surprisingly, `sim("church", "cross")` was much lower than `sim("barn", "cross")`. This explains exactly why the program did not predict the answer correctly.

Next, we would like to see how to increase the probability of `ans("ID1", "church")` with minimum cost. Our goal was to make "Church" the answer with the highest probability. So we ran the Influence Query, and selected the unique tuples that only appeared in the provenance of `ans("ID1", "church")`. The top 3 unique most influential tuples are shown in the following table:

Table 4: Top 3 unique influential tuple for `ans("ID1", "church")`

Tuple	Influence
`sim("church", "cross")`	0.04
`sim("church", "horse")`	0.02
`sim("church", "cloud")`	0.01

It is reasonable to have `sim("church", "cross")` as the most influential tuple. We set the probability of `ans("ID1", "barn")` as the target probability value for `sim("church", "cross")` and further computed the increment using the Modification Query, which returns a result value of 0.42. The value of `sim("church", "cross")` is updated to 0.51. Again, this met with our expectation that `sim("church", "cross")` should be greater than `sim("barn", "cross")`.

This use case demonstrates how multiple queries can be used in tandem to explain and debug unexpected answers caused by input data errors in probabilistic logic programs.

5.2 Mutual Trust in Social Network

For this graph network reachability use case, we use the Bitcoin OTC trust weighted signed network dataset[2]. This is a who-trusts-whom network of people who trade using Bitcoin on a platform called Bitcoin OTC [15, 16]. Each weighted edge in the network graph represents the trust between two users with the degree of trust as weight value. To fit the data in our probabilistic setting, we re-scale the weights of edges from [-10,10] to [0,1] to represent the probability score of trust.

In this use case, the input tuples are `trust` relations between people. For example, tuple `trust(1,2)` of score 0.7 means Person 1 trusts Person 2 with probability 0.7. We introduce the ProbLog program shown in Figure 7 to find `trustPath` and `mutualTrustPath` tuples that can be derived. Rule `r1` is a base case that each `trust` relation tuple is also a one-hop `trustPath` relation tuple. Rule `r2` is a recursive rule used to derive all the reachable `trustPath` tuples. Rule `r3` defines `mutualTrustPath` tuples that can be derived when the `trustPath` between any two nodes are bi-directional. The `Trust` ProbLog program can help finding any indirect trust relations between people, which is of significant interest during actual transactions.

```
r1 1.0: trustPath(P1,P2) :- trust(P1,P2).
r2 1.0: trustPath(P1,P3) :-
        trust(P1,P2), trustPath(P2,P3),
        P1!=P3.
r3 0.8: mutualTrustPath(P1,P2) :-
        trustPath(P1,P2),trustPath(P2,P1).
```

Figure 7: `Trust` ProbLog program

The original network graph is quite large, so for quality check purpose, we use a sample of 30 nodes to evaluate the provenance query results.

Query 2A: Show the derivations of `mutualTrustPath(1,6)`. The answer returned by P3 system is the provenance graph for queried tuple `mutualTrustPath(1,6)`, shown in Figure 8. The provenance graph shows Person 1 and Person 6 mutually trust each other because of the existence of trust paths from 6 to 1 (denoted by `trustPath(1,6)`) and from 1 to 6 (denoted by `trustPath(6,1)`). It further shows that there is one single derivation for `trustPath(6,1)` where Person 2 is the middle man that connects this trust path; on the other hand, `trustPath(1,6)` has two derivations, namely through path $1 \rightarrow 2 \rightarrow 6$ or path $1 \rightarrow 13 \rightarrow 2 \rightarrow 6$.

Query 2B: Show the most influential base tuple for `mutualTrustPath(1,6)`.
Next, we perform a query to understand which base tuples, i.e., the `trust` tuples, are most critical to the mutual trust between Person 1 and Perosn 6. We initialize the base tuples with probability values shown as follows (we omit the ones that are not involved in the derivation of `mutualTrustPath(1,6)`):

Table 5: Initial probability values of base tuples

Literal	Prob.	Literal	Prob.
`trust(1,2)`	0.9	`trust(1,13)`	0.65
`trust(2,1)`	0.9	`trust(2,6)`	0.75
`trust(6,2)`	0.7	`trust(13,2)`	0.6

Given this initialization, the P3 system returns that `trust(6,2)` is the most influential literal with an influence value of 0.51. The second most influential literal is `trust(2,6)` with an influence value of 0.48. Observing the provenance structure in Figure 8, we find that this result comply with human's intuition: `trust(6,2)` is influential[3] because its existence is the basis of the trust path from Person 6 to Person 1; `trust(2,6)` is also influential, more so than `trust(1,2)` and `trust(1,13)`, for the existence of the trust path from Person 1 to Person 6.

More intuitively, the result indicates that if Person 6 wants to increase the mutual trust to Person 1 without directly reaching him, strengthening the trust to Person 2 might be the most effective approach.

Query 2C: Show the optimal way to increase the probability of `mutualTrustPath(1,6)`. Here, we assume that each literal's probability can reach to 1.0 as maximum. The original **P**[mutualTrustPath(1, 6)] is 0.3524. Now we want to approximately double it to a target value 0.7. The strategy returned by P3 is as follows:

[2]https://snap.stanford.edu/data/soc-sign-bitcoin-otc.html

[3]`trust(6,2)` is considered to have a higher influence value than `trust(2,1)` due to the initial probability assignment: whether `trust(6,2)` exist or not has a higher influence because its existence would *almost* imply the existence of the trust path from 6 to 1 as **P**[`trust(2,1)`] is very close to 1.

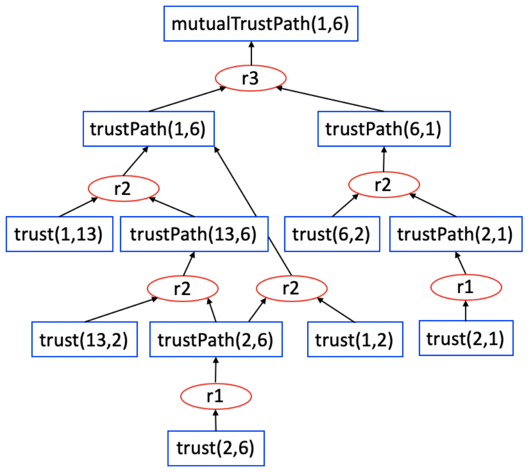

Figure 8: Provenance graph of queried tuple `mutualTrustPath(1,6)`

Table 6: Optimal strategy (total change = 0.58)

	Literal	Change	Overall prob.
Step 1	`trust(6,2)`	0.7 ⟶ 1.0	0.51
Step 2	`trust(2,6)`	0.75 ⟶ 1.0	0.68
Step 3	`trust(2,1)`	0.9 ⟶ 0.93	0.7

To show the effectiveness of our heuristic-based algorithm, we compare the cost, in terms of total change in base tuple's probability values, of its strategy with another randomly generated strategy where a random base tuple is chosen to update in each step. The result of a random strategy is shown as follows:

Table 7: Random strategy (total change = 1.36)

	Literal	Change	Overall prob.
Step 1	`trust(1,13)`	0.65 ⟶ 1.0	0.37
Step 2	`trust(13,2)`	0.6 ⟶ 1.0	0.38
Step 3	`trust(6,2)`	0.7 ⟶ 1.0	0.54
Step 4	`trust(1,2)`	0.9 ⟶ 1.0	0.55
Step 5	`trust(2,6)`	0.75 ⟶ 0.96	0.7

We find that the strategy provided by P3 significantly outperforms the random strategy (0.58 vs 1.36 in total change). We make similar observations for other Modification Queries.

6 EVALUATION

We developed a prototype of P3 based on enhancements to the ExSPAN provenance engine [31]. While ExSPAN was a distributed provenance engine designed for networks, we focused on using ExSPAN primarily in a single-node centralized setting. ExSPAN provides provenance for Datalog programs and provides basic provenance explanations. We enhanced the system to implement ProbLog, collect provenance, and support the three additional types of P3 queries (derivation, influence, and modification).

Experimental setup. Our experiments were performed on a Dell PowerEdge R730 server equipped with dual Intel Xeon E5-2640 CPUs and 32GB memory running Ubuntu 16.04 LTS 64-bit operating system.

As our workload, we evaluated the program shown in Figure 7. The output derivation of interest was the `mutualTrustPath` relation, over which we would run provenance queries. We selected this program as it had all the features of our use case. Meanwhile, there existed real-world data that we could use for our experiments. Specifically, we used the Bitcoin OTC data set described in Section 5.2. The data set consisted of a directed graph network with 5,881 nodes (bitcoin users) and 35,592 edges (trust relations). We sampled the graph with different sizes of nodes, and evaluated the performance of provenance queries elaborated in Section 4 for each sample.

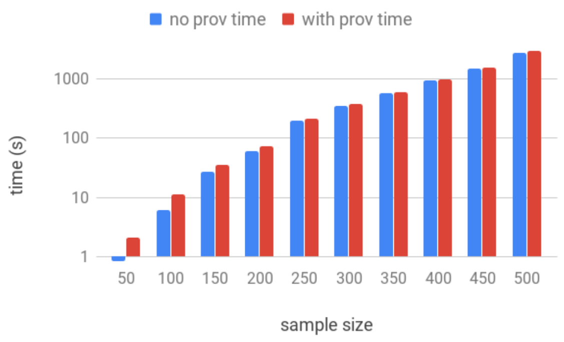

Figure 9: Running time with and without provenance

6.1 Provenance Maintenance and Querying

To evaluate the provenance maintenance and querying performance, we sampled subgraphs from the original trust network with 50, 100, 150, . . . , 500 nodes. For each sample, we randomly chose a small set of seed nodes, and expanded the graph by performing a breadth-first search within the trust network from these seed nodes, until the graph reaches a given number of nodes. We then collected all traversed edges. For each size, we repeated our experiments 10 times with different samples and calculated the average running time.

Maintenance. Our first set of experiments aimed to measure the overhead of provenance maintenance. We compared the running time between running the `Trust` program with and without provenance maintenance. The overhead is shown in Figure 9. We observe that the evaluation time, both with and without provenance, increases exponentially as the sample size grows, which complies with our expectation. In addition, as provenance is maintained at the runtime as a side-computation along each rule evaluation, the provenance maintenance incurs a small overhead. We observed that, in average, the maintenance time is less than 10% of the total running time, and will not impact the asymptotic scalability of PLP programs. Thus, the provenance maintenance is efficient and its overhead in P3 for ProbLog-like PLP programs is low enough to be accepted.

Query. We next measured the overhead to obtain the provenance of a queried tuple, as a generic **explanation query**. Figure 10 summarizes our evaluation results. We fixed the hop limit to 4, which means we only retrieved the mutual trust paths whose length are no greater than 4 hops. Limiting the path length can remove overly long derivation paths from the provenance and expedite the querying process: The number of derivation paths grows exponentially with the path length, however, the long paths contribute little to the derivability of the queried tuple (intuitively, people are less likely to trust a relationship that has many hops). As shown on the figure, the query time is roughly on the same order of magnitude compared to the maintenance time, but grows slower for larger-sized graphs owing to the use of hop limits. Overall, the provenance querying is reasonably efficient

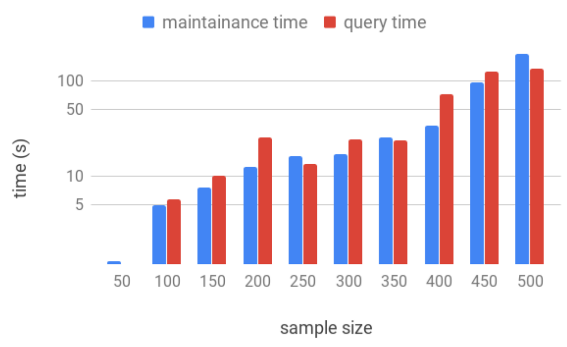

Figure 10: Provenance query time compared with maintenance time. Hop limit is set to 4

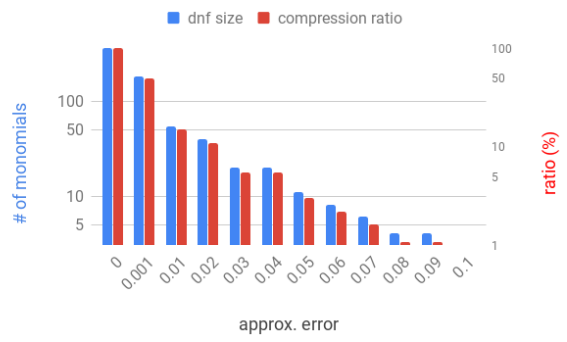

Figure 11: Compression ratio of sufficient provenance

to be practical, and can be further optimized by parallelizing the provenance graph traversal.

6.2 Performance for Different Queries

We have evaluated the overhead of provenance maintenance for a PLP program, and the execution time of generic **explanation query** (i.e., to obtain the provenance for a queried tuple). In this section, we perform a set of experiments to measure the performance of answering other types of provenance queries elaborated in Section 4.

Derivation Query. To evaluate this type of query, we sampled graphs consisting of 150 nodes and 150 edges from the trust network (we repeated the experiment 10 times with different sampled graphs). We queried all possible mutual paths between two specific users and set the hop limit to 6. We ran the query on each sampled graph and calculated the average. For each returned provenance polynomial λ, varying the approximation error ϵ leads to sufficient provenance of different sizes – a more forgiving approximation error (i.e., larger ϵ) leads to a smaller-sized sufficient provenance. We evaluated the compression ratio of sufficient provenance with approximation error from 0.1% to 10% (X% means X percent of $\mathbf{P}[\lambda]$). Compression ratio is defined as the number of monomials in the sufficient provenance divided by the number of monomials in the original provenance polynomials. Our evaluation result is shown in Figure 11. We observed that, as expected, sufficient provenance leads to significant compression: it warrants a 50% deduction in provenance size even with merely 0.1% approximation error; 10% approximation error allows approximately 99.8% deduction.

We further evaluated the computation time of our naïve approach; we observe that the computation time was consistently under 1 second. In fact, it decreased tremendously as we increased the approximation error. This is because the computation of Derivation Queries heavily relies on Monte-Carlo simulation (for evaluating whether more monomials should be removed), and larger approximation error shifts the search for optimal sufficient provenance towards shorter polynomials and therefore a shorter overall query time.

Influence Query. Our next set of experiments evaluates the performance of Influence Queries. We used the same set of sampled graphs as the Derivation Query, that is, each sampled graph consists of 150 nodes and 150 edges. We observe that the average time for computing the influence of all literals (and identifying the most influential literal) is 9.6 seconds; according to the definition of influence presented in Section 4, the computation time of influence queries highly depends on the size of the provenance, more specifically, the number of monomials in the provenance polynomial and the number of distinct literals. We consider two optimizations that significantly reduce the computation time of influence queries.

Parallelize Monte-Carlo simulation. Monte-Carlo simulation repeatedly evaluates the truth value of a Boolean polynomial given a random value assignment of the variables (which can be either true or false). This process is embarrassingly parallel and can greatly benefit from using hardwares such as GPUs. We therefore evaluated the computation time of the Influence Query using a parallel implementation of Monte-Carlo simulation. The experiment was run on a workstation equipped with an Intel i7 9800X CPU, 64GB memory and four Nvidia GTX 1080 Ti GPUs. Table 8 summarizes the time required to compute the influence value sequentially or in parallel.

Table 8: Comparison of influence query time

Seq total	Seq per-literal	Para total	Para per-literal
9.60	0.14	0.85	0.01

We observe that the parallel implementation provides a 10x speed improvement owing to the high degree of parallelization, and reduces the total computation time to under 1 second.

Preprocess using sufficient provenance. We noticed that most literals have a negligibly small influence value. If our goal is to identify the most influential literal, we might be able to avoid computing the influences of most literals. Our approach is to use sufficient provenance as a preprocessing step, such that the influence query runs on a much small provenance polynomial. To evaluate the effectiveness of this method, we first examined whether the returned sufficient provenance still retains the most influential literals. We computed the sufficient provenance when allowing different approximation errors, and compared the top-5 most influential literals to the ones computed from the original provenance. As shown in Figure 12, the rank of the top-5 most influential literals remained the same when the error limit was less than 2%, and then started to fluctuate as the error limit increased. However, the most influential tuple remained the same even the error limit was as high as 10%.

Second, we evaluated the computation time of Influence Query after the preprocessing step retrieves the sufficient provenance. Figure 13 shows the evaluation results with varying approximation error limits. We observe that, since the number of monomials decreased exponentially as we increased the error limit, the computation time of Influence Query also decreased exponentially.

We further measured the total execution time of computing influence queries with sufficient provenance. The result is shown

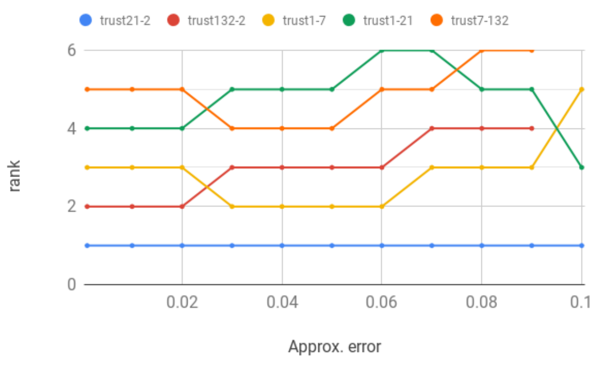

Figure 12: Rank change of top-5 most influential literals

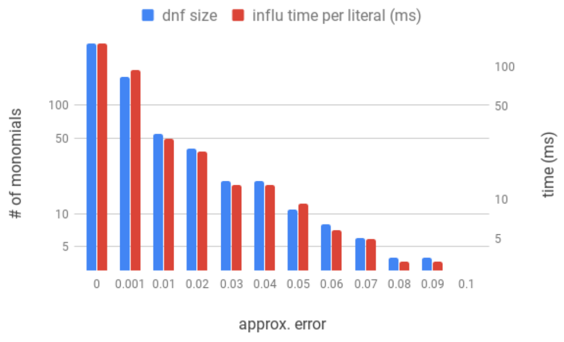

Figure 13: Influence query time for a single literal

in Figure 14. We observed that, for large provenance polynomial, allowing even a small approximation error would reduce the query time tremendously. We compared it with Figure 12 and observed that, when the approximation error limit was set appropriately (around 2% in this case), the returned top influential literals remained unchanged while the computation time could be reduced substantially. For example, we observed an order of magnitude reduction in computation time when setting the error limit to 2%.

Modification Query In our last set of experiments, we evaluated the performance of modification query where we change the provenance probability to a target value with minimum cost. Recall that the changed tuple in each step is the most influential one to the provenance. We tested the Modification query on a given provenance polynomial that consists of 366 monomials and 65 distinct literals. The probability of the provenance was 0.873, and we wanted to reduce it to 0.373. We conducted the experiment using three methods: sequential without sufficient provenance, parallel without sufficient provenance, and sequential with sufficient provenance (with an error limit of 0.01). All the three method returned the same change sequence: a) modify the probability of `trust21-2` by -0.75 (i.e., set its probability to 0), and b) modify the probability of `trust132-2` by -0.196. The computation time are shown in Table 9.

Table 9: Compare running times of modification query

Sequential	Parallel	Seq. with suff. prov.
20.66	1.55	2.44

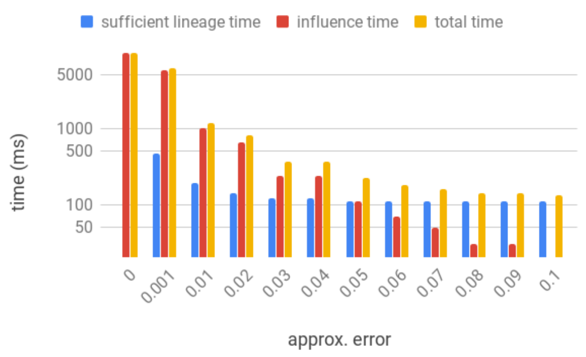

Figure 14: Influence query on sufficient provenance

We observed that sufficient provenance can give the same result while its computation time is in the same order of magnitude compared to the hardware-aided parallel processing.

7 RELATED WORK

We briefly summarize related works in provenance for relational databases (regular and probabilistic), as well as a reference to other probabilistic logic programs.

7.1 Data Provenance

Data provenance is widely used in declarative logic programs like Datalog and NDlog (Network Datalog) [17–19]. Provenance information is stored using *graph representation* and *algebraic representation* [11, 31]. The graph representation is also called provenance graph, and the algebraic representation is commonly encoded as provenance polynomials.

Tuple-level provenance graph is a fine-grained derivation graph. In ExSPAN [31], the provenance graph is acyclic. There are two types of vertices in the graph. One is the tuple vertex, and the other is the rule execution vertex. Each tuple vertex is either a base tuple or a derived tuple; each rule execution vertex denotes an instance of a rule execution. The edges in the provenance graph are unidirectional, and represent data flows between tuple vertices and rule execution vertices.

Provenance can also be represented as *provenance polynomials* [11] which is encoded as an algebraic expression with two binary operations: addition "+" and multiplication "·". Each base tuple is encoded as one literal in the polynomials. Specifically, "+" indicates the combination of tuples with union and projection operations, and "·" denotes a natural join over tuples.

As we will describe later in our paper, P3 also uses ExSPAN style execution to maintain and process provenance, with several extensions in order to support a new provenance model.

7.2 Provenance in Probabilistic Databases

In probabilistic databases community, lineage is the synonym of provenance. Each tuple has an associated probability score in probabilistic databases. For SQL-like queries in probabilistic databases, provenance can support explanations for the queried tuple probabilities. For instance, Trio [30] is an innovative database management system (DBMS) based on an extended relational model called *Uncertainty-Lineage Databases* (ULDBs) to handle the uncertainty of data and data lineage. It extends the traditional model by adding a confidence value (probability of being true) for each tuple. Trio introduces a SQL-based language called *TriQL* for querying confidences and lineage in ULDBs. In our paper, for PLP programs, we do not consider SQL-like queries.

In addition, for probabilistic databases, approximation of lineage such as *sufficient lineage* [25] is used for only keeping track of the most important derivations for the derived tuple given some approximation error ϵ. Kanagal et al. presented a further discussion and provided an efficient approach for sensitivity and explanation analysis [13]. This approach works on read-once lineages from conjunctive queries without self-joins. However, read-once is not a universal property of the provenance polynomials extracted from PLP programs.

7.3 Probabilistic Logic Programs

Milch et al. introduced the BLOG language [20] to define probabilistic models with unknown objects and identity uncertainty. Unlike BLOG based on first-order logic, Goodman et al. developed Church[10], a LISP-like language based on lambda calculus to describe stochastic generative processes. Furthermore, Pfeffer introduced an object-oriented language called Figaro for probabilistic programming. Beside these languages, for probabilistic inference, Alchemy[26] is a system based on Markov logic representation to construct knowledge bases. Niu et al. and Gribkoff et al. introduced Tuffy[22] and SlimShot[12] respectively such that MLN inference can perform on large scale data sets. Compared to the aforementioned studies, our contribution is on providing a feasible solution to perform quantitative query evaluations for debugging purposes.

8 CONCLUSIONS AND FUTURE WORK

This paper proposes P3, a platform and system for capturing provenance in probabilistic logic programs. P3 maintains the provenance information using both graph representation (directed acyclic provenance graph) and algebraic representation (provenance polynomials as Boolean DNF formulas). P3 enables a wide range of novel query types, including explanation query, derivation query, influence query, and modification query. We conduct the theoretical analysis of P3's provenance model and queries. Our evaluation on a P3 prototype demonstrate the feasibility of P3 across multiple use cases with low overhead.

Moving forward, we are working on expanding the scope of PLP programs supported by P3. We plan to extend provenance model and system to support first-order PLP programs with negation, and machine-learning style inference [3, 6, 26]. As we support more language features, we would also like to broaden our use cases to include learning-based applications, such as explainable recommendation through relational learning. Finally, we are exploring ways to improve our performance further, leveraging parallel query execution across multiple machines in a cluster.

ABSTRACT

The *containment rate* of query $Q1$ in query $Q2$ over database D is the percentage of $Q1$'s result tuples over D that are also in $Q2$'s result over D. We directly estimate containment rates between pairs of queries over a specific database. For this, we use a specialized deep learning scheme, Containment Rate Network (CRN), which is tailored to representing pairs of SQL queries (inspired by the MSCN model [22]). Result-cardinality estimation is a core component of query optimization. We describe a novel approach for estimating queries' result-cardinalities using estimated containment rates among queries. This containment rate estimation may rely on CRN or embed, unchanged, known *cardinality* estimation methods. Experimentally, our novel approach for estimating cardinalities, using containment rates between queries, on a challenging real-world database, realizes significant improvements to state of the art cardinality estimation methods.

1 INTRODUCTION

Query $Q1$ is contained in (resp. equivalent to), query $Q2$, analytically, if for all database states D, $Q1$'s result over D is contained in (resp., equals) $Q2$'s result over D. Query containment is a well-known concept that has applications in query optimization. It has been extensively researched in database theory, and many algorithms were proposed for determining containment under different assumptions [8, 9, 16, 40]. However, determining query containment analytically is not practically sufficient. Two queries may be analytically unrelated by containment, although, the execution result on a *specific* database of one query may actually be contained in the other. For example, consider the queries:
Q1: *select * from movies where title = 'Titanic'*
Q2: *select * from movies where release = 1997 and director = 'James Cameron'*
Both queries execution results are identical since there is only one movie called Titanic that was released in 1997 and directed by James Cameron (he has not directed any other movie in 1997). Yet, using the analytic criterion, the queries are unrelated at all by containment.

To our knowledge, while query containment and equivalence have been well researched in past decades, determining the containment rate between two queries on a *specific* database, has not been considered by past research.

By definition, the containment rate of query $Q1$ in query $Q2$ on database D is the percentage of rows (tuples) in $Q1$'s execution result over D that are also in $Q2$'s execution result over D. Determining containment rates allows us to solve other problems, such as determining equivalence between two queries, or whether one query is fully contained in another, on the same *specific* database. In addition, containment rates can be used in many practical applications, for instance, query clustering, query recommendation [11, 15], and in cardinality estimation as will be described subsequently.

Our approach for estimating containment rates is based on a specialized deep learning model, CRN, which enables us to express query features using sets and vectors. An input query is converted into three sets, T, J and P representing the query's tables, joins and column predicates, respectively. Each element of these sets is represented by a vector. Using these vectors, CRN generates a single vector that represents the whole input query. Finally, CRN estimates the containment rate of two input queries by using their representative vectors as input to another specialized neural network. Thus, the CRN model relies on the ability of the neural network to learn the vector representation of queries relative to the *specific* database. As a result, we obtain a small and accurate model for estimating containment rates.

In addition to the CRN model, we introduce a novel technique for estimating queries' cardinalities using estimated query containment rates. We show that using the proposed technique we improve current cardinality estimation techniques significantly. This is especially the case when there are multiple joins, where the known cardinality estimation techniques suffer from under-estimated results and errors that grow exponentially as the number of joins increases [14]. Our technique estimates the cardinalities more robustly (x150/x175 with 4 joins queries, and x1650/x120 with 5 joins queries, compared with PostgreSQL and MSCN, respectively).

As shown in [26], to obtain an efficient query plan, the query optimizer chooses the cheapest alternative from semantically equivalent plan alternatives. Since the cost model uses the cardinality estimates as a principal input, the more accurate the cardinality estimates are, the more accurate the predicted plans costs are. Thus, by using the more accurate cardinality estimates obtained from our technique, the query optimizer can generate better query plans, resulting in faster query execution time.

We compare our technique with PostgreSQL [1], and the pioneering multi-set convolutional network (MSCN) model [22], by examining, on the real-world IMDb database [26], join crossing correlations queries which are known to present a tough challenge to cardinality estimation methods [26, 28, 35].

We show that by employing known existing cardinality estimation methods for containment estimation, we can improve on their cardinality estimates as well, without changing the methods themselves. Thus, our novel approach is highly promising for solving the cardinality estimation problem, the "Achilles heel" of query optimization [30], a cause of many performance issues [26].

The rest of this paper is organized as follows. In Section 2 we define the containment rate problem and in Sections 3-4 we describe and evaluate the CRN model for solving this problem. In Sections 5-6 we describe and evaluate our new approach for estimating cardinalities using containment rates. In Section 7 we show how one can adapt the new ideas to improve existing cardinality estimation models, and in Section 8 we compare the prediction time among the different approaches. Finally, Sections 9-10 present related work, conclusions and future work.

2 CONTAINMENT RATE DEFINITION

We define the containment rate between two queries $Q1$, and $Q2$ on a *specific* database D. *Query $Q1$ is $x\%$-contained in query $Q2$ on database D if precisely $x\%$ of $Q1$'s execution result rows on database D are also in $Q2$'s execution result on database D.* The containment rate is formally a function from **QxQxD** to **R**, where **Q, D** and **R** are the set of all queries, all databases, and the Real numbers, respectively. This function can be directly calculated as follows. Let $Q1(D) = (A, m_1)$ and $Q2(D) = (B, m_2)$ be multisets[1] representing queries $Q1$ and $Q2$ execution results on database D, respectively, then:

$$x\% = \frac{\sum_{x \in (A \cap B)} m_1(x)}{\sum_{x \in A} m_1(x)} * 100$$

Where operator $\cap$ is the regular set intersection operator (in case $Q1$'s execution result is empty, then $Q1$ is 0%-contained in $Q2$). Note that the containment rate is defined only on pairs of queries whose SELECT and FROM clauses are *identical.*

Since we aim to estimate cardinalities using containment rates, we consider only queries with SELECT * clauses, then, given a query Q whose SELECT clause includes specific columns, Q's cardinality is identical to the cardinality of the query with a SELECT * clause instead (as long as the *DISTINCT* keyword is not used). Therefore, in practice, the requirement that the clauses need to be *identical* applies only to the FROM clauses.

2.1 Containment Rate Operator

We denote the containment rate *operator* between queries $Q1$ and $Q2$ on database D as:

$$Q1 \subset^{D}_{\%} Q2$$

Operator $\subset^{D}_{\%}$ returns the containment rate between the given input queries on database D. That is, $Q1 \subset^{D}_{\%} Q2$ returns $x\%$, if $Q1$ is $x\%$-contained in query $Q2$ on database D. For simplicity, we do not mention the *specific* database, as it is usually clear from context. Hence, we write the containment rate operator as $\subset_{\%}$.

3 LEARNED CONTAINMENT RATES

From a high-level perspective, applying machine learning to the containment rate estimation problem is straightforward. Following the training of the CRN model with pairs of queries $(Q1, Q2)$ and the actual containment rates $Q1 \subset_{\%} Q2$, the model is used as an estimator for other, unseen pairs of queries. (Later on, as described in Section 5, we will make use of this model to estimate cardinalities of single queries). There are, however, several questions whose answers determine whether the machine learning model (CRN) will be successful. (1) Which supervised learning algorithm/model should be used. (2) How to represent queries as input and the containment rates as output to the model ("featurization"). (3) How to obtain the initial training dataset ("cold start problem"). Next, we describe how we address each one of these questions.

[1]From Wikipedia: A multiset may be formally defined as a 2-tuple $(S,\ m)$ where S is the underlying set of the multiset, formed from its distinct elements, and $m : S \rightarrow N_{\geq 1}$ is a function from S to the set of the positive integers, giving the multiplicity. The number of occurrences of element x in the multiset is $m(x)$.

3.1 Cold Start Problem

3.1.1 Defining the Database. We generated a training-set, and later on evaluated our model on it, using the IMDb database. IMDb contains many correlations and has been shown to be very challenging for cardinality estimators [26]. This database contains a plethora of information about movies and related facts about actors, directors, and production companies, with more than 2.5M movie titles produced over 130 years (starting from 1880) by 235,000 different companies with over 4M actors.

3.1.2 Generating the Development Dataset. Our approach for solving the "cold start problem" is to obtain an initial training corpus using a specialized queries generator that randomly generates queries based on the IMDB schema and the actual columns values. Our queries generator generates the dataset in three main steps. In the first step (similarly to MSCN's queries generator), it repeatedly generates multiple SQL queries as follows. It randomly chooses a set of tables t ($t = \{bt_1, bt_2, ..., bt_{|t|}\}$). Then, it adds $|t| - 1$ join edges to the query, $bt_i.col_a = bt_{i+1}.col_b$, $1 \leq i < |t|$. Each of these joins is on a column containing the ID of movies (each table in IMDB has such a column). Note that when $|t| = 1$, there are no joins in the query.

For each base table bt in t, it uniformly draws the number of query predicates p_{bt} ($0 \leq p_{bt} \leq$ number of columns in table bt). Subsequently, for each predicate it uniformly draws a column from the relevant table bt, a predicate type ($<$, $=$, *or* $>$), and a value from the corresponding column values range in the database. To avoid a combinatorial explosion, and to simplify the problem that the model needs to learn, we force the queries generator to create queries with up to two joins and let the model generalize to a larger number of joins (that is, the maximum cardinality of set t is 3). Note that all the generated queries include a SELECT * clause. They are denoted as *initial-queries.*

To create pairs of queries that are contained in each other with different containment rates, we generate, in the second step, queries that are "similar" to the *initial-queries*, but still, different from them, as follows. For each query Q in *initial-queries*, the generator repeatedly creates multiple queries by randomly changing query Q's predicates' types, or the predicates' values, and by randomly adding additional predicates to the original query Q. This way, we create a "hard" dataset, which includes pairs of queries that look "similar", but having mutual containment rates that vary significantly. Finally, in the third and last step, using the queries obtained from both previous steps, the queries generator generates pairs of queries whose FROM clauses are identical.

After generating the dataset, we execute the dataset queries on the IMDb database, to obtain their true containment rates and skip query pairs that include a query with an empty result set. Using this process, we obtain an initial training set of 100,000 pairs of queries with zero to two joins. We split the training samples into 80% training samples and 20% validation samples.

3.2 Model

Featurizing all the queries' literals and predicates as one "big hot vector", over all the possible words that may appear in the queries, is impractical. Also, serializing the queries' SELECT, FROM, and WHERE clauses elements into an ordered sequence of elements, is not practical, since the order in these clauses is arbitrary. Thus, standard deep neural network architectures such as simple multi-layer perceptrons [6], convolutional neural networks [6], or recurrent neural networks [6], are not directly applicable to our problem.

Our *Containment Rate Network* (CRN) model uses a specialized vector representation for representing the input queries and the output containment rates. As depicted in Figure 1, the CRN model runs in three main stages. Consider an input queries pair $(Q1, Q2)$. In the first stage, we convert $Q1$ (resp., $Q2$) into a set of vectors $V1$ (resp., $V2$). Thus $(Q1, Q2)$ is represented by $(V1, V2)$. In the second stage, we convert set $V1$ (resp., $V2$) into a unique single representative vector $Qvec1$ (resp., $Qvec2$), using a specialized neural network, MLP_i, for each set separately. In the third stage, we estimate the containment rate $Q1 \subset_{\%} Q2$, using the representative vectors $Qvec1$ and $Qvec2$, and another specialized neural network, MLP_{out}.

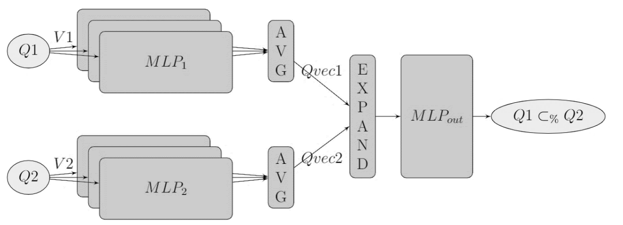

Figure 1: CRN Model Archeticture.

3.2.1 *First Stage, from $(Q1, Q2)$ to $(V1, V2)$.* In the same way as MSCN model [22], we represent each query Q as a collection of three sets (T, J, P). T is the set of all the tables in Q's FROM clause. J is the set of all the joins (i.e., join clauses) in Q's WHERE clause. P is the set of all the (column) predicates in Q's WHERE clause. Using sets T, J, and P, we obtain a set of vectors V representing the query, as described later. Unlike MSCN, in our model all the vectors of set V have the same dimension and the same segmentation as depicted in Table 1, where $\#T$ is the number of all the tables in the database, $\#C$ is the number of all the columns in all the database tables, and $\#O$ is the number of possible predicates operators. In total, the vector dimension is $\#T + 3 * \#C + \#O + 1$, denoted as L.

The queries tables, joins and column predicates (sets T, J and P) are inseparable, hence, treating each set individually using different neural networks may disorientate the model. Therefore, we choose to featurize these sets using the same vector format in order to ease learning.

Type	Table	Join		Column Predicate		
Segment	T-seg	J1-seg	J2-seg	C-seg	O-seg	V-seg
Segment size	$\#T$	$\#C$	$\#C$	$\#C$	$\#O$	1
Featurization	*one hot*	*one hot*	*one hot*	*one hot*	*one hot*	*norm*

Table 1: Vector Segmentation.

Element of sets T, J, and P, are represented by vectors as follows (see a simple example in Figure 2). All the vectors have the same dimension L. Each table $t \in T$ is represented by a unique one-hot vector (a binary vector of length $\#T$ with a single non-zero entry, uniquely identifying a specific table) placed in the T-seg segment. Each join clause of the form $(col1, =, col2) \in J$ is represented as follows. $col1$ and $col2$ are represented by a unique one-hot vectors placed in J1-seg and J2-seg segments, respectively. Each predicate of the form $(col, op, val) \in P$ is represented as follows. col and op are represented by a unique one-hot vectors placed in the C-seg and V-seg segments, respectively. val is represented as a normalized value $\in [0, 1]$, normalized using the minimum and maximum values of the respective column, placed in the V-seg segment. For each vector, all the other unmentioned segments are zeroed. Given input queries pair, $(Q1, Q2)$, we convert query $Q1$ (resp., $Q2$) into sets T, J and P, and *each* element of these sets is represented by a vector as described above, together generating set $V1$ (resp., $V2$).

3.2.2 *Second Stage, from $(V1, V2)$ to $(Qvec1, Qvec2)$.* Given set of vectors V_i, we present each vector of the set into a fully-connected one-layer neural network, denoted as MLP_i, converting each vector into a vector of dimension H. The final representation $Qvec_i$ for this set is then given by the average over the individual transformed representations of its elements, i.e.,

$$Qvec_i = \frac{1}{|V_i|} \sum_{v \in V_i} MLP_i(v)$$

$$MLP_i(v) = Relu(vU_i + b_i)$$

Where $U_i \in R^{LxH}$, $b_i \in R^H$ are the learned weights and bias, and $v \in R^L$ is the input row vector. We choose an average (instead of, e.g., sum) to ease generalization to different numbers of elements in the sets, as otherwise the overall magnitude of $Qvec$ would vary depending on the number of elements in the set V_i.

3.2.3 *Third Stage, from $(Qvec1, Qvec2)$ to $Q1 \subset_{\%} Q2$.* Given the representative vectors of the input queries,$(Qvec1, Qvec2)$, we aim to predict the containment rate $Q1 \subset_{\%} Q2$ as accurately as possible. Since we do not know what a "natural" containment rate measure is in the representative queries vector space, encoded by the neural networks of the second step, we use a fully-connected two-layer neural network, denoted as MLP_{out}, to compute the estimated containment rate of the input queries, leaving it up to this neural network to learn the correct containment rate measure.

MLP_{out} takes as input a vector of size $4H$ which is constructed using function *ExpandFunction* that creates a row of concatenated vectors of size $4H$ using vectors $Qvec1$ and $Qvec2$. We use this function in order to provide the final network, MLP_{out}, with additional information that may enhance its learning and thus obtain more accurate containment rates estimations.

The first layer in MLP_{out} converts the input vector into a vector of size $2H$. The second layer converts the obtained vector of size $2H$, into a single value representing the containment rate.

$$\hat{y} = MLP_{out}(Expand(Qvec1, Qvec2))$$

$$MLP_{out}(v) = Sigmoid(ReLU(vU_{out1} + b_{out1})U_{out2} + b_{out2})$$

$$Expand(v_1, v_2) = [v_1,\ v_2,\ abs(v_1 - v_2),\ v_1 \odot v_2]$$

Here, $\hat{y}$ is the estimated containment rate (a number in $[0, 1]$), $U_{out1} \in R^{4Hx2H}$, $b_{out1} \in R^{2H}$ and $U_{out2} \in R^{2Hx1}$, $b_{out2} \in R^1$ are the learned weights and bias, abs is the absolute value function, and $\odot$ is the dot-product function.

We use the $ReLU$[2] activation function for hidden layers in all the neural networks, as they show strong empirical performance advantages and are fast to evaluate.

In the final step, we apply the $Sigmoid$[3] activation function in the second layer to output a float value in the range [0,1], as the containment rate values are within this interval. Therefore, we do not apply any featurization on the containment rates (the output of the model) and the model is trained with the actual containment rate values without any featurization steps.

[2]ReLU(x) = max(0,x); see [36].
[3]Sigmoid(x) = $1/(1 + e^{-x})$; see [36].

3.2.4 *Loss Function.* Since we are interested in minimizing the ratio between the predicted and the actual containment rates, we use the q-error metric in our evaluation. We train our model to minimize the mean q-error [33], which is the ratio between an estimated and the actual containment rate (or vice versa). Let y be the true containment rate, and $\hat{y}$ the estimated rate, then the q-error is defined as follows.

$$q - error(y, \hat{y}) \;=\; \hat{y} > y \;?\; \frac{\hat{y}}{y} \;:\; \frac{y}{\hat{y}}$$

The q-error is not defined when y (or y') equals zero. Therefore, in creating the training and testing datasets we skip query pairs that include a query with an empty results set (see Section 3.1.2).

In addition to optimizing the mean q-error, we also examined the mean squared error (MSE) and the mean absolute error (MAE) as optimization goals. MSE and MAE would optimize the squared/absolute differences between the predicted and the actual containment rates. Optimizing with theses metrics makes the model put less emphasis on heavy outliers (that lead to large errors). Therefore, we decided to optimize our model using the q-error metric which yielded better results.

3.3 Training and Testing Interface

Building CRN involves two main steps. (1) Generating a random training set using the schema and data information as described in Section 3.1. (2) Repeatedly using this training data, we train the CRN model as described in Section 3.2 until the mean q-error of the validation test starts to converges to its best absolute value. That is, we use the early stopping technique [39] and stop the training before convergence to avoid over-fitting. Both steps are performed on an immutable snapshot of the database.

After the training phase, to predict the containment rate of an input query pair, the queries first need to be transformed into their feature representation, and then they are presented as input to the model, and the model outputs the estimated containment rate (Section 3.2). We train and test our model using the Tensor-Flow framework [34], and make use of the efficient Adam optimizer [21] for training the model.

3.4 Hyperparameter Search

To optimize our model's performance, we conducted a search over its hyperparameter space. In particular, we focused on tuning the neural networks hidden layer size (H) as we found out that this hyperparameter has the most impact on the results.

Note that the same H value is shared in all the neural networks of the CRN model, as described in section 3.2. During the tuning of the size hyperparameter of the neural network hidden layer, we found that increasing the size of our hidden layer generally led to an increase in the model accuracy, till it reached the best mean q-error on the validation test. Afterwards, the results began to decline in quality because of over-fitting (see Figure 3). Hence, we choose a hidden layer of size 512, as a good balance between accuracy and training time.

Overall, we found that our model performs uniformly well across a wide range of settings when considering different batch sizes and learning rates. We use a learning rate of 0.001, and batch size of 128, as these settings lead to the best results on the validation test.

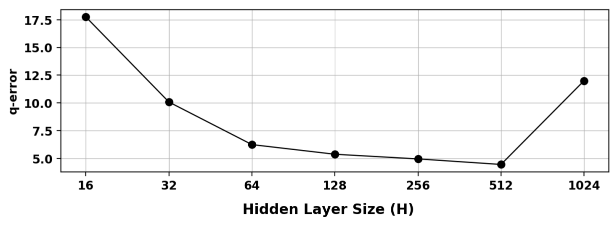

Figure 3: The mean q-error on the validation set with different hidden layer sizes.

3.5 Model Computational Costs

We analyze the training, prediction, and space costs of the CRN model with the default hyperparameters (H=512, batch size=128, learning rate=0.001).

3.5.1 *Training Time.* Figure 4 shows how the mean q-error of the validation set decreases with additional epochs, until convergence to a mean q-error of around 4.5. The CRN model requires almost 120 passes on the training set to converge. On average, measured across six runs, a training run with 120 epochs takes almost 200 minutes.

3.5.2 *Prediction Time.* The prediction process is dominated by converting the input queries into the corresponding vectors, and presenting these vectors as input to the CRN model. On average, the prediction time is 0.5ms per single pair of queries, including the overhead introduced by the Tensor-Flow framework.

3.5.3 *Model Size.* The CRN model includes all the learned parameters mentioned in Section 3.2 (U_1, U_2, U_{out1}, U_{out2}, b_1, b_2, b_{out1}, b_{out2}). In total, there are $2*L*H+8*H^2+6*H+1$ learned parameters. In practice, the size of the model, when serialized to disk, is roughly $1.5MB$.

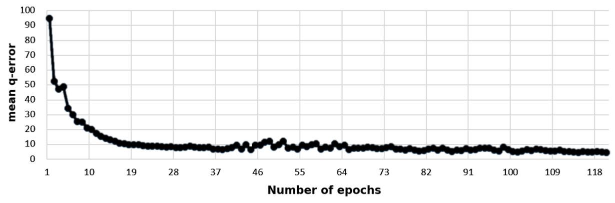

Figure 4: Convergence of the mean q-error on the validation set.

4 CONTAINMENT EVALUATION

Since the focus of this paper is on cardinality estimation using containment rates, in this section we only briefly present the containment evaluation results of the CRN model when compared to other (baseline) methods. In the following sections, we present in detail the experiments of the cardinality estimation technique.

Since to the best of our knowledge, the problem of determining containment rate has not been addressed till now, we use a transformation as described in Section 4.1 below.

4.1 From Cardinality to Containment

To our knowledge, this is the first work to address the problem of containment rate estimation. In order to compare our results with different baseline methods, we used existing cardinality estimation methods to predict the containment rates, using the Crd2Cnt transformation, as depicted in the middle part diagram in Figure 5. (This transformation will be used also in our technique to improve existing cardinality estimation models in Section 7).

4.1.1 The Crd2Cnt Transformation. Given a cardinality estimation model M, we can convert it to a containment rate estimation model using the Crd2Cnt transformation which returns a model M' for estimating containment rates. The obtained model M' functions as follows. Given input queries $Q1$ and $Q2$, whose containment rate $Q1 \subset_{\%} Q2$ needs to be estimated:

- Calculate the cardinality of query $Q1 \cap Q2$ using M.
- Calculate the cardinality of query $Q1$ using M.
- Then, the containment rate estimate is:

$$Q1 \subset_{\%} Q2 = \frac{|Q1 \cap Q2|}{|Q1|}$$

Here, $Q1 \cap Q2$ is the intersection query of $Q1$ and $Q2$ whose SELECT and FROM clauses are identical to $Q1$'s (or $Q2$'s) clauses, and whose WHERE clause is $Q1$'s AND $Q2$'s WHERE clauses. Note that, by definition, if $|Q1| = 0$ then $Q1 \subset_{\%} Q2 = 0$.

Given model M, we denote the obtained model M', via the Crd2Cnt transformation, as Crd2Cnt(M).

4.2 Experimental Results

We compared the CRN model predictions to those based on the other examined cardinality estimation models, using the Crd2Cnt transformation. We evaluated the models with several workloads, that included over 2000 queries with zero to five joins, on the challenging real-world IMDB database [26]. In terms of mean q-error [33], the CRN model reduced the mean q-errors by a factor of roughly 8 compared with the estimates obtained from Crd2Cnt(PostgreSQL) and Crd2Cnt(MSCN).

To provide a fuller picture, in Table 2 we show the percentiles, maximum, and mean q-errors, on one of the examined evaluation workloads. Additional details may be found in *arXiv* [18].

	50th	75th	90th	95th	99th	max	mean
Crd2Cnt(PostgreSQL)	4.5	46.22	322	1330	39051	316122	1345
Crd2Cnt(MSCN)	4.1	17.85	157	754	14197	768051	1238
CRN	**3.64**	**13.19**	**96.6**	**255**	**2779**	**56965**	**161**

Table 2: Estimation errors on 1200 examined queries with zero to five joins, equally distributed in the number of joins. In all the similar tables presented in this paper, we provide the percentiles, maximum, and the mean q-errors of the tests. The *p*'th percentile, is the q-error value below which *p*% of the test q-errors are found. For example, 50% of the CRN test q-errors are smaller than 3.64.

5 CARDINALITY ESTIMATION USING CONTAINMENT RATES

In this section we consider one application of the proposed containment rate estimation model: cardinality estimation. We introduce a novel approach for estimating cardinalities using query containment rates, and we show that using the proposed approach, we improve cardinality estimations significantly, especially in the case when there are multiple joins.

A traditional query optimizer is crucially dependent on cardinality estimation, which enables choosing among different plan alternatives by using the cardinality estimation of intermediate results within query execution plans. Therefore, the query optimizer must use reasonably good estimates. However, estimates produced by all widely-used database cardinality estimation models are routinely significantly wrong (under/over-estimated), resulting in not choosing the best plans, leading to slow executions [26].

Three principal approaches for estimating cardinalities have emerged. (1) Using database profiling [1]. (2) Using histograms [3, 7]. (3) Using sampling techniques [5, 27, 37]. Recently, deep learning neural networks were also used for solving this problem [22, 45]. However, all these approaches, with all the many attempts to improve them, have conceptually addressed the problem *directly* in the same way, as a black box, where the input is a query, and the output is its cardinality estimation, as described in the leftmost diagram in Figure 5. In our proposed approach, we address the problem differently, and we obtain better estimates as described in Section 6.

In prior works, the answers to previous queries were used for speeding up new queries, by incrementally updating histograms, and in the context of query re-optimization [3, 7, 13, 20]. Similarly, using the CRN model for predicting containment rates, we are making use of these previous answers to reveal the underlying relations between the new queries and the previous ones.

Our new technique for estimating cardinalities mainly relies on two key ideas. The first one is the new framework in which we solve the problem. The second is the use of a *queries pool* that maintains multiple previously executed queries along with their actual *cardinalities*, as part of the database meta information. The queries pool provides new information that enables our technique to achieve better estimates. Using a containment rate estimation model, we make use of previously executed queries along with their actual cardinalities to estimate the result-cardinality of a new query. This is done with the help of a simple transformation from the problem of containment rate estimation to the problem of cardinality estimation (see Section 5.1).

5.1 From Containment to Cardinality

Using a containment rate estimation models, we can obtain cardinality estimates using the Cnt2Crd transformation, as depicted in the rightmost diagram in Figure 5.

5.1.1 The Cnt2Crd Transformation. Given a containment rate estimation model[4] M, we convert it to a cardinality estimation model using the Cnt2Crd transformation which returns a model M' for estimating cardinalities. The obtained model M' functions as follows. We are given a "new" query, denoted as Q_{new}, as input to cardinality estimation. Assume that there is an "old" query, denoted as Q_{old}, whose FROM clause is the same as Q_{new}'s

[4]The term "model" may refer to an ML model or simply to a method.

Figure 5: A novel approach, from cardinality estimation to containment rate estimation, and back to cardinality estimation by using a queries pool.

FROM clause, that has already been executed over the database, and therefore $|Q_{old}|$ is known, then M' functions as follows:

- Calculate $x\_rate = Q_{old} \subset_{\%} Q_{new}$ using M.
- Calculate $y\_rate = Q_{new} \subset_{\%} Q_{old}$ using M.
- Then, the cardinality estimate equals to:

$$|Q_{new}| = \frac{x\_rate}{y\_rate} * |Q_{old}|$$

provided that $y\_rate = Q_{new} \subset_{\%} Q_{old} \neq 0$. This is true, since:

$$x\_rate = \frac{|Q_{new} \cap Q_{old}|}{|Q_{old}|}, \;\; y\_rate = \frac{|Q_{new} \cap Q_{old}|}{|Q_{new}|}$$

And therefore,

$$\frac{x\_rate}{y\_rate} = \frac{|Q_{new} \cap Q_{old}|}{|Q_{old}|} * \frac{|Q_{new}|}{|Q_{new} \cap Q_{old}|} = \frac{|Q_{new}|}{|Q_{old}|}$$

where the query intersection operator, ∩, is as defined in Section 4.1.1. Given model M, we denote the obtained model M', via the Cnt2Crd transformation, as Cnt2Crd(M).

5.2 Queries Pool

Our technique for estimating cardinality relies mainly on a queries pool that includes records of multiple queries.

The queries pool is envisioned to be an additional component of the DBMS, along with all the other customary components. It includes multiple queries with their actual cardinalities[5], but without the queries execution results. Therefore, holding such a pool in the DBMS as part of its meta information does not require significant storage space or other computing resources. Maintaining a queries pool in the DBMS is thus a reasonable expectation. The DBMS continuously executes queries, and therefore, we can easily configure the DBMS to store these queries along with their actual cardinalities in the queries pool.

In addition, we may construct in advance a queries pool using a queries generator that randomly creates multiple queries with many of the possible joins, and with different column predicates. We then execute these queries on the database to obtain and save their actual cardinalities in the queries pool.

Notice that we can combine both approaches (actual computing and a generator) to create the queries pool. The advantage of the first approach is that in a real-world situation, queries that are posed in sequence by the same user, may be similar and therefore we can get more accurate cardinality estimates. The second approach helps in cases where the queries posed by users are diverse (e.g., different FROM clauses). Therefore, in such cases, we need to make sure, in advance, that the queries pool contains sufficiently many queries that cover all the possible cases.

[5]Due to limited space, we do not detail the efficient hash-based data structures used to implement the queries pool.

Given a query Q whose cardinality is to be estimated , it is possible that we fail to find any appropriate query, in the queries pool, to match with query Q. This happens when all the queries in the queries pool have a different FROM clause than that of query Q, or that they are not contained at all in query Q. In such cases we can always use the *known* basic cardinality estimation models. In addition, we can make sure that the queries pool includes queries with the most frequently used FROM clauses, with empty column predicates. That is, queries of the following form:

$$SELECT\ *\ FROM\ \ -set\ of\ tables-\ \ WHERE\ TRUE$$

In this case, for most of the queries posed in the database, there is at least one query that matches in the queries pool with the given query, and hence, we can estimate the cardinality (perhaps less accurately) without resorting to the basic cardinality estimation models.

5.3 A Cardinality Estimation Technique

Consider a new query Q_{new}, and assume that the DBMS includes a queries pool as previously described. To estimate the cardinality of Q_{new} accurately, we use *multiple* "old" queries instead of *one* query, using the same Cnt2Crd transformation of Section 5.1.1, as described in Figure 6.

```
EstimateCardinality(Query $Q_{new}$, Queries Pool $QP$):
    $results$ = empty list

    For every pair ($Q_{old}$, $|Q_{old}|$) in $QP$:
        if $Q_{old}$'s FROM clause ≠ $Q_{new}$'s FROM clause:
            continue
        Calculate $x\_rate = Q_{old} \subset_{\%} Q_{new}$
        Calculate $y\_rate = Q_{new} \subset_{\%} Q_{old}$
        if $y\_rate <= epsilon$: /* y essentially zero */
            continue
        $results$.append($x\_rate/y\_rate * |Q_{old}|$)

    return F($results$)
```

Figure 6: Cardinality Estimation Technique.

Algorithm EstimateCardinality considers all the *matching* queries whose FROM clauses are identical to Q_{new}'s FROM clause. For each matching query, we estimate Q_{new}'s cardinality using the Cnt2Crd transformation and save the estimated result in the *results* list. The final cardinality is obtained by applying the final function, F, that converts all the estimated results recorded in the *results* list, into a single final estimation value. Note that the technique can be easily parallelized since each iteration in the For loop is independent, and thus can be calculated in parallel.

5.3.1 *Comparing Different Final Functions.*
We examined various final functions (F), including:

- Median, returning the median value of the *results* list.
- Mean, returning the mean value of the *results* list.
- Trimmed mean, returning the trimmed mean of the *results* list without the 25% outliers (trimmed removes a designated percentage of the largest and smallest values before calculating the mean).

Experimentally, the cardinality estimates using the various functions were very similar in terms of q-error. But the Median function yielded the best estimates as it is more stable to outliers (we do not detail these experiments due to limited space).

5.3.2 *Early Stopping.*
The described cardinality estimation technique considers all the matching queries to the given input query on the queries pool. However, we can configure the technique for early stopping. That is, taking into account all the matching queries in the pool is not always necessary. We can set a limit on the number of matching queries that are used to estimate the input query cardinality, and thus obtain predictions faster by considering only a subset of the matching queries.

In the reported experiments we consider all the queries in the pool since the pool size is limited as described in Section 6.2.

6 CARDINALITY EVALUATION

We evaluate our proposed technique for estimating cardinality, with different test sets, while using the CRN model as defined in Section 3.2 for estimating containment rates.

We compare our cardinality estimates with those of the PostgreSQL version 11 cardinality estimation component [1], a simple and commonly used method for cardinality estimation. In addition, we compare our cardinality estimates with those of the MSCN model [22]. MSCN was shown to be superior to the best methods for estimating cardinalities such as Random Sampling (RS) [5, 37] and the state-of-the-art Index-Based Join Sampling (IBJS) [27].

In order to make a fair comparison between the CRN model and the MSCN model, we train the MSCN model with the *same* data that was used to train the CRN model. The CRN model takes two queries as input, whereas the MSCN model takes one query as input. Therefore, to even the playing field, we created the training dataset for the MSCN model as follows. For each pair of queries ($Q1, Q2$) used in training the CRN model, we added the following two input queries to the MSCN training set:

- $Q1 \cap Q2$, along with its actual cardinality.
- $Q1$, along with its actual cardinality.

Finally, we ensure that the training set includes only unique queries without repetition. This way, both models, MSCN and CRN, are trained with the *same* information. Note that comparing with the profiling and histograms-based PostgreSQL does not require generating training set.

We create the test workloads using the same queries generator used for creating the training set of the CRN and the MSCN models (described in Section 3.1.2), while skipping its last step. That is, we only run the first two steps of the generator. The third step creates query pairs which are irrelevant for the cardinality estimation task.

6.1 Evaluation Workloads

We evaluate our approach on the (challenging) IMDb dataset, using three different query workloads:

- crd_test1, a synthetic workload generated by the same queries generator that was used for creating the training data of the CRN model, as described in Section 3.1 (using a different random seed) with 450 unique queries, with zero to two joins.
- crd_test2, a synthetic workload generated by the same queries generator as the training data of the CRN model, as described in Section 3.1 (using a different random seed) with 450 unique queries, with zero to *five* joins. This dataset is designed to examine how the technique generalizes to additional joins.
- scale, another synthetic workload, with 500 unique queries, derived from the MSCN test set as introduced in [22]. This dataset is designed to examine how the technique generalizes to queries that were *not* created with the same queries generator used for training.

number of joins	**0**	**1**	**2**	**3**	**4**	**5**	**overall**
crd_test1	150	150	150	0	0	0	450
crd_test2	75	75	75	75	75	75	450
scale	115	115	107	88	75	0	500

Table 3: Distribution of joins.

6.2 Queries Pool

Our technique relies on a queries pool, we thus created a synthetic queries pool, QP, generated by the same queries generator as the training data of the containment rate estimation model, as described in Section 3.1 (using a different random seed) with 300 queries, equally distributed among all the possible FROM clauses over the database. In particular, QP, covers all the possible FROM clauses that are used in the test workloads. Note that, there are no shared queries between the QP queries and the test workloads queries.

Consider a query Q whose cardinality needs to be estimated. On the one hand, the generated QP contains "similar" queries to query Q. These can help the machine in predicting the cardinality. On the other hand, it also includes queries that are not similar at all to query Q. These may cause erroneous cardinality estimates. Therefore, the generated queries pool QP, faithfully represents a real-world situation.

6.3 Experimental Environment

In all the following cardinality estimation experiments, for predicting the cardinality of a given query Q in a workload W, we use the whole queries pool QP as described in Section 6.2 with all its 300 queries. That is, the "old" queries used for predicting cardinalities, are the queries of QP. In addition, in all the experiments we use the Median function as the final F function.

6.4 The Quality of Estimates

Figure 7 depicts the q-error of the Cnt2Crd(CRN) model as compared to MSCN and PostgreSQL on the crd_test1 workload. While PostgreSQL's errors are more skewed towards the positive domain, MSCN is competitive with Cnt2Crd(CRN) in all the described values. As can be seen in Table 4, while MSCN provides the best results in the margins, the Cnt2Crd(CRN) model is more accurate in 75% of the tests (as it is less accurate, in the margins, than MSCN with queries that have up to two joins). In addition, we show in the next section (Section 6.5) that the Cnt2Crd(CRN) model is more robust when considering queries with more joins than in the training dataset.

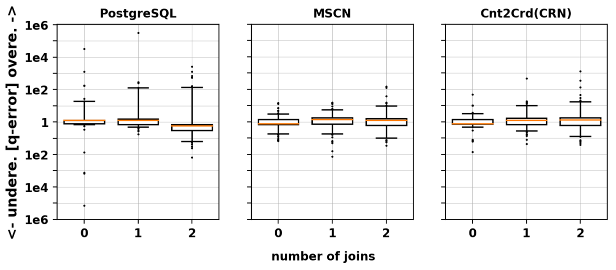

Figure 7: Estimation errors on the crd_test1 workload. In all the similar plots presented in this paper, the box boundaries are at the 25th/75th percentiles and the horizontal lines mark the 5th/95th percentiles. Hence, 50% of the tests results are located within the box boundaries, and 90% are located between the horizontal lines. The orange horizontal line mark the 50th percentile.

	50th	75th	90th	95th	99th	max	mean
PostgreSQL	1.74	3.72	22.46	149	1372	499266	1623
MSCN	2.11	4.13	**7.79**	**12.24**	**51.04**	**184**	**4.66**
Cnt2Crd(CRN)	**1.83**	**3.71**	10.01	18.16	76.54	1106	9.63

Table 4: Estimation errors on the crd_test1 workload.

6.5 Generalizing to Additional Joins

We examine how our technique generalizes to queries with additional joins, without having seen such queries during training. To do so, we use the crd_test2 workload which includes queries with zero to *five* joins. Recall that we trained both the CRN model and the MSCN model only with query pairs that have between zero and two joins.

From Tables 5 and 6, and Figure 8, it is clear that Cnt2Crd(CRN) model is significantly more robust in generalizing to queries with additional joins. This is clearly illustrated in the Cnt2Crd(CRN) box plot. The boxes are almost within the same q-error interval, close to q-error 1, which is the best q-error (obtained when an estimate is 100% accurate). In terms of mean q-error, the Cnt2Crd(CRN) model reduces the mean by a factor x100 and x1000 compared with MSCN and PostgreSQL, respectively.

	50th	75th	90th	95th	99th	max	mean
PostgreSQL	9.22	289	5189	21202	576147	4573136	35169
MSCN	4.49	119	3018	6880	61479	388328	3402
Cnt2Crd(CRN)	**2.66**	**6.50**	**18.72**	**72.74**	**528**	**6004**	**34.42**

Table 5: Estimation errors on the crd_test2 workload.

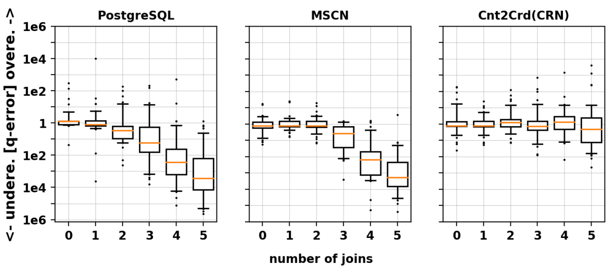

Figure 8: Estimation errors on the crd_test2 workload.

	50th	75th	90th	95th	99th	max	mean
PostgreSQL	229	3326	22249	166118	2069214	4573136	70569
MSCN	121	1810	6900	25884	83809	388328	6801
Cnt2Crd(CRN)	**4.28**	**10.84**	**43.71**	**93.11**	**1103**	**6004**	**61.26**

Table 6: Estimation errors on the crd_test2 workload considering only queries with three to five joins.

To highlight these improvements, we describe, in Table 7 and Figure 9, the mean and median q-error for each possible number of joins separately (note the logarithmic y-axis scale in Figure 9).

The known cardinality estimation models suffer from producing under-estimated results and errors that grow exponentially as the number of joins increases [14]. This also happens in the cases we examined. The Cnt2Crd(CRN) model was better at handling additional joins (even though CRN was trained only with queries with up to two joins, as was MSCN). The reason why the Cnt2Crd(CRN) model successfully generalizes to additional joins lies in its use of the queries pool. The queries pool contains queries with a *similar number of joins* as the input queries, along with their true cardinalities. The underlying CRN model estimates the containment rates accurately even when considering a high number of joins. As a result, the Cnt2Crd(CRN) cardinality estimates are accurate as well.

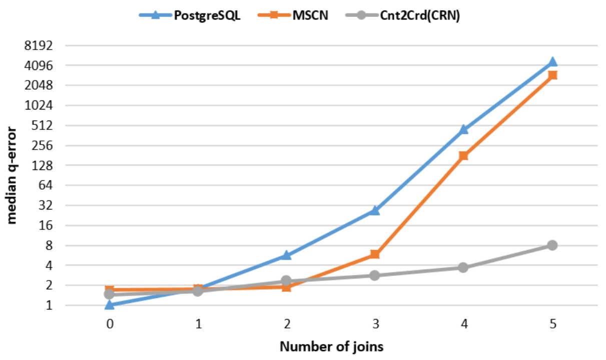

Figure 9: Q-error medians for each number of joins.

number of joins	0	1	2	3	4	5
PostgreSQL	10.41	216	25.38	355	4430	210657
MSCN	**3.44**	3.56	**3.31**	81.95	5427	14895
Cnt2Crd(CRN)	12.43	**3.54**	6.77	**23.24**	**30.51**	**129**

Table 7: Q-error means for each number of joins.

6.6 Generalizing to Different Kinds of Queries

In this experiment, we explore how the Cnt2Crd(CRN) model generalizes to a workload that was not generated by the same queries generator that was used for creating the CRN model training set. To do so, we examine the *scale workload* that is generated using another queries generator in [22]. As shown in Table 8, Cnt2Crd(CRN) is clearly more robust than MSCN and PostgreSQL in all the described percentiles. Examining Figure 10, it is clear that the Cnt2Crd(CRN) model is significantly more robust with queries with 3 and 4 joins. Recall that the *QP* queries pool in this experiment was not changed, while the scale workload is derived from *another* queries generator. In summary, this experiment shows that Cnt2Crd(CRN) generalizes well to workloads that were created with a different generator than the one used to create the training data.

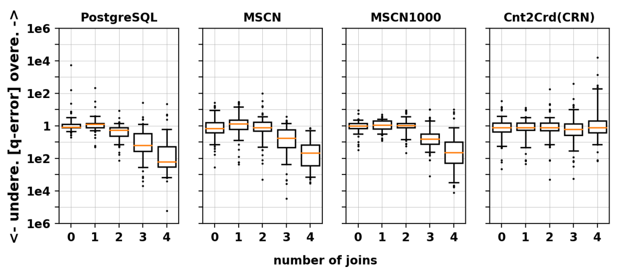

Figure 10: Estimation errors on the scale workload.

	50th	75th	90th	95th	99th	max	mean
PostgreSQL	2.62	15.42	183	551	2069	233863	586
MSCN	3.76	16.84	100	448	3467	47847	204
Cnt2Crd(CRN)	**2.53**	**5.88**	**24.02**	**95.26**	**598**	**19632**	**69.85**

Table 8: Estimation errors on the scale workload.

To further examine how Cnt2Crd(CRN) generalizes, we conducted the following experiment. We compared the Cnt2Crd(CRN) model with an improved version of the MSCN model that combines the deep learning approach and sampling techniques by using samples of 1000 materialized base tables, as described in [22]. We denote this model as MSCN1000.

We make the test "easier" for MSCN1000 model by training the MSCN1000 model with a training set that was created with the *same* queries generator that was used for generating the scale workload. As depicted in Figure 10, the MSCN1000 model is more robust in queries with zero to two joins, still, the Cnt2Crd(CRN) model is superior on queries with additional joins. Recall that the CRN model training set *was not changed*, while the MSCN1000 model was trained with queries obtained from the *same* queries generator that was used for creating the test (i.e., scale) workload. In addition, note that the MSCN1000 model uses sampling techniques whereas Cnt2Crd(CRN) does not. Thus, this experiment further demonstrates the superiority of Cnt2Crd(CRN) in generalizing to additional joins.

We obtain these improvements for the same reason described in Section 6.5. The CRN model is more robust in generalizing for additional unseen (during training) joins. As a result, the Cnt2Crd(CRN) model generalizes well for cardinality estimation.

7 IMPROVING EXISTING CARDINALITY ESTIMATION MODELS

In this section we describe how existing cardinality estimation models can be improved using the idea underlining our proposed technique. The proposed technique for improving existing cardinality estimation models relies on the same technique for predicting cardinalities using a containment rate estimation model, as described in Section 5.3.

In the previous section we used the CRN model in predicting containment rates. CRN can be replaced with *any* other method for predicting containment rates. In particular, it can be replaced with any existing cardinality estimation model after "converting" it to estimating containment rates using the Crd2Cnt transformation, as described in Section 4.1.

At first glance, our proposed technique seems to be a more complicated method for solving the problem of estimating cardinalities. However, we show that by applying it to known existing models, we improve their estimates, without changing the models themselves. These results indicate that the traditional approach, which directly addressed this problem, straightforwardly, using models to predict cardinalities, can be improved upon.

In the remainder of this section, we described the proposed approach, and show how existing cardinality estimation methods are significantly improved upon, by using this technique.

7.1 Approach Demonstration

Given an existing cardinality estimation model M, we first convert M to a model M' for estimating containment rates, using the Crd2Cnt transformation, as described in Section 4.1. Afterwards, given the obtained containment rate estimation model M', we convert it to a model M'' for estimating cardinalities, using the Cnt2Crd transformation, as described in Section 5.3, which uses a queries pool.

To summarize, our technique converts an existing cardinality estimation model M to an intermediate model M' for estimating containment rates, and then, using M' we create a model M'' for estimating cardinalities with the help of the queries pool, as depicted in Figure 5 from left to right.

For clarity, given cardinality estimation model M, we denote the model M'' described above, i.e., model Cnt2Crd(Crd2Cnt(M)), as *Improved M* model.

7.2 Existing Models vs. Improved Models

We examine how our proposed technique improves the PostgreSQL and the MSCN models, by using the crd_test2 workload as defined in Section 6.1, as it includes the most number of joins. Table 9 depicts the estimates when using directly the PostgreSQL or MSCN models, compared with the estimates when adopting our technique with each one of these models (i.e., the Improved PostgreSQL model and the Improved MSCN model). Examining the results, it is clear that the proposed technique significantly improves the estimates (by a factor x7 for PostgreSQL and x122 for MSCN in terms of mean q-error) without changing the models themselves (embedded within the Improved version).

The reason why the existing cardinality estimation models obtain better estimates (when adopting our technique) stems from the fact that these models are generalizing better when they are converted to estimate containment rates. Thus, along with the use of the queries pool, when these models are converted back to estimate cardinalities, they obtain better estimates.

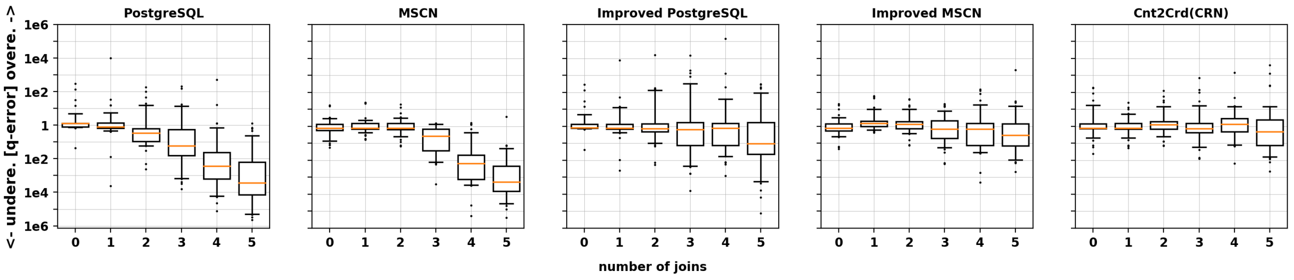

Figure 11: Estimation errors on the crd_test2 workload, compared with all models.

These results highlight the power of our proposed approach. The approach provides an effective and simple technique for improving existing cardinality estimation models. By adopting our approach and crating a queries pool in the database, cardinality estimates can be improved significantly.

	50th	75th	90th	95th	99th	max	mean
PostgreSQL	9.22	289	5189	21202	576147	4573136	35169
Improved PostgreSQL	**2.61**	**19.3**	**155**	**538**	**17697**	**1892732**	**5081**
MSCN	4.49	119	3018	6880	61479	388328	3402
Improved MSCN	**2.89**	**7.43**	**25.26**	**55.73**	**196**	**3184**	**27.78**

Table 9: Estimation errors on the crd_test2 workload.

7.3 Improved Models vs. Cnt2Crd(CRN)

Using the crd_test2 workloade, we examine how our technique improves PostgreSQL and MSCN, compared with Cnt2Crd(CRN). Examining Table 10, it is clear that in 90% of the tests, the best estimates are those obtained when directly using the CRN model to estimate the containment rates, instead of converting existing cardinality estimation models to obtain containment rates (Improved MSCN and Improved PostgreSQL). It seems that the CRN model is more accurate in estimating containment rates since it is directly designed for performing this task, whereas existing cardinality estimation models need to first be converted in order to estimate containment rates using the Crd2Cnt transformation.

	50th	75th	90th	95th	99th	max	mean
Improved PostgreSQL	2.61	19.3	155	538	17697	1892732	5081
Improved MSCN	2.89	7.43	25.26	**55.73**	**196**	**3184**	**27.78**
Cnt2Crd(CRN)	**2.66**	**6.50**	**18.72**	72.74	528	6004	34.42

Table 10: Estimation errors on the crd_test2 workload.

8 CARDINALITY PREDICTION TIME

Using the idea of using containment rates estimations to predict cardinalities, the cardinality prediction process is dominated by calculating the containment rates of the given input query with the relevant queries in the queries pool, and calculating the final function F on these results to obtain the predicted cardinality, as described in Section 5.3. Therefore, the larger the queries pool is, the more accurate the predictions are, and the longer the prediction time is. Table 11, shows the medians and the means estimation errors on the crd_test2 workload, along with the average prediction time for a single query, when using the Cnt2Crd(CRN) model for estimating cardinalities, with different sizes of QP (equally distributed over all the possible FROM clauses in the database) while using the same final function F (the Median function).

QP Size	50	100	150	200	250	300
Median	3.68	2.55	2.63	2.55	2.61	2.66
Mean	1894	90	41	40	35	34
Prediction Time	3.2ms	7.1ms	9.8ms	11.3ms	14.5ms	16.1ms

Table 11: Median and mean estimation errors on the crd_test2 workload, and the average prediction time, considering different queries pool (QP) sizes.

In table 12, we compare the average prediction time for estimating the cardinality of a single query using all the examined models (when using the whole QP queries pool of size 300). The default MSCN model is the fastest model, since it directly estimates the cardinalities without using a queries pool. The Cnt2Crd(CRN) model is the fastest among all the models that use a queries pool. That is, the Cnt2Crd(CRN) model is faster than the Improved MSCN model and the Improved PostgreSQL model. This is the case, since in the Improved MSCN model or the Improved PostgreSQL model, to obtain the containment rates, both models need to estimate cardinalities of two different queries as described in Section 4.1, whereas the CRN model directly obtains a containment rate in one pass within 0.5ms (see Section 3.5).

Although the prediction time of the models that use queries pools is higher than the most common cardinality estimation model (PostgreSQL), the prediction time is still in the order of a few tens milliseconds. In particular, it is similar to the average prediction time of models that use sampling techniques, such as the MSCN version with 1000 base tables samples.

For the results in Table 12, we used a queries pool (QP) of size 300. We could have used a smaller pool (or adapt the early stopping technique as mentioned in Section 5.3.2), resulting in faster prediction time, and still obtaining better results, as depicted in Table 11. Furthermore, all the the models that use queries pools may be easily parallelized as discussed in Section 5.3, and thus, reducing the prediction time (we ran these models serially in the reported tests).

Model	Prediction Time
PostgreSQL	1.75ms
MSCN	0.5ms
MSCN with 1000 samples	33ms
Improved PostgreSQL	70ms
Improved MSCN	35ms
Cnt2Crd(CRN)	16ms

Table 12: Average prediction time of a single query.

9 RELATED WORK

Over the past five decades, conjunctive queries have been studied in the contexts of database theory and database systems. Conjunctive queries constitute a broad class of frequently used queries. Their expressive power is roughly equivalent to that of the Select-Join-Project queries of relational algebra. Numerous problems and associated algorithms have been researched in depth in this context. Chandra and Merlin [10] showed that determining (analytic) containment of conjunctive queries is an NP-complete problem. Finding the minimal number of conditions that need to be added to a query in order to ensure containment in another query is also an NP-complete problem [44]. This also holds in additional settings involving inclusion and functional dependencies [2, 19, 44].

Although determining whether query $Q1$ is contained in query $Q2$ (analytically) in the case of conjunctive queries is an intractable problem in its full generality, there are many tractable cases. For instance, in [41, 42] it was shown that query containment of conjunctive queries could be solved in linear time, if every database (edb) predicate occurs at most twice in the body of $Q1$. In [12] it was proved that for every $k \geq 1$, conjunctive query containment could be solved in polynomial time, if $Q2$ has querywidth smaller than $k + 1$. In addition to the mentioned cases, there are many other tractable cases [8, 9, 16, 40]. Such cases result from imposing syntactic or structural restrictions on the input queries $Q1$ and $Q2$.

Whereas analytic containment was well researched in the past, to our knowledge, the problem of determining the containment rate on a *specific* database has not been investigated. In this paper, we address this problem using ML techniques.

Lately, we have witnessed extensive adoption of machine learning, and deep neural networks in particular, in many different areas and systems, and in particular in databases. Recent research investigates machine learning for classical database problems such as join ordering [31], index structures [23], query optimization [24, 38], concurrency control [4], and recently in cardinality estimation [22, 45]. MSCN, a recently conceived sophisticated NN model, estimates cardinalities [22]. MSCN has been shown to be superior in estimating cardinalities for queries that have the same number of joins as that in the queries training dataset. However, MSCN proved less effective when considering queries with more joins. In this paper, we propose a deep learning-based approach, inspired by the MSCN model, for predicting containment rates on a *specific* database. Additionally, we show how containment rates can be used to predict cardinalities more accurately.

There were many attempts to tackle the problem of cardinality estimation; for example, Random Sampling techniques [5, 37], Index based Sampling [27], and recently deep learning [22, 45]. However, all these attempts have addressed, conceptually, the problem directly in the same way, as a black box, where the input is a query, and the output is the cardinality estimate. In this paper, we address this problem differently by using information (the actual cardinalities) about queries that have already been executed in the database.

A similar idea of using the information contained in the execution results of queries was used to refine and update columns of histograms. In this approach, histograms are incrementally refined every time they are used, by comparing the histogram estimated selectivity to the actual selectivity. This leads to more accurate histograms, and to better cardinality estimates [3, 7, 13, 20].

10 CONCLUSIONS AND FUTURE WORK

We introduced a new problem, that of estimating containment rates between queries over a *specific* database, and introduced the CRN model, a new deep learning model for solving it (inspired by MSCN [22]). We trained CRN with generated queries, uniformly distributed within a constrained space, and showed that CRN usually obtains the best results in estimating containment rates as compared with other examined models.

We introduced a novel approach for cardinality estimation, based on the CRN-based containment rate estimation model, and with the help of a queries pool. We showed the superiority of our new approach in estimating cardinalities more accurately than state-of-the-art approaches. Further, we showed that our approach addresses the weak spot of existing cardinality estimation models, which is handling multiple joins.

In addition, we proposed a technique for improving *any* existing cardinality estimation model (M) without the need to change the model itself, by embedding it within a three step method ($Cnt2Crd(Crd2Cnt(M))$). Observe that it is possible to further improve the estimation by using the obtained improved model $Cnt2Crd(Crd2Cnt(M))$, and generating models (repeatedly), e.g., $Cnt2Crd(Crd2Cnt(Cnt2Crd(Crd2Cnt(M))))$[6]. Given that the estimates of state-of-the-art models are quite fragile, and that our technique for estimating cardinalities is simple, has low overhead, and is quite effective, we believe that it is highly promising and practical for solving the cardinality estimation problem.

We considered cardinality estimation for SQL queries *not* using the *DISTINCT* keyword. For various intermediate results, a query planner requires the set-theoretic cardinality (without duplicates). For example, employing counting techniques for handling duplicates, considering sorting, creating an index or a hash table, and more. This requirement may therefore limit our techniques' usability. One may use our (inaccurate for this case) predictions as proxies. However, a better technique is needed and we are currently evaluating a promising extension of our machine learning approach for predicting set-theoretic cardinalities (i.e., queries with the *DISTINCT* keyword).

To make our containment based approach suitable for more general queries, the CRN model for estimating containment rates can be extended to support other types of queries, such as queries that include complex predicates. In addition, the CRN model can be configured to support databases that are updated from time to time. Next, we discuss some of these extensions, and sketch possible future research directions.

Strings. A simple addition to our current implementation may support equality predicates on strings. To do so, we could hash all the possible string literals in the database into the integer domain (similarly to MSCN). This way, an equality predicate on strings can be converted to an equality predicate on integers, which the CRN model can handle.

Complex predicates. Complex predicates, such as LIKE, are not supported since they are not represented in the CRN model. To support such predicates we need to change the model architecture to handle such predicates. Note that predicates such as BETWEEN and IN, may be converted to ordinary predicates.

EXCEPT Operator. Given a query Q of the form $Q1$ EXCEPT $Q2$, we can estimate its cardinality using our technique as follows:

$$|Q1\ EXCEPT\ Q2| = |Q1| - |Q1 \cap Q2|$$

[6]This observation is due to one of the referee.

UNION Operator. Given a query Q of the from $Q1$ UNION $Q2$, we can estimate its cardinality using our technique as follows:

$$|Q1\ UNION\ Q2| = |Q1| + |Q2|$$

Observe that for handling both the EXCEPT and the UNION operators, the cardinality of queries $Q1$, $Q2$ and $Q1 \cap Q2$ can be estimated using our technique, as they are conjunctive queries.

The OR operator. Given queries that include the OR operator in their WHERE clause, the CRN model does not handle such queries straightforwardly. But, we can handle such queries using a promising recursive algorithm that we are currently evaluating.

Database updates. Thus far, we assumed that the database is static (read-only database). However, in many real world databases, updates occur frequently. In addition, the database schema itself may be changed. To handle updates we can use one of the following approaches:

(1) We can always completely re-train the CRN model with a new updated training set. This comes with a considerable compute cost for re-executing queries pairs to obtain up-to-date containment rates and the cost for re-training the model itself. In this approach, we can easily handle changes in the database schema, since we can change the model encodings prior to re-training it.

(2) We can *incrementally* train the model starting from its current state, by applying new updated training samples, instead of re-training the model from scratch. While this approach is more practical, a key challenge here is to accommodate changes in the database schema. To handle this issue, we could hold, in advance, additional place holders in our model to be used for future added columns or tables. In addition, the values ranges of each column may change when updating the database, and thus, the normalized values may be modified as well. Ways to handle this problem are the subject of current research.

ABSTRACT

Data structures like indexes are typically used to accelerate dataflow execution locating and accessing data more efficiently. The automated management of data structures has been a challenging problem, traditionally constrained by the time and storage required to build and maintain them. As cloud computing is becoming an attractive platform for the execution of dataflows with the usage of compute and storage resources being charged by cloud providers, monetary cost is becoming an equally important factor for the user to consider. In this work, we identify the opportunity of interleaving dataflow and index build operators in the execution schedule to utilize idle slots for the creation of indexes which may be beneficial for future dataflows. In that way, the cost of building indexes can be eliminated without impacting dataflow execution. We propose an online auto-tuning approach to assess the importance of indexes for the workload based on historical data taking into account the trade-off between the dataflow speed-up they offer and the monetary cost needed to maintain them. The results show that the proposed approach can dynamically adapt to the workload and significantly reduce the average execution time and cost spent per dataflow building and maintaining a proper set of indexes.

1 INTRODUCTION

Modern applications face the need to process large amounts of data using complex functions for analysis [40], data mining [32], Extract-Transform-Load processes (ETL) [45], and more. Such rich tasks are typically expressed in high-level languages like Pig Latin [39], optimized and transformed into data processing flows, or simply dataflows, that describe computations (operators) and flow dependencies between them [34],[33],[48].

Dataflows are usually executed on distributed systems to process independent operators in parallel and reduce overall execution time. Among these, clouds have evolved to a popular platform for large-scale data processing, mainly due to the lack of any upfront investment and *elasticity* (the ability to lease resources on demand for as long as needed). Cloud providers offer compute resources in the form of virtual machines (VMs) which are typically charged based on a per quantum pricing scheme (e.g. one hour) such as Amazon EC2 [3], and storage resources which are usually charged per GB per month [5].

Data structures like indexes and materialized views are additionally used to improve the performance of dataflows, encapsulating prior computations to access data more quickly and avoid unnecessarily large data movements during dataflow execution [36]. Building and maintaining indexes may be costly in terms of computation and storage, often exceeding the gain in performance [30]. However, in several cases the costs can be amortized. For example, the time overhead required for the creation of indexes may be reduced by building them in parallel. Also, indexes are usually associated to multiple dataflows and can thus be exploited for the execution of future dataflows. As the existence of indexes may improve application performance, but may also affect the monetary cost incurred [22, 41], it is important to find a good trade-off between these two conflicting objectives. Hence, index tuning (the selection of indexes based on their usefulness) is required to avoid uncontrolled creation and maintenance of data structures. This task may become even more challenging, when the workload is not known a-priori and the set of indexes may change dynamically over time.

We envision a Query-as-a-Service (QaaS) platform to manage the execution of complex dataflow workloads on clouds, like Google's BigQuery[1]. Dataflows, such as exploratory data-intensive queries, are issued sequentially by the user, e.g. a data scientist, to extract knowledge from data. Each dataflow is associated with a set of indexes that can benefit its execution. The service incorporates automated management of suggested indexes by creating and deleting them based on their usefulness on the dataflow workload. These indexes can either be computed automatically or incorporate feedback from administrators to generate useful recommendations [16, 29, 43]. This is an orthogonal problem and the integration of already proposed solutions would easily work with our approach. For example, most index advisors can output a set of indexes that might be useful (e.g., by doing a what-if analysis). This would be the input to our system.

Building a generic model that captures dataflows and indexes is an open research problem, mainly because operators may have arbitrary user code that is often impossible to analyze, and the usefulness of an index may be specific to each dataflow. However, this is beyond the scope of this work. We identify five generic categories of dataflow operators where indexes can be useful:

- *Lookup*. The complexity of finding a particular record from an input table of size n is $O(n)$ when no data structure is used and can be reduced to $O(log\ n)$ using a B-tree index or $O(1)$ using a hash index.

[1]Google Big Query, https://cloud.google.com/products/big-query

- *R*ange select. Selecting records in a particular range from the input can be efficiently performed using a B-Tree index because the leaves of the tree are sorted. The complexity is $O(log\ n) + k$ where k is the number of records in the range.
- *S*orting. The complexity of operators that perform sorting is $O(n \cdot log\ n)$ and can be reduced to $O(n)$ using a B-Tree index.
- *G*rouping. Grouping can be efficiently performed using sorting, as described above.
- *J*oin. Several algorithms, such as nested loops join, hash join, sort-merge join, can be used. Such algorithms are faster when an appropriate index is provided. For example, the complexity of sort-merge join is $O(n + m)$ if the inputs (of size n and m) are sorted.

In this work, we propose an online auto-tuning approach to assess the usefulness of indexes for the execution of dataflows taking into account the trade-off between the dataflow speed-up they offer and the monetary cost needed to maintain them (the storage cost in the cloud). We identify the opportunity to build indexes and eliminate their cost using slots of *idle time* on compute resources. These may be created due to data dependency constraints between the execution of dataflow operators but also the provider's quantized pricing policy. Building entire indexes sequentially using idle compute resources may not be feasible due to the large data volume [41]. Hence, indexes on partitions of tables or files are built independently. In this way, indexes can be built in parallel and, most importantly, may fit inside idle slots. The approach proposed in this work is generic and can be used in several large-scale data processing platforms, like Hadoop [7], Hive [46], or Pig [39]. Several systems like [26, 35, 46] have been developed to provide highly scalable distributed architectures for data processing on the Cloud; however, the monetary cost and the quantized pricing of resources need to be considered [23]. To the best of our knowledge, there is no index management solution that takes into account the monetary cost of using cloud resources, while related work on execution time and cost optimization of dataflows does not consider building and maintaining indexes.

The main contributions of this work are the following:

- We identify the opportunity to use idle slots on compute resources created when executing data-intensive flows due to data dependency constraints between operators but also the quantum-based pricing policy of compute resources.
- We propose an online auto-tuning approach to assess the importance of indexes based on the trade-offs between the dataflow execution speed-up they offer and the monetary cost needed to maintain them.
- We develop two index interleaving algorithms, namely linear program based interleaving and online interleaving algorithms, to utilize idle slots in the dataflow execution schedule and build indexes in parallel without increasing the monetary cost and the time required for the execution of each dataflow.
- We provide an experimental evaluation to show the effectiveness of the proposed approach to accelerate dataflow execution and eliminate the related monetary costs.

The rest of the paper is organized as follows. Related work is discussed in Section 2. The problem description follows in Section 3, while the optimization problem is defined in Section 4. The online auto-tuning approach and interleaving algorithms proposed are described in Section 5. The experimental evaluation and its results follow in Section 6, while Section 7 concludes the paper.

2 RELATED WORK

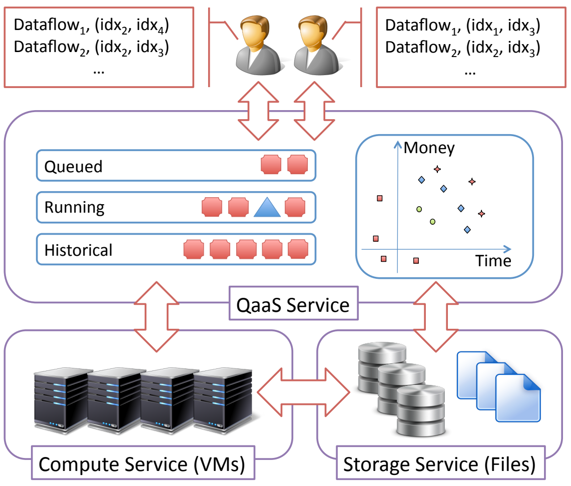
A considerable body of work focuses on VM consolidation to exploit underutilized resources for the execution of multiple workloads [14, 51]. However, consolidating different workloads may greatly affect application performance due to interference, as consolidated VMs may compete for resources [53]. In contrast, the idea of this work is to interleave dataflow and index build operators in the execution schedule to accelerate dataflow execution while eliminating the cost of building indexes.

Offline algorithms for index tuning on centralized systems like [10, 16] do not consider a dynamic environment where the service is unaware of the dataflows and a priori predictions of how long to keep and when to delete indexes cannot be made. Our approach is closer to online algorithms like [9, 38, 52]. However, we target a distributed and elastic environment where VMs are allocated dynamically and compute resources are prepaid for the whole time quanta. Also, what-if optimizations that improve index tuning [16] are complementary to our work and can be used to accelerate the computation of index usefulness. Approaches that incorporate feedback from administrators to improve index recommendations [29, 43] are also orthogonal to our work, as user feedback can be beneficial for the computation of index usefulness. The problem of index interactions has also been studied [42, 44]. Such efforts could be leveraged in our work to delete indexes that become obsolete when index interactions in the dataflow workload are identified.

Online algorithms for distributed environments like [13, 20, 41, 47] focus on replicated databases, investigating which sets of indexes to build on each replica and how to route queries properly to take advantage of them. Such approaches can be used in combination with our proposed approach since multiple replicas for each partition are typically created in distributed environments to increase efficiency and fault tolerance [24]. Indexing mechanisms on clouds like [11, 15, 36] mainly focus on the optimization of application performance and ignore the monetary cost of using the resources. The monetary cost of data structures has been considered in multi-user environments [30, 49] to distribute the creation and maintenance costs of data structures among multiple users. However, our work focuses on single-user environments where resources allocated to the user are dedicated and data structures built are not shared among multiple users. This way, each user is independent and the provider's pricing policy for compute and storage resources like Amazon Elastic MapReduce [4] can be directly used, without considering complex cost sharing policies that users may or may not agree with. Finally, the work in [21] considers the problem of data structure reuse by future queries, materializing and storing the output of operators of MapReduce jobs. To the best of our knowledge, there is no index management approach for single-user environments that takes into account the monetary cost of using cloud resources.

3 PROBLEM DESCRIPTION

Figure 1 shows the architectural framework envisioned in this work. The typical users of the QaaS service are data scientists that issue exploratory query tasks to extract knowledge from data, such as data intensive transformations that perform processing and aggregations on data read from tables or files. The data can be partitioned for flexibility, performance, and fault tolerance and indexes on each partition of tables or files can be built. Each user interacts with the service by issuing dataflows sequentially,



Dataflow$_1$, (idx$_2$, idx$_4$)
Dataflow$_2$, (idx$_2$, idx$_3$)
Dataflow$_1$, (idx$_1$, idx$_3$)
Dataflow$_2$, (idx$_2$, idx$_3$)

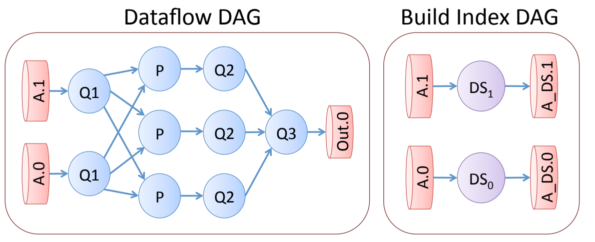
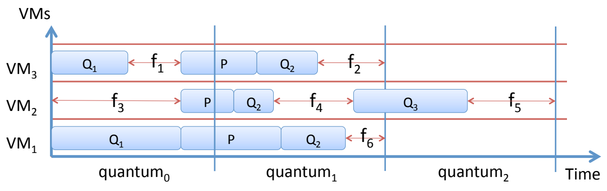
usually observing the results obtained from the execution of a single dataflow before submitting the next one. The service executes the dataflows on top of clouds according to selected execution schedules with desired time-money trade-offs using compute and storage services offered by cloud providers. The execution of the dataflow is interleaved with the execution of build index operators and the indexes created are stored in the cloud storage. Each dataflow submitted for execution has access to currently available indexes and each operator can make use of those associated to partitions it accesses.

Motivation. A dataflow example is shown in Figure 2a. As can be seen in the graph of the DAG (left part of the figure), the dataflow uses two partitions, $A.0$ and $A.1$, of an input table A and performs processing ($Q1$, $Q2$), partitioning (P), and aggregations ($Q3$). The dataflow is associated to a set of indexes ($A\_DS.0$ and $A\_DS.1$) built for the table partitions ($A.0$ and $A.1$, respectively) as shown in the right part of the figure. There are two indexes to be built: A built in three parts $A0$, $A1$ and $A2$ and B built in parts $B0$, $B1$ and $B2$. Parts can be created in parallel using different VMs. Figure 2b shows an execution schedule of the dataflow operators when using 3 VMs ($VM1$, $VM2$, $VM3$). Arrows show the idle slots created due to data dependency constraints and the quantized pricing policy ($f1 - f6$). For example, slot $f4$ on $VM2$ remains idle as $Q3$ cannot be executed until all $Q2$ operators have finished. Such idle slots can be used for the building of indexes without incurring any additional cost, as shown in Figure 2c. Different indexes can be built in parallel such as the case of A_1 and B_0. The execution of the index build operator A_1 at $VM2$ is stopped as it is not completed before the execution of the dataflow operator P starts so that the execution of the dataflow is not delayed. Similarly, B_2 is stopped before the time the leased quantum expires to avoid unnecessary costs for building indexes.

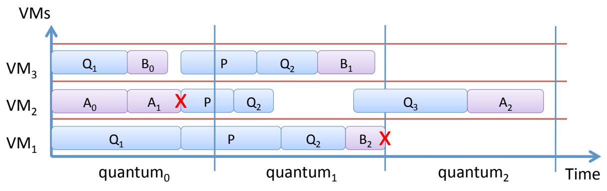
Application Model. A dataflow d is modelled as $d(expr, R, N, t)$, where $expr$ is its definition expressed in an appropriate language, R is the set of input tables, N is the set of indexes that can accelerate its execution, and t is the time point that the dataflow is issued to the service. The dataflow is modelled as a DAG where the nodes correspond to operators and the edges to data dependencies (flows) between them. An *operator* is modelled as $op(cpu, memory, disk, time)$, where cpu is the CPU utilization,



(a) dataflow and build index DAGs.



(b) Execution schedule of the dataflow DAG.



(c) Interleaving of dataflow and build index operators.

Figure 2: Execution of an example dataflow and indexes

mem is the maximum memory needed for its normal operation, $disk$ is the disk resources, and $time$ is its execution time. A flow between two operators is labelled with the size of the data transferred between them. The estimations of operators can be computed analytically or can be collected by the system at runtime [37]. Since we target large datasets, the statistics (e.g., histograms) do not change radically over time (a 10GB update on 1TB dataset is not large enough to change the statistics). The dataflow processing rate is much higher than the rate at which the data is updated. This is the typical case in many settings: updates are done every few days and the datasets are processed much more frequently [27]. Also, operators come from a set that does not change frequently, which is typical for exploratory data analysis [36].

Cloud Model. Compute resources are offered in the form of VMs (or containers) with a fixed capacity of resources, CPU, memory, disk, and network, respectively. Each VM is charged at a fixed price (M_c) per time quantum (Q) and can be dynamically allocated and deallocated based on the workload needs. In this work, homogeneous VMs are assumed. This is typical for many installations; most VMs are of the same size and only few VMs which run critical services are significantly larger (like namenodes of Hadoop [7]). An idle VM (a VM that is not used) is deleted when its currently leased time quantum expires, since the resources are prepaid for whole time quanta [3]. Each VM has a local disk that can be used to store temporary results or data. After deleting a particular VM, the files stored in its local disk cannot be recovered.

A storage service is used to store data persistently; VMs retrieve data from the storage service and cache it to their local disks and transfer data to the storage service after the execution of an operator finishes. This scheme is flexible as compute from storage resources are decoupled. Typically, cloud providers charge a fixed amount of money per GB per month (MC). In the model used, the cost of storing data, M_{st}, is measured in GB per time quantum (Q). As a year has approximately 365.25 days and, assuming that Q is measured in minutes, we compute M_{st} as $(MC \cdot 12 \cdot Q)/(365.25 \cdot 24 \cdot 60)$.

Data Model. Tables can be partitioned and stored to the storage service of the cloud. As mentioned, allocated VMs can cache table partitions to their local disk to avoid network overheads when possible. Data updates are performed in batches periodically (every day or week). Each update creates a new version of the table partitions changed [2], invalidating old versions and indexes built on them. A table t in the database is modelled by its schema (i.e., the names and types of its columns), its ordered set of partitions, and its statistics: $t(schema, P, S)$. A partition $p \in P$ is modelled by its id, its number of records n and a particular path in the storage service where the partition is located: $p(id, n, path)$. The statistics contain the average size of the fields of each column.

An index idx built on table t is modelled as $idx(t, C, T)$, where C is the ordered set of columns based on which the index is built and T is the ordered set with the respective creation time points of its partitions. Each index consists of several index partitions built on different table partitions. Index partitions can be built on different time periods. The *index size* is computed by adding the sizes of its partitions. The size of a partition can be computed based on the type of the index (e.g. Hash, B^+Tree). We assume without loss of generality that B^+Trees are used. The size of partition p of index idx is computed as follows:

$$size(idx, p) = (1 - k^{\log_k(p.n)}) \cdot RecSize/(1 - k),$$

where $RecSize$ is the average size of the record in the index, computed from column statistics, and k is the width of the tree computed from the block size on the disk and the record size $RecSize$. Assuming that the tree is balanced, its size is computed using geometric series as follows: the total number of records including the non-leaf blocks is $\sum_{i=0}^{m} k^i = (1-k^m)/(1-k)$, where m is the height of the tree computed as $m = \log_k N$. Parameter N represents the number of records in the partition. The time to build an index idx, $t_i(idx)$, is computed by adding the time to build all the index partitions of the corresponding table. The time to build the index on a partition p is computed as:

$$t_{ip}(idx, p) = t_{io}(idx, p) + C(idx) \cdot p.n \cdot \log_k(p.n)/T_Q,$$

where $C(idx)$ is a constant calculated using the columns in the index. The time to read and write the partition $t_{io}(p)$ is computed as:

$$t_{io}(idx, p) = (p.n \cdot RecSize + size(idx, p))/cont.net,$$

where $cont$ is the container to which the build index operator is assigned for execution. The building of indexes can be expressed as a DAG with operators that take as input one partition and build the partial index on that partition. Operators are independent to each other (there are no edges between the operators in the DAG) and as a result there is a large degree of parallelism. Hence, indexes can be built incrementally (not all index partitions need to be built in order to use the index) and in parallel (two or more index partitions can be built simultaneously). The storage cost of index idx for a time period W (given in time quanta) is computed by adding the cost $stp(idx, p, W)$ of storing each index partition p for that period, where

$$stp(idx, p, W) = W \cdot size(idx, idx.t.P[p]) \cdot M_{st}.$$

Our approach can work with different pricing models. A pricing model is plugged to the scheduler by using the appropriate pricing formulas for the cost of a VM (M_C) and the cost of storage (M_{st}). Also, although we consider a homogeneous environment with a single VM type, the scheduler can consider slots at different VM types.

Dataflow and Index Management. The dataflows are issued sequentially to the service. Historical dataflows (dataflows that have already been executed) are stored in a list called H_d. An execution schedule S_d of a dataflow graph d is a set of assignments of its operators to containers. An execution schedule is computed taking into account the network communication cost using the model in [33]. The execution time of a dataflow in schedule S_d, $t_d(S_d)$, is defined as the time period from the time the first operator starts executing until the time the execution of the last operator finishes. The monetary cost $m_d(S_d)$ is computed taking into account the sum of the total time quanta of the VMs leased. The monetary cost and execution time are measured in quanta in order to have the same unit. An idle slot $f(id, q, c, S_d)$ in schedule S_d is a continuous time period inside the leased time quantum q of the container, c, that has no operators running. The fragmentation of the schedule is the set of all the idle slots in the leased containers and shows the time the compute resources are not used during the execution schedule, but they are charged by the cloud provider.

Idle slots can be used for the building of indexes. We denote as I the evolving ordered set of indexes built and maintained by the service. The set of indexes available at time t is denoted as $I(t)$ and the set of all indexes created during the operation of the service (independently of whether they are deleted or not) is denoted as I. Potential indexes are indexes that are associated with one or more dataflows, but they are not beneficial to build. Indexes built on table partitions that are updated are deleted and marked as *not built* to support index updates.

4 OPTIMIZATION PROBLEM

This work considers the problem of interleaving indexes with the execution of dataflows so that dataflow execution, in terms of execution time and monetary cost, is not affected. The aim is to determine the set of beneficial indexes required to build and maintain over time to achieve good trade-offs between the dataflow speedup and the monetary cost required taking into account the storage cost needed to maintain the indexes.

The optimization problem is formulated as a weighted single objective problem using a linear function to express the different tradeoffs between the time and money objectives:

$$\max_I \Big[\sum_i M_c \cdot (\alpha \cdot \delta t_d(d_i) + (1-\alpha) \cdot \delta m_d(d_i)) - \sum_j st(I[j]) \Big], \quad (1)$$

where d is the dataflow, $st(I[j])$ is the storage cost of index $I(j)$, $\delta t_d(d_i)$ is the difference (given in quanta) in dataflow execution time without and with the use of indexes and $\delta m_d(d_i)$ is the difference (quanta) in the monetary cost required without and with the use of indexes. Parameter α essentially expresses how much money a time quantum is valued, taking values between 0 and 1 that correspond to scenarios where the optimization

Table 1: Notation used.

Parameter	Meaning
T_Q	Quantum size
M_c	VM price (per quantum)
M_{st}	Storage cost (per GB per quantum)
$I(t)$	The set of indexes available at time t
a	Parameter for time-cost trade-off
$st(idx, W)$	Storage cost of index idx within a time window W
$gt(idx, t)$	Gain in time for index idx at time t
$gm(idx, t)$	Gain in money for index idx at time t
$dc(t)$	Gain fading function
$t_i(idx)$	Time for building index idx
$m_i(idx)$	Monetary cost for building index idx

problem becomes one-dimensional. Small values of α indicate that monetary cost (or money) is more important, while large values of α indicate scenarios where time is more important. The difference in time $\delta t_d(d_i)$ is multiplied with the container price per quantum (M_c) so that the time and money objectives have the same units.

In a dynamic environment where arbitrary dataflows are issued at arbitrary time points using different sets of potential indexes, it is hard to find the optimal sequence of index sets ($I(t)$), i.e., determine when to build and delete indexes using Equation 1. We formulate the optimization problem to a more suitable form (Equation 2) for the computation in an online fashion:

$$I(t) = arg \max_{I} \Big[\sum_{idx \in I} (\alpha \cdot M_c \cdot gt(idx, t) + (1-\alpha) \cdot gm(idx, t)) \Big], \quad (2)$$

where functions $gm(idx, t)$ and $gt(idx, t)$ (described in Equations 4 and 5) compute the gain in money and time, respectively, when using a particular index idx at time point t and within a time window of predefined size W (e.g., two quanta). Table 1 summarizes the notation used to define the optimization problem. Equation 2 can be approximated in an online fashion by computing the gain of each index individually, building and maintaining only those that contribute in a positive way to the summation at any given point in time. More specifically, an index idx is said to be beneficial at time point t if its gain (the weighted summation of time and money gain of Equation 3) is positive.

$$g(idx, t) = \alpha \cdot M_c \cdot gt(idx, t) + (1 - \alpha) \cdot gm(idx, t) \quad (3)$$

Indexes are built as soon as they become beneficial and are deleted as soon as they become non beneficial.

The gain in money $gm(idx, t)$ of index idx is computed by adding the gain in money $gm_d(idx, d_i)$ of the index on each related dataflow d_i (the dataflows that use it and are evaluated inside time window $[t - W, t]$ and the currently running dataflow) and the monetary cost required to build and store the index for time period W, as described in Equation 4:

$$gm(idx, t) = \sum_i \Big(\delta(d_i, t) \cdot dc(\delta T_{d_i}) \cdot M_c \cdot gm_d(idx, d_i)\Big) - (M_c \cdot m_i(idx) + st(idx, W)) \quad (4)$$

where $\delta(d_i, t)$ is 1 if the dataflow f has been executed during time period $[t - W, t]$ or else 0, δT_{d_i} is the number of quanta passed since the dataflow d_i was executed (0 for the ones that are currently running or queued) and $dc(t)$ is a function that reduces with time in order to fade the gain of the historical dataflows. An exponential function is used to fade the gain: $dc(t) = e^{-t/D}$, where parameter D controls the degree the historical dataflows affect it. A small value of D means that $dc(t)$ approaches quickly to 0 and, as a consequence, $gm(idx)$ becomes negative. We assume that D is the same for all indexes. However, different values of the controller D can be used for each individual index. Automatic learning of the controller for each index based on predictions is a direction for future work. Also, $m_i(idx)$ is the monetary cost required to build the index, $st(idx, W)$ the storage cost required to maintain it for a time window W and $gm_d(idx, d_i)$ is the gain in money of dataflow d_i when using index idx which is computed based on the time gain of the index on d_i. The gain in money $gm_d(idx, d_i)$ also includes the monetary cost spent to read the index from the storage service, which is equivalent to the time to read the index, as both of them are measured in quanta. If dataflow d_i does not use index idx, then $gm_d(idx, d_i) = 0$.

Similarly, the time gain $gt(idx, t)$ of index idx at time point t is computed taking into account the gains of index idx on the dataflows executed within the time window W, subtracting the time needed to build it as follows:

$$gt(idx, t) = \sum_i \Big(\delta(d_i, t) \cdot dc(\delta T_{d_i}) \cdot gt_d(idx, d_i)\Big) - t_i(idx) \quad (5)$$

where $gt_d(idx, d_i)$ is the gain in time of dataflow d_i when using index idx.

An example to illustrate the proposed approach is presented. Assume the dataflows shown in Table 2 are issued to the service at the time points specified. The dataflows use two indexes, A (of size 100 MB) and B (of size 500 MB). The time and money gain of the indexes for each dataflow is included in the table. Figure 3 shows the gain of each index computed over time for the case of $\alpha = 0.5$ and $D = 60$. It can be seen that the gain of both indexes, A and B, is negative in the beginning due to their storage cost. As dataflows specify them as useful, the gain becomes positive at some point (the indexes become beneficial) and then decreases over time because of parameter D (that impacts index usefulness). For example, index B becomes beneficial at time point 30 and will be deleted at time point 125 where it stops being useful.

Table 2: Dataflows Issued using Indexes A and B.

Dataflow	Time Gain	Money Gain
$d_1(-, -, \{B\}, 10)$	$gt_d(B, d_1) = 1.0$	$gm_d(B, d_1) = 3.0$
$d_2(-, -, \{B\}, 30)$	$gt_d(B, d_1) = 2.0$	$gm_d(B, d_1) = 5.0$
$d_3(-, -, \{A, B\}, 50)$	$gt_d(A, d_1) = 2.0$ $gt_d(B, d_1) = 3.0$	$gm_d(A, d_1) = 8.0$ $gm_d(B, d_1) = 8.0$
$d_4(-, -, \{A\}, 100)$	$gt_d(A, d_1) = 3.0$	$gm_d(B, d_1) = 5.0$

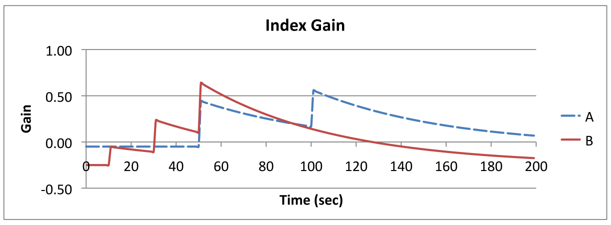


Figure 3: Gain over time of two indexes A and B.

5 AUTO-TUNING APPROACH

In this section, we propose an auto-tuning approach to select and build an optimal set of indexes over time. Statistics from historical (issued) dataflows and their specified indexes are continuously collected and used to make decisions about which indexes to build or delete at each time point. Dataflows to be executed can only use indexes that are currently available, while new indexes to be built are scheduled with the currently issued dataflow. Indexes are built using idle slots in the execution schedule of the issued dataflow so that the dataflow execution is not affected. However, beneficial

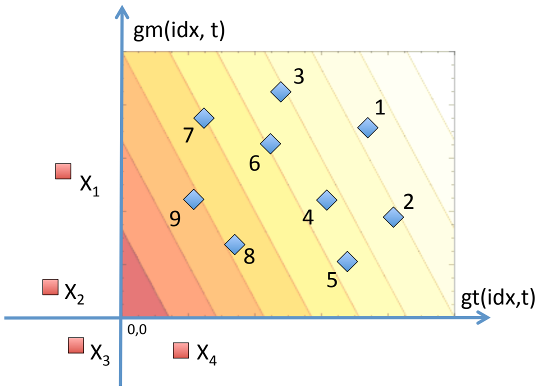

Figure 4: Index ordering based on α at time point t.

indexes to be built may not fit in the currently available slots and selecting which beneficial indexes to build is required. Since the goal is to maximize the optimization objective of Equation 2, indexes are ranked based on their usefulness and the best subset to be built is selected.

5.1 Index Ranking

Equation 3 is used to compute the usefulness or gain of indexes at each time point, as described earlier in Section 4. Non beneficial indexes are not built or are deleted if they are already available. Note that an index that is not used for a long time may become non-beneficial because of the increased storage cost. We only consider beneficial indexes with $gm(idx, t)$ and $gt(idx, t)$ (Equations 4 and 5) larger than 0 and among them higher values of gain (Equation 3) are preferred. Essentially, indexes can be depicted in a bi-dimensional space based on their time and money gain as shown in Figure 4. Indexes at the lighter areas are prioritized. For example, point 1 has the highest priority for a=0.7, while indexes X_1, X_2, X_3, and X_4 are not beneficial.

5.2 Online Index Tuning

The online index tuning approach proposed is shown in Algorithm 1. The algorithm schedules the issued dataflow along with the subset of potential indexes that maximize the total gain. Beneficial indexes are assigned to idle compute resources in the dataflow execution schedule without violating the constraints (i.e, the time and the monetary cost of the dataflow are not affected). Indexes that are not beneficial or cannot fit to the schedule are deleted. Note that partitions of a particular index can be built in the context of several dataflows if there is not enough idle time to build it entirely in the context of one dataflow. The algorithm is triggered every time a new dataflow is issued, the execution of a dataflow finishes or periodically at fixed time intervals to delete indexes that become non beneficial when there is not any new dataflow to be issued. In more detail, the procedure triggered is the following. The gains in time and cost for each index are computed and beneficial indexes are ranked (lines 2-9 of Algorithm 1) as described in Section 5.1. Then, the algorithm calls the index interleaving procedure to compute the skyline of execution schedules of the dataflow df interleaved with build index operators and selects from the skyline the schedule to be executed (lines 10-11). Different methodologies can be used to choose the schedule to be executed. In this work, the fastest schedule is chosen. In lines 13-19 the algorithm identifies index partitions that are not beneficial and need to be deleted.

Algorithm 1 Online Index Tuning

```
                    Input:
      $H_d$: The historical dataflows.
      $A_i$, $B_i$, $P_i$: The index lists.
      $df$: The next dataflow to schedule.
                    Return:
      $S_{df}$: The schedule of the dataflow.
      $S_{BI}$: The schedule of the build indexes.
      $DI$: The indexes that should be deleted.
 1: $GAINS \leftarrow \emptyset$
 2: for $i \in P_i$ do
 3:     $gt \leftarrow gt(i, H_d \cup df)$
 4:     $gm \leftarrow gm(i, H_d \cup df)$                ▷ Compute the index gains
 5:     if $gt > 0$ and $gm > 0$ then
 6:         $GAINS \leftarrow GAINS \cup \{i\}$
 7:     end if
 8: end for
 9: $RANK \leftarrow rank2Dspace(GAINS)$                    ▷ rank the indexes
10: $skyline \leftarrow schedule(df, A_i, RANK)$
                       ▷ Scheduling of both the dataflow and indexes
11: $S_{df}, S_{BI} \leftarrow select(skyline)$       ▷ Select the schedule from skyline
12: $DI \leftarrow \emptyset$
13: for $i \in A_d$ do
14:     $gt \leftarrow gt(i, H_d \cup df)$
15:     $gm \leftarrow gm(i, H_d \cup df)$
16:     if $gt \leq 0$ and $gm \leq 0$ then
17:         $DI \leftarrow DI \cup \{i\}$                      ▷ Indexes to be deleted
18:     end if
19: end for
20: return ($S_{df}, S_{BI}, DI$)
```

5.3 Index interleaving approaches

In this section, we propose two different approaches to schedule dataflows interleaved with build index operators without using additional monetary cost, namely the Linear program based interleaving algorithm (LP) and the online interleaving algorithm. The LP interleaving algorithm initially schedules the currently issued dataflow and finds the idle slots in the compute resources. Then, it uses a linear programming algorithm to determine the subset of potential index partitions and tries to assign them on the idle slots based on their ranking (gain). The online interleaving algorithm schedules the current dataflow and the index build operators together labeling the index build operators as optional operators to be scheduled.

5.3.1 Linear program based interleaving algorithm. The LP interleaving algorithm shown in Algorithm 2 schedules indexes after the dataflows. More specifically, the algorithm initially updates the operator runtimes based on the available index partitions. Estimations of runtimes can be provided based on existing models [50]. The algorithm calls the scheduler described in Algorithm 4 to compute the skyline of the execution schedules (line 6). For each schedule in the skyline, the algorithm finds the set of idle slots and sorts them in decreasing order based on their size (lines 8-10). For each slot, a linear program (line 12) is solved to determine the subset of potential indexes that maximize the total gain. The build index operators in each idle slot are sorted by gain so that the building of less useful indexes is stopped when the time quantum ends or the next assigned operator is scheduled (as shown in Figure 2c) before the build index operator finishes due to runtime estimation errors. The build index operators whose execution has been stopped are queued and scheduled with the next dataflow issued. Overall, the algorithm does not violate the constraints (i.e. index interleaving does not affect dataflow execution in terms of time and money) as indexes are built on slots that are not used for the execution of dataflow operators, but they are charged.

Algorithm 2 Linear program based interleaving algorithm

Input:
df: The current dataflow from the input.
A_i: The available indexes.
I: The ranked list of indexes.
Return:
$skyline$: The skyline of solutions.

```
 1: for $op \in df$ do
 2:     if $op$ uses indexes in $A_i$ then
 3:         update($op$, $A_i$)             ▷ op. runtimes based on available indexes
 4:     end if
 5: end for
 6: skyline ← Skyline($df$)           ▷ generate skyline of execution schedules
 7: for s in skyline do
 8:     idle_time ← FindIdleTime(s)
 9:     ordered_idle_time ← OrderBySize(idle_time)
10:     indexes ← $\cup(I.P)$
11:     for i in ordered_idle_time do
12:         maxset ← SolveLinearProgram(i, indexes)
                                  ▷index set to be built based on linear program
13:         for m in maxset do
14:             schedule(m, i)                   ▷ assign indexes to idle slots
15:         end for
16:         indexes ← indexes - maxset
17:     end for
18:     add $indexes$ to $s$
19: end for
20: return skyline              ▷ schedules of dataflow ops and index build ops
```

Algorithm 3 Linear Program Algorithm

Input:
f: The size of the idle time segment.
p_i: The sizes of all the build index partition operators.
g_i: The gain of all the build index partition operators.
Return:
The subset of the build index operators that maximize Equation 2

```
1: $max\left[\sum_i (w_i * g_i)\right]$
   w.r.t
2: $\sum_i (w_i * p_i) \leq f$
3: $0 \leq w_i \leq 1, \forall i$
4: $integer(w_i), \forall i$
5: return $(w_1, w_2, \ldots w_n)$
```

Linear program approximation algorithm. The problem of assigning build index operators into idle time slots on compute resources is a variation of the Knapsack [31] problem, which is NP-hard. The Linear program approximation algorithm shown in Algorithm 3 is an approximation algorithm to solve a 0/1 knapsack problem for each idle time slot. The algorithm solves the relaxed problem setting the weights of the build index operators between the values 0 and 1 and calls a branch and bound algorithm to find integer values.

Skyline dataflow scheduler. Different execution schedules that vary in the achieved execution time and monetary cost can be created by assigning the dataflow operators to potential slots of the available VMs. Between them, non-dominated solutions (solutions that outperform others in terms of execution time and monetary cost) may be preferred. The set of non-dominated solutions achieved comprises the obtained *skyline* of execution schedules. The algorithm in [12] is used to develop the skyline of execution schedules for each dataflow. An operator is candidate for assignment when all of its predecessors are assigned, starting from operators without data dependencies (entry nodes in the dataflow graph). At each iteration, the algorithm (Algorithm 4) assigns the next available operator to the partial solutions of the current skyline taking into account the communication costs and data dependency constraints between the operators. After the assignment of the new operator to all the possible slots, the new skyline is computed. Between schedules with the same execution

Algorithm 4 Skyline Dataflow Scheduler

Input: df: The dataflow DAG.
C: The maximum number of containers to use.
Output: $skyline$: The solutions in the skyline.

```
 1: $skyline \leftarrow \oslash$
 2: $ready$ ←{operators in $df$ that have no dependencies}
 3: $firstOperator \leftarrow ready.peek()$
 4: $firstSchedule \leftarrow \{assign(firstOperator, 1, -, -)\}$
 5: $skyline$ ←{$firstSchedule$}
 6: while $ready \neq \oslash$ do
 7:     $next \leftarrow ready.peek()$
 8:     $S \leftarrow \oslash$
 9:     for all schedules $s$ in $skyline$ do
10:         for all containers c (c ≤ C) do
11:             $S \leftarrow S \cup \{s + assign(next, c, -, -)\}$
12:         end for
13:     end for
14:     $skyline$ ← skyline of $S$              ▷ new skyline of schedules
15:     $ready \leftarrow ready - \{next\}$ ∪ {operators in $df$ that dependency con-
        straints no longer exist}
16: end while
17: return $skyline$
```

time and monetary cost, the schedule with the most sequential idle compute time is selected, since the aim of our work is to use idle slots where index build operators may fit. The procedure described is repeated for the next available operator. The algorithm terminates when all operators are assigned and the final skyline is generated. Note that the impact of data transfers on the execution of data-intensive dataflows may be significant and overhead may be introduced [18]. Thus, each dataflow is scheduled offline to generate more efficient schedules where the overhead from data transfers is considered.

5.3.2 Online interleaving algorithm. The online interleaving algorithm is a modification of the scheduler in [12] to use optional operators and schedule index build operators along dataflows. To do so, operators are separated to optional and non optional using a boolean variable; the variable is set to $true$ (optional operators for execution) for each index build operator while the variable is $false$ for all dataflow operators. Algorithm 4 is modified so that the schedules in each iteration may vary in the number of assigned operators. The ready operators list (line 2 of Algorithm 4) includes optional index build operators which are candidate for scheduling. If the operator *next* in line 7 is optional, the previous skyline (*skyline*) is kept and unioned with the set of schedules *S* (line 11) before computing the new skyline in line 14. As a result, the newly generated skyline may consist of schedules with different numbers of operators. Between schedules with the same execution time and money, schedules with a larger number of operators are preferred. Also, the schedules kept in the new skyline do not violate the constraints of the optimization problem, as solutions that belong to the initial skyline and have lower execution time or monetary cost will dominate solutions in the unioned set where the assignment of optional operators have affected dataflow execution. Hence, only schedules where the assignment of optional operators does not affect the dataflow execution time and monetary cost will be kept in the newly computed skyline.

6 EXPERIMENTAL EVALUATION

In this section, the proposed approach is evaluated based on simulation. The skyline dataflow scheduler described in Section 5.3.1 (*offline*) is evaluated using an online load balance scheduler (*online*) typically deployed in elastic clouds as baseline. The *online* algorithm examines the dataflow graph in an online greedy

Table 3: Experiment Parameters

Parameter	Values
Quantum size	60 seconds
Quantum cost	\$0.1
Storage Cost	\$$10^{-4}$ per MB per Quantum
Max Containers	100
Dataflow	Montage, Ligo, Cybershake
Operators / Dataflow	100
α	0.5
Index gain fading D	1 quantum
Poisson Generator λ	1 quantum
Total Time	720 quanta

fashion scheduling the operators to the available containers so that load balance is achieved. Finally, the two index interleaving algorithms, the *LP interleaving* algorithm and the *online interleaving* algorithm, are evaluated and compared using two baseline index management approaches: a naive approach that does not create indexes at all (*no indexes*) and an approach that randomly selects indexes from the potential set and randomly assigns them to containers to be built (*random*).

6.1 Experimental Setup

Table 3 summarizes the parameters used in the experiments. Homogeneous containers with similar capacity in resources (CPU, memory, disk, and network) are assumed. Each container has one CPU and one disk. The CPU and memory needs of each operator is specified as a percentage of container's CPU and memory respectively. A disk size of 100 GB and a speed of 250 MB/sec (typical SSD) are assumed. Allocated containers cache table partitions and indexes read from the storage service. A time quantum Q of 60 seconds is assumed. Pricing is based on *Amazon*'s billing policy [6]. The price M_c charged for the provisioning of each container per time quantum is set equal to \$0.1 and the storage cost M_{st} is set equal to \$$10^{-4}$ per MB per quantum. The storage of the cloud is computed by counting the number of bytes transferred and charging appropriately over time.

In the simulator used, user queries are sent to the scheduler, which adds them to a queue. Each query is transformed into an execution graph of operators with data dependencies. Given the execution graph, the scheduler selects a subset of containers and schedules the execution of the graph operators on these containers, respecting the graph dependencies. The set of active containers can be dynamically varied based on the demand. Each operator has a priority specified and each container has a queue with operators that are executed as soon as the memory needed is sufficient. Dataflow operators have priority 1 and build index operators have priority -1. Operators with negative priority are stopped when operators with positive priority arrive to the container or its current time quantum expires. A network bandwidth of 1 Gbps is assumed. The execution of an operator is delayed until its input data are transferred. Also, if an index is available and beneficial, the container reads the index in addition to the input of the operator, depending on the speedup it offers.

In the simulator used, each container has a local disk to cache input files from the storage service. If the data required as input from the operator are already in the cache, data transfer is considered to be 0. If the container cache gets full, LRU policy is used to create empty space. Containers that do not have any dataflow operators scheduled on them are deleted at the end of the leased quantum.

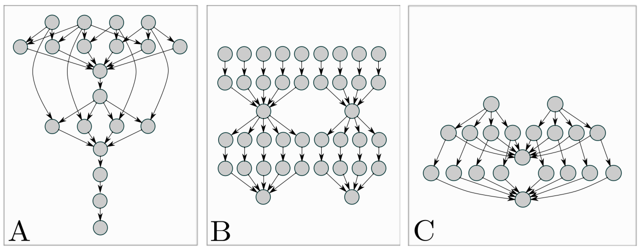

Figure 5: The dataflow graphs Montage(A), Ligo(B), and Cybershake(C).

Table 4: Basic statistics of the scientific dataflows.

Time (sec)	#	Min	Max	Mean	Stdev
Montage	100	3.82	49.32	11.32	2.95
Ligo	100	4.03	689.39	222.33	241.42

Montage	20	0.01	4.02	3.22	1.65
Ligo	53	0.86	14.91	14.24	2.70
Cybershake	52	1.81	19169.75	1459.08	5091.69

Table 5: Indexes on table lineitem.

Column	Type	Index Size	% Table Size
comment	text	422.30 MB	30.16 %
shipinstruct	20 chars	248.95 MB	17.78 %
commitdate	date	225.91 MB	16.13 %
orderkey	integer	146.99 MB	10.49 %

Synthetic data of three real scientific applications, namely Montage [28], Ligo [19] and Cybershake [17], are used to evaluate the proposed approach. Montage shown in Figure 5A is used to generate image mosaics of the sky, LIGO shown in Figure 5B is used to analyze galactic binary systems and Cybershake shown in Figure 5C is used for the characterization of earthquakes. The dataflows are produced using the generator in [8] which specifies the execution time of each operator, the dependencies between them and the sizes of the input/output files of each operator. The basic statistics of the operators are shown in Table 4.

The input files of the dataflows shown in Table 4 are used as a database of files. The total number of files is 125 and their total size is 76.69 GB. The maximum size of a file partition is set equal to 128 MB, resulting in a total number of 713 file partitions. The TPC-H benchmark [1] is used to compute the sizes of typical indexes and model the speed-ups they provide. Table `lineitem` with scale 2 which has approximately 12 million rows and a size of 1.4 GB is used. Table 5 shows the sizes of indexes on four different columns of the table. To model the speed-up that indexes offer, the following SQL queries were created based on the categories presented in Section 1:

Order by:
```
SELECT orderkey FROM lineitem
ORDER BY orderkey;
```
Select range (large):
```
SELECT orderkey FROM lineitem
WHERE orderkey > 1000000
  AND orderkey < 2000000;
```
Select range (small):

Table 6: Index speedup.

Query	No-Index	Index	Speedup
Order by	44.730 sec	6.010 sec	7.44x
Select range (large)	5.103 sec	0.054 sec	94.44x
Select range (small)	4.921 sec	0.016 sec	307.50x
Lookup	4.393 sec	0.007 sec	627.14x

```
SELECT orderkey FROM lineitem
WHERE orderkey > 10000
  AND orderkey < 20000;
```

Lookup:

```
SELECT orderkey FROM lineitem
where orderkey = 1000000;
```

Table 6 shows the speed-up the index on column orderkey offers. Four potential indexes for each file are used. Each index size is computed using the percentages shown in Table 5 and its speed-up is randomly chosen from the values of Table 6.

A *Dataflow Generator Client* issues dataflows at time points that follow a Poisson distribution. More specifically, the generator implemented computes the arrival time k (in seconds) of the next dataflow as $f(k;\lambda) = \Pr(X = k) = \lambda^k e^{-\lambda}/k!$, with λ equal to 60 seconds. Dataflows are generated using two settings: randomly (*random generator*) and with phases (*phase generator*). The phase generator produces dataflows to measure the adaptability of the proposed approach to workload changes as follows: Cybershake dataflows for 33.3 quanta (10000 sec), Ligo dataflows for 16.6 quanta (5000 sec), Montage dataflows for 66.6 quanta (20000 sec) and Cybershake dataflows for 27.3 quanta (8200 sec) with each generated dataflow having different speed-ups for the indexes it uses.

6.2 Scheduler robustness for estimation errors

In reality, operator runtimes and data sizes may be overestimated or underestimated. In the first set of experiments, the sensitivity of the scheduler to estimation errors is investigated. To do so, the runtime of operators and the data sizes they generate are randomly varied within a certain percentage and the difference between the actual and estimated values for time, money and fragmentation are computed. For example, for an estimation error of 10% a random value in the range of [90 - 110] seconds is selected to modify the runtime of an operator initially estimated at 100 seconds. Figure 6 shows the results for different values of estimation errors added on the CPU time (operator runtime) and data used. As can be seen, the estimations are robust considering that an error of more than 20% in operator runtime and datasize estimations is relatively high. When the estimations are extremely poor (large errors), the performance of the algorithm can be significantly affected. This is because the algorithm makes scheduling decisions offline (before dataflow execution) based on estimations of operator runtimes and datasizes and does not adapt to unpredicted changes. Future work could investigate how to incorporate estimation errors on decision making to account for inaccurate estimates and yield better performance.

6.3 Comparison of dataflow schedulers

In this set of experiments, the skyline dataflow scheduler proposed (*offline*) is compared with the online load balance scheduler typically used in IaaS clouds (*online*). Operator runtimes and data

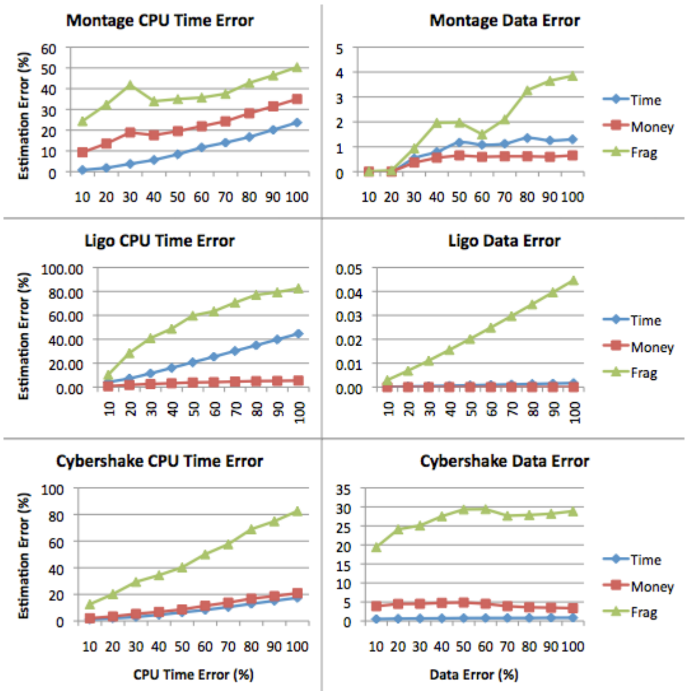

Figure 6: Sensitivity of the offline scheduler to inaccurate estimations.

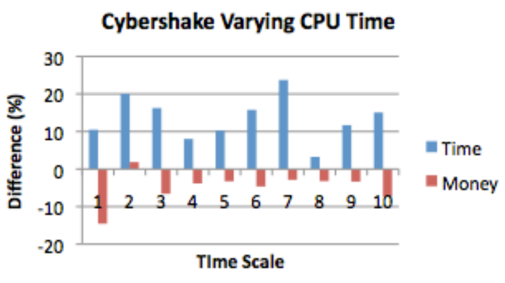
sizes are scaled to evaluate the efficiency of the proposed scheduler for different scenarios. Since the online scheduler generates a single execution schedule, the fastest schedule from the skyline obtained using the proposed skyline dataflow scheduler (offline) is used for the comparison. The results for Cybershake (the results are similar for the other dataflows) are presented in Figure 7; the y-axis shows the difference (%) between the offline and the online scheduler. The left part of Figure 7 shows the results when scaling the operator runtimes up to 10x (shown in the x-axis) and keeping the data sizes small (scaled to 0.01 of the original size). The online scheduler performs well for these type of dataflows (CPU-intensive) generating faster but slightly more expensive schedules by balancing the load. However, load balancing does not work well for data-intensive dataflows where data placement greatly affects the execution of dataflows. The right part of Figure 7 shows the results when scaling the size of data up to 100x. It can be seen that the schedules generated by the online load balance scheduler are up to 2x slower and up to 4x more expensive compared to the proposed offline scheduler.

6.4 Comparison of index interleaving algorithms

In this experiment, we compare the two index interleaving algorithms proposed; the *LP interleaving* algorithm and the *online* interleaving algorithm. Figure 8 shows the number of indexes built at each schedule in the skylines obtained for Montage using the two index interleaving algorithms (the results are similar for the other two dataflows). The first observation is that the LP interleaving algorithm is able to schedule significantly more build index operators. This is because the information about the fragmented resources is available before the algorithm runs. In contrast, the online algorithm schedules the index build operators and the dataflow operators at the same time. Also, the two skylines obtained are not the same (as can be seen from the monetary cost that corresponds to each point). This is because the



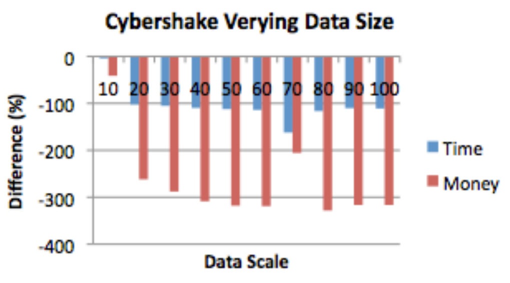


Figure 7: Comparison of the *online* and *offline* scheduler performance.

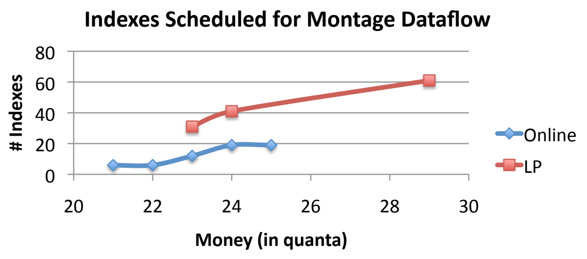

Figure 8: Number of indexes scheduled using different algorithms for Montage dataflow.

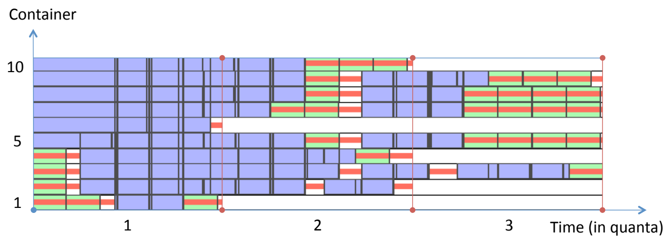

Figure 9: Montage with build index ops (green).

online algorithm interferes with the scheduling of the dataflow operators resulting in cheaper schedules.

Figure 9 shows an example with the timeline of Montage interleaved with build index operators scheduled by the LP interleaving algorithm. Dataflow operators are shown in blue and build index operators are shown in green. The red line indicates idle compute resources. We observe that the LP interleaving algorithm uses a significant amount of idle compute time. The initial idle time is 7.14 quanta and after the assignment of the build index operators, the fragmentation is reduced to 1.6 quanta.

We also compute an upper bound of the quality of the solution found by the LP algorithm by merging all the individual idle time periods and solving the knapsack problem using only one large continuous time segment. We do this using the example of Figure 10, which shows the times of the build index operators and the fragmented resources we used. For simplicity, we set the gain of each operator to be equal to its execution time. As a baseline, we compare with the following greedy algorithm (inspired by Graham [25]): first, we order the operators by descending execution times (and gain in this case) and proceed by assigning each operator to the idle time segment with the most remaining time. A build index operator that does not fit anywhere is not scheduled. Figure 11 shows the results of the LP interleaving algorithm compared to the baseline and the upper bound. We observe that the LP interleaving algorithm is able to find a solution close to the theoretical upper bound (within 5% in this experiment).

6.5 Dynamic Dataflow Workload

In this experiment, the efficiency of the proposed auto-tuning approach (shown in Algorithm 2) is evaluated and compared using the *no-indexes* and *random* approaches as baseline algorithms.

6.5.1 Dataflow Generator with Phases. Initially, the results obtained using the dataflow generator client with phases are presented. Figure 12 shows the number of dataflows finished after 720 time quanta using the different approaches. It can be seen that the number of dataflows executed is doubled when using the proposed approach compared to the baseline where no index is used. Furthermore, the monetary cost spent per dataflow is significantly reduced. It can also be seen that the random approach does not greatly affect the number of finished dataflows compared to the scenario of not using indexes (no index). However the average monetary cost per dataflow is significantly increased due to the storage cost required, which is not taken into account. Finally, the cost per dataflow is increased when non beneficial indexes are maintained, as can be seen by comparing the columns labelled as Gain (no delete) and Gain.

Table 7 shows the total number of operators executed and stopped due to quantum expiration or preemption for the execution of a dataflow operator. It can be seen that the packing achieved by the LP interleaving algorithm is better compared to the random algorithm and fewer build index operators are stopped prematurely.

Table 7: Operators executed.

Algorithm	Total Ops	Killed Ops	Percentage
No Index	22402	0	0
Random	25649	1143	4.4
Gain	49549	1418	2.8

Figure 13 shows the number of indexes built and the total storage cost over time. It can be seen that the proposed approach adapts to the workload by creating and deleting indexes when they become non-beneficial. When Cybershake is re-issued in the final phase, some previously deleted indexes become beneficial again and are recreated.

6.5.2 Random Dataflow Generator. In this experiment, a random dataflow generator client is used. Figure 14 shows the number of dataflows finished after 720 time quanta. The number of dataflows executed is larger using the proposed approach. This is because the average execution time per dataflow is reduced.

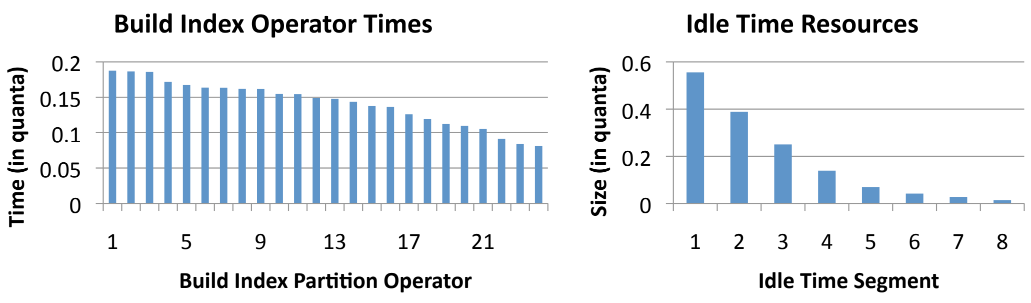

Figure 10: Histogram with execution times of build index operators and idle time resources.

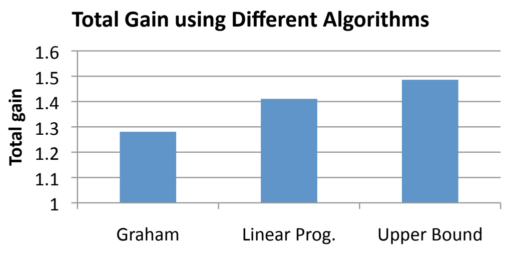

Figure 11: Total gain using different algorithms using the build index operators and idle compute times of Figure 10.

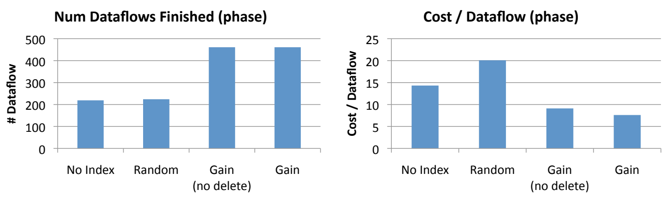

Figure 12: Executed dataflows and average cost/dataflow (phase dataflow generator).

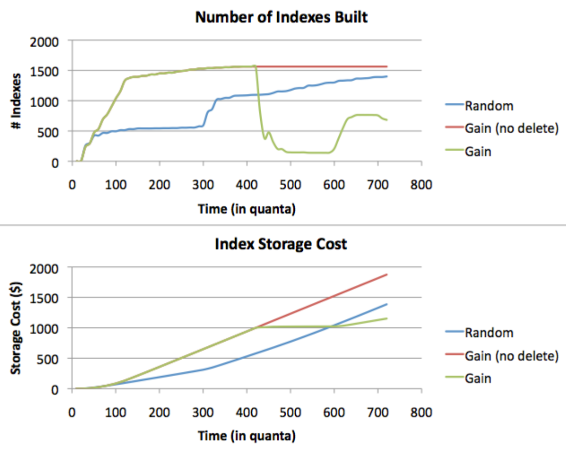

Figure 13: Adaptation of the algorithm to the dataflow workload.

Also, the cost per dataflow is reduced, but not as much as in the previous experiment where the phase dataflow generator client was used. This is because the input is totally at random and, as a result, indexes are stored for a longer period (essentially, they never become non-beneficial). Even in this case, the proposed approach outperforms the baseline approaches.

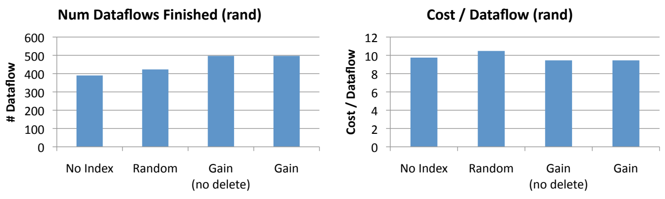

Figure 14: Executed dataflows and average cost per dataflow (random dataflow generator).

7 CONCLUSIONS

In this paper the problem of index management to improve the performance of data-intensive flows on the Cloud is considered. An online auto-tuning approach to assess the usefulness of indexes for the execution of dataflows and utilize idle slots in the execution schedule to build a proper set of indexes is described. The results show that the proposed approach can significantly reduce the average execution time and monetary cost required per dataflow. Future work could evaluate the benefits of index management for scenarios with heterogeneous cloud resources. Also, in this work, we consider a conservative approach to build indexes using idle slots so that they do not interfere with the user workload. Building indexes in a delayed manner for scenarios were idle slots are short is an interesting direction of our future work. Finally, automatic learning of the index gain fading controller to select proper respective values for each index and improve the performance of the proposed approach is another research direction.

ABSTRACT

Histograms are a well studied and simple way to summarize data. As such, they are used extensively in a variety of applications that require estimates of data frequency values. Significant previous work has studied the problem of finding optimal histograms with respect to an error measure. In this paper we study the classic problem of finding an optimal histogram for a dataset, with a new twist: The histogram must contain at least $n - k$ of the n data points. The k excluded data points are considered outliers.

We consider two notions of excluding data items, by allowing arbitrary items to be excluded, or only removing items while retaining a *consistent* histogram. Polynomial algorithms are presented for these problems. Significant experimentation demonstrates that our algorithms work well in practice to reduce the histogram error.

1 INTRODUCTION

Covering a set of data points with a histogram is a fundamental problem that lays at the heart of many database applications. Problems of this sort appear as optimization problems with various constraints on the type and size of the histogram, as well as an error function that must be minimized. Among these problems, finding an optimal histogram covering all but a few input points is of interest in view of outlier removal. In such a problem, given n data points, we are asked to find the optimal histogram covering at least $n - k$ of the n input points. From the viewpoint of optimization, excluding k points reduces the error and in this sense, the excluded data points can be considered outliers. In computational geometry, variations of this problem have been studied in many different settings.

A histogram provides the user with an estimate of frequencies of data elements within each bucket. For example, consider a histogram over integer exam grades. The bucket $([51, 60]; 40)$ indicates that there are 40 exam grades between 51 and 60, inclusive, in the dataset. Without additional information, a uniform distribution of elements within the bucket will be assumed, i.e., 4 grades each for every number between 51 and 60. In practice, this may be far from the correct frequencies, e.g., it is possible that there are 19 occurrences each of grade 59 and 60 and two occurrences of grade 51.

Using an error metric, such as sum-squared error, it is possible to measure the distance between the histogram's estimation and the actual frequencies. When the error is large, the histogram poorly captures the data. The simplest way to decrease the error is to increase the number of buckets. By using more buckets, the user has a more fine-grained view of the data. This, however, is not always an appropriate solution, and in particular, is inappropriate if the histogram is given to a human to view (and not simply to a computer program to continue manipulating for some purpose). If the user is given a very large number of buckets she loses the ability, to some degree, of seeing "the big picture" of the data. It is more difficult to grasp the meaning of the data when many buckets are displayed. A large number of buckets also degrades the quality of the user interface, particularly on mobile devices.

Histograms with a limited number of buckets can have high error as they must cover all elements within the dataset. However, there can be elements that are outliers, in the sense that it is their inclusion that causes the error to increase. In the above example of a dataset of grades, the occurrences of grade 51 can be seen as outliers. Indeed, if these elements did not have to be covered by a bucket, one could use $([59, 60]; 38)$, for which the uniform distribution perfectly estimates the actual grades in the bucket range.

In this paper our goal is to find optimal histograms, given a bound β on the number of buckets, as well as a bound k on the number of outliers that need not be covered. In other words, the goal is to optimally choose up to k elements and a histogram with up to β buckets, so as to minimize the total error.

The main contributions of the paper are:

- We introduce two intuitive notions for an optimal histogram (called a *summary*) with deletions.
- We present several algorithms for solving this problem, including algorithms that are provably optimal.
- Extensive experimentation demonstrates the quality of our solutions.

This paper is organized as follows. We start by discussing related work in Section 2. In Section 3 we set up the framework by providing the necessary definitions. In Sections 4 and 5 we study the optimal summary with deletion problem when there is only a single bucket, or when multiple buckets are allowed. In Section 6 we consider datasets with multiple columns. Extensive experimentation appears in Section 7, and Section 8 concludes.

2 RELATED WORK

Related work falls into two sub-areas: finding optimal histograms and identifying outliers in data. We discuss each of these aspects below.

Histograms. Histograms summarize data by storing the number of values within a given data range. They are traditionally used for estimating costs of query plans, as well as for approximate query answering. Various types of histograms have been considered in the past. These differ both on their maintenance efficiency over dynamic data, and their effectiveness for approximating query answers. Some of the classical types of histograms considered include equi-width (in which all buckets have the same range size), equi-depth (in which all buckets have the same number of data elements), serial (which group elements according to frequency) and end-biased (in which all buckets except one have a single element range). This paper considers the popular v-optimal histograms [9] which has been proven to be optimal in minimizing the variance of element frequencies within the buckets. A taxonomy of histogram types was presented in [12]

Due to their popularity, there has been much effort to efficiently compute histograms from data. In [11], a polynomial time algorithm was presented to compute v-optimal histograms. This work was later expanded in [10] for the case in which there is a bound on the total number of buckets that can be used to summarize several different columns of data. There has also been work on approximating histograms, e.g., [7, 8], and using sampling for constructing histograms [5].

No previous work has considered the setting of computing histograms when not all of the elements must be covered. Among previous work, our paper is most related to [11] as we also present an optimal algorithm for histogram creation, albeit in a new setting.

Outliers. Intuitively, an outlier is a data element that is distant from other elements. Many different criteria have been considered in the past to determine when a data point is an outlier, and outlier detection algorithms have been presented. In particular, algorithms differ as to whether they compare data elements with the entire set, or only with a small local subset. In our work, we assume that the user provides us with a number k of outliers that can be removed. This differs from most previous work, in which no such number is provided. In [4, 14] algorithms for top-k outliers are presented. However, they may return less than k elements if, fewer are deemed to be outliers. (In addition, they differ in their notion of an outlier, as they do not attempt to minimize histogram error.)

Histograms have been used to efficiently find outliers [6, 13]. Our algorithms can also be viewed as finding outliers using histograms. However, our approach is significantly different from previous work. In [6, 13], histograms are built over the entire data set, and then data elements that significantly differ from their fellow bucket elements are considered outliers. In our work, we find the optimal set of data elements that should be removed in order to generate a histogram with low error.

Several works have considered similar types of problems, i.e., covering all but k data elements in an optimal manner (in some sense). In particular, [2] considers optimality in terms of minimum diameter, minimum area bounding box or minimal area convex hull. In [3], the goal is to optimally remove k data elements so that the remaining have a minimum-width square or rectangular annulus. Covering all but k data elements with disjoint boxes is considered in [1]. While these works have a similar goal, they differ in the type of cover that must be created and in error function that should be minimized. Hence, previous techniques cannot carry over to our framework.

3 DEFINITIONS

Datasets and Frequencies. The goal of this paper is to find a method to effectively summarize a large dataset, such as the contents of a relation in a database, or the result of a query. In the following, a *dataset* P is a multiset of elements. To simplify the presentation, we assume that the domain of P is $\mathbb{Z}$. However, all our results immediately generalize to arbitrary completely ordered discrete domains.[1]

Given a multiset of elements P, for all $q \in \mathbb{Z}$, we use $card(q, P)$ to denote the number of copies of q that appear in P. We use $\vec{f_P}$ to denote the *frequency vector* of P, i.e., $\vec{f_P}[q] = card(q, P)$. Note that $\vec{f_P}$ has finitely many non-zero elements. We differentiate between the *elements* of $\vec{f_P}$ denoted p, q, r, and the *frequency values* (or simply *values* for short) of $\vec{f_P}$, denoted v, w.

Example 3.1. Consider the multiset, used as running example,

$$P = \{\!\{10, 20, 30, 20, 30, 40, 10, 40, 50, 0, 0, 0, 0\}\!\}.$$

The frequency vector of P, when considering only non-zero elements, is

$$\vec{f_P}[q] = \{0{:}4, 10{:}2, 20{:}2, 30{:}2, 40{:}2, 50{:}1\} \quad \square$$

Summaries. A *bucket* is written $b = ([p, q]; n)$, where

- $p \le q$ are integers defining the bucket *endpoints* and
- n is a *positive* natural number indicating the number of elements in the bucket.

We say that $\{p, \dots, q\}$ is the range of b.

Now, consider a multiset P and a bucket $b = ([p, q]; n)$. We say that b is *consistent* with P if $\sum_{r=p}^{q} \vec{f_P}[r] = n$, i.e., n is precisely the sum of frequencies of all elements within the range of b in P.

We say that a set of buckets B is a *summary* of P if

- every two buckets in B have disjoint ranges,
- all buckets in B are consistent with P,
- for every $r \in P$, there is some $b \in B$ such that r is in the range of b.

Thus, intuitively, a summary of P is a set of disjoint consistent buckets that cover all elements appearing in P.

Example 3.2. The following are different summaries of dataset P from Example 3.1, with one and two buckets, respectively:

$$B_1 = \{([0, 50]; 13)\} \qquad B_2 = \{([0, 0]; 4), ([10, 50]; 9)\} \quad \square$$

Remark 1. *A summary of a multiset of elements is very similar to the well-studied notion of a histogram of a multiset of elements. Much of the previous work on histograms assumed that the buckets fully covered the domain. This was important, as data was dynamically added to the dataset and had to be incorporated into the histogram (and therefore, had to have a bucket to which it could be added). In this work, since our goal is to summarize the current contents of a dataset, we only create non-empty buckets, with endpoints corresponding to actual elements in the dataset. Empty buckets are not of interest.*

We associate a summary B with a vector $\vec{e}_B$ used to *estimate* frequencies of elements, as follows. Let r be an integer. If r is within the range of a bucket $([p, q]; n) \in B$, then $\vec{e}_B[r] = \frac{n}{q-p+1}$. Otherwise, $\vec{e}_B[r] = 0$.

Now, the *error* of B w.r.t. P, denoted $err(B, P)$ is the distance of $\vec{e}_B$ from $\vec{f_P}$. In general, different distance metrics can be employed. In this paper, we use the sum-squared-error (SSE) metric as, used by [11]:

$$err(B, P) = \sum_{q \in \mathbb{Z}} (\vec{f_P}[q] - \vec{e}_B[q])^2 .$$

However, the work generalizes to additional metrics. It has been shown [11] that this error metric can be equivalently computed as:

$$err(B, P) = \sum_{([p,q];n) \in B} \left(\sum_{p \le r \le q} (\vec{f_P}[r])^2 - \frac{n^2}{q - p + 1} \right) . \quad (1)$$

Example 3.3. Recall B_1 and B_2 from Example 3.2. Then, $err(B_1, P) = 29.7$ and $err(B_2, P) = 15$. $\square$

[1] This work considers only discrete domains. For attributes over continuous domains, our work can be applied if a discretization function is used, e.g., by rounding to a given decimal place.

Optimal Summaries. For any dataset P, it is possible to find a summary B with $err(B, P) = 0$ by simply creating a singleton bucket for each element appearing in P. However, such a summary will be of size similar to that of P itself, and will be unwieldy for large datasets. Hence, we will be interested in creating summaries of bounded size.

Let β be a positive integer, called the *bucket size bound*. A summary B is size-bounded by β if the number of buckets in B is at most β. Given a dataset P and a bucket size bound β, the *optimal summary problem* is to find a summary B of P that is size-bounded by β, and has minimal error. This problem has been considered in the past, and has been shown to be solvable in polynomial time using dynamic programming [11].

Optimal Summaries with Deletion. In practice, some of the elements in the dataset may be outliers that greatly contribute to the error of the summary, while adding little information of interest. When we are interested in summarizing the data to understand the general trends, such outliers may not be of interest. Indeed, a better understanding of the data may be derived when some elements are removed, to derive a smoother dataset, before creating a summary.

We say that P' is a *k-deletion* of P if P' is derived by removing at most k elements from P. We consider two different types of summaries after deletion. We say that B is a *k-deletion summary* of P if there is a k-deletion P' of P such that B is a summary of P'. A stronger requirement on the summary can be formulated as follows: We say that B is a *consistent k-deletion summary* of P if there is a k-deletion P' of P such that B is a summary of P' *and* every bucket in B is consistent with P.

Example 3.4. Consider the dataset

$$P = \{\!\{1, 1, 2, 2, 2, 3, 3\}\!\}.$$

Suppose that we can only use a single bucket, but we may delete up to $k = 2$ elements.

The optimal choice is to delete a single occurrence of element 2, yielding the dataset $P' = \{\!\{1, 1, 2, 2, 3, 3\}\!\}$, which can be summarized using one bucket with an error of 0. This summary $B' = ([1, 3]; 6)$, however, is not consistent with P.

An optimal consistent 2-deletion summary can be derived by removing all occurrences of the element 1 (or all occurrences of the element 3) yielding the consistent summary $B'' = ([2, 3]; 5)$ with error 0.5.

This example also serves to demonstrate why consistent summaries have an added benefit. The summary B'' accurately reflects the dataset, namely that it contains five elements in the range $[2, 3]$. The summary B' can be seen as being somewhat confusing, as it seems to imply that the dataset has six elements in the range $[1, 3]$, when in fact there are seven such elements (and one occurrence of element 2 has been removed to reduce the error). □

Problems of Interest. In this paper we study the following problem, called the (consistent) optimization problem: *Let P be a dataset, β be a bucket size bound and k be a natural number. Find P', B such that P' is a k-deletion of P and B is a summary of P' (and B is consistent with P) such that $err(B, P')$ is minimized.*

4 SINGLE BUCKET SUMMARIES

Before studying the general optimization problems, we start by assuming that only a single bucket may be used. We note that even in this case there can be exponentially many different choices of k elements to delete. Hence, finding an optimal k-deletion summary with one bucket is not a trivial problem. In addition, the ability to optimize for a single bucket is an important component in a solution for multiple buckets. Therefore, in this section we present algorithms that find an optimal k-deletion summary in polynomial time, when only a single bucket can be used. We start by considering arbitrary single bucket summaries with deletions, and then consider the special case of consistent single bucket summaries with deletions.

4.1 Arbitrary Single Bucket Summaries

We use $minArbErr(\vec{f}, \beta, k)$ to denote the minimal error that can be achieved for a multiset with frequency vector $\vec{f}$, when up to k elements can be deleted from the multiset, and up to β buckets can be used. The algorithms that we will present compute this error value directly. As is standard with dynamic programming, to find the k elements to be deleted from the multiset and the bucket boundaries that should be used, some additional book-keeping is necessary. This is quite straight-forward, but clutters the presentation. Hence, we focus on computing $minArbErr(\vec{f}, \beta, k)$.

In this section, we study the problem of computing the value $minArbErr(\vec{f}, 1, k)$ for a given $\vec{f}$ and k, i.e., our optimization problem for the special case where only one bucket can be used. Intuitively, there are two different ways to choose elements to remove, in order to reduce the error:

(1) we can remove the first or last elements with non-zero frequency in $\vec{f}$, thereby allowing a bucket with smaller range to cover $\vec{f}$;
(2) we can remove elements that have the greatest frequency, thereby reducing the variance of the frequencies within the bucket.

Before presenting our algorithm, we introduce some necessary notion used in the algorithms throughout this paper. Let $\vec{f}$ be a frequency vector. We use $\mathsf{size}(\vec{f})$ to denote the number of different non-zero elements in $\vec{f}$, and $\mathsf{first}(\vec{f})$ and $\mathsf{last}(\vec{f})$ to denote the first and last elements with non-zero frequency in $\vec{f}$, respectively. Finally, $\mathsf{next}(\vec{f}, p)$ and $\mathsf{prev}(\vec{f}, p)$ denote the element immediately after and immediately preceding p in $\vec{f}$ with non-zero frequency, respectively. When $\vec{f}$ is clear from the context, it will be omitted, and we will simply write size, first, last, $\mathsf{prev}(p)$, $\mathsf{next}(p)$.

For elements p, q, let $\vec{f}_{[p,q]}$ be the frequency vector

$$\vec{f}_{[p,q]}[r] = \begin{cases} \vec{f}[r] & p \le r \le q \\ 0 & \text{otherwise} \end{cases}$$

The algorithm ArbSingleBErr in Figure 1 computes the value $minArbErr(\vec{f}, 1, k)$. ArbSingleBErr starts by first checking if all elements in the vector can be removed (Lines 1–2), in which case an error of zero is returned. Next, the algorithm considers all options of removing first or last elements, as well as other elements with high frequency. Intuitively, the values k_{left} and k_{right} in the algorithm are used to specify how many elements can be removed from the beginning and end, respectively, of $\vec{f}$. This leaves $k_{mid} = k - k_{left} - k_{right}$ elements of high frequency to be removed from the remainder of $\vec{f}$.

The algorithm ArbSingleBErr therefore iterates over values of $k_{left} \le k$ (Line 6), and values of $k_{right} \le k - k_{left}$ (Line 9). We note that we always choose values for k_{left} and k_{right} that are sufficient to reduce the frequency of elements at the beginning

```
Algorithm ArbSingleBErr($\vec{f}, k$)
1.  if $\sum_{p=\text{first}}^{\text{last}} \vec{f}[p] \le k$
2.    then return 0
3.  $e_* \leftarrow \infty$
4.  $p \leftarrow$ first
5.  $k_{left} \leftarrow 0$
6.  while $k_{left} \le k$
7.    do $q \leftarrow$ last
8.      $k_{right} \leftarrow 0$
9.      while $k_{right} \le k - k_{left}$
10.       do $k_{mid} \leftarrow k - k_{left} - k_{right}$
11.         $e \leftarrow$ LowerMaxError($\vec{f}_{[p,q]}, k_{mid}$)
12.         $e_* \leftarrow \min\{e_*, e\}$
13.         $k_{right} \leftarrow k_{right} + \vec{f}[q]$
14.         $q \leftarrow$ prev($q$)
15.     $k_{left} \leftarrow k_{left} + \vec{f}[p]$
16.     $p \leftarrow$ next($p$)
17. return $e_*$
```

```
Algorithm LowerMaxError($\vec{f}, k$)
1.  $p_{min}{:}v_{min} \leftarrow$ minFreqVal($\vec{f}$)
2.  $p_{max}{:}v_{max} \leftarrow$ maxFreqVal($\vec{f}$)
3.  while ($k > 0$ and $v_{max} > v_{min}$)
4.    do $\vec{f}[p_{max}] \leftarrow \vec{f}[p_{max}] - 1$
5.      $k \leftarrow k - 1$
6.      $p_{max}{:}v_{max} \leftarrow$ maxFreqVal($\vec{f}$)
7.  $n_{\text{sum}} \leftarrow \sum_{p=\text{first}}^{\text{last}} \vec{f}[p]$
8.  $n_{\text{sqsum}} \leftarrow \sum_{p=\text{first}}^{\text{last}} (\vec{f}[p])^2$
9.  return $n_{\text{sqsum}} - {n_{\text{sum}}}^2/(\text{last} - \text{first} + 1)$
```

Figure 1: Returns *minArbErr*($\vec{f}, 1, k$)**.**

and end of $\vec{f}$ to zero. This is achieved by increasing k_{left} and k_{right} by the actual frequency values appearing in $\vec{f}$ (Lines 15 and 13).

For given values of k_{left} and k_{right} we have p and q that correspond to the first and last elements of $\vec{f}$ whose frequency has not been reduced. They determine the range of values in $\vec{f}$ for which we will attempt to reduce the highest frequency values (to reduce variance) using the algorithm LowerMaxError.

LowerMaxError uses minFreqVal (resp. maxFreqVal) to return the element and corresponding frequency value which is minimal (resp. maximal) in $\vec{f}$. While more elements can be removed ($k > 0$) and there is still non-zero variance within the range ($v_{max} > v_{min}$) the frequency of the most frequent element is reduced by one (Line 4). Finally, Line 9 returns the error for the single bucket that would be created for the updated $\vec{f}$, using Equation 1. ArbSingleBErr keeps track of the lowest error option (Line 12), and returns this value (Line 17).

Correctness and runtime of ArbSingleBErr are stated in the following theorem.

Theorem 4.1. *For a given $\vec{f}$ and k,* ArbSingleBErr($\vec{f}, k$) *computes minArbErr($\vec{f}, 1, k$) in time $O(k^2(\text{size}\log\text{size} + k))$.*

Proof. ArbSingleBErr iterates over all options of removing all occurrences of elements (i.e., reducing to a zero frequency) from the beginning and end of $\vec{f}$. For each such option, LowerMaxError is used to reduce the frequencies of highest frequency elements. Hence, it is sufficient to show that LowerMaxError returns the minimal error that can be derived by k-deletions that do not remove all occurrences of the first and last elements of $\vec{f}$.

In the following, assume that p and q are the first and last elements, respectively, with non-zero frequency in $\vec{f}$. Thus, the single bucket over a k-deletion of $\vec{f}$ will have the form $([p, q]; n)$ where n is the sum of frequencies of the remaining elements of $\vec{f}$.

Recall that LowerMaxError does the following simple action: while there are still elements that can be deleted and not all frequencies in $\vec{f}$ (between p and q) are equal, find the most frequent element, and reduce its frequency by one. We will prove that this strategy achieves minimal error.

Assume, by way of contradiction, that there exist a different strategy to delete up to k elements from $\vec{f}$, that achieves the minimal error e_0. Let $\vec{f}'$ be this k-deletion. Let

$$v_{est} = (\sum_{p \le r \le q} \vec{f}'[r])/(q - p + 1).$$

Note that v_{est} is the estimated frequency value for each element in the bucket. The error of $\vec{f}'$ is

$$e_0 = \sum_{p \le r \le q} (\vec{f}'[r] - v_{est})^2 .$$

We will show that LowerMaxError also returns e_0.

Let $v_- = \min_{p \le r \le q}\{\vec{f}'[r] \mid \vec{f}'[r] \ne \vec{f}[r]\}$, i.e., v_- is the minimal frequency in $\vec{f}'$ changed by the deletion. Let $v_+ = \max_{p \le r \le q}\{\vec{f}'[r]\}$, i.e., v_+ is the maximal frequency value in $\vec{f}'$.

Now we consider the frequency vector derived by reducing the frequency v_+ by one and increasing the frequency v_- by one. The error of this new frequency vector e_0' differs from e_0 only in the summation for frequencies v_+ and v_-. Now we will show that $e_0' - e_0 \le 0$ i.e, this change did not increase the error. Observe that

$$\begin{aligned} e_0' - e_0 = {} & (v_+ - 1 - v_{est})^2 + (v_- + 1 - v_{est})^2 - \qquad (2)\\ & \Big((v_+ - v_{est})^2 + (v_- - v_{est})^2\Big) \\ = {} & 2(v_- - v_{est}) - 2(v_+ - v_{est}) + 2 \qquad (3)\\ \le {} & 2(v_- - v_{est}) - 2(v_- + 1 - v_{est}) + 2 = 0 \qquad (4) \end{aligned}$$

where Equation 4 holds since $v_- + 1 \le v_+$, since otherwise we could have produced $\vec{f}'$ using LowerMaxError.

Now, by repeating this change up to k times, the result of LowerMaxError will be equal to the minimum error.

To prove the runtime, observe that ArbSingleBErr makes at most k^2 calls to LowerMaxError. Each call to LowerMaxError costs size log size + k. To achieve this time, we first sort the vector $\vec{f}_{[p,q]}$ sent to the algorithm. This allows us to efficiently evaluate all calls to minFreqVal and maxFreqVal. Then, we require another k operations to lower the frequencies, giving a total of $O(\text{size}\log\text{size} + k)$ for algorithm LowerMaxError, and $O(k^2(\text{size}\log\text{size} + k))$ for ArbSingleBErr, as required. □

4.2 Consistent Single Bucket Summaries

We use *minConErr*($\vec{f}, \beta, k$) to denote the minimal error that can be achieved for a multiset with frequency vector $\vec{f}$, when a k-deletion is taken and up to β buckets can be used, and the summary created *must be consistent* with $\vec{f}$. In this section we show how to compute this value for the special case where $\beta = 1$.

ConSingleBErr (Figure 2) uses a precomputed matrix SSE of dimensions size($\vec{f}$)×size($\vec{f}$), where $SSE[p, q]$ is the sum-squared error for a single bucket over the range $[p, q]$ of $\vec{f}$, with no

```
Algorithm ConSingleBErr($\vec{f}, k$)
1.  if $\sum_{p=\text{first}}^{\text{last}} \vec{f}[p] \le k$
2.     then return 0
3.  $q \leftarrow$ last
4.  $k_{right} \leftarrow 0$
5.  while $k_{right} + \vec{f}[q] \le k$
6.      do $k_{right} \leftarrow k_{right} + \vec{f}[q]$
7.         $q \leftarrow \text{prev}(q)$
8.  $e \leftarrow SSE[\text{first}, q]$
9.  $p \leftarrow$ first
10. $k_{left} \leftarrow 0$
11. while $k_{left} + \vec{f}[p] \le k$
12.     do $k_{left} \leftarrow k_{left} + \vec{f}[p]$
13.        $p \leftarrow \text{next}(p)$
14.        while $k_{left} + k_{right} > k$
15.            do $q \leftarrow \text{next}(q)$
16.               $k_{right} \leftarrow k_{right} - \vec{f}[q]$
17.        $e \leftarrow \min\{e, SSE[p, q]\}$
18. return $e$
```

Figure 2: Returns *$minConErr(\vec{f}, 1, k)$*.

deletions,[2] i.e., $SSE[p, q] = \sum_{p \le r \le q} (\vec{f}[r] - v_{est})^2$ where $v_{est} = (\sum_{p \le r \le q} \vec{f}[r])/(q - p + 1)$.

The algorithm ConSingleBErr first checks if all elements in $\vec{f}$ can be deleted. In this case, the error is zero (Lines 1–2). Otherwise, it begins by considering the case in which elements on the right-hand side of $\vec{f}$ are maximally deleted and computes the error in this case (Lines 5–8). Then, in Lines 11–17 we slowly increase the number of elements removed on the left-hand side, while reducing the number of elements removed on the right-hand side, so as to remain within the limit of k. For each such option, we compute the error, and keep the minimal value.

We show the following result.

Theorem 4.2. *For a given $\vec{f}$ and k,* ConSingleBError($\vec{f}, k$) *computes $minConErr(\vec{f}, 1, k)$ in time $O(\min\{k, \text{size}\})$.*

Proof. To prove correctness, it is important to note that only maximal deletions from the two sides of $\vec{f}$ need to be considered. Thus, for example, in Lines 5–7 we maximally remove elements from the right-hand side of $\vec{f}$. This follows from the following claim: Let $\vec{f}$ be a frequency vector, and $p < q$ be elements with non-zero frequencies in $\vec{f}$. Let n be the total frequency of all elements in $\vec{f}$ and let n' be the total frequency of all elements between p and q (including) in $\vec{f}$. Then, $err(\{([\text{first}, \text{last}]; n)\}, \vec{f}) \ge err(\{([p, q]; n')\}, \vec{f}_{[p,q]})$. This follows from Lemma 2 in [11].

Finally, to show the runtime, observe that we iterate over $\vec{f}$ twice: once from right to left (Lines 5–7) and once from left to right (Lines 11-17). Thus, the time is at most $O(\text{size})$. Since in both our iterations over $\vec{f}$ we do at most k operations (we increase k_{right} or k_{left} until k), the time is at most $O(k)$. Together, this proves our claim of runtime. □

[2] In practice, it is not necessary to store a matrix of size size × size. Instead this value can be computed in time $O(1)$ given two arrays of size size each, as discussed in [11].

```
Algorithm NoDeletionSummary($\vec{f}, \beta$)
1. for $p \leftarrow$ first to last
2.     do $M[p, 1] \leftarrow SSE[\text{first}, p]$
3. for $\beta' \leftarrow 2$ to $\beta$
4.     do for $q \leftarrow$ next(first) to last
5.            do $M[q, \beta'] \leftarrow \infty$
6.               for $p \leftarrow$ prev($q$) down-to first
7.                   do $e \leftarrow M[p, \beta' - 1] +$
                        $SSE[\text{next}(p), q]$
8.                      $M[q, \beta'] \leftarrow \min\{M[q, \beta'], e\}$
9. return $M[\text{last}, \beta]$
```

Figure 3: Returns *$minArbErr(\vec{f}, \beta, 0)$* **(which is also equal to** *$minConErr(\vec{f}, \beta, 0)$***).**

5 MULTI-BUCKET SUMMARIES

We now consider the problem of finding summaries that can have multiple buckets. The problem of finding an optimal summary, when no deletions are permitted ($k = 0$) is well studied. Hence, as a baseline approach it is natural to try to directly leverage algorithms that find an optimal summary, in order to solve our problem.

5.1 Baseline Approaches

Before discussing how to find summaries with deletions, we review the dynamic algorithm proposed in [11] for building optimal sum-squared-error histograms without deletions.

Optimal Summary without Deletions. Figure 3 presents the algorithm NoDeletionSummary from [11] which computes the optimal error for a multiset with frequency vector $\vec{f}$ when using β buckets but no deletions. Note that in this special case, clearly $minArbErr(\vec{f}, \beta, 0) = minConErr(\vec{f}, \beta, 0)$ will always hold. Hence, the algorithm can be seen as computing either of these values. Intuitively, the algorithm dynamically iterates over all possible divisions of the input into β buckets and returns the minimal sum-square error found.

NoDeletionSummary utilizes two matrices:

- the precomputed matrix SSE discussed earlier;
- a matrix M of dimensions size($\vec{f}$) × β, in which we will update $M[p, \beta']$ to contain $minArbErr(\vec{f}_{[\text{first}(\vec{f}), p]}, \beta', 0)$.

Hence, $M[\text{last}(\vec{f}), \beta]$ is precisely what we are computing.

The algorithm starts by initializing the matrix M with the error elements for the case of a single bucket (Lines 1–2). Note that this loop, (as well as all other loops in this paper that iterate over elements from $\vec{f}$, such as Line 4 and 6) should be understood as implicitly only looping over elements p for which $\vec{f}[p] > 0$. Thus, for each element p with positive frequency, we update $M[p, 1]$.

To compute the remainder of M, the algorithm uses three nested for loops. In the outer loop, it iterates over the number of β' from 2 to β (Line 3). In the first inner loop, it iterates over elements q from next(first) to last (Line 4). In the inner-most loop, the algorithm iterates over all possible elements p for the left side of the right most bucket (Line 6). Using previously computed values, it then calculates the error, under the assumption that the last bucket ranges from just after p to q, (Line 7) and saves the minimal error in $M[q, \beta']$ (Line 8). Finally, the algorithm returns the minimal error that can be achieved with β buckets, i.e., $M[\text{last}, \beta]$

```
Algorithm SumThenDelErr($\vec{f}, \beta, k$)
1.  $B \leftarrow$ NoDeletionSummaryBuckets($\vec{f}, \beta$)
2.  $([p_1, q_1]; n_1) \leftarrow B[1]$
3.  for $k' \leftarrow 0$ to $k$
4.      do $M[1, k'] \leftarrow$ SingleBErr($\vec{f}_{[p_1,q_1]}, k'$)
5.  for $\beta' \leftarrow 2$ to $\beta$
6.      do for $k' \leftarrow 0$ to $k$
7.          do SDUpdateMatrix($\vec{f}, \beta', k', M, B$)
8.  return $M[\beta, k]$
Algorithm SDUpdateMatrix($\vec{f}, \beta, k, M, B$)
1.  $M[\beta, k] \leftarrow \infty$
2.  $([p, q]; n) \leftarrow B[\beta]$
3.  for $k' \leftarrow 0$ to $k$
4.      $e \leftarrow M[\beta - 1, k - k']$
5.      $e' \leftarrow$ SingleBErr($\vec{f}_{[p,q]}, k'$)
6.      $M[\beta, k] \leftarrow \min\{M[\beta, k], e + e'\}$
```

Figure 4: Returns either *minArbSDErr*($\vec{f}, \beta, k$) **or** *minConSDErr*($\vec{f}, \beta, k$)**, depending on the version of** SingleBucketError **used.**

(Line 9). It is not difficult to see that NoDeletionSummary runs in time $O(\beta\,\text{size}^2)$.

Example 5.1. As a running example, to compare algorithms returning multi-bucket summaries, we consider a dataset with the frequency vector $\vec{f}$, defined as

$$\{1{:}2, 2{:}1, 3{:}2, 4{:}1, 5{:}2, 6{:}3, 7{:}2, 8{:}1\}.$$

The optimal 2-bucket summary of $\vec{f}$, without deletions is

$$B = \{([1,7]; 13), ([8,8]; 1)\}$$

with error 2.86. □

Summarize, then Delete. One approach to finding a summary with deletions is to

- *first* compute an optimal summary B without deletions (using NoDeletionSummary) and
- *then* choose the best elements to delete from the buckets, adjusting bucket boundaries accordingly.

We denote the minimal possible error that can be achieved when following this two-step methodology for a dataset with frequency vector $\vec{f}$, bucket bound β and a number k of deletions as *minArbSDErr*($\vec{f}, \beta, k$) and *minConSDErr*($\vec{f}, \beta, k$) for arbitrary and consistent summaries, respectively.

While a-priori it may not be clear how to choose elements to delete, in fact, an optimal choice can be found in polynomial time using dynamic programming. SumThenDelErr in Figure 4 computes the minimal error by filling in a matrix M of dimensions $\beta \times k$. The position $M[\beta', k']$ is updated to be the optimal error of the first β' buckets while allowing up to k' deletions. Hence, the value of interest will be in $M[\beta, k]$ at the end of the algorithm.

Algorithm SumThenDelErr begins by calling an algorithm named NoDeletionSummaryBuckets, which is a version of the previously presented NoDeletionSummary that returns the set of buckets B, for which the error, with no deletions, is minimal. Next the algorithm initializes all entries of M for $\beta = 1$ by calling an algorithm that computes the error for a single bucket (Lines 2–3). In practice, SingleBErr should be replaced with ArbSingleBErr if the goal is to compute *minArbSDErr*($\vec{f}, \beta, k$) and with ConSingleBErr if the goal is to compute *minConSDErr*($\vec{f}, \beta, k$).

Finally, the algorithm considers all choices for $2 \le \beta' \le \beta$, as well as all values of $k' \le k$, by calling SDUpdateMatrix for each combination. Algorithm SDUpdateMatrix is used to update $M[\beta, k]$, by considering all choices k' of how to split the deletions between the first $\beta - 1$ buckets (i.e., $M[\beta - 1, k - k']$) and the final bucket (i.e., SingleBErr($\vec{f}_{[p,q]}, k'$)).

Example 5.2. Recall the frequency vector $\vec{f}$ from Example 5.1. When running SumThenDelErr($\vec{f}, 2, 2$) once with ArbSingleBErr and once with ConSingleBErr we derive the summaries B_1 and B_2, respectively:

$$B_1 = \{([1,7]; 11), ([8,8]; 1)\} \qquad \textit{err}{:}\ 0.18$$
$$B_2 = \{([2,7]; 11), ([8,8]; 1)\} \qquad \textit{err}{:}\ 0.35$$

where the former is derived by deleting two occurrences of element 6, and the latter is derived by removing two occurrences of element 1. □

If we can show that the algorithm returns a value close to *minArbErr*($\vec{f}, \beta, k$) or *minConErr*($\vec{f}, \beta, k$), we can leverage optimizations presented in the past for finding optimal summaries without deletions to solve the problem at hand. Unfortunately, the following theorem states that SumThenDelErr can be arbitrarily bad.

Theorem 5.3. *For any β, k and $e > 0$, there exists a multiset P with frequency vector $\vec{f}$ such that*

$$\textit{minArbSDErr}(\vec{f}, \beta, k) - \textit{minArbErr}(\vec{f}, \beta, k) > e\,,$$
$$\textit{minConSDErr}(\vec{f}, \beta, k) - \textit{minConErr}(\vec{f}, \beta, k) > e\,.$$

Proof. Due to space limitations, we only show the result for $k = 1$ and $\beta = 2$. The more general case, however, can be shown similarly. Let $e > 0$ be an error gap. Let n be a natural number such that $n > max\{10, 5e\}$. Let $\vec{f}$ be the frequency vector $\{0{:}n, 2{:}1, 4{:}n, 7{:}n\}$.

If we can delete elements before choosing the buckets, the optimal strategy is to reduce the frequency of the element 2 in $\vec{f}$, thus deriving the frequency vector $\vec{f}' = \{0{:}n, 4{:}n, 7{:}n\}$. Then the optimal summary would be $\{([0,0]; n), ([4,7]; 2n)\}$. This summary is also consistent. Hence, *minArbErr*($\vec{f}, 2, 1$) = *minConErr*($\vec{f}, 2, 1$) = n^2.

There are three possible no-deletion summaries of $\vec{f}$ with two buckets. These are specified below with their errors.

$$B_1{:}\ \{([0,4]; 2n+1), ([7,7]; n)\} \qquad \textit{err}_1{:}\ \frac{6}{5}n^2 + \frac{4}{5}n + \frac{4}{5}$$
$$B_2{:}\ \{([0,2]; n+1), ([4,7]; 2n)\} \qquad \textit{err}_2{:}\ \frac{5}{3}n^2 + \frac{2}{3}n + \frac{2}{3}$$
$$B_3{:}\ \{([0,0]; n), ([2,7]; 2n+1)\} \qquad \textit{err}_3{:}\ \frac{4}{3}n^2 - \frac{2}{3}n + \frac{5}{6}$$

It is not difficult to see that for a sufficiently large n, the optimal summary without deletions is $B_1 = \{([0,4]; 2n+1), ([7,7]; n)\}$. Thus, this summary would then be returned by the algorithm NoDeletionSummaryBuckets.

No deletion can be made from B_1 if the summary must be consistent. Hence, SumThenDelErr would return precisely err_1 if ConSingleBucketError is used. It easily follows that

$$\textit{minConSDErr}(\vec{f}, \beta, k) - \textit{minConErr}(\vec{f}, \beta, k) > e.$$

For arbitrary summaries, that need not be consistent, the largest decrement in the error of B_1 that can be achieved by deleting one element is derived by reducing the frequency of element 0 (or equivalently of element 4) by one, which gives us the frequency vector $\vec{f}_1' = \{0{:}n-1, 2{:}1, 4{:}n, 7{:}n\}$ and the summary $B_1' = \{([0,4];2n), ([7,7];n)\}$. Thus, we have that $minArbSDErr(\vec{f}, 2, 1) = \frac{6}{5}n^2 - 2n + 2$.

Now, $minArbSDErr(\vec{f}, 2, 1) - minArbErr(\vec{f}, 2, 1)$ equals

$$\frac{6}{5}n^2 - 2n + 2 - n^2 = \frac{1}{5}n^2 - 2n + 2$$

which is greater than e when n is chosen to be greater than $max\{10, 5e\}$, as required. □

The above theorem implies that one cannot create an optimal summary without deletions, and only afterwards delete elements from the pre-chosen buckets without paying an arbitrarily large penalty in error. However, this algorithm was worth discussion as in practice we will show that it often works quite well. See Section 7 for experimental results.

Delete, then Summarize. An alternative approach that also uses previous work on optimal summaries without deletions is to

- *first* choose k outliers in the dataset to delete, thereby deriving a k-deletion P' of the original dataset P
- *then* compute an optimal summary without deletions for P' (using NoDeletionSummary).

This approach may not return consistent summaries, but it can be used to produce arbitrary summaries. It is difficult to formally prove the quality of the results that this approach will derive. In particular, there are many different ways to define the notion of an outlier. Hence in the first step it is not even clear what we are attempting to delete. Second, most outlier detection algorithms return a set of outliers given a dataset, but cannot be tuned to find a specific number of outliers. This poses a significant technical challenge. Thus, instead of trying to formally prove that this approach will not yield optimal outcomes, we defer consideration of this approach to the experimentation. There we experimentally show that the results returned using this methodology are significantly inferior to all other approaches considered in this paper.

5.2 Optimal Multi-Bucket Summaries

We consider the problem of computing $minArbErr(\vec{f}, \beta, k)$ for arbitrary values of β. Algorithm ArbMultiBErr in Figure 5 is inspired by NoDeletionSummary. ArbMultiBErr uses dynamic programming to fill in a matrix M of dimension size $\times\ \beta \times k$. The position $M[p, \beta', k']$ is updated to be the minimal error of a k'-deletion summary of $\vec{f}_{[\text{first},p]}$ with β' buckets, i.e., $minArbErr(\vec{f}_{[\text{first},p]}, \beta', k')$. Hence, the value of interest will be in $M[\text{last}, \beta, k]$ at the end of the algorithm.

ArbMultiBErr begins by initializing all entries of M for $\beta = 1$ by calling ArbSingleBErr (Lines 1–3). Next, the algorithm considers all choices for $2 \le \beta' \le \beta$, as well as all elements p, other than the first, and all values of $k' \le k$. Algorithm ArbUpdateMatrix is used to update $M[p, \beta', k']$.

Given p, β, k, ArbUpdateMatrix computes $M[p, \beta, k]$, by considering the minimal choice among several options:

- If the frequency value $\vec{f}[p]$ of p is at most k, then we can create β buckets for $\vec{f}_{[\text{first},p]}$ by removing all occurrences of p, and then finding the optimal buckets for $\vec{f}_{[\text{first},\text{prev}(p)]}$ with $k - \vec{f}[p]$ deletions, using the precomputed value in M. (Lines 1–3)

```
Algorithm ArbMultiBErr($\vec{f}, \beta, k$)
1. for $p \leftarrow$ first to last
2.     do for $k' \leftarrow 0$ to $k$
3.         do $M[p, 1, k'] \leftarrow$ ArbSingleBErr($\vec{f}_{[\text{first},p]}, k'$)
4. for $\beta' \leftarrow 2$ to $\beta$
5.     do for $p \leftarrow$ next(first) to last
6.         do for $k' \leftarrow 0$ to $k$
7.             do ArbUpdateMatrix($\vec{f}, \beta', k', p, M$)
8. return $M[\text{last}, \beta, k]$
Algorithm ArbUpdateMatrix($\vec{f}, \beta, k, p, M$)
1. if $\vec{f}[p] \le k$
2.    then $M[p, \beta, k] \leftarrow M[\text{prev}(p), \beta, k - \vec{f}[p]]$
3.    else $M[p, \beta, k] \leftarrow \infty$
4. for $q \leftarrow$ first to prev($p$)
5.     do for $k' \leftarrow 0$ to $k$
6.         do $e \leftarrow M[q, \beta - 1, k - k']$
7.            $e' \leftarrow$ LowerMaxError($\vec{f}_{[\text{next}(q),p]}, k'$)
8.            $M[p, \beta', k'] \leftarrow \min\{M[p, \beta, k], e + e'\}$
```

Figure 5: Returns $minArbErr(\vec{f}, \beta, k)$.

- In addition, for every element q preceding p, and for every $k' \le k$ we consider the case that $\beta - 1$ buckets are used to cover $\vec{f}_{[\text{first},q]}$ with $k - k'$ deletions and a final bucket covers the range from next(q) to p, using k' deletions. The error of such a summary is $M[q, \beta - 1, k - k'] +$ LowerMaxError($\vec{f}_{[\text{next}(q),p]}, k'$). (Lines 4–8)

Example 5.4. Recall the frequency vector $\vec{f}$ from Example 5.1. With ArbMultiBErr we will get an error of 0.125 corresponding to the deletion of one occurrence of the element of 6, as well as the element 8, and the buckets $\{([1,4];6), ([5,7];6)\}$. □

Theorem 5.5. *Given $\vec{f}$, β and k,* ArbMultiBErr($\vec{f}, \beta, k$) *computes $minArbErr(\vec{f}, \beta, k)$ in time*

$$O(\beta k^2 \text{size}^2 + \text{size}^2(\text{size} \log \text{size} + k)).$$

Proof. Correctness is easy, and follows from Theorem 4.1, and from the fact that the algorithm considers all possible ways to divide the frequency vector into buckets, and all possible choices of deletions. Note that the algorithm directly considers removals of elements only on the right-hand of buckets. (For the first bucket both sides are considered). However, any removals of elements at the left-hand side of these buckets can equivalently be thought of as removals from the right-hand side of the previous bucket.

To achieve the stated runtime, we pre-compute the values of LowerMaxError($\vec{f}_{[p,q]}, k'$) for all $p < q$ (with non-zero frequencies) and for all $k' \le k$. For a choice of p and q, we can compute LowerMaxError($\vec{f}_{[p,q]}, k'$) for all values of k' in time size log size + k, by sorting $\vec{f}_{[p,q]}$ by frequency values, and then computing the results incrementally starting with $k = 0$. This give a total time of $\text{size}^2(\text{size} \log \text{size} + k)$ for LowerMaxError computations. These values are then read from a pre-computed data structure, in $O(1)$ when running ArbUpdateMatrix.

The remainder of the algorithm runs in time $O(\beta k^2 \text{size}^2)$ due to the nested loops of length β (Line 4 of ArbMultiBErr), of length size (Line 5), of length k (Line 6) and the loop of lengths size (Line 4 of ArbUpdateMatrix) and length k (Line 5). □

```
Algorithm ConUpdateMatrix($\vec{f}, \beta, k, p, M$)
1.  if $\vec{f}[p] \le k$
2.      then $M[p, \beta, k] \leftarrow M[\text{prev}(p), \beta, k - \vec{f}[p]]$
3.      else $M[p, \beta, k] \leftarrow \infty$
4.  for $q \leftarrow \text{prev}(p)$ to first
5.      do $e \leftarrow M[q, \beta - 1, k] + SSE[\text{next}(q), p]$
6.          $M[p, \beta, k] \leftarrow \min\{M[p, \beta, k], e\}$
```

Figure 6: Used as a sub-procedure in order to compute *minConErr*($\vec{f}, \beta, k$).

5.3 Optimal Consistent Multi-Bucket Summaries

We now consider the problem of computing the error for optimal consistent summaries, i.e., *minConErr*($\vec{f}, k, \beta$). Let ConMultiBErr be an algorithm identical to ArbMultiBErr, except that in Line 3 it calls ConSingleBErr and in Line 7 it calls ConUpdateMatrix. Recall that ConSingleBErr appears in Figure 2. ConUpdateMatrix appears in Figure 6. It remains to explain how this algorithm works.

ConUpdateMatrix($\vec{f}, \beta, k, b, M$) is called to update the value in $M[p, \beta, k]$ for $\beta > 1$. It first considers the case that the right-most element (which is now p) can be completely removed (Lines 1–3), in which case the previously computed error can be used. It then (Lines 4–6) considers all splits of $\vec{f}$ into two, such that $\beta - 1$ buckets are used to summarize $\vec{f}_{[\text{first},q]}$ (with error appearing in $M[q, \beta - 1, k]$) and one bucket is used to summarize $\vec{f}_{[\text{next}(q),p]}$ (with error appearing in $SSE[\text{next}(q), p]$). Note that in this case, we can assume that no deletions occur in the rightmost bucket, as:

(1) we already considered the case that occurrences of p are removed and
(2) any removals of elements at the left-hand side of the final bucket can equivalently be thought of as removals from the right-hand side of the previous bucket.

Example 5.6. Recall once again $\vec{f}$ from Example 5.1. With algorithm ConMultiBErr we will get an error of 0.17 corresponding to the deletion of the element of 4, as well as the element 8, and the buckets $\{([1, 3]; 5), ([5, 7]; 7)\}$. □

We can show the following result. Observe that ConMultiBError is only slower than algorithm NoDeletionSummary by a factor of k.

Theorem 5.7. *For a given $\vec{f}$, β and k,* ConMultiBErr($\vec{f}, \beta, k$) *computes minConErr*($\vec{f}, \beta, k$) *in time $O(\beta\, k\, \text{size}^2)$.*

Proof. Correctness is easy to show as the different ways to split $\vec{f}$ to different buckets, while deleting all occurrences of elements not in these buckets, is considered. To show the runtime, observe that ConSingleBErr runs in $O(\text{size})$. Therefore, Lines 1–3 of ConMultiBErr run in time $O(k\,\text{size}^2)$. ConUpdateMatrix runs in time $O(\text{size})$. Therefore, Lines 4–7 of ConMultiBErr run in time $O(\beta\, k\, \text{size}^2)$, as required. □

6 SUMMARIES OF DATASETS WITH MULTIPLE COLUMNS

We now briefly consider the problem of finding an optimal summary for datasets with multiple columns, in the presence of outliers. Let $\mathcal{R}$ be a relation with n columns, $(\beta_1, \dots, \beta_n)$ be a n- tuple indicating the number of buckets per column that can be allocated and let k be a number. We consider two types of outliers:

- *value deletions*: a specific value in some tuple t can be considered an outlier in a specific column (even though the other values in t are not outliers), and thus, be deleted from the column;
- *tuple deletions*: a tuple t can be considered an outlier, and thus, be deleted from the relation.

Our goal is to find a summary with β_i buckets for column i, that minimizes the sum of error over all columns, when there can be at most k value or tuple deletions.

	C	X
t_1^1	2	10
t_2^1	2	20
t_3^1	2	30
t_1^2	4	20
t_2^2	4	30
t_3^2	4	40
t_1^3	6	10
t_2^3	6	40
t_3^3	6	50
t^0	1	0
t^1	3	0
t^2	5	0
t^3	7	0

$\mathcal{R}$

	C	X
t_1^1	2	10
t_2^1	2	20
t_3^1	2	30
t_1^2	4	20
t_2^2	4	30
t_3^2	4	40
t_1^3	6	10
t_2^3	6	40
t_3^3	6	50
t^0	1	0
t^1	3	0
t^2	5	0
t^3	7	0

$\mathcal{R}$

Figure 7: Example multicolumn dataset

Example 6.1. Consider the relation $\mathcal{R}$ repeated twice in Figure 7. (Ignore the first column which names the tuples for convenience.) Suppose $k = 6$. In the version of $\mathcal{R}$ on the left, we have chosen up to k values to be deleted per column, while in the version on the right we have chosen up to k tuples to be deleted. (Both are indicated by the color blue.)

Now, suppose we can allocate one bucket for the first column C and three buckets for the second column X. For both types of deletions we can find a *perfect summary* (i.e., one with no error). For the deletions of the left we would choose buckets:

- $([1, 7]; 7)$ for column C and
- $([0, 0]; 4)$, $([20, 20]; 2)$, $([30, 30]; 2)$ for column X.

For the deletions on the right we would choose buckets:

- $([1, 7]; 7)$ for column C and
- $([0, 0]; 4)$, $([20, 20]; 1)$, $([40, 40]; 2)$ for column X.

The above example demonstrated summaries with $(1, 3)$ buckets for the columns and six value/tuples deletions that are clearly optimal (as they have no error at all). The problem arises as to how hard it is to find such optimal summaries in the general case.

Theorem 6.2. *Let $\mathcal{R}$ be a relation with n columns, let $(\beta_1, \dots, \beta_n)$ be the bucket size bounds and let k be natural number. Then:*

(1) *An optimal summary satisfying the bucket size bounds, with up to k value deletions per column can be found in polynomial time.*
(2) *The problem of determining whether there exists a perfect summary of $\mathcal{R}$ with up to k tuple deletions is NP-complete, even if*
   - *the dataset has two attributes* or
   - *all attributes can have at most two buckets.*

The first claim is easy to show as we can simply apply the algorithms from the previous section to each column separately. For the second claim, in the case in which there are only two attributes we can show hardness by a reduction from the monotone satisfying assignment problem. For the case where there are at most two buckets per attribute we can show hardness by a reduction from 1-in-3 SAT. The proofs are omitted due to space limitations, but the main ideas of the second claim are demonstrated in the following examples.

Example 6.3. We demonstrate hardness when the relation contains only two columns.

Let ψ be a positive 3-SAT formula with m clauses $C_1, \dots, C_m$, over the variables $x_1, \dots, x_n$. We say that ψ is h-monotone satisfiable if ψ can be satisfied by an assignment in which at most h variables are assigned true. This is a well-known NP-complete problem.

Let $\mathcal{R}$ be a relation of cardinality 2, containing two types of tuples:

- For each clause $C_i = x_{i_1} \vee x_{i_2} \vee x_{i_3}$ we add to $\mathcal{D}$ three tuples $t_1^i = (2i, 10i_1)$, $t_2^i = (2i, 10i_2)$, $t_3^i = (2i, 10i_3)$.
- For every $0 \geq j \geq m$ we add the tuple $t^j = (2j + 1, 0)$.

Observe that $\mathcal{R}$ contains $4m + 1$ tuples. For example, the formula

$$(x_1 \vee x_2 \vee x_3) \wedge (x_2 \vee x_3 \vee x_4) \wedge (x_1 \vee x_4 \vee x_5)$$

corresponds to the relation $\mathcal{R}$ in Figure 7.

Now, we choose $k = 2m$ and $(1, h + 1)$ as our bucket bound, i.e., a single bucket for the first column and $h + 1$ buckets for the second column. We can show that ψ is h-monotone if and only if there is a k-tuple deletion for which there is a summary bounded by $(1, h + 1)$ with zero error.

For example, suppose that $h = 2$. Consider the k-tuple deletion $\mathcal{R}'$ derived by removing the blue tuples in the relation on the right. It is easy to see that we can use a single bucket for the first column, and $h + 1 = 3$ buckets for the second column, to derive a summary with error of zero. Observe also that $\mathcal{R}'$ corresponds to a satisfying assignment that assigns at most h variables the value true (in this case x_2 and x_4 as the elements 20 and 40 remain after the k-tuple deletion).

One can show (omitting some precise details due to space limitations) that the opposite holds too, i.e., that any k-deletion that has a summary bounded by $(1, h + 1)$ with an error of zero corresponds to an h-monotone satisfying assignment. □

Example 6.4. We demonstrate why determining whether there exists a k-tuple deletion $\mathcal{R}'$ with a perfect summary S is a difficult problem, even when there are only two buckets per column.

Consider a positive 3-SAT formula with m clauses $C_1, \dots, C_m$, over the variables $x_1, \dots, x_n$. Recall that the 1-in-3 SAT problem is to determine whether there exists an assignment that satisfies precisely one variable in each clause.

We create a relation $\mathcal{R}$ with $n + 1$ columns, and three types of tuples:

	X_1	X_2	X_3	X_4	X_5	C
t_1^1	2	-2	-2	0	0	1
t_2^1	-2	2	-2	0	0	1
t_3^1	-2	-2	2	0	0	1
t_1^2	0	2	-2	-2	0	2
t_2^2	0	-2	-2	-2	0	2
t_3^2	0	-2	-2	2	0	2
t_1^3	2	0	0	-2	-2	3
t_2^3	-2	0	0	2	-2	3
t_3^3	-2	0	0	-2	2	3
$t_1^{c,1}$	0	0	0	0	0	1
$t_2^{c,1}$	0	0	0	0	0	1
$t_1^{c,2}$	0	0	0	0	0	2
$t_2^{c,2}$	0	0	0	0	0	2
$t_1^{c,3}$	0	0	0	0	0	3
$t_2^{c,3}$	0	0	0	0	0	3
t_1^0	0	0	0	0	0	0
t_2^0	0	0	0	0	0	0
t_3^0	0	0	0	0	0	0

Figure 8: Example relation in 1-in-3 SAT reduction.

- For each clause $C_i = x_{i_1} \vee x_{i_2} \vee x_{i_3}$ we add three tuples as follows:
  - for all $j = 1, 2, 3$ we have $t_j^i[n + 1] = i$;
  - for all $j = 1, 2, 3$ and $k \notin \{i_1, i_2, i_3\}$ we have $t_j^i[k] = 0$;
  - for all $j = 1, 2, 3$ and $k = 1, 2, 3$ we have $t_j^i[i_k] = 2$ if $k = j$ and $t_j^i[i_k] = -2$, otherwise.
- For each $i \leq m$, we add two tuples $t_1^{c,i} = t_2^{c,i} = (0, \dots, 0, i)$.
- Finally, we add three tuples $t_1^0 = t_2^0 = t_3^0 = (0, \dots, 0)$.

In total, $\mathcal{R}$ has $5m + 3$ tuples. For example, the formula

$$(x_1 \vee x_2 \vee x_3) \wedge (x_2 \vee x_3 \vee x_4) \wedge (x_1 \vee x_4 \vee x_5)$$

corresponds to the dataset in Figure 8.

Now, suppose that $k = 2m$ and our bucket bound allows two buckets per attribute. For the example in Figure 8, we can remove up to 6 tuples. It is not difficult to see that if we remove the blue tuples, we are left with a data set $\mathcal{R}'$ for which we can create a summary with error of zero. This holds since each column $x_1, \dots, x_5$ has precisely two different elements (which can be placed in different buckets) and column C has three occurrences each of every value from 0 to 3. Observe also that the remaining rows define an assignment that satisfies precisely one variable in each clause, if we assign each x_i true if $\mathcal{R}'[X_i]$ contains element 2, and false otherwise. (In the example given this corresponds to mapping x_2 and x_5 to true.)

Indeed, with a bit of reasoning it is possible to show the opposite direction too, i.e., a k-tuple deletion $\mathcal{R}'$ for which there is a summary with error of zero corresponds to a solution to the 1-in-3 SAT problem. Intuitively, this holds since such a tuple-deletion must retain, for each x_i, only the elements 0 and 2 or only the elements 0 and -2 (thus, corresponding to a truth assignment).

Dataset	size_P	$\text{size}_{\bar{f}}$
ForestAspect	581,012	361
ForestDistHydro	581,012	136
IncomeCapitalGain	48,842	123
IncomeHoursWeek	48,842	96

Figure 9: Real datasets.

In addition, we must retain precisely one tuple from every triple t_1^i, t_2^i, t_3^i so as to have error of zero on the column C, i.e., we will map precisely one variable in each clause to the value true.[3] □

7 EXPERIMENTAL RESULTS

In the following we discuss our experimental results which consider different datasets, and varying β and percentage of elements that can be deleted, denoted ρ. As default values, we use $\beta = 10$ and $\rho = 2\%$. In our experiments, we prefer to consider the percentage of elements to be deleted (ρ) instead of an absolute number (k), as the size of the dataset should determine the number of elements we are willing to delete. We set a time limit of five minutes, i.e., tests that exceeded the time limit were excluded from the results.

All experimentation was run on a standard Win7 desktop with 16GB RAM and an Intel i5-4570 processor. The algorithms were implemented in Java, and experimentation was run with a limit of 1GB of main memory.

Algorithms. We implemented five algorithms for the k-deletion problem. We abbreviate the algorithm names as follows. We use Arb for ArbMultiBErr and Con for ConMultiBErr. We implemented algorithm SumThenDelErr with ArbSingleBErr, and ConSingleBErr, henceforth referred to as SDArb and SDCon, respectively. Finally, we implemented the *delete then summarize* strategy using a well-known distance-based outlier detection algorithm [4] to remove outliers and then summarizing the result using NoDeletionSummary. This algorithm is referred to as DS.

Datasets. We run our algorithms on both synthetic datasets and real datasets. The synthetic datasets were generated by two different distributions—randomly permuted zipf distribution with skew parameter $z = 0.85$ (as in [11]), and normal distribution with variance proportional to 25% of the value range. For each experiment over the synthetic datasets, we generated three instances of the dataset with the same parameters, ran the tests on all three, and computed the average result. Our default synthetic datasets have 50,000 elements and a range of 100, i.e., the elements were sampled from $[1, 100]$.

We also use several real datasets, taken from the UCI KDD Archive[4] and the UCI Machine learning repository[5]. When considering the size of these datasets, there are two factors of importance: the number of elements in the dataset, called size_P and the number of different elements in the dataset (i.e., the number of non-zero elements in the frequency vector), called $\text{size}_{\bar{f}}$. Note that $\text{size}_{\bar{f}}$ corresponds to the value size discussed in the previous sections. The dataset sizes are summarized in Figure 9.

[3]More details are required to make a precise proof, e.g., an assumption that no variable appears in all clauses, but these are omitted due to space limitations.

[5]http://archive.ics.uci.edu/ml/index.php

The Forest dataset contains data obtained from US Forest Service, where the Aspect column is aspect in degrees azimuth, and DistHydro is the horizontal distance to nearest surface water features. For DistHydro we rounded to the nearest 10 meters. The Income dataset (referred to as Adult in the repository) was originally extracted from the Census Bureau 1994 database. We use the columns CapitalGain and HoursWeek, which is the number of work hours per week.

In all runtime graphs, the y-axis is in log scale and the units are in seconds. In all error graphs, the data points represent the ratio of the error in the current setting to the minimum error of the same settings with no deletions. Intuitively, lower values indicate a larger percentage of reduction in error due to deletions.

Comparing All algorithms. In our first test, we compare the error and runtime of all algorithms over the Income dataset and synthetic dataset, using the default values for β and ρ. The results of this test appear in Figures 10a, 10b, 10c and 10d. Due to space limitations, we omit the Forest dataset from this experiment, but similar trends can be seen there.

Algorithm DS, which uses distance based outlier detection, is mostly unsuccessful in improving the error. In our testing, there have even been cases in which the error increases using this algorithm. This is not surprising, both due to the fact that outliers are removed before determining bucket boundaries and because the algorithm does not always even produce enough outliers to delete. This result was consistent in all experiments and therefore, we do not consider it in remainder of the experimentation.

For the other algorithms, the graphs show a consistent order of the error reduction—Arb always finds the optimal error, then SDArb, Con and finally SDCon have increasing errors. The runtime performance, on the other hand, is in almost the opposite order, albeit Con and SDCon are very close in runtime. One can observe that Con achieves error that is fairly close to Arb and SDArb with runtime that is better in orders of magnitude.

Note that the runtime of Arb is so poor over the permuted zipf dataset, that it timed out, and therefore its runtime and error are missing. This occurs often in the experiments both for Arb and for SDArb, as these algorithms have a runtime that is a function of k^2, even when a single bucket is used.

Varying percentage of Deletions. We tested the effect of changing the percentage of elements deleted by varying the value of ρ, and running our algorithms with k chosen as $\rho \cdot \text{size}_P$. The error and runtime results of these tests appear in Figures 10e, 10g, 11a ,10f, 10h and 11b. Note that for the synthetic datasets, we present the error for both permuted zipf and normal distribution, but the runtime only for the former. Since the runtime is not affected by the data distribution, the graph omitted is almost identical to the one appearing.

As expected, in all algorithms and datasets, the error is reduced as ρ grows. The degree to which the error is reduced differs between the datasets, due to differences in the data distributions. For the synthetic data, deletions are more significant in normal distribution than in permuted zipf distribution. Almost consistently, Con and SDCon have significantly lower runtimes than SDArb which is much faster than Arb. It is interesting to see that in most tests, on lower values of ρ, SDCon is faster than Con, but as ρ increases, SDCon becomes slower. The only exception in our tests was on the dataset ForestAspect, where the number of distinct values i.e., $\text{size}_{\bar{f}}$, is much higher than in the other

Figure 11: Experiments for varying ρ, β, size_P and $\text{size}_{\vec{f}}$

datasets, and larger $\text{size}_{\vec{f}}$ degrades the runtime of Con. This phenomenon will be discussed later in our experiments, when we consider varying the value $\text{size}_{\vec{f}}$.

Varying Number of Buckets. Next, we tested the results of our algorithms when varying the number of buckets. The runtimes, which do not appear in graphs due to space limitations, increase linearly together with β. The error reduction is shown in Figures 11c, 11d, and 11e. In general, as the number of buckets increase, the error decreases. On IncomeCapitalGain for instance, the error goes down to zero with 30 buckets, but On ForestDistHydro on the other hand, the improvement in error with 30 bucket is only a little under 80%. There are also cases where the reduction in error actually increases when buckets are added. This counter-intuitive result is because the error ratio is computed with respect to the *same settings* (and thus, the same number of buckets) without deletions. As the number of buckets increases, the relative gain by removing elements may decrease. This is particularly noticeable for SDCon.

Varying the Values of size_P *and* $\text{size}_{\vec{f}}$. We studied how the total number of elements size_P affects the results. To this end, we created synthetic datasets of increasing size. In Figures 11f and 11g depict the change in error and in runtime over different sizes of multisets of elements. The relative error remains approximately the same even as the dataset size increases. This apparently is the result of the fact that the proportion of elements deleted relative to the entire set remains the same. In contrast, the runtime grows linearly with the size of the dataset. (Note that both axes of Figure 11g are on log scale.) The linear increase in runtime occurs as the constant 2% element deletion translates to bigger absolute numbers of k-deletions as the dataset size increases. Similarly to before, for larger datasets (i.e., larger values of k), SDCon runs slower than Con.

In the next experiment we considered increasing the number of distinct elements $\text{size}_{\vec{f}}$. In this experiment the dataset remained at the default size of 50,000 elements, but we increased the range of values so as to increase $\text{size}_{\vec{f}}$. Due to space limitations, the

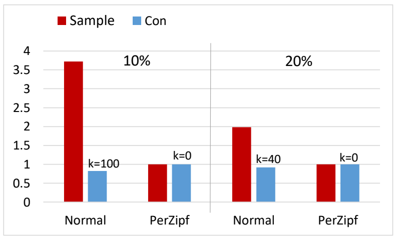

Figure 12: Error of Sampling versus Optimal Deletion

error graph is omitted, as it had the same trends as in Figure 11f. Figure 11h shows the runtime as size$_{\vec{f}}$ increases. As expected, all algorithms have runtime that grow with size$_{\vec{f}}$, except for SDCon whose runtime is independent of size$_{\vec{f}}$.

Comparison with Sampling for Summary Construction. Since histogram construction is costly, in many systems histograms are computed over a sample of the dataset. Intuitively, it might appear that such a sampling based approach will yield similar results to our algorithms that allow for optimal deletions, as perhaps outliers will not be chosen in the sample. In order to check how sampling affects the error in practice, for each dataset P, we constructed a summary B over sampled data using the NoDeletionSummary algorithm. Some of the elements in the original dataset P did not fall into the range of any of the buckets, and were considered to have been "deleted" from the dataset, yielding a new dataset P'. We then computed $err(B, P')$ and compared this value with the error of the optimal consistent summary allowing for $|P - P'|$ deletions.

The results of this experiment on the synthetic datasets, with sampling of 10% and 20% are depicted in Figure 12. (The results on the real datasets were similar.) The size of $|P - P'|$, i.e., the value that was then used as k in the input of ConMultiBErr, appears on top of the bars. The results show two cases. With the permuted Zipf dataset there were no deletions at all as a result of the sampling, and thus, the error is exactly the same as the original error of NoDeletionSummary algorithm. With the normal dataset, there was a larger number of deletions, but the elements deleted by the sampling actually increased the error significantly. When ConMultiBErr was run with the same number of deletions, the error was reduced. We conclude that sampling cannot be used as an effective technique in order to reduce the error of a summary.

8 CONCLUSION

This paper studied the problem of an optimal summary with β buckets, when k outliers need not be covered. We presented the first algorithms for this problem, by taking two different approaches for deleting elements (arbitrarily and consistently), and attempting to determine which elements to delete at different stages (before, during and after finding the optimal summary). We also considered the problem of multi-column datasets. The experimentation shows that algorithm Con has the best balance between low error and low runtime. In addition, on smaller datasets Arb performs very well, providing significantly lower error.

As future work, we intend to consider domains in which there is no natural (useful) ordering over the values, and hence, buckets cannot be described by their endpoints. While our algorithms work well for moderately large datasets, they degrade when the dataset becomes huge. We intend to develop approximation algorithms to deal with this case. Finally, another important direction is finding optimal summaries with outliers over streaming data.

ABSTRACT

How can we efficiently generate large-scale signed networks following real-world properties? Due to its rich modeling capability of representing trust relations as positive and negative edges, signed networks have spurred much interests with various applications. Despite its importance, however, existing models for generating signed networks do not correctly reflect properties of real-world signed networks.

In this paper, we propose BalanSiNG, a novel, scalable, and fully parallelizable method for generating large-scale signed networks following realistic properties. We identify a self-similar balanced structure observed from a real-world signed network, and simulate the self-similarity via Kronecker product. Then, we exploit noise and careful weighting of signs such that our resulting network obeys various properties of real-world signed networks. BalanSiNG is easily parallelizable, and we implement it using Spark. Extensive experiments show that BalanSiNG efficiently generates the most realistic signed networks satisfying various desired properties.

Signed Network Modeling; Balance Theory; Stochastic Kronecker Signed Graph; Balanced Signed Network Generator

1 INTRODUCTION

Signed networks [26] exhibit relationships between nodes as positive (trust) and negative (distrust) edges, and various online social services such as Epinions [10] have naturally formed signed networks by allowing users to express their trust. Inspired by these interesting trust relationships, many researchers have been recently attracted to mining useful information from signed networks, inducing advanced techniques for diverse applications such as sign prediction [22, 25], link prediction [40, 47], node ranking [15, 16, 28], node embedding [20, 46], node classification [42], anomaly detection [21], and community detection [5, 48].

Even though signed networks are important resources in social network analysis, the understanding of synthetically generating realistic signed networks from scratch was nascent. In unsigned networks, many sophisticated generation models have been proposed, including Barabási-Albert (BA) [1], Forest Fire (FF) [27], Stochastic Kronecker Graph (SKG) [23], and Recursive Matrix (R-MAT) [4]. Among those models, SKG and R-MAT have received significant interest from data mining communities [12, 13, 31, 34, 37] since they well capture various properties of real-world graphs such as power-law degree distributions [1, 8, 9, 23, 31], shrinking effective diameters [3, 9, 27], power-law singular value distribution [4, 9, 23], etc.

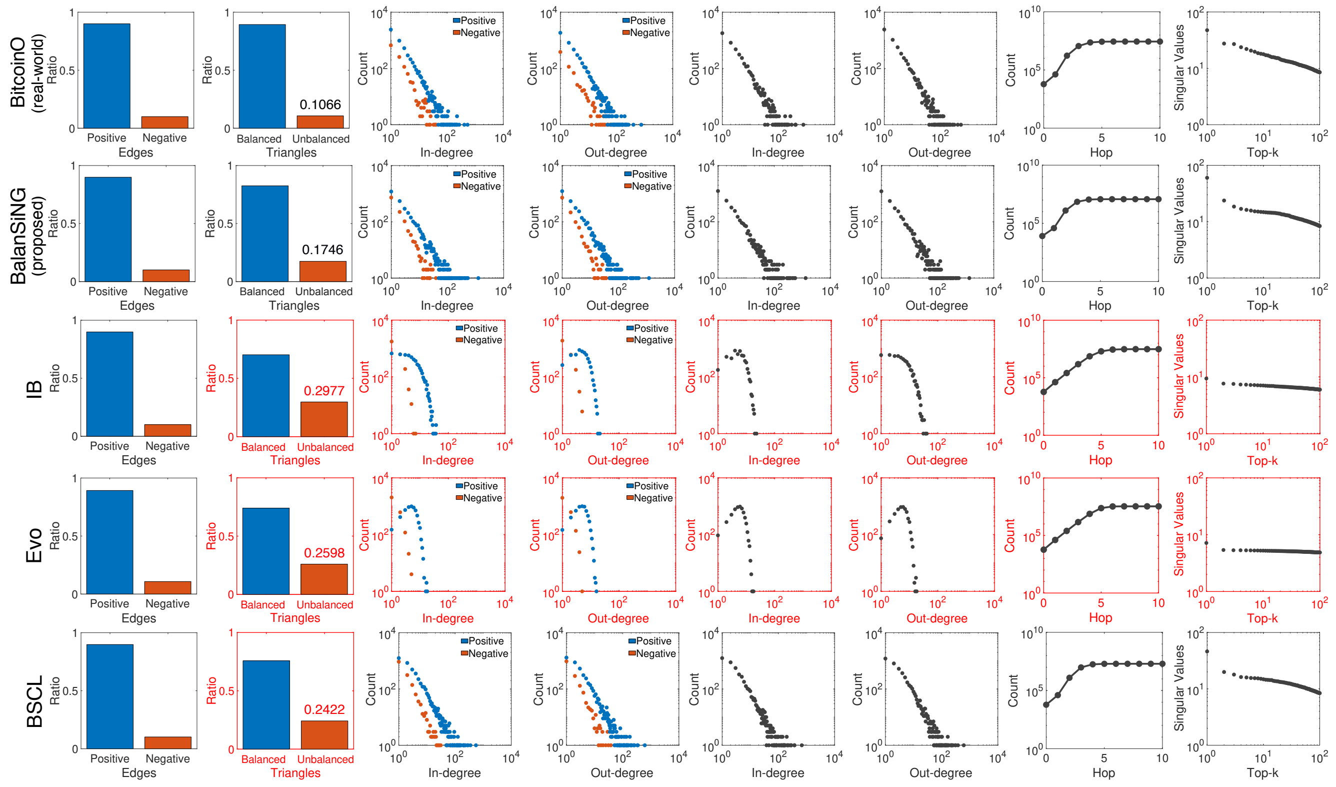
However, the existing models cannot generate realistic signed networks because they do not provide a mechanism for determining signs of edges. Real-world signed networks exhibit not only the traditional properties in unsigned networks, but also distinct characteristics derived from signs (Figure 11). Especially, real-world signed networks are dominated under balance theory [2, 11] that plays a crucial role in the construction of signed networks [6, 26]. According to the balance theory, balanced triangles are more likely to be created than unbalanced ones in real signed networks (details in Section 2). Thus, modeling signed networks demands careful considerations on how to positively or negatively associate three nodes on each triangle.

Motivated by this, several methods have been proposed for signed network generation considering the balance theory. Vukašinović et al. [45] proposed an interaction based model (IB) simulating the generation of signed edges using ant pheromone mechanism and the balance theory. Ludwig et al. [29] suggested an evolutionary model (Evo) that randomly inserts or removes signed edges over time so that the evolving network follows the balance theory. Derr et al. [6] have recently proposed Balanced Signed Chung-Lu (BSCL), the state-of-the-art model imitating an input network based on Transitive Chung-Lu [35] and the balance theory. However, they are limited in generating realistic signed networks (see Figure 1), and computationally inefficient. Furthermore, the scale of existing signed networks remains small; consequently, researchers have suffered from the lack of large-scale signed networks when testing the scalability of their methods. Thus, generating realistic large-scale networks is extremely useful to evaluate the scalability [14, 19, 30–32], simulate their performance depending on various properties of networks [17, 18, 23, 39], and anonymize their data [6, 24].

In this paper, we propose BalanSiNG (Balanced Signed Network Generator), a novel and scalable method for generating synthetic but realistic signed networks. We first identify a self-similar pattern observed from a real signed network. Then, we design Basic Stochastic Kronecker Signed Graph (SKSG-B), a basic model that simulates the self-similarity using Kronecker product and generates fully balanced signed networks. On top of SKSG-B, we propose Stochastic Kronecker Signed Graph (SKSG) by adding random noises to the self-similar pattern and introducing careful weighting to increase the probability of forming positive edges to generate signed networks following real-world properties. From SKSG, we derive BalanSiNG that efficiently creates signed edges fully in parallel. Through extensive experiments, we show that BalanSiNG efficiently generates the most realistic signed networks capturing various properties of real-world signed networks.

Our main contributions are summarized as follows:

- **Novel self-similarity.** We suggest a novel self-similar pattern called *self-similar balanced structure* to be satisfied for generating signed networks (Figure 4).
- **Method.** We propose BalanSiNG, an efficient and parallel method that simulates the suggested self-similarity



(a) Global sign distribution (b) Balanced triangle distribution (c) Signed in-degree distribution (d) Signed out-degree distribution (e) In-degree distribution (f) Out-degree distribution (g) Hop plot (h) Singular value distribution

Figure 1: BalanSiNG generates the most similar network to the real-world network, compared to other methods. The plots show the comparison of properties from real-world signed networks and those from BalanSiNG and competitors. We use BitcoinO dataset [22] for representing the properties of real-world signed networks; other real-world networks give similar results. (a)-(d) illustrate properties derived from edge signs, and (e)-(h) depict traditional properties of real-world networks regardless of edge signs (see Section 2.1). Red colored boxes denote that the corresponding graph does not match the corresponding property.

by using Kronecker product, exploiting noise, and careful weighting (Algorithm 3). BalanSiNG generates signed networks satisfying various desired properties of real-world signed networks listed in Section 2.1.

- **Experiments.** We demonstrate that BalanSiNG generates the most realistic signed networks following real-world properties compared to competitors as shown in Figure 1. We also show that BalanSiNG generates signed networks up to 265× faster than the state-of-the-art method, and near linearly scales up w.r.t. the number of edges on both single and distributed machines (Figure 9).

The source code of BalanSiNG and datasets are available at **https://datalab.snu.ac.kr/balansing**.

2 PRELIMINARIES

We describe the desired properties of real-world signed networks to consider when generating a synthetic signed network in Section 2.1. We formally define the problem addressed in this paper in Section 2.2. We then review Stochastic Kronecker Graph (SKG), a representative generation model for unsigned networks to capture the concept of self-similarity simulation in Section 2.3.

Symbols used in this paper are summarized in Table 1. Throughout the paper, we use a blue arrow and a red arrow to indicate a positive edge and a negative edge, respectively.

2.1 Desired Properties of Signed Networks

We investigate real-world signed networks to grasp their unique properties to be satisfied when generating signed networks. As shown in the first row of Figure 1, there are not only unique properties derived from signs on edges but also traditional ones studied in unsigned networks. The properties of other real-world networks are in Figure 11. We examine properties induced by signs in Section 2.1.1, and then review the typical ones regardless of signs in Section 2.1.2.

2.1.1 *Properties with respect to signs on edges.*

- **D1) Positively skewed sign proportion [25, 26, 43].** Real-world signed networks contain much more positive edges than negative ones, as demonstrated in the first row of Figure 1(a).
- **D2) Highly balanced triangle proportion [6, 11, 26, 41, 43, 48].** Signed triangles have been extensively studied in signed networks based on balance theory [2, 11] stating that triangles $\triangle_{+++}$ with three positive signs and those $\triangle_{+--}$ with one positive sign are much more plausible than other types of triangles $\triangle_{++-}$ and $\triangle_{---}$. The former are called *balanced triangles*, and the latter are *unbalanced triangles.* Thus, the ratio of balanced triangles is much larger than that of unbalanced triangles as shown in Figure 1(b).
- **D3) Power-law degree distribution for only positive or negative edges [43].** In scale-free networks, in- and out-degree distributions follow a power-law [1]. In real-world signed networks, when we consider only positive (or negative) edges, corresponding degree distributions also follow power-laws as shown in Figures 1(c) and 1(d).

Figure 2: Overview of our approach. (a) We suggest *self-similar balanced structure* observed from a real-world signed network (Section 3.1). (b) We design SKSG-B, a basic version of our model, that simulates the self-similarity using Kronecker product, and generates a fully balanced signed network (Section 3.2). (c) We then propose SKSG, an advanced version that produces realistic signed networks by introducing noise and weight splitting (Section 3.3). From SKSG model, we derive BalanSiNG which quickly generates realistic signed networks satisfying the desired properties in parallel (Section 3.4).

2.1.2 Properties without respect to signs on edges.

- **D4) Power-law degree distribution [1, 8, 9, 23, 31].** Real-world networks without signs also show power-law degree distributions as shown in Figures 1(e) and 1(f).
- **D5) Small effective diameter (hop plot) [3, 9, 27].** The hop plot shows the ratio of node pairs reachable from each other within k-hop for each integer k. It is closely related to the effective diameter, the 90 percentile distance in the hop plot. As seen in Figure 1(g), the effective diameters of real-world graphs are small (typically between 4 and 5).
- **D6) Power-law singular value distribution [4, 9, 23].** The singular values in the adjacency matrix of a real graph follow a power-law distribution as shown in Figure 1(h).

2.2 Problem Definition

Problem 1 (Signed Network Generation). *Given the target numbers* $|\mathrm{V}|$ *and* $|\mathrm{E}|$ *of nodes and edges, respectively, we aim to synthetically generate a directed signed network from scratch having* $|\mathrm{V}|$ *nodes and* $|\mathrm{E}|$ *signed edges where the output network should follow the desired properties of real-world signed networks listed in Section 2.1.* ■

2.3 SKG: Stochastic Kronecker Graph Model

SKG [23] is an unsigned network generation model based on Kronecker product. Its motivation is that power-law phenomena in nature occur due to self-similarity, i.e., a self-similar object is approximately similar to a part of itself [36]. SKG stochastically simulates a self-similarity with a tiny seed graph using Kronecker product denoted by $\otimes$ (Definition D.1 in Appendix D). Specifically, SKG creates a self-similar graph by recursively computing $\mathcal{A}^{(k)} = \mathcal{A}_{\text{seed}} \otimes \mathcal{A}^{(k-1)}$ where $\mathcal{A}^{(k)}$ is k-th Kronecker product result over the adjacency matrix $\mathcal{A}_{\text{seed}}$ of the seed graph. In SKG, (u, v)-th entry of $\mathcal{A}^{(k)}$ is the probability $P(u, v)$ that edge $u \rightarrow v$ exists in the graph. When a randomly generated value for each entry is within the probability, the corresponding edge is created. Several methods such as FastKronecker [24] and R-MAT [4] were proposed to reduce the generation time of SKG.

Although many research works [23, 37] have shown that SKG well captures various real-world properties (e.g., D4-6) in unsigned networks, the model is not proper for modeling signed networks since it does not consider how to form signs on edges. More essentially, it has not been revealed which self-similarity should be simulated when we generate signed networks through Kronecker products. Hence, our main challenge is to identify a desirable self-similarity for generating signed networks based on Kronecker product so that a resulting network establishes a solid foundation for the aforementioned properties.

Table 1: Table of symbols.

Symbol	Definition
V	set of nodes
E	set of singed edges
$\otimes$	Kronecker product
L	target recursion depth
$\mathbf{T}$	stochastic signed tensor $\mathbf{T} \in \mathbb{R}^{\lvert \mathrm{V}\rvert \times \lvert \mathrm{V}\rvert \times 2} = \{+\mathcal{P}, -\mathcal{M}\}$
$\mathbf{T}_{\text{seed}}$	$2 \times 2 \times 2$ seed stochastic signed adjacency tensor, i.e., $\mathbf{T}_{\text{seed}} = \{+\mathcal{P}_{\text{seed}}, -\mathcal{M}_{\text{seed}}\}$
$\mathbf{N}^{(l)}_{\text{seed}}$	$2 \times 2 \times 2$ seed tensor with noise at level l
$f_b(\cdot)$	balanced sign aggregator in Definition 3.2
$f_\alpha(\cdot)$	weight splitter with α in Definition 3.4
$\tilde{\mathbf{T}}^{(l)}$	l-th Kronecker product result with $f_b(\cdot)$ and $f_\alpha(\cdot)$
γ	parameter for noise
α	parameter for weight splitting
$\rho(\cdot)$	ratio of a given input
$\triangle_b$ and $\triangle_u$	balanced and unbalanced triangles, respectively
$\triangle_{+++}$	balanced triangles with three + signs
$\triangle_{++-}$	unbalanced triangles with two + signs and one − sign
$\triangle_{+--}$	balanced triangles with one + sign and two − signs
$\triangle_{---}$	unbalanced triangles with three − signs

3 PROPOSED METHOD

We propose BalanSiNG, a novel method for generating realistic signed networks following the desired properties in Section 2.1. The technical challenges and our approaches are as follows:

- Which self-similarity should be satisfied for generating signed networks (Section 3.1)? We suggest a novel self-similarity called *self-similar balanced structure* to be satisfied for generating balanced signed networks by investigating a real-world signed network.
- How can we generate signed networks following the self-similarity (Section 3.2)? We design Basic Stochastic Kronecker Signed Graph (SKSG-B), a basic model that produces a fully balanced signed network by simulating the self-similarity via Kronecker product.
- How can we generate realistic signed networks (Section 3.3)? We propose Stochastic Kronecker Signed Graph (SKSG), an advanced model introducing noise and weight splitting to SKSG-B so that the resulting network exhibits the aforementioned characteristics in Section 2.1.
- How can we efficiently generate large-scale signed networks (Section 3.4)? We derive Balanced Signed Network Generator (BalanSiNG) from SKSG, a fully parallelizable method that quickly generates signed edges.

We illustrate the overview of our approaches in Figure 2. Our main goal is to design a generation method for signed networks showing the distinct properties of real world signed networks. Among the various properties, we mainly focus on the balanced

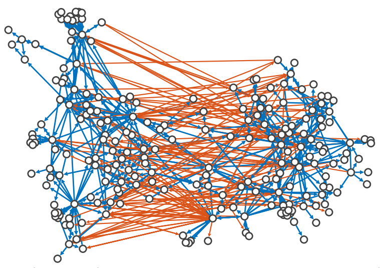

Figure 3: Balanced Structure in Congress dataset [44] where two large clusters are observed. Most nodes in each cluster are positively connected, and nodes between the clusters are negatively connected.

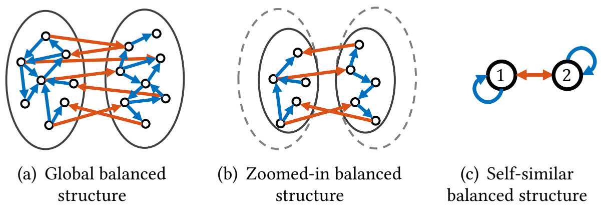
triangle distribution indicating *balanced signed networks* since it is one of the most distinct properties derived from signs [6, 26]. For that purpose, we first design a self-similarity to be satisfied for balanced signed networks, inspired from balanced structure in signed networks as shown in Figure 2(a).

We then propose a basic model SKSG-B and an advanced model SKSG. SKSG-B simulates the self-similarity using Kronecker product so that it produces a fully balanced signed network (i.e., there are no unbalanced triangles) as depicted in Figure 2(b). However, we observe that the fully balanced network of SKSG-B has different properties than those from real-world signed networks in terms of edge sign and balanced triangle proportions as shown in Figure 2(b). Thus, we suggest SKSG by introducing noise and weight splitting to SKSG-B so that SKSG produces realistic signed networks following the desired properties as seen in Figure 2(c). Furthermore, we develop BalanSiNG that generates balanced signed networks fully in parallel while supporting SKSG.

3.1 Self-Similarity for Signed Networks

We investigate a real-world signed network to understand its structure with signs, and then model a self-similarity behind the structure. We analyze the Congress dataset [44], a real-world signed network where nodes represent politicians, and signed edges indicate supports (i.e., positive) or oppositions (i.e., negative) between nodes. The detailed statistics of the dataset are summarized in Table 4. We visualize the signed network of the Congress dataset in Figure 3. Note that two distinct clusters appear where most nodes are mutually friends in each cluster while nodes between the clusters exhibit mutual antagonism. This structure is called *balanced signed network.* If a signed network is *fully balanced* [7], there are *two groups*; nodes in each group create only positive edges while nodes between the groups form only negative edges as in Figure 4(a). This structure is directly related to balance theory [11] since there are only balanced triangles in a fully balanced network, i.e., there are only triangles $\triangle_{+++}$ in each group and triangles $\triangle_{+--}$ between the groups.



(a) Global balanced structure (b) Zoomed-in balanced structure (c) Self-similar balanced structure

Figure 4: Self-similar pattern in balanced signed networks.

From this structure, we observe a self-similar pattern, called *self-similar balanced structure*, as illustrated in Figure 4. Figure 4(a) represents a fully balanced signed network. Then, if we zoom in the network as in Figure 4(b), a smaller but similar structure to that of Figure 4(a) appears. Note that the structure in Figure 4(b) is also balanced; hence, the balanced structure is self-similar according to the definition of self-similarity [36]. We abstract the self-similar balanced structure as shown in Figure 4(c) where each node indicates a group, and blue edges represent that positive edges are created within each group while red edges indicate that negative edges are formed between the groups.

Algorithm 1: SKSG-B

```
Input: seed tensor $\mathbf{T}_{\text{seed}} \in \mathbb{R}^{2\times2\times2}$, target recursion level $L$, and target
    number $|\text{E}|$ of edges
Output: set E of signed edges
 1: set $\tilde{\mathbf{T}}^{(1)} \leftarrow \mathbf{T}_{\text{seed}}$ and $\text{E} \leftarrow \emptyset$
 2: for $l = 2$ to $L$ do
 3:     compute $\tilde{\mathbf{T}}^{(l)} \leftarrow f_b(\tilde{\mathbf{T}}^{(1)} \otimes \tilde{\mathbf{T}}^{(l-1)})$ in Equation (4)
 4: for each $(u, v)$ such that $u, v \in \text{V}$ do
 5:     set $P(u, v, s) \leftarrow \tilde{\mathbf{T}}^{(L)}_{uvs}$ where $s \in \{+, -\}$
 6:     compute $P(u, v)$ and $P(s|u, v)$ using Equation (2)
 7:     toss a biased coin with $P(u, v)$
 8:     if head appears, i.e., $u \rightarrow v$ is formed then
 9:         $\hat{s} \leftarrow \text{argmax}_{s\in\{+,-\}} P(s|u, v)$
10:         insert a signed edge $(u \rightarrow v, \hat{s})$ into E if $|\text{E}| < m$
11: return set E of signed edges
```

3.2 SKSG-B: Basic Stochastic Kronecker Signed Graph Model

We describe our basic model SKSG-B for modeling signed networks. The main intuition of SKSG-B is to simulate the self-similarity explained in Section 3.1 using Kronecker product.

3.2.1 Formulation of SKSG-B. First of all, we define *stochastic signed tensor* used for constructing a signed network G as follows:

Definition 3.1 (Stochastic Signed Tensor). Let $|\text{V}|$ be the number of nodes. A stochastic signed tensor $\mathbf{T} \in \mathbb{R}^{|\text{V}|\times|\text{V}|\times2}$ consists of two stochastic adjacency matrices $\mathcal{P} \in \mathbb{R}^{|\text{V}|\times|\text{V}|}$ and $\mathcal{M} \in \mathbb{R}^{|\text{V}|\times|\text{V}|}$ with signs, i.e., $\mathbf{T} = \{+\mathcal{P}, -\mathcal{M}\}$ where $\mathcal{P}$ and $\mathcal{M}$ represent probabilities for positive and negative edges, respectively. ■

Then, the self-similar balanced structure in Figure 4(c) is represented as follows:

$$\mathbf{T}_{\text{seed}} = \{+\mathcal{P}_{\text{seed}}, -\mathcal{M}_{\text{seed}}\} = \left\{+\begin{bmatrix} p_{11} & 0 \\ 0 & p_{22} \end{bmatrix}, -\begin{bmatrix} 0 & m_{12} \\ m_{21} & 0 \end{bmatrix}\right\} \quad (1)$$

where + and − indicate positive and negative signs, respectively. Each entry $\mathbf{T}_{uvs}$ is a joint probability $P(u, v, s)$ where u and v are nodes, and $s \in \{+, -\}$ is a sign, e.g., $\mathbf{T}_{12-} = m_{12} = P(1, 2, -)$. The sum of all $P(u, v, s)$ is 1, i.e., $\sum_{(u,v,s)} P(u, v, s) = 1$. If we know $P(u, v, s)$, we are able to determine the creation process of edge $u \rightarrow v$ and its sign. First, we compute $P(u, v) = P(u, v, +) + P(u, v, -)$, toss a biased coin with $P(u, v)$, and determine to create the edge if the coin's head appears (line 7 in Algorithm 1). If $u \rightarrow v$ is formed, we decide its sign based on $P(s|u, v)$ as follows:

$$P(s|u, v) = \frac{P(u, v, s)}{\sum_{t\in\{+,-\}} P(u, v, t)} = \frac{P(u, v, s)}{P(u, v)} \quad (2)$$

If $P(+|u, v) > P(-|u, v)$, then its sign is determined to be positive, otherwise, it is negative (line 9 in Algorithm 1). Note that we call this approach *deterministic sign decision.*

Given a small seed signed tensor $\mathbf{T}_{\text{seed}}$, SKSG-B repeats Kronecker product multiple times over $\mathbf{T}_{\text{seed}}$. Kronecker product between two signed tensors is defined as follows:

$$\begin{aligned} \mathbf{T}^{(2)} = \mathbf{T}^{(1)} \otimes \mathbf{T}^{(1)} &= \{+\mathcal{P}, -\mathcal{M}\} \otimes \{+\mathcal{P}, -\mathcal{M}\} \\ &= \{+\mathcal{P} \otimes \mathcal{P}, -\mathcal{P} \otimes \mathcal{M}, -\mathcal{M} \otimes \mathcal{P}, +\mathcal{M} \otimes \mathcal{M}\} \end{aligned} \quad (3)$$

where $\mathbf{T}^{(k)}$ is k-th Kronecker product result on $\mathbf{T}_{\text{seed}} = \mathbf{T}^{(1)} \in \mathbb{R}^{n\times n\times2}$. Note that the dimension of $\mathbf{T}^{(2)}$ is $n^2 \times n^2 \times 2^2$ where the last dimension indicates $\{++, +-, -+, --\}$. Each entry of $\mathrm{T}^{(2)}$ indicates a joint probability $P(u, v, \{s, s\})$. However, this is not the probability that we want since we need $P(u, v, s)$ to determine the edge's sign. Hence, we aggregate the terms according to their sign using *balanced sign aggregator* $f_b(\cdot)$ defined as follows:

Definition 3.2 (Balanced Sign Aggregator). Balanced sign aggregator $f_b : \mathbb{R}^{N \times N \times 4} \rightarrow \mathbb{R}^{N \times N \times 2}$ aggregates the terms in Equation (3) according to their signs as follows:

$$\tilde{\mathrm{T}} = f_b(\mathrm{T} \otimes \mathrm{T}) = \{+(\mathcal{P} \otimes \mathcal{P} + \mathcal{M} \otimes \mathcal{M}), -(\mathcal{P} \otimes \mathcal{M} + \mathcal{M} \otimes \mathcal{P})\}$$
$$= \{+\tilde{\mathcal{P}}, -\tilde{\mathcal{M}}\}$$

where $\tilde{\mathrm{T}} \in \mathbb{R}^{N \times N \times 2}$ is a signed tensor aggregated by $f_b(\cdot)$, $\tilde{\mathcal{P}} = \mathcal{P} \otimes \mathcal{P} + \mathcal{M} \otimes \mathcal{M}$, and $\tilde{\mathcal{M}} = \mathcal{P} \otimes \mathcal{M} + \mathcal{M} \otimes \mathcal{P}$. ■

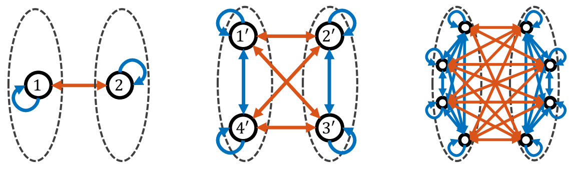
The Kronecker product result with $f_b(\cdot)$ is guaranteed to form a fully balanced signed network (see Section 3.2.2 and Lemma 3.3). Let $\tilde{\mathrm{T}}^{(l)}$ denote l-th Kronecker product result with $f_b(\cdot)$, and $\tilde{\mathrm{T}}^{(1)}$ is initially set to T_{seed} in Equation (1). Then, we generalize the Equation (3) as follows:

$$\tilde{\mathrm{T}}^{(l)} = f_b(\tilde{\mathrm{T}}^{(1)} \otimes \tilde{\mathrm{T}}^{(l-1)}) \tag{4}$$

where $\tilde{\mathrm{T}}^{(l)} \in \mathbb{R}^{n^l \times n^l \times 2}$ is used for building a signed network G given the recursion level l. Algorithm 1 summarizes SKSG-B based on Equation (4). Given T_{seed} in Equation (1), a target recursion level L, and a number $|\mathrm{E}|$ of edges, SKSG-B generates a signed network having 2^L nodes and $|\mathrm{E}|$ edges (line 3). For each pair of nodes, it decides the creation of the edge (line 7) and its sign (line 9) based on $\tilde{\mathrm{T}}^{(L)}$.

3.2.2 *Self-similar Balanced Network Simulated by SKSG-B.*

We illustrate how SKSG-B simulates the self-similarity for balanced signed networks. Given $\tilde{\mathrm{T}}^{(1)} = \mathrm{T}_{\text{seed}}$ in Equation (1), we compute $\tilde{\mathrm{T}}^{(2)}, \tilde{\mathrm{T}}^{(3)}, \cdots$ based on Equation (4). Figure 5 depicts the results of $\tilde{\mathrm{T}}^{(1)}$, $\tilde{\mathrm{T}}^{(2)}$ and $\tilde{\mathrm{T}}^{(3)}$. Note that the balanced structure is kept as level l increases, i.e., only positive edges are formed within each group (dotted ellipses), and only negative edges are allowed between the groups when we start from T_{seed} in Equation (1).



(a) $\tilde{\mathrm{T}}^{(1)}$ (b) $\tilde{\mathrm{T}}^{(2)}$ (c) $\tilde{\mathrm{T}}^{(3)}$

Figure 5: Illustrations on how SKSG-B simulates the self-similarity for balanced signed networks given $\mathrm{T}_{\text{seed}} = \tilde{\mathrm{T}}^{(1)}$.

We formalize this property of the balanced structure generated by SKSG-B in the following lemma:

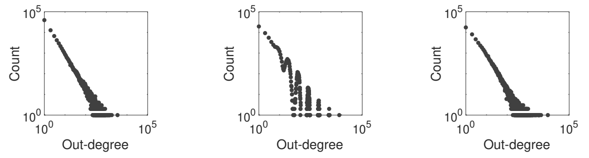
LEMMA 3.3. *Given* T_{seed} *in Equation* (1), $\tilde{\mathrm{T}}^{(l)}$ *of Equation* (4) *produces a fully balanced signed network.*

PROOF. See the detailed proof in Appendix B. □

3.3 SKSG: Exploiting Noise and Weight for Realistic Signed Networks

We propose STOCHASTIC KRONECKER SIGNED GRAPH (SKSG), an advanced model from SKSG-B for generating signed networks following the desired properties in Section 2.1. Although SKSG-B simulates a fully balanced signed network, we will observe that the network's properties deviate from those of real signed networks. We explain the issues of SKSG-B step by step, and suggest how to resolve each issue in the following subsections. The approaches of SKSG are summarized in Algorithm 2.

```
Algorithm 2: SKSG
Input: seed tensor $\mathrm{T}_{\text{seed}} \in \mathbb{R}^{2\times2\times2}$, target recursion level $L$, target
    number $|\mathrm{E}|$ of edges, noise parameter $\gamma$, and weight parameter $\alpha$
Output: set E of signed edges
 1: generate random noises $\mu^{(l)} \in [-\gamma, \gamma]$ [37], and obtain noisy seed
    tensors $\mathrm{N}^{(l)}_{\text{seed}}$ using Equation (6) with $\mathrm{T}_{\text{seed}}$ and $\mu^{(l)}$ for $1 \le l \le L$
 2: set $\tilde{\mathrm{T}}^{(1)} \leftarrow \mathrm{N}^{(1)}_{\text{seed}}$ and $\mathrm{E} \leftarrow \emptyset$
 3: for $l = 2$ to $L$ do
 4:     compute $\tilde{\mathrm{T}}^{(l)} \leftarrow f_\alpha(f_b(\mathrm{N}^{(l)}_{\text{seed}} \otimes \tilde{\mathrm{T}}^{(l-1)}))$ in Equation (7)
 5: for each $(u, v)$ such that $u, v \in \mathrm{V}$ do
 6:     set $P(u, v, s) \leftarrow \tilde{\mathrm{T}}^{(L)}_{uvs}$ for $s \in \{+, -\}$
 7:     compute $P(u, v)$ and $P(s|u, v)$ using Equation (2)
 8:     toss a biased coin with $P(u, v)$
 9:     if head appears, i.e., $u \rightarrow v$ is formed then
10:         toss a biased coin with $P(+|u, v)$
            if head appears, then $\hat{s} \leftarrow +$, otherwise, $\hat{s} \leftarrow -$
11:         insert a signed edge $(u \rightarrow v, \hat{s})$ into E if $|\mathrm{E}| < m$
12: return set E of signed edges
```



(a) Real network (b) SKSG-B without noises (c) SKSG with noises

Figure 6: Out-degree distributions of (a) the Epinions dataset, (b) a network from SKSG-B, and (c) a network from SKSG.

3.3.1 *Introducing Noise (line 1 in Algorithm 2).*

We investigate whether a degree distribution of a graph from SKSG-B follows a power-law. We focus on degree distributions regardless of edge signs (i.e., D4). For T_{seed}, we use the values of Equation (9) in Section 4.1.3. Figure 6(b) shows the out-degree distribution of SKSG-B. Note that the distribution exhibits oscillations; it is far from being monotonically decreasing unlike that of real networks as in Figure 6(a). In fact, the oscillatory behavior is a well-known issue of the standard SKG [37]. Since the edge formation of SKSG-B is equivalent to that of SKG (see the details in Appendix E), SKSG-B naturally inherits the oscillatory behavior from SKG.

Seshadhri et al. [37] analyzed the oscillatory issue of SKG, and provided a technique called Noisy SKG. For each level l, Noisy SKG defines a noise seed matrix $\mathcal{A}^{(l)}_{\text{seed}} \in \mathbb{R}^{2\times2}$ by introducing a random noise $\mu^{(l)}$ to the seed matrix $\mathcal{A}_{\text{seed}} \in \mathbb{R}^{2\times2}$. More specifically, $\mu^{(l)}$ is chosen uniformly at random in $[-\gamma, \gamma]$ for $\gamma \le \min(\frac{a_{11}+a_{22}}{2}, a_{12})$ while a_{ij} denotes (i, j)-th entry of $\mathcal{A}_{\text{seed}}$ defined as follows:

$$\mathcal{A}^{(l)}_{\text{seed}} = \begin{bmatrix} a_{11} - \frac{2\mu^{(l)} a_{11}}{a_{11}+a_{22}} & a_{12} + \mu^{(l)} \\ a_{21} + \mu^{(l)} & a_{22} - \frac{2\mu^{(l)} a_{22}}{a_{11}+a_{22}} \end{bmatrix} \tag{5}$$

Note that its entries sum to 1, and the expectation of $\mathcal{A}^{(l)}_{\text{seed}}$ is $\mathcal{A}_{\text{seed}}$. This approach introduces randomness to the degree of each node so that the fluctuation in the degree distribution is removed, which is theoretically and empirically proved in [37, 38].

In this work, we adopt this technique to our advanced model SKSG for power-law degree distributions in its signed networks. We aim to obtain a noisy seed tensor $\mathrm{N}^{(l)}_{\text{seed}}$ by adding a noise $\mu^{(l)}$ to the seed tensor $\mathrm{T}_{\text{seed}} = \{+\mathcal{P}_{\text{seed}}, -\mathcal{M}_{\text{seed}}\}$ of Equation (1) for each level l as follows (line 1 in Algorithm 2):

$$\mathbf{N}_{\text{seed}}^{(l)} = \{+\mathcal{P}_{\text{seed}}^{(l)}, -\mathcal{M}_{\text{seed}}^{(l)}\} \tag{6}$$
$$= \left\{+\begin{bmatrix} p_{11} - \frac{2\mu^{(l)}p_{11}}{p_{11}+p_{22}} & 0 \\ 0 & p_{22} - \frac{2\mu^{(l)}p_{22}}{p_{11}+p_{22}} \end{bmatrix}, -\begin{bmatrix} 0 & m_{12} + \mu^{(l)} \\ m_{21} + \mu^{(l)} & 0 \end{bmatrix}\right\}$$

where $\mu^{(l)}$ is a uniform random noise selected in $[-\gamma, \gamma]$ for $\gamma \leq \min(\frac{p_{11}+p_{22}}{2}, m_{12})$. Note that Equation (6) is derived from Equation (5) such that $\mathcal{A}_{\text{seed}}^{(l)} = \mathcal{P}_{\text{seed}}^{(l)} + \mathcal{M}_{\text{seed}}^{(l)}$, while preserving the self-similar balanced structure in Equation (1). Thus, our approach is able to model the probability of edge sign as well as the randomness of node degree while Noisy SKG with Equation (5) cannot model the probability for deciding the sign of an edge.

When generating a signed edge, we exploit $\mathbf{N}_{\text{seed}}^{(l)}$ according to level l instead of the original $\mathbf{T}_{\text{seed}}$ as in line 4 of Algorithm 2 (see Equation (7) in Section 3.3.2). Figure 6(c) depicts the out-degree distribution of SKSG using $\mathbf{N}_{\text{seed}}^{(l)}$ with $\gamma = 0.1$. The in-degree distribution of SKSG also shows the similar tendency.

3.3.2 Weight Splitting (line 4 in Algorithm 2). We analyze the properties about signs in a network of SKSG-B. As shown in Table 2, the ratio of positive edges in a network of SKSG-B is almost equal to that of negative ones, and there are only balanced triangles because SKSG-B generates fully balanced signed networks. However, real signed networks exhibit positively skewed sign and highly balanced triangle proportions (i.e., there are few unbalanced triangles) as seen in the 'BitcoinO' column of Table 2.

Table 2: Sign and balanced triangle ratios. $\rho(+)$ and $\rho(-)$ are the ratios of positive and negative edges, respectively. $\rho(\triangle_b)$ and $\rho(\triangle_u)$ are the ratios of balanced and unbalanced triangles, respectively.

	BitcoinO	SKSG-B	SKSG
$\rho(+)$	0.8999	0.5001	0.8993
$\rho(-)$	0.1001	0.4999	0.1007
$\rho(\triangle_b)$	0.8934	1.0000	0.8254
$\rho(\triangle_u)$	0.1066	0.0000	0.1746

To alleviate this issue, we suggest a weight splitting technique that increases the probabilities on generating positive signs. Note that SKSG-B produces a larger number of negative edges than expected; hence, we move a proportion of probabilities for negative signs into that for positive signs using the following function:

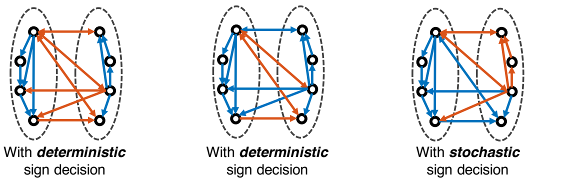
Definition 3.4 (Weight Splitter). For $0 < \alpha < 1$, weight splitter $f_\alpha : \mathbb{R}^{N\times N\times 2} \to \mathbb{R}^{N\times N\times 2}$ is defined as follows:

$$f_\alpha(\mathbf{T}) = f_\alpha(\{+\mathcal{P}, -\mathcal{M}\}) = \{+(\mathcal{P} + \alpha\mathcal{M}), -(1-\alpha)\mathcal{M}\} \quad \blacksquare$$

The function f_α increases the probabilities $\mathcal{P}$ of positive signs by $\alpha\mathcal{M}$. Equation (4) is extended with f_α and $\mathbf{N}_{\text{seed}}^{(l)}$ as follows:

$$\tilde{\mathbf{T}}^{(l)} = f_\alpha(f_b(\mathbf{N}_{\text{seed}}^{(l)} \otimes \tilde{\mathbf{T}}^{(l-1)})) \tag{7}$$

where $\tilde{\mathbf{T}}^{(l)}$ is the level-l result with f_α and f_b. The effects of f_α are that it 1) increases the proportion of positive edges, and 2) forms a few unbalanced triangles $\triangle_{++-}$ as in Figure 7(b). The reason for the latter is as follows. SKSG-B produces a fully balanced network; thus, there are two groups as in Figure 7(a). Since f_α decreases probabilities of negative sign by $\alpha\mathcal{M}$ at each level l in Equation (7), a negative edge between the groups in SKSG-B could become positive in SKSG, resulting in $\triangle_{++-}$ as in Figure 7(b). Note that after $f_\alpha(\cdot)$, probabilities for positive signs do not decrease (Definition 3.4); thus, SKSG with f_α still produces only positive edges inside a group if the edge sign is decided deterministically.



With ***deterministic*** sign decision
With ***deterministic*** sign decision
With ***stochastic*** sign decision

(a) SKSG-B without f_α (b) SKSG with f_α (c) SKSG with f_α

Figure 7: Effects of weight splitter f_α with (b) deterministic sign decision (Section 3.3.2) and (c) stochastic sign decision (Section 3.3.3).

3.3.3 Stochastic Sign Decision (line 10 in Algorithm 2). SKSG-B deterministically decides the sign of an edge based on $P(+|u,v) > P(-|u,v)$ (line 9 in Algorithm 1). However, this approach incurs a subtle issue: such decision does not produce $\triangle_{---}$ at all even though in real signed networks, there are a very few $\triangle_{---}$ as shown in Table 5. Although we introduce f_α in Section 3.3.2, SKSG with f_α does not form $\triangle_{---}$ since it generates only positive edges inside a group while for the case in Figure 7(b), the formation of $\triangle_{---}$ needs one negative edge inside a group with two negative ones between the groups. To resolve this issue, we suggest *stochastic sign decision* where SKSG stochastically decides the edge sign by tossing a biased coin with $P(+|u,v)$ (line 10 in Algorithm 2). This allows an edge to become negative with a low probability inside a group; thus, a few $\triangle_{---}$ are formed as in Figure 7(c). Based on $\tilde{\mathbf{T}}^{(L)}$ with f_α and stochastic sign decision, SKSG introduces the skewness of the sign and balanced triangle ratios similarly to those of the real network as shown in Table 2 where we use $\gamma = 0.1$, $\alpha = 0.75$, $L = 13$ and $\mathbf{T}_{\text{seed}}$ in Equation (9).

3.4 BalanSiNG: Fast and Scalable Balanced Signed Network Generator

We propose BalanSiNG, an efficient method for generating signed edges in parallel, while supporting SKSG. Algorithm 2 of SKSG is not scalable since its time and space complexities are $O(|V|^2)$, respectively, where $|V|$ is the number of nodes to be generated. The reason is that SKSG explicitly constructs signed tensor $\tilde{\mathbf{T}}^{(L)} \in \mathbb{R}^{2^L\times 2^L\times 2}$ through Kronecker product. Our main intuition to design a scalable method for the problem is to directly determine edge and track its sign probabilities without constructing $\tilde{\mathbf{T}}^{(L)}$ explicitly.

We summarize BalanSiNG in Algorithm 3. At each iteration, it exploits Generate-Edge function which determines an edge (u, v) and its sign probabilities $P(u,v,+)$ and $P(u,v,-)$ (line 4). We first explain how the function determines the edge (u, v). Intuitively, this function divides the whole region of $2^L\times 2^L$ adjacency matrix represented by $\tilde{\mathcal{P}}^{(L)} + \tilde{\mathcal{M}}^{(L)}$ of $\tilde{\mathbf{T}}^{(L)}$ into four quadrants. Then, it selects one of them with the corresponding probability, and repeats the process recursively in the chosen quadrant until the quadrant becomes a single cell where an edge is inserted.

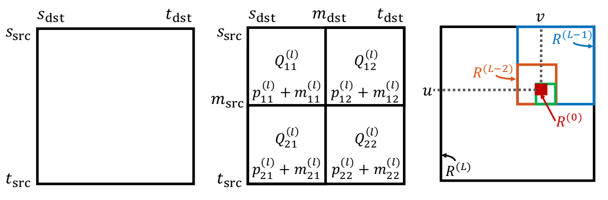
To formalize this process, we need to define *selected region* at level l of Generate-Edge as follows:

Definition 3.5 (Selected Region). $R^{(l)} = \{[s_{\text{src}}, t_{\text{src}}], [s_{\text{dst}}, t_{\text{dst}}]\}$ represents a region of an adjacency matrix, which is selected at level l, where $[s_{\text{src}}, t_{\text{src}}]$ is a range of source nodes, and $[s_{\text{dst}}, t_{\text{dst}}]$ is that of destination nodes as shown in Figure 8(a). $\blacksquare$

Suppose Generate-Edge is given $R^{(l)}$ at level l. It splits the region $R^{(l)}$ equally into four quadrants $Q_{ij}^{(l)}$ (line 9) for $1 \leq i, j \leq 2$ which are defined as follows:

Algorithm 3: BalanSiNG

```
Input: seed tensor $\mathbf{T}_{\text{seed}} \in \mathbb{R}^{2\times2\times2}$, target recursion level $L$, target
    number $|\mathrm{E}|$ of edges, noise parameter $\gamma$, and weight parameter $\alpha$
1: generate random noises $\mu^{(l)} \in [-\gamma, \gamma]$ [37], and obtain noisy seed
   tensors $\mathbf{N}^{(l)}_{\text{seed}}$ using Equation (6) with $\mathbf{T}_{\text{seed}}$ and $\mu^{(l)}$ for $1 \le l \le L$
2: parallel for $k \leftarrow 1$ to $|\mathrm{E}|$ do
3:     set $R^{(L)} \leftarrow \{[1, 2^L], [1, 2^L]\}$ as an initial region
4:     $\{+P(u,v,+), -P(u,v,-)\}$ and $(u, v) \leftarrow$ Generate-Edge($L$, $R^{(L)}$)
5:     compute $P(+|u, v)$ using Equation (2)
6:     toss a biased coin with $P(+|u, v)$
       if head appears, then $\hat{s} \leftarrow +$, otherwise, $\hat{s} \leftarrow -$
7:     write $(u \rightarrow v, \hat{s})$
8: procedure Generate-Edge(level $l$, region $R^{(l)}$)
9:     divide $R^{(l)}$ into four quadrants $Q^{(l)}_{ij}$ for $1 \le i, j \le 2$
10:    randomly select a quadrant $Q^{(l)}_{ij}$ according to probabilities
       $p^{(l)}_{ij} + m^{(l)}_{ij}$ in $\mathbf{N}^{(l)}_{\text{seed}}$ for $1 \le i, j \le 2$
11:    set $R^{(l-1)} \leftarrow Q^{(l)}_{ij}$ as a selected region for level $l-1$
12:    if $l$ is 1 then
13:        return $\{+p^{(1)}_{ij}, -m^{(1)}_{ij}\}$ and $(u, v)$ in $R^{(0)}$
14:    else
15:        $\{+\tilde{p}^{(l-1)}_{uv}, -\tilde{m}^{(l-1)}_{uv}\}$ and $(u, v) \leftarrow$ Generate-Edge($l-1$, $R^{(l-1)}$)
16:        compute $\{+\tilde{p}^{(l)}_{uv}, -\tilde{m}^{(l)}_{uv}\}$ using Equation (8)
17:        return $\{+\tilde{p}^{(l)}_{uv}, -\tilde{m}^{(l)}_{uv}\}$ and $(u, v)$
```



(a) Region $R^{(l)}$ (b) Quadrants $Q^{(l)}_{ij}$ in $R^{(l)}$ (c) Base region $R^{(0)}$

Figure 8: The concept of region and quadrants.

Definition 3.6 (Quadrants in $R^{(l)}$). Given $R^{(l)}$, let $m_{\text{src}} = s_{\text{src}} + \lfloor \frac{t_{\text{src}} - s_{\text{src}}}{2} \rfloor$ and $m_{\text{dst}} = s_{\text{dst}} + \lfloor \frac{t_{\text{dst}} - s_{\text{dst}}}{2} \rfloor$. Each quadrant $Q^{(l)}_{ij}$ is defined as in Figure 8(b) for $1 \le i, j \le 2$. ■

Then, it randomly selects a quadrant $Q^{(l)}_{ij}$ with the probability $p^{(l)}_{ij} + m^{(l)}_{ij}$ which is based on the noisy seed tensor $\mathbf{N}^{(l)}_{\text{seed}}$ (line 10). Note that $p^{(l)}_{ij} + m^{(l)}_{ij}$ indicates $P(i, j, +) + P(i, j, -) = P(i, j)$ interpreted as the probability of selecting (i, j)-th quadrant in $R^{(l)}$. For the next level $l-1$, it sets $R^{(l-1)}$ to the selected $Q^{(l)}_{ij}$ (line 11). The function recursively repeats this process for $R^{(l-1)}$ (line 15) until l becomes 1 when the selected region $R^{(0)}$ (called *base region*) is a single cell representing the edge (u, v) (line 13) as shown in Figure 8(c), after starting from the initial region $R^{(L)}$ (line 3).

The edge sign probabilities $P(u, v, +)$ and $P(u, v, -)$ are also recursively computed using the following equation (line 16):

$$\{+\tilde{p}^{(l)}_{uv}, -\tilde{m}^{(l)}_{uv}\} \leftarrow f_\alpha \left(f_b \left(\{+p^{(l)}_{ij}, -m^{(l)}_{ij}\} \otimes \{+\tilde{p}^{(l-1)}_{uv}, -\tilde{m}^{(l-1)}_{uv}\} \right) \right) \quad (8)$$

which is the entry-wise version of Equation (7) where $p^{(l)}_{ij}$ and $m^{(l)}_{ij}$ are the selected quadrant probabilities at line 10 (derivation in Lemma C.1 of Appendix C). The terms $\tilde{p}^{(l)}_{uv}$ and $\tilde{m}^{(l)}_{uv}$ denote the entries of $\tilde{\mathcal{P}}^{(l)}$ and $\tilde{\mathcal{M}}^{(l)}$ corresponding to edge (u, v), respectively, where $\tilde{\mathrm{T}}^{(l)} = \{+\tilde{\mathcal{P}}^{(l)}, -\tilde{\mathcal{M}}^{(l)}\}$. Note that each probability is scalar, i.e., $p^{(l)}_{ij}, m^{(l)}_{ij} \in \mathbb{R}^{1\times1}$; thus, $\{+p^{(l)}_{ij}, -m^{(l)}_{ij}\} \in \mathbb{R}^{1\times1\times2}$. Similarly, $\{+\tilde{p}^{(l-1)}_{uv}, -\tilde{m}^{(l-1)}_{uv}\} \in \mathbb{R}^{1\times1\times2}$. The Kronecker product result in $f_b(\cdot)$ is $\{+p^{(l)}_{ij}\tilde{p}^{(l-1)}_{uv}, -p^{(l)}_{ij}\tilde{m}^{(l-1)}_{uv}, -m^{(l)}_{ij}\tilde{p}^{(l-1)}_{uv}, +m^{(l)}_{ij}\tilde{m}^{(l-1)}_{uv}\} \in \mathbb{R}^{1\times1\times4}$ which is consistent with the input definition of $f_b(\cdot)$ when $N = 1$ (see Definition 3.2). For level $l-1$, $\{+\tilde{p}^{(l-1)}_{uv}, -\tilde{m}^{(l-1)}_{uv}\}$ is recursively computed by Generate-Edge (line 15). The final $\{+\tilde{p}^{(L)}_{uv}, -\tilde{m}^{(L)}_{uv}\}$ returned by the function is $\{+P(u,v,+), -P(u,v,-)\}$ (line 4).

Note that the generation of a signed edge of Generate-Edge is independent of the generation of other edges; thus, Algorithm 3 of BalanSiNG generates signed edges in parallel (line 2). We let Algorithm 3 call the Generate-Edge function in parallel using Apache Spark, a widely used distributed computing framework.

Table 3: BalanSiNG has the smallest time and space complexities. $|\mathrm{E}|$ and $|\mathrm{V}|$ are the number of edges and nodes, respectively, and $d_{\max}$ is the maximum node degree.

Method	Time	Space	Parallel?
IB [45]	$O(\lvert\mathrm{E}\rvert\lvert\mathrm{V}\rvert)$	$O(\lvert\mathrm{E}\rvert)$	No
Evo [29]	$O(d^3_{\max}\lvert\mathrm{E}\rvert\lvert\mathrm{V}\rvert)$	$O(\lvert\mathrm{E}\rvert)$	No
BSCL [6]	$O(d^2_{\max}\lvert\mathrm{E}\rvert + \lvert\mathrm{V}\rvert)$	$O(\lvert\mathrm{E}\rvert)$	No
BalanSiNG (proposed)	$O(\lvert\mathrm{E}\rvert \log \lvert\mathrm{V}\rvert)$	$O(\log \lvert\mathrm{V}\rvert)$	**Yes**

3.4.1 *Complexity Analysis.*

We analyze the complexities of BalanSiNG. To compare BalanSiNG with other sequential methods, we analyze the sequential complexities as follows:

Lemma 3.7 (Complexity of BalanSiNG). *The time complexity of BalanSiNG is $O(|\mathrm{E}| \log |\mathrm{V}|)$ where $|\mathrm{E}|$ and $|\mathrm{V}|$ are the number of edges and nodes, respectively. The space complexity is $O(\log |\mathrm{V}|)$.*

Proof. Let $T(L)$ be the time complexity of Generate-Edge given L; then, $T(L) = T(L-1) + O(1)$ since there is a recursive call with $L-1$ at line 15 of Algorithm 3, and other lines demand $O(1)$. Hence, it is obvious that $T(L)$ is in $O(L) = O(\log |\mathrm{V}|)$ where we set $|\mathrm{V}| = 2^L$. BalanSiNG generates $|\mathrm{E}|$ edges; thus, the total time complexity is $O(|\mathrm{E}| \log |\mathrm{V}|)$. BalanSiNG needs to have L noisy seed tensors $\mathbf{N}^{(l)}_{\text{seed}} \in \mathbb{R}^{2\times2\times2}$ where each tensor exhibits constant space complexity, i.e., $O(1)$ (line 1 in Algorithm 3). Therefore, the space complexity is $O(L) = O(\log |\mathrm{V}|)$. □

Table 3 compares signed network generation methods (see Section 4.1.2) in terms of complexities and parallelism. The time and space complexities of BalanSiNG are less than those of other sequential methods such as IB, Evo, and BSCL. Especially, these competitors require to store all generated edges in memory (i.e., they require $O(|\mathrm{E}|)$ space) since they need to retrieve the common neighbors of two nodes to determine the edge's sign between the nodes based on balance theory. On the other hand, BalanSiNG is free of such restriction; i.e., as soon as an edge is created, BalanSiNG is able to write it onto disk (line 7 of Algorithm 3).

4 EXPERIMENT

We aim to answer the following questions from experiments:

- **Q1. Properties of signed networks (Section 4.2).** Is our proposed BalanSiNG able to synthetically generate signed networks following the desired properties of real-world networks?
- **Q2. Fine-grained comparison of signed triangles (Section 4.3).** Does BalanSiNG generate graphs with realistic signed triangle distributions, compared to other methods?
- **Q3. Effects of parameters (Section 4.4).** How do weight parameter α and recursion level L of BalanSiNG affect the properties of generated networks?
- **Q4. Computational performance (Section 4.5).** How efficient is BalanSiNG for generating large-scale signed networks compared to other competitors? How does BalanSiNG scale up in terms of the number of workers and the data size on distributed machines?

4.1 Experimental Settings

We explain the detailed settings for our experiments.

4.1.1 Datasets. The datasets used for our experiments are summarized in Table 4. The BitcoinO and BitcoinA datasets [22] were extracted from online trust and directed networks served by Bitcoin Alpha and Bitcoin OTC, respectively. The Epinions dataset [10] is a directed signed network, and was scraped from Epinions, a product review site where users are able to mark their trust or distrust to others. We use the datasets to investigate their distinct properties and provide baseline statistics on signed triangle distributions in Table 5.

4.1.2 Competitors. We compare our proposed method BalanSiNG to the following competitors:

- **IB** [45]: IB (Interaction-based model) generates signed edges based on global and local interactions between nodes under ant pheromone mechanism and balance theory.
- **Evo** [29]: Evo (Evolutionary model) randomly generates signed edges, and keeps track of the number of unbalanced triangles over time. Once a node reaches a certain threshold of unbalanced triangle ratio, it randomly removes a link from the node until the threshold is not exceeded.
- **BSCL** [6]: BSCL (Balanced Signed Chung-Lu) is the-state-of-the-art model based on Transitive Chung-Lu model [35] and balance theory, which synthetically produces a signed network by imitating an input signed network.

4.1.3 Parameters. We describe the setting of the parameters for each method as follows:

- **BalanSiNG**: For the weight parameter α, we search for α on a grid between 0 and 1 by 0.05, and choose α which minimizes the absolute difference for edge signs in Equation (12) between a generated network and a real network. We set the noise parameter γ to 0.1 and the seed tensor $\mathbf{T}_{\text{seed}} = \{+\mathcal{P}_{\text{seed}}, -\mathcal{M}_{\text{seed}}\}$ to the following values:
$$\mathbf{T}_{\text{seed}} = \left\{+\begin{bmatrix}0.57 & 0\\ 0 & 0.05\end{bmatrix}, -\begin{bmatrix}0 & 0.19\\ 0.19 & 0\end{bmatrix}\right\} \quad (9)$$
which are derived from $\mathcal{A}_{\text{seed}} = \begin{bmatrix}0.57 & 0.19\\ 0.19 & 0.05\end{bmatrix}$. Many researches [30, 31, 37, 38] have empirically proved that these values produce monotonically decreasing power-law degree distributions. Note that other values of γ and $\mathbf{T}_{\text{seed}}$ can be used as well.
- **IB**: M_G and M_L are the numbers of edges added globally and locally, respectively. p_G and p_L are the probabilities of the positive sign of the globally and locally added edges, respectively. δ is the initial weight of an added edge. ϵ is the parameter for the evaporation. According to their work [45], we set $M_G = M_L$ to 1 and $p_G = p_L$ to $\rho(+)$ for each dataset in Table 4. For δ and ϵ, we perform grid searches from 0 to 1.0 by 0.05 to minimize the absolute difference for edge signs in Equation (12).
- **Evo**: In Evo, α is a friendliness index affecting the formation of the positive sign of an edge, and β is a tolerance threshold for unbalanced triangles. For α and β, we perform grid searches from -1 to 1 by 0.05 to minimize the absolute difference for edge signs in Equation (12).
- **BSCL**: ρ_{BSCL} is a parameter for closing wedge, α_{BSCL} is for creating positive edge, and β_{BSCL} is for closing balanced triangle. Given a real network, those parameters are approximately tuned by the estimation phase of BSCL.

Table 4: Dataset statistics. |V| is the number of nodes, |E| is the number of edges, and $\rho(+)$ is the ratio of positive edges.

Dataset	|V|	|E|	$\rho(+)$	Description
Epinions[1]	131,828	841,372	0.85	Online social network
BitcoinO[2]	5,881	35,592	0.89	Bitcoin social network
BitcoinA[2]	3,783	24,186	0.93	Bitcoin social network
Congress[3]	219	764	0.78	Politician network

4.1.4 Machines and Implementation. We describe the settings of machines and implementation used for evaluating the computational performance of each method in Section 4.5 as follows:

- **Setting on single machine (Section 4.5.1).** We use a single thread in a machine with an Intel Xeon E3-1240v5 CPU and 32GB RAM, and implement all tested methods including BalanSiNG based on g++ v5.4.0.
- **Setting on distributed machines (Section 4.5.2).** We implement BalanSiNG on Spark to test the scalability on a cluster (managed by Hadoop YARN) that consists of 17 machines: a master and 16 worker nodes. Each worker node has 4 physical cores (Intel Xeon E3-1240v5 CPU) with 32GB RAM, and can run 4 workers. Java v1.8.0, Scala v2.11.8, Hadoop v2.7.3, and Spark v2.11.9 are used.

4.2 Properties of Signed Networks (Q1)

We compare real-world signed network BitcoinO with those generated by BalanSiNG and competitors in Figure 1 to investigate if they exhibit the desired properties of real-world signed networks listed in Section 2.1. We omit the comparisons for other datasets due to the space limit, but the overall tendency is similar. We adjust the parameters of each method so that the resulting networks have almost the same positive edge sign ratios as that of BitcoinO (details in Appendix F); thus, the sign distributions in Figure 1(a) are similar for all graphs.

The signed network generated by BalanSiNG follows the desired properties w.r.t. signs (D1-3) as well as those regardless of signs (D4-6). The balanced triangle distribution is highly skewed as shown in Figure 1(b), and degree distributions follow a power-law as seen from Figure 1(c) to Figure 1(f). The hop plot of BalanSiNG in Figure 1(g) is similar to that of BitcoinO. Also, top-k singular values of graphs from BalanSiNG and BitcoinO monotonically decrease as shown in Figure 1(h).

On the other hand, the signed networks generated by IB and Evo do not follow power-law degree distributions as shown in the third and forth rows (Figure 1(c) to Figure 1(f)). The main reason is that IB and Evo naively create random edges without the consideration of power-law degree distribution. The hop plot and singular value distributions of both methods are also different from those of the real-world network as shown in Figures 1(g) and 1(h). BSCL generates signed networks obeying most of the desired properties, but its balanced triangle distribution (D2) does not; it is not skewed enough compared to the real network (at the first row) and BalanSiNG (at the second row) as shown in Figure 1(b). We further provide the fine-grained comparison about these signed triangles in Section 4.3.

4.3 Fine-grained Comparison of Signed Triangles (Q2)

We compare BalanSiNG to other competitors in terms of signed triangle distribution. As described in Section 2.1, the balanced

Table 5: Comparison of signed triangle distributions by BalanSiNG and competitors. $\rho(\triangle_b)$ and $\rho(\triangle_u)$ indicate the ratios of balanced and unbalanced triangles, respectively. $\rho(\triangle_{+++})$, $\rho(\triangle_{+--})$, $\rho(\triangle_{++-})$, and $\rho(\triangle_{---})$ denote the ratios of the triangle types $\triangle_{+++}$, $\triangle_{+--}$, $\triangle_{++-}$, and $\triangle_{---}$, respectively. Note that BalanSiNG (marked †) generates the most closest signed networks to the corresponding real-world signed networks in terms of absolute difference and Kolmogorov–Smirnov statistic (the lower the better).

triangle proportion is the most distinct property in real-world signed networks. Hence, we analyze signed triangles of generated signed networks to check if they exhibit distributions similar to that of a real-world signed network.

For the purpose, we first enumerate directed signed triangles in each real signed network as in [43] since all of the signed networks used in this paper are directed, and then measure the ratio $\rho(\cdot)$ for each triangle type. For example, $\triangle_{+++}$ indicates triangles with three positive signs; thus, $\rho(\triangle_{+++}) = |\triangle_{+++}|/|\triangle_{\text{total}}|$ where $|\triangle_{\text{total}}|$ is the total number of triangles. For large-scale signed networks, distributed algorithms [33] can be used to enumerate triangles. Then, we generate synthetic signed networks for each dataset following the procedure in Section 4.2 (see the parameters of each method in Appendix F), and compare the triangle distributions of both real and synthetic networks. To measure the distance between two distributions, we utilize *Absolute Difference* [6] and *Kolmogorov–Smirnov statistic* (K-S statistic) metrics. The absolute difference [6] is defined as the sum of absolute differences between each ratio of real and synthetic triangles (see Definition D.2). The K-S statistic is defined as the maximum gap between the two cumulative distributions; it has been traditionally used for measuring the difference between two distributions. We repeat the above procedure 10 times, and report the average for each method and each dataset. For both of the metrics, small values indicate that the synthetic network has a similar tendency to the corresponding real network in terms of signed triangles.

Table 5 shows the fine-grained comparison on the four types of signed triangles by BalanSiNG and competitors for each dataset. Note that BalanSiNG gives the best signed triangle distribution, showing the smallest absolute difference and K-S statistic. Specifically, BalanSiNG shows about 1.5 $\sim$ 2× better performance than the second best method for each dataset.

4.4 Effect of Parameters (Q3)

We investigate the effect of parameters of BalanSiNG. We focus on the effects of weight parameter α and target recursion level L while noise parameter γ is set to 0.1 and seed ten sor $\mathbf{T}_{\text{seed}}$ is set to the values of Equation (9), as described in Section 4.1. The weight parameter α is introduced to increase the probability of generating positive edges, and the level L controls the size of networks to be generated.

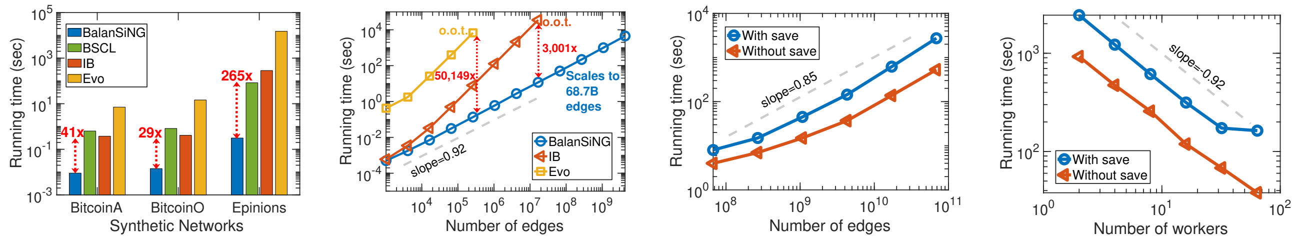
Figure 10(a) shows the effect of the weight parameter α on positive sign ratio $\rho(+)$ and balanced triangle ratio $\rho(\triangle_b)$. We set $L = 17$ and $|\mathrm{E}| = 2^{19}$, and vary α form 0.1 to 0.9. As shown in the figure, both of the ratios $\rho(+)$ and $\rho(\triangle_b)$ increase as α increases. The reason is that according to Definition 3.4, as we increase α, the probability of the positive term becomes large while that of the negative term diminishes. Also, as the number of positive edges increases, balanced triangles $\triangle_{+++}$ and $\triangle_{++-}$ are more likely to be formed. Note that α between 0.7 and 0.85 introduces the skewness of both ratios similarly to those of real signed networks. Thus, our method is able to control the skewness of those ratios according to users' preference through adjusting α.

Figures 10(b) and 10(c) demonstrate the effect of the recursion level L on the ratios $\rho(+)$ and $\rho(\triangle_b)$, and the out-degree distributions of networks generated by BalanSiNG. We set α to 0.8, and vary L from 12 to 21 to generate networks with $|\mathrm{V}| = 2^{L+1}$ and $|\mathrm{E}| = 2^{L+6}$. In Figure 10(b), $\rho(+)$ and $\rho(\triangle_b)$ do not change much as L increases. Also, as shown in Figure 10(c), the degree distributions for different L have almost the same tendency w.r.t. power-law distribution. These results indicate the effect of L on those ratios and degree distribution is marginal, i.e., our method is able to control the size of signed networks to be generated while the tendency of such properties is preserved.

4.5 Computational Performance (Q4)

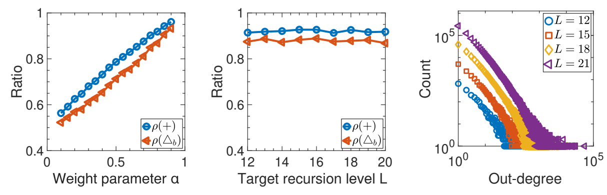
We evaluate the computational performance of BalanSiNG on single and distributed machines.

4.5.1 Performance on Single Machine. We examine the performance of BalanSiNG and competitors on a single machine. The detailed setting is in Section 4.1.4. We fix the size of each synthetic network to that of the corresponding real-world network, and compare the generation time of each method. As shown in Figure 9(a), the generation time of BalanSiNG is up to 265× faster than that of BSCL. Figure 9(b) shows the data scalability of methods. Note that BSCL is excluded since it cannot generate synthetic networks having arbitrary numbers of nodes and edges. BSCL aims to imitate an input network, and thus the size of the generated network of BSCL is fixed to that of the input network. We vary $|V| = 2^{L+1}$ and $|E| = 2^{L+6}$ for $L = 4..26$ where L is the target recursion level. We report out of time (o.o.t.) error when the generation time is more than 24 hours. As shown in Figure 9(b), only BalanSiNG generates the largest network for $L = 26$ within the limited time while IB and Evo generate o.o.t. errors. BalanSiNG is 50, 149× and 3, 001× faster than Evo and IV, respectively. Furthermore, the slope of BalanSiNG is 0.92, indicating the data scalability of BalanSiNG is near linear w.r.t. the number of edges. To sum, BalanSiNG provides the fastest running time and the best scalability.



(a) Generation time on a single machine (b) Data scalability on a single machine (c) Data scalability on distributed machines (d) Distributed machine scalability

Figure 9: Computational performance of BalanSiNG. (a) BalanSiNG generates signed networks up to 265× faster than existing methods. (b-c) The data scalability of BalanSiNG is near linear w.r.t. the number of edges on both single and distributed machines where o.o.t. stands for out of time (more than 24 hours). (d) BalanSiNG also scales up well with the increase of the number of workers on distributed machines.



(a) Effect of weight parameter α (b) Effect of level L on $\rho(+)$ and $\rho(\triangle_b)$ (c) Effect of level L on out-degree distributions

Figure 10: Effects of weight parameter α, and target recursion level L. BalanSiNG generates graphs of various sizes following the power laws, while controlling the positive sign ratio $\rho(+)$ and the balanced triangle ratio $\rho(\triangle_b)$.

4.5.2 Performance on Distributed Machines. We demonstrate the performance of BalanSiNG on distributed machines. The detailed setting is in Section 4.1.4. We report the generation times *with* and *without* writing edges onto disks (line 7 of Algorithm 3). The former is execution time with disk I/O, and the latter is only CPU execution time without disk I/O. To evaluate data scalability, we use 64 workers, and vary $|V| = 2^{L+1}$ and $|E| = 2^{L+6}$ for $L = 20..30$ where L is the target level. Figure 9(c) shows that BalanSiNG has near linear scalability w.r.t. the number of edges with the slope 0.85 in the plot. Note that BalanSiNG generates $|E| = 2^{36} \simeq 68.7$ billion signed edges within 45.5 minutes including disk I/O time on the distributed machines; the generated network is 81,675× larger than the Epinions dataset, the largest real signed network currently open to the public, with respect to the number of edges. Figure 9(d) shows BalanSiNG also scales up well with the increase of the number of workers from 2 to 64 where we set $|V| = 2^{27}$ and $|E| = 2^{32}$. The last point of the blue line at 64 is due to the bottleneck of HDFS I/O, i.e., there are too many workers trying to write edges to disks at the same time.

5 RELATED WORK

Models for generating graphs from scratch. There are various methods for generating unsigned networks following real-world properties described in Section 2.1.2. Barabási et al. [1] proposed Barabási-Albert model through a preferential attachment process for generating scale-free networks. Leskovec et al. [27] identified densification laws and shrinking diameters inherent in graphs over time, and developed Forest Fire for modeling such graphs. Also, they proposed Stochastic Kronecker Graph (SKG) [23], a general generation model that simulates a self-similarity using Kronecker product. They developed FastKronecker [24] that chooses edges in a recursive way to reduce the generation time. However, those models cannot generate signed networks, while BalanSiNG generates signed networks following real-world properties. There are a few methods for generating signed networks from scratch. Vukašinović et al. [45] proposed an interaction based model (IB) using ant pheromone mechanism and balance theory for simulating signed edge generation. Ludwig et al. [29] suggested an evolutionary model (Evo) that simulates an evolving network by inserting or removing signed edges so that the network keeps obeying balance theory. However, their resulting networks give different properties from those of the real-world signed networks, while BalanSiNG generates realistic signed networks as shown in Figure 1.

Models for generating graphs imitating an input network. Chung-Lu [35] model aims to generate a synthetic unsigned network by randomly selecting an edge with its associated degree probability. Transitive Chung-LU (TCL) model [35] stochastically performs a two-hop random walk from a node in order to explicitly form at least one triangle, thereby imitating clustering coefficients in the input graph. Derr et al. [6] proposed Balanced Signed Chung-LU (BSCL) model, the state-of-the-art model for synthetic signed networks. They combined balance theory and TCL model in order that the resulting network imitates the signed triangle distribution of the input graph. However, BSCL is not fast, does not generate networks which fully follow the properties of real-world signed networks, and cannot generate signed networks having an arbitrary number of nodes from scratch. On the other hand, BalanSiNG is fast and scalable, generates the most similar networks to real signed networks as in Table 5, and generates graphs of arbitrary sizes as in Figure 9.

6 CONCLUSION

We propose BalanSiNG, a novel, scalable, and fully parallelizable method for generating realistic signed networks from scratch. BalanSiNG exploits the self-similar balanced structure with Kronecker product, and produces realistic signed networks by introducing noises and weights. We implement BalanSiNG in parallel using Spark, a widely used distributed computing platform. Experiments show that BalanSiNG generates the most realistic signed networks. BalanSiNG is up to 265× faster than existing methods for generating signed networks, and scales up near linearly with the size of networks and the number of workers on both single and distributed machines, successfully generating graphs with 68.7 billion edges.

APPENDIX

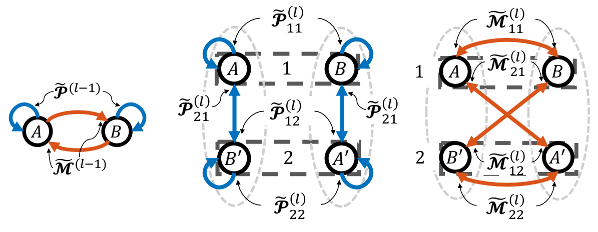
A PROPERTIES OF SIGNED NETWORKS

Figure 11 shows properties of other real-world signed networks. The properties of the BitcoinO dataset are depicted in Figure 1.

B PROOF OF LEMMA 3.3

PROOF. We use mathematical induction. For the base case, $\tilde{\mathrm{T}}^{(1)} = \mathrm{T}_{\text{seed}}$ is trivially fully balanced as shown in Figure 5(a). Assume $\tilde{\mathrm{T}}^{(l-1)}$ is fully balanced. Then, $\tilde{\mathrm{T}}^{(l)}$ of Equation (4) with $\mathrm{T}_{\text{seed}} = \tilde{\mathrm{T}}^{(1)}$ is represented as follows:

$$f_b(\tilde{\mathrm{T}}^{(1)} \otimes \tilde{\mathrm{T}}^{(l-1)})$$
$$= \{+(\mathcal{P} \otimes \tilde{\mathcal{P}}^{(l-1)} + \mathcal{M} \otimes \tilde{\mathcal{M}}^{(l-1)}), -(\mathcal{P} \otimes \tilde{\mathcal{M}}^{(l-1)} + \mathcal{M} \otimes \tilde{\mathcal{P}}^{(l-1)})\}$$



$\tilde{\mathcal{P}}^{(l-1)}$
$\tilde{\mathcal{M}}^{(l-1)}$
A
B
$\tilde{\mathcal{P}}^{(l)}_{11}$
$\tilde{\mathcal{P}}^{(l)}_{21}$
$\tilde{\mathcal{P}}^{(l)}_{12}$
$\tilde{\mathcal{P}}^{(l)}_{22}$

$\tilde{\mathcal{M}}^{(l)}_{11}$
$\tilde{\mathcal{M}}^{(l)}_{21}$
$\tilde{\mathcal{M}}^{(l)}_{12}$
$\tilde{\mathcal{M}}^{(l)}_{22}$

(a) $\{+\tilde{\mathcal{P}}^{(l-1)}, -\tilde{\mathcal{M}}^{(l-1)}\}$ (b) $\tilde{\mathcal{P}}^{(l)}$ (c) $\tilde{\mathcal{M}}^{(l)}$

Figure 12: Structures of (a) $\tilde{\mathcal{P}}^{(l-1)}$&$\tilde{\mathcal{M}}^{(l-1)}$, (b) $\tilde{\mathcal{P}}^{(l)}$, & (c) $\tilde{\mathcal{M}}^{(l)}$.

$$= \left\{ + \begin{bmatrix} p_{11}\tilde{\mathcal{P}}^{(l-1)} & m_{12}\tilde{\mathcal{M}}^{(l-1)} \\ m_{21}\tilde{\mathcal{M}}^{(l-1)} & p_{22}\tilde{\mathcal{P}}^{(l-1)} \end{bmatrix}, - \begin{bmatrix} p_{11}\tilde{\mathcal{M}}^{(l-1)} & m_{12}\tilde{\mathcal{P}}^{(l-1)} \\ m_{21}\tilde{\mathcal{P}}^{(l-1)} & p_{22}\tilde{\mathcal{M}}^{(l-1)} \end{bmatrix} \right\}$$

$$= \left\{ + \begin{bmatrix} \tilde{\mathcal{P}}^{(l)}_{11} & \tilde{\mathcal{P}}^{(l)}_{12} \\ \tilde{\mathcal{P}}^{(l)}_{21} & \tilde{\mathcal{P}}^{(l)}_{22} \end{bmatrix}, - \begin{bmatrix} \tilde{\mathcal{M}}^{(l)}_{11} & \tilde{\mathcal{M}}^{(l)}_{12} \\ \tilde{\mathcal{M}}^{(l)}_{21} & \tilde{\mathcal{M}}^{(l)}_{22} \end{bmatrix} \right\} = \left\{ +\tilde{\mathcal{P}}^{(l)}, -\tilde{\mathcal{M}}^{(l)} \right\}$$

Figure 12(a) shows $\tilde{\mathrm{T}}^{(l-1)}$ where $\tilde{\mathcal{P}}^{(l-1)}$ represents edges within each group (A and B), and $\tilde{\mathcal{M}}^{(l-1)}$ represents edges between the two groups. We depict the block structure of $\tilde{\mathcal{P}}^{(l)}$ in Figure 12(b) where $\tilde{\mathcal{P}}^{(l)}_{ij}$ indicates (i, j)-th block of $\tilde{\mathcal{P}}^{(l)}$. Figure 12(b) has two copies: (A, B) of 1st copy and (A', B') of 2nd copy. Then, $\tilde{\mathcal{P}}^{(l)}_{11}$ means edges within A and B of 1st copy because they are from $p_{11}\tilde{\mathcal{P}}^{(l-1)} = \tilde{\mathcal{P}}^{(l)}_{11}$. Also, $\tilde{\mathcal{P}}^{(l)}_{12}$ represents directed edges from A to B', and from B to A' by $m_{12}\tilde{\mathcal{M}}^{(l-1)}$. Other blocks in $\tilde{\mathcal{P}}^{(l)}$ are similarly interpreted; thus, there are two groups (A, B') and (A', B) having positive between-group edges in the graph of $\tilde{\mathcal{P}}^{(l)}$. Each block in $\tilde{\mathcal{M}}^{(l)}$ represents edges between the groups as shown in Figure 12(c). These indicate $\tilde{\mathrm{T}}^{(l)}$ is also fully balanced. Hence, $\tilde{\mathrm{T}}^{(l)}$ is fully balanced for any $l \geq 1$. □

C LEMMA OF ENTRY-WISE RECURSIVE REPRESENTATION OF BALANSING

Lemma C.1. *Let $R^{(l)}$ be the selected region at level l with probability $p^{(l)}_{ij} + m^{(l)}_{ij}$ in* Generate-Edge. *Let (u, v) be decided through $R^{(L)}, \cdots, R^{(0)}$. Equation* (7) *for (u, v) is equivalent to Equation* (8).

Proof. Equation (7) is represented as follows:

$$\tilde{\mathrm{T}}^{(l)} = f_\alpha(f_b(\mathrm{N}^{(l)}_{\text{seed}} \otimes \tilde{\mathrm{T}}^{(l-1)})) \Leftrightarrow \tag{10}$$

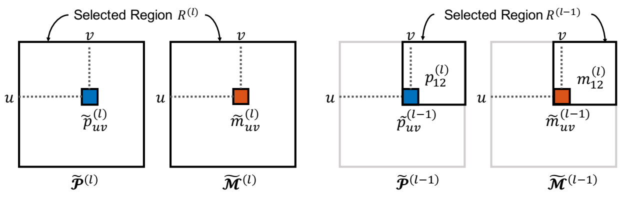
$$\{+\tilde{\mathcal{P}}^{(l)}, -\tilde{\mathcal{M}}^{(l)}\} = f_\alpha(f_b(\{+\mathcal{P}^{(l)}_{\text{seed}}, -\mathcal{M}^{(l)}_{\text{seed}}\} \otimes \{+\tilde{\mathcal{P}}^{(l-1)}, -\tilde{\mathcal{M}}^{(l-1)}\}))$$

Let $\tilde{p}^{(l)}_{uv}$ and $\tilde{m}^{(l)}_{uv}$ indicate the fixed location (u, v) in $\tilde{\mathcal{P}}^{(l)}$ and $\tilde{\mathcal{M}}^{(l)}$ under $R^{(l)}$ as shown in Figure 13(a). Let $g(\cdot)$ be a function that extracts entries participating in the computation related to (u, v) in a signed tensor of Equation (7). For $\{+\tilde{\mathcal{P}}^{(l)}, -\tilde{\mathcal{M}}^{(l)}\}$, $g(\cdot)$ extracts $\tilde{p}^{(l)}_{uv}$ and $\tilde{m}^{(l)}_{uv}$:

$$\{+\tilde{p}^{(l)}_{uv}, -\tilde{m}^{(l)}_{uv}\} \leftarrow g\left(\{+\tilde{\mathcal{P}}^{(l)}, -\tilde{\mathcal{M}}^{(l)}\}, (u, v)\right)$$

Note that $R^{(l-1)}$ is a selected region with probability $p^{(l)}_{ij} + m^{(l)}_{ij}$ where $p^{(l)}_{ij} \in \mathcal{P}^{(l)}_{\text{seed}}$ and $m^{(l)}_{ij} \in \mathcal{M}^{(l)}_{\text{seed}}$. As shown in Figure 13(b), suppose $p^{(l)}_{ij}$ and $m^{(l)}_{ij}$ correspond to $(1, 2)$-th quadrant, respectively, i.e., $p^{(l)}_{ij} = p^{(l)}_{12}$ and $m^{(l)}_{ij} = m^{(l)}_{12}$. Then, other quadrant probabilities except for $p^{(l)}_{12}$ and $m^{(l)}_{12}$ do not affect the computation of $\{+\tilde{p}^{(l)}_{uv}, -\tilde{m}^{(l)}_{uv}\}$ through Kronecker product. Also, since (u, v) is fixed, the only locations corresponding to (u, v) of $\tilde{\mathcal{P}}^{(l-1)}$ and $\tilde{\mathcal{M}}^{(l-1)}$ affect the final result as shown in Figure 13(b). In other words, only $\tilde{p}^{(l-1)}_{uv}$ and $\tilde{m}^{(l-1)}_{uv}$ participate in the computation for $\{+\tilde{p}^{(l)}_{uv}, -\tilde{m}^{(l)}_{uv}\}$, and $\{+\tilde{p}^{(l-1)}_{uv}, -\tilde{m}^{(l-1)}_{uv}\}$ are recursively obtained by $g(\cdot)$ as follows:

$$\{+\tilde{p}^{(l-1)}_{uv}, -\tilde{m}^{(l-1)}_{uv}\} \leftarrow g\left(\{+\tilde{\mathcal{P}}^{(l-1)}, -\tilde{\mathcal{M}}^{(l-1)}\}, (u, v)\right)$$



Selected Region $R^{(l)}$
v
u
$\tilde{p}^{(l)}_{uv}$
$\tilde{m}^{(l)}_{uv}$
$\tilde{\mathcal{P}}^{(l)}$
$\tilde{\mathcal{M}}^{(l)}$
Selected Region $R^{(l-1)}$
$p^{(l)}_{12}$
$m^{(l)}_{12}$
$\tilde{p}^{(l-1)}_{uv}$
$\tilde{m}^{(l-1)}_{uv}$
$\tilde{\mathcal{P}}^{(l-1)}$
$\tilde{\mathcal{M}}^{(l-1)}$

(a) Recursion level l (b) Recursion level $l-1$

Figure 13: The locations corresponding to (u, v) in (a) $\{+\tilde{\mathcal{P}}^{(l)}, -\tilde{\mathcal{M}}^{(l)}\}$ and (b) $\{+\tilde{\mathcal{P}}^{(l-1)}, -\tilde{\mathcal{M}}^{(l-1)}\}$.

Hence, Equation (10) is represented with $g(\cdot)$ as follows:

$$g\left(\{+\tilde{\mathcal{P}}^{(l)}, -\tilde{\mathcal{M}}^{(l)}\}, (u, v)\right)$$
$$= f_\alpha\left(f_b\left(\{+p^{(l)}_{ij}, -m^{(l)}_{ij}\} \otimes g\left(\{+\tilde{\mathcal{P}}^{(l-1)}, -\tilde{\mathcal{M}}^{(l-1)}\}, (u, v)\right)\right)\right)$$
$$\Leftrightarrow \{+\tilde{p}^{(l)}_{uv}, -\tilde{m}^{(l)}_{uv}\} = f_\alpha(f_b(\{+p^{(l)}_{ij}, -m^{(l)}_{ij}\} \otimes \{+\tilde{p}^{(l-1)}_{uv}, -\tilde{m}^{(l-1)}_{uv}\})). \quad \square$$

Note that Generate-Edge$(\cdot)$ represents the recursive function $g(\cdot)$, and $\tilde{p}^{(L)}_{uv} = P(u, v, +)$ and $\tilde{m}^{(L)}_{uv} = P(u, v, -)$.

D DEFINITIONS

Definition D.1 (Kronecker Product). Given $\mathbf{A} \in \mathbb{R}^{m \times n}$ and $\mathbf{B} \in \mathbb{R}^{p \times q}$, the Kronecker product of $\mathbf{A}$ and $\mathbf{B}$ is defined as follows:

$$\mathbf{A} \otimes \mathbf{B} = \begin{bmatrix} a_{11}\mathbf{B} & \cdots & a_{1n}\mathbf{B} \\ \vdots & \ddots & \vdots \\ a_{m1}\mathbf{B} & \cdots & a_{mn}\mathbf{B} \end{bmatrix}$$

where a_{ij} is the (i, j)-th entry of $\mathbf{A}$, and $\mathbf{A} \otimes \mathbf{B} \in \mathbb{R}^{mp \times nq}$. ■

Definition D.2 (Absolute Difference for Signed Triangles and Edge Signs [6]*).* Let $\rho_{\text{real}}(\cdot)$ and $\rho_{\text{syn}}(\cdot)$ denote ratios from a real network and a synthetic network, respectively. Let T be the set of signed triangles, i.e., $\mathrm{T} = \{\triangle_{+++}, \triangle_{++-}, \triangle_{+--}, \triangle_{---}\}$. Then, *absolute difference* for signed triangles is defined as follows:

$$\text{Abs. Diff. (T)} = \sum_{\triangle \in \mathrm{T}} |\rho_{\text{real}}(\triangle) - \rho_{\text{syn}}(\triangle)| \tag{11}$$

Let S be the set of signs, i.e., $\mathrm{S} = \{+, -\}$. Then, *absolute difference* for edge signs is defined as follows:

$$\text{Abs. Diff. (S)} = \sum_{s \in \mathrm{S}} |\rho_{\text{real}}(s) - \rho_{\text{syn}}(s)| \tag{12}$$

E CONNECTION TO SKG AND NOISY SKG

In terms of edge determination process (line 7 in Algorithm 1 and line 8 in Algorithm 2) without signs, SKSG-B and SKSG are equivalent to Stochastic Kronecker Graph (SKG) [23] and Noisy SKG [37], respectively. SKG constructs a stochastic adjacency matrix $\mathcal{A}$ using Kronecker product where each entry $\mathcal{A}_{uv}$ indicates a probability $P(u, v)$ of forming edge $u \longrightarrow v$. In our models, the probability $P(u, v)$ is divided into $P(u, v, +)$ and $P(u, v, -)$, i.e., $P(u, v) = P(u, v, +) + P(u, v, -)$, implying that $\mathcal{A} = \mathcal{P} + \mathcal{M}$ where $\{+\mathcal{P}, -\mathcal{M}\}$ is a stochastic signed tensor. Thus, the formation of edges without signs in SKSG-B is equivalent to that of SKG; consequently, networks from SKSG-B naturally inherit characteristics of those of SKG. Similarly, the edge formation of SKSG with noises corresponds to that of Noisy SKG.

F PARAMETER SETTING

ABSTRACT

Top-k rankings are a commonly used technique to summarize the most important entities of a specific domain. In this work, we focus on efficiently solving the problem of similarity joins for top-k rankings, for instance, for determining users with similar affinity, or for grouping related queries in search engines, based on their results. We put forward a novel algorithmic multi-step solution, realized via Apache Spark, harnessing mathematical properties of the distance function and a preceding near-duplicate detection phase, for search-space pruning. We further show how existing state-of-the-art algorithms for set similarity joins can be adapted to handle top-k rankings and how the data partitioning internals of Spark can be used to enable efficient data processing. The experimental study over standard benchmark datasets reveals that the proposed solution outperforms the state-of-the-art competitor by up to a factor of 5, despite involving additional stages of processing.

1 INTRODUCTION

Similarity joins have been a popular research topic in the database community for more than a decade now. Previous research in this topic is concerned with solving the problem of similarity joins for sets [7, 11, 25, 28], strings [13] or the more general problem of finding the similar objects in metric space [12]. Many distributed solutions, developed for the MapReduce framework, have also been proposed. Recently, Fier et al. [10] summarized and compared these distributed solutions. In this paper, we specifically focus on solving the problem of similarity joins for top-k rankings. Top-k rankings are a very popular and widely used technique to summarize the most relevant entities from a certain domain. Fast and efficient solutions for similarity joins of top-k rankings is of great value in many contexts. For instance, the case of query suggestion or expansion in search engines based on finding similar queries by comparing their result lists, in a dating portal where we can use the preferences and affinities of users, presented in a form of top-k lists, for matchmaking, or in the case of recommender systems, where the similarity between the top sold (liked, favored) items for different clients can help in recommending products. For instance, consider Table 1 containing favorite movies of members of some dating portal. By comparing the lists, we see that Alice and Chris have similar taste so the system should match them for a date.

Spearman's Footrule distance is used as a distance measure for comparing two top-k lists. Fagin et al. [9] show that there is a Spearman's Footrule adaptation for top-k rankings that is a metric. This immediately entails the use of existing metric space similarity join approaches. On the other hand, rankings

5.	Titanic	E. T	Titanic

Table 1: Dating portal users' favorite movies

can be considered as plain sets and accordingly indexed using inverted indices, that keep for each item a list of rankings where this item appears. Thus, many of the distributed algorithms that solve the problem of similarity joins for sets can be applied for top-k rankings. The best performing one, according to a recent study [10], is the algorithm proposed by Vernica et al. [24], based on the principle of prefix filtering. This approach, as shown in the study [10], also outperforms existing metric space similarity join approaches. Furthermore, Fier et al. [10] showed that the existing distributed solutions in MapReduce do not scale well, and propose that Apache Spark is used as a platform for developing new alternative solutions. In this paper, we specifically focus on studying an efficient and scalable top-k rankings similarity joins using Apache Spark [4].

We propose a novel approach implemented in Apache Spark that is better tailored to the properties of this platform. In contrast to MapReduce, where each stage is composed from only a *map* and *reduce* function, and the data from each stage is written to disk, Apache Spark is more suitable for iterative processing of data and performs the computation in memory. Thus, we propose an iterative approach that computes the similarity join in several stages, while storing the intermediate results in memory. As Spearman's Footrule adaptation for top-k rankings is a metric, the algorithm uses the triangle inequality to reduce the number of candidate pairs generated. Very similar rankings are clustered together, and then, only the cluster representatives are joined, reducing the size od the data processed, and thus, finding more efficiently the join results. Through a detailed experimental study we show that our algorithm outperforms the competitor, especially for larger values of the similarity threshold θ.

1.1 Problem Statement and Setup

As **input** we are provided with a dataset $\mathcal{T}$ of rankings τ_i (Table 2). Each ranking has a domain D_{τ_i} of items it contains. We consider fixed-length rankings of size k, i.e., $|D_{\tau_i}| = k$, but investigate the impact of different choices of k on the join performance [1]. The considered rankings do not contain any duplicate items.

The ranked items in a ranking are represented as arrays or lists of items, where the left-most position denotes the top ranked item. In addition, each ranking has an id associated to it. Without

[1]Working with fixed-length rankings gives better insights into the difference of performance of the algorithms. For handling variable-length rankings, only the length boundaries for the Footrule distance, given a distance threshold, need to be computed .

ranking id	ranking content
τ_1	[2, 5, 4, 3, 1]
τ_2	[1, 4, 5, 9, 0]
τ_3	[0, 8, 5, 7, 3]

Table 2: Sample dataset $\mathcal{T}$ of top-5 rankings (items are represented by their ids).

loss of generality, in the remainder of the paper, we assume that items are also represented by their ids. The rank of an item i in a ranking τ is given as $\tau(i)$.

A distance function d quantifies the distance between two rankings—the larger the distance the less similar the rankings are. *Given a dataset of top-k rankings $\mathcal{T} = \{\tau_1, \ldots, \tau_n\}$ and a distance threshold θ we want to find all pairs (τ_i, τ_j), $\tau_i, \tau_j \in \mathcal{T}$, $i \neq j$, where the distance d between τ_i and τ_j is smaller or equal to θ, i.e., $d(\tau_i, \tau_j) \leq \theta$.*

In this work, we focus on the computation of Spearman's Footrule distance, but the proposed algorithm can be applied on any distance measure that satisfies the triangle inequality. Spearman's Footrule distance is computed as a sum over the difference in position of the items in the two rankings, i.e., $F(\tau, \sigma) = \sum_{i \in D_\tau \cup D_\sigma} |\tau(i) - \sigma(i)|$. An artificial rank l for items not contained in a ranking, i.e., $\tau(i) = l$ if $i \notin D_\tau$, is considered. Consider the rankings τ_1 and τ_2, in Table 2. For a rank $l = 6$ for not-contained items, we obtain $F(\tau_1, \tau_2) = 4+1+1+5+2+2+1 = 16$. A more detailed introduction to rankings, specifically top-k rankings, distance functions, and how to handle items i that are not in a ranking τ is described in Section 3.

1.2 Contributions and Outline

The contributions of our work can be summarized as follows.

- We adapt existing set-based similarity join algorithm to the problem of top-k rankings. We furthermore implement and adapt this algorithm to the Apache Spark framework.
- We introduce a new iterative, highly configurable algorithm that combines metric space distance-based filtering with state-of-the-art set-based similarity join algorithms.
- We propose further optimization to the proposed algorithm by presenting a method for repartitioning large partitions.
- We implemented our methods and competitors in Apache Spark and through an extensive experimental study on two real-world datasets we show that our methods consistently outperform state-of-the-art approaches for larger values of the threshold θ.

The rest of the paper is structured as follows. Section 2 discusses related work and, in Section 3, we present background on top-k rankings, a state-of-the-art distributed set similarity join algorithm, and Apache Spark. In Section 4, we describe how existing set-based similarity join algorithm is adapted to top-k rankings. The clustering algorithm and its components is introduced in Section 5. Section 6 proposes a Spark-based repartitioning technique. We experimentally evaluate the presented approaches in Section 7. Finally, we give the conclusion in Section 8.

2 RELATED WORK

To the best of our knowledge, the problem of similarity join for top-k rankings has not been addressed so far. As top-k rankings can also be seen as sets, we mainly focus here on explaining set-based similarity joins.

In-memory similarity join approaches: There is an ample work on computing the similarity join for sets or strings. Mann et al. summarize and compare the in-memory based approaches in [16]. Previous approaches are mainly based on a filter and verification framework which uses inverted indices as the initial filter for pairs that do not have any items in common and applying additional filters that prune dissimilar pairs. In the verification phase the candidates are verified by computing their true similarity score. The prefix-filtering approach, initially proposed by Chaudhuri et al. [7] is the most well know algorithm for finding the similar pairs. It works by first sorting all records in the dataset in the same canonical order and then indexing only a prefix of the record with an inverted index. The size of the prefix depends on the threshold and distance, i.e., the similarity measure used. The records are usually sorted by the ascending frequency of the elements in the sets. There are many works [5, 6, 21, 25, 28] that propose improvements over the initial prefix-filtering algorithm, by introducing additional position or length-based filters, reducing the size of the prefix, introducing variable length prefixes, grouping based on the prefix, etc. Recently Wang et al. [26], motivated by the conclusions presented in [16], proposed an approach that improves upon existing prefix-filtering approaches by introducing index level and answer-level skipping. The index level skipping reduces the unnecessary checks done by position and length-based filters, by using length-sorted skipping blocks in the posting lists, augmented with the positions of the elements in the sets. The answer-level skipping is based on the idea that the answer sets of similar sets should be also similar, thus the already computed answer set of one set is used for computing the answer set of another, similar, set. Bouros et al. [6] propose an approach for spatio-textual similarity joins. They describe algorithms that partitions and filters the data based on the spatial (Euclidean) distance between the points in the dataset, and, in addition, they extend the prefix-filtering method by introducing grouping based on the prefix of the textual data. The grouping based on the prefix of the textual data is orthogonal to our presented approach, i.e., it can be applied in our approach in addition to (instead of) the VJ algorithm. Their method for distance based partitioning of the data space resembles our idea for clustering based on the distance threshold. However, the solution proposed in [6] works specifically for two dimensional data. Top-k rankings, on the other hand, can be interpreted as points in multidimensional space, where the dimension is determined by the size of the rankings, usually 10 or larger. In addition, our clustering approach is more general, and works for any data in metric space.

MapReduce-based similarity join approaches: To handle larger datasets, many distributed solutions for similarity join of sets have also been proposed. Recently, Fier et al. [10] summarized and compared the MapReduce-based similarity join solutions. Vernica et al. [24] present a distributed solution, referred to as VJ, based on the well known prefix filtering method. Since we use this algorithm in our implementation, we describe it in more details in Section 3. The *V-SMART* algorithm [17] adopts a different idea, by computing the ingredients of the similarity measure in a distributed manner, which are later joined to compute the final results. It works in two phases, a joining phase and a similarity phase. In the first phase, the joining phase, the partial results for each set is computed and joined to all the elements in the sets. In the similarity phase, the algorithm takes as input the output from the first phase, builds an inverted index, and then, while traversing the posting lists for each element s_i, emits pairs of sets together with information needed to compute the final similarity. Deng et al. present MassJoin [8]. This approach is based on PassJoin [15], a main memory method for string similarity joins. The idea behind their method is to generate signatures for the sets $r \in R$, and then for each signature of r they generate signatures for $s \in S$. In order for s and r to be similar, they should share at least one signature. Additional filters are applied to reduce the number of candidate pairs generated. Rong et al. present FS-Join [20]. They claim that their algorithm outperforms the competitors because it addresses some of the issues that previous approaches had, i.e., it does not generate duplicate results and achieves better load balancing. The dataset is vertically partitioned, by dividing each set into segments and then partitioning the data according to the segments. Interestingly, Fier et al. [10] came to the conclusion that the approach proposed by Vernica et al. [24] outperforms the other approaches in most scenarios. Therefore, in this work we compare our approach to the one presented in [24]. Distributed metric space approaches have also been proposed [22, 27]. Wang et al. [27] for a dataset D, partition the input dataset D into N disjoint partitions P_i, $P_i \cup P_j = \emptyset, \cup_{i=1}^{N} P_i = D$, created by randomly choosing N centroids p_i and assigning each point $p \in D$ to the partition represented by the closest centroid. Further, they define inner and outer sets of a partition and based on that they decide the data distribution. The proposed MapReduce algorithm consists of two main stages, partitioning the data, and, in the second stage, computing the similarity join. Sarma et al. [22] propose a MapReduce method that works very well for very small distance thresholds. In fact, they evaluate their approach using only threshold values up to 0.1. The novelty in their work is that they apply several filtering techniques, both distance specific and not, which lead to having tighter partitions, and thus, fewer comparisons.

In prior work [18], we solve the problem of answering similarity range queries over top-k rankings. There, in addition to an algorithm based to the prefix-filtering framework, we also presented a so-called coarse index, that combines an inverted index with a metric index structure to reduce the number of distance function computations.

3 PRELIMINARIES

Complete rankings are considered to be permutations over a fixed domain $\mathcal{D}$. We follow the notation by Fagin et al. [9] and references within. A permutation σ is a bijection from the domain $\mathcal{D} = \mathcal{D}_\sigma$ onto the set $[n] = \{1, \ldots, n\}$. For a permutation σ, the value $\sigma(i)$ is interpreted as the rank of element i. An element i is said to be ahead of an element j in σ if $\sigma(i) < \sigma(j)$. We consider incomplete rankings, called top-k lists in [9]. Formally, a top-k list τ is a bijection from D_τ onto $[k]$. The key point is that individual top-k lists, say τ_1 and τ_2 do not necessarily share the same domain, i.e., $D_{\tau_1} \neq D_{\tau_2}$.

Pairwise similar rankings can be retrieved by means of distance functions, like Kendall's Tau or Spearman's Footrule distance. In this work we use Spearman's Footrule adaptation for top-k lists proposed in [9]. Spearman's Footrule distance is computed as a sum over the difference in position of the two rankings, i.e., $F(\tau, \sigma) = \sum_{e \in D_\tau \cup D_\sigma} |\tau(i) - \sigma(i)|$. An artificial rank l for items not contained in a ranking, i.e., $\tau(i) = l$ if $i \notin D_\tau$ is considered.

In this work, we assume that $\tau(i)$ takes values from 0 to $k - 1$ (instead of 1 to k), and we fix the value of l to k as suggested in [9]. It is clear that this does not affect our algorithms. We further consider only rankings of same size k, thus the largest possible value of the Footrule distance is $k * (k + 1)$ and occurs if two disjoint rankings are compared. The smallest distance is 0, for the compared rankings are identical. In the rest of the paper, for ease of presentation, we use normalized values for the Footrule distance and the threshold values, ranging from 0 to 1.

3.1 Vernica Join (VJ) Algorithm

According to a recent experimental study [10], the VJ algorithm outperforms other distributed similarity join algorithms in most cases. The algorithm is implemented in MapReduce and is based on the well known prefix filtering method. It works in several phases, each representing one map reduce job. For each phase, the authors propose several variations, however, here we describe the version which, according to their evaluation, showed the best performance.

In the first phase, all records are read and the tokens in the universe are sorted according to the increasing frequency of appearance in the sets. Then, in the next phase, the sorted tokens are loaded into the memory of the mappers and used for sorting the sets into a canonical form. Then the mappers emit a composite key consisting of the token and the size of the set, plus the whole set as value, but only those elements that belong to the prefix. For grouping the records in the reducers, only the token is used, while the size of the set is used for sorting the records by size. The latter allows utilizing size-based filters. At the reducers, for all the rankings that share at least one element together, the PPJoin+ algorithm [28] is used, to find the similar rankings. In the final phase, duplicate pairs must be removed, since the same pair can be generated at several machines.

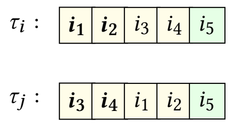
3.2 Apache Spark

Apache Spark [4] is a general purpose platform that enables easy and fast development and execution of distributed applications. It can be considered successor of MapReduce, as it provides similar capabilities with generally better performance. Additionally, several other functionalities are provided and many libraries are built on top of its core. The parallelization of applications is easier when using Apache Spark due to the notions of RDD, *transformations* and *actions* used in the platform. RDDs are collections of elements distributed across the nodes of a cluster [14]. Once created, they are then partitioned among the available nodes of a cluster. This way, each node handles a subset of the input. RDDs are evaluated lazily, meaning that, instead of directly computing each RDD transformation, the computation is performed only at the end, when the final RDD data needs to be materialized. This allows Spark to optimize job execution, by analyzing and grouping the transformations that are performed over the RDDs.

Another important characteristic of Apache Spark is its ability to execute iterative processes, using the main memory of the nodes, in order to reduce disk I/O, thus, reducing the overall execution time of the application, leading to superior performance over MapReduce, as shown by Shi et al. [23].

4 A VJ-STYLE ALGORITHM FOR TOP-K RANKINGS

To find all pairs of similar top-k rankings for a given set of rankings $\mathcal{T}$ and a threshold θ, we can use the Vernica Join (VJ) algorithm. However, in order to be able to apply it on top-k rankings,



τ_i :
$\boldsymbol{i_1}$ $\boldsymbol{i_2}$ i_3 i_4 i_5
τ_j :
$\boldsymbol{i_3}$ $\boldsymbol{i_4}$ i_1 i_2 i_5

Figure 1: Example rankings with $k = 5$ and $p = 2$ with maximum Footrule distance $F(\tau_i, \tau_j) = 8$.

we need to derive the prefix size p of top-k rankings, when Spearman's Footrule distance is used to compare them[2]. There are two ways for computing the prefix size of top-k rankings, one considering the overlap of the rankings, and the other, considering their position. The latter provides slightly tighter prefix sizes than the first. However, the former allows more freedom in choosing the items in the prefix. In prior work [18], we found the minimum overlap between two rankings τ_i and τ_j, such that $F(\tau_j, \tau_j) = \theta$, as $\omega = \lfloor 0.5 * (1 + 2 * k - \sqrt{1 + 4 * \theta})$ and the prefix size as $p = k - \omega + 1$. We refer to this as **prefix based on overlap**. In addition, we define an ordered prefix, p_o, as:

Lemma 4.1. *For a given Spearman's Footrule distance threshold θ and a ranking length k, the* **ordered prefix** *p_o of the top-k rankings is given by the best ranked:*

$$p_o = \lfloor \frac{\sqrt{\theta}}{\sqrt{2}} \rfloor + 1$$

items of the rankings.

Proof. The lowest Footrule distance that two top-k rankings τ_i and τ_j can have, when none of the first p items of each ranking are overlapping, $L(p, k)$, is when the items are overlapping in the rankings, i.e., $D_{\tau_i} = D_{\tau_j}$, but they are positioned in the next p places in the other ranking. This is so, because the partial Footrule distance of an item we get either by the difference in its positions, when they are overlapping, or as $k - \tau_i(i)$ when the item is non overlapping. For the items i positioned in the first p places in ranking, where $p < \frac{k}{2}$, the partial distance of the items being overlapping and placed at the next p places is always lower than if an item is non overlapping. $L(p, k)$ can be computed as $\frac{(p*2)^2}{2}$. An example of such rankings,where $p = 2$, are the rankings τ_i and τ_j, shown in Figure 1. These rankings have the same domain, i.e., $D_{\tau_i} = D_{\tau_j} = \{i_1, i_2, i_3, i_4, i_5\}$, however, when looking only the first p items, written in bold, they have no overlap. The Footrule distance between them is $F(\tau_i, \tau_j) = 8$, the lowest that they can have when the first p items are not shared.

Solving $L(p, k) = \theta$ gives us the first $p = \lfloor \frac{\sqrt{\theta}}{\sqrt{2}} \rfloor$ items that can be non-overlapping in case of θ. Taking one more item guaranties that we will not miss any candidate pair. [3] □

Given the Footrule distance threshold θ, we now describe the VJ algorithm for top-k rankings. The first step in the VJ algorithm is counting the frequency of the elements in the sets and ordering them by frequency. This step is not needed for top-k rankings and can be skipped. However, since most real world datasets follow a skewed distribution, through experiments we concluded that reordering the rankings by the item's frequency leads to major performance gains, and thus, we keep this step for top-k rankings as well. This entails that the prefix size based on the overlap between the rankings should be used. To perform the reordering, we first count the frequency of the items in the rankings. Then, in order to make this collection available to all the nodes, in Spark, we use a broadcast variable which is cached on each machine and then used to sort the items of all rankings $\tau \in \mathcal{T}$ by increasing order of their frequency. Note that, while we reorder the items in the rankings, we still need to keep track of their original rank for the computation of the Footrule distance, thus rankings are transformed to arrays of $(i_{id}, \tau(i))$ pairs. In the next step we transform the rankings, into (i_{id}, τ) pairs, where as key we have the item id, and as value we have the ranking. This we only do for the items that belong to the prefix of the ranking. Then in the next step, in order to bring all rankings that share an item to the same partition, we aggregate the tuples (RDD), created in the previous step, by key. In the next step, for the rankings that share an item, a main memory approach for finding the similar pairs is applied. For the rankings on each item list we index their prefixes using an inverted index. In addition, based on our previous work [19] we apply a position filter in order to filter out more candidate pairs. In [19], we proved that two rankings τ_i and τ_j cannot have distance smaller than θ if at least one of the items in the rankings have a difference in their ranks larger than $\frac{k*(k+1)*\theta}{2}$. That means, if there is at least one item $i \in \tau_i, \tau_j$, such that, $|\tau_i(i) - \tau_j(i)| > \frac{k*(k+1)*\theta}{2}$, we can be sure that $d(\tau_i - \tau_j) > \theta$. For the candidate pairs that pass the filters, we compute the Footrule distance. Note that, since we work with rankings of same size k, filtering based on the length of the rankings is not applicable. Finally, before writing the final result, we remove the duplicate pairs.

4.1 Improved Memory Usage

Previous distributed approaches for similarity joins were designed and implemented in MapReduce. Spark, as a successor of MapReduce, has different characteristics than MapReduce, and thus existing approaches can be adapted to the computational properties of Spark in order to improve their performance.

Datasets in Spark are represented as RDDs, which are immutable, distributed collections of objects, stored in the memory of the executors. This means that for every transformation of an RDD, a new RDD is created. In addition to this, Spark runs in the JVM, which means that garbage collection can easily cause performance issues for Spark jobs. Thus, keeping objects in the memory of executors is not recommended, since it can lead to crashes or performance degradation when dealing with large datasets. Instead, working with iterators is more native to the Sparks computational model, since this allows the framework to spill some data to disk, when needed.

The VJ algorithm that shows the best performance, according to [24] works such that rankings that share the same item are distributed to different partitions. Next, on each partition, an in memory join algorithm is executed, to compute the rankings with distance smaller than θ. This entails, first, storing a dictionary of the items, second, storing an inverted index for the rankings for this partition, and storing the partial result sets until the final computation is done. In addition to this, since Spark works with immutable objects, sorting the objects for performing the per partition in memory join, imposes creating new objects for each ranking. This means that the VJ algorithm can lead to having

[2]To use another distance measure with a prefix-filtering based algorithm, these bounds will need to be recomputed. However, our approach is flexible and any other algorithm can be used.

[3]Note that this only holds when $\theta \leq \frac{k^2}{2}$. In the case when $\theta > \frac{k^2}{2}$ computing the formula for the ordered prefix size is more complicated and we leave it as future work, since using values of $\theta \leq \frac{k^2}{2}$ is more than enough for our problem setting, as it is common practice to use values of $\theta \leq 0.4$. $\theta = \frac{k^2}{2}$ is around 0.45 when normalized, depending on the value of k.

Expansion

Figure 2: Overall architecture. The algorithm has four main phases: ordering, clustering, joining and expansion.

both issues that we mentioned above, bad performance caused by the garbage collector overhead, and, memory overhead crashes, due to keeping data structures and objects in memory.

Instead, we claim that a nested loop modification to the VJ algorithm, is more native to Spark's processing style. Instead of indexing the rankings per partition, we propose using iterators to walk through the rankings in a nested loop fashion. For each ordered pair of rankings,(τ_i, τ_j), where $\tau_i < \tau_j$ that passes the position filter defined above, we compute the Footrule distance, and output those pairs where $d(\tau_i, \tau_j) \leq \theta$. This approach, as we will show in our experiments, performs better for large datasets, since allows Spark to spill the data to disk, when needed.

5 APPROACH

Driven by the idea that similar rankings should have similar result sets, we propose a novel approach having a pre-processing step, where very similar rankings are grouped. Then, only one representative ranking from the clusters, called centroid, is considered in the next similarity join phase. The idea is that by doing this, the number of records being joined is reduced and, thus, the execution time of the main joining phase is reduced too—which is actually the most expensive part of similarity join algorithms. Since Spark is suitable for iterative processing, adding an additional phase should be acceptable. However, this pre-processing phase should be very efficient, such that we do not end up with having a higher overhead than real benefit. Another key observation is that the Footrule distance is a metric and, thus, the triangle inequality can be used for forming, and expanding the clusters, after finding the similar centroids, to compute the final result set more efficiently.

Making use of the above observations, we propose an approach consisting of four main phases: Ordering, Clustering, Joining, and Expansion, depicted in Figure 2.

Ordering: The first phase of our approach is ordering the items in the rankings by their occurrence, i.e., items that occur less frequently in the rankings, are moved to the top positions of the rankings. In our proposed algorithm, as later described, the VJ similarity join algorithm is applied twice, once for clustering the rankings, and once for finding the similar clusters. Instead of reordering the rankings twice, we choose to do this only once, using the original dataset $\mathcal{T}$. As our approach does not depend on the similarity join algorithm used for clustering or for joining the clusters, the re-ordering of the items in the rankings can be skipped if it is of no use to the joining algorithm applied later on. The reordering is done just for determining which items will be included into the prefix of the rankings, while the rankings still preserve their original item ordering for the computation of the distance.

Clustering: The second phase of our approach is forming clusters, such that similar rankings will belong to the same cluster, C_i. First, a similarity join algorithm is executed, to find the similar rankings that need to be grouped together. Our experiments revealed that VJ is the most efficient one to be used here, which supports the findings by Fier et al. [10]. In principle, however, any similarity algorithm could be employed at this stage. Then, clusters are formed such that the pairwise distance between each member of the cluster and its representative is at most θ_c. We will refer to θ_c as the *clustering threshold*. In contrast to other similarity join algorithms in metric space, where clusters have different radius, the radius of all clusters formed by our approach is bounded by the clustering threshold, θ_c. We write $\tau_i \prec c_i$ to denote that ranking τ_i belongs to the cluster, C_i, represented by ranking (centroid) c_i. Rankings in the dataset $\mathcal{T}$ that do not have any similar rankings with distance smaller than the clustering threshold, θ_c, form *singleton* clusters, i.e., one element clusters.

Joining: In this phase a similarity join algorithm is executed over the *centroids* with a threshold $\theta_o = \theta + 2 * \theta_c$. Using threshold θ_o instead of θ is necessary in order to insure the correctness of the algorithm. Note that any similarity join algorithm can be applied here, independently from the algorithm used in the clustering phase. Due to the aforementioned reason, we implement the VJ algorithm.

Expansion: In the last step of the algorithm the final result set is computed, by joining the results from the joining phase with the formed clusters in the clustering phase. The members of the joined clusters from the joining phase are checked against each other if the distance between them is smaller than θ. Using the metric properties of the distance measure, we are able to directly filter out some candidates, and thus compute the final result list more efficiently.

Before we describe each phase more formally, how each phase is realized and how the final join results is computed, we first discuss the correctness of the proposed algorithm.

Lemma 5.1. *For given join threshold θ and clustering threshold θ_c, in the joining phase, all pairs of centroids c_i, c_j with distance $d(c_i, c_j) \leq \theta + 2 * \theta_c$ need to be retrieved in order not to miss a potential join result.*

Lemma 5.1 ensures that pairs $\{(\tau_i, \tau_j) | \tau_i \prec c_i, \tau_j \prec c_j \wedge d(\tau_i, \tau_j) \leq \theta \wedge d(c_i, c_j) > \theta\}$ will not be omitted from the result set.

In other words, Lemma 5.1 avoids missing result rankings with distance $\leq \theta$, which are represented by centroids which are with distance larger than θ from each other.

This follows from the fact that for all rankings $\{\tau_i | \tau_i \prec c_i \wedge d(\tau_i, c_i) \leq \theta_c\}$. It follows that for any pair of rankings $\{\tau_i, \tau_j | \tau_i \prec c_i, \tau_j \prec c_j\}$ the distance of the corresponding centroids $d(c_i, c_j)$ must be $\leq \theta + 2 * \theta_c$. Thus, using a threshold $\theta_o = \theta + 2 * \theta_c$ in the joining phase is enough to ensure that no true result will be missed.

5.1 Clustering

When forming the clusters the following points need to be considered: ***(i)*** To ensure correctness, the radius of all the clusters should be the same, i.e., for any ranking $\tau_i \in C_i$, represented by a ranking c_i, $d(\tau_i, c_i) \leq \theta_c$. ***(ii)*** The clustering method should be very efficient, otherwise the cost of the clustering would overweight its benefit. ***(iii)*** The performance of the expansion phase depends on the clusters formed. We address each point individually while explaining our design choices for the clustering algorithm.

For forming the clusters, we could turn to existing methods [22, 27], where, first, the centroids of the clusters are randomly chosen, and then, by computing the distance from the centroids to the other points in the dataset, the members of the clusters are found. However, considering that we aim at forming equal range clusters, where the points are very close to each other, this approach has two main drawbacks, which make it not suitable for our use case. First, due to the very small clustering threshold, and the random choice of the clusters, it could happen that for some, or in the worst case for all, of the chosen centroids, there are no other points in the dataset such that their distance to the centroids is smaller than the clustering threshold, θ_c. This leads to having singleton clusters which do not cause any performance benefit in the joining phase. Another drawback of this approach is that the number of clusters needs to be chosen upfront.

First, to find the rankings that are very similar to each other, instead of selecting the centroids first, and comparing the distance for each point to the centroids, we execute a similarity join algorithm with the clustering threshold over the whole dataset, $\mathcal{T}$. Any similarity join algorithm can be applied, however, since prefix filtering approaches are especially efficient for very small thresholds, in our implementation we use the VJ algorithm. Note that the rankings have already been sorted, so we do not perform any additional sorting in this phase. The result of the VJ algorithm are all pairs of rankings (τ_i, τ_j) whose distance is smaller than the clustering threshold, i.e. $d(\tau_i, \tau_j) \leq \theta_c$. The clusters are formed such that, from the pairs, we take the first ranking, i.e., the one with a smaller id, as the cluster centroid, and the second one as their member. This does not only keep the clustering phase efficient, but also simplifies the expansion of the results in the last phase, since then the expansion can simply be performed by joining the result set from the joining and clustering phase. Furthermore, this way we can also efficiently apply filters based on the distance of the elements to their centroids, explained in Section 5.3. Clusters formed this way theoretically correspond to clusters formed by grouping the results by the first ranking, and taking the first ranking as the centroid. For instance, in Figure 3, the following clusters would be formed $C_1 = \{\tau_1, \tau_2, \tau_5\}$, $C_2 = \{\tau_3, \tau_4\}$ with centroids τ_1 and τ_3, respectively.

Since Spearman's Footrule distance is a metric, we know that for any two rankings $\tau_i, \tau_j \in C_i$ it holds that $d(\tau_i, \tau_j) \leq 2 * \theta_c$, and thus, members of the same clusters can directly be written to disk as partial results, as long as $\theta_c * 2 < \theta$.

By creating the clusters in this way, all of the aforementioned requirements are satisfied. The radius of all the clusters is the same and both forming the clusters and expanding the result set is kept simple, and thus, very efficient. One minor drawback of this approach is that the formed clusters would be overlapping. However, resolving this overlap would negatively impact the performance of the clustering and the expansion phase.

As input to the next, joining phase, we union the set of centroids C_m that contains all centroids representatives of clusters with at least two members, i.e., $|C| \geq 2$ with the set of centroids C_s that represent the singleton clusters, i.e., $|C| = 1$. The set C_s is derived from the original dataset, by finding those rankings $\tau_i \in \mathcal{T}$ such that there is no other ranking $\tau_j \in \mathcal{T}$, such that, $d(\tau_i, \tau_i) \leq \theta_c$. An example of a singleton cluster in Figure 3 is $C_3 = \{\tau_6\}$.

Figure 3: Example of how clusters are formed and centroids (marked with red) are chosen, where $\theta_c = 0.1$.

Example 5.2. Figure 3 shows through an example the creation of the clusters, for $\theta_c = 0.1$. The items in the rankings $\tau_1, \ldots \tau_6$ have already been sorted by increasing order of their frequency. For instance, in τ_1 item 1 with position $\tau_1(1) = 4$ is placed on the first position, as it appears three times in the rankings (ties are arbitrarily broken). After running a similarity join algorithm with distance threshold $\theta_c = 0.1$ on these rankings, the pairs (τ_1, τ_5), (τ_1, τ_2) and (τ_3, τ_4). In the following step clusters $C_1 = \{\tau_1, \tau_2, \tau_5\}$, $C_2 = \{\tau_3, \tau_4\}$ with centroids τ_1 and τ_3, respectively are formed. Furthermore, the ranking τ_6 forms a singleton cluster since it does not belong to any of the formed clusters C_1, C_2.

5.2 Joining

In the joining phase we need to find all centroids pairs (c_i, c_j) such that $d(c_i, c_j) \leq \theta_o$. To do this, we execute the VJ algorithm over all centroids c_i, with a threshold $\theta_o = \theta + 2 * \theta_c$. However, the VJ algorithm, as almost all similarity join algorithms, is sensitive to the threshold value—for larger threshold values the algorithm performs worse. Thus, it could happen that, even though we are joining a dataset $C \subseteq \mathcal{T}$, due to the larger threshold used, the joining phase performs worse than simply executing the VJ algorithm over the whole dataset $\mathcal{T}$. Again, note that we do not perform additional reordering of the rankings here, but the VJ algorithm is executed on the initially ordered rankings.

According to Lemma 5.1, using a threshold θ_o is only needed to avoid missing pairs of rankings $\{(\tau_i, \tau_j) | \tau_i \prec c_i, \tau_j \prec c_j \wedge d(\tau_i, \tau_j) \leq \theta \wedge d(c_i, c_j) > \theta)\}$. Furthermore, due to the small clustering threshold, in the dataset C we have many centroids which are representatives of singleton clusters. For these centroids, we can avoid unnecessary computation, by using a smaller threshold, without missing any true result. Lemma 5.3 defines this:

Lemma 5.3. *Given join threshold θ and clustering threshold θ_c, and a set of centroids $C = C_m \cup C_s$, where C_s is the set of centroids that represent the singleton clusters and $C_m = C \setminus C_s$ is the set of centroids representing non-singleton clusters. The following pairs of centroids need to be retrieved in order not to miss a potential join result:*

$$\{(c_i, c_j) \mid d(c_i, c_j) \leq \theta + 2 * \theta_c \quad if \ c_i, c_j \in C_m\} \tag{1}$$
$$\{(c_i, c_j) \mid d(c_i, c_j) \leq \theta + \theta_c \quad if \ c_i \in C_m \wedge c_j \in C_s \quad or \ v.v.\} \tag{2}$$
$$\{(c_i, c_j) \mid d(c_i, c_j) \leq \theta \quad if \ c_i, c_j \in C_s\} \tag{3}$$

Figure 4: Example of computing the final result set using the result set from the joining phase and the clusters where $\theta_c = 0.1$ and $\theta = 0.2$. Cluster's centroids are marked with red.

Lemma 5.3 allows us to more efficiently join the centroids. It follows that, only for the centroids $c_m \in C_m$ we need to use θ_o for joining and, thus, only for these centroids, we need to use a prefix based on the threshold θ_o. For the centroids $c_s \in C_s$, we can actually use the prefix based on the original threshold θ. Then, when computing the distance between the candidate pairs, we keep track of the type of the centroid, and accordingly, we output the pair if it satisfies the corresponding threshold. This is outlined in Algorithm 1.

Since we propose using small values for the clustering threshold θ_c, we expect that in practice, the cardinality of C_m will be significantly smaller than $|C|$, and thus, by applying a threshold of θ_o only for centroids $c_m \in C_m$, the savings should be notable.

5.3 Expansion

In the last phase, the final result set is generated. For this purpose, the results from the clustering phase, $\mathcal{R}_c$, and the result from the joining phase $\mathcal{R}_j$, need to be joined together, and the generated pairs need to be verified. Depending on the joined pairs from the joining phase, the expansion is done differently. The pairs where both centroids are singletons do not need to be expanded and are directly written to disc. Pairs where at least one of the rankings is not a singleton, need to be joined with the set of clusters, so that similar pairs of rankings between cluster members from different clusters, or with other singleton centroids, are generated.

Algorithm 2 outlines how the final result set is computed. First, the result set from the join phase, $\mathcal{R}_j$, is divided into two sets: $\mathcal{R}_s = \{(c_i, c_j) | c_i, c_j \in C_s \wedge d(c_i, c_j) \leq \theta\}$ and $\mathcal{R}_m = \mathcal{R}_j \setminus \mathcal{R}_s$. $\mathcal{R}_s$ is the set of candidate pairs, where both centroids are singletons. These pairs can be directly written to disc without further processing and verification. In addition, a subset of $\mathcal{R}_m$,

```
method: expand
input: Dataset $\mathcal{R}_c$, $\mathcal{R}_j$, double $\theta$, $\theta_c$
output: all pairs $(\tau_i, \tau_j)$ s.t. $d(\tau_i, \tau_j) \leq \theta$
    $\mathcal{R}_m, \mathcal{R}_s \leftarrow$ split($\mathcal{R}_m$)
    $\mathcal{R}_p \leftarrow$ get_partial_results($\mathcal{R}_m$, $\theta$, $\theta_c$)
    $\mathcal{R}_j, \mathcal{R}_m \leftarrow$ prepare_for_join($\mathcal{R}_j$, $\mathcal{R}_m$)
    $\mathcal{R}_{R_j \bowtie R_m} \leftarrow$ join($C_m, \mathcal{R}_j, \mathcal{R}_j$)
    $\mathcal{R}_{m,c} \leftarrow$ get_partial_results($\mathcal{R}_{R_j \bowtie R_m}$, $\theta$, $\theta_c$)
    $\mathcal{R}_{R_j \bowtie R_m} \leftarrow$ prepare_for_join($\mathcal{R}_{R_j \bowtie R_m}$ )
    $\mathcal{R}_{(R_j \bowtie R_m) \bowtie R_j} \leftarrow$ join($\mathcal{R}_{R_j \bowtie R_m}, C$)
    $\mathcal{R}_{m,c}, \mathcal{R}_{m,m} \leftarrow$ get_partial_results($\mathcal{R}_{(R_j \bowtie R_m) \bowtie R_j}, \theta, \theta_c$)
return distinct($\mathcal{R}_p \cup \mathcal{R}_s \cup \mathcal{R}_{m,c} \cup \mathcal{R}_{m,m}$)
```

Algorithm 2: Computation of the final result set.

i.e., pairs $(c_i, c_j) | \theta_c < d(c_i, c_j) \leq \theta$, can already be included to the final results set.

Candidate pairs, where at least one centroid is not a singleton, $\mathcal{R}_m$, need to be further joined with the set of clusters $\mathcal{R}_c$, in order to find the result pairs where at least one ranking is a cluster member. These pairs are missing from $\mathcal{R}_j$, since in the joining phase the join was performed only over the centroids. To do this, first the set of clusters and the set $\mathcal{R}_j$ are transformed, so that they are brought into a format where as key we have the centroids. Next, $\mathcal{R}_m$ and $\mathcal{R}_c$ are joined into $\mathcal{R}_{R_c \bowtie R_m}$. Then, $\mathcal{R}_{R_c \bowtie R_m}$ is used to generate the following result pairs:

$$\mathcal{R}_{m,c} = \{(\tau_i, c_j) \mid (\tau_i, c_j) \leq \theta \wedge \tau_i \prec c_i \wedge (c_i, c_j) \in \mathcal{R}_j\}$$

$$\mathcal{R}_{m,m} = \{(\tau_i, \tau_j) \mid (\tau_i, \tau_j) \leq \theta \wedge \tau_i \prec c_i \wedge \tau_j \prec c_j \wedge (c_i, c_j) \in \mathcal{R}_j\}$$

To generate the first result set $\mathcal{R}_{m,c}$, the candidate tuples in $\mathcal{R}_{R_c \bowtie R_m}$ need to be transformed into the needed pairs and further verified, if their distance is in fact smaller then θ. For pairs (τ_i, c_j), where $\tau_i \prec c_i$, we already know $d(\tau_i, c_i)$ and $d(c_i, c_j)$. Thus, using the triangle inequality, we verify only those candidate pairs (τ_i, c_j) such that $|d(c_i, c_j) - d(\tau_i, c_i)| \leq \theta$ and the remaining ones we can filter out since we can be certain that their distance is larger than θ.

For generating the set $\mathcal{R}_{m,m}$, the set $\mathcal{R}_{R_c \bowtie R_m}$ is first transformed, so that the second centroid is set as key of the tuples, and then it is joined with the set of clusters. The joined set is then used to add pairs to the set $\mathcal{R}_{m,c}$. These will be candidate pairs from the members of the newly joined centroids to the centroids we already had in $\mathcal{R}_{R_c \bowtie R_m}$. Filtering based on the triangle inequality is applied here as well. As last step, we generate all candidate pairs (τ_i, τ_j), such that $\tau_i \prec c_i$, $\tau_j \prec c_j$ and $d(c_i, c_j) \leq \theta + 2 * \theta_c$. For these, the Footrule distance is computed, and the ones where $d(\tau_i, \tau_j) \leq \theta$ are written to disk. Before writing the results to disc, the duplicates are removed.

Example 5.4. Figure 4 illustrates the expansion through an example. As results from the clustering phase, we have tuples (τ_1, τ_5), (τ_1, τ_2), and (τ_3, τ_4). The centroids of these clusters are τ_1 and τ_3—the clusters are the same as in the aforementioned example. The join results $\mathcal{R}_j$ are split into $\mathcal{R}_s = \{(\tau_7, \tau_9), (\tau_9, \tau_{12})\}$, where none of the rankings in the pairs is a centroid and $\mathcal{R}_m = \{(\tau_1, \tau_8), (\tau_1, \tau_6), (\tau_1, \tau_3)\}$, where at least one ranking in the pair is a centroid. Pairs in $\mathcal{R}_s$ are directly written to disk. Tuples in $\mathcal{R}_c$ and $\mathcal{R}_m$ are transformed such that the centroids, τ_1 and τ_3 are placed as keys of the tuples. They are joined and $\mathcal{R}_m, c$ =

$\{(\tau_5, \tau_8), (\tau_5, \tau_6), (\tau_2, \tau_8), (\tau_2, \tau_6), (\tau_2, \tau_3), (\tau_5, \tau_3)\}$ are verified. Then we take only those pairs in $\mathcal{R}_{R_c \bowtie R_m}$ where two rankings are centroids, in the example the last two elements of $\mathcal{R}_{R_c \bowtie R_m}$. For these, we switch the places of the centroids τ_1 and τ_3 so that the members of the second cluster could be joined with members of the first cluster, (τ_4, τ_5) and (τ_4, τ_2). These pairs need to be verified if their distance is smaller than θ.

6 REPARTITIONING USING JOINS

Naturally, the way data is distributed across partitions/machines greatly influences the performance of distributed algorithms. The VJ algorithm partitions the rankings based on the items that they contain—rankings that share an item end up at the same partition. This means that in the case of a skewed data distribution, which is often the case for real-world data, items that appear very frequently cause very large partitions. This problem is partially solved by the prefix filtering framework, especially for smaller values of θ, since the most frequent items would not be included. However, as we increase the value of θ, the size of the prefix increases, leading to skewed a distribution of data across the partitions, thus, having few partitions that dominate the overall execution time of the algorithm.

To tackle this issue, we propose an algorithm where large partitions are split into smaller sub-partitions. Then, the resulting pairs are computed for each small partition, and for each pair of sub-partitions. Algorithm 3 describes this procedure. First, using a user defined partitioning threshold δ we divide the inverted index into two parts, one where the partitions per item have more that δ rankings, $\mathcal{I}_{>\delta}$, and those whose partitions per item are smaller then the partitioning threshold, δ, $\mathcal{I}_{<\delta}$. In Spark, this can be easily computed, since the distributed inverted index is kept in one RDD, which allows easy access to the sizes of each partition. For those partitions that are smaller than the partitioning threshold, we compute the similarity join as before. The partitions larger than the partitioning threshold, $\mathcal{I}_{>\delta}$, are first split into smaller sub-partitions with at most δ rankings. This is done by assigning to each sub-partition a random number as a secondary key. To compute the final result set, we first compute the similarity join over each sub-partition. Then, we self join the sub-partitions by the item id, and for those join results where the secondary key of the first join pair is smaller than the secondary key of the second join pair, we execute a R-S similarity join algorithm for the joined partitions. To better handle the increased load due to data replication and to redistribute the working load equally among nodes, we partition by both the primary and secondary key, i.e., by both the item id and the randomly assigned number and increase the number of partitions.

Example 6.1. Figure 5 illustrates through an example the similarity join computation in case of repartitioning. In this example, the posting list for items $i_2, i_{10}, \dots i_m$ have size larger than δ and thus are split into smaller partitions. For instance, the posting list for item i_2 is split into three smaller lists with keys $(i_1, 1)$, $(i_1, 5)$, and $(i_1, 9)$. In order to keep the correctness of the algorithms, in addition to generating the pairs for each of these lists, they are self joined, and an R-S join algorithm over the joined posting lists (with keys $(i_1, 1, 5)$, $(i_1, 1, 9)$, and $(i_1, 5, 9)$) is performed.

Choosing the Partitioning Threshold δ. In our experiments, we show that the performance of the algorithm does not significantly vary, when changing the partitioning threshold δ. However, the partitioning threshold still needs to be chosen carefully, such that it is not set to a very small value, leading to too many partitions being split into many small sub-partitions. If this happens then joining the sub-partitions in step 5 of Algorithm 3 becomes too expensive, and the benefit of the repartitioning is lost. In addition, due to the use of Spark joins, choosing a very small value of δ can also lead to memory crashes of the executors.

As a general guidance for choosing the value of the parameter δ an estimation for the size of the posting lists can be used. In our previous work on similarity search for top-k rankings [18], we devised a formula for estimating this:

$$E[\mathit{index\ list\ length}] = \sum_i n * f(i; s, v')^2 \tag{4}$$

where n is the number of rankings indexed, and $f(i; s, v')$ is the frequency of the item at rank i, when the items follow a Zipf's distribution with skewness parameter s. v' is the distinct number of items in the prefix of the rankings.

7 EXPERIMENTS

We deployed all algorithms on a Spark 1.6 (using YARN and HDFS) cluster running Ubuntu 14.04.5 LTS. The cluster consists of 8 nodes, each equipped with two Xeon E5-2603@ 1.6GHz/ 1.7GHz of 6 cores each, 128GB of RAM, out of which 40GB is reserved for execution of jobs by YARN, and 4TB hard disks. All nodes are connected via a 10GBit Ethernet connection.

Datasets: Due to the lack of real top-k ranking datasets, for the experiments we used datasets that are often used in previous work on similarity joins for sets and were also used for performing the experimental study for distributed similarity join algorithms [10]. Specifically, we use the DBLP [1] and ORKU [2] datasets. To transform the records of these dataset into top-k

spark.driver.memory	12G
spark.executor.memory	8GB
spark.executor.instances	24
spark.executor.cores	5

Table 3: Spark parameters used for the evaluation

rankings, we simply take the first k tokens in the sets, and consider them as items in the rankings. Since we are working with rankings of same size, we remove records with size smaller than k. In addition, the datasets are preprocessed as in [10], without the sorting of the records. Note that, while in the preprocessing step duplicates are removed from the dataset, since we cut the records to size k it can happen that we have a small amount of records with distance 0 to each other. However, this should *not* affect the performance of the algorithms, since duplicate records are *not* handled differently, i.e., the performance of the algorithms should be the same as if there are no duplicates. As we will show later on in our experimental study, what affects the performance of our algorithm is the number of records with distance smaller than θ_c.

After the preprocessing the DBLP dataset has approximately 1.2 million top-10 rankings, and ORKU has approximately 2 million top-10 rankings. Each datasets has a size of 67MB and 173MB. Since these datasets are relatively small for a distributed setting, we also increase their size using the same method as in [10, 24], where the domain of the items remains the same, and the join result increases approximately linearly with the size of the dataset. We use suffix xn to denote the number of times the dataset has been increased. For instance, "ORKUx5" represents the ORKU datasets increased 5 times.

The files in Spark are read as text files, and are directly partitioned into the number of partitions specified at input. Throughout the experiments we write the number of partitions that the data is divided into. Additionally, we show experiments that illustrate the behavior of the effect that the number of partitions has to the performance of the algorithms.

Algorithms under investigation We investigate the performance of the following algorithms:

- The adaptation of VJ to top-k rankings in Spark (VJ)
- The adaptation of VJ to top-k rankings using iterators instead of inverted index (VJ-NL)
- The clustering algorithm using iterators (CL)
- The clustering algorithm with iterators and re-partitioning of the data (CL-P)

Based on general recommendations for running Spark jobs, which suggest to not run 'tiny' or 'fat' executors, we assign 5 cores per executor. Then, based on the total number of cores and the available memory of the nodes in the cluster, we set the other execution parameters, reported in Table 3. The memory assigned to the executers also corresponds to the amount assigned to the reducers in a previous experimental study [10]. In case we use different settings, we write these changes for the specific experiments. We report on the average wall-clock time measured in seconds over 3 runs. If an algorithm runs more than 10 hours we stop its execution.

7.1 Results

Performance Based on the Distance Threshold θ. We first evaluate and compare the performance of the above listed algorithms when we vary the distance threshold θ. Figure 6 reports on the performance of the four algorithms for both datasets DBLP and ORKU, for values of θ ranging from 0.1 to 0.4. We see that our algorithm outperforms the competitor algorithm VJ for larger values of θ. Most importantly, we see that, with the exception of the DBLP dataset, each optimization that we propose, brings additional performance improvement. For all algorithms, the execution time increases, as we increase the distance threshold θ, however, for our proposed algorithms, CL and CL-P, the increase in performance is smaller, especially for the latter. For instance, for the DBLPx5 dataset, the execution of the VJ algorithm for the largest threshold value, 0.4, is 100 times more expensive than when executing it for the smallest threshold value of 0.1. On the other hand, the increase in execution time for the CL and CL-P algorithms is 33 and 13 times, respectively. This can be attributed to the design of the CL algorithm. Since in the joining phase less rankings are being processed, the algorithm is not too much affected by the skewness of the dataset. With the partitioning of the large partitions into smaller ones, and their redistribution among the nodes in the cluster, the CL-P algorithm shows even larger performance improvement, for larger threshold values.

Furthermore, we see that for the datasets DBLPx5 (Figure 6(b)) and ORKU (Figure 6(d)) the gains in performance are the largest. Here, we can clearly see that using iterators over an inverted index is more efficient when it comes to a Spark implementation. Additionally, we see that the largest performance benefit from our clustering algorithm are for values of θ of 0.3 and 0.4. When θ is set to 0.4, clustering combined with partitioning based on joins (CL-P) performs 5 and 3 times better than the VJ and VJ-NL algorithms, respectively, for the ORKU dataset (Figure 6(d)). For the DBLPx5 dataset, the CL-P algorithm outperforms the VJ and VJ-NL algorithms by almost 4 and 3 times, respectively (Figure 6(b)). For lower values of the partitioning threshold, i.e., when $\theta = 0.1$ or $\theta = 0.2$, the CL and CL-P algorithms either perform slightly worse than the VJ or VJ-NL, or the gain in performance is not that large. This is especially true for $\theta = 0.1$. This is due to the fact that the VJ algorithm is very efficient for a very small thresholds, since the prefix size is then small. In these cases, the overhead from the additional clustering phase in the CL approach, or partitioning for the CL-P, is larger than the benefit that we could get from it.

Note that in all cases, the clustering threshold for the CL and CL-P algorithms is set to 0.03. The reason for this is explained bellow, where we study the effect that this threshold has on the performance of the algorithms. The value of the partitioning threshold δ differs depending on the dataset, and the threshold value, θ. For larger thresholds θ, we choose larger partitioning threshold δ, since we expect an increase in the size of the posting lists. Later we discuss how choosing the partitioning threshold δ affects the performance. For the smallest dataset, DBLP (Figure 6(a)), where the original VJ algorithm is already very efficient, the proposed optimizations lead to worse performance. The CL-P algorithm in this case always performs worse than VJ, since it brings additional overhead of repartitioning and joining already small posting lists. The CL algorithm outperforms VJ only for large values of θ. On the other hand, for the ORKUx5 dataset (Figure 6(e)), for $\theta = 0.4$, only the CL-P algorithm finished under 10 hours. Similarly, for the DBLPx10 dataset (Figure 6(c)), the VJ algorithm did not finish under 10 hours.

Scalability. To test the scalability of the proposed algorithm, we varied the number of nodes in our cluster. We executed the CL-P algorithm on a cluster with 4 nodes and with 8 nodes. For

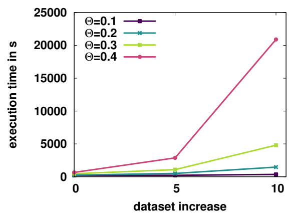

Figure 8: Performance of CL-P algorithm when varying the dataset size for the DBLP dataset.

this experiment, we reduced the number of cores per executor to 3, and we did not fix the number of executors to be used, i.e., this was left to be decided by YARN, based on the cluster size. The memory restriction per executor and for the driver were kept as specified in Table 3. Figure 7 shows the performance of the CL-P algorithms for different values of the theshold θ, for the DBLPx5 and ORKU datasets. The values for the clustering threshold θ_c and the partitioning threshold δ were kept the same as for the previous experiment. We see that for both datasets, the CL-P algorithm exhibits better performance, when the number of nodes is increased. For the DBLPx5 dataset, when increasing the number of nodes from 4 to 8, the time cost decreases from 22% to 46%, and for the ORKU dataset the time savings are similar, ranging from 26% to 44%. Again, the largest performance improvement is observed for $\theta = 0.4$.

Furthermore, in Figure 8 we plotted the performance of the CL-P algorithm as we increase the size of the DBLP dataset. Note that the result size increases approximately linearly with the increase in the number of records. The rise of the execution time is the largest, i.e., for $\theta = 0.4$, when we increase the dataset size from x5 to x10. In this case the CL-P algorithm executes 7 times slower. However, the reason for this we see in the value of the partitioning threshold δ. We believe that with a more carefully chosen value for δ this increase in the execution time can be avoided. For all other cases of θ the decrease in performance is lower than 5 times.

Effect of the Clustering Threshold θ_c. Another threshold that can have impact on the performance of the proposed clustering algorithm is the clustering threshold θ_c. Depending on the value of this threshold, the size and number of the formed clusters varies, and thus the performance of the whole algorithm. Figure 9 shows the performance of the CL algorithm for different values of θ_c for both datasets. We see that, in almost all cases, setting $\theta_c = 0.03$ brings the best performance for the CL algorithm. This can be explained by two reasons. First, as we increase the clustering threshold θ_c, the running time of the clustering phase increases, since here we use the VJ algorithm to find the similar pairs. Second, the benefit by the additionally formed clusters does not seem to compensate for this increase in the running time. Thus, setting the clustering threshold θ_c to a very small value is the recommend choice, and in all further experiments we set θ_c to 0.03 for both CL and CL-P.

Effect of the Partitioning Threshold δ. The partitioning threshold δ is a parameter which decides which and how many posting lists need to be partitioned, and as such, it influences the performance of the CL-P algorithm. In Figure 10 we see the performance of the CL-P algorithm as the partitioning threshold changes, for both datasets DBLP and ORKU and for different values of the threshold θ. For the DBLP dataset we show only the DBLPx5 increased dataset, since, as we showed in Figure 6(a), the DBLP dataset is small and does not benefit from the partitioning of the posting lists. For each dataset, we chose different varying

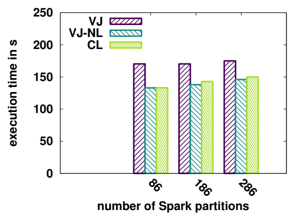
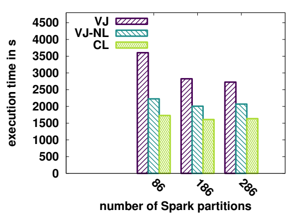
ranges for the partitioning threshold, since its value is directly dependent from the size of the dataset. For ORKU (Figure 10(a)) we vary δ from 500 to 5000, for ORKUx5 (Figure 10(b)) we vary δ from 10000 to 50000 and for DBLPx5 (Figure 10(c)) we vary δ from 1000 to 50000. Furthermore, for ORKU and DBLPx5 we plot the performance for $\theta = 0.3$ and $\theta = 0.4$ (Figures 10(c) and 10(a), respectively), while for ORKUx5, for practical reasons, due to the large execution times when having large values of θ, we plot the performance for $\theta = 0.1$ and $\theta = 0.2$ (Figure 10(b)). In Figure 6(a) we see that the performance of CL-P is not widely influenced by the partitioning threshold δ. Starting with small values of δ, the performance is slightly worse, due to the larger number of posting lists that need to be joined, and thus the overhead imposed by the Spark join is larger. Then, as we increase δ, the performance at first drops and reaches its minimum, and then starts to slightly increase. This is important to note, since it gives us more freedom of choosing the value for δ. Note, however, that choosing very small values can lead to either bad performance or crashes of the executors due to memory overhead caused by the joins. During our experiments execution, we experienced crashes due to memory overhead, whenever the δ value was set to an inappropriately small value, when considering the number of records being processed. On the other hand, setting δ to a very large value will not bring any performance benefit, since no postings lists will be partitioned.

Increasing the size of the rankings. Top-k rankings usually contain only very few items. In fact in our study [3] we showed that most of the rankings are of size 10 or 20. Therefore, in the previous experiments we focused on rankings of size 10. To see how the performance of the algorithms changes, when we have rankings of larger size, we also run experiments where $k = 25$. For this purpose we used the ORKU dataset, which contains also longer records. From the original dataset, we extracted around 1.5 million top-25 rankings, as described above. This dataset has a size of 289MB. The DBLP dataset contained only shorter records, and thus for this experiment we rely only on the ORKU dataset. Figure 11 shows the performance of the four algorithms when varying the distance threshold θ. While our algorithms still outperform the VJ algorithm, there are two important things to note here. First, the difference in the performance between VJ-NL and VJ is not so significant, and second CL performs almost the same as VJ-NL. This might be explained with the size of the dataset, since our clustering algorithms, CL and CL-P, perform better on larger datasets. The CL-P algorithm shows the best performance, except for $\theta = 0.1$, and is, as with rankings of size 10, least susceptible to the increase of the threshold θ. For $\theta = 0.1$, the VJ-NL algorithm performs slightly better than the other algorithms. The CL-P algorithm outperforms the VJ-NL algorithm for 1.5 and 1.9 times for $\theta = 0.2$, and $\theta = 0.3$ and 0.4, respectively. Note that for this experiment, for both CL and CL-P, we set $\theta_c = 0.03$ and the partitioning threshold, δ, for CL-P, we set to 5000, for all values of θ.

Varying the number of Spark partitions. The general recommendation when executing Spark jobs is to set the number of partitions to be at least four times as the number of executors running. In our setting, this means that the general recommendation is to have at least 100 partitions. Figure 12 shows the performance of different algorithms (VJ, VJ-NL and CL) for different number of partitions. For this experiments the partitioning threshold θ is fixed to 0.3. We see that for both DBLP and DBLPx5, the performance does not change much as we increase the number of partitions. In fact, we see that whether the performance increases or decreases—as we increase the number of partitions—depends on the size of the dataset. For the smaller dataset, DBLP, the best performance is observed when the number of partitions is set to 86, and then the performance slightly decreases. For DBLPx5, on the other hand, we have the best performance of both CL and VJ-NL for 186 partitions. Figure 13 shows the performance of the CL-P algorithm when changing the number of partitions. For CL-P we used a larger span of the number of partitions, from



(a) DBLP



(b) DBLPx5

Figure 12: Performance of VJ, VJ-NL and CL when varying the number of Spark partitions, $\theta = 0.3$ (DBLP and DBLPx5).

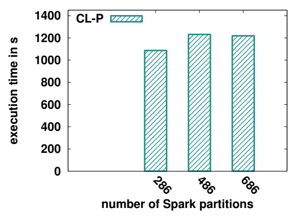


Figure 13: Performance of CL-P when varying the number of Spark partitions, $\delta = 10000$, $\theta = 0.3$ (DBLPx5).

286 to 686. Since here we additionally repartition the large partitioning into smaller ones, we believe that using a larger number of partitions is more appropriate for this approach However, as we can see from Figure 13, the performance is again not greatly influenced by the change of the number of the partitions. In fact, there is also a slight drop in the performance in the initial increase in the number of partitions, from 286 to 486. In all of the experiments presented before, the number of partitions was set to 286.

Lessons Learned. The proposed clustering algorithms, CL and CL-P, outperform the adaptation of the state-of-the-art algorithm for similarity joins over sets, VJ, for higher values of the distance threshold θ. For small values of θ the VJ algorithm is very efficient on its own, and thus, the benefits introduced by the additional stages of the CL approach, do not seem to pay off. This is also the case for small datasets. However, more importantly, for larger datasets, the CL and CL-P approaches seem to bring larger performance improvements over the VJ algorithm. Additionally, they both seem to be less susceptible to the increase of the distance threshold. This seems to be especially true for the CL-P algorithm, in particular, when the partitioning threshold is chosen right. Furthermore, our approach is more appropriate for handling datasets with skewed distribution, as first, the dataset is reduced for the joining phase, and second, large posting lists are split into smaller ones and processed in parallel. For choosing the partitioning threshold δ, statistics like the number of records in the dataset, and the size of the vocabulary, or item domain, can be used, as discussed in Section 3. For choosing the clustering threshold, as a rule of thumb, we suggest choosing a very small value, namely to set θ_c to be smaller than 0.05. A drawback of our solution is that, since we rely on Spark joins, it can run out of memory, especially where the result set is large.

8 CONCLUSION AND OUTLOOK

In this paper, we addressed distributed similarity join processing techniques for a datasets of top-k rankings. As a distance for comparing the rankings, we specifically considered Spearman's Footrule adaptation to top-k rankings. The presented approach synthesizes existing state-of-the-art, set-based, distributed similarity join algorithm with the advantages of metric-space, distance-based, filtering. It works in several stages, where each can be independently configured from each other. Furthermore, our algorithms are designed and implemented in Apache Spark, as suggested by a recent experimental study. By a comprehensive performance evaluation using two real-world datasets, we showed that the presented approach exhibits better performance than the competitor, Vernica Join. In the future, we plan to extend our approach to sets where the Jaccard distance is used as a distance measure.

ABSTRACT

Modern mixed (HTAP) workloads execute fast update-transactions and long-running analytical queries on the same dataset and system. In multi-version (MVCC) systems, such workloads result in many short-lived versions and long version-chains as well as in increased and frequent maintenance overhead.

Consequently, the *index pressure* increases significantly. Firstly, the frequent modifications cause frequent creation of new versions, yielding a surge in index maintenance overhead. Secondly and more importantly, index-scans incur extra I/O overhead to determine, which of the resulting tuple-versions are visible to the executing transaction (visibility-check) as current designs only store version/timestamp information in the base table – not in the index. Such *index-only visibility-check* is critical for HTAP workloads on large datasets.

In this paper we propose the *Multi-Version Partitioned B-Tree (MV-PBT)* as a version-aware index structure, supporting index-only visibility checks and flash-friendly I/O patterns. The experimental evaluation indicates a 2x improvement for analytical queries and 15% higher transactional throughput under HTAP workloads. MV-PBT offers 40% higher tx. throughput compared to WiredTiger's LSM-Tree implementation under YCSB.

1 INTRODUCTION

The spread of large-scale, data-intensive, real-time analytical applications is increasing. Such applications result in Hybrid Transactional and Analytical Processing workloads (*HTAP*) combining long running analytical queries (OLAP) as well as frequent and low-latency update transactions (OLTP) on the same dataset and even on the same system [19].

Multi-versioning is at the core of many approaches and system designs suitable for HTAP. Under *Multi-Version Concurrency Control (MVCC)* reading transactions, executing long-running queries, do not block the frequent low-latency modifying transactions. Under such approaches multiple versions of each data item (i.e. tuple) may physically co-exist, whereas every transaction operates against a snapshot of the database comprising all versions it is allowed to see for consistent execution. Read operations simply operate on the latest committed version, visible to them and are therefore never blocked, yielding good read performance and concurrency. An update operation produces a new version of the updated data item and invalidates the predecessor version.

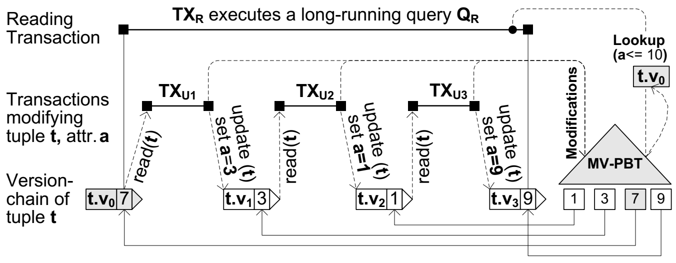

Figure 1: HTAP and Version-Chain Lengths: $TX_{U1} \ldots TX_{U3}$ **create new versions of tuple** ***t*****, which are indexed. The index scan of** TX_R **returns only the index entries (**$t.v_0$**) visible to** TX_R **filtering the invisible ones (**$t.v_1 \ldots t.v_3$**), matching the search predicate.**

All versions of a tuple form a version-chain. Timestamps placed on every physical version-record are used to determine, which of the exisiting tuple-versions is *visible* to a transaction.

Under OLTP workloads, version-chains tend to be short, due to the predominantly short-lived transactions. For instance, under TPC-C the average version-chain length is approx. 1.2 [9]. *Under HTAP the DBMS needs to handle much longer version-chains due to the mix of long-running and short-lived transactions (Figure 1).* Whenever a transaction TX_R reads a tuple *t* the DBMS returns the latest version of that tuple $t.v_0$, committed before the start of TX_R. Even though, in the meantime multiple low-latency updating transactions $TX_{U1} \ldots TX_{U3}$ might have committed, producing successor-versions ($t.v_1 \ldots t.v_3$), $t.v_0$ cannot be garbage collected as long as, it is visible to an active transaction, i.e. TX_R. Thus, the amount of such transient versions can be as high as *several hundred millions* in real systems [14].

HTAP workloads in combination with long version-chains exercise significant pressure on indices. In a single-versioned system there is one index entry per tuple. However, in a multi-versioned system, the DBMS needs to index at least all committed tuple-versions (Figure 1), even the transient ones. Thus, long version-chains put extra pressure on the index. *Although most of today's systems are multi-versioned, the majority of index approaches still handle tuple-versions of the same tuple as if they were separate tuples, ignoring the version semantics.* If naïvely integrated, these slow down index lookups and may cause significant maintenance overhead to persistent indices, as index updates are very frequent and since index entries corresponding to obsolete tuple-versions need to be frequently garbage collected. Given the read/write asymmetry of modern persistent storage technologies these operations result in prohibitively expensive in-place updates. In this context append-based index structures trading sequential writes for complex reads are a good candidate.

All in all, the following observations can be made:
1) *Version-obliviousness:* Although, all tuple-versions need to be indexed, current indexing approaches lack version information.
2) *Lack of index-only visibility-checks:* It is currently impossible to determine, which of the index-entries resulting from an index lookup/scan correspond to versions, visible to the calling transaction solely based on the index.
3) *I/O overhead:* Version-oblivious indices or naïve support for multi-versioning yield significant I/O overhead.

In the present paper we propose the *Multi-Version Partitioned B-Tree (MV-PBT)* as a version-aware index structure for MV-DBMS, in an attempt to address the above issues. MV-PBT is based on a variant of B$^+$-Trees called *Partitioned B-Trees* [13]. The contributions of this paper are:

- MV-PBT is a version-aware index structure. It contains version information and supports index-only visibility-checks.
- MV-PBT supports append-based write-behavior and exhibits much lower write-amplification compared to LSM-Trees.
- MV-PBT has been implemented in PostgreSQL. The performance evaluation under HTAP workloads (CH-Benchmark [2]) indicates 2x analytical throughput improvement due to index-only visibility-checks, while improving the transactional throughput by 15% compared to PostgreSQL's highly-optimized B$^+$-Tree. Under TPC-C MV-PBT performs 15% better.
- MV-PBT has also been implemented in WiredTiger (MongoDB). The performance evaluation indicates approx. 40% higher throughput under YSCB compared to WiredTiger's highly-optimized LSM-Trees.

The rest of the paper is organized as follows. We motivate the missing *version-awareness* and the need for *index-only visibility-checks* in Section 2, while Section 3 provides some background on various multi-versioning aspects. The design and implementation of MV-PBT is described in detail in Section 4, while the experimental evaluation is presented in Section 5. We. discuss related approaches in Section 6 and conclude in Section 7.

2 MOTIVATION

In this section we give a more comprehensive perspective on the above issues of: 1) *Version-obliviousness in indices*; 2) *missing index-only visibility-check*; and 3) *I/O overhead*. Consider the example in Figure 2, which is a more detailed version of Figure 1 with a conventional B$^+$-Tree. An initial transaction TX_{U0} (not depicted) inserts tuple t prior to TX_R, creating its initial version $t.v_0$. While TX_R is running, multiple concurrent transactions $TX_{U1} \dots TX_{U3}$ update tuple t and each of them produces new versions of it ($t.v_1 \dots t.v_3$). Only TX_{U3} inserts tuple y in its initial version $y.v_0$ in addition to creating $t.v_3$. Each tuple-version is a separate physical version record (Figure 2.A). It contains *version-information*: the *recordID* of the predecessor version and two timestamps, $t_{creation}$ - the timestamp of the transaction that created that tuple-version; and $t_{invladiation}$ the timestamp of the transaction that invalidated it by creating a successor version. The invalidation-timestamp is *null* if there is no successor. If a tuple gets deleted a special *tombstone* version-record is inserted to mark the logical end of the chain. *The version-information is only available on the version-record.*

Since version-records are independent physical entities they can be stored on any DB-page with enough free space. Figure 2.B depicts an example of the physical version-storage. *For consistency, an index on a table must contain index-entries for each committed version of every tuple.* Therefore, a B$^+$-Tree index *idx* on attribute *a* of table *R* (Figure 2.C) should reflect all versions of each tuple of *R*. *Since the index is version-oblivious it contains no version-information, and treats each tuple-version as if it were a separate tuple.* Consequently, if TX_R uses the index to count all tuples satisfying *"$a \le 10$"* (Figure 2.D), the index scan will return the matching index entries (referencing versions $t.v_0 \dots t.v_3$). Now, each one of them must be checked for visibility, i.e. is it latest committed tuple-version prior to the start of TX_R. However, the necessary timestamps are available only on the version-records. Therefore, all of them are retrieved, at the cost of random I/Os.

Figure 2: Index-Only Visibility-Check in Multi-Version DBMS: (a) logical tuples (t and y) of a table R and their versions; (b) the physical storage of these versions into database pages; (c) an index created over table R must index all versions; (d) an index-scan retrieves all versions matching the predicate, out of which (e) the visibility-check returns only the ones visible to calling transaction TX_R.

In our example (Figure 2.D, C and E), the index-scan for the condition *"$a \le 10$"* will return versions $t.v_3$, $t.v_0$, $t.v_1$ and $t.v_2$. Subsequently, they are read to extract the *version-information* ($t_{creation}$ and $t_{invalidation}$ – Figure 2.A) yielding four random I/Os. The visibility-check then determines the latest version committed prior to the start of TX_R, returning the recordID of $t.v_0$ and ignoring the rest. *Since the index is version-oblivious and thus does not support index-only visibility-checks, the I/O costs amount to: COST(Index-Scan) + 1 random I/O for each matching tuple-version. Especially for HTAP workloads this yields significant performance degradation depending on the length of the version-chains.*

To quantify the combined effect, we designed a simple experiment with *YCSB* [7] and PostgreSQL. We run YCSB workloads A (update) and E (scan) combined, performing frequent scans and updates. In parallel, we perform a point-query on a tuple every 30 seconds (simulating an HTAP workload). Additionally, we continuously increase the version-chain, by updating the tuple, until 50 versions are reached. In realistic HTAP settings, the amount of active versions can be as high as *several hundred millions*, while analyses can take as long as 1000s [14]. The experimental results

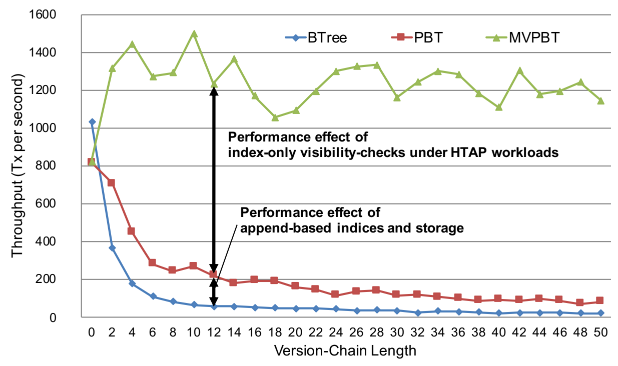

Figure 3: Performance Impact of Version Visibility Check.

are shown in Figure 3. The highly-optimized B$^+$-Tree implementation in PostgreSQL performs better than *MV-PBT* on a single tuple-version. However, as the version-chain length increases (6-8 versions) the performance drops rapidly to *approx. 50 transactions/sec*, due to version-obliviousness and random I/O. Basic Partitioned B-Trees (PBT), are likewise *version-oblivious*, but exhibit append-based write behaviour, avoiding in-place updates and perform therefore slightly better (*approx. 150 tx/sec*). Due to its *version-awareness* and support for *index-only visibility-check* MV-PBT exhibits much higher and robust performance (*approx. 1200 tx/sec*) with growing chain lengths. MV-PBT shows a performance increase with chain-lengths of two or more due to the partition buffer since: (a) the initial YCSB data load, producing the first version fills partition P_0 and evicts it; while (b) the second version is created by the benchmark workload and is in P_N.

3 BACKGROUND

Multi-Version Concurrency Control (MVCC) is one of the most popular transaction management schemes and is used in most modern DBMS: Oracle, Microsoft SQL Server, HyPer, SAP HANA, MongoDB WiredTiger, NuoDB, PostgreSQL or MySQL-InnoDB, just to name a few. These DBMS make different design decisions regarding various MVCC aspects described below.

3.1 Version Storage

Under MVCC a logical tuple corresponds to one or more tuple-versions (Figure 2.A). They form a singly linked list, which represents a version chain. There are two possible physical representations of a tuple-version (Figure 4): *physically materialized* or *delta-record based*. The former implies that each tuple-version record is stored physically materialized in its entirety and is in the focus of this paper. The latter implies that each modification of a logical tuple results in a delta-record, indicating the difference to another version (à la BW-Tree [15, 22]). The delta-records are connected and retrieved on demand by the DBMS storage manager to restore a tuple-version. *Delta-record based* system designs typically store a single version (oldest or newest) in the main store and use a separate store for the delta-records, which may be the undo log (à la InnoDB) or a temporary version store (à la MS SQL Server). Both organizations can perform modifications in-place or out-of-place. Out-of-place updates with *physically materialized* version-maintenance insert a new version-record in the base table. Based on the version ordering, additional modifications may be necessary to maintain logical timestamps or references.

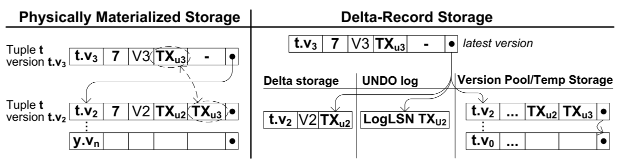

Figure 4: Version Storage Alternatives

Considering the characteristics of modern storage technologies, physically materialized version storage and out-of-place updates are preferable, due to lower write-amplification and the higher parallelism. Delta records tend to consume less space than materialized tuple-versions, but require additional processing and all predecessors or successors for tuple reconstruction.

3.2 Version Ordering

The set of tuple-versions of a database tuple is organized as a singly linked list. There are two different ordering methods (Figure 5): *old-to-new* and *new-to-old*.

Old-to-New ordering: The entry-point is the oldest tuple-version in version chain and each version contains a reference (recordID) to its successor. A visibility-check must therefore process all successors, beginning from the oldest tuple-version. This behavior is beneficial for lookups of long-running analytical (OLAP) queries under HTAP workloads, where older tuple-versions are likely to be the visible ones. Alternatively, OLTP workloads mostly require the newest version and would need to process the whole version chain. *New-to-Old ordering* implies that the entry-point is the newest tuple-version, which refers to its predecessor. Queries in the typically short OLTP transactions find the visible version very fast, but long-running OLAP queries may need to process several successors in version chain (Figure 3). *In-place* and *out-of-place* update strategies are are possible for both methods.

Considering the characteristics of modern storage technologies new-to-old ordering for physical version storage results in lower write-amplification and matches append-only storage. All other approaches require in-place updates.

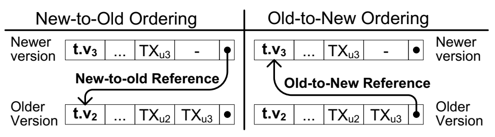

Figure 5: Version Ordering Alternatives

3.3 Version Invalidation Model

Under MVCC a version is said to be invalidated whenever a successor version exists. There are two possible invalidation models [9] (Figure 6). First, *two-point invalidation* is the state-of-the-art model, where the creation timestamp of the successor version is also placed as invalidation timestamp on the predecessor. *Two-point invalidation* works well with old-to-new ordering. However, with new-to-old ordering, the invalidation timestamp must be set on the predecessor version, yielding an in-place update and possibly a random write. Second, with *one-point invalidation* [11], the existence of a successor implicitly invalidates the predecessor and all version-records contain only the creation timestamp. *One-point invalidation* matches well new-to-old ordering, the use of indirection layer (VIDs, and entry-points) as well as append-based storage.

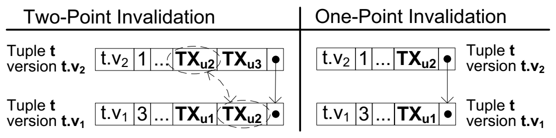

Figure 6: Version Invalidation Model

3.4 Garbage Collection

Under MVCC modifications of a tuple result in the creation of a new tuple-version. Old tuple-versions become obsolete, if they are no longer visible to any of the active transactions. Therefore, some form of *version GC* is necessary to reclaim space and can improve performance. However, GC causes performance spikes (as it interferes with foreground I/O), reduces concurrency (as some form of locking is required) and increases write-amplification on secondary storage. GC [23] can be performed on transaction [14], tuple and index levels [15, 22]. Index-level GC (Section 4.6) purges index entries, resulting from index updates, maintenance or tuple-level GC.

3.5 Version/Index-Record Referencing

There are two possibilities to map index records to tuple-versions in base tables (Figure 7). *First*, classical physical references (recordIDs) can be used. Thus, the latest tuple-version in base tables (entry-point in the version chain) can be accessed directly, but changes to the latest version or its location result in index-record modifications. Such changes comprise: creation of a successor-version; storage management and physical movement (as in append storage) or garbage collection. *Second*, an indirection layer with logical references can be employed. Each tuple-version is augmented with an unique tuple-identifier (Virtual Tuple Identifier – VID), which is also stored in the index records. An index operation resolves the VID using a mapping table (indirection layer) to locate the physical entry-point. *An indirection layer can reduce index maintenance costs for in-place and out-of-place updates, but requires additional structures and processing.*

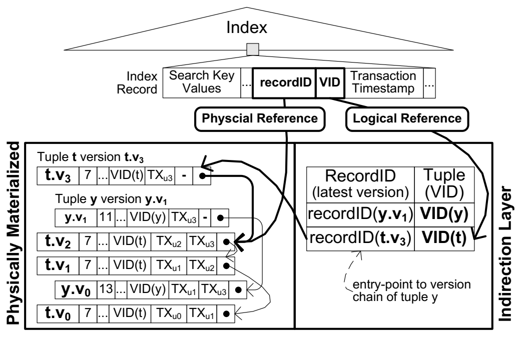

Figure 7: Version/Index-Record Referencing

Traditional index designs use physical references and contain no version-information, which tends to increase index maintenance overhead as well as the visibility check costs for lookups and scans. Alternatively, modern index-structures (BW-Tree) use an indirection layer, but contain no version-information and support no index-only visibility check. This can cause massive read amplification for mixed workloads. An optimal index structure should reduce write amplification and return only references to tuple-versions that are visible to a transaction snapshot. MV-PBT uses physical or logical references, is version-aware and produces append-only sequential write pattern.

3.6 Discussion

We have outlined some relevant design decisions for storing tuple-versions in multi-version DBMS. Modifications are preferably stored as *physically materialised tuple-versions* in base tables, rather than deltas, due to tuple reconstruction costs. Moreover, this enables direct access to each tuple-version from additional access paths. *Out-of-place updates* reduce write amplification to secondary storage. Garbage collection is required for space reclamation, but brings additional complexity to data structures.

A *new-to-old* version ordering requires index maintenance for every new tuple-version, because the entry-point of the version chain for that tuple changes. A logical indirection layer ensures fast lookups by efficiently returning the entry-point of a version chain and reduces index maintenance effort. *New-to-old* ordering is beneficial for OLTP and speeds up visibility-check as the latest version ist typically the visible one, yet older versions may require slow reconstruction. Alternatively, *old-to-new* ordering is supports long-running OLAP operations and visibility-check in HTAP settings, as the oldest version is directly accessible. Yet, modifications and maintenance may suffer low performance.

Indices for mixed workloads and large datasets should rather return visible tuple-versions. Alternatively, traditional index structures only return version candidates, which have to be subsequently verified, fetching version-records from base tables by performing random I/O. For these reasons *MV-PBT* rely on physically materialised versions, out-of-place updates, a new-to-old ordering, one-point invalidation and can do without an indirection layer.

3.7 Storage Characteristics

Modern database storage management needs to address the characteristics of semiconductor storage technologies [20]. Consider Figure 8, which deptics the I/O characteristics of the enterprise Flash storage used in the evaluation. Typical index search operations result in large amount of small (8K) random reads. Hence, optimize for read IOPS and sequential writes (≥64K). We derive the following tradeoffs for the I/O behaviour of MV-PBT: (a) transform random writes in sequential writes with higher granularity (MB); and (b) trade sequential writes for complex and possibly random reads with higher parallelism and smaller granularity (KB). Thus, append-based storage managers are beneficial for the base tables [9, 11]. Write-sequentialization is therefore necessary for indices, and MV-PBT supports it intrinsically, like LSM-Trees.

		Read		Write	
	Blocksize [KB]	8	64	8	64
Sequential	Iops	122382	24180	11104	1343
	MB/s	956	1511	87	84
Random	Iops	112479	23631	7185	56
	MB/s	879	1477	1184	74

Figure 8: I/O Characteristics of Intel DC P3600 SSD.

4 MULTI-VERSION PARTITIONED B-TREES

Multi-Version Partitioned B-Trees (Figure 9) are based on Partitioned B-Trees (PBT), introduced by Goetz Graefe [12, 13]. PBT in turn represent an enhancement on traditional B^+-Trees[4]. PBT (and MV-PBT) create index partitions based on an artificial, leading key-column – *the partition number*. All index-entires in a partition have the same partition number in the search key. PBT (and MV-PBT) utilize a portion of the database buffer (*partition buffer*) to host the latest partition P_N, where insertions and updates to existing partitions ($P_0 \ldots P_{N-1}$) are placed. Updates to existing index entries are treated as *replacement records* to avoid in-place updates. Once P_N gets full it is appended to persistent storage and becomes immutable.

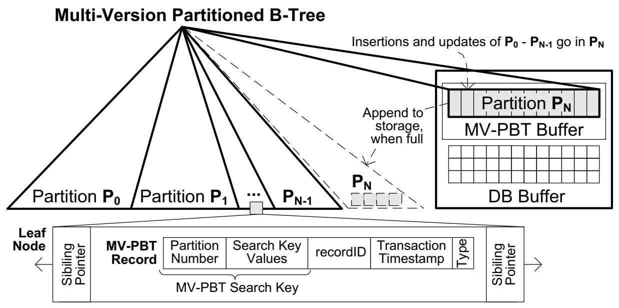

Figure 9: Structure of a Multi-Version Partitioned B-Tree.

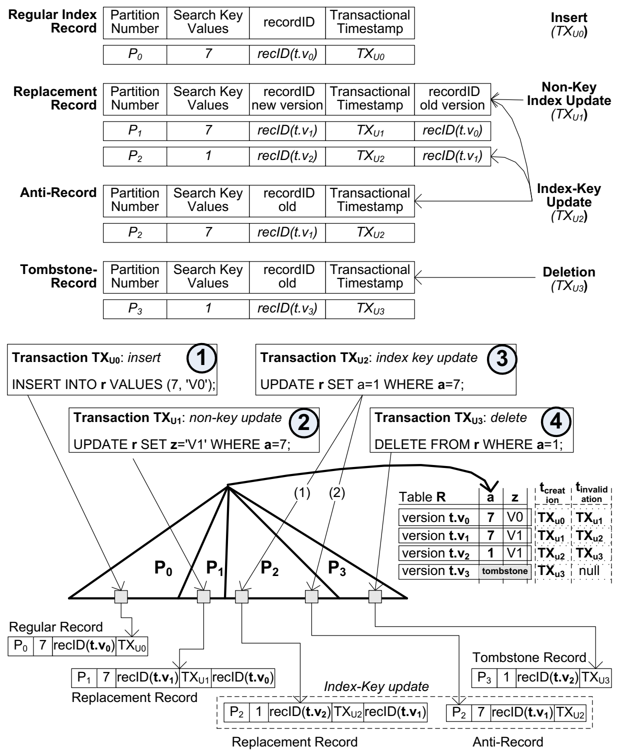
Regular MV-PBT records comprize of a *partition number*, its *search key columns*, and a *recordID (set)*. Furthermore, MV-PBT index records contain version-information: *logical transaction timestamp* for validation or invalidation of the tuple-version and optionally an *unique virtual identifier* (indirection layer). Each partition number identifies a single partition. Partition numbers are unique, monotonically increasing, two-byte integer values. This enables the MV-PBT to maintain partitions within one single tree structure in alphanumeric sort order. The partition number is an artificial column and is therefore transparent to higher database layers. Each MV-PBT maintains partitions independent of other MV-PBTs. Partitions appear and vanish as simple as inserting or deleting records. They can be reorganized and optimized on-line in system-transaction merge steps, depending on the workload. Partitions can support additional functionalities, like bulk loads or can serve as multi-version store[13].

MV-PBTs write any modification of index records exactly once – upon eviction of a partition, except for later reorganization or garbage collection operations. This is realized by forcing sequential writes of all leaf nodes in a partition (Figure 9). Leaf nodes of modifiable main memory partitions are stored in a separate buffer cache – the *MV-PBT Buffer*. This area is shared for all MV-PBT indices in the database. Once the MV-PBT Buffer gets full, a victim MV-PBT is selected and its P_N is written to secondary storage. The MV-PBT Buffer is managed by a special replacement policy, giving active partitions the chance to grow (Section 4.5).

4.1 MV-PBT Record Types

Persistent index partitions are immutable. Direct modification-operations are forbidden. Therefore, modifications to existing index-records as well as insertions are placed in the buffered partition P_N. To handle this behavior MV-PBT introduces new index-record types. Currently the following are defined.



Regular Index Record
Partition Number | Search Key Values | recordID | Transactional Timestamp
P0 | 7 | recID(t.v0) | TXU0
Insert (TXU0)
Replacement Record
Partition Number | Search Key Values | recordID new version | Transactional Timestamp | recordID old version
P1 | 7 | recID(t.v1) | TXU1 | recID(t.v0)
P2 | 1 | recID(t.v2) | TXU2 | recID(t.v1)
Non-Key Index Update (TXU1)
Anti-Record
Partition Number | Search Key Values | recordID old | Transactional Timestamp
P2 | 7 | recID(t.v1) | TXU2
Index-Key Update (TXU2)
Tombstone-Record
Partition Number | Search Key Values | recordID old | Transactional Timestamp
P3 | 1 | recID(t.v3) | TXU3
Deletion (TXU3)
Transaction TXU0: insert
INSERT INTO r VALUES (7, 'V0');
1
Transaction TXU2: index key update
UPDATE r SET a=1 WHERE a=7;
3
Transaction TXU1: non-key update
UPDATE r SET z='V1' WHERE a=7;
2
Transaction TXU3: delete
DELETE FROM r WHERE a=1;

Tombstone Record
P3 | 1 | recID(t.v2) | TXU3

Figure 10: MV-PBT Index-Record Types and Their Use: MV-PBT record format (top), an example including a sequence of transactions and their index records (bottom).

Regular Index Records are created upon the insertion of new tuples. The *partition number* of the newest MV-PBT partition P_N is inserted together with the search key values. The *recordID* (pageID and slot) of the newly inserted tuple-version is included as well as the *transaction timestamp* of the inserting transaction (Figure 10). The latter is essential for index-only visibility-checks. For example, transaction TX_{U0} (Figure 10) inserts a new tuple (t), in its initial version ($t.v_0$), causing the creation of a *regular index record* in partition P_0.

Replacement-Records result from tuple-updates on *non-index key columns* on existing index-entries. Such updates yield a new tuple-version that becomes the new chain entry-point, which needs to be reflected in the index. Although the index-record for the previous version has not changed (non-index-key update) the version-information and recordID of the new version need to be replaced. However, this is not possible, if the index-record is already in an immutable partition ($P_0 \ldots P_{N-1}$). Therefore a *replacement record* is inserted in the newest partition P_N to logically replace the old one with the recordID and the version-information. The *Replacement Record* (Figure 10) contains: the recordID of the new version, its creation-timestamp as well as the recordID of the predecessor version. Hence the record includes some "anti-matter" [13] (recordID) invalidating the predecessors as well as some "matter", i.e. recordID and timestamp if the new version. For example, transaction TX_{U1} (Figure 10) updates the attribute z of the previously inserted tuple (t), producing a new version ($t.v_1$). Although the index-key *7* remains unchanged, the version-information of ($t.v_1$) has to be updated, causing the creation of a *replacement-record* in partition P_1.

Anti-Records are required for updates on index-key attributes and are always used in combination with *replacement records* in the same partition. If the index-key of an existing index-record (in the immutable partitions) gets updated, MV-PBT inserts a combination of an *anti-record* and a *replacement record. Anti-records* are pure "anti-matter" as they mark the extinction of the old index record (from partitions $P_0 \ldots P_{N-1}$), whereas the simultaneously inserted *replacement record* represents the new "matter" and reflects the new index-key and the new version-information. The anti-record and the replacement record are inserted in P_N and are placed according to the sort-order of the search-key value. An anti-record contains the recordID of the old version, together with its search key and the transaction timestamp of the updating transaction (Figure 10). For example, transaction TX_{U2} (Figure 10) updates the indexed attribute *a* of the previously inserted and updated tuple (*t*), producing new version ($t.v_2$), modifying the index-key from *7* to *1*. The *anti-record* (marking the extinction of the replacement-record from partition P_1) reflects the recordID of the predecessor version ($t.v_1$), contains its index-key values (7) and the transaction-timestamp of the current updating-transaction (TX_{U2}). The simultaneously inserted replacement record reflects the new and updated value of the search key (i.e. *1*), the recordIDs of the old and the new tuple-versions ($t.v_1$ *and* $t.v_2$) as well as the transaction-timestamp of TX_{U2}. Since the index records are kept in sort order of the search-key values within a partition (as in a B-Tree), the replacement record is placed first in order, followed by the anti-record.

Tombstone-records indicate the deletion of a tuple. If a tuple is logically deleted, it does not become erased immediately in MV-DBMS, because it could be visible to a concurrent transaction. Rather a tombstone tuple-version record is inserted in the DB, which needs to be reflected in the MV-PBT index. *Tombstone-records* are similar to *Anti Records* in that they represent pure "anti-matter", marking the extinction of the whole tuple-version chain. The difference is that if a tombstone-record is visible to a transaction, no further tuple-version belonging to this chain can be visible, even no *replacement record. Tombstone-records* (Figure 10) contain the recordID of the latest tuple-version and the transaction-timestamp of the deleting transaction.

For example, transaction TX_{U3} (Figure 10) deletes tuple (*t*), creating a tombstone-version ($t.v_3$) in the DB. Therefore a tombstone record is inserted in partition P_3 with the recordID of the deleted tuple-version $t.v_2$, reflecting deletion of the whole version chain $t.v_2 \longrightarrow t.v_1 \longrightarrow t.v_0$.

4.2 MV-PBT Operations

In the following we describe the index operations in an MV-PBT:

- *Insert Operations* are only performed in P_N. An *insertion* yields the creation of an *regular index-record* in P_N with the recordID of the newly created tuple-version and the timestamp of the creating transaction. The insertion traverses the buffered partition P_N and places the new index record according to the alphanumeric sort-order of the search-key (ordering issues are described in Section 4.3). The MV-PBT buffer management strategy (Section 4.5) guarantees sufficient space for the insertion and possible maintenance. In case of an *non-unique index* the insertion is performed directly. Alternatively, given a *unique index*, a lookup operation (see Search and Scan) is performed ahead of the inseartion to guarantee the non-existence of the new index-key.
- *Update Operations* are performed in different ways. If a transaction modifies a tuple-version in a way that a non-index-key attribute is changed (*non-key update*) a new tuple-version is created and its version-information needs to be reflected in the index. In case of *non-key updates* MV-PBT inserts a *replacement-record* in P_N (Figure 10), containing the version-information (recordID and timestamp) of the modifying transaction. By doing so, it logically *replaces* the index-record, which is located in an older partition, and reflects the predecessor version.
  Alternatively, if the modifying transaction updates an index-key attribute (*index-key update*) a *replacement record* as well as an *anti-record* are inserted in P_N (ordering issues are described in Section 4.3). The former reflects the new and modified index-key value in the new tuple-version, the latter indicates the extinction of the old index-record, reflecting the index-key value of the predecessor version. In case of an *unique index*, the MV-PBT first performs a lookup to ensure the non-existence of the new key-value.
- *Delete Operations* cause the insertion of a *tombstone record* in P_N. If a transaction deletes a logical-tuple a tombstone version is created indicating the deletion of the whole version-chain, to transactions to which it is visible. Analogously, MV-PBT inserts a *tombstone record* to indicate the extinction of all index-records corresponding to the version chain. Ordering issues are described in Section 4.3.
- *Search and Scan Operations* process partitions in reverse order from P_N to P_0. Filter techniques such as *Partition Range Keys*, *Minimum Transaction Timestamp* or *Bloom- and Range Filters* (Section 4.7) are needed for selecting the predeceasing partition which may contain an index record, matching the search conditions (Algorithm 1). The search conditions are extended to match the format of an MV-PBT – the partition number is prepended to the first search key column. A regular root-to-leaf traversal operation is performed and the cursor is positioned. Afterwards, the next matching index record is requested and checked for visibility (Section 4.4). This process is repeated until an index record, visible to current transaction is found, and can be returned together with the respective *recordID. Partition number* and *timestamp* are transparent for higher database layers. Index records of most recent tuple versions are found and processed first, due to index-record ordering (Section 4.3), which is very beneficial for simple search conditions, like point lookups.
  Complex scan operations (Algorithm 2) build a set of all matching index records, spreading all MV-PBT partitions. Every partition is pre-selected by filter techniques and processed from P_N to P_0. Traversal operations benefit from commonly buffered higher levels of the tree-structure. Matching index records of any record type in a partition are processed by the index-only visibility-check. Visible index records are added to the result set without *partition number* and *timestamp* in regular sort order. If no further index record matches the scan conditions, the algorithm proceeds with the preceding partition. Finally, the result set is returned. It is filled with all index records (including *recordIDs*), matching the scan and visibility conditions of the calling transaction.
  A single scan process without rechecking for concurrent modifications in P_N is sufficient, due to transaction snapshots as concurrent modifications in P_N are invisible, anyway. Expensive retrieval of version-records from the base-table (*random read I/O*) for *version-information* is avoided. In case of selection of non-index attributes, the recordID indicates the location

of version-record in the base-table, which can be directly accessed.

Algorithm 1 MV-PBT Search

```
1:  function SEARCH(Search conditions $|attr_{val,cond}|, \ldots$)
2:  Output: $IndexRecord$
3:      while HASNEXT( ) do
4:          Let $idx\_record \leftarrow$ NEXT( )  ▷ fetch next index record
5:          if VISCHECK($idx\_record$) equals $VISIBLE$ then
6:              return SET_RETURN_FORMAT($idx\_record$)
                    ▷ hide $partitionnumber$ and $timestamp$
7:      while $part \leftarrow$ PREVIOUSPARTITION($part$) do
8:          if $|attr_{val,cond}| \in part.filter$ then
9:              Let $|skeys_{part}| \leftarrow$
                    FORM_REC($part, |attr_{val,cond}|$)
10:             TRAVERSE($|skeys_{part}|$)
11:             return SEARCH( )
12:     return $\emptyset$
```

Algorithm 2 MV-PBT Scan

```
1:  function SCAN(Scan conditions $|attr_{val,cond}|, \ldots$)
2:  Output: ResultSet of $|IndexRecords|$
3:      $part \leftarrow \emptyset$    ▷ PREVIOUSPARTITION returns $P_N$ for $\emptyset$
4:      while $part \leftarrow$ PREVIOUSPARTITION($part$) do
5:          if $|attr_{val,cond}| \in part.filter$ then
6:              Let $|skeys_{part}| \leftarrow$
                    FORM_REC($part, |attr_{val,cond}|$)
7:              TRAVERSE($|skeys_{part}|$)
8:          while HASNEXT( ) do
9:              Let $idx\_record \leftarrow$ NEXT( )  ▷ neighbor in BTree
10:             if VISCHECK($idx\_record$) equals $VISIBLE$ then
11:                 $|IndexRecords|$.ADD(
                        SET_RETURN_FORMAT($idx\_record$))
12:     return $|IndexRecords|$
```

4.3 MV-PBT Index-Record(Version) Ordering

The version/partition-placement in MV-PBT is governed by modification, search and scan algorithms. *Index-records of predecessor versions are likely to be located in lower-numbered partitions, successors in higher-numbered ones (Figure 10).* This however necessitates multiple memory partitions for an MV-PBT.

To address such issues the current MV-PBT design uses a single main-memory partition P_N for each MV-PBT. *However, for index-records with the same index-key it is mandatory that records for newer/successor versions are always placed before index-records for older/predecessor versions in P_N*. In other words the *primary sort-order* of the index-records in a P_N is on the search-key (mostly descending), however all records with the same search-key are sorted in inverse *secondary sort-order* (mostly ascending) on the transactional timestamp.

Search and scan operations traverse partitions *backwards*: starting from buffered partition P_N (i.e. $P_N \rightarrow P_{N-1} \cdots \rightarrow P_0$). Yet, given the above ordering, index-records of newer tuple-versions, matching the search predicates, are processed *first* in forward direction (i.e. in descending timestamp-order). Only then the next lower-numbered partition is traversed and processed. *This is how MV-PBT ensures that in a search and scan operation, newer versions can always be found before older ones in the same partition, and across partitions.*

Consider for example Figure 11, where we have only two partitions and index-records reflecting updates to the same tuple go to P_1, and contrast to Figure 10, where all index-records with higher-timestamps are placed in higher-numbered partitions. Observe that the index-records in P_1 (Figure 11) appear in their primary-order (on the search key), i.e. records with search-key 1 precede those with 7. Observe also that the *tombstone record* with key 1 precedes the *regular record* as a result of the *secondary sort-order* since $timestamp(TX_{U3}) > timestamp(TX_{U2})$.

4.4 MV-PBT Index-Only Visibility-Check

MV-PBT is *version-aware* and supports *index-only visibility-check*, i.e. it returns a set of index records matching the search condition and *visible* to the calling transaction. In doing so, MV-PBT avoids the expensive retrieval of base-table version-records to extract their *version-information.*

The *index-only visibility-check* (Algorithm 3) is inherently supported by the data structure. MV-PBT index records (Section 4.1) contain version-information and define modifications and recordIDs of tuple-versions. The respective *index-record ordering* is essential to scans (Section 4.3), whereby records indicating the invalidation of a tuple-version are guaranteed to be placed before the *"validating"-records* for a given transactional timestamp.

Index records of any type, matching the search-conditions are processed by the visibility check. They are *invisible* to a transaction, if:

(a) the index record is *flagged for garbage collection*;
(b) the transaction timestamp of the index-record is *greater than* the timestamp of the calling transaction; or
the transaction corresponding to the index-record timestamp is *concurrent* to the calling transaction;
(c) visible record with *anti-matter* for the recordID (anti-matter, replacement- and tombstone-records) was already encountered (in this case also checked for GC); or

(d) the index record is either a *tombstone record* or an *anti-record.* An additional visibility-check by processing the version chain in base table is not required. Skewed updates on tuples do not lower the performance of the index-only visibility check, due to well performing garbage collection and well-cached version-chains in the main-memory partition P_N.

Algorithm 3 MV-PBT Index-Only Visibility-Check

```
1:  function VisibilityCheck( $idx\_record$)
2:  input: $idx\_record$ at current scan position
3:  output: $BOOL\_VISIBLE$
4:      Let $anti\_map \leftarrow Map$ of $(recID|TS)$            ▷ anti-matter
5:      if IS_SET($idx\_record, FLAG\_GC$) then
6:          return $INVISIBLE$
7:      if not precedes($idx\_record.ts, CurrentTxId$) OR
                isConcurrent($idx\_record.ts, CurrentTxId$) then
8:          return $INVISIBLE$
9:      if $ts_{anti} \leftarrow anti\_map$.get($idx\_record.recID_{matter}$)
          and precedes($idx\_record.ts, ts_{anti}$) then
10:         checkForGC($idx\_record$)
11:         return $INVISIBLE$
12:     if IS_SET($idx\_record, FLAG\_ANTI\_MATTER$) then
13:         $anti\_map$.put($idx\_record.recID_{anti}, idx\_record.ts$)
14:     if IS_SET($idx\_record, FLAG\_MATTER$) then
15:         return $VISIBLE$
16:     return $INVISIBLE$
```

4.5 MV-PBT Buffer Management

MV-PBT accumulate modifications to persistent partitions in the latest partition P_N, which is held in the MV-PBT partition buffer (Figure 9). All MV-PBT indices place their respective P_N in the MV-PBT buffer, which rises the question of the proper buffer management strategy. Well-known replacement policies (like LRU or ARC) are not suitable for managing the set of leaf nodes contained in the respective P_N as well as different P_N. The MV-PBT buffer should (a) only evict partitions as a whole instead of individual pages (like in LRU) to achieve sequential write patterns; and (b) give partitions of update intensive indices a fair chance to grow, and balance it across all indices. Remember that MV-PBT read operations place persistent partition nodes in the main/shared DB-Buffer. MV-PBT buffer-management strategy can be summarized as follows. Whenever the buffer-size threshold is reached the MV-PBT buffer manager selects the largest partition of all indices as a *victim* for eviction. Smaller, less update-intensive partitions are frequently evicted to avoid imbalanced number of partitions per MV-PBT and shrinking partition sizes.

The *eviction process* (Algorithm 4) can be summarized as follows. A new partition numbered P_{N+1} (initially P_{N+2}) is created for ongoing modifications. The current victim partition P_N becomes *immutable* and is scanned, as following operations are performed cooperatively and latch-free, piggybacking that *scan.*

(1) Version-chains are built for each of the Scan-ResultSet records, using their timestamps and RecordIDs, and creating a temporary VID for each chain. While doing that, obsolete index-records (parts of the version-chain) are detected and marked for garbage collection.
(2) *Garbage Collection* is performed on the marked records (no longer needed/invisible records are removed) and the result is *written out* to new leaf nodes.
(3) During this process index-records and leaf nodes are transformed to an on-disk format, whereby prefix-truncation, compression and encoding as well as dense-packing (Section 4.7) are performed. Furthermore, the partition number of each index record is decremented from P_N to P_{N-1}. Now P_{N-1} is a separate partition, which is yet unknown in the MV-PBT partition metadata. The process resembles a leaf-build in PostgreSQL: having full leaf pages the intermediary index nodes can be easily built on top. Concurrent, lookups and scans are still performed on the old P_N nodes.
(4) In parallel, well-sized *(prefix-) bloom filters* are created (Section 4.7).
(5) Dense-packing, compression and read-optimizations are performed to higher level intermediary nodes, resembling a bottom-up build. All nodes are *sequentially written out.*
(6) Finally, P_{N-1} is added to the MV-PBT partition metadata. The old P_N leaf nodes, on which concurrent non-blocking reads had been executing, are detached from the MV-PBT and are freed for reuse.

Algorithm 4 MV-PBT Partition Eviction

```
1:  function evict($|P_N|$)
2:  Input: set of $P_N$ in MV-PBT buffer
3:      Let $p_{evict} \leftarrow$SelectEvictionVictim($|P_N|$)
4:      Add $Partition\ p_{evict+1}$ to B$^+$-Tree $PartitionsList$
5:      SET($p_{evict}, FLAG\_IMMUTABLE$)
6:      Let $recordSet \leftarrow$ scanRecords($p_{evict}$)
7:      garbageCollectionP3($recordSet$)
8:      $worker1$.loadAndFlush($p_{evict}.pNo - 1, recordSet$)
9:      $worker2$.createFilters($p_{evict}, recordSet$)
10:     wait( )
11:     Let $p_{evict\_new} \leftarrow$decrementPartitionNumber($p_{evict}$)

4.6 MV-PBT Partition Garbage Collection

Mixed workloads with high update-rates result in massive amount of tuple-versions, which need to be garbage collected once a long-running reading/analytical query completes [14]. Same is true for the corresponding index-records. With high probability these records are located in the main-memory partition P_N of an MV-PBT due to their temporal locality. Therefore, we implemented a cooperative page-level garbage collection (GC) for P_N.

Phase (1): The GC *piggybacks* regular index-scans to identify index-records of versions, that are not visible to any active transaction (*cutoff-transaction*). As a page is already latched (shared), the following checks a performed on each record: (a) comparison with the lowest active transaction timestamp and if lower, mark predecessors as *victim-versions* for GC; (b) if higher, but a successor exists, mark all predecessors as victims for GC. In both cases, a *hasGarbage* flag is set in the page header (no exclusive latch required). This step also *piggybacks* the in-memory structures of the scan and index-only visibility check algorithms. Records with *anti-matter* (anti-matter, replacement and tombstone records) require special attention, as they are still required for invalidation of predecessors. Hence the *anti-matter* record with the highest timestamp smaller than *cutoff* transaction timestamp must not be garbage collected. Index-record ordering (Section 4.3) supports GC while scanning, since successors are mostly processed first.

Phase (2): Update operations check the *hasGarbage* flag in page header. If set they first set the *recordID* of the oldest required

record with *anti-matter* (anti-matter, replacement and tombstone records) to the recordID of the oldest victim-version of that chain on the page. Next, GC victims are removed on that page, the space is reclaimed and only then the update operation proceeds. This behavior saves memory, speeds up scans and visibility checks as well as reduces index maintenance operations (split).
Phase (3): To handle version-chains spanning several pages, and for final cleanup before partition eviction the whole partition is scanned and the version chains (based on timestamps and records) are built in memory. This scan is also piggybacked for filter creation and dense-packing (Section 4.7). Before switching to sibling page, obsolete versions are removed after updating invalidation reference and in-memory version chain is updated.

4.7 MV-PBT Filters and Optimizations

Various optimizations can be performed, based on the fact that once written to storage MV-PBT partitions are *immutable*.

Bloom Filters. Each MV-PBT partition has a bloom filter (*BF*) on the search key. Using bloom filters accelerates key lookups (point-queries) in a partition, by avoiding unnecessary scans. Whenever a key lookup is performed, a BF-query executed first, to verify whether the key does *not* exist in the partition. If it does not exist MV-PBT proceeds with the next partition. Alternatively, if the BF returns true (i.e. the key may exist), MV-PBT scans the whole partition.

Our experimental evaluation (Figure 13) indicates that the average BF size is small – in the order of few hundred KB. Therefore frequently used filters are usually cached in the MV-PBT buffer. Furthermore, their precision is *98%* on average, thus false positives and therefore superfluous scans are rare. BF is is computed efficiently on eviction, piggybacking existing maintenance scan and is persisted as part of the partition metadata.

Range Filters. Partition bloom filters accelerate point lookups, but cannot handle range predicates. Currently, we employ *prefix Bloom Filters (pBF)*, if appropriate, to speedup range scans.

Dense-packed, Read-Optimized immutable storage. Since a partition is immutable once persisted, various space and read-optimization techniques can be applied. *Dense-packing* is used to perform coalescing and free-space optimzation. When in-memory leaf nodes are on average 67% full to accumulate modifications and avoid splitting, however when persisted the the space utilization can be maximized. MV-PBT performs *dense-packing* as part of the final garbage collection and space reclamation.

Especially for *non-unique indices* MV-PBT performs *reconceliation* upon eviction to convert all regular records with the same search key to a single regular record with a set of {recordID, timestamp}, instead of holding separate record for each key instance. The same is true for replacement records, where for the same search key sets of $\{recordID_{NEW}, Timestamp_{NEW}, recordID_{OLD}\}$ are created. Last but not least, compression techniques such as *prefix-truncation* or *delta-compression* are performed on the search key. Along the same lines, various read and cache-aware optimizations can be performed.

5 EXPERIMENTAL EVALUATION

We present the analysis of Partitioned B-Trees (PBT) and MV-PBT together with traditional B^+-Trees (which serve as *baseline*) in PostgreSQL 9.04. Standard, PostgreSQL uses an *old-to-new* version ordering, *physically materialized version storage* and *two-point invalidation.* Index records have a physical reference to base tables – denoted as B-Tree (PG/HOT). PostgreSQL base table storage was also modified to Snapshot Isolation Append Storage (SIAS) [9, 11] with a beneficial append-only write pattern, one-point invalidation and new-to-old version ordering. We implemented and evaluated B^+-Trees and PBT with physical references and with logical tuple references on top of SIAS [9, 11].

Experimental Setup. We deployed PostgreSQL 9.04 and PostgreSQL with SIAS [11] on an *Ubuntu 16.04.4 LTS* server with an eight core *Intel(R) Xeon(R) E5-1620* CPU, 2GB RAM and an *Intel DC P3600 400GB SSD* drive. We used the well-known DBT-2[1] TPC-C-like OLTP benchmark and mixed workload CH-Benchmark [6] in OLTP-Bench [2, 8] for experimental evaluation. The OS page cache is cleaned every second to ensure repeatable and reliable results (even though conservative).

Mixed Workloads: CH-Benchmark. MV-PBT is designed for large datasets and mixed workloads. We evaluate the throughput of B^+-Trees, PBT and MV-PBT under the CH-Benchmark [6] in OLTP-Bench [2, 8]. MV-PBT *doubles* the analytical throughput compared to B^+-Trees (Figure 12a), improving it from 0.29 to 0.61 queries/transactions per minute. In the same time, MV-PBT yield *15%* higher transactional throughput than B^+-Trees (Figure 12a).

The performance improvements are mainly due to *index-only visibility-check* and *partition garbage collection.* To illustrate the combined effect we turn off both and repeat the experiment. Consider now the lower MV-PBT performance bars in Figure 12a. Without *partition garbage collection* and *index-only visibility-check* the OLAP performance drops by 75% from 0.61 to 0.16 queries per minute, whereas the OLTP throughput plummets from 4232 from to 3093 tx/min.

Mixed Workloads: Index-Only Visibility-Check and Garbage Collection. In a further experiment we investigate MV-PBT GC and visibility-check in more detail varying the version-chain length. We run the OLTP part of the CH-Benchmark and execute a query on the same dataset (Figure 12b), however we pause it (using *pg_sleep*) for 30/60/90/120 seconds to simulate a long-running query and vary the amount of transient versions and the chain length. Clearly, as the version-chain length increases, index-only visibility-checks gain importance, because unnecessary read I/O on base table can be reduced.

We compare PBT and standard *visibility-check in base table (VC)* to MV-PBT and *index-only visibility-check (idxVC)* (Figure 12b). As the query processing time and version-chain length increase, index scans and *VC* of slow down PBT by an order of magnitude. Even if the version-chain length has no linear growth, pages in base table get evicted and need to be fetched more frequently. MV-PBT performs *idxVC* however without garbage collection (Figure 12b *MV-PBT w/o GC*), every index record of successor tuple-versions has to be processed, likewise the scan time increases proportionally with the length of the version-chain. With garbage collection (Figure 12b *MV-PBT w/ GC*), the number of scanned index records and the scan time remain almost constant. However, GC requires additional processing and latches index nodes in P_N. Reading transactions have to wait for latches and scan time increases - consider Figure 12b at 30 seconds sleep time. As more index record get garbage collected, GC improves the index scan time - compare MV-PBT with and without GC at 30 and 120 second (Figure 12b).

Sequential write-pattern/Append-based storage. Based on the tradeoffs derived in Section 3.7. MV-PBT needs to support write sequentialization and append based storage. In this experiment we evaluate the write pattern of MV-PBT (Figure 12c). Using *blktrace* and *blkparse* we record an I/O trace during the partition eviction from MV-PBT buffer. The X-axis represents the

(d) Requests / Cache Hit Rate for PostgreSQL Heap-Only Tuples (HOT), Logical(LR) and Physical(PR) references

Figure 12: Index Performance under Mixed Workloads (CH-Benchmark)

eviction time; the average write I/O time is about 1ms. The Y-axis represents the logical block addresses (LBA), i.e. the file system addresses where the blocks of the index file are written. Each red cross indicates the write of a single index node. A horizontal line, therefore indicates a *sequential write*, i.e multiple blocks are written onto neighbouring addresses over time. *Hence the sequential write pattern of MV-PBT.* The horizontal lines in Figure 12c represent *database extents* and result from the database *space allocation strategy*. Each evicted partition comprises leaf nodes allocated in new extents of the index file, allocated at (mostly) adjacent addresses by the file system. The overall *sequential pattern* confirms the sequential append behaviour of MV-PBT.

MV-PBT Buffer Efficiency. Figure 12d shows the fetch requests on index nodes (blue) and base table nodes (red) for an OLTP benchmark. Furthermore, the cache hit-rate is depicted. Requests yielding a cache-hit are displayed in brighter colours than fetches (cache-misses) from secondary storage. The scale of requests is logarithmic. The results are calculated for equal throughput over the test duration and all tables and indices.

PBT and MV-PBT require more requests on index nodes due to partitioning of index records and greater record sizes. Most requests are on buffered nodes, because many queries can be answered in the main memory partition. Index records of new tuple-versions are common to be located there. MV-PBT reduces the requests on base table by up to 40%, because the base table is not required for visibility-check. The version chains are short for this benchmark, for mixed workloads this effect is more weighty. This can be seen at the reduced cache hit rate on base table nodes in comparison to PBT. Most saved requests on base tables are on new tuple-versions, which are located in main memory.

Partition Filters. Partition-based indices like MV-PBT, PBT or LSM-Trees incur higher lookup and scan overhead than B-Trees, since matching records may exist in older partitions. Hence, the effort of lookups and especially of scans increases with number of index-partitions, since in the worst case every partition has to be traversed. Point lookups can stop partition traversal after finding the first matching record, which is visible to a transaction, since older partitions are guaranteed to contain older records.

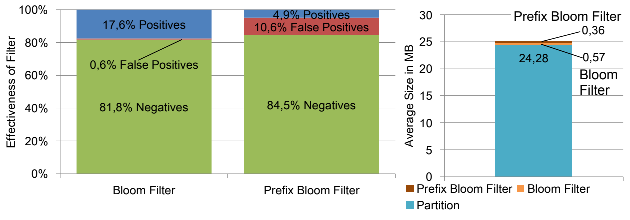

Figure 13: Effectiveness and Size of Partition Filters

Using *Bloom filters (BF)* (Section 4.7) point lookups can skip partitions and increase throughput up to 10% under TPC-C (Figure 14c). Furthermore, *prefix Bloom filters (pBF)* may under certain conditions speedup scans by skipping partitions not matching the range predicate. *pBF* including a fixed set of scan attributes,

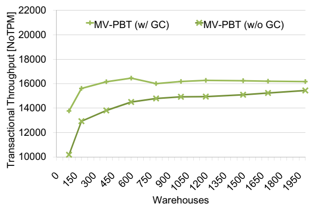
(c) **Influence of filter techniques on Throughput under TPC-C**



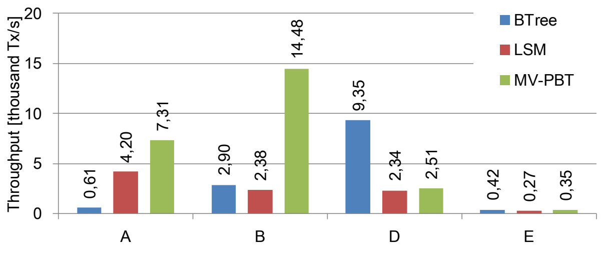
(d) **MV-PBT Garbage Collection under TPC-C**

Figure 14: OLTP Performance Evaluation under TPC-C

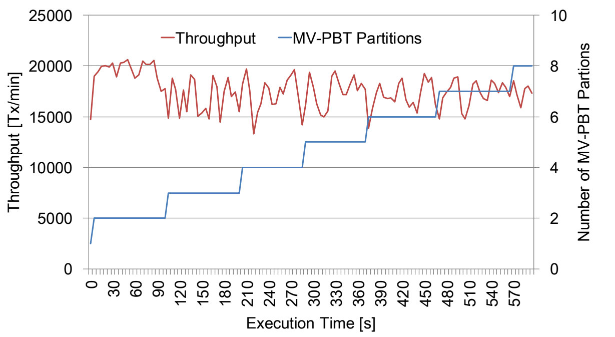
increase the throughput by another 10% (Figure 14c). The precision of both Bloom filters is relatively high (Figure 13): the false positives rate is 2% for *BF* and 10% for *pBF*, while the negatives (skipping) rate is approx. 82% for *BF* and 84.5% for *pBF*. The size *BF* and *pBF* is small relative to the partition size (Figure 14c): for a 24MB partition *BF* is 0.57MB, while *pBF* is 0.36MB.

Since index operations only have a fair share of the whole database operations under TPC-C (besides logging, CC and I/O) the above numbers yield moderate performance improvements.

Comparison to LSM-Trees. LSM-Trees [17] are used as workhorse storage structure in many Key/Value stores for large datasets. Today's highly-optimized multi-level LSM-Trees with levelling or tiering resemble MV-PBT as they exhibit an append-behaviour and employ buffered components. We implemented MV-PBT in WiredTiger [3], the high-performance KV-Store of MongoDB. In this experiment we compare MV-PBT to LSM-Tree in WiredTiger under YCSB [7] (Figure 15a). YCSB has been instrumented as follows: a dataset of 100 million keys (approx. 100GB); workloads A (30 mil. requests), B and D(10 mil. req.) and E (2 mil. req).



(a) **MV-PBT, BTree, LSM-Tree under YCSB.**



(b) **YCSB Throughput (workload A) vs. Number of MV-PBT Partitions**

Figure 15: Performance Evaluation under YCSB [7]

Workload *A* comprises 50% read and 50% update requests, which require fast lookups and updates. MV-PBT is approx. 42% faster than LSM-Trees. Each LSM level comprises multiple components, which themselves are small read-optimised BTrees. A search needs to process separate LSM components even though some can be skipped (bloom filters). MV-PBT partition search is faster than LSM component search, since the leaf nodes in each partition are under the same common index. Updates in MV-PBT hit P_N, which accommodates more KV-pairs than the main memory L_0 in LSM-Trees. Workload *B* comprises 95% read and 5% update requests, with *zipfian* distribution. BTree performs random reads, the LSM Tree caches the updates, but has an equal amount of random reads spread over more components. MV-PBT have much lower index maintenance compared to BTrees and place the updates in P_N. The reads are performed with maximum I/O parallelism. Workload *D* comprising 95% read and 5% update requests, which given the *latest* distribution stress the memory components and BTrees performs most of the operations in memory. MV-PBT is marginally better than LSM-Tree. Last but not least, we run workload *E* comprising 95% scans and 5% insert requests. Even though the *scans* are slow under MV-PBT, they outperform LSM-Trees due to the faster search and updates.

Consider, Figure 15b depicting the YCSB throughput (workload A) and the number of MV-PBT partitions over time. The throughput remains stable as the number of partitions increases.

OLTP: comparison of B-Tree alternatives. To establish the baseline we first compare standard PostgreSQL B-Trees (PG/HOT) to B$^+$-Trees with physical reference and indirection layer on top of append-only storage (SIAS [9, 11]) under TPC-C. In Figure 14a, we show the throughput for different dataset sizes. The buffer cache of the DBMS is fixed to 600MB. B-Tree(PG/HOT) performs well (Figure 14a) as long as the database buffer can accommodate most modifications. Under standard Postgres updates are performed in base tables by Heap-Only Tuples (HOT), i.e. the predecessor version is cached on the same page, on which its successor is located. Therefore the index maintenance effort is low. With growing data sizes (and therefore more modifications), the throughput falls rapidly. Append-based storage and one-point invalidation (SIAS [9, 11]) exhibit a *robust* throughput: (a) *physical references* (Section 3.5) yield lower performance, due to the higher index management overhead; (b) an *indirection layer* reduces index maintenance for insertions and index-key updates, yielding up to 30% better throughput. *With larger datasets (≥ 1200 warehouses) B-Trees with indirection outperform standard PostgreSQL PG/HOT.*

Indexing Approaches under OLTP. In a follow-up experiment, we compare B-Tree with indirection layer (Section 3.5), to

PBT and *MV-PBT* under TPC-C (Figure 14b). PBT and MV-PBT exhibit robust performance, which improves with larger datasets compared to B-Tree. PBT with *indirection layer* exhibits high and robust performance (Figure 14b). PBT with *physical reference* to close the performance gap for larger datasets as the update density decreases decreases with larger datasets. *MV-PBT are slower than PBT under OLTP workloads for several reasons.* First, less MV-PBT index records fit on the same sized P_N, since their sizes are larger because of the version-information (transaction timestamps). Consequently, the number of partitions increases, yielding more I/O. Second, the average version-chain length under TPC-C is short: 1.15/2.18 versions for *customer*/*stock* respectively [9]. Therefore, index-only visibility-checks cannot improve performance significantly. Thus, MV-PBT exhibit 6% lower performance than PBT under TPC-C (Figure 14b). We implemented MV-PBT with an *indirection layer* as well as with *physical references* (Section 3.5). Figure 14b depicts on the performance with *physical references* for brevity, both curves are almost identical. *Therefore, MV-PBT are general enough to be implemented matching the rest of the system design.*

OLTP Garbage Collection. In this experiment (Figure 14d) we quantify the performance effect of MV-PBT partition garbage collection (Section 4.6). It improves performance between 5% and 17% since old invisible versions are purged and need not be processed by scans as well as space is reclaimed letting more index records fit in P_N. The opportunity of improvement under OLTP is however limited by the short average version-chain length: 1.15 versions for *customer* and 2.18 versions for *stock* under TPC-C [9]. With HTAP workloads the amount of 'transient' (short-lived versions visible only throughout the duration of an analytical query) versions increases rapidly as does the effect of garbage collection. Garbage collecting larger amounts transient versions has a major role on the performace improvment of MV-PBT over PBT and B-Tree under mixed workloads (Figure 12a).

6 RELATED WORK

Most popular indexing approaches in database management systems are based on B^+-Trees. Their alphanumeric sorted structure can result in high write amplification for high update rates and visibility-checks require information, that is only located at tuple-versions in base table. PostgreSQL uses Heap-Only Tuples (HOT) to reduce index management operations. Index records reference items in base table, which point to tuple-versions in the heap node. Corresponding tuple-versions are held on the same node and can be located by processing the version chain. If a tuple-version become garbage collected, the item is modified to reference the next version. This indirection layer reduces index modifications, but cannot avoid write amplification of index nodes and requires the base table for visibility-checking. Furthermore the write amplification of base table nodes is increased for large datasets. MV-IDX[10] maintains a virtual identifier for each tuple and data nodes for each version as an indirection layer. With Snapshot Isolation Append Storage (SIAS)[11] write amplification on base tables is reduced in comparison to HOT, but index management operations can cause a high write amplification and base table nodes are still required for visibility-checking[21]. LSM-Trees[18] reduce write amplification due to collecting modifications in main memory components, but there is no concept for managing tuple-versions and perform an index-only visibility-check[21]. Time-Split B-Trees [16] and Multiversion B-Trees [5] are able to separate index records of old tuple-versions from current dataset and to perform an index-only visibility-check, but maintenance operations are complex and can cause a high write amplification of index nodes[21].

7 CONCLUSION

In the present paper we introduce MV-PBT as an approach to multi-version indexing. An MV-PBT is an extension of a B-Tree, where an artificial leading column is prepended to the search key of each index record and index records are placed in a buffered index partition, which if full gets evicted and appended to persistent storage. MV-PBT is version-aware, since index records contain version-information and allow for index-only visibility check. This is particularly beneficial for HTAP workloads since long chains of transient versions exist due to the mix of short-lived updating transactions and long-running queries. Furthermore, MV-PBT exhibit a sequential write pattern due to the concept of partition, which leads to less write-amplification and better utilization of modern storage technologies. Under mixed workloads (CH-Benchmark) MV-PBT doubles the analytical throughput 2x, while improving the transactional throughput by 15%.

Lineage-Preserving Anonymization of the Provenance of Collection-Based Workflows

Khalid Belhajjame
PSL, Université Paris-Dauphine, LAMSADE
Paris, France
khalid.belhajjame@dauphine.fr

ABSTRACT

We examine in this paper the problem of anonymizing the provenance of collection-oriented workflows, in which the constituent modules use and generate sets of data records. Despite their popularity, this kind of workflows has been overlooked in the literature w.r.t privacy. We, therefore, set out in this paper to examine the following questions: *How the provenance of a collection-based module can be anonymized? Can lineage information be preserved? Beyond a single module, how can the provenance of a whole workflow be anonymized?* As well as addressing the above questions, we report on evaluation exercises that assess the effectiveness and efficiency of our solution. In particular, we tease apart the parameters that impact the quality of the obtained anonymized provenance information.

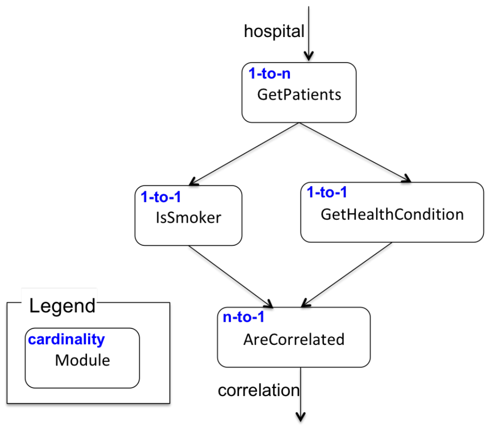

Fig. 1: Example workflow.

1 INTRODUCTION

Automated workflows have been shown to facilitate and accelerate scientific data exploration and analysis in many areas of sciences [11]. Figure 1 illustrates a simple workflow that is used to establish correlations between smoking and health conditions. Workflow provenance information, recorded during workflow executions, facilitates the interpretation of the results delivered by workflow execution. Beyond verification, workflow provenance information represents a useful dataset on its own right, that can be leveraged to answer queries that are relevant for an experiment that is (possibly related but) different from the original experiment, to learn new hypotheses, or to gain insight on the characteristics and quality of the data generated by given modules. Collected workflow provenance information can also be used to respond to the requirements of funding agencies that are increasingly requesting the publication of the data generated in the context of research investigations.

In fields such as biomedicine and social sciences, workflow executions manipulate and generate sensitive information about individuals. To promote the publication and sharing of the provenance of workflow executions, we set out in this paper to examine the problem of anonymizing workflow provenance.

1.1 Related Work

Related work has focused on the problem of securing workflow provenance and policing their access. For example, Chebotko *et al* [9] and Biton *et al* [7] proposed solutions that derive a partial view on a workflow provenance by hiding the data records of given modules Our objective is different from the above line of work in that we seek to provide the user with the provenance of all the modules of the workflow by leveraging anonymization.

Davidson *et al.* [12] investigated the problem of module privacy, whereby some of the parameters (attributes) characterizing the inputs and outputs of the modules are hidden to guarantee the privacy of modules. In our work, we seek, instead, to guarantee the privacy of the data records used and generated by the modules, instead of the behavior of the module.

We have examined in a previous work, the problem of identification of the k-anonymity degree that needs to be enforced when anonymizing the datasets used and generated by workflows [6]. In doing, we assumed that the modules that compose the workflow are 1-to-1 in that they produce a single data record, given a single data record, and we did not give much thought to the problem of lineage preservation. In this paper, we are interested in what we refer to as collection-based workflows [16–18, 27]. The modules that compose such workflows can take as input a collection of data records and deliver a collection of data records. Such workflows have been advocated as a way to better meet the needs of non-expert users to model scientific data [20], and to structure complex relationships among related pieces of information that are processed together by the workflow [22]. This class of workflows has been overlooked in the literature w.r.t. privacy.

Different techniques have been proposed in the literature for protecting the privacy of individuals, notably, k-anonymity [26] and differential privacy [15]. In particular, differential privacy [15] has recently gained momentum as the method of choice in statistical databases. It involves adding random noise to the data so that the distribution of the resulting dataset is almost invariant to the inclusion of any data record. While powerful, differential privacy is not suitable for our purposes. It assumes that the user knows up-front the queries s/he wants to issue prior to the anonymization. This is not the case in our setting, where the scientist issues exploratory queries for understanding and eventually interpreting the results of the workflows. Furthermore, for it to be useful, the scientist should be able to inspect individual data records and their relationships (lineage), both of which are not possible using differential privacy. Indeed, differential privacy is more suited for statistical (i.e., aggregation-based) queries.

For our work, we chose to use k-anonymity [26]. This method is not as powerful as differential privacy when it comes to privacy guarantees. Yet, it is better suited for our purposes since it can be instrumented, as we will show, to allow users to query and examine individual data records and their lineage within workflow provenance. k-anonymity is also still perceived by practitioners as sufficient for mitigating risk while maximizing utility, and real-world applications still utilize it for data sanitization (see e.g., [3, 10]). It is also widely popular and is used, e.g., in the healthcare world [1, 25], and is still recommended by data protection agencies (see e.g., [2]). This technique has been extensively investigated in the database and data mining communities [28]. Most of the proposals have focused on anonymizing a single relational table. In workflow provenance, however, we need to anonymize different datasets considering and preserving lineage relationships between them. One solution that can be used to anonymize workflow using k-anonymity would be to create a global relational table that is obtained by joining relations representing the input and output data records of the modules that compose the workflows. However, this solution suffers from the following issues. First, information about the same individual can be found in different records. This is because we consider collection based modules, e.g., a patient can be associated with multiple practitioners. Second, the same tuple in the global table may contain information about multiple individuals, e.g., a patient, one of its practitioners, etc. Moreover, as we will see later, different kinds of individuals may be associated with different k-anonymity degrees. For example, the k-anonymity degree associated with patients may be higher than that associated with practitioners. Traditional k-anonymity is not equipped to deal with the above issues. In this respect, the proposal by Nergiz *et al.* [24] is related to ours. They elaborated a technique that anonymizes multiple relations of a given database schema. While useful, this proposal makes a number of limiting assumptions. In particular, they consider snowflake schemas, in which there is a single relational table that represents individuals with the remaining relations containing quasi-attributes and having a single foreign key. In our work, we drop these assumptions and show that the anonymization of workflow provenance can be achieved in the presence of multiple datasets representing individuals with multiple relationships (foreign keys constraints) between them.

1.2 Contributions

Our first contribution is the formulation of the problem of k-anonymization of the provenance of collection-based workflows. This is, to our knowledge, the first paper that extends the notion of k-anonymization from a single relation to the provenance of workflows. Our second contribution is a technique for k-anonymizing the provenance of a single module, i.e., input and output records together with their lineage information. Indeed, lineage information tracing the dependencies between the output and input of a module (and more generally a workflow) is key for third-party scientists to understand and examine the validity of workflow results. We examine this problem for modules that use and generate collections of data records. Our third contribution extends the technique proposed to cater for the anonymization of the provenance of a workflow as a whole. Central to the solution we present is the notion of k-group anonymity, which we define based on the k-anonymity degree and the magnitude of the smallest input (or output) set of data records used and generated by a module. This concept allows us to gracefully reason over the different k-anonymity degrees that may be associated with the inputs and outputs of the workflow's modules. We also show how the NP-hard problem of identifying the sets of data records to be grouped together into equivalence classes that meet k-anonymity requirements can be cast as a scheduling problem that we solve using integer programming.

The paper is organized as follows. We start by laying the foundations of our work and stating the problem in Section 2. We then focus on the problem of anonymizing the provenance of a module in Section 3, and the provenance workflow in Section 4. In Section 5, we address an issue that is inherent to our anonymization technique, namely grouping sets of data records, and cast it as a scheduling problem. We report on evaluation exercises that we empirically conducted to assess the effectiveness and efficiency of our solution in Section 6, and conclude the paper in Section 7.

2 FOUNDATIONS

2.1 Collection-Based Module and Workflow

Definition 2.1 (module). A module $\mathtt{m}$ is defined by the tuple $(\mathtt{I_m}, \mathtt{O_m}, \mathtt{card})$, where $\mathtt{I_m}$ (resp. $\mathtt{O_m}$) is a set of ordered input (resp. output) ports, and $\mathtt{card}$ specifies the cardinality of $\mathtt{m}$. A port $\mathtt{p} = \langle \mathtt{a_1}, \ldots, \mathtt{a_n} \rangle$ is a list of attributes, each characterized with a basic type, e.g., String, Integer.

Assigning a data value to each attribute in a port gives rise to a data item, and assigning a data item to each input (output) port of a module gives rise to a data record.

$\mathtt{card} \in$ {1-to-1,1-to-n,n-to-1,n-to-n}: 1-to-1 specifies that the invocation of $\mathtt{m}$ takes as input a single data record and produces a single data record; n-to-1 (resp. 1-to-n) specifies that the invocation of $\mathtt{m}$ takes as input a list (ordered set) of data records (resp. single data record) and produces a single data record (resp. a list of data records); n-to-n specifies that the invocation of the module takes as input a list of data records and produces a list of data records.

Definition 2.2 (data link). A data link $\mathtt{dl}$ is defined by the pair $\mathtt{dl} = (\mathtt{m_i} : \mathtt{o_{m_i}}, \mathtt{m_j} : \mathtt{i_{m_j}})$, where $\mathtt{m_i} : \mathtt{o_{m_i}}$ designates an output port $\mathtt{o_{m_i}}$ of the module $\mathtt{m_i}$, and $\mathtt{m_j} : \mathtt{i_{m_j}}$ designates an input port $\mathtt{i_{m_j}}$ of the module $\mathtt{m_j}$.

Definition 2.3 (workflow). A workflow specification is defined by a pair $\mathtt{w} = (\mathtt{M}, \mathtt{E})$, where $\mathtt{M}$ is a set of modules and $\mathtt{E}$ is a set of data links. $\mathtt{w}$ has one initial module with no incoming data links, and one final module with no outgoing data links.

We consider acyclic workflows that have a single initial module and a single final module, and where each module in the workflow, other than the initial module, is reachable from the initial module. Workflow execution follows a pure dataflow model: a module $\mathtt{m}$ is invoked (is fireable) as soon as all of its input ports are bound to data items. During the workflow execution, data items are transferred between connected output and input ports. For example, the following data link binding $((\mathtt{m_1} : \mathtt{o_{m_1}}, \mathtt{m_2} : \mathtt{i_{m_2}}), \mathtt{di})$ specifies that the data item $\mathtt{di}$ was transferred using the data link connecting the output port $\mathtt{o_{m_1}}$ of $\mathtt{m_1}$ to the input port $\mathtt{i_{m_2}}$ of $\mathtt{m_2}$. The technical report [5] provides more information about the workflow execution model. It specifies how input data records of a module are constructed using the data records of the preceding modules in the workflow. It also specifies how mismatches in cardinalities between connected modules' outputs and inputs are resolved at execution time.

2.2 Workflow Provenance as Relations

Definition 2.4. Given a workflow w, its provenance, denoted by prov(w), is the collection of modules and data link bindings that take place as a result of the executions of w.

For ease of exposition of our anonymization solution, we encode the provenance of a module m using two relational tables denoted by prov(m, w).in and prov(m, w).out. They contain the data records that were used and generated, respectively, by the invocations of m within the executions of a workflow w. we call prov(m, w).in (resp. prov(m, w).out) the input (resp. output) provenance of m. When the referred workflow w is clear from the context, we abuse the notation and simply use prov(m).in and prov(m).out to refer to such relations. The schema of such relations contains the attributes of the input ports (resp. output ports) of m. We assume that the attribute names are unique within the input (resp. output) ports of a module. From a provenance point of view, we do not keep information about the order of the data records in an input or output list, which is, therefore, viewed as a set. This is the case, for example, in the Taverna workflow system [30]. Because of this, we use in what follows the terms input/output set of data records, as opposed to list of data records. W.l.o.g, we assume that the attributes of two succeeding modules that have the same name are connected (via their ports) by data links. In other words, we can deduce data link bindings from module bindings, which allows us to write: $\text{prov(w)} = \bigcup_{\text{m} \in \text{w.M}} (\text{prov(m).in} \cup \text{prov(m).out})$

Consider a module admittedTo that given a set of patients returns a set of hospitals that those patients were admitted to[1]. Table 1 illustrates an example of two relations representing input provenance and output provenance of the admittedTo module. The names of identifying attributes are written in bold, and the names of quasi-identifying attributes are underlined. Notice that the relations contain also two additional attributes: ID and Lin. The first is an ID that is generated internally by the workflow system to identify data records, and the second is used to encode lineage information. In the case of the input provenance, Lin specifies the data records produced by the preceding modules in the workflow and that were used in the construction of the data record in question. For example, the data record p_1 was constructed using two data records r_1 and r_2 that were produced by some preceding modules. The Lin column is empty for the relational table used to store the data records used as input to the initial module in the workflow. Regarding the output provenance of admittedTo, the Lin column identifies the data records that were used as input to obtain the output data record in question. For example, it specifies that h_1 and h_2 were generated given the inputs p_1 and p_3. The lineage information we consider here is in line with the *why provenance* semantics (see [8]).

2.3 Problem Statement

Adversary Model. The data records used and generated by a workflow module are characterized by three kinds of attributes: (i) Identifying attributes allow identifying individuals, e.g., the attribute name is an identifying attribute. (ii) Sensitive attributes are attributes that carry sensitive information, e.g., health condition. (iii) Quasi-identifying attributes are non-identifying attributes, but their combination can be used to identify an individual, e.g., address, phone number, etc. Notice that the ID attribute is not considered as an identifying attribute because it is generated by the workflow system and does not carry information that allows identifying individuals such as name for example.

We assume that an adversary may know identifying and quasi-identifying attribute values about individuals, e.g., name, address, date of birth. However, we assume that s/he does not know sensitive attribute values, e.g., health-condition, income tax.

In relational databases, a relation r is k-anonymized, where k is an integer greater than 2, if any data record d in r is not distinguishable from (at least) $k - 1$ other records in r. This condition is met by masking the values of identifying attributes, and generalizing the values of quasi-identifying attributes (e.g., address, visited hospital, etc.). Sensitive attributes, such as health condition, salary, are not masked: adversaries are assumed not to be knowledgeable of the values of sensitive attributes. In what follows, we use the term identifier record to refer to a data record that has an identifying attribute value, and the term quasi-identifier record to refer to a data record that has no identifying attribute value but has a quasi-identifying attributes value. A module input (resp. output) that is bound to identifier records following module invocation is called identifier input (resp. output). It is called quasi-identifier input (resp. output) if it is bound to quasi-identifier records.

Anonymity degree of Identifier Inputs and Outputs. We assume that every identifier input (resp. identifier output) of a module m is associated with an anonymity degree, which we denote by k^i_m (resp. k^o_m) to be enforced. Note that non-identifier module inputs and output are not associated with an anonymity degree because they are not bound at execution time to records that represent individuals. We do not make the assumption that the anonymity degrees associated with the identifier inputs and outputs of the modules that compose the workflow are the same. This is because the modules that compose a workflow are likely to use different underlying data sources that are supplied by different providers who may impose different requirements when it comes to the anonymity degree to be enforced on their data. Moreover, the same data provider may impose different anonymity degrees depending on the data that is retrieved from its source. For example, an input that provides information about patients and their health condition is likely to be associated with an anonymity degree that is higher than an output that informs on the trips of practitioners. In this paper, we apply k-anonymization to the provenance prov(w) of a workflow prov(w) by creating equivalence classes for the relations prov(m).in and prov(m).out for each identifier input and output of the modules in w.M.

Definition 2.5 (Equivalence Classes). Consider the input provenance prov(m).in of a module m. We say that the set $\{E1^m_{in}, \ldots, E1^m_{in}\}$, $n \geq 1$, is a set of input equivalence classes for m and write $\text{prov}^a(\text{m}).\text{in} = \{E1^m_{in}, \ldots, E1^m_{in}\}$ iff:

1)- The set $\{E1^m_{in}, \ldots, E1^m_{in}\}$ forms a partitioning for prov(m).in. That is $\text{prov(m).in} = \bigcup_{i \in [1,n]} Ei^m_{in}$, and $Ei^m_{in} \cap Ej^m_{in} = \emptyset$ for $i, j \in [1, n]$ s.t. $i \neq j$.

2)- The identifying attribute values of the data records in every equivalence class Ei^m_{in} are masked, and their quasi-identifying attribute values are generalized such that the data records in an

[1]A hospital appears in the result only if it was visited by each of the patients in the input set.

equivalence class $\texttt{Ei}^{\texttt{m}}_{\texttt{in}}$ are indistinguishable w.r.t. their quasi-identifying attribute values.

A set of output equivalence classes are defined in a similar manner: $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{out} = \{\texttt{E1}^{\texttt{m}}_{\texttt{out}}, \ldots, \texttt{E1}^{\texttt{m}}_{\texttt{out}}\}$.

Note that the `ID` and `Lin` attribute values of the data records are not generalized. This is because the values of the `ID` attribute are generated internally by the workflow system. In other words, they are not meaningful for human users. More importantly, they are used within the `Lin` attribute to encode lineage information that we seek to preserve.

Lineage information needs to be considered when k-anonymizing the input provenance (resp. output provenance) of an identifier module input (resp. output). To illustrate this, let us consider the `admittedTo` module. It has an identifier input and a quasi-identifier output. Consider that the anonymity degree associated with its input is $\texttt{k}^{\texttt{admittedTo}}_{\texttt{i}} = 2$. Notice that its output is not associated with an anonymity degree because it is not an identifier output. Table 2 illustrates the input and output provenance of `admittedTo`, where the input provenance is 2-anonymized. The anonymization consisted in partitioning the set of input data records into input equivalence classes of size ≥ 2. Notice that this anonymization operation does not guarantee k-anonymization, however. To illustrate this, consider that an adversary knows that `Garnick` was born in `1990` and that he visited the `StLouis` hospital. By examining the output data records together with lineage information in `prov(admittedTo).out` (see Table 2), an adversary will be able to infer that the data record $\texttt{p}_1$ refers to `Garnick`. This can be more of an issue when the data record contains sensitive information such as health condition.

Problem 1 (K-anonymization of the input and output provenance of a module). *Consider a module* `m` *with an identifier input (resp. output). k-anonymizing the input provenance* `prov(m).in` *(resp.* `prov(m).out`*) of* `m` *using an anonymity degree* $\texttt{k}^{\texttt{m}}_{\texttt{i}}$ *(resp.* $\texttt{k}^{\texttt{m}}_{\texttt{o}}$*) gives rise to anonymized input provenance* $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in}$ *(resp. anonymized output provenance* $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{out}$*) where:*
1)- $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in} = \{\texttt{E1}^{\texttt{m}}_{\texttt{in}}, \ldots, \texttt{En}^{\texttt{m}}_{\texttt{in}}\}$ *(resp.* $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{out} = \{\texttt{E1}^{\texttt{m}}_{\texttt{out}}, \ldots, \texttt{En}^{\texttt{m}}_{\texttt{out}}\}$*), is a set of input (resp. output) equivalence classes for the input (resp. output) provenance of* `m`*, with* $\texttt{n} \geq 1$.
2)- *An input equivalence class* $\texttt{Ei}^{\texttt{m}}_{\texttt{in}}$ *(resp. output equivalence class* $\texttt{Ei}^{\texttt{m}}_{\texttt{out}}$*) contains at least* $\texttt{k}^{\texttt{m}}_{\texttt{i}}$ *(resp.* $\texttt{k}^{\texttt{m}}_{\texttt{o}}$*) data records.*
3)- *The data records in an input equivalence class* $\texttt{Ei}^{\texttt{m}}_{\texttt{in}}$ *(resp. output equivalence class* $\texttt{Ei}^{\texttt{m}}_{\texttt{out}}$*) cannot be distinguished by examining their lineage, i.e., by examining the data records that (transitively) contributed to the data records in* $\texttt{Ei}^{\texttt{m}}_{\texttt{in}}$ *(resp.* $\texttt{Ei}^{\texttt{m}}_{\texttt{out}}$*) or by examining the data records that the records in* $\texttt{Ei}^{\texttt{m}}_{\texttt{in}}$ *(resp.* $\texttt{Ei}^{\texttt{m}}_{\texttt{out}}$*) contributed to through workflow execution.*

Condition (3) is formally defined in the technical report using the notions of backward- and forward-lineage in a workflow [5].

Problem 2 (K-anonymization of the provenance of a workflow). *The provenance of a workflow* `w` *is said to be k-anonymized iff the input provenance of every identifier module input and the output provenance of every identifier module output in* `w.M` *are k-anonymized.*

The above problem is NP-Hard: Meyerson and Williams [21] demonstrated that optimal k-anonymity for a single relational table without considering lineage is an NP-hard problem. We present in this paper a heuristic that seeks to satisfy k-anonymity, to reduce the generalization (information-loss) incurred as a result, and to preserve lineage information in doing so.

3 ANONYMIZATION OF MODULE PROVENANCE

We show, in this section, how the input provenance and output provenance of a module are anonymized. The solution we present is applicable to many-to-many modules but also to modules with other cardinalities. We distinguish the case where the module input is an identifier input and its output is a quasi-identifier output, and the case where the module input and output are identifier input and identifier output. In the first case, the attribute values of the output data records are treated as quasi-identifying attribute values for their counterpart input data records. The second case is slightly more complex in the sense that the attribute values of the output data records are treated as quasi-identifying attribute values for their counterpart input data records, and vice-versa. We will not examine the case where both the module input and output carry quasi-identifier records. Indeed, it only makes sense to perform the anonymization when the input and/or the output carry identifier records, and as such associated with an anonymity degree to be enforced. That said, we will show in Section 4 how modules that carry quasi-identifier input and output records are dealt with in situations where they are used in workflows containing other modules with identifier records.

3.1 Module with Identifier Input and Quasi-Identifier Output

Consider the `admittedTo` module, presented earlier, that given a set of individuals returns a set of hospitals that those patients visited (see Table 1). And consider that the input dataset has been 2-anonymized as illustrated in Table 2. As discussed earlier, the lineage associating the output dataset to the input dataset may allow an adversary to pinpoint patients in the input dataset, even if this is anonymized. To avoid this, the hospital dataset needs to be anonymized in a way not to be able to distinguish between the hospitals visited by the patients that belong to the same equivalence class as a result of the anonymization of the patient dataset. For example, p_1 and p_2 must be associated with the same set of hospitals, and so do p_3 and p_4. Given lineage information, one way to do so consists in generalizing the hospitals in a way not to be able to distinguish between the hospitals corresponding to $\{\texttt{p}_1, \texttt{p}_3\}$ and those corresponding to $\{\texttt{p}_2, \texttt{p}_4\}$. An example of generalization of the hospital dataset that achieves this is illustrated in Table 3. Notice that similar generalization is applied to the hospitals corresponding to the groups of patients $\{\texttt{p}_5, \texttt{p}_7\}$ and $\{\texttt{p}_6, \texttt{p}_8\}$.

While acceptable, there is a more effective manner in this case to anonymize the patient and hospital datasets that yields less generalization of the quasi-attributes, thereby reducing the information loss incurred by the anonymization. Indeed, we can exploit the fact that patients are grouped into input sets to guide

the anonymization process. In particular, we put sets of data records that are used as input to a module invocation within the same equivalence class. For example, the patients p_1 and p_3 are put within the same equivalence class. Using this approach, we obtain the 2-anonymized patient dataset illustrated in Table 4. Notice that by doing so, we actually do not need to anonymize the hospital dataset. Indeed, starting from the hospital dataset, we cannot single out any patient: the same set of hospitals are visited by 2 patients. The approach we have just described is more effective as far as information loss is concerned. For example, one would know that $\mathtt{p}_1$ and $\mathtt{p}_3$ visited St Louis and St Antonio. Using the previous approach (described in Table 3), we would infer less specific information: that $\mathtt{p}_1$ and $\mathtt{p}_3$ visited St Louis or St Anne, and St Antonio or St Augustine.

With the above consideration in mind, we revisit the definition of equivalence classes introduced in Section 2 by requiring equivalence classes to contain sets of data records that are used as input or generated as output of module invocations. We will also introduce the notion of $\mathtt{k-group}$ anonymity degree, which allows us to gracefully reason about k-anonymity for collection-oriented modules.

Definition 3.1 (Equivalence Classes - Revisited). Given a module $\mathtt{m}$, we say that the set $\{\mathtt{E1}^{\mathtt{m}}_{\mathtt{in}}, \ldots, \mathtt{En}^{\mathtt{m}}_{\mathtt{in}}\}$ (resp $\{\mathtt{E1}^{\mathtt{m}}_{\mathtt{out}}, \ldots, \mathtt{En}^{\mathtt{m}}_{\mathtt{out}}\}$) is a set of input (resp. output) equivalence classes for $\mathtt{m}$, and write: $\mathtt{prov^a(m).in} = \{\mathtt{E1}^{\mathtt{m}}_{\mathtt{in}}, \ldots, \mathtt{E1}^{\mathtt{m}}_{\mathtt{in}}\}$ (resp. $\mathtt{prov^a(m).out} = \{\mathtt{E1}^{\mathtt{m}}_{\mathtt{out}}, \ldots, \mathtt{E1}^{\mathtt{m}}_{\mathtt{out}}\}$) iff:
1)- The conditions in Definition 2.5 are satisfied.
2)- An input (resp. output) equivalence class $\mathtt{Ei}^{\mathtt{m}}_{\mathtt{in}}$ (resp. $\mathtt{Ei}^{\mathtt{m}}_{\mathtt{out}}$) contains entire sets of input sets (resp. output sets) of data records. That is, two data records that belong to the same input set (resp. output set) that was used (resp. generated) by the invocation of $\mathtt{m}$ in $\mathtt{prov(m).in}$ (resp. $\mathtt{prov(m).out}$) cannot belong to different input (resp. output) equivalence classes.

Definition 3.2 (k-group anonymity (kg)). We say that the input provenance $\mathtt{prov^a(m).in}$ (resp. output provenance $\mathtt{prov^a(m).out}$) of a module $\mathtt{m}$ is k-group anonymized using the k-group anonymity degree $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}}$ (resp. $\mathtt{kg}^{\mathtt{m}}_{\mathtt{o}}$) iff each equivalence class in $\mathtt{prov^a(m).in}$ (resp. $\mathtt{prov^a(m).out}$) contains at least $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}}$ input sets of data records (resp. $\mathtt{kg}^{\mathtt{m}}_{\mathtt{o}}$ output sets of data records)

Property 1. *Consider a module* $\mathtt{m}$ *with an identifier input associated with an anonymity degree* $\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}$ *(resp. identifier output with an anonymity degree* $\mathtt{k}^{\mathtt{m}}_{\mathtt{o}}$*). And, let* $\mathtt{l}^{\mathtt{m}}_{\mathtt{i}}$ *(resp.* $\mathtt{l}^{\mathtt{m}}_{\mathtt{o}}$*) be the magnitude of the smallest input (resp. output) set of data records in* $\mathtt{prov(m).in}$ *(resp.* $\mathtt{prov(m).out}$*). k-group anonymyzing* $\mathtt{prov(m).in}$ *(resp.* $\mathtt{prov(m).out}$*) using the k-group anonymity degree* $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}} = \left\lceil \frac{\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}}{\mathtt{l}^{\mathtt{m}}_{\mathtt{i}}} \right\rceil$ *(resp.* $\mathtt{kg}^{\mathtt{m}}_{\mathtt{o}} = \left\lceil \frac{\mathtt{k}^{\mathtt{m}}_{\mathtt{o}}}{\mathtt{l}^{\mathtt{m}}_{\mathtt{o}}} \right\rceil$*) yields input provenance* $\mathtt{prov^a(m).in}$ *(resp. output provenance* $\mathtt{prov^a(m).in}$*) that is k-anonymized using the anonymity degree* $\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}$ *(resp.* $\mathtt{k}^{\mathtt{m}}_{\mathtt{o}}$*).*

Proof. An input equivalence class in $\mathtt{prov^a(m).in}$ contains at least $\left\lceil \frac{\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}}{\mathtt{l}^{\mathtt{m}}_{\mathtt{i}}} \right\rceil$ input sets of data records. Given that $\mathtt{l}^{\mathtt{m}}_{\mathtt{i}}$ is the magnitude of the smallest input set in $\mathtt{prov(m).in}$, we conclude that an input equivalence class in $\mathtt{prov^a(m).in}$ contains at least $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}} \cdot \mathtt{l}^{\mathtt{m}}_{\mathtt{i}}$ data records, which is equal to or greater than $\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}$. In other words, $\mathtt{prov^a(m).in}$ is k-anonymized using the k-anonymity degree of $\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}$. The same reasoning can be applied to show that the output provenance is k-anonymized using the degree of $\mathtt{k}^{\mathtt{m}}_{\mathtt{o}}$. □

We are now ready to discuss the general case. To anonymize the input provenance and output provenance of a module $\mathtt{m}$ with an identifier input and quasi-identifier output, we start by k-group anonymizing its input provenance using the k-group anonymity degree of $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}} = \left\lceil \frac{\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}}{\mathtt{l}^{\mathtt{m}}_{\mathtt{i}}} \right\rceil$. This yields input provenance $\mathtt{prov^a(m).out}$ that is k-anonymized using the degree of $\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}$ (see Property 1). Because the data records in the output provenance act as quasi-identifying records for the data records in the input provenance, we also need to anonymize the output provenance. To do so, we partition $\mathtt{prov(m).out}$ into a set of output equivalence classes $\mathtt{prov^a(m).out}$. This is done by putting the output sets of data records, that correspond to input sets pertaining to the same input equivalence class in $\mathtt{prov^a(m).in}$, within the same output equivalence class in $\mathtt{prov^a(m).out}$. This way, an adversary cannot distinguish the data records in an input equivalence class by examining their corresponding output data records, since these belong to the same output equivalence class and as such have the same quasi-identifying attribute values.

The above solution is applicable to modules with quasi-identifier input and identifier output, by inverting the roles of the input and output used above.

3.2 Modules with Identifier Input and Identifier Output

Consider a module $\mathtt{m}$ with an identifier input and an identifier output. To anonymize the input provenance and output provenance of $\mathtt{m}$, we reason using the k-group anonymity degrees associated with the input and output of $\mathtt{m}$. Specifically, we distinguish the following cases:

Case 1: $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}} \geq \mathtt{kg}^{\mathtt{m}}_{\mathtt{o}}$. We k-group the input provenance using the k-group degree $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}}$. This yields k-anonymized input provenance with an anonymity degree of $\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}$ (according to Property 1). The output provenance is anonymized by partitioning it into a set of output equivalence classes $\mathtt{prov^a(m).out}$: output sets of data records, that correspond to input sets pertaining to the same input equivalence class in $\mathtt{prov^a(m).in}$, are put within the same output equivalence class in $\mathtt{prov^a(m).out}$.

An output equivalence contains the sets of data records that correspond to input sets of data records in the same input equivalence class. Given that an input equivalence class contains at least $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}}$ input sets of data records, it follows that an output equivalence class in $\mathtt{prov^a(m).out}$ contains at least $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}}$ output sets of data records. Given that $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}} \geq \mathtt{kg}^{\mathtt{m}}_{\mathtt{o}}$, it follows that $\mathtt{prov^a(m).out}$ is k-group anonymized using the k-group anonymity degree of

$\mathtt{kg}_\mathtt{o}^\mathtt{m}$, which implies that $\mathtt{prov}^\mathtt{a}(\mathtt{m})\mathtt{.out}$ is k-anonymized using the anonymity degree of $\mathtt{k}_\mathtt{o}^\mathtt{m}$ (see Property 1). Note also that data records in the same input (resp. output) equivalence class cannot be distinguished by examining their corresponding output (resp. input) data records. This is because the data records in a given input equivalence class will have their corresponding output data records in the same output equivalence class, and, therefore, cannot be distinguished by examining their quasi-identifying attribute values, and vice-versa.

As an example, consider a module, `getPractitioners`, that takes a set of patients and returns the set of practitioners that have examined those patients[2]. Table 5 illustrates the input provenance and the output provenance of `getPractitioners`. We omit the lineage information (Lin column) in the input provenance because it is not useful in the example. Consider that the input of `getPractitioners` is associated with $\mathtt{k}_\mathtt{i}^\mathtt{getPractitioners} = 2$, and its output with $\mathtt{k}_\mathtt{o}^\mathtt{getPractitioners} = 2$. Given that $\mathtt{l}_\mathtt{i}^\mathtt{getPractitioners} = 2$ and $\mathtt{l}_\mathtt{o}^\mathtt{getPractitioners} = 3$ (see Table 5), we have $\mathtt{kg}_\mathtt{i}^\mathtt{getPractitioners} = \mathtt{kg}_\mathtt{o}^\mathtt{getPractitioners} = 1$. The k-group anonymity degree for both input and output in this case is 1. Tables 6 shows the anonymized input and output provenance obtained using the solution we have just described. Notice that the resulting patient dataset is 2-anonymized and that the resulting practitioner dataset is 3-anonymized. Moreover, we cannot distinguish between the practitioners of the patients in the same input equivalence class, and, similarly, we cannot distinguish between the patients of the practitioners that belong to the same output equivalence class.

Case 2: $\mathtt{kg}_\mathtt{i}^\mathtt{m} < \mathtt{kg}_\mathtt{o}^\mathtt{m}$. We perform the same processing as in (case 1) by inverting the roles of the input and output.

4 DATA PRIVACY OF WORKFLOW PROVENANCE

Given a workflow `w`, we seek to anonymize its provenance `prov(w)` by anonymizing the input provenance and output provenance of its constituent modules. In doing so, we can use the method presented in the previous section as is to anonymize the data used and generated by each module, in an independent fashion. Unfortunately, this solution may lead to a breach of privacy. Indeed, equivalence classes will be formed without consideration to lineage between data records output by given modules and the data records used to feed the succeeding modules within the workflow, which may lead to a privacy breach. The technical report [5] contains a detailed example that illustrates this case.

We, therefore, designed an algorithm that ensures that lineage information cannot be used by an adversary to uncover private information about individuals. For the purpose of the anonymization algorithm, we will be shortly presenting, we group the workflow modules into levels as illustrated in Figure 2. A module belongs to level `0` if it does not have a previous module. A module belongs to a level `i` where `i > 0`, if it has at least an incoming data link connected to a module in level `i − 1`, and it does not have any incoming data link connected to a module in level ≥ `i`.

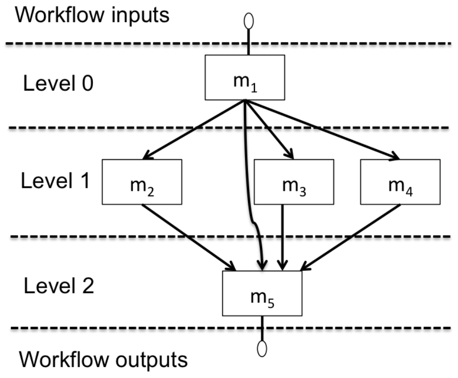

Fig. 2: Workflow levels.

Algorithm 1 Anonymize Workflow Provenance

```
Input:  w, the workflow specification.
Input:  Modules = {L_0, ..., L_k} // workflow modules grouped into levels (breadth)
     from the sink to the source.
          prov(w), the provenance of the workflow w.
          kg, group anonymity degree.
Output: Prov^a(w) // anonymized provenance
 1: for Level in Modules do
 2:     for m in Level do
 3:         if (m is the initial module) then
 4:             prov^a(m).in ← anonymizeInitialInput(m, prov(m).in, kg)
 5:             prov^a(m).out ← anonymizeOutput(m, prov(m).out, prov^a(m).in)
 6:         else
 7:             prov^a(m).in ← constructInputRecords(m, prec(m))
 8:             prov^a(m).out ← anonymizeOutput(m, prov(m).out, prov^a(m).in)
 9:         end if
10:     end for
11: end for
12: prov^a(w) ← $\bigcup_{m \in w.M}$ prof^a(m)
13: return prov^a(w)
```

To anonymize the provenance of a workflow `w`, Algorithm 1 takes as input the modules that compose the workflow organized into levels from the source to the sink, the provenance of the workflow `prov(w)`, as well as a group anonymity degree `kg` to be applied to the input provenance of the initial module of the workflow. (We will see later which k-group anonymity degree is used.) The algorithm examines the modules by level. For the first level composed of the initial module $\mathtt{m}_\mathtt{init}$, the operation `anonymizeInitialinput()` (line 4) anonymizes the input data of such module using the k-group degree `kg` and produces the set of equivalence classes $\mathtt{prov}^\mathtt{a}(\mathtt{m}_\mathtt{init})\mathtt{.in}$. The output data records of the initial module are used to feed the operation

[2]A practitioner appears in the output set only if it has examined every patient in the input set.

anonymizeOutput(), which produces $\texttt{prov}^{\texttt{a}}(\texttt{m}_{\texttt{init}}).\texttt{out}$ (line 5). For a module m that belongs to a level other than the initial one, the algorithm starts by constructing the anonymized input data records by using the anonymized data records of the preceding output in the previous level using the constructInputRecords() operation (lines 7). The output data records of m are, then, anonymized by using the same grouping applied to its inputs to produce $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{out}$ using the anonymizeOuput() operation (line 8). The algorithm terminates when the provenance of the module that belongs to the sink level is anonymized.

Having described how Algorithm 1 operates, we will describe in detail the operations used in the algorithm. We will also list the guarantees respected by each operation. Due to space limitations, the poofs of the guarantees can be found in the technical report [5]. Before proceeding to the presentation of the operations used in our algorithm, we start by defining the notion of lineage-related equivalence classes.

Definition 4.1 (Lineage-Related Equivalence Classes). Let E1 and E2 be two different equivalence classes. We say that E1 and E2 are lineage-related iff there are data records in E1 that (transitively) contributed through workflow executions to data records in E2, or vice-versa.

anonymizeInitialInput(m, prov(m).in, $\mathbf{k_g}$). This operation generates input equivalence classes for the initial module m: $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in} = \{\texttt{E1}^{\texttt{m}}_{\texttt{in}}, \ldots, \texttt{En}^{\texttt{m}}_{\texttt{in}}\}$, $n \geq 1$. Such equivalences classes are obtained by partitioning the input sets of data records in prov(m).in into groups, each containing at least $\texttt{k}_{\texttt{g}}$ input sets. Each group gives rise to an equivalence class by masking the identifying attribute values of its data records and generalizing their quasi-identifying attribute values such that the data records in the group are indistinguishable w.r.t. their quasi-identifying attribute values. Details about the partitioning operation are presented later in Section 5.

Guarantees:

- **$\mathbf{G_1}$**: $\texttt{prov}(\texttt{m}_{\texttt{init}})^{\texttt{a}}.\texttt{in}$ is $\texttt{k}_{\texttt{g}}$ group anonymized.

anonymizeOutput(m, prov(m).out, $\mathbf{prov^a}$(m).in). Given anonymized input provenance $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in} = \{\texttt{E1}^{\texttt{m}}_{\texttt{in}}, \ldots, \texttt{En}^{\texttt{m}}_{\texttt{in}}\}$ of a module m, this operation generates anonymized output provenance of that module: $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{out} = \{\texttt{E1}^{\texttt{m}}_{\texttt{out}}, \ldots, \texttt{En}^{\texttt{m}}_{\texttt{out}}\}$. To do so, for every input equivalence class $\texttt{Ei}^{\texttt{m}}_{\texttt{in}}$, a group $\texttt{Gi}^{\texttt{m}}_{\texttt{out}}$ containing the output sets of data records in prov(m).out that are lineage dependent on input sets of data records in $\texttt{Ei}^{\texttt{m}}_{\texttt{in}}$, is constructed. Each group $\texttt{Gi}^{\texttt{m}}_{\texttt{out}}$ gives rise to an output equivalence class $\texttt{Ei}^{\texttt{m}}_{\texttt{out}}$ by masking the identifying attribute values of the data records in $\texttt{Gi}^{\texttt{m}}_{\texttt{out}}$ and by generalizing their quasi-identifying attribute values such that the data records in the group are indistinguishable w.r.t. their quasi-identifying attribute values.

Guarantees:

- **$\mathbf{G_2}$**: for every equivalence class $\texttt{E}^{\texttt{m}}_{\texttt{in}}$ in $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in}$, anonymizeOutput() generates one lineage-related equivalence $\texttt{E}^{\texttt{m}}_{\texttt{out}}$ in $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{out}$.
- **$\mathbf{G_3}$**: anonymizeOutput() preserves k-group anonymity degree. That is, the number of output sets of data records in an output equivalence class $\texttt{E}^{\texttt{m}}_{\texttt{out}}$, generated by anonymizeOutput(), is equal to the number of input sets of data records in the input equivalence class $\texttt{E}^{\texttt{m}}_{\texttt{in}}$ that is used as input to that operation.

ConstructInputRecords(m, prec(m)). construct input equivalence classes for m given the output equivalence classes of its preceding modules prec(m). We distinguish two cases:

Case 1: m is preceded by one module: prec(m) = {m′} There are data links connecting the output ports of m′ to the input ports of m. Given the anonymized output provenance $\texttt{prov}^{\texttt{a}}(\texttt{m}').\texttt{out} = \{\texttt{E1}^{\texttt{m}'}_{\texttt{out}}, \ldots, \texttt{En}^{\texttt{m}'}_{\texttt{out}}\}$ of m′, this operation generates the anonymized input provenance of m, $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in} = \{\texttt{E1}^{\texttt{m}}_{\texttt{in}}, \ldots, \texttt{En}^{\texttt{m}}_{\texttt{in}}\}$, as follows: For every output equivalence class $\texttt{Ei}^{\texttt{m}'}_{\texttt{out}}$, a group $\texttt{Gi}^{\texttt{m}}_{\texttt{in}}$ is constructed containing the input sets of data records in prov(m).in that are lineage dependent on output sets of data records in $\texttt{Ei}^{\texttt{m}'}_{\texttt{out}}$. The data records in $\texttt{Gi}^{\texttt{m}}_{\texttt{in}}$ are, then, anonymized by masking their identifying attribute values, and by replacing their quasi-identifying attribute values, with the values used in their lineage-dependent data records in $\texttt{Ei}^{\texttt{m}'}_{\texttt{out}}$. Thereby, each group $\texttt{Gi}^{\texttt{m}}_{\texttt{in}}$ gives rise to an input equivalence class $\texttt{Ei}^{\texttt{m}}_{\texttt{in}}$.

Case 2: m is preceded by multiple modules. Suppose that $\texttt{prec}(\texttt{m}) = \{\texttt{m}_1, \texttt{m}_2\}$. Cases, where a module has more than two preceding modules, are handled in the same manner. Given the anonymized output provenance $\texttt{prov}^{\texttt{a}}(\texttt{m}_1).\texttt{out}$ of $\texttt{m}_1$ and the anonymized output provenance $\texttt{prov}^{\texttt{a}}(\texttt{m}_2).\texttt{out}$ of $\texttt{m}_2$, the anonymized input provenance $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in}$ of m is obtained using the following process:

For pair $(\texttt{Ei}^{\texttt{m}_1}_{\texttt{out}}, \texttt{Ej}^{\texttt{m}_2}_{\texttt{out}})$ in $(\texttt{prov}^{\texttt{a}}(\texttt{m}_1).\texttt{out}, \texttt{prov}^{\texttt{a}}(\texttt{m}_1).\texttt{out})$, if there exists a data record d in prov(m).in that is lineage dependent on a data record in $\texttt{Ei}^{\texttt{m}_1}_{\texttt{out}}$ and a data record in $\texttt{Ej}^{\texttt{m}_2}_{\texttt{out}}$, a group $\texttt{Gij}^{\texttt{m}}_{\texttt{in}}$ containing the data records in $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in}$ that are lineage-dependent on data records from both equivalence classes $\texttt{Ei}^{\texttt{m}_1}_{\texttt{out}}$ and $\texttt{Ej}^{\texttt{m}_2}_{\texttt{out}}$, is constructed. The data records in $\texttt{Gij}^{\texttt{m}}_{\texttt{in}}$ are anonymized, thereby giving rise to $\texttt{Eij}^{\texttt{m}}_{\texttt{in}}$, as follows. The identifying attribute values of the data records in $\texttt{Gij}^{\texttt{m}}_{\texttt{in}}$ are masked, and their quasi-identifying value attributes are replaced by the attribute values of their lineage-wise corresponding data records in $\texttt{Ei}^{\texttt{m}_1}_{\texttt{out}}$ and $\texttt{Ej}^{\texttt{m}_2}_{\texttt{out}}$.

Guarantees:

- **$\mathbf{G_4}$**: Using the operation ConstructInputRecords(), an output equivalence class of a module in prec(m) contributes to one lineage-related input equivalence class of m.
- **$\mathbf{G_5}$**: The operation constructInputRecord() preserves k-group anonymity. In other words, the number of input sets of data records in an input equivalence class $\texttt{E}^{\texttt{m}}_{\texttt{in}}$ is equal to or greater than the number of output sets of data records in the corresponding output equivalence classes of the preceding modules.

4.1 Privacy Analysis

We will show, in this section, that an adversary cannot break k-anonymized workflow provenance that is obtained using Algorithm 1. In doing so, we need to show that: i)- The data records in the anonymized input provenance $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in}$ (resp. anonymized output provenance $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{out}$) of every identifier input (resp. identifier output) of a module m in w, belong to equivalence classes of size $\geq k_i^m$ (resp. $\geq k_o^m$). ii)- The data records in an equivalence class in $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{in}$ (resp. $\texttt{prov}^{\texttt{a}}(\texttt{m}).\texttt{out}$) cannot be distinguished by examining their lineage (i.e., by examining the data records they have been (transitively) generated from or the data records that they have (transitively) contributed to within workflow executions). To do so, we present in what follows a lemma and a theorem, each of which is accompanied by proof.

Lemma 1. An input equivalence class (resp. output equivalence class) of a given module:

(1) is lineage-related with at most one input equivalence class and one output equivalence class of a different module in the same workflow, and
(2) is lineage-related with one output equivalence class (resp. input equivalence class) of the same module, and
(3) is not lineage-related with any input equivalence class (resp. output equivalence class) of the same module.

Proof. We start by showing (1). Let $\mathtt{m}$ and $\mathtt{m}'$ be two modules in a workflow $\mathtt{w}$, and let $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$ and $\mathtt{E}^{\mathtt{m}}_{\mathtt{out}}$ be an input and output equivalence classes of $\mathtt{m}$. There are three possible cases:
a)- There is exist a dataflow path connecting $\mathtt{m}$ to $\mathtt{m}'$ in $\mathtt{w}$. For ease of exposition, we denote $\mathtt{m}$ by $\mathtt{m}_1$, and $\mathtt{m}'$ by $\mathtt{m}_n$, and, therefore, the data flow path connecting $\mathtt{m}$ to $\mathtt{m}'$, can be represented by the sequence $(\mathtt{m}_1, \ldots, \mathtt{m}_n)$, with $n \geq 2$. The sequence $(\mathtt{m}_1, \ldots, \mathtt{m}_n)$ denotes a dataflow, i.e. there are data links connecting the output ports of $\mathtt{m}_i$ to the input ports of $\mathtt{m}_{i+1}$ for $i \in [1, n-1]$. Given the guarantees G_2 and G_4, it follows that

- Every input equivalence class in $\mathtt{m}_i$ gives rise to one lineage-related output equivalence class of $\mathtt{m}_i$ for $i \in [1, n]$.
- Every output equivalence class in $\mathtt{m}_i$ gives rise to one lineage-related input equivalence class of $\mathtt{m}_{i+1}$ for $i \in [1, n-1]$.

Given that we consider acyclic workflow, a module cannot appear twice in the dataflow path $(\mathtt{m}_1, \ldots, \mathtt{m}_n)$, which allows us to conclude that every input or output equivalence class of $\mathtt{m}_1$ gives rise to one lineage-related input equivalence class for $\mathtt{m}_n$ and one lineage-related output equivalence class for the output of $\mathtt{m}_n$. Given that we use $\mathtt{m}_1$ to denote $\mathtt{m}_1$ and $\mathtt{m}_n$ to denote $\mathtt{m}'$, we can conclude that $\mathtt{m}'$ has one input equivalence class and one output equivalence class that are lineage-related with $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$ (resp. $\mathtt{E}^{\mathtt{m}}_{\mathtt{out}}$).
b)- There is exist a dataflow path connecting $\mathtt{m}'$ to $\mathtt{m}$ in the workflow. The same analysis in (a) allows to conclude that $\mathtt{m}'$ has one input equivalence class and one output equivalence class that are lineage-related with $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$ (resp. $\mathtt{E}^{\mathtt{m}}_{\mathtt{out}}$).
c)- There does not exist a data flow path connecting $\mathtt{m}$ to $\mathtt{m}'$, or vice-versa. Given that we consider a data-driven workflow execution module, the data records used and generated by $\mathtt{m}$ cannot possibly contribute to the data records used and generated by $\mathtt{m}'$, and vice-versa. It follows from Definition 4.1 that the equivalence classes associated with the input or output of $\mathtt{m}$ cannot be lineage-related to the equivalence classes associated with the input or output of $\mathtt{m}$.

(a), (b) and (c) allows us to conclude (1).
We now show (2). According to G_2, given a module $\mathtt{m}$ in a workflow $\mathtt{w}$, the operation anonymizeOutput() generates one lineage-related output equivalence class $\mathtt{E}^{\mathtt{m}}_{\mathtt{out}}$ of $\mathtt{m}$, for every input equivalence class $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$ of $\mathtt{m}$. Given that $\mathtt{w}$ is acyclic, it follows that $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$ contains all the data records bound to the input of $\mathtt{m}$ that contributed to $\mathtt{E}^{\mathtt{m}}_{\mathtt{out}}$, and the data records in $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$ contribute to no data records bound to the output of $\mathtt{m}$, other than those in $\mathtt{E}^{\mathtt{m}}_{\mathtt{out}}$. In other words, $\mathtt{E}^{\mathtt{m}}_{\mathtt{out}}$ is the only output equivalence class of $\mathtt{m}$ that is lineage-related with $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$, and $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$ is the only input equivalence class of $\mathtt{m}$ that is lineage-related with $\mathtt{E}^{\mathtt{m}}_{\mathtt{out}}$.
We now show (3). Given that we consider acyclic workflows, input data records (resp. output data records) of a given module cannot possibly contribute data records bound to the same input module (resp. module output). It follows then that an input equivalence class (resp. output equivalence class) of a given module is not lineage-related with any input equivalence class (resp. output equivalence class) of the same module. □

Theorem 4.2 (Soundness). *The workflow provenance generated for the provenance* $\mathtt{prov}(\mathtt{w})$ *of a workflow* $\mathtt{w}$ *by Algorithm 1 using as input the k-group anonymity degree:*

$$\mathtt{kg}^{\mathtt{max}} = \mathtt{max}\Big(\bigcup_{\mathtt{m_j} \in \mathtt{WF.modules}} \{\mathtt{kg}^{\mathtt{m_j}}_{\mathtt{i}}, \mathtt{kg}^{\mathtt{m_j}}_{\mathtt{o}}\}\Big) \tag{1}$$

is k-annoymized.

Proof. To prove this theorem, we need to show: i) that every equivalence class in $\mathtt{prov}^{\mathtt{a}}(\mathtt{m}).\mathtt{in}$ of an identifier input of (resp. $\mathtt{prov}^{\mathtt{a}}(\mathtt{m}).\mathtt{out}$ of an identifier output) of every module $\mathtt{m}$ in the workflow $\mathtt{w}$, contains at least $\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}$ (resp. $\mathtt{k}^{\mathtt{m}}_{\mathtt{o}}$) data records, and ii) that data records in an equivalence class of the input or output of $\mathtt{m}$ cannot be distinguished by examining their lineage within the executions of $\mathtt{w}$ (see the problem statements in Section 2).

The input equivalence classes of the initial module in the workflow are generated using anonymizeInitialInput. According to G_1, the input equivalence classes generated by anonymizeInitialInput are k-grouped using the k-group anonymity degree $\mathtt{kg}^{\mathtt{max}}$. Such equivalence classes give rise to other equivalence classes by repeatedly applying the the operations anonymizeOutput() and ConstructInputRecords(). According to the guarantees G_3 and G_5 , such operations preserve k-group anonymity. It follows, then, that every equivalence class of an input (or output) of a module $\mathtt{m}$ that is generated by the algorithm contains a number of input (or output) sets that is equal to or greater than $\mathtt{kg}^{\mathtt{max}}$. In other words, the equivalence classes in $\mathtt{prov}^{\mathtt{a}}(\mathtt{m}).\mathtt{in}$ (resp. $\mathtt{prov}^{\mathtt{a}}(\mathtt{m}).\mathtt{out}$) contain at least $\mathtt{kg}^{\mathtt{max}} \cdot \mathtt{l}^{\mathtt{m}}_{\mathtt{in}}$ data records (resp. $\mathtt{kg}^{\mathtt{max}} \cdot \mathtt{l}^{\mathtt{m}}_{\mathtt{out}}$ data records). Given that, $\mathtt{kg}^{\mathtt{max}} \cdot \mathtt{l}^{\mathtt{m}}_{\mathtt{in}}$ is equal to or greater than $\mathtt{kg}^{\mathtt{m}}_{\mathtt{i}} \cdot \mathtt{l}^{\mathtt{m}}_{\mathtt{i}}$, which by definition is equal to or greater than $\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}$. It follows that the equivalences classes in $\mathtt{prov}^{\mathtt{a}}(\mathtt{m}).\mathtt{in}$ contain at least $\mathtt{k}^{\mathtt{m}}_{\mathtt{i}}$ data records. Similarly, given that, $\mathtt{kg}^{\mathtt{max}} \cdot \mathtt{l}^{\mathtt{m}}_{\mathtt{o}}$ is equal to or greater than $\mathtt{kg}^{\mathtt{m}}_{\mathtt{o}} \cdot \mathtt{l}^{\mathtt{m}}_{\mathtt{o}}$, which by definition is equal to or greater than $\mathtt{k}^{\mathtt{m}}_{\mathtt{o}}$. It follows that the equivalences classes in $\mathtt{prov}^{\mathtt{a}}(\mathtt{m}).\mathtt{out}$ contain at least $\mathtt{k}^{\mathtt{m}}_{\mathtt{o}}$ data records. Thereby, we have just shown (i).

We will now show (ii). Every input equivalence class $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$ in $\mathtt{prov}^{\mathtt{a}}(\mathtt{m}).\mathtt{in}$ is, according to lemma 1, not lineage-related to any equivalence class of the same input, and it is lineage-related with at most one input equivalence class $\mathtt{E}^{\mathtt{m}'}_{\mathtt{in}}$ of any other module input in the workflow, and is lineage-related with at most one output equivalence class $\mathtt{E}^{\mathtt{m}'}_{\mathtt{in}}$ of any module in the workflow (including $\mathtt{m}$). The data records in any lineage-related input equivalence class $\mathtt{E}^{\mathtt{m}'}_{\mathtt{in}}$ or output equivalence class $\mathtt{E}^{\mathtt{m}'}_{\mathtt{out}}$) do not carry identifying attribute values and are indistinguishable w.r.t. their quasi-identifying attribute values. Therefore, an adversary is unable to distinguish between the data records in $\mathtt{E}^{\mathtt{m}}_{\mathtt{in}}$ of an input equivalence class of a module $\mathtt{m}$ by examining the data records of its lineage-related equivalence classes. The same reasoning can be applied to the output equivalences classes in $\mathtt{prov}^{\mathtt{a}}(\mathtt{m}).\mathtt{out}$. This implies that data records in an equivalence class $\mathtt{E}$ cannot be distinguished by examining the records of any of its lineage-related equivalence class $\mathtt{E}'$. And, by recursion, the data records in $\mathtt{E}'$ cannot be distinguished by examining the data records in the equivalence classes that are lineage-related with E'., etc. That is, the data records in an equivalence class cannot be distinguished by examining their lineage, thereby showing (ii). □

5 GROUPING OF DATA RECORD SETS

Consider that the initial module of a workflow took as input the following sets of records $D = D_1 \cup \cdots \cup D_n$, with $l = \min_{i \in [1 \cdots n]} |D_i|$. Consider now that the target k-group anonymity degree is kg, i.e., the target anonymity degree $k = kg * l$. If $k > 1$, i.e. $kg > 1$, then the method for anonymization that we have described so far states that the inputs sets in $D = D_1 \cup \cdots \cup D_n$ need to be grouped (unionied) into equivalence sets of a magnitude at least equal to k. In doing so, the method we presented does not specify which inputs sets in D to group together to form equivalence classes. A naïve solution to this problem would be to union all the datasets in D into a single group, i.e. a single equivalence class, and anonymize the quasi-identifying attributes of the data records accordingly. However, the records obtained using this approach are likely to be useless since the scientists will not be able to distinguish between any of the data records used as input to the module in question. A more desirable solution would, therefore, generate groups that have a small magnitude of at least k, and yet try to keep the magnitude of such groups as close as possible to k. We can formally define the above problem as follows[3].

Given sets of data records $D = D_1 \cup \cdots \cup D_n$, and an anonymity degree k, group the sets D_i, $i = 1 \ldots n$, into groups $G = G_1 \cup \cdots \cup G_m$, $m \leq n$, such that:

(1) $|G_i| \geq k$, and
(2) $\max_{i=1 \ldots m}(|G_i|)$ is minimal.

The above problem can be viewed as a variant of the scheduling problem [29], in which the datasets D_i represent independent and non-preemptive jobs, and the cardinalities of such datasets represent jobs' lengths. There is a maximum of n machines. If a machine is used then its load must be greater or equal to k. The objective of such a scheduling problem is to minimize the makespan. To our knowledge, there does not exist any variant of the scheduling problem in the literature that meets the above criteria. We prove in the technical report that this is a strongly NP-hard problem, by reducing the *3-partition* problem to the above problem (see [5], page 14, for the proof).

Given that our problem is strongly NP-hard, we turn our attention to approximation algorithms. In particular, we devised the minimizeG integer problem (see below) to produce a good quality solution. x_{ij} is an integer that can takes the value 1 if the set D_i participates in the union that forms the group G_j, and 0, otherwise (Constraint C_4). y_j is an integer that can takes the value 1 if the group G_i contains at least one set in D, and 0, otherwise (Constraint C_5). $card_i$ represents the cardinality of the set D_i. Constraints (C_1) states that a set D_i must participate in the union of exactly one group. Constraint (C_2) specifies that a group G_j can have a cardinality of 0 (when y_j equals to 0), or a cardinality greater or equal to k (when y_j equals to 1). Constraint (C_3) specifies that the cardinalities of the groups $G_1, \ldots, G_n$ is smaller than a variable Z, which represents the makespan. The objective of the integer program is, therefore, to minimize the value of Z. Constraints (C_6) states that y_j is definitely equal to 1 if x_{ij} is equal to 1. More specifically, if the set D_i has been affected to the group G_j (i.e., $x_{ij} = 1$), then the group G_j contains at least one set (i.e.$y_j = 1$).

$$\begin{array}{llll}
\text{minimizeG} & Z & & \\
\text{subject to} & \sum_{j\in\{1,\cdots,n\}} x_{ij} \; = \; 1, & i = 1, \ldots, n & (C_1)\\
& \sum_{i\in\{1,\cdots,n\}} card_i \cdot x_{ij} \geq k.y_j, & j = 1, \ldots, n & (C_2)\\
& \sum_{i\in\{1,\cdots,n\}} card_i \cdot x_{ij} \leq Z, & j = 1, \ldots, n & (C_3)\\
& x_{ij} \in \{0,1\}, & i, j = 1, \ldots, n & (C_4)\\
& y_j \in \{0,1\}, & j = 1, \ldots, n & (C_5)\\
& y_j \geq x_{ij}, & i, j = 1, \ldots, n & (C_6)
\end{array}$$

Notice that we need to invoke the minimiseG program only once per workflow to identify the way the input sets of the initial module are to be grouped. The output of the initial module, as well as the input and output of the remaining modules in the workflow, use groupings that are derived based on lineage information (see Algorithm 1, lines 4 – 8).

6 VALIDATION

We implemented the solution that we have described in this paper using Python 2.7. We used the COIN Branch and Cut solver (CBC) provided by the LP Modeler Pulp[4] for solving the integer program MinimizeG presented in Section 5.

6.1 Experimental Setup

There is no existing solution that we can utilize as a base solution for comparison. Nonetheless, the approach that we have described raises the question as to which parameters impact the quality of the provenance anonymized using our solution. The analysis of the k-group anonymity degree computed for a workflow (see Equation 1), which dictates the degree of generalization, i.e., information loss, to be applied to the provenance of a workflow, reveals that the quality of the provenance (level of generalization) can be influenced by the anonymity degrees and magnitudes of the sets of data records used and generated by the parameters (inputs or outputs) of the workflow's modules. Note that on the other hand, the same equation allows us to rule out the topology (structure) of the workflow as a possible influencing factor. Because of this, we focus in our experiment on assessing the impact that the difference in the anonymity degrees and the magnitudes of the sets associated with two module parameters, which we take w.l.o.g to be the input and output of a module, has on the quality of anonymized provenance.

To be able to control the parameters of our experiment, we implemented a python program that given l^m_{in}, l^m_{out} and a number of module invocations, automatically generates module provenance. The provenance identifies the data records that are automatically generated by our tool. Regarding the content of data records, we use the Adult dataset [14], a de facto benchmark for anonymization solutions.

To assess the quality of anonymized data, we used the average equivalence class size [19] and the discernability metric [19]. For conciseness sake, we focus in what follows on the average equivalence class size. Readers interested in examining the results for discernability are referred to [5].

The average equivalence class measures how well equivalence classes created by the anonymization do not exceed what is required by the anonymization degree k. It can be defined as follows: $AEC(DS^*) = \frac{|DS|}{|EQ(DS^*)| \cdot k}$
where $EQ(DS^*)$ represents the set of equivalence classes created as a result of anonymizing DS, i.e., $|EQ(DS^*)|$ is the number of equivalence classes created. k represents the k-anonymity degree

[3]The problem statement formulated in Section 2.3 contains this condition.

[4] https://pypi.org/project/PuLP

required. The best value of AEC is 1. It means that none of the equivalence classes created as a result of anonymization exceeds the required anonymity degree when performing the generalization. We chose AEC as a measure because it is a good indicator for the quality of the anonymized data, with respect to a minimum requirement that is set by the anonymity degree.

As well as examining the impact of the anonymity degree and magnitude of sets of data records on the quality of anonymized provenance (in Sections 6.2, 6.3 and 6.4), we assess the utility of anonymized workflow provenance by examining the degree to which they can be used for answering workflow provenance challenge queries using real-world workflows [23] (in Section 6.5), and assess the efficiency of our solution (in Section 6.6).

6.2 Impact of the Disparity of k^m_{in}, k^m_{out} on the Quality of Anonymization

Given the provenance of the module m, one would expect that disparity between k^m_{in} and k^m_{out}, or more specifically between the ratios kg^m_{in} and kg^m_{out} have an impact on the quality of the obtained anonymized input and output datasets of m. Specifically, if kg^m_{out} is larger than kg^m_{in} then the inputs records of m will be grouped into equivalence classes that are beyond what is required by k^m_{in} to meet k^m_{output}. Thereby, the average equivalence class of the obtained anonymized input datasets is likely to suffer as a results. On the contrary, if kg^m_{in} and kg^m_{out} are close then one would expect that the average equivalence class for both the input and output anonymized datasets to be of good quality. To assess this intuition, we ran an experiment in which:
1) We generated the provenance of a module m that associates sets of input data records with sets of output data records. (Note that we ran our experiments using different numbers of module invocations, namely 50, 100, 200, 300, 400 and 500 module invocation. The results we obtained presented similar trends. We, therefore, focus on reporting on the results obtained for 100 module invocations.) We set l^m_{in} and l^m_{out} to the same value, viz. 1. Specifically, an input (resp. output) set of data records that are used or generated by m has a magnitude between 1 and 3 (resp. 1 and 4). (We did so to examine the interplay between k^m_{in} and k^m_{out}. Later on, we report on an experiment that we ran to assess the impact of the magnitudes of the sets of data records and their variability.) **2)** We then set the value of k^m_{in} to 2, and anonymized the input and output datasets using our method by varying the value of k^m_{in} between 2 and 20.

We ran this experiment three times. Figures 3 illustrates the average of the AEC obtained. Notice that the AEC of the output dataset is close (if not equal) to 1, indicating that the quality of the anonymized dataset is optimal as far as the constructed equivalence classes are concerned. On the other hand, we observe that the AEC of the input dataset increases as the disparity between k^m_{in} and k^m_{out} increases. This confirms our initial observation.

6.3 Impact of the Disparity of k^m_{in}, l^m_{in} on the Quality of Anonymization

Another aspect that can impact the quality of the anonymized datasets is the difference between the anonymity degree and the magnitude of the smallest input (resp. output) set of data records. Without loss of generality, let us consider the input of a module m. If l^m_{in} is greater than the anonymity degree k^m_{in}, then the magnitude equivalence classes obtained as a result of anonymization will be greater than what is required by k^m_{in}, thereby impacting negatively the AEC. To empirically examine this aspect, we set

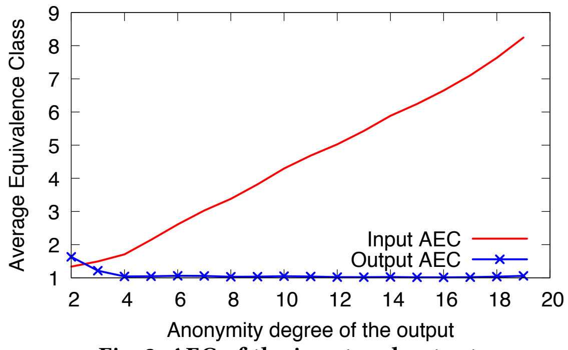

Fig. 3: AEC of the input and output.

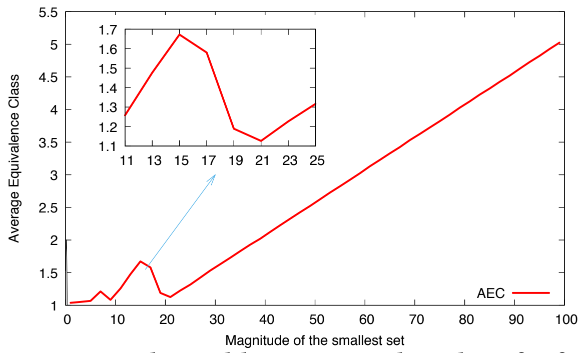

Fig. 4: AEC obtained by sweeping the value of l for $k = 20$.

the anonymity degree k^m_{in} to 20. We then varied the parameter l^m_{in} between 1 and 99, with a unit of 2, i.e., [1, 3, . . . , 97, 99]. In particular, for a given value of l^m_{in}, the input sets generated for a module have a magnitude between l^m_{in} and $l^m_{in} + 3$. In other words, the input sets have a magnitude that is close to the value of l^m_{in}. We did so to factor out the impact that the variability in the magnitude of the input sets, which we will examine later on.

For each value of l^m_{in}, we generated the provenance for the module m (100 module invocation) and anonymized the obtained input dataset. We ran this experiment three times, and averaged the results, which are depicted in Figure 4 for the average equivalence class. The chart can be partitioned into two parts. The first part where l^m_{in} ranges from 1 to 20, and in the second part where it ranges from 20 to 100. In the first part, we notice that the AEC remains relatively close to 1 until it reaches the value of 15 and 17 where we notice an increase of the AEC 1.5. The AEC then decreases to values that are close to 1 for l^m_{in} values of 19 and 21. To explain this increase in the AEC, consider the case where $l^m_{in} = 15$. The magnitude of the input sets ranges between 15 and 18 according to the above experiment setting. Consequently, the magnitude of the sets obtained using the grouping ranges between 30 and 36. Indeed, an input set on its own has a magnitude lower than the required anonymity degree of 20, and two unionied input sets will definitely have a magnitude between 30 and 36, which is larger than the required anonymity degree. This explains the fact that the AEC value is close to 1.5. In the second phase, we observe that the value of the AEC grows linearly as the magnitude of the smallest set grows. This can be explained by the following. For values of l^m_{in} greater than 20, no set grouping is actually performed: the magnitude of the input set is greater than the required anonymity degree. The larger is the magnitude of l^m_{in}, the larger the disparity between l^m_{in} and $k^m_{in} = 20$, and subsequently, the larger is the AEC.

6.4 Impact of the Disparity of the Size of Input (resp. Output) Sets

In the experiment that we ran this far, we assumed that the size of the input (resp. output) set of data records are close to 1^{m}_{in} (resp. 1^{m}_{out}). We have examined the provenance of the workflows available in ProvBench[5], namely the workflow provenance collected the workflow systems Taverna and Wings (120 workflows). For each workflow and each of its modules, we computed 1^{m}_{in} and 1^{m}_{out}. We then examined the variability of the magnitude of the input and output sets. This analysis revealed that in the majority of the cases the magnitude of the sets used and output by the modules that compose the workflow follows a uniform distribution. However, for an important proportion of the modules ($\approx$ 15%), we observed that the distribution is instead geometric in the sense that the input (resp. output) sets have a magnitude that is close to 1^{m}_{in} (resp. 1^{m}_{out}).

Given the above results, we decided to empirically examine the variability of the magnitude of the parameter sets on the quality of the anonymization considering the two distributions. For the random uniform distribution, we used three distributions where the maximum magnitude of a set is 20, 50 and 100, respectively. Regarding the geometric distribution, we used three distributions with the probabilities of 30, 50 and 80, respectively.

We then ran an experiment in which we computed the AEC by varying the anonymity degree k_{in} between 2 and 20. The results of the experiment for geometric distributions are illustrated in Figure 5, and those obtained for uniform distribution are illustrated in Figure 6. For geometric distribution, we observe that the higher the success probability, the better the AEC obtained. For example, the AEC quickly converges to the value of 1 when the success probability is equal to 0.8. On the other hand, the AEC converge to 1 only when the anonymity degree reaches 11 when the success probability is set to 0.3. That said, overall, geometric distribution delivers better results compared with uniform distribution: the AEC is much smaller. This can be explained by the fact that the variability in the magnitudes of the sets of data records is smaller in the case of the geometric distribution. And, the lower the variability of the magnitude of the data record sets, the better is the grouping of sets in the sense that it yields groups (i.e. equivalence classes) with magnitudes close to k, and therefore the better the AEC obtained (close to 1).

6.5 Assessing Utility Using Real Workflows

We assessed the degree to which anonymized provenance can be used to answer the following 3 queries that are representative of the queries defined by the workflow provenance challenge community [23].[6].

q_1 Find the workflow executions that led to a given record in the workflow results.

q_2 Find the input data records that contributed to a given data record in the workflow result.

q_3 Find the difference between two workflow execution.

For this experiment, we used 14 real-world Taverna workflows. The size of the workflows ranges from 3 modules to 24 modules, and have different structures patterns. We ran each workflow 30 times, and captured the provenance obtained using the Taverna workflow systems. We then anonymized the provenance by

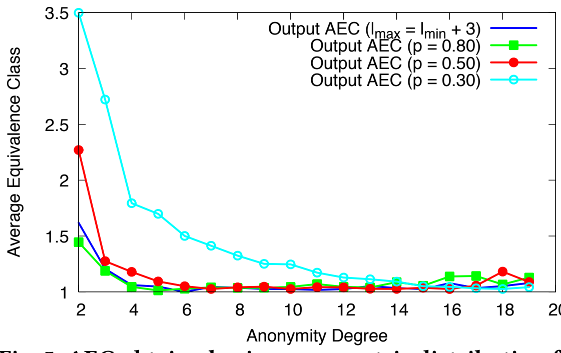

Fig. 5: AEC obtained using a geometric distribution for the magnitude of 1

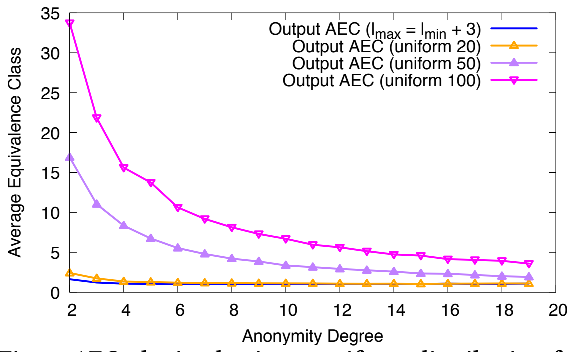

Fig. 6: AEC obtained using a uniform distribution for the magnitude of 1

varying the group anonymity degree kg^{max} from 1 to 10, and examined whether queries of the form listed above can be answered using the anonymized provenance.

Regarding q_1 and q_2, a user is presented with anonymized workflow provenance, and as such cannot pinpoint a single data record in the results that can be used as input to q_1 and q_2. Instead, s/he chooses a (set) of data records that belong to the same equivalence class. As expected, the larger is the anonymity degree, the larger is the set of data records to be considered (see Table 7). Note that on the other hand, the query results obtained had 100% precision and recall, regardless of the value of group-anonymity degree used. This was possible thanks to the fact that our anonymization method preserves lineage across data records.

Table 7: Size of the data record sets used as input to q_1 and q_2 given kg^{max}, averaged over the 14 workflows.

kg^{max}	1	2	4	6	8	10
avg size of the set of data records	3	6	11	20	25	33

Regarding q_3, the provenance challenge does not formally specify what it is meant by the difference of workflow executions [23]. That said, this question has later been thoroughly examined by Bao *et al.* [4]. They defined the difference between workflow executions of the same workflow specification using the edit distance which is the minimum number of edit operations that transform one provenance graph structure to the other. Using this definition, the edit distance between every pair of anonymized provenance graphs (of the 14 workflow specifications that we used) was the same as the edit distance computed using their counterpart original provenance graphs. This can be explained by the fact that our anonymization solution preserves the structure of the provenance graph as-is (since one of the requirements that we set is to preserve lineage information). Therefore, the

[5]https://github.com/provbench

[6]We could not use the provenance challenge queries as they are since they were specified for a single specific workflow on image processing.

original provenance graph of a given workflow specification is homomorphic to its anonymized counterpart.

This experiment has shown the utility of the workflow provenance anonymized using our solution since we were able to answer the three classes of queries. This evaluation exercise has also shown that for q_1 and q_2, the input of the query size (number of records) depends on the anonymity degree. Smaller anonymity degrees allow having smaller sets of data records that can be used for the queries, and vice-versa.

6.6 Efficiency

The only operation that is costly in the anonymization solution presented is the grouping of sets of data records, which we implemented using the integer program `minimizeG` (Section 5). Note, however, that such an operation is performed only once for the input of the initial module of the workflow. Indeed, the remaining parameters of the modules that compose the workflow apply the same grouping as the one applied to the input of the initial module. That said, we investigated the cost of such an operation to group n data sets, where n = 50, 100, 100, $\cdots$, 500. As expected, this experiment showed that time required increased as does the number of module invocations. Interestingly, the experiment also showed that the time required for performing the grouping of the sets of data records is primarily impacted by the distribution of the magnitude of the sets of data records to be grouped.

This experiment showed that using a uniform distribution, the range has little impact on the time required for grouping: it took between 16 and 18 seconds. On the other hand, it showed that sets that follow a geometric distribution with high success probability (50% and higher) require a considerable time compared to sets that follow a uniform distribution: it took up to 17 minutes. This can be explained by the fact that for a geometric distribution with high success probability, the majority of the sets have the same (or close) magnitudes. Therefore, many of the groupings that are explored by the integer program yield similar values for the objective function, hence recording little progress. The above results prompted us to develop an alternative solution when the magnitudes of the sets follow a geometric distribution with high success probability. The alternative solution we developed is simple, yet it group sets of data records in the orders of microseconds with a small impact on the AEC, which was higher by a margin of 0.03 on average compared with the situation in which we used our integer program `minimizeG`. More details can be found in the technical report [5].

7 CONCLUSIONS

We presented, in this paper, a solution for systematically anonymizing the provenance of collection-oriented workflows. Evaluation exercises allowed us to tease apart the aspects that impact the quality of the anonymization, namely the disparity between the anonymity degrees of the input and output sets of a module (or more generally the inputs and outputs of the modules that compose the workflow), the disparity between the anonymity degree and the magnitude of the sets of data records, and the distribution of the magnitudes of the record sets. We also examined the utility of the anonymized provenance using real-world workflows, and assessed the efficiency of our solution. In our ongoing work, we are investigating the applicability of our solution to anonymization techniques, other than k-anonymity, e.g., l-diversity and t-closeness [13]. We are also investigating the incorporation of vocabularies (hierarchies of concepts) to our solution. In the solution we presented, we substitute each quasi-identifier attribute value with a set containing the values that that attribute takes given a group (i.e. equivalence class) of data records. We will investigate how the use of vocabularies can be incorporated in our solution for generalizing the values of quasi-identifier attributes.

ACKNOWLEDGMENTS

I warmly thank Eun Jung Kim and Florian Sikora from the Paris-Dauphine University for the enlightening discussions on scheduling problems and integer programming. I would also like to thank the reviewers for their time and constructive comments, which helped improve the quality of the paper.

Sharing Computations for User-Defined Aggregate Functions

ftoumani@isima.fr

ABSTRACT

UDAFs (user-defined aggregate functions) are becoming a type of fundamental operators in advanced data analytics. The UDAF mechanism provided by most of the modern systems suffers, however, from at least two severe drawbacks: defining a UDAF requires hardcoding the routine that computes an aggregation, and the semantics of a UDAF is totally or partially unknown to the query processor, which hampers the optimization possibilities. This paper presents SUDAF (Sharing User-Defined Aggregate Functions), a declarative framework that allows users to write UDAFs as mathematical expressions and use them in SQL statements. SUDAF rewrites partial aggregates of UDAFs in users' queries using built-in aggregate functions and supports efficient dynamic caching and reusing of partial aggregates. Our experiments show that rewriting UDAFs using built-in functions can significantly speed up queries with UDAFs, and the proposed sharing approach can yield up to two orders of magnitude improvement in query execution time.

1 INTRODUCTION

An aggregate function has the inherent property of taking several values as input and generating a single value based on specific criteria [17, 25]. This ability to summarize information, the intrinsic feature of aggregation, has always been a fundamental task in data analysis [18, 24]. While earlier data management and analysis systems come equipped with a set of built-in aggregate functions, e.g., max, min, sum and count, it becomes clear that a limited set of predefined functions is not sufficient to cover the needs of the new applications in the age of analytics. In addition to augmenting the set of their built-in functions, most modern systems (e.g., [1, 2, 4, 21, 28, 29]) enable users to extend the system functionalities by defining their own aggregations. The UDAF (User-Defined Aggregate Function) mechanism provides a flexible interface to allow users to define new aggregate functions that can then be used for advanced data analytics, i.e., queries with statistical functions or ML workloads.

Current UDAF mechanisms suffer, however, from at least two drawbacks. Firstly, defining a UDAF is not an easy task since it is up to users to implement the routine that computes their aggregation functions. For example, to write a custom UDAF in Spark SQL [4], a user needs to map the UDAF to four methods: initialize, update, merge and evaluate, a.k.a. the IUME pattern. The user must ensure that the merge method is commutative and associative such that the UDAF can be computed correctly in a distributed architecture. In other words, to take benefit from distributed computations in Spark SQL, it is up to the user to identify whether her function supports partial aggregates (i.e., whether it is an algebraic function [18]). Secondly, the semantics of a UDAF, i.e., computation details, are not fully captured by a query engine, which hampers optimization possibilities. For example, when computing a UDAF that is created using the IUME pattern, a query engine can only be aware of calling an update function if there is a tuple or calling a merge function if there are intermediate results. However, the specific computations that are required to compute update and merge functions are unknown to a query engine since these two functions are hardcoded. The loss of such computation details prevents a query engine from sharing partial results of different UDAFs.

In the context of aggregate queries optimization, materialized views with aggregates or cached queries are among the techniques that can be used to accelerate query processing. In this context, most existing works focus on the data dimension [8, 11, 12, 15], i.e., sharing identical aggregates computed over overlapping range predicates or different data granularities. Admittedly, considering only the data dimension restricts the sharing possibilities to queries with identical aggregation operators. To cope with such a limitation, few works propose to use predefined rules to specify how a given aggregate can be computed from the results of another one [10, 33]. However, such a static approach requires one to explicitly predefine the computation rules across prefixed aggregates, which hinders the optimization for UDAFs defined on the fly.

The objective of this work is twofold: firstly, we aim at giving full flexibility to users by providing a declarative framework that allows them to write UDAFs as mathematical expressions and use them in SQL queries[1]. Then, a UDAF is decomposed into partial aggregates, which are then rewritten using built-in functions, i.e., scalar functions and aggregations. Secondly, our goal is to develop a *dynamic* approach for caching and reusing partial aggregates of UDAFs to optimize the computations of UDAFs. More precisely, we aim at identifying when it is possible to reuse cached partial aggregates of past UDAFs to compute new UDAFs.

Contributions. Our main contributions, implemented in the SUDAF framework, are as follows:

- We present SUDAF, a declarative UDAF framework that allows users to formulate a UDAF as a mathematical expression and use them within SQL queries. When executing a given query with UDAFs, SUDAF identifies appropriate partial aggregations from the mathematical expression of a UDAF and rewrites them using built-in functions of an underlying data management and analysis system.
- We formalize the problem of identifying when a partial aggregate of a given UDAF can be used in the computation of another UDAF as the *sharing problem*, and we show that this problem is undecidable in a general setting.
- To deal with the undecidability of the *sharing problem*, we restrict the set of UDAFs supported in SUDAF by providing classes of primitive functions that can be used to describe mathematical expressions of UDAFs. This practical framework is powerful enough to be used in practical applications. From a theoretical standpoint, we characterize

[1]This approach is more intuitive than programming the procedure of an aggregation, e.g., Wolfram Mathematica provides mathematical expressions to define advanced statistical computation [34].

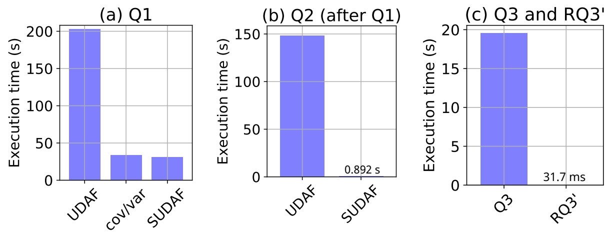

Figure 1: Experiments in PostgreSQL with the TPC-DS dataset (scale = 20). UDAFs theta1() and qm() are created in PL/pgSQL.

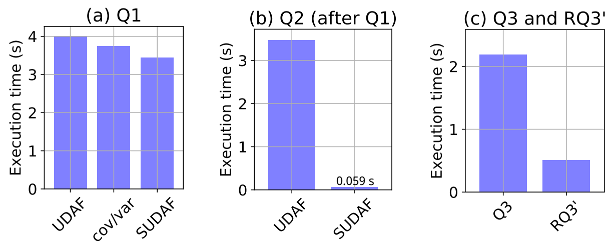

Figure 2: Experiments in Spark SQL with the TPC-DS dataset (scale = 100). UDAFs theta1() and qm() are created using UserDefinedAggregateFunction in Scala.

the sharing problem in SUDAF and provide corresponding sharing conditions (Theorem 4.1). From a practical standpoint, we design an approach based on symbolic representations of mathematical expressions to efficiently verify the proposed conditions.

- We implemented a SUDAF prototype and report on experiments using SUDAF with both PostgreSQL and Spark SQL. Our experiments show that rewriting partial aggregates of UDAFs using built-in aggregates can significantly speed up query execution. In addition, the proposed sharing technique can yield up to two orders of magnitude improvement in query execution time.

The rest of this paper is organized as follows. We present a motivating example to illustrate SUDAF's main features in Section 2. In Section 3, we introduce a canonical form of UDAFs and discuss the sharing problem in this context. In Section 4, we present the SUDAF framework and show that the sharing problem is decidable in this context. In Section 5, we introduce a practical approach, based on symbolic representations of partial aggregates, to solve the sharing problem in the SUDAF framework. In Section 6, we present an experimental evaluation of SUDAF. We discuss related works in Section 7 and conclude in Section 8. All related proofs are included in our online technical report [31].

2 MOTIVATING EXAMPLE

In this section, we present a motivating example demonstrating two SUDAF's functionalities: (i) rewriting UDAFs using built-in functions, and (ii) sharing partial aggregation results between different UDAFs. In addition, we also illustrate how the sharing mechanism can be used to extend query rewriting using aggregate views. In the following example, we consider 4 relations of the TPC-DS [27] dataset, store_sales, store, date_dim and stores.

Suppose that a user wants to analyze the price of every item sold by the stores in the state Tennessee (TN) in the past every year. Specifically, the user has a hypothesis of a *simple linear regression*: $y = \theta_1 x + \theta_0$, where y represents a value in the sales_price column and x a value in the list_price column. Using the least square error function, we have $\theta_1(X,Y) = \frac{n\sum x_i y_i - \sum x_i \sum y_i}{n\sum x_i^2 - (\sum x_i)^2}$, and $\theta_0(X,Y) = avg(Y) - \theta_1 avg(X)$.

One can hardcode θ_1 as a user-defined function and then uses it in an SQL statement, e.g., one writes a piece of Java or Scala code to create θ_1 in Spark SQL (see Scala code in [31]). Assume that a hardcoded user-defined function theta1(), that implements the function $\theta_1()$, is created and the following query Q1 is issued:

```
Q1: SELECT  ss_item_sk, d_year, avg(ss_list_price),
            avg(ss_sales_price),
            theta1(ss_list_price,ss_sales_price)
    FROM    store_sales, store, date_dim
    WHERE   ss_sold_date_sk = d_date_sk and
            ss_store_sk = s_store_sk and s_state = 'TN'
    GROUP BY ss_item_sk, d_year;
```

Alternatively, in SUDAF the function theta1() is defined declaratively by providing its mathematical expression without the needs of any programming effort.

Now, assume that a user defines the expressions of theta1() and avg() and uses them in the query Q1. We illustrate in the rest of this section two benefits of using SUDAF to execute the query Q1: (i) the partial aggregates of theta1() and avg() used in the query Q1 are rewritten into a set of partial aggregates using the built-in functions *sum* and *count*, and (ii) the partial aggregates computed during the execution of Q1 can be cached and reused to compute various other UDAFs.

Rewriting partial aggregates using built-in functions. The first step of processing Q1 in SUDAF is to factor out partial aggregates of theta1() and avg() and rewrite them using built-in functions to compute. More precisely, SUDAF identifies the following 5 partial aggregates in the expression of θ_1: $s_1 = count(), s_2 = \sum x_i, s_3 = \sum x_i^2, s_4 = \sum y_i$ and $s_5 = \sum x_i y_i$. Hence, SUDAF rewrites Q1 to the following query RQ1 where the partial aggregates are first computed and then theta1() is computed using the partial aggregates, $\theta_1 = \frac{s_1 s_5 - s_4 s_2}{s_1 s_3 - (s_2)^2}$.

```
RQ1: SELECT ss_item_sk, d_year, s2/s1 avg_list_price,
            s4/s1 avg_sales_price,
            (s1*s5-s4*s2)/NULLIF((s1*s3-power(s2,2)),0) theta1
     FROM   (SELECT ss_item_sk, d_year, count(*) s1,
                   sum(ss_list_price) s2,
                   sum(power(ss_list_price,2)) s3,
                   sum(ss_sales_price) s4,
                   sum(ss_sales_price*ss_list_price) s5
             FROM  store_sales, store, date_dim
             WHERE ss_sold_date_sk = d_date_sk and
                   ss_store_sk = s_store_sk and
                   s_state = 'TN'
             GROUP BY ss_item_sk, d_year) TEMP;
```

Compared to the original query Q1, RQ1 uses only built-in aggregate functions and hence it is expected to be much more efficient because built-in functions are better handled by existing query optimizers and execution engines than hardcoded user-defined functions. Figure 1 (a) shows that the execution of Q1 using SUDAF on top of PostgreSQL can be $10X$ faster compared to running Q1 directly over PostgreSQL. Similar results can be observed in Figure 2 (a) using SUDAF on top of Spark SQL, where Q1 is $1.25X$ faster compared to the direct execution of Q1 over Spark SQL. To be fair in our analysis, we should mention that in the context of PostgreSQL and Spark SQL systems, where the covariance (*cov*) and the variance (*var*) are built-in functions, an alternative and efficient implementation of theta1() can be obtained using the formula theta1() = cov/var. We also report the query time of using *cov/var* in Q1, respectively in Figure 1 (a) and Figure 2 (a), which is at the same order of magnitude as SUDAF execution time. However, even in this case, the benefit of using SUDAF comes from the fact that the performance of SUDAF is independent of the user's programming skill and, as shown in the next example, the partial aggregates computed by SUDAF using sum and count aggregates open wider sharing possibilities than the variance and covariance functions.

Note that SUDAF decomposes a UDAF into two parts, a set of partial aggregates and a terminating function T, then only the partial aggregates of a UDAF are rewritten using built-in functions. This is because a terminating function T is essentially a scalar function applied only on several partial aggregates, and hence it does not impact the computation time of a UDAF. Moreover, there are some UDAFs where it is not possible to write their corresponding terminating functions using built-in functions, e.g., the MomentSolver [16] used to approximate a quantile.

Sharing partial aggregates across UDAFs. Caching the result of Q1, which contains the aggregate values of theta1(), is of little interest from the sharing perspective. However, the partial aggregates $s_1, \ldots, s_5$ computed by the query RQ1 offer more possibilities to be reused in future UDAF computations. We illustrate the sharing idea by the following example. Consider a new query Q2 that computes quadratic mean qm() and standard deviation stddev() of list prices of every item sold by stores in TN for every year:

```
Q2: SELECT  ss_item_sk, d_year, qm(ss_list_price),
            stddev(ss_list_price)
    FROM    store_sales, store, date_dim
    WHERE   ss_sold_date_sk = d_date_sk and
            ss_store_sk = s_store_sk and s_state = 'TN'
    GROUP BY ss_item_sk, d_year;
```

Using SUDAF, qm() (an instance of power mean with $p = 2$ shown in Table 1) and stddev() are defined using the mathematical expressions given in Table 1. When executing Q2, SUDAF factors out their partial aggregations and generates the following query RQ2 which uses the same partial aggregates s_1, s_2 and s_3 as the query RQ1.

```
RQ2: SELECT ss_item_sk, d_year, sqrt(s3/s1) qm_list_price,
            sqrt(s3/s1-power(s2/s1,2)) std_list_price
     FROM   (SELECT ss_item_sk, d_year, count(*) s1,
                    sum(ss_list_price) s2,
                    sum(power(ss_list_price,2)) s3
             FROM   store_sales, store, date_dim
             WHERE  ss_sold_date_sk = d_date_sk and
                    ss_store_sk = s_store_sk and
                    s_state = 'TN'
             GROUP BY ss_item_sk, d_year) TEMP2;
```

SUDAF can cache the partial aggregates in the query RQ1 and identify the opportunity to reuse them for computing aggregates in the query RQ2 automatically. This makes the execution of Q2 in SUDAF significantly faster than executing the query Q2 from base data. We report the query time of Q2 when it is executed by SUDAF on top of PostgreSQL in Figure 1 (b) and on top of Spark SQL in Figure 2 (b). In both figures, the execution time of SUDAF is compared to the execution time of the query Q2 computed respectively over PostgreSQL and Spark SQL. We would like to stress the fact that the result of the UDAF theta1() computed by the query RQ1 cannot be reused to compute the UDAF qm() and stddev() of the query RQ2. However, identifying the appropriate partial aggregates of RQ1 and RQ2 enables to increase the sharing opportunities between these two queries.

Note that we only consider in our example the computation dimension, i.e., computing a UDAF from other UDAFs. Full implementation of our approach requires handling the data dimension, i.e., whether a query is semantically contained in the cached query, which is not addressed in this paper. We point out existing techniques [15, 33] based on data partitioning that can be used in our context to handle the data dimension issue. The main idea of such techniques is to partition the data into predefined chunks and then to map a given query to chunks. Extending SUDAF with such techniques enables us to share partial aggregates over predefined data chunks.

We would like to stress the following three features of the SUDAF sharing mechanism:

- Firstly, it increases performance significantly compared to SUDAF without sharing. In this example, using SUDAF without sharing over PostgreSQL to compute Q2 will take 33.61 s, which is far slower compared to 0.892 s shown in Figure 1 (b). Similarly, in the case of using SUDAF over SparkSQL, SUDAF without sharing will take 2.953 s, which is also significantly slower compared to 0.059 s shown in Figure 2 (b).
- Moreover, the sharing opportunity is dynamically identified in SUDAF by analyzing the expressions of partial aggregates in UDAFs. Note that, using a static approach, one has to predefine computation rules for specific aggregations, e.g., defining $stddev \rightarrow s_1, s_2, s_3$ to share results between RQ1 and RQ2, which is not required in SUDAF.
- Finally, the sharing mechanism of SUDAF covers also the case where partial aggregates are not identical (we present sharing conditions in Section 4.2). For example, SUDAF enables sharing computations between geometric mean and the aggregate $\sum ln(x_i)$, an element of the moment sketch [16]. This is because the partial aggregate $\prod x_i$ of geometric mean (see Table 1) can be computed from $\sum ln(x_i)$, i.e., $\prod x_i = exp(\sum ln(x_i)), \forall x_i > 0$ (see detailed experiments in Section 6).

Extending query rewriting using aggregate views. We show that factoring out partial aggregations of UDAFs can improve traditional query rewriting using aggregate views. Assuming a user is interested in computing qm() and stddev() of the list prices of all items in the category of sports sold by stores in TN for every year since 2000. This is expressed by the following query Q3.

```
Q3: SELECT  d_year, qm(ss_list_price), stddev(ss_list_price)
    FROM    store_sales, store, date_dim, item
    WHERE   ss_sold_date_sk = d_date_sk and ss_item_sk =
            i_item_sk and ss_store_sk = s_store_sk and
            i_category = 'Sports' and s_state = 'TN'
            and d_year >= 2000
    GROUP BY d_year;
```

Now, assume that a materialized view VQ1 corresponding to the query Q1 is given. One can realize that the view VQ1 is useless for rewriting Q3 since it is not possible to compute qm() and stddev() from theta1() and avg().

However, if a materialized view V1 corresponding to the subquery of RQ1 is given and if we factor out partial aggregations of qm() and stddev() in Q3 to generate the following query RQ3:

```
RQ3: SELECT d_year, sqrt(s3/s1) qm_list_price,
            sqrt(s3/s1-pow(s2/s1,2)) std_list_price
     FROM   (SELECT  d_year, count(*) s1,
                     sum(ss_list_price) s2,
                     sum(power(ss_list_price,2)) s3
             FROM    store_sales, store, date_dim, item
             WHERE   ss_sold_date_sk = d_date_sk and
                     ss_item_sk = i_item_sk and
                     ss_store_sk = s_store_sk and
                     i_category = 'Sports'
                     and s_state = 'TN'and d_year >= 2000
             GROUP BY d_year) TEMP3;
```

Then it is possible to use the rewriting algorithm proposed in [13] to rewrite the subquery of RQ3 using V1. The obtained rewriting, denoted by RQ3', is shown below.

Table 1: Examples of aggregations in canonical forms.

Aggregation	Expression	Canonical form $\left(\text{F}, \oplus, \text{T}\right)$
Power mean	$(\frac{\sum(x_i)^p}{n})^{1/p}$	$\left((1, x_i^p), (+,+), (\frac{s_2}{s_1})^{1/p}\right)$
Geometric mean	$(\prod x_i)^{1/n}$	$\left((x_i, 1), (\times, +), (s_1)^{1/s_2}\right)$
Stddev	$\sqrt{\frac{\sum x_i^2}{n} - (\frac{\sum x_i}{n})^2}$	$\left((1, x_i, x_i^2), (+,+,+), \sqrt{\frac{s_3}{s_1} - (\frac{s_2}{s_1})^2}\right)$
Central moment	$\frac{\sum(x_i - avg)^k}{n}$	$\left(((x_i - avg)^k, 1), (+,+), s_1/s_2\right)$
LogSumExp	$ln(\sum exp(x_i))$	$\left((exp(x_i)), (+), ln(s_1)\right)$

Aggregation	Expression	Canonical form $\left(\text{F}, \oplus, \text{T}\right)$
Skewness	$\frac{(\sum(x_i - avg)^3)/n}{((\sum(x_i - avg)^2)/n)^{3/2}}$	$\left(((x_i - avg)^3, (x_i - avg)^2, 1), (+,+,+), \frac{(s_1/s_3)}{(s_2/s_3)^{3/2}}\right)$
Covariance	$\frac{\sum(x_i y_i)}{n} - \frac{\sum x_i \sum y_i}{n^2}$	$\left((x_i, y_i, x_i y_i, 1), (+,+,+,+), \frac{s_3}{s_4} - \frac{s_1 s_2}{s_4}\right)$
Correlation	$\frac{n\sum(x_i y_i) - \sum x_i \sum y_i}{\sqrt{n\sum x_i^2 - (\sum x_i)^2}\sqrt{n\sum y_i^2 - (\sum y_i)^2}}$	$\left((x_i, x_i^2, y_i, y_i^2, x_i \times y_i, 1), (+,+,+,+,+,+), \frac{s_6 s_5 - s_1 s_3}{\sqrt{s_6 s_2 - (s_1)^2}\sqrt{s_6 s_4 - (s_4)^2}}\right)$

```
RQ3': SELECT d_year, sqrt(s3/s1) qm_list_price,
             sqrt(s3/s1-pow(s2/s1,2)) std_list_price
      FROM   (SELECT  d_year, sum(s1) s1, sum(s2) s2,
                      sum(s3) s3
              FROM    V1, item
              WHERE   ss_item_sk = i_item_sk and
                      d_year >= 2000 and
                      i_category = 'Sports'
              GROUP BY d_year) TEMP3;
```

The key reason that enables such a rewriting comes from the fact that the UDAFs have been rewritten using built-in aggregates: sum() and count() (we recall that the rewriting algorithm proposed in [13] supports only the *sum* and *count* aggregates). We report the execution time of Q3 and RQ3' in PostgreSQL in Figure 1 (c) and Spark SQL in Figure 2 (c).

To conclude this section, we would like to emphasis the fact that the main features of SUDAF, factoring out the partial aggregations of UDAFs, computing partial aggregations using built-in functions and sharing partial aggregates, provide abundant opportunities to speed up queries with UDAFs. In the rest of this paper, we address the following challenges:

- *how to identify appropriate partial aggregations of UDAFs to maximize sharing opportunities?*
- *how to efficiently determine when cached results of partial aggregations of UDAFs can be reused to compute other UDAFs?* (hereafter, called the sharing problem)

3 IDENTIFYING AND SHARING PARTIAL AGGREGATES

We aim at speeding up queries with UDAFs by reusing cached answers to previous queries with UDAFs during the evaluation of new ones. We deal with the following two issues in this section.

What computation results should be cached to optimize the evaluation of UDAFs? We identify a canonical form of UDAFs [10], which captures the computation pipelines of UDAFs. We analyze the caching possibilities based on the computation pipelines and identify the appropriate level of aggregation to be kept in caches.

How can we identify if a cached answer can be reused in the evaluation of a given UDAF? We formalize the problem of identifying a reusable answer as the sharing problem. Then we show that it is an undecidable problem for arbitrary cases. In Section 4, we present a restricted, yet powerful enough, framework to handle the sharing problem for practical cases.

3.1 Canonical forms of UDAFs

An aggregate function takes as inputs several values and produces as output a *single representative* value [17]. In our work, we consider aggregations operating on multisets. Let D_s and D_t be two domains i.e., countably infinite sets of values, and let $\mathcal{M}(D_s)$ denote the set of all nonempty multisets of elements from D_s. An aggregate function α is a function: $\mathcal{M}(D_s) \rightarrow D_t$.

We use the notion of well-formed aggregation to define a canonical form of aggregate functions. Well-formed aggregation was introduced in [10] to capture the manner in which a UDAF is created. An aggregation $\alpha : \mathcal{M}(D_s) \rightarrow D_t$ is a *well-formed aggregation* if α can be expressed as a triple $(F, \oplus, T)$, where F is a translating function, $\oplus$ is a commutative and associative binary operation and T is a terminating function, such that $\forall X = \{\!\{x_1, ..., x_n\}\!\} \in \mathcal{M}(D_s), \alpha(X) = T(F(x_1) \oplus \ldots \oplus F(x_n))$, or briefly $\alpha(X) = T(\sum_\oplus F(x_i))$.

In this paper, we consider the well-formed aggregation as the canonical form of UDAFs. We list some examples of aggregations with their canonical forms in Table 1 (an input of a terminating function T is denoted as s_i). It is interesting to note that practical aggregations usually have addition and multiplication as an element of $\oplus$ function in their canonical forms, e.g., the $\oplus$ function of geometric mean is $(\times, +)$.

Given an aggregation, $\alpha = (F, \oplus, T)$, the associative and commutative property of $\oplus$ ensures that $\alpha(X)$ can be computed by first applying F and $\oplus$ on arbitrary subsets of X and then the intermediate results can be merged using $\oplus$ and T to produce the final result $\alpha(X)$. Hence, we call the intermediate results $\sum_\oplus F(x_i)$ the *partial aggregations* of α.

3.2 Caching aggregate data

To obtain more sharing possibilities, we identify which results of an aggregation are worth caching based on its canonical form. Consider two aggregations $\alpha = (F_\alpha, \oplus_\alpha, T_\alpha)$ and $\beta = (F_\beta, \oplus_\beta, T_\beta)$. Suppose a scenario where an implementation of α based on its canonical form is executed first. When the UDAF β is evaluated, there are three possibilities to reuse partial or whole computation results of α: (1) the result of F_α, (2) the result of $\sum_{\oplus_\alpha} F_\alpha$, or (3) the final result of α. It is clear that caching the 1st result does not provide any added value to the computation of β since F_α is a scalar function. Storing the 3rd result is of little interest as it offers very restricted possibilities [2] to be reused in the computation of other UDAFs, e.g., β. However, the partial aggregation $\sum_{\oplus_\alpha} F_\alpha$ offers much more potentials to reuse than the others. For example, if α is a *stddev* and β is a *power mean* ($p = 2$) shown in Table 1, it is not possible to reuse the final result of α to compute β. However, using their canonical forms, one can observe that the fragments, s_1 and s_3, in the partial aggregation of α can be used to compute β. Therefore, we choose to cache the partial aggregation $\sum_{\oplus_\alpha} F_\alpha(x_i)$.

[2]Theoretically, T_α should not be expected to have an inverse function [10], such that we cannot always have the 2nd result if we cache the 3rd one. However, we can indeed have the 3rd result if we cache the 2nd result.

Table 2: **Classes of primitive functions provided in SUDAF.**

Class	**Functions**
PS	a; x; ax; x^a; $log_a x$; a^x.
PB	$+$; $-$; $\times$; $/$; ^.
PA	$\sum$; $\prod$.
PS°	$g(x) = h_l \circ ... \circ h_1(x)$, with $h_j \in PS$, for $j \in [1, ..., l]$.
$PS^\odot$	$f(x) = g_k(x) \odot_{k-1} ... \odot_1 g_1(x)$, with $g_j \in PS^\circ, \odot_z \in PB$, for $j \in (1, ..., k), z \in (1, ..., k-1), k \in \mathbb{N}_{>0}$.
PA°	$agg(X) = f' \circ \sum_\oplus \circ f(x_i)$, with $f, f' \in PS^\odot, \sum_\oplus \in PA$.
$PA^\odot$	$bagg(X) = T'(agg_k(X) \odot_{k-1} ... \odot_1 agg_1(X))$, with $agg_j \in PA^\circ$,$\odot_z \in PB$ for $j \in (1, ..., k)$,$z \in (1, ..., k-1), k \in \mathbb{N}_{>1}$ and $T' \in PS^\odot$.

3.3 Sharing aggregation states

Let $\alpha = (F, \oplus, T)$ be an aggregation and $\sum_\oplus F(x_i)$ be the partial aggregation of α. We decompose the partial aggregation as follows, $\sum_\oplus F(x_i) = \left(\sum_{\oplus_1} f_1(x_i), ..., \sum_{\oplus_m} f_m(x_i) \right)$, where the f_is are scalar functions and the $\oplus_i$s are commutative and associative binary operations, e.g., the partial aggregation of geometric mean is $(\prod x_i, count)$. In the sequel, we call an individual element $s_j(X) = \sum_{\oplus_j} f_j(x_i)$ as an *aggregation state*, e.g., both $\prod x_i$ and *count* are aggregation states of geometric mean.

We rely on aggregation states to define when a partial result of a UDAF α can be reused in the computation of another UDAF β. More precisely, we define below when an aggregation state s of α can be *shared* by an aggregation state s' of β.

Definition 3.1. Let $s'(X)$ and $s(X)$ be two aggregation states of two UDAFs. Then, s' shares s iff there exists a computable function r such that $s'(X) = r \circ s(X), \forall X \in \mathcal{M}(D)$.

The function r is a scalar function that enables computing the aggregation state s' without scanning the base dataset X, e.g., r is the identity function if $s'(X) = s(X)$. If an aggregation state s is cached, the sharing problem is then to decide whether s can be reused in the computation of another aggregation state s'.

We denote the problem whether s' shares s as share(s', s). As stated by the following theorem, it is not possible to solve share(s', s) in a general setting. The proof for Theorem 3.2 is included in our online technical report [31].

Theorem 3.2. *The problem share(s', s) is undecidable.*

4 THE SUDAF PRACTICAL FRAMEWORK

In this section, we present a declarative UDAF framework SUDAF, which rests on the canonical form of UDAFs to generate and share partial aggregation states of UDAFs automatically. The following main objective guided the design of SUDAF.

How to deal with the undecidability of the sharing problem? We adopt a pragmatic approach to solve this problem by restricting the class of UDAFs that can be used in SUDAF. The proposed practical framework is powerful enough to be useful in many real-world applications while making the sharing problem decidable.

We argue that it is not realistic to ask a user to provide UDAFs in their canonical forms. Therefore, SUDAF enables users to formulate UDAFs as mathematical expressions and then generates a corresponding canonical form. Consequently, in a generated canonical form, SUDAF knows the semantics of partial aggregations, i.e., computation details, which can be exploited to analyze sharing possibilities during computing UDAFs.

4.1 Declarative UDAF framework

SUDAF provides a set of predefined functions that can be used by users to write UDAFs. Three classes of primitive functions are proposed (cf. Table 2):

- *Primitive scalar functions.* This class, denoted PS (primitive scalar), contains six types of functions: constant, identity, linear, power, logarithmic and exponential functions. The elements of PS are presented in line 1 of Table 2, where a is an arbitrary constant defined by users.
- *Primitive binary functions.* This class, denoted PB (primitive binary), contains the following binary functions: addition $+$, subtraction $-$, multiplication $\times$, division $/$ and exponentiation ^.
- *Primitive aggregate functions.* This class, denoted PA (primitive aggregate functions), contains two functions: summation $\sum$ and product $\prod$.

As explained below, primitive functions can be combined using the composition operator and binary functions to create more complex scalar and aggregate functions.

Complex scalar functions. SUDAF provides a *composition operator*, denoted $\circ$, that enables creating complex scalar functions from the primitive ones. The class of such functions is denoted PS°. A function $g(x) \in PS^\circ$ can be expressed as a composition of primitive scalar functions (cf. Table 2). The length of $g(x)$, denoted $|g|$, gives the number of primitive functions used in the definition of $g(x)$. For example, if $g(x) = h_l \circ ... \circ h_1(x)$, with $h_j \in PS$, then $|g| = l$. Besides, more complex scalar functions can be expressed by using binary functions to combine scalar functions from PS°. The set of such functions, i.e., scalar functions containing binary operations, is denoted $PS^\odot$. The shape of functions in $PS^\odot$ is shown in Table 2.

Supported aggregations. SUDAF also allows using the composition operator $\circ$ between scalar functions and primitive aggregate functions to define new aggregations. More precisely, in this context, the composition can be used in two ways: *(i)* to apply a scalar function on an output of a primitive aggregate function, or *(ii)* to apply a primitive aggregation on a set of data transformed using a scalar function. The class of such functions is denoted as PA°. The expression of aggregation $agg \in PA^{\circ}$ is presented in Table 2. Moreover, more complex aggregations can be expressed using primitive binary functions to combine several aggregations in PA°. The class of such functions is denoted as $PA^{\odot}$, and a UDAF $bagg \in PA^{\odot}$ has the expression shown in Table 2.

Scope of UDAFs in SUDAF. SUDAF restricts the set of UDAFs that can be declared to the classes presented in Table 2. We shall show in the next section that this restriction enables us to cope with the undecidability of sharing problems. However, this restriction does not hamper the usability of SUDAF in real world applications since the proposed framework covers a wide range of aggregations such as the classes of power mean, arbitrary central moments [7], arbitrary standardized moments [32] and other multi-variate aggregations [3] such as covariance, correlation, and cofactor aggregates [30] used in training linear regression. Generally, algebraic aggregations can be defined in SUDAF. Although holistic aggregations, e.g., median, cannot be expressed in SUDAF, aggregates used in their approximation algorithms are supported by SUDAF, e.g., moment sketch [16],

Mapping SUDAF functions into canonical forms. SUDAF supports two scenarios to define UDAFs. We explain below how to derive canonical forms and aggregation states from UDAFs defined in each scenario.

The first scenario is that a terminating function is described using an element from $PS^{\odot}$. Such functions are expressed using a function $T' \in PS^{\odot}$ applied on compositions, using binary operations in PB, of aggregations from PA° and have the following general form:

$$\alpha(X) = T'\big(\big(f'_k \circ \sum_{\oplus_k} \circ f_k(x_i)\big) \odot_{k-1} \dots \odot_1 \big(f'_1 \circ \sum_{\oplus_1} \circ f_1(x_i)\big)\big).$$

The f_j, f'_j, for $j \in [1, ..., k]$, are scalar functions from $PS^{\odot}$ and $\sum_{\oplus_j}$ are primitive aggregations from PA. Given such a function $\alpha(X) \in PA^{\odot}$, a canonical form canonical$(\alpha) = (F, \oplus, T)$ is derived from the general expression of α as follows:

- $F = (f_1, \dots, f_k)$;
- $\oplus = (\oplus_1, \dots, \oplus_k)$ and
- $T = T'\big((f'_1 \circ \sum_{\oplus_1} \circ f_1) \odot_1 \dots \odot_{k-1} (f'_k \circ \sum_{\oplus_k} \circ f_k)\big)$.

The aggregation states of α are shown as follows: $s_j(X) = \sum_{\oplus_j} f_j(x_i)$, for $j \in [1, \dots, k]$. For instance, aggregations in Table 1 can be defined in SUDAF using their expressions in the second column. SUDAF generates their canonical forms and aggregation states from their expressions (the s_i elements in Table 1).

The second scenario is that a terminating function is created by hardcoding. Such functions have the following shapes, $\alpha(X) = T(s_1, ..., s_k)$, where $s_j, j \in (1, ..., k)$ is an aggregation state. For example, if one wants to use the MomentSolver [16] taking the MomentSketch as inputs to approximate a quantile, the MomentSketch can be defined as a set of aggregation states from PS° and the MomentSolver as a terminating function.

4.2 Dealing with the sharing problem in SUDAF

In this section, we present sharing conditions to deal with the sharing problem in SUDAF. Let $s_1(X) = \sum_{\oplus_1} f_1(x_i)$ and $s_2(X) = \sum_{\oplus_2} f_2(x_i)$ be two aggregation states of two UDAFs in the scope of SUDAF. Then both f_1 and f_2 belong to $PS^{\odot}$. We carry out a case analysis to identify the conditions that characterize situations where s_1 shares s_2. Our case analysis is based on the properties of the scalar functions f_1 and f_2 used by the aggregation states s_1 and s_2. In fact, all scalar functions in PS°, except constant functions, are either injective, or even (i.e., $f(x) = f(-x)$)), while scalar functions in $(PS^{\odot} \setminus PS^{\circ})$ are not injective because of the presence of the arithmetic binary functions $\odot$ (cf. Figure 3). Therefore, we split the *sharing problem* share(s_1, s_2) into four main cases depending on whether f_1 and f_2 are injections or even functions. The studied cases are presented in Table 3. Our main results provide a full characterization for the first three cases in Table 3. Specifically, we provide complete conditions in Theorem 4.1 for the first two cases in Table 3, and then we reduce the third case to the second case in Table 3. We also propose an incomplete solution to deal with the fourth case in Table 3.

THEOREM 4.1. *Let $X \in \mathcal{M}(\mathbb{Q})$ and let $s_1(X) = \sum_{\oplus_1} f_1(x_i)$ and $s_2(X) = \sum_{\oplus_2} f_2(x_i)$ be two aggregation states with $\sum_{\oplus_1} \in PA$ and $\sum_{\oplus_2} \in PA$, f_1 a non constant function and $s_1 \neq s_2$. Then, we have:*

(Case 1) *if f_1 is injective and f_2 is not injective, then s_1 does not share s_2.*

(Case 2) *if f_2 is injective, then: there exists a computable function r_{12} such that $s_1(X) = r_{12} \circ s_2(X)$ iff one of the following conditions holds:*

(2.1) *$\sum_{\oplus_1} = \sum_{\oplus_2} = \sum$ and $f_1 \circ f_2^{-1}(x) = ax$ with $a \in \mathbb{Q}_{\neq 0}$ a constant. Then we have $r_{12}(x) = f_1 \circ f_2^{-1}(x)$.*

(2.2) *$\sum_{\oplus_1} = \sum$, $\sum_{\oplus_2} = \prod$ and $f_1 \circ f_2^{-1}(x) = a(log_b|x|)$ with $b \in \mathbb{Q}_{>0,\neq 1}$ and $a \in \mathbb{Q}_{\neq 0}$ two constants. Then we have $r_{12}(x) = f_1 \circ f_2^{-1}(x)$.*

(2.3) *$\sum_{\oplus_1} = \prod$, $\sum_{\oplus_2} = \sum$ and $f_1 \circ f_2^{-1}(x) = b^{ax}$ with $b \in \mathbb{Q}_{>0,\neq 1}$ and $a \in \mathbb{Q}_{\neq 0}$ two constants. Then we have $r_{12}(x) = f_1 \circ f_2^{-1}(x)$.*

(2.4) *$\sum_{\oplus_1} = \sum_{\oplus_2} = \prod$ and with a constant $a \in \mathbb{Q}_{\neq 0}$:*
  (i) *when $f_1 \circ f_2^{-1}(-1) = 1$, $f_1 \circ f_2^{-1}(x) = |x|^a$;*
  (ii) *when $f_1 \circ f_2^{-1}(1) = -1$, $f_1 \circ f_2^{-1}(x) = sgn(x) \times |x|^a$;*
  Then we have $r(x) = f_1 \circ f_2^{-1}(x)$.

The proof for Theorem 4.1 is included in a technical report [31].

The case 1 of Theorem 4.1 states that, given two aggregation states $s_1(X) = \sum_{\oplus_1} f_1(x_i)$ and $s_2(X) = \sum_{\oplus_2} f_2(x_i)$ in the scope of SUDAF, when f_1 is injective and f_2 is non-injective, then except the special case of an identity function when $s_1 = s_2$, it is not possible to find a computable function r_{12} such that $s_1(X) = r_{12} \circ s_2(X)$. The case 2 of Theorem 4.1 provides necessary and sufficient conditions to characterize solutions for the problem share(s_1, s_2) when f_2 is injective. It carries out a case analysis for the four possible combinations obtained from the instantiation of $\sum_{\oplus_1}$ and $\sum_{\oplus_2}$ as operations in PA, i.e., either sum or product.

Example 4.2. We explain how Theorem 4.1 can be used as follows. Consider the problem whether $s_1(X) = \sum 4x_i$ shares $s_2(X) = \prod 2^{x_i}$. Since $\sum_{\oplus_1} = \sum$ and $\sum_{\oplus_2} = \prod$, then the case 2.2 of Theorem 4.1 is selected. Then, we have $f_1 \circ f_2^{-1}(x) = 4log_2(x)$, which satisfies the shape $a(log_b(x))$ with constants $a = 4$ and $b = 2$. Thus, we have $s_1(X) = r \circ s_2(X)$ with $r(x) = 4log_2(x)$.

The case of even scalar functions. The third case to deal with is when both $f_1(x)$ and $f_2(x)$ are not injections but even functions (case 3 of Table 3). As depicted in Figure 3, non-injective scalar functions of PS° are *even* functions. We exploit this property to reduce the study to a sharing problem over a positive domain of scalar functions and show that the case 2 of Theorem 4.1 can be applied in this setting. We denote $U_X = \{u_x = |x| | x \in X\}$.

[3]Multi-variate aggregations can be seen as a combination of several uni-variate aggregations, each of which is expressed using functions in Table 2. Moreover, the cofactor aggregate $\sum x_i y_i$ computed over columns X and Y can be seen as a uni-variate aggregate over an abstract column $Z = X \cdot Y$ with the scalar product $\cdot$.

Then, whatever x is, we have $u_x \geqslant 0$. Let $s_1(X) = \sum_{\oplus_1} f_1(x_i)$ and $s_2(X) = \sum_{\oplus_2} f_2(x_i)$ be two aggregation states in SUDAF such that $\{f_1, f_2\} \subset PS^{\circ}$. Observe that $s_1(X)$ shares $s_2(X)$ iff $s_1(U_X)$ shares $s_2(U_X)$. This is because $f_1(x) = f_1(u_x)$ (since f_1 is even), and similarly for f_2. Consequently, one can focus on solving the sharing problem only over positive domains of f_1 and f_2. In this setting (positive domain), all primitive scalar functions of SUDAF (non-constant elements in PS) are injections and hence the complex scalar functions, elements of PS°, are also injective functions. Therefore, the case 2 of Theorem 4.1 can be exploited to solve the sharing problem in this context.

The case of neither even nor injective scalar functions. The last case to deal with is when both $f_1(x)$ and $f_2(x)$ are neither injections nor even functions (case 4 of Table 3). As depicted in Figure 3, such scalar functions are from $(PS^{\odot} \setminus PS^{\circ})$. We propose splitting rules to deal with such cases. W.l.o.g, let $s(X) = \sum_{\oplus}(g_1(x_i) \odot g_2(x_i))$, $\sum_{\oplus} \in PA$, $\{g_1, g_2\} \in PS^{\circ}$. Then, we define the following two splitting rules (SR):

SR1: $\sum(g_1(x_i) \odot g_2(x_i)) = \sum(g_1(x_i)) \odot \sum(g_2(x_i)), \odot \in \{+, -\}$;
SR2: $\prod(g_1(x_i) \odot g_2(x_i)) = \prod(g_1(x_i)) \odot \prod(g_2(x_i)), \odot \in \{\times, /\}$.

By applying the above two rules, aggregation states in $(PS^{\odot} \backslash PS^{\circ})$ can be split into new ones with scalar functions in PS°, which can still be verified using Theorem 4.1. If aggregation stares are not covered by splitting rules in this case, SUDAF simply proceeds syntactic comparison between their mathematical expressions. Note that syntactic comparison is sufficient but not necessary.

5 A PRACTICAL APPROACH TO SOLVE THE SHARING PROBLEM

We present in this section a practical approach to solve the sharing problem based on the results provided by Theorem 4.1. Turning the conditions of Theorem 4.1 into an algorithm could be cumbersome because equivalent mathematical expressions may have different syntactic shapes.

Example 5.1. Consider the problem whether $s_1(X) = \sum 4x_i^2$ shares $s_2(X) = \sum(3x_i)^2$. Using Theorem 4.1, one needs to construct $f_1 \circ f_2^{-1}(x) = 4x \circ x^2 \circ \frac{1}{3}x \circ \sqrt{x}$ (over the positive domain since both f_1 and f_2 are even). Then, according to case 2.1 of Theorem 4.1, we need to check whether $f_1 \circ f_2^{-1}(x) = ax$, for some constant a. This is not an easy task, particularly for general cases, since it requires mathematical transformations of the original expression as follows: $f_1 \circ f_2^{-1}(x) = 4x \circ x^2 \circ \frac{1}{3}x \circ \sqrt{x} = 4x \circ \frac{1}{9}x \circ x^2 \circ \sqrt{x} = \frac{4}{9}x$. The first transformation is a *reordering* of $x^2 \circ \frac{1}{3}x$, which generates $\frac{1}{9}x \circ x^2$, and it is then followed by a *removal* of the composition $x^2 \circ \sqrt{x}$. Finally, $f_1 \circ f_2^{-1}(x)$ is transformed to $\frac{4}{9}x$, which satisfies the condition $f_1 \circ f_2^{-1}(x) = ax$, with $a = \frac{4}{9}$, of the case 2.1 of Theorem 4.1.

In addition, a straightforward implementation of Theorem 4.1 leads to redundant computations as illustrated below.

Example 5.2. Checking whether $s_1' = \sum 6x_i^3$ shares $s_2' = \sum(5x_i)^3$ requires redoing identical transformations as in the previous example (i.e., checking whether $s_1(X) = \sum 4x_i^2$ shares $s_2(X) = \sum(3x_i)^2$). This is because we have as a general property: $\sum a_2 x_i^{a_1}$ shares $\sum(b_1 x_i)^{b_2}$ if $a_1 = b_2$.

Hence, our general idea to deal with the two previous issues is: (i) to use symbolic representations of aggregation states to avoid redundant computations, i.e., using $\sum a_2 x_i^{a_1}$ and $\sum(b_1 x_i)^{b_2}$, where a_1, a_2, b_1 and b_2 are parameters, to represent the *concrete* states $\sum 4x_i^2$ and $\sum(3x_i)^2$, and (ii) to precompute sharing relationships between symbolic representations to avoid cumbersome transformations of mathematical expressions at execution time. For example, we precompute the relationship stating that $\sum a_2 x_i^{a_1}$ shares $\sum(b_1 x_i)^{b_2}$ if $a_1 = b_2$. Then, at execution time, this relationship can be used to efficiently identify that the *concrete* aggregation state $\sum 4x_i^2$, an instance of the abstract state $\sum a_2 x_i^{a_1}$, shares the concrete state $\sum(3x_i)^2$, an instance of the abstract state $\sum(b_1 x_i)^{b_2}$, because the condition $a_1 = b_2$ is satisfied.

5.1 Symbolic representations

In this section, we first present symbolic representations of scalar functions and then use them to introduce symbolic representations of aggregation states. In the sequel, we assume an infinite set of parameters, distinct from the set of constants. Hereafter, the parameters are denoted $p, p_1, \ldots$.

Symbolic primitive scalar functions. Intuitively, px with a parameter p is the symbolic representation of the primitive scalar function $2x$. In this case, $2x$ is an instance of px. Formally, we consider four symbolic primitive scalar functions with a parameter p: $px = \{ax | \forall a \neq 0\}$; $log_p x = \{log_a x | \forall a > 0, \neq 1\}$; $p^x = \{a^x | \forall a > 0, \neq 1\}$; $x^p = \{x^a | \forall a \neq 0\}$. We use the notation $sf_{\bar{p}}(x)$ for a symbolic primitive scalar function with a sequence $\bar{p} = (p)$ of a parameter p.

Symbolic scalar functions. Intuitively, $p_2 x^{p_1}$ with a parameter sequence (p_2, p_1) is the symbolic representation of the scalar function $3x^2$, and in this case $3x^2$ is an instance of $p_2 x^{p_1}$. Formally, let every $sf_{i\bar{p}_i}(x)$ for $i \in [1, \ldots, l]$ be a symbolic primitive scalar function. Then, $sf_{\bar{p}}(x) = sf_{l\bar{p}_l} \circ \ldots \circ sf_{1\bar{p}_1}(x)$ is a symbolic scalar function $sf_{\bar{p}}(x)$ with a sequence $\bar{p} = (p_l, \ldots, p_1)$ of parameters. Similarly, $|sf_{\bar{p}}| = l$.

Symbolic aggregation states. Intuitively, $\sum p_2 x_i^{p_1}$ is the symbolic representation of $\sum 3x_i^2$. In this case, $\sum p_2 x_i^{p_1}$ is called a symbolic (aggregation) state and we say that the concrete state $\sum 3x_i^2$ is an instance of the symbolic state $\sum p_2 x_i^{p_1}$. Formally, let $\sum_{\oplus} \in PA$ and $sf_{\bar{p}}(x)$ be a symbolic scalar function. Then, $ss(X) = \sum_{\oplus} sf_{\bar{p}}(x_i)$ is a symbolic aggregation state.

Specifically, we let $\sum x_i$ and $\prod x_i$ be also two symbolic aggregation states, which contain respectively only one instance $\sum x_i$ and $\prod x_i$, and we define $|f| = 0$ with $f(x) = x$.

5.2 Precomputed sharing relationships

Informally, we say that a symbolic state ss_1 shares a symbolic state ss_2 if and only if for any instance s_1 of ss_1, there exists an instance s_2 of ss_2, such that s_1 shares s_2. As explained previously, our aim is to precompute and store the sharing relationships between symbolic aggregation states. Specifically, we conduct an exhaustive analysis to identify the sharing relationships between symbolic states in a preprocessing step, which is performed once when SUDAF is deployed, and then the precomputed relationships are reused at runtime to handle the sharing problem between concrete aggregation states. Note that the space of symbolic states may be very huge (theoretically infinite) because symbolic scalar functions may be of arbitrary lengths. In addition, aggregation states having scalar functions with a higher length are useless from the practical point of view. For example in our experiments presented in Section 6 it was enough to use aggregation states, whose scalar functions have a length up to 2, to express aggregations in real-world applications. Therefore, SUDAF enables a user to bound the space of symbolic aggregation

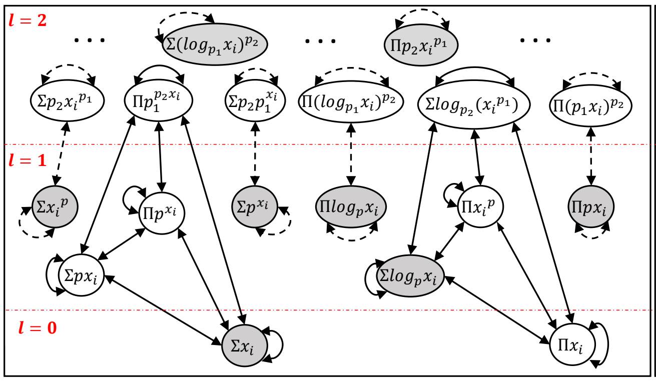

Figure 4: The digraph G of $saggs_2(X)$.

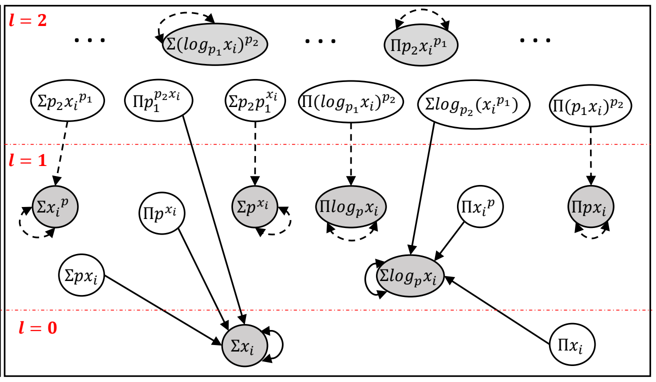

Figure 5: The simplified digraph G of $saggs_2(X)$.

states that is prebuilt in the preprocessing step using a configuration parameter, denoted by l. The obtained space, denoted by $saggs_l(X)$, is introduced below.

l-bounded symbolic space. Let $l \geqslant 0$ be an integer. We define the space $saggs_l(X)$ of symbolic aggregation states as follows: $saggs_l(X) = \{\sum_{\oplus} sf_{\bar{p}}(x_i) | sf_{\bar{p}}$ is a symbolic scalar function with $|sf_{\bar{p}}| \leqslant l\}$. We say $saggs_l(X)$ is a l-bounded symbolic space. Note that the size of the set $saggs_l(X)$ is bounded by $\frac{2(4^{l+1}-1)}{3}$.

Once the parameter l is fixed by a user, SUDAF builds space $saggs_l(X)$ and precomputes the sharing relationships between every two symbolic aggregation states in $saggs_l(X)$. An excerpt of $saggs_2(X)$ is shown in Figure 4, where each symbolic aggregation state is depicted as a node labeled with its expression (the meaning of edges in Figure 4 is explained later). As it can be observed in Figure 4, the space $saggs_2(X)$ is organized in three levels, where each level i, with $i \in \{0, 1, 2\}$, contains the symbolic states of the form $\sum_{\oplus} sf_{\bar{p}}(x_i)$ with $|sf_{\bar{p}}| = i$. Figure 4 shows all the symbolic states of level 0 and 1, and some states of level 2.

5.3 Organizing the space $saggs_l(X)$

We briefly discuss the organization of $saggs_l(X)$, w.l.o.g., focusing on the case $l = 2$. In the sequel, we first consider that the input multiset X contains only positive values, i.e., $X \in \mathcal{M}(\mathbb{Q}_+)$, then we extend the results to the case where X contains both negative and positive values. We represent the sharing relationships between symbolic states in $saggs_2(X)$ using a digraph $G = (V, E)$ where the set of vertices $V = saggs_2(X)$ is the space $saggs_2(X)$ and the set of edges $E \subseteq V \times V$ represent the sharing relationship, i.e., $(ss', ss) \in E$ if and only if ss' shares ss. Figure 4 depicts the digraph associated with the space $saggs_2(X)$. We distinguish between two kinds of sharing relationships in G (two types of edges are depicted in Figure 4). The first one is called *strong relationships* and relates two symbolic states (ss', ss) if ss' shares ss without requiring any condition on the parameters. The second one is called *weak relationships* and relates two symbolic states (ss', ss) if ss' shares ss under some conditions defined over the parameters of ss and ss'. For example, since any instance of $\sum px_i$ shares any instance of $\prod p^{x_i}$, then $\sum px_i$ and $\prod p^{x_i}$ have a strong sharing relationship denoted as $\sum px_i \rightarrow \prod p^{x_i}$. As another example, the state $\sum x_i^p$ shares $\sum p_2 x^{p_1}$ with the condition $p = p_1$, then $\sum x_i^p$ and $\sum p_2 x^{p_1}$ have a weak sharing relationship denoted as $\sum x_i^p \xrightarrow{p=p_1} \sum p_2 x^{p_1}$.

We observed that in the space $saggs_2(X)$, the sharing relationships are *equivalence relations*. For example, $\sum px_i \leftrightarrow \prod p^{x_i}$ and $\sum x_i^p \overset{p=p_1}{\longleftrightarrow} \sum p_2 x^{p_1}$. Consequently, the space $saggs_2(X)$ can be partitioned into *equivalence classes*. Intuitively, for a symbolic state ss, its associated equivalence class, denoted $[ss]$, is made of the set of symbolic aggregation states that shares (and are shared by) ss. For example, as depicted in Figure 4: $[\sum x_i] = \{\sum x_i, \sum px_i, \prod p^{x_i}, \prod p_1^{p_2 x_i}\}$ and $[\sum x_i^p] = \{\sum x_i^p, \sum p_2 x_i^{p_1}\}$.

We select a unique element in each equivalence class $[ss]$ to be a *representative* of the class, which is denoted as $rep([ss])$ and depicted as a shaded node in Figure 4. It is clear that, given an equivalence class $[ss]$, one only needs to focus on the instances of its representative $rep([ss])$ since they are able to compute an instance of any other element in $[ss]$.

We simplify G presented in Figure 5 based on the equivalence relations derived from the sharing relationships. More precisely, it is only necessary for any state $ss \in saggs_2(X)$ to store such a sharing relationship $ss \rightarrow rep([ss])$, or $ss \xrightarrow{pcon} rep([ss])$ with a parameter condition ($pcon$). Consequently, when an instance s of ss is given, we use an edge $ss \rightarrow rep([ss])$, or $ss \xrightarrow{pcon} rep([ss])$ to get a cached instance of $rep([ss])$ to compute s.

Extension to an arbitrary multiset. When a multiset X contains negative values, instances of some symbolic states in $saggs_2(X)$ do not exist, which will cause the miss of sharing opportunities. We take $\sum log_p x_i$ as an example to explain the issue. As we know that, an instance $\sum ln(x_i)$ of $\sum log_p x_i$ can only be computed over the positive domain, such that the caches for $\sum log_p x_i$ are empty in this context. To deal with this issue, we separate input values from their signs. Specifically, we translate an input multiset $X = \{x_1, \ldots, x_n\}$ to the following multiset $\hat{X} = \{(|x_1|, sgn(x_1)), \ldots, (|x_n|, sgn(x_n))\}$, where $|x_j|$ denotes the absolute value of x_j and $sgn(x_j)$ is its sign. Then, we keep in the cache such a result $(\sum ln|x_i|, \prod sgn(x_i))$ for $\sum log_p x_i$. By this way, a new aggregation state $\sum ln(x_i^2)$ can still be computed using the cache $(\sum ln|x_i|, \prod sgn(x_i))$ that is stored for $\sum log_p x_i$.

6 EXPERIMENTAL EVALUATION

We implemented a SUDAF prototype in Java and Scala, which can be used on top of PostgreSQL (through JDBC) and Spark SQL. The SUDAF prototype also comes equipped with a UDAF editor that enables users to write SUDAF-compatible UDAFs and integrate them in SQL queries.

The general scheme of our experiments is the following. We select 3 query models, and we instantiate each query model using 11 aggregations. We simulate the 11 instances of each query model coming in 2 different orders, i.e., two different sequences of

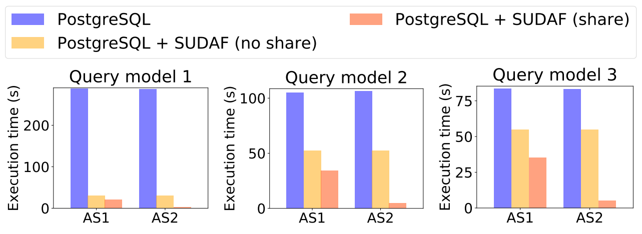

Figure 6: Total execution time of each query sequence in each query model.

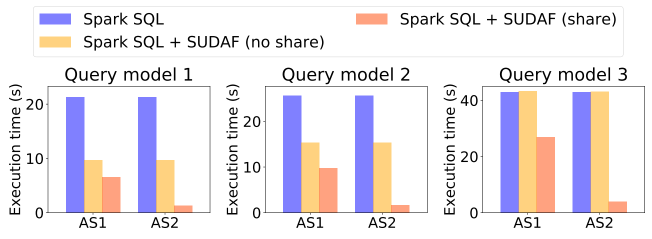

Figure 7: Total execution time of each query sequence in each query model.

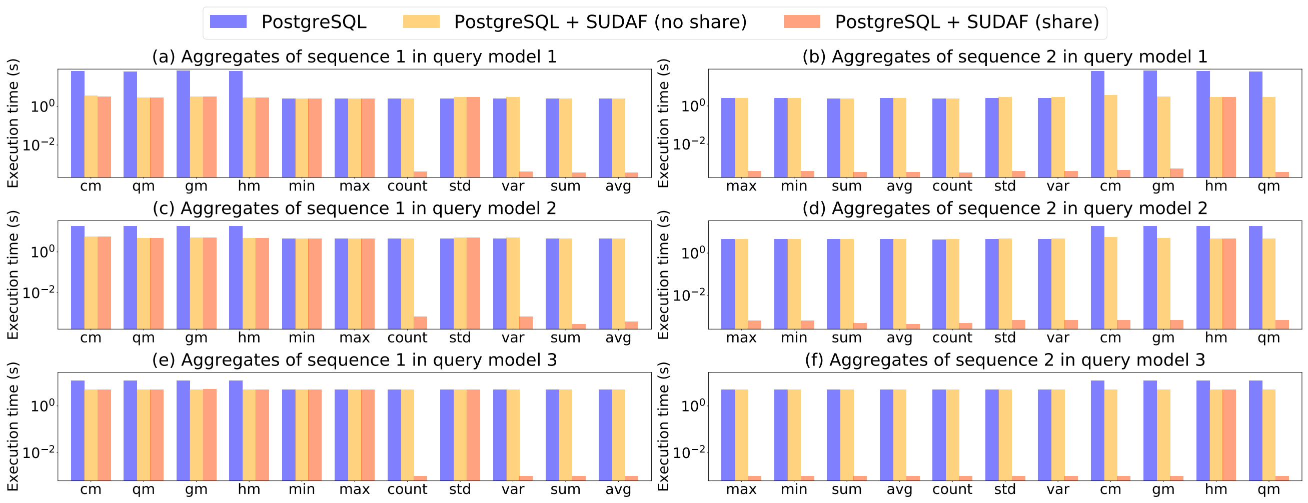

Figure 8: Execution time in PostgreSQL of each query in each query sequence.

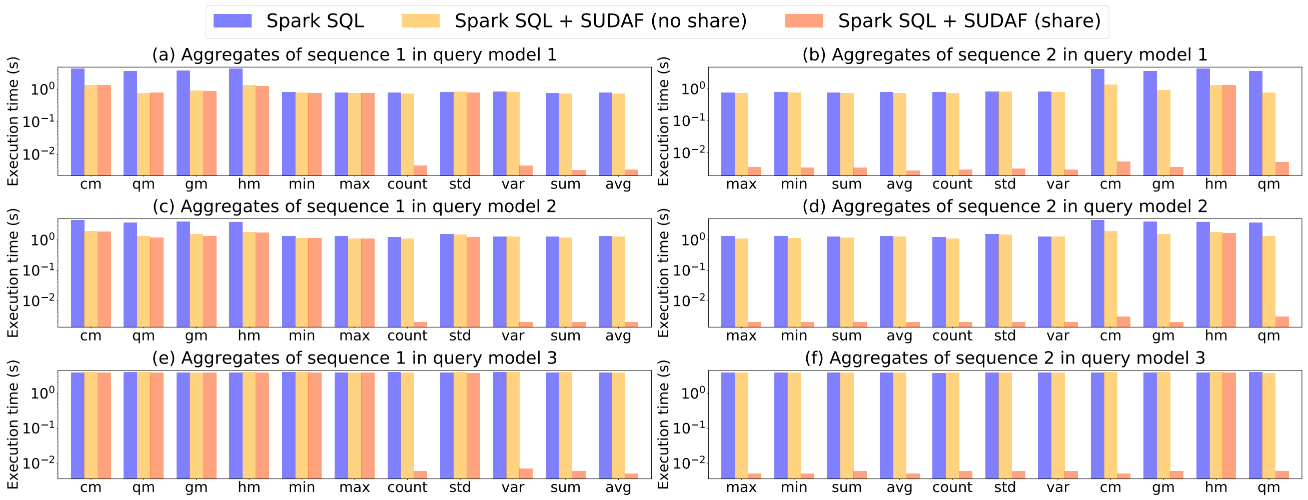

Figure 9: Execution time in Spark SQL of each query in each query sequence.

queries. Thus, the tested workload consists of 6 query sequences, where each sequence has 11 queries. We execute the query sequences in three technical contexts (i) PostgreSQL and Spark SQL, (ii) SUDAF without the sharing functionality, and (iii) SUDAF with the sharing functionality. In the PostgreSQL environment (case (i)), the aggregations are either PostgreSQL built-in or hard-coded user-defined functions, and similarly for the Spark SQL environment. PostgreSQL UDAFs are created using PL/pgSQL, and Spark SQL UDAFs are created using the UserDefinedAggregateFunction interface in Scala code. In the SUDAF environment (cases (ii) and (iii)), UDAFs are provided as mathematical expressions and used in the SQL queries. And in case (iii) of SUDAF, the precomputed sharing relationships in $saggs_2(X)$ are exploited to reuse cached aggregation states to compute new ones. In SUDAF sharing environment, we prefetch a moment sketch (MS) [16, 26] under one of the two selected query orders. At the end of this section, we also present a scenario of running a random sequence of 200 queries in the Spark SQL context.

Our main findings are twofold. First, we observed that SUDAF without sharing outperforms both PostgreSQL and Spark SQL despite the overhead in SUDAF due to the analysis and decomposition of UDAF expressions. The main reason that explains these performances comes from the fact that rewriting of UDAFs by SUDAF, which is based on canonical forms, leads to implementations that use PostgreSQL or Spark SQL built-in functions, these later ones being much faster than PostgreSQL or Spark SQL UDAFs. The second finding is SUDAF with sharing outperforms both PostgreSQL and Spark SQL. In particular, the fine-grained unit of caching used in SUDAF improves the sharing possibilities and increases the gain brought by sharing.

Experiment setup. All experiments of Spark SQL are performed on a cluster with 1 master node and 6 worker nodes, running Ubuntu server 16.04, Spark 2.2.0 and Hadoop 2.7.4. The master node has a processor of 6 cores (XEON E5-2630 2.4GHz), 16 GB of main memory and 160 GB of disk space, and every worker node has a processor of 4 cores (XEON E5-2630 2.4GHz), 8 GB of main memory and 80 GB of disk space. All experiments on PostgreSQL are only performed on the master node running PostgreSQL 11.4.

Query models. The three query models used in experiments are illustrated below, where AGG represents an aggregation.

```
-- Query model 1
SELECT AGG(internet_traffic) FROM milan_data;
-- Query model 2
SELECT square_id, AGG(internet_traffic) FROM milan_data
GROUP by square_id ORDER by square_id LIMIT 20;
-- Query model 3, the TPC-DS query 7 when AGG is avg
SELECT i_item_id, AGG(ss_quantity) agg1, AGG(ss_list_price) agg2,
       AGG(ss_coupon_amt) agg3, AGG(ss_sales_price) agg4
FROM   store_sales, customer_demographics, date_dim, item, promotion
WHERE  ss_sold_date_sk = d_date_sk and
       ss_item_sk = i_item_sk and
       ss_cdemo_sk = cd_demo_sk and
       ss_promo_sk = p_promo_sk and cd_gender = 'M'
       and cd_marital_status = 'S' and
       cd_education_status = 'College' and
       (p_channel_email = 'N' or p_channel_event = 'N')
       and d_year = 2000
GROUP BY i_item_id ORDER BY i_item_id LIMIT 100;
```

Datasets. The first two query models are evaluated on the Milan dataset [22] and the third query model is evaluated on the TPC-DS [27] dataset. For the experiments of PostgreSQL, the Milan dataset consists of 72.6 million rows in total and the TPC-DS dataset comes with scale = 20. For the experiments of Spark SQL, the Milan dataset consists of 319 million rows in total and the TPC-DS dataset comes with scale = 100. All data files in Spark SQL experiments are in Parquet format.

Aggregate functions. We use the following 11 aggregate functions to instantiate our query models: cubic_mean (cm), quadratic_mean (qm), geometric_mean (gm), harmonic_mean (hm), min, max, count, sum, average (avg), standard deviation (std), variance (var). In the used PostgreSQL and Spark SQL version, all of these functions are built-in functions except the functions cm, qm, gm and hm which are implemented using PL/pgSQL in PostgreSQL and using *UserDefinedAggregateFunction* interface in Scala code in Spark SQL.

Query sequences. We instantiate each query model using each of the 11 aggregations and define the following two sequences of query executions for each instantiated query model:
AS1 = [cm, qm, gm, hm, min, max, count, std, var, sum, avg]
AS2 = [max, min, sum, avg, count, std, var, cm, gm, hm, qm]
Thus, we obtain 6 query sequences in total, where each query sequence is made of 11 aggregate queries. In the SUDAF sharing environment (cases (ii)) with the sequence AS2, we prefetch a moment sketch (MS) [16, 26] with parameter k = 10, which consists of a set of aggregate functions ($min, max, count, \sum x_i, ..., \sum x_i^k, \sum ln(x_i), ... \sum ln^k(x_i)$) and can be used to approximate a percentile, e.g., median.

Experimental results. We executed the 6 query sequences on PostgreSQL or Spark SQL, SUDAF without sharing, and SUDAF with sharing, and we report the execution time of every query. In scenarios with sharing, we use precomputed sharing relationships of symbolic aggregation states in $saggs_2(X)$, and we also add three additional relationships for SQL standard aggregates, max, min, and count, that they share themselves. Note that in the reported results we do not take into account the overhead needed to precompute sharing relationships in $saggs_2(X)$ which is part of the initialization of SUDAF and takes 110 *ms*. However, the overhead due to the cache access is included in the global execution time reported for each query. This overhead is about 2 *ms* for query model 1 or 2, and about 5 *ms* for query model 3. Moreover, the prefetching of a moment sketch is a preprocessing step in the aggregate sequence AS2, and the corresponding time is not taken into account. In the context of PostgreSQL, the prefetching time is 13.06 *s* for query model 1, 15.16 *s* for query model 2, and 14.53 *s* for query model 3. In the context of Spark SQL, the prefetching time is 1.87 *s* for query model 1, 2.17 *s* for query model 2, and 3.82 *s* for query model 3.

The total execution time of each query sequence in each query model is presented in Figure 6 for the case of PostgreSQL and in Figure 7 for the case of Spark SQL. We observe that PostgreSQL or Spark SQL (respectively, SUDAF without sharing) always have the same execution time for the two sequences of the same model. Also, we observe that SUDAF without sharing outperforms both PostgreSQL and Spark SQL in all the considered scenarios except query model 3 in Spark SQL (the reason is explained later). SUDAF with sharing shows the best performances, whatever the considered sequence or query model. In the sequel, we discuss the execution time of every individual query depicted in Figure 8 and 9 for the cases of PostgreSQL and Spark SQL.

SUDAF without sharing. In this scenario, SUDAF only rewrites aggregations to built-in ones and it does not share computations in processing query sequences. For the case of PostgreSQL, compared to PostgreSQL UDAF queries, SUDAF speeds up UDAF queries up to 20X in query model 1 (Figure 8 (a) and (b)), 4X in query model 2 (Figure 8 (c) and (d)), and 2X in query model 3 (Figure 8 (e) and (f)). For the case of Spark SQL, compared to Spark UDAF queries, SUDAF speeds up UDAF queries up to 3X in query model 1 (Figure 9 (a) and (b)), 2X in query model 2 (Figure 9 (c) and (d)), and have identical query time in query model 3 (Figure 9 (e) and (f)). The major reason for this improvement is that SUDAF rewrites queries with UDAFs to queries with partial aggregations that can be evaluated using PostgreSQL or Spark SQL built-in functions, which are faster compared to PostgreSQL or Spark UDAFs. The performance improvements of such a rewriting depends on the number of data to be aggregated. The instances of query model 1 have the highest number of values to be aggregated while the instances of query model 3 have the smallest number of values as aggregation inputs. Therefore, for the case of query model 3, the difference between SUDAF only with the rewriting functionality and Spark SQL is less noticeable.

SUDAF with sharing. In this scenario, SUDAF rewrites aggregations to built-in ones and shares the computation results of partial aggregations in every query sequence. For the sequence AS1, we observe in Figure 8 (a), (c) and (e) and in Figure 9 (a), (c) and (e) that for all the considered query models the computation times of count, variance (var), sum and average (avg) decrease drastically w.r.t. the no sharing option. This is because SUDAF

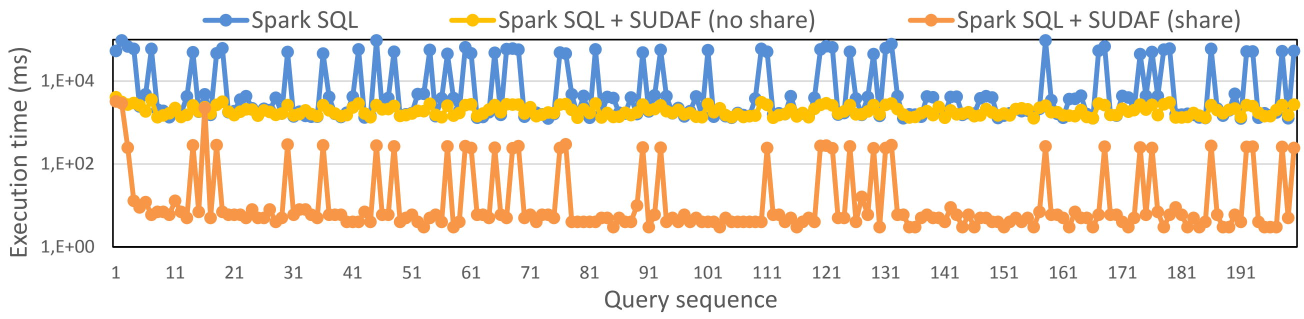

Figure 10: Execution time in Spark SQL of a random sequence of 200 queries.

is able to reuse cached results from earlier aggregates in the sequence AS1. As it can be observed in Figure 8 (b), (d) and (f) and in Figure 9 (b), (d) and (f), the sequence AS2 is more advantageous for sharing due to the prefetched moment sketch. Indeed, the moments sketch consists of 33 partial aggregates which are cached by SUDAF and reused for the computation of all the remaining aggregations in the sequence AS2 except the harmonic mean (hm). Computing queries with the harmonic mean in AS2 still requires data access since the aggregation state $\sum x_i^{-1}$ in the harmonic mean is not evaluated in previous computing.

Random query sequence. We present in Figure 10 the scenario of running a random sequence of 200 queries in Spark SQL, which are instances of the query model 2 having the following 16 aggregate functions: (min, max, sum, avg, harmonic_mean, quadratic_mean, cubic_mean, geometric_mean, stddev, variance, skewness, kurtosis, approx_median, count, approx_first_quantile, approx_thrid_quantile). The benefits of using SUDAF in this scenario are more obvious (the orange line in Figure 10).

7 RELATED WORKS

There is a wealth of research on queries with aggregations, earlier works focusing on standard aggregations (e.g., [8, 9, 12, 18, 19, 35]) and then extended to UDAFs (e.g., [6, 10, 20, 24]). Partial aggregation appeared as an essential technique used to improve the performances of aggregations: instead of computing aggregations on a complete multiset, applying aggregations on subsets and merging intermediate results is an efficient solution in numerous scenarios. In OLAP applications, partial aggregation enables computing aggregation by merging summaries of cells with different granularities across multi-dimensional data, thereby allowing aggregate queries to be executed on pre-computed results instead of base data [8]. In join-aggregate query optimization, partial aggregation enables to compute group-by aggregation before joins to decrease the size of intermediate results [35], i.e., the eager group-by technique. In distributed computing, partial aggregation allows to push the execution of aggregation before transferring data on networks [36], thereby decreasing the overhead of data shuffling, which is usually called initial reduce in MapReduce-like frameworks. An original classification of aggregations [18] distinguishes between algebraic aggregations having partial aggregation with fixed size results, and holistic functions where there is no constant bound on the storage size for partial aggregation. Several properties are proposed to have partial aggregations from algebraic aggregations, such as decomposable aggregation [35], commutative semi-group aggregation [11] and associative and commutative aggregation [36].

Most modern data management and analysis systems support UDAFs (e.g., [1, 2, 4, 21, 28, 29]). In the original MapReduce (*MR*) framework [3, 14], UDAFs are implemented according to the *MR* paradigm without requiring any specific template. This makes the semantics of UDAFs hidden in the implementations and hinders optimization possibilities (e.g., reordering with relational operators and other UDAFs [20]). However, in most of recent systems, users define UDAFs using an *IUME* pattern (initialize function, update function, merge function and evaluate function). Although such an approach enables exploiting the properties of the merging functions to allow optimization based on partial aggregations, e.g., parallel computation of the merging functions, part of the UDAF semantics still remains hidden in the implementation, which hampers the opportunity of aggregate sharing. In addition, implementing UDAFs in existing frameworks may be a tedious task since it is up to the user to map a UDAF to the implementation paradigm (*MR* or *IUME*). We build on a canonical form of UDAFs proposed in [10] to design SUDAF by allowing users to specify UDAFs as mathematical expressions and then automatically generate canonical forms of UDAFs which are compliant with the $IUME$ pattern. Consequently, with SUDAF a user does not need to handle the problem of how to obtain partial aggregations from UDAFs. Moreover, SUDAF knows the semantics of partial aggregations (primitive functions used in partial aggregation) which extends the optimization opportunities.

Different facets of the sharing problem have been studied in the literature, e.g., rewriting aggregate queries using materialized views [11, 12], reusing caches to accelerate multi-dimensional queries [8, 15], or identifying overlapping processing for multiple aggregate queries with various selection predicates [19], group-by attributes [9] and sliding-windows [5, 23]. Most of these approaches focus on the data dimension, i.e., they consider the problem of sharing the same aggregation across different ranges or granularities of data. Our work does not consider the data granularity dimension where existing techniques, e.g., [15, 33], can be used to extend SUDAF in this direction. [10, 11] proposes to predefine computation rules for sharing between different aggregations. However, SUDAF automatically identifies sharing opportunities on partial aggregates across different UDAFs.

The closest work to SUDAF is DataCanopy [33]. DataCanopy caches the basic aggregates (e.g., $\sum x_i$, $\sum x_i^2$ and $\sum x_i y_i$) of statistical measures and then is able to reuse them for queries with various range predicates. Basic aggregates are maintained at a granularity of a chunk (smallest portion of data), and DataCanopy allows sharing across queries covering overlapping chunks. In DataCanopy, basic aggregates are fixed in advance and the decomposition of an aggregate into basic ones is predefined (see Table 1 of [33]). We discuss the differences between DataCanopy and SUDAF as follows. From a theoretical standpoint, the sharing condition in SUDAF allows having a scalar function between two aggregates (see Theorem 4.1), which is more general compared to sharing identical basic aggregates in DataCanopy. From a practical standpoint, our approach is complementary to DataCanopy in the sense that DataCanopy deals with sharing w.r.t. the data dimension and proposes a static approach for sharing on the aggregation dimension, whereas SUDAF extends its static approach to a dynamic one w.r.t. the aggregation dimension. More precisely, the sharing opportunities w.r.t the aggregation dimension are automatically identified in SUDAF, which do not require any decomposition rule and are not restricted to a fixed set of aggregates. For example, if we restrict the attention to the set of predefined basic aggregates introduced in [33], the execution of a geometric mean ($gm(X) = exp(\frac{\sum ln(x_i)}{count}, \forall x_i > 0)$ cannot take any benefit from the static caching solution used in DataCanopy (i.e., cannot reuse the basic aggregates stored in the cache and do not lead to any new cached computation results). In contrast, SUDAF can reuse partial aggregates from the cache to compute *gm* and if not possible, it caches the partial aggregates $(\sum ln(x_i), count)$ after computing *gm* from base data. To obtain similar behavior, one needs to explicitly define additional basic aggregates in DataCanopy together with the appropriate decomposition rules for *gm*. In addition to being cumbersome, such a task requires to know in advance the query workloads that will be issued.

8 CONCLUSIONS AND FUTURE WORKS

In this paper, we introduce the design principles underlying SUDAF, a framework that provides a set of primitive functions together with a composition operator to enable users to define mathematical expressions of their UDAFs. SUDAF comes equipped with the ability to automatically rewrite partial aggregations, which are factored out from mathematical expressions of UDAFs, using built-in aggregates, and supports efficient dynamic caching and sharing of partial aggregates. We showed experimentally the benefits of rewriting partial aggregates of UDAFs using built-in functions and sharing partial aggregates to improve the performances of queries with UDAFs.

In this paper, we focus on the issue of *how to compute a UDAF from another UDAF*. In practice, to share computation results of different queries, we need to consider the data dimension, e.g., different range queries, or different OLAP queries. Sharing over data dimension has been extensively studied in existing works [15, 33]. The general idea is to split cached query results using chunks. For the case of range queries, a chunk is a range predicate over an attribute. For the case of OLAP queries, a chunk is a region in a multi-dimensional space. Merging our sharing approach with such approaches, we can share computation results for different queries with different UDAFs. As another future work, we envision to exploit the fact that the semantics of UDAFs is known by SUDAF to investigate query optimization and query rewriting problems for join and group-by queries with UDAFs.

Tracing nested data with structural provenance for big data analytics

Ralf Diestelkämper Melanie Herschel

ralf.diestelkaemper|melanie.herschel@ipvs.uni-stuttgart.de

ABSTRACT

Big data analytics systems such as Apache Spark natively support nested data formats since they offer operators to manipulate nested lists and complex types. Compared to flat data, nested data introduces further complexity and sources of error, e.g., when developing data processing pipelines, performing auditing tasks, or performance tuning. To ease such tasks, we propose a provenance-based solution tailored to nested data processing in big data analytics systems. Unlike previous solutions, it combines (i) tracing provenance of *nested data* with (ii) *efficient* and *scalable* provenance processing, leveraging a newly proposed *structural provenance* that traces structural manipulations through data processing pipelines in addition to data. We provide a formal definition of structural provenance, as well as methods to efficiently capture and succinctly backtrace it. We implement them in our Pebble system in Apache Spark and validate its performance and usefulness on up to 500GB of real-world data.

1 MOTIVATION

Big data analytics systems such as Apache Spark or Flink are frequently the means of choice to build data processing pipelines that process large quantities of nested data. These pipelines transform nested lists and complex types stored in nested data formats like JSON, protocol buffer, or parquet. Provenance solutions that capture meta-data about the data processing [14] have proven to be useful for analyzing the internals of data processing pipelines, e.g., for debugging purposes. These solutions typically have two phases, a provenance capture phase to collect the meta-data and a provenance query phase to analyze the meta-data. For big data analytics systems, we distinguish two categories of provenance solutions: (i) Efficient and scalable solutions that track individual, flat data items (i.e., tuples) from the input to the output over each execution step [15–17, 22]. They capture so-called lineage or why-provenance [7]. (ii) System prototypes that compute provenance polynomials of nested data [2, 28]. They capture how-provenance, which provides both the input items contributing to the result and the data combination process an item undergoes.

Solutions of the first category fail to track nested items accurately. Solutions of the second category do not efficiently scale to big data processing pipelines. To capture the how-provenance, these solutions propagate the growing provenance polynomial through the entire pipeline or require annotation of each nested element, which imposes a very high and practically unacceptable overhead [16, 17]. Further, these solutions have to offload the provenance to external tools to query the captured provenance. Thereby, they miss potential performance and usability benefits compared to solutions that are fully integrated into the big data analytics or data-intensive, scalable computing (DISC) system.

We, therefore, present a *DISC system integrated* provenance solution for nested data that is as *efficient* and *scalable* as solutions of the first category while, at the same time, at least as *accurate* as solutions of the second category [9]. Our solution leverages our newly defined *structural provenance* to provide both features.

Structural provenance records identifiers for top-level data items only. For attributes and nested data items, it captures paths on a schema level. To provide accurate provenance when queried, it employs these identifiers and paths to trace back individual nested items at attribute level. Capturing paths instead of identifier annotations for nested data further allows us to distinguish between paths that are used for access (e.g., during filtering) or manipulation (e.g., during flattening). We can thereby differentiate contributing attributes, i.e., attributes needed to reproduce a result item, and influencing attributes that are accessed during data processing but not required to reproduce a result. This distinction, which is unique compared to existing data provenance models, qualifies structural provenance for use-cases beyond debugging such as auditing or determining data-usage patterns for partitioning, data compression, and workload optimization.

Auditing. Auditing aims at identifying and analyzing data breaches. These breaches commonly stem from attacks of company insiders who extract sensitive data by querying data and leaking the query result. Auditing solutions are designed to identify both these insiders and the customers whose data are leaked [19]. To address the latter challenge, the solutions typically leverage some sort of data provenance. It serves to identify those input tuples that are exposed in a leaked query result. However, after the European Union has introduced the European general data protection regulation *GDPR* [26], European companies are not only required to identify the customers (tuples) whose data are leaked, but also which of their data are leaked (i.e., attributes such as name, address, or payment details). Structural provenance precisely provides the attributes and items in nested collections that contribute to a query result. Unlike existing data provenance solutions, it further reveals which attributes are not exposed in the result but have influenced it to create awareness for reconstruction attacks.

Data-usage patterns. Data-usage patterns reveal frequently used subsets of the input data over a query workload. These patterns serve to optimize data layout and compression or to improve query performance [25]. State-of-the-art scalable provenance solutions for DISC systems can identify subsets of the input data that are frequently used. This knowledge allows for horizontal (or row-based) data partitioning and distribution. Structural provenance further provides all the information needed for vertical (or column-based) partitioning since it reveals which attributes and nested items are accessed or manipulated. It even provides insights on attribute combinations that are frequently used together for data layout optimizations.

Capturing provenance imposes runtime and space overhead during pipeline execution. The mentioned use-cases are performed infrequently. Thus, keeping the overhead low during pipeline execution is essential to ensure efficiency and scalability. During the *provenance capture* phase, a system can typically opt for computing and storing the provenance of all processed data (*eager* approach) or decide to capture it on demand when users query the provenance (*lazy* approach). Consequently, during the *provenance query* phase, retrieving the desired provenance is more or less time-consuming. We consider the provenance capture and provenance query phases holistically. To this end, we devise a meet-in-the-middle approach that eagerly collects the necessary "pebbles" (i.e., identifiers and paths on schema level) during pipeline execution to later reconstruct or backtrace attribute-level provenance of nested data at query time. Our evaluation shows that capturing structural provenance introduces comparable overhead to state-of-the-art lineage solutions in DISC systems [17], while providing attribute-level precision.

This paper also presents the first provenance solution for nested data that seamlessly integrates into a big data analytics system (Apache Spark in our implementation). Existing solutions [2, 28] require offloading captured provenance for querying to separate, non-distributed applications. This has three drawbacks: (i) It prevents adopting a holistic provenance capture and querying approach to keep capture and query overhead reasonable; (ii) it forces users to leave their familiar environment; and (iii) it prevents scalable provenance querying.

Contributions and structure. To summarize, this paper presents research on processing structural provenance in big data analytics systems to accurately trace nested data in an efficient, scalable, and integrated way. This approach enables novel use-cases that arise in the context of big data processing. After discussing a running example in Sec. 2 and related work (Sec. 3) this paper covers the following contributions:

- **Structural provenance (Sec. 4).** We present a novel provenance model for nested data that tracks structural manipulations in addition to data dependencies, and distinguishes between data access and manipulation to support use-cases beyond debugging.
- **Lightweight structural provenance capture (Sec. 5).** We discuss how to capture structural provenance in big data analytics programs composed of filter, select, map, join, union, flatten, grouping, nesting, and aggregation operations. The capture is devised to incur a minimal overhead compared to the capture of flat provenance in DISC systems.
- **Backtracing for provenance query processing (Sec. 6).** We formalize the backtracing algorithm used at provenance query time. As input, users provide a tree-pattern that, upon its scalable execution, identifies data items for which provenance is requested. The backtracing algorithm computes provenance for these items based on the previously captured information.
- **Implementation and evaluation (Sec. 7)**. We implement our contributions in Pebble [9], our system for integrated provenance capturing and querying within Apache Spark. We conduct a quantitative evaluation of runtime and space overhead incurred by our solution on two large real-world data sets, validating the scalability of our solution. In comparison to the state-of-the-art lineage solution Titian [17], Pebble has comparable runtime and space overhead. However, as our workload shows, Pebble provides sufficient insight to support the above use-cases, unlike other solutions.

2 RUNNING EXAMPLE

To distinguish our research from related work and for illustration, we use a running example based on Twitter data. Among its roughly 1000 attributes, we focus on the tweeted *text*, the *user* tweeting, the *user_mentions* in the tweet, and the *retweet_cnt*. The input data is nested as shown in Tab. 1 (ignore colors and number annotations for now). This sample data is processed in the big data processing pipeline shown in Fig. 1. It results in a list of distinct users associated with tweets that they authored or were mentioned in, as shown in Tab. 2. The upper branch of the pipeline describes how authoring users become part of the result. Their tweets require a *retweet_cnt* of 0 before the pipeline reduces them to the *text*, *id_str*, and *name*. The lower branch processes tweets mentioning users. First, it flattens the *user_mentions* attribute to select the tweeted *text*, *id_str*, and *name* of each mentioned user. Then the pipeline unifies the results of both branches and groups by the user to aggregate the tweeted *texts* into a nested list.

In the result, a duplicate *Hello World* text occurs in the nested *tweets* of user *Lisa Paul*, short *lp*. To find out how this potential data quality issue occurred, we debug the pipeline by tracing back the duplicate texts in the context of user *lp*, which are highlighted in dark-green in Tab. 2. The solution presented in this paper returns the dark- and medium-green items in Tab. 1. The dark-green items are contributing data. They suffice to reproduce the dark-green items in the result. The medium-green items reveal which attributes potentially influence the result of the pipeline.

If trivially extended to nested data, scalable lineage solutions [15–17, 22] provide all input tweets that contain the user *lp*. They are highlighted in light-grey in the input. In reality, a user typically authors more than a handful of tweets and is potentially mentioned in more than a million tweets. These tweets would all be in the provenance returned by the lineage solutions. They mask the actual two tweets causing the duplicate text.

PROVision [28] supports the unnesting of data but does not explicitly support the nesting of data. Extending it with nesting requires a list collection UDF *cl*, which yields the following provenance polynomial for the entire result item 102 in Tab. 2:

$$(p_1+p_{12}+p_{17}+(p_{29}\cdot P_{flatten}(p_{29}\cdot[0])))\cdot$$
$$P_{cl}((p_1+p_{12}+p_{17}+(p_{29}\cdot P_{flatten}(p_{29}\cdot[0]))),(\langle p_1\rangle+\langle p_{12}\rangle+\langle p_{17}\rangle+\langle(p_{29}\cdot P_{flatten}(p_{29}\cdot[0]))\rangle))$$

	text	user		user_mentions		retweet_cnt
		id_str	name	id_str	name	
1	Hello @ls @jm @ls^{2}	lp^{3}	Lisa Paul^{4}	ls^{5} jm^{7} ls^{9}	Lauren Smith^{6} John Miller^{8} Lauren Smith^{10}	0^{11}
12	Hello World^{13}	lp^{14}	Lisa Paul^{15}			0^{16}
17	Hello World^{18}	lp^{19}	Lisa Paul^{20}			0^{21}
22	This is me @jm^{23}	jm^{24}	John Miller^{25}	jm^{26}	John Miller^{27}	0^{28}
29	Hello @lp^{30}	jm^{31}	John Miller^{32}	lp^{33}	Lisa Paul^{34}	1^{35}

			Hello World
			Hello World
			Hello @lp
103	jm	John Miller	Hello @ls @jm @ls
			This is me @jm
			This is me @jm

Table 2: Example result data

Essentially, the first line tells us that the result item is based on the source tuples annotated with 1, 12, and 17, denoted as p_1, as well as p_{12}, p_{17} (all these are processed by the upper branch of the pipeline in Fig. 1), and p_{29}, with some of its data flattened out during processing (corresponds to the lower part of the pipeline). The second line makes use of our extension and describes how data is combined by the remainder of the pipeline where the tuples mentioned above are grouped and aggregated. The example shows that the provenance is very verbose while not precisely tracing the dark-green data items of the user question. This is the case since it collects tuple-based provenance polynomials only.

Lipstick [2] traces provenance polynomials for each nested item. This allows pinpointing the dark-green nested values *Hello World* and *lp* correctly. However, Lipstick requires annotating all values, not just the tuples, e.g., 35 rather than 5 annotations, as indicated by the superscript italic numbers in Tab. 1. This entails a significant runtime and space overhead, rendering the solution impractical when needing to scale to large volumes of data.

We also differentiate structural provenance from where-provenance [4], which determines where a (nested) result value is copied from. In our example, the where-provenance (extended to the processing pipelines we consider) would include, for the value *lp* the "cells" with superscript annotation 14, 19, and 33 of Tab. 1. This is combined with the where-provenance of the *Hello World* result values via product. The result is not sufficiently accurate because it cannot capture that the dark-green values of the output need to be traced within their common context.

No existing solution allows recognizing (i) that the *user* attribute is unnested and nested again, (ii) that the *id_str*, *lp*, and the *text* attribute *Hello World* are subject to different, independent, structural manipulations, and (iii) that the medium-green *retweet_cnt* and *name* values in Tab. 1 are accessed for filtering and grouping, respectively. Even though these values are not needed to reproduce the queried result, they are influencing the result, which is valuable information in certain use-cases. Structural provenance captures all this information since it captures not only data dependencies but also path dependencies.

To get an understanding of querying structural provenance, consider the right tree in Fig. 2. The string labels of tree nodes denote attribute names whereas numbers refer to provenance ids (e.g., 102) or positions in nested collections (e.g., 2 and 3). The displayed tree represents the structure associated with our sample user query. It encodes the path to user *lp* and the duplicate *Hello World* items in the context of top-level data item 102. Note that *name* is absent from this tree since it is not pertinent to the user query. Backtracing this tree yields the two trees on the left of Fig. 2. These distinguish between data items that contribute to the result (dark-green) and data items that influence it (medium-green). The nodes match the green items in Tab. 1. A closer look at the medium-green *name* node reveals that this node influences the queried result since it is accessed for grouping

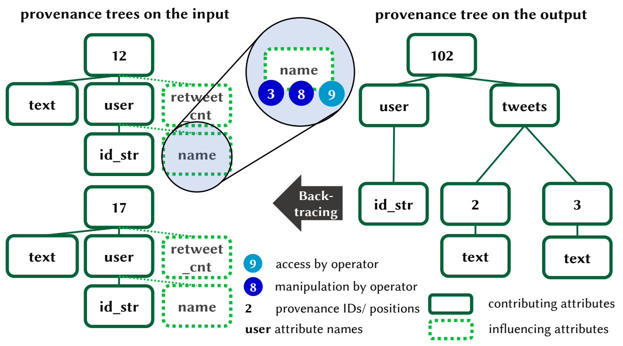

Figure 2: Example provenance trees. Tracing the tree on the right back to the input yields the trees on the left

(light-blue 9). Similarly, the *retweet_cnt* influences the result since it is accessed for filtering. Further, the *name* node undergoes structural manipulations at operator 3 and 8 (dark-blue).

3 RELATED WORK

This section generalizes the discussion of existing approaches that we provided along with the running example. We divide our discussion into research on data provenance in DISC systems and provenance models for nested data, summarized in Tab. 3.

3.1 Data provenance in DISC systems

Data provenance has been studied for various applications [14]. While the majority of approaches has focused on relational data processed by relational queries, first solutions have emerged for tracing provenance in DISC systems such as Titian [12, 16, 17] for Spark, Lipstick for PigLatin (Hadoop) [2], as well as RAMP [15], Newt [22], and PROVision [28] for multiple DISC systems.

Titian, RAMP, and Newt trace lineage of data items, i.e., they determine which top-level data items contribute to which output item. These solutions scale well but do not trivially extend to nested data. PROVision extends the provenance model for top-level data (or flat) items to also capture provenance of data items in nested collections. It lacks information on attribute level access. Lipstick is the only solution that supports provenance capture for nested data at attribute level. However, it requires annotations for each data value, not only the top-level data items. Structural provenance provides provenance on attribute level but requires annotation on top-level items only since it records access to attributes and nested data using paths. These paths are recorded on a schema level, saving space and runtime overhead.

All the above solutions except for Titian require offloading the provenance to an external tool. Titian integrates provenance querying directly into the DISC system. Thus, provenance queries can be integrated into a big data processing pipeline just like any other query. Our system extends Titian's integrated querying means with tree-patterns [13, 23] to address combinations of nested data items. Further, we present the first solution that tracks access and manipulation of attributes.

3.2 Provenance models for nested data

Focusing on nested data, at least three major directions to formalize provenance models have been researched: (i) models for why-, how-, and where-provenance, (ii) graph-based provenance models, and (iii) program slicing models.

For unions of conjunctive queries, Buneman et al. [4] define a why- and where-provenance model for nested data. This model

Table 3: Feature overview of related work

does not extend to the programs defining data analytics pipelines in DISC systems, like the one shown in Fig. 1, since they may include map or reduce functions or any other higher-order functions in general. To model the how-provenance of nested data, a semiring-model for a subset of XQuery has been proposed [10, 18]. However, this model does not include complex operations over nested data, such as aggregations. The only how-provenance model supporting aggregations that we are aware of applies to relational data only [3].

Lipstick [2], makes use of a graph model to describe the how-provenance. This model only applies semiring annotations where possible. It provides no formal model definition for aggregations, nesting, and flattening of nested data. Kwasnikowska and Acar et al. [1, 20] also employ a graph-based provenance model to track nested data items. These solutions are essentially limited to the operations defined in the Nested Relational Calculus (NRC) [5], which do not include aggregations or joins. Also, the reported implementation and evaluation (if any) indicate that they neither integrate nor scale sufficiently to apply on DISC systems.

All provenance solutions mentioned so far do not distinguish between access and manipulation as they focus on tracing data values. In that respect, the work closest to our structural provenance model is the program slicing model [6], which tracks provenance traces for NRC operators over nested data. To provide formal guarantees, the model is limited to a small set of semantically fully specified NRC operators. In practice, it is infeasible to provide semantics for all higher-order functions such as map operations, which allow for user-defined functions. Via trace slicing it is possible to query provenance for individual nested items. However, like the other described models, this model is designed to trace data values and manipulations of them rather than structural manipulations. It is not expressive enough to faithfully capture and query structural manipulations. Its implementation is not designed or evaluated for efficiency or scalability.

The final column of Tab. 3 summarizes the capabilities of our system, which we have highlighted previously. These capabilities are based on processing structural provenance, discussed next.

4 STRUCTURAL PROVENANCE

This section formalizes structural provenance. We first present the data model and the execution model to define the corresponding structural provenance model afterwards.

4.1 Data model

DISC systems process collections of typed nested data items, which we refer to as (nested) datasets. These datasets support positional access, and, thus, the handling of ordered datasets.

Definition 4.1. (*Nested dataset*) A nested dataset D comprises constants, data items, bags, and sets, denoted and typed as shown in Tab. 4. D is a list of data items $d_1, \ldots, d_n$ with or without duplicates (ordered bag vs. set), i.e., $D = B|S$. Each data item d is a list of $a_i : v_i$ pairs. Attribute names $a_1, ..., a_n$ are unique labels within each data item. Values $v_1, ..., v_n$ may be bags, sets, data items, or constants, i.e., $v = B|S|c|d$.

Name	Notation	Type $\tau(\cdot)$
Constant	c	$Int\|Double\|String\|\ldots$
Data item	$d = \langle a_1 : v_1, ..., a_n : v_n \rangle$	$\langle a_1 : \tau(v_1), ..., a_n : \tau(v_n)) \rangle$
Bag	$B = \{\{d_1, ..., d_n\}\}$	$\{\{\tau(d)\}\}, \forall d, d' \in B, \tau(d) = \tau(d')$
Set	$S = \{d_1, ..., d_n\} \| d_1 \neq \ldots \neq d_n$	$\{\tau(d)\}, \forall d, d' \in S, \tau(d) = \tau(d')$

Table 4: Notation and types for nested collections

The type of D is defined recursively based on the type of its building blocks as described in Tab. 4, where $\tau(\cdot)$ returns the type of its parameter. Bags and sets are restricted to containing elements of the same type.

Example 4.2. All data shown in our running example conform to the above definition. The result data of Tab. 2 has type:
$\{\{\langle user{:}\langle id\_str{:}String, name{:}String\rangle, tweets{:}\{\{\langle text{:}String\rangle\}\}\rangle\}\}$

To access the different components defined by the data model, we define *access paths*, inspired by XPath expressions [24] to navigate XML data. Provided a context data item d, an access path navigates to "deeper" data in the nested model. Given that the data model ensures the order of data items in lists, we also model positional accesses in paths.

Definition 4.3. (Access path w.r.t. d) In the context of a data item d, we define an access path p by $p = d.p'$, $p' = x \mid x.p'$, $x = a \mid a[i]$. Here, p' is the path accessing x either directly or recursively. The accessed x is either an attribute a in the schema of the context data item, evaluating to its value, or the i-th component of a, denoted $a[i]$, evaluating to the item at the i-th position of a's value. For the recursive definition of p', the context data item is updated to the item referred to by x.

For simplification, we denote a path p with context data item d by p^d when the context is not clear. We refer to the enumeration of all paths that exist in a context d as path set PS^d.

Example 4.4. Considering the data item d_{102} in Fig. 2, the path $d_{102}.tweets$ evaluates to a list of four data items. Path $d_{102}.tweets[2].text$ points to the first *Hello World* in that list.

4.2 Execution model

The execution model defines the processing semantics of data analytics programs like the one in Fig. 1. These programs process data complying with our data model. We model a program as a directed acyclic graph (DAG) of individual operators, such as filter, flatten, join, etc. Each operator has its own execution semantics.

Definition 4.5. (Operator) An operator O takes a set of datasets $I = \{I_1, \ldots, I_k\}$ as input and returns a single result dataset R. Inference rules describe the execution semantics of an operator O. O has a unique identifier, a type, and its arguments.

Definition 4.6. (Program execution model) Let $G(V, E)$ be a DAG. $V = \{O_1, \ldots, O_n\}$ is the set of algebraic operators and E the set

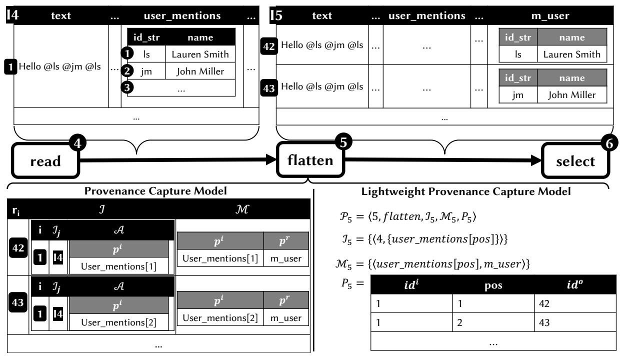

Figure 3: Provenance model and lightweight provenance capture applied on the flatten operator from the example

of directed edges that model the data flow. If and only if the result set R_i of O_i is in the set I_j of input datasets of operator O_j an edge $(O_i, O_j) \in E$ directed from O_i to O_j exists. While G may contain multiple source nodes (in-degree of 0), G has only one sink node (out-degree of 0), which outputs the final result dataset.

Example 4.7. The graph in Fig. 1 represents the execution model of our running example. The type and parameters of each operator are displayed inside the operator nodes. Further, each node is labeled with its identifier in the top right corner.

We abstract from a particular language to define the semantics of individual operators by extending the inference rules from [11] to describe the filter, select, map, join, union, flatten, grouping and aggregation operator with their semantics.

Example 4.8. We illustrate how inference rules work on our inference rule for a *join* operator:

$$\frac{\varphi(i,j) \Rightarrow \text{true}}{I_1.join[\varphi(i \in I_1, j \in I_2)](I_2) \Rightarrow \{\{\langle i,j\rangle \mid i \in I_1, j \in I_2\}\}}$$

The rule joins two input datasets I_1 and I_2 into a single result dataset. More precisely, the operator associates elements $i \in I_1$ with elements $j \in I_2$ based on a join condition ($\varphi(i,j) \rightarrow boolean$). With the precondition that φ evaluates to true, i.e., $\varphi(i,j) \Rightarrow$ true, the data item $\langle i,j\rangle$ becomes part of the result.

4.3 Provenance model

Our provenance model extends the program execution model described above by adding annotations to each node in G. More precisely, for each operator O represented by a node in G, it generates the result provenance $\mathcal{R}$ that contains the provenance of each result data item r_i in the result R of operator O.

Definition 4.9. (Result provenance w.r.t. result R of operator O) Let $\mathcal{R} = \{\rho_1, \ldots, \rho_n\}$ be the result provenance associated with $R = \{r_1, \ldots, r_n\}$. For each data item $r_i \in R$, we record the result data item provenance $\rho_i = \langle r_i, \mathcal{I}, \mathcal{M}\rangle$, where $\mathcal{I}$ is the provenance of input data items that contribute to r_i (see definition below) and $\mathcal{M}$ is a set of path pairs mapping access paths of input data items to paths of r_i to describe restructuring performed by O.

Definition 4.10. (Input provenance $\mathcal{I}$ w.r.t. result data item provenance ρ in result R of O) The input provenance $\mathcal{I}$ is a bag of triples $\langle i, I_j, \mathcal{A}\rangle$, where i is a data item from one of the input datasets of O, i,e., $i \in I_j, I_j \in I$, and $\mathcal{A}$ a set of paths recording the elements of i that are accessed by O to produce the result data item $r \in \rho$.

The above provenance model does not only contain information on the relationship between input and result data items of an operator (which is the previously mentioned lineage), it also records accesses and manipulations in $\mathcal{M}$ and $\mathcal{A}$ while transforming input items to result data items.

Example 4.11. To illustrate our model for structural provenance, we focus on the $flatten$ operator labeled 5 in Fig. 1. It unnests the nested items of attribute *user_mentions*. An excerpt from its input and output data is given at the top of Fig. 3. Black headers encode bag data types, light gray headers identify complex data items as nested data type. At the bottom left, Fig. 3 shows the provenance for the result items 42 and 43. The flatten operator derives item 42 from input item 1. It accesses path *user_mentions*[1] as recorded in $\mathcal{A}$. Further, it copies the first user of the *user_mentions* list (and implicitly, all paths in the path set $PS^{user\_mentions[1]}$) to the new item *m_user* as recorded in the mapping $\mathcal{M}$. Ignore the bottom right for now.

5 PROVENANCE CAPTURE

Based on the provenance model, we introduce inference rules describing the provenance capture of our supported operators. When the rules in Tab. 5 are annotated with a $*$, we extend an existing inference rule from [11]. Otherwise, we formalize the inference rule with and without provenance extension. Due to space constraints, we only show the complete set of inference rules with provenance. After explaining the map, flatten and aggregation rule, we show how we capture the structural provenance obtained from these rules efficiently.

5.0.1 Map. For the *map* operator, we assume that the function $\lambda(i)$ over input data item i returns a result of type data item, denoted as $\tau(\lambda(i)) \rightarrow \langle\ldots\rangle$. Given this precondition, without provenance capture, *map* returns the result of applying $\lambda(i)$, for each i in the input dataset I_1. The inference rule for the *map* operator in Tab. 5 additionally produces the provenance for each data item i. More formally, *map*, parameterized by a function λ, produces the result provenance $\mathcal{R}$, which is a bag of data items. Each data item extends the "normal" result of *map*, i.e., $\lambda(i)$ with two additional attributes: the input provenance $\mathcal{I}$ and mapping $\mathcal{M}$. For $\mathcal{I}$, the only input data item participating in producing an output data item $\lambda(i)$ is i, which originates from the single input dataset I_1. Because we generally do not know the internals of an arbitrary function λ, the set $\mathcal{A}$ is set to undefined, denoted by $\perp$. Thus, $\mathcal{I} = \{\{\langle i, I_1, \perp\rangle\}\}$. The structural mapping $M = \perp$ is also undefined because we have no knowledge of how elements from the input are restructured in the result.

Based on the rule for the *map* operator, we derive more general observations concerning our inference rules. The rules only capture structural provenance when the operator semantics clearly pinpoint paths to populate $\mathcal{A}$ and $\mathcal{M}$. Thus, the rule for the map operator captures the "undefined" semantics in $\mathcal{M} = \perp$ and $\mathcal{A} = \perp$. This semantics distinguishes from $\mathcal{M} = \emptyset$ and $\mathcal{A} = \emptyset$ semantics in the $filter$ and *union* rules. Both rules feature $\mathcal{M} = \emptyset$ since they do not restructure the data items. Each item's input structure is maintained in its entirety in the result. Further, the rule for the *union* operator holds $\mathcal{A} = \emptyset$ since it only performs an item-independent schema comparison of the input datasets.

5.0.2 Flatten. We introduced the flatten operator in Ex. 4.11 to illustrate our provenance model. Here, we explain the inference rule in Tab. 5 that captures the provenance for the $flatten$.

As preconditions, the rule requires the type of a_{col} to be either a list with duplicates (bag) or without duplicates (set). The result of the $flatten$ consists of items $r = \langle i, a_{new} : j\rangle$, where i refers

Filter*	$\dfrac{\varphi(i) \Rightarrow \text{true}}{I_1.filter[\varphi(i \in I_1)] \Rightarrow \{\{\langle i, \{\{\langle i, I_1, \cup p^i \in \varphi(i)\rangle\}\}, \emptyset\rangle \mid i \in I_1\}\}}$
Select*	$\dfrac{a_1, ..., a_n \in schema(I_1)}{I_1.select(a_1, ..., a_n) \Rightarrow \left\{\left\{\left\langle r, \left\{\left\{\left\langle i, I_1, \bigcup_{k=1}^{n} (a_k)^i \right\rangle\right\}\right\}, \bigcup_{k=1}^{n} \langle (a_k)^i, (a_k)^r \rangle \right\rangle \mid r = \langle i.a_1, ..., i.a_n\rangle, i \in I_1\right\}\right\}}$
Map*	$\dfrac{\tau(\lambda(i)) \Rightarrow \langle ... \rangle}{I_1.map[\lambda(i \in I_1)] \Rightarrow \{\{\langle \lambda(i), \{\{\langle i, I_1, \bot\rangle\}\}, \bot\rangle \mid i \in I_1\}\}}$
Join	$\dfrac{\varphi(i,j) \Rightarrow \text{true}}{I_1.join[\varphi(i \in I_1, j \in I_2)](I_2) \Rightarrow \left\{\left\{\left\langle r, \left\{\left\{\left\langle i, I_1, \bigcup_{p^i \in \varphi(i,j)} p^i \right\rangle, \left\langle j, I_2, \bigcup_{q^j \in \varphi(i,j)} q^j \right\rangle\right\}\right\}, \left\{\left\langle p^i, p^r\right\rangle \mid p^i \in schema(I_1)\right\} \cup \left\{\left\langle q^j, q^r \right\rangle \mid q^j \in schema(I_2)\right\}\right\rangle \mid r = \langle i, j\rangle, i \in I_1, j \in I_2\right\}\right\}}$
Union*	$\dfrac{\tau(I_1) = \tau(I_2)}{I_1.union(I_2) \Rightarrow \{\{\langle i, \{\{\langle i, I_1, \emptyset\rangle\}\}, \emptyset\rangle \mid i \in I_1\}\} \uplus \{\{\langle j, \{\{\langle j, I_2, \emptyset\rangle\}\}, \emptyset\rangle \mid j \in I_2\}\}}$
Flatten	$\dfrac{\tau(a_{col}) \Rightarrow \{\{\}\} \vee \tau(a_{col}) \Rightarrow \{\}}{I_1.flatten(a_{new}, explode(a_{col})) \Rightarrow \{\{\langle r, \{\{\langle i, I_1, \{\langle (a_{col}[x])^i \rangle\}\rangle\}\}, \{\langle (a_{col}[x])^i, a^r_{new}\rangle\}\rangle \mid r = \langle i, a_{new} : j\rangle, i \in I_1, j \in i.a_{col} \text{ at position } x\}\}}$
Grouping*	$\dfrac{G = \{\{g_1, ..., g_n\}\} \qquad \pi_G(i) = \langle g_1 : i.g_1, ..., g_n : i.g_n\rangle}{I_1.groupBy(g_1, ..., g_n) \Rightarrow \{\{\{\{\langle i, \{\{\langle i, I_1, \{g_1, \ldots, g_n\}\rangle\}\}, \emptyset\rangle \mid i \in I_1, \pi_G(i) == j\}\} \mid j \in set(\{\{\pi_G(i) \mid i \in I_1\}\})\}\}}$
Aggregation	$\dfrac{\begin{array}{c} \tau(I) == \{\{\tau(I_1), ..., \tau(I_n)\}\} \qquad \tau(I_1) == \ldots == \tau(I_n) == \{\{...\}\} \\ A_c == \left\{\alpha_{c_1}(a_1), ..., \alpha_{c_m}(a_m)\right\} \text{ with } \tau(\alpha_{c_k}(a_k)) \Rightarrow c \qquad A_B == \left\{\alpha_{B_1}(b_1), ..., \alpha_{B_p}(b_p)\right\} \text{ with } \tau(\alpha_{B_k}(b_k)) \Rightarrow \{\{...\}\} \\ \forall I_k \in I, \forall i, j \in I_k, \pi_G(i) == \pi_G(j) \text{ with } G == schema(I_k) \setminus \{a_1, \ldots, a_m, b_1, \ldots, b_p\} \end{array}}{I.agg(A_c, A_B) \Rightarrow \left\{\left\{\left\langle \begin{array}{l} r = \left\langle d, a_{\alpha_{c_1}} : \alpha_{c_1}\left(\pi_{a_1}(I_k)\right), \ldots, a_{\alpha_{c_m}} : \alpha_{c_m}\left(\pi_{a_m}(I_k)\right), a_{\alpha_{B_1}} : \alpha_{B_1}\left(\pi_{b_1}(I_k)\right), \ldots, a_{\alpha_{B_p}} : \alpha_{B_p}\left(\pi_{b_p}(I_k)\right)\right\rangle, d \in set(\{\{\pi_G(i) \mid i \in I_k\}\}), I_k \in I, \\ \left\{\left\{\left\langle i, I_k, \bigcup_{g \in G} g^i \cup \bigcup_{a \in A_c} a^i \cup \bigcup_{b \in A_B} b^i \right\rangle \mid i \in I_k, I_k \in I\right\}\right\}, \\ \left\{\left\langle g^i, g^r\right\rangle \mid g \in G, i \in I_k\right\} \cup \left\{\left\langle a^i_k, \left(a_{\alpha_{c_k}}\right)^r\right\rangle \mid k = 1, ..., m, i \in I_k\right\} \cup \left\{\left\langle a^i_k, \left(a_{\alpha_{B_k}}\right)^r\right\rangle \mid k = 1, ..., p, i \in I_k\right\} \end{array}\right\rangle\right\}\right\}}$

Table 5: Provenance capture semantics partially based on operator semantics from [11]. Access $\mathcal{A}$ and manipulation $\mathcal{M}$ provenance is highlighted.

to the input item and a_{new} to the newly created attribute. This attribute holds item j that is unnested from i's attribute a_{col}, i.e., $i \in I_1, j \in i.a_{col}$. In our structural provenance, we need to refer to the position of j within its bag (or set) in the context of i. Therefore, we denote the position of j in $i.a_{col}$ by pos. For each result item r, the structural provenance is $\rho = \langle r, \mathcal{I}, \mathcal{M}\rangle$ with $\mathcal{I} = \left\{\left\{\left\langle i, I_1, \left\{(a_{col}[pos])^i\right\}\right\rangle\right\}\right\}$ and $\mathcal{M} = \left\{\left\langle (a_{col}[pos])^i, a^r_{new}\right\rangle\right\}$. Here, $(a_{col}[pos])^i$ denotes the access path on the pos-th element of attribute a_{col} in the context of the input item i. a^r_{new} is the path to the new attribute in the context of the result item r.

5.0.3 Aggregation. The *aggregation* in Tab. 5 requires a bag of equally structured input collections (we only show bags for conciseness) as input, i.e., $\tau(I) = \{\{\tau(I_1), \ldots, \tau(I_n)\}\}$ such that $\tau(I_1) == \ldots == \tau(I_n) == \{\{\ldots\}\}$. These nested bags are constructed by the *grouping*. Further, the *aggregation* supports multiple aggregation functions. Among those supported by data analytics systems, we distinguish between aggregation functions that, given a bag as input, return an atomic constant value c (e.g., *count*, *sum*, *max*) and aggregation functions returning nested collections (e.g., *collect_list* and *collect_set*). We denote these by A_c and A_B, respectively. The rule also requires that all attributes G that are not aggregated by either a function in A_c or A_B, but that are present in the schema of a collection $I_k \in I$ are equal.

Given these preconditions, *aggregation* reduces each of the nested bags $I_k \in I$ to a single data item. It returns the unique value present in I_k for non-aggregated attributes in G and the results of the specified aggregate functions that are applied on the input attributes. The result of this process is the item r in the first line at the bottom of the *aggregation* rule. The second line shows $\mathcal{I}$. A result item r is based on input items that all originate from the same input collection $I_k \in I$. Thus, for each $i \in I_k$, the rule creates a data item $\langle i, I, \mathcal{A}\rangle \in \mathcal{I}$. The set of attribute accesses performed during aggregation includes the paths to all attributes in G, the paths to all attributes aggregated by functions in A_c, and the paths to all attributes aggregated by functions in A_B. That is, $\mathcal{A} = \bigcup_{g \in G} g^i \cup \bigcup_{a \in A_c} a^i \cup \bigcup_{b \in A_B} b^i$. For $\mathcal{M}$ in line 3, the rule maps aggregated attributes to the newly created attributes of r, which hold the aggregated items.

5.1 Lightweight provenance capture

The provenance capture rules have the potential for optimization, since they hold redundant information. First, recording a unique identifier suffices to identify each top-level item. Second, recording the paths accessed and manipulated on a schema level once per operator suffices since the paths are the same for all processed data items. They only differ in the identifier of the top-level item and the positions of items in nested collections. The lightweight operator provenance $\mathcal{P}$ exploits these observations to keep overhead at capture time low.

Definition 5.1. (Operator provenance $\mathcal{P}$) The operator provenance $\mathcal{P}$ is the following 5-tuple:

$$\mathcal{P} = \langle oid, type, \mathcal{I} : \{\{\langle p, \mathcal{A}\rangle\}\}, \mathcal{M}, P\rangle$$

$\mathcal{P}$ has an operator identifier oid and a $type$. The bag $\mathcal{I}$ holds one tuple for each of the operator's inputs. This tuple holds a reference to the preceding operator p and the paths accessed $\mathcal{A}$ on the input at a schema level. They are data item independent. Similarly, $\mathcal{P}$ has a bag of manipulated paths $\mathcal{M}$ on a schema level. Positions of items in nested bags are replaced with placeholders. The bag P in $\mathcal{P}$ holds the unique identifiers of the top-level input

Operator	Provenance structure
$map, select, filter$	$P = \{\{\langle id^i, id^o \rangle\}\}$
$join, union$	$P = \{\{\langle id^i_1, id^i_2, id^o \rangle\}\}$
$flatten$	$P = \{\{\langle id^i, pos, id^o \rangle\}\}$
$groupby$ and $aggregation$	$P = \{\{\langle ids^i : \{\{id^i\}\}, id^o \rangle\}\}$

Table 6: Operator-dependent provenance structure

and output items, as well as positions of accessed or manipulated items in nested collections, if needed.

The content of P depends on the operator type as summarized in Tab. 6. In this table, the attributes id^i and id^o hold the unique identifiers of top-level items in the input and the output, respectively. If the operators have multiple inputs, attributes id^i_1 and id^i_2 are indexed in the order of appearance in $\mathcal{I}$. The structure P of the flatten operator has a reference to the *pos*ition of the nested item being flattened. The aggregation holds a collection of input ids^i for each group. The position of the input id^i is equal to the position of any nested item that the aggregation produces.

Example 5.2. Fig. 3 shows the reduced operator provenance $\mathcal{P}_5$ for the flatten operator at the bottom right.

In the following section, we describe how the backtracing algorithm computes the structural provenance of nested data from the lightweight provenance structures $\mathcal{P}$.

6 BACKTRACING

Querying the provenance of items or structures in the result involves two major phases. In the first phase, the backtracing algorithm identifies those data items, for which a user queries provenance (Sec. 6.1). In the second phase, it traces these items back to the input data (Sec. 6.3).

6.1 Structural query processing

DISC systems have rudimentary means to address individual nested items, at most. They lack sophisticated means to address arbitrary combinations of them, which is essential for querying structural provenance. Thus, we devise an extension to a DISC system (i.e., Apache Spark) to support tree-pattern queries. Tree-patterns allow for addressing combinations of nested items that are related by their structure [13]. Intuitively, they express structural queries in the form of a tree, in which each node represents an attribute and edges define parent-child or ancestor-descendant relationships (depending on edge type) that should exist between two connected nodes. Further constraints may be imposed on attribute nodes, e.g., equality of an attribute's value to a constant. Therefore, we define a novel distributed tree-pattern matching algorithm to return the query result in an efficient and scalable way. Due to space constraints, we omit details on processing tree-pattern queries but show an example.

Example 6.1. Fig. 4 shows a tree-pattern for the provenance question introduced in Sec. 2. Its *root* has an ancestor-descendant edge to the *id_str* node. All other edges indicate parent-child relationships. The *id_str* and *text* nodes hold equality conditions, which require values of those attributes to be equal to *lp* and *Hello World*, respectively. Further, as indicated by the black box, the value *Hello World* has to occur twice in the nested collection.

Our algorithm matches the tree-pattern against a dataset D (in our example, the final result of the processing pipeline) to then return the matching data in the form of a backtracing structure, which we introduce next.

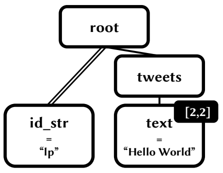

Figure 4: Example tree-pattern in a provenance question

6.2 Backtracing structure

The backtracing structure describes the items that are queried in the provenance question and traced back to the input. The backtracing algorithm updates its content while stepping backward.

Definition 6.2. (Backtracing structure) The backtracing structure $\mathcal{B} = \{\{\langle id, \mathcal{T} \rangle\}\}$ is a bag of provenance identifiers id of top-level data items associated with a backtracing tree $\mathcal{T}$ (see next definition), referencing attributes in the schema of id.

The nodes in the backtracing trees also hold information about the access and manipulation of the attribute and whether the attribute is contributing or just influencing the items queried.

Definition 6.3. (Backtracing tree) The backtracing tree $\mathcal{T} = \langle root, N \rangle$ holds complex nodes $n \in N$. Each node $n = \langle name, parent, C, A, M, c \rangle$ has a $name$ equal to the attribute name it references. Further, it references its parent node p, and its children C. A node also holds the set of operators A that access the referenced attribute and a set of operators M that manipulate the attribute. A boolean value c indicates whether the attribute contributes to the items in the provenance question ($c = true$) or whether it influences the items ($c = false$).

Example 6.4. Examples of backtracing trees are provided in Fig. 2. The right tree corresponds to the backtracing tree obtained from matching the tree-pattern in Ex. 6.1 on the data in Tab. 2. The left trees correspond to backtracing trees resulting from recursively updating the backtracing structure while stepping back through the processing pipeline to the input data.

The following two methods manipulate the trees, and the backtracing algorithm calls them repeatedly during backtracing. Their execution context is an instance of an operator provenance $\mathcal{P}$ and a backtracing structure $\mathcal{B}$.

The $manipulatePath$ method performs two tasks. First, it manipulates the nodes in $\mathcal{T}$. For each input and output path in $m \in \mathcal{P}.M$ it transforms the output path back to the specified input path in m, if the output path exists in $\mathcal{T}$. After the transformations, the nodes in the tree $\mathcal{T}$ conform to the schema of the input. Second, it adds the current operator identifier $\mathcal{P}.oid$ to each node's manipulation collection M.

The $accessPath$ method records access to attributes in the nodes of $\mathcal{T}$. During that process, one of two cases applies. In the first case, all nodes of the path $a \in \mathcal{A}, \mathcal{A} \in \mathcal{P}.\mathcal{I}$ already exist in $\mathcal{T}$. Then the method adds the $\mathcal{P}.oid$ to each node's access collection A. In the second case, nodes in path a do not exist in $\mathcal{T}$, because these attributes are neither needed to reproduce the result nor have been accessed by other operators so far. Then, the $accessPath$ method adds the according nodes to $\mathcal{T}$ but sets the contribution value to $c = false$ since these nodes are not required to reproduce the queried data items.

6.3 Backtracing algorithm

Alg. 1 shows the backtracing algorithm that traces the queried items recursively back from the result to the input. It takes the

Algorithm 1: backtrace($\mathcal{P}, \mathcal{B}$)

```
   Input: $\mathcal{P}$, $\mathcal{B}$
   Output: $\mathcal{B}$
1  switch $\mathcal{P}.type$ do
2      case "$filter$" do
3          $\langle \mathcal{P}', \mathcal{B}' \rangle \leftarrow$ backtraceFilter($\mathcal{P}, \mathcal{B}$)
4      case "$flatten$" do
5          $\langle \mathcal{P}', \mathcal{B}' \rangle \leftarrow$ backtraceFlatten($\mathcal{P}, \mathcal{B}$)
6      ...
7  if $\mathcal{P}'$ is defined then
8      backtrace($\langle \mathcal{P}', \mathcal{B}' \rangle$)
9  return $\mathcal{B}'$
```

Algorithm 2: backtraceFlatten($\mathcal{P}, \mathcal{B}$)

```
   Input: $\mathcal{P}$, $\mathcal{B}$
   Output: $\langle \mathcal{P}', \mathcal{B}' \rangle$
1  $\langle \mathcal{P}', \mathcal{B}' \rangle \leftarrow backtraceOperatorGeneric(\mathcal{P}, \mathcal{B})$
2  $\mathcal{B}' \leftarrow \alpha_{mergeTrees(\mathcal{T},pos)}(\gamma_{id}(\mathcal{B}'))$
3  return $\langle \mathcal{P}', \mathcal{B}' \rangle$
```

Algorithm 3: backtraceOperatorGeneric($\mathcal{P}, \mathcal{B}$)

```
   Input: $\mathcal{P}$, $\mathcal{B}$
   Output: $\langle \mathcal{P}', \mathcal{B}' \rangle$
1  $\mathcal{B}' \leftarrow \pi_{id^i \rightarrow id, pos, \mathcal{T}}(\mathcal{P}.P \bowtie_{id^o = id} \mathcal{B})$
2  for $t \in \mathcal{B}'.\mathcal{T}$ do
3      for $m \in \mathcal{P}.\mathcal{M}$ do
4          $manipulatePath(t, m, \mathcal{P}.oid)$
5      for $a \in \mathcal{P}.\mathcal{I}_1.\mathcal{A}$ do
6          $accessPath(t, a, \mathcal{P}.oid)$
7  return $\langle \mathcal{P}' \leftarrow \mathcal{P}.\mathcal{I}_1.p, \mathcal{B}' \rangle$
```

operator provenance of the last operator $\mathcal{P}$ in the pipeline and the backtracing structure $\mathcal{B}$ as input to call the operator-dependent backtracing method, which returns its predecessor's operator provenance $\mathcal{P}'$ and an updated backtracing structure $\mathcal{B}'$. The algorithm recursively calls the backtrace method until the input is reached. Then $\mathcal{P}'$ is not defined so that the recursion ends.

Flatten, Select, Filter, Map. As shown in Alg. 2, backtracing the flatten operator has two steps. In the first step (l. 1), the algorithm calls *backtraceOperatorGeneric* (Alg. 3) to undo the flatten on each item in $\mathcal{B}$ individually. At this step, the algorithm does not consider positions in the flattened collection. As a result, it obtains $\mathcal{P}'$ and $\mathcal{B}'$. In the second step (l. 2), the algorithm groups the trees and positions in $\mathcal{B}'$ by the top-level item *id* and merges all trees of the same *id*, considering the position *pos*.

The generic backtracing algorithm, shown in Alg. 3, also has two major steps. In the first step (l. 1), it joins B with the provenance associations P of $\mathcal{P}$ to obtain the input identifiers of the top-level items along with the trees in B (l. 1). These identifiers become the new *ids* in $\mathcal{B}'$ so that they match the id^o of the projection's predecessor $\mathcal{P}.\mathcal{I}_1.p, \mathcal{B}'$. This join is essentially the same one that existing lineage solutions [15, 17, 22] apply for backtracing. In the second step (ll. 2-6), the algorithm iterates over all the trees in $\mathcal{B}'$ to undo all recorded structural manipulations in the *manipulatePath* method and record the access to attributes in the *accessPath* method.

Example 6.5. The example input of Alg. 2 is $\mathcal{P}_5$ in Fig. 3 (bottom right) and a backtracing structure $\mathcal{B}$ with the two items of $id = 42$ and $id = 43$. They reference the items with the same identifier in Fig. 3. For simplicity, the example subtree $\mathcal{T}$ is reduced to the path *m_user.id_str*. The *backtraceFlatten* algorithm calls the *backtraceOperatorGeneric* algorithm (Alg. 2, l. 1), which joins P_5 with $\mathcal{B}$ (Alg. 3, l.1). Afterwards, both items are assigned $id = 1$. Then the algorithm modifies the trees to $user\_mentions.[pos].id_{str}$ so that they comply with the input schema of the flatten operator (Alg. 3, l.4). However, instead of

Algorithm 4: backtraceAggregation($\mathcal{P}, \mathcal{B}$)

```
    Input: $\mathcal{P}$, $\mathcal{B}$
    Output: $\langle \mathcal{P}', \mathcal{B}' \rangle$
1   $P^* \leftarrow pos\_flatten(\mathcal{P}.P.ids^i, id^i, p_P)$
2   $\mathcal{B}' \leftarrow P^* \bowtie_{id^o = id} \mathcal{B}$
3   $\mathcal{B}' \leftarrow withCol(\mathcal{B}', inProv, false)$
4   for $b \in \mathcal{B}'$ do
5       for $m \in \mathcal{P}.\mathcal{M}$ do
6           if $contains(m.out, [pos])$ then
7               $out \leftarrow replace(m.out, b.p_P)$
8           else
9               $out \leftarrow m.out$
10          if $out \in b.\mathcal{T}$ then
11              $b.inProv = true$
12              $manipulatePath(b.\mathcal{T}, \langle m.in, out \rangle, \mathcal{P}.oid)$
13          $removeNodes(b.\mathcal{T}, m.out)$
14  for $t \in \mathcal{B}'.\mathcal{T}$ do
15      for $a \in \mathcal{I}.A$ do
16          $accessPath(t, a, \mathcal{P}.oid)$
17  $\mathcal{B}' \leftarrow \pi_{id^i \rightarrow id, \mathcal{T}}(\sigma_{inProv = true}(\mathcal{B}'))$
18  return $\langle \mathcal{P}' \leftarrow \mathcal{I}.p, \mathcal{B}' \rangle$
```

holding the position of the nested items, they hold [*pos*] placeholders. The *mergeTrees* method in Alg. 2 (l. 2) replaces them with $pos = 1$ and $pos = 2$ for the items with the former $id = 42$ and $id = 43$, respectively. Further, it merges their trees because both items have $id = 1$ and, thus, are grouped together. Finally, the algorithm returns a $\mathcal{B}'$ with the item of $id = 1$ and the tree referring to positions 1 and 2 in the nested collection *user_mentions*.

The algorithms to backtrace a select, filter, or map operator are basically the same as Alg. 3, except that they do not project on the *pos* attribute (l. 1). Some optimizations are applicable to the filter. Since the filter does not manipulate any data, its backtracing algorithm does not loop over the manipulations $\mathcal{P}.\mathcal{M}$. The backtracing algorithm for the map operator has no information on the paths manipulated or accessed. Thus, it marks all nodes in the input schema as manipulated by default.

Aggregation and Nesting. As described in Sec. 5, aggregation and nesting are preceded by a grouping. Further, our model allows multiple aggregations and nestings over different attributes. Alg. 4 describes the procedure to trace aggregation and nesting back to the input of the preceding grouping.

Unlike the provenance structures of other operators, $\mathcal{P}.P$ of an aggregation holds a nested collection of input ids^i (cf. Tab. 5.1). Thus, Alg. 4 first flattens the ids^i and their positions into the columns id^i and p_P, respectively (l. 1). After joining P^* with $\mathcal{B}$ to $\mathcal{B}'$ (l.2), the algorithm adds a column *inProv* to $\mathcal{B}'$ (l. 3). This column is initialized with $false$ and used later to indicate, whether items in $\mathcal{B}'$ remain in the backtraced provenance. Then, the algorithm iterates over each item in $\mathcal{B}'$ and each manipulated path in $\mathcal{P}.\mathcal{M}$ (ll. 4-13). For each manipulated path $m.out$, it checks for a position placeholder [*pos*] (l.6), which only occurs when the operator performs bag nesting. In this case, the input item with id^i contributes exactly to the item in the nested bag that also has position p_P. Thus, the algorithm replaces the placeholder in $m.out$ and stores the result in *out* (l. 7). Otherwise, *out* is assigned $m.out$ (l. 9). If the exact path *out* is in the provenance tree, item *b* is marked as relevant and the path is adjusted accordingly (ll.10-12). In case of a bag nesting, the provenance tree may also hold information of items at other positions. The algorithm removes these nodes calling the *removeNodes* method (l. 13). It marks the accessed paths, to which the grouping attributes also belong (ll.14-16). In a final step, the algorithm removes all items and attributes from $\mathcal{B}'$ that are irrelevant for further backtracing. Their value in *inProv* was not set to true.

Example 6.6. Let us apply Alg. 4 on the nesting operator in our running example, which collects all tweeted texts in a nested bag. The backtracing structure $\mathcal{B}$ contains just the item with $id = 102$ and the right tree $\mathcal{T}$ of Fig. 2, which refers to the duplicate text *Hello World*. The operator Provenance $\mathcal{P}$ contains a provenance structure P that Alg. 4 flattens out to the following P^*:

id^i	p_P	id^o
81	1	102
82	2	102
93	3	102
95	4	102

After joining $\mathcal{B}$ with P^*, each entry with $id^o = 102$ holds a copy of the same tree $\mathcal{T}$. For a single loop iteration over $\mathcal{B}'$ and $\mathcal{M}'$ (ll. 4-13), we choose $b \in \mathcal{B}'$ with $id^i = 82$, $p_P = 2$, $id^o = 102$ and path $m.out = tweets.[pos]$. The algorithm replaces placeholder $[pos]$ with 2, so that $out = tweets.2$ (l. 7). Since out is part of $\mathcal{T}$, it sets $b.inProv = true$ (l. 11) and transforms the subtree $tweets.2.text$ to the subtree $text$ (l. 12). Then, it removes the node $tweets$ and all its children from its copy of $\mathcal{T}$ (l. 13), which includes the nodes in path $tweets.3.text$. Now, the nodes in $\mathcal{T}$ describe a subset of the schema of the aggregation's input data. The algorithm marks the accessed attributes and removes all items that are not part of the provenance. Here, it marks the $user$ and its children as accessed (ll. 14-16), since these attributes are used for grouping. Further, it removes items from $\mathcal{B}'$ whose provenance is not queried (l. 17), e.g., b' with $id^i = 95$ and $p_P = 4$.

Join and Union. Unlike the other operators, the join and the union operator have two predecessors. Thus, the backtracing algorithms require an additional parameter to specify which of the two inputs is traced back to. Based on that parameter, the algorithms pick the appropriate input tuple from the operator provenance $\mathcal{P}.\mathcal{I}$ and the appropriate input identifiers id_1^i or id_2^i from the provenance structure $\mathcal{P}.P$ (cf. Tab. 4). Then they call the generic backtracing algorithm from Alg. 3. Afterwards, the algorithm for the join operator removes all nodes in the provenance trees $\mathcal{B}'.\mathcal{T}$ that are not part of the chosen input schema, since they reference elements in the schema of the other input. The algorithm for the union operator filters out all items in $\mathcal{B}'$ whose value is undefined in the chosen field id_1^i or id_2^i . These items originate from the other input of the union operator.

7 IMPLEMENTATION & EVALUATION

We integrate the contributions described in this paper into a system prototype named Pebble. Sec. 7.1 provides some details of the system implementation, demonstrated in [9]. Sec. 7.2 then describes our evaluation setup and workload, which we use for our experimental evaluation (Sec. 7.3).

7.1 Implementation

While our contributions are generally applicable to DISC systems, we implement Pebble as a library extension for Apache Spark. This allows us to better compare it to Titian, which is the only other fully integrated provenance solution for DISC systems that has been implemented over Spark [16].

Fig. 5 shows Pebble's architecture (blue) on top of the *SparkSQL* API (grey), which is independent of the *Spark Core* module and further modules (grey) such as the MLlib. To provide a transparent user experience, Pebble has an API wrapper *PebbleAPI*. It directs user requests to the *SparkSQL* module or the *Pebble Core* module, which contains the *Capture* and *Query* submodules.

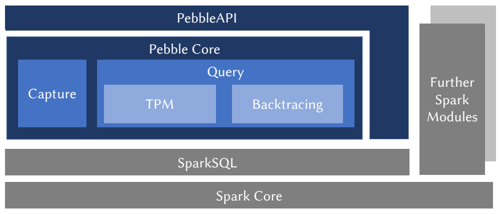

Figure 5: Pebble's architecture

S	Description (detailed descriptions available in [8])
T1	filters tweets containing the text *good*, flattens and groups by the mentioned users to collect a bag of complex tweet objects
T2	flattens the nested lists *hashtags, media, user mentions*
T3	running example
T4	associates all occurring hashtags with the authoring and mentioned users
T5	finds all users that tweet about *BTS*, and are mentioned in a *BTS* tweet
D1	associates inproceedings from 2015 with the their according proceeding(s)
D2	unites and restructures conference proceedings and articles
D3	computes nested list for aliase, co-authors, and works per author
D4	computes nested list of all associated inproceedings for each proceeding
D5	is D4 extended with a UDF in map that returns the number of authors per proceeding

Table 7: Short informal scenario descriptions

The former submodule extends Spark's dataframes and operators to capture the structural provenance as described in Sec. 5. The latter submodule implements the backtracing algorithm from Sec. 6. It utilizes maps to represent the provenance trees $\mathcal{T}$ and modifies the tree in place with user-defined functions. Each of the Algs. 2-4 iterate over all items in the backtracing structure $\mathcal{B}$ and perform changes impacting only one item at a time. Thus, the for-loops with iterator variables t or b in Algs. 2-4 are parallelized across the DISC system. However, the backtracing needs to be called for each input dataframe independently, because Spark operators always generate just one result dataframe.

7.2 Test setup & workload

For our experimental validation, we run Pebble on a cluster with three worker nodes, each having 8 cores, 256GB main memory, and SSD storage. All nodes run Scala 2.11, Hadoop 3.1.0 and Spark 2.3.1. We average five test runs framed in an additional warm-up and cool-down run. The error bars displayed in our graphs show the standard deviation. We write the result to disk to ensure that Spark computes the full result. Otherwise, Spark "optimizes" attributes away. The experiments run on 100GB input data, if not mentioned otherwise.

We base our evaluation on a nested Twitter and a DBLP dataset. We scale the datasets from 100GB to 500GB in steps of 100GB. For each of the datasets, we define five scenarios containing a Spark program to be executed with and without provenance capture and a corresponding structural query. Each supported operator occurs at least once in the scenarios. The Twitter dataset contains up to 130 million tweets (500GB). Each tweet has up to 1000 attributes and eight layers of nesting [27]. We define five test scenarios T1 - T5 (Tab. 7). The DBLP dataset contains up to 1.5 billion records (500GB) that are extracted from the dblp.xml. Records have one of ten types such as article or proceeding [21]. They are split by type and upscaled, such that important characteristics such as the average number of inproceedings per proceeding are preserved. We define five test scenarios D1 - D5 (Tab. 7).

7.3 Experimental evaluation

We conduct experiments to study the runtime and space overhead when capturing lightweight structural provenance. We also evaluate the performance of querying the structural provenance. Further, we perform a comparative evaluation with Titian [17],

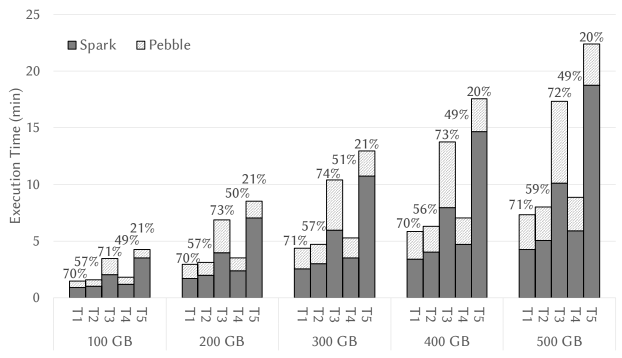

Figure 6: Runtime overhead on Twitter dataset

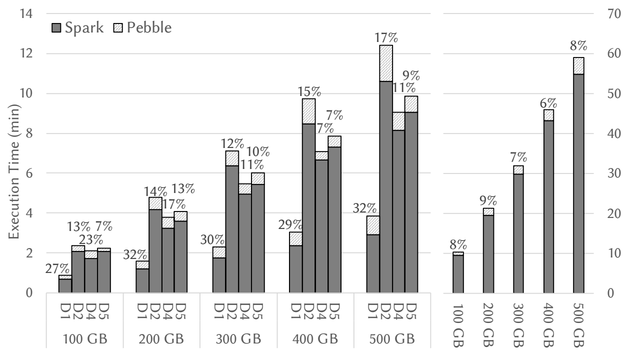

Figure 7: Runtime overhead on DBLP dataset (right: D3)

kindly provided to us by the authors, and fully lazy provenance capture as described by PROVision [28]. We conclude our evaluation with a use-case analysis for auditing and data-usage patterns.

7.3.1 Capture runtime overhead. The first series of measurements shows the runtime overhead imposed by the lightweight provenance capture for increasing data sizes. Our goal is to show (i) how Pebble scales over the input data size and (ii) how data size affects the runtime overhead.

We measure the execution time for each of the Twitter scenarios T1 to T5, once without provenance capture, i.e., with Spark's regular operator semantics, and once with Pebble's provenance capture as defined in Sec. 5.1. Fig. 6 shows the results on datasets from 100GB to 500GB. The solid dark grey part of each part shows the runtime that Spark requires without provenance collection. The textured light grey part on top of each bar shows the overhead when running provenance capture. The percentage on top of the textured bars indicate the relative overhead between the former and the latter types of experiments. Analogously, Fig. 7 reports runtimes for scenarios D1 to D5.

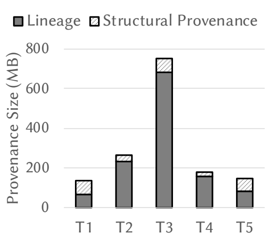
As expected, across all experiments, the runtime increases when provenance is collected since Pebble performs extra work. Runtime with and without provenance grows linearly with the data size. As the overhead percentages indicate, the relative overhead imposed by provenance capture remains constant with increasing data sizes for most scenarios. Thus, we conclude that Pebble scales with the input data size. However, the relative overhead varies significantly between the scenarios. It ranges from 75% (T3) down to 8% (D3, shown on the right of Fig. 7). A detailed analysis of D3 reveals that spilling large final and intermediate results to disk – or more generally speaking disk I/O – dominates the runtime. The time to compute the extra provenance is small. In contrast, scenario T3 reads the input tweets twice to perform a union operation. As a consequence, Pebble annotates the input data twice during provenance capture, hindering Spark to optimize reading the input.

We further investigate overhead incurred by Pebble for each individual operator (no graphs shown due to space constraints). Overall, the overhead highly depends on the size ratio between the collected provenance and the processed input data. In general, for operators with constant provenance annotation overhead (filter, select, union, join, and flatten), the relative overhead decreases with an increasing number of attributes in the input data. In the case of the DBLP dataset, which has less than 50 attributes, the overhead ranges between 5% and 25% for the mentioned operators. The overhead is particularly high for aggregations that reduce many input items to a single value. Then, Pebble stores a collection with all item identifiers contributing to the aggregated item. This collection typically is orders of magnitude larger than the result item itself. Consequently, the observed runtime overhead exceeds 100% of the actual execution time for the aggregation. However, even this overhead is negligible when disk I/O operations dominate the execution time.

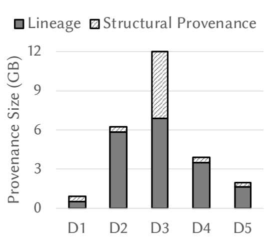
7.3.2 Capture space overhead. The second series of measurements shows the space required to store captured provenance. We show (i) that the provenance size depends on dataset and scenario characteristics, (ii) that large provenance sizes do not necessarily correlate with high runtime overhead, and (iii) that the captured structural provenance typically adds an overhead of less than 200MB compared to lineage. Thus, it typically does not significantly affect scalability. Results are reported in Fig. 8(a) and Fig. 8(b). The dark grey part of each bar shows the size of lineage for top-level items and the stacked and textured bars show the additional space required by structural provenance.

The y-axis of the Twitter graph has a Megabyte scale, whereas the y-axis of the DBLP graph has a Gigabyte scale. The reason is that the items in the Twitter dataset have about 1000 attributes, whereas the items in the DBLP dataset have less than 50 attributes. Therefore, 100GB of DBLP data contain more than 100 times as many data items as 100GB of Twitter data. Given that Pebble associates identifiers to top-level data items only, it stores more than 100 times the annotations for DBLP scenarios compared to the Twitter scenarios. Hence, the DBLP provenance is orders of magnitude larger than the Twitter provenance and lets us conclude that the size of the provenance significantly depends on the number of tracked top-level data items in the input.

Further, the sizes significantly differ among the scenarios of the same dataset. For instance, the provenance of scenario T3 amounts to 750MB, 5.5 times the size of T1's provenance. There are three reasons for the different size: (i) As mentioned above, in T3, our solution annotates the input data twice; (ii) The processing pipeline of T3 consists of 7 processing steps that trigger provenance collection, whereas the pipeline of T1 only consists of 5 steps; (iii) The filter in T1 reduces the total amount of tracked

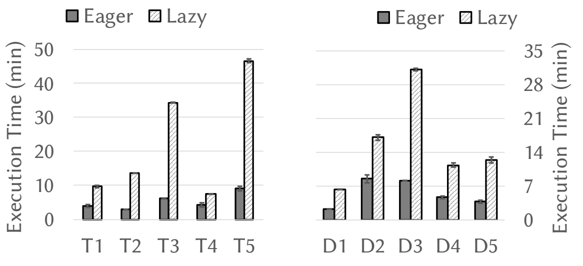


(a) Twitter dataset



(b) DBLP dataset

Figure 8: Size of collected structural provenance



(a) Twitter dataset (b) DBLP dataset

Figure 9: Runtime of Pebble's backtracing

data items early in the pipeline. Clearly, space overhead also depends on the number of operators in a program and the number of top-level items in intermediate results.

The scenarios T3 and T1 have comparable runtime overhead (see Fig. 6(a)) of around 70 - 75% and, thus, highest across all scenarios. While scenario T3 is also the scenario with the largest provenance size, T1 has a comparable runtime overhead but a much smaller provenance size. Similarly, the relationship of the runtime and space overhead is actually the inverse for scenario D3 and D1 in Fig. 8(b). D3 has the largest and D1 the smallest provenance size. However, D1 has a runtime overhead of 27%, whereas D3 only has 7%. Therefore, it is not generally true that a high runtime overhead correlates with a high space overhead.

Looking at the space overhead of lineage and structural provenance, we see that in most scenarios, structural provenance takes less than 200MB additional space, even in scenarios where lineage itself takes Gigabytes. The only exception is D3, where a flatten occurring early in the pipeline followed by a very selective join causes the comparatively high size difference.

Concerning the above experiments, which are all related to provenance capture, we make the following general observations. The provenance size highly depends on the number of top-level items in the input and intermediate results. As explained, the provenance size may not correlate with the runtime overhead. Other factors, such as processing optimizations, data width, or significant disk I/O potentially have a higher impact on the relative runtime overhead than the provenance size. While the size difference between lineage and structural provenance is small in many practical scenarios, the overhead can increase when flatten operators store positions that lineage solutions do not capture.

7.3.3 Querying structural provenance. Our third series of experiments focuses on processing structural queries over provenance-annotated result datasets. The runtimes reported in Fig. 9 include both the tree-pattern matching on the program's result items and the time needed to backtrace these result items to the input with the help of structural provenance. We report results on query processing time in our holistic approach (i.e., where structural provenance has been eagerly captured and is traced back). We also implement a fully lazy query approach that can be considered an extension of PROVision [28] to our processing pipelines. The query runtime for these two approaches, labeled eager and lazy respectively, are shown for both the Twitter scenarios (Fig. 9(a)) and the DBLP scenarios (Fig. 9(b)).

The graphs in Fig. 9 do not explicitly show the time for tree-pattern matching since the matching is integrated into Spark's processing pipeline. It becomes part of Spark's execution plan and undergoes optimizations such as filter push down. Therefore, time cannot be measured independently in a reliable way.

The dark bars in Fig. 9 show that querying structural provenance (eagerly) takes more time than the actual program execution (cf. Fig. 6 and 7). We identify two reasons for this behavior: (i) the backtracing presented in Sec. 6 performs a join operation for each operator in the actual program, even for computationally less expensive operators such as filters and selects. (ii) Backtracing has to manipulate the provenance trees for each operator.

When comparing the performance of our holistic capture and query approach with a completely lazy query approach such as PROVision [28], we see that our holistic provenance querying approach (eager) is always faster than the lazy approach. In the scenarios T3, T5, and D3 the difference amounts to a factor four to seven for two reasons. First, lazy processing needs to trace back result items for each input dataset independently and these scenarios have multiple input datasets. Hence, the extra time to query provenance lazily add up for each input. Second, the processing pipelines in these scenarios are deep, yielding high provenance query times for each input dataset.

Based on the above experiments, we draw the following conclusions for provenance querying. Lazily querying structural provenance is less attractive the more operators a program has and the more input datasets it processes. It is less time consuming to rerun a program with provenance capture and query the provenance eagerly than using lazy provenance querying approaches such as [28].

7.3.4 Comparison with Titian. We compare Pebble to Titian [17] since it is the only other provenance system integrated into a DISC system. The purpose of the evaluation is to compare the runtime overheads for capturing provenance of flat data items. A detailed comparison is not possible since Titian neither supports nested data, nor structural provenance, nor the programs in our scenarios. We run the test on a local machine with two worker nodes, using the unscaled articles and inproceedings records of the DBLP dataset. The test program reads each record as a long string value and filters lines containing *2015*. Then, the program computes the union over the filtered articles and inproceedings. Titian's program is implemented in the RDD API. Pebble's program is implemented in the SparkSQL API. Without provenance computation, the programs have an average runtime of 7.13 seconds and 7.36 seconds, respectively. The overall execution time is lower for the RDD program since the SparkSQL API imposes overhead on top of the underlying RDD API. Titian's overhead is 5.89%, Pebble's overhead is 6.98%.

The result indicates that for workloads on flat data supported by both systems, Pebble only adds marginal runtime overhead compared to Titian, even though it is capturing structural provenance. However, Pebble outperforms Titian in the sense that it additionally supports nested data and the collection and querying of structural provenance at attribute level.

7.3.5 Use-case analysis. To validate that structural provenance supports the use-cases described in our motivation, we revisit these use-cases with a prototypical implementation to analyze how they benefit from structural provenance.

Data-usage patterns. Pebble reveals data-access patterns, as well as hot items that frequently contribute to a query result and cold data items that do not influence any result. In Fig. 10, we show a heatmap of 25 randomly selected data items from the DBLP inproceedings dataset after running test scenarios D1 through D5. For that purpose, we merge the provenance of the individual scenarios. The more often a data item is used the redder (hot) it is. Items that do not influence any result are colored

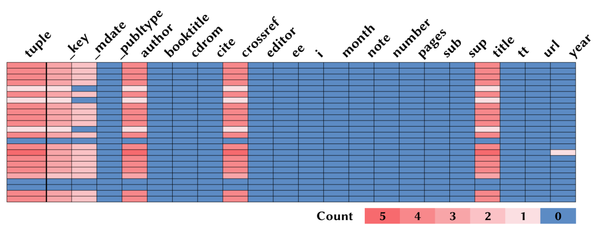


Figure 10: HeatMap for 25 data items in the DBLP inproceedings dataset after running scenarios D1-D5

blue (cold). The leftmost column indicates how often the top-level item (tuple) contributed to a result. The other columns refer to attributes of the top-level data items. The heatmap only shows top-level attributes due to space constraints. All but three top-level items have influenced at least one result. A horizontal (tuple-based) partitioning of hot and cold items, therefore, may not significantly improve system performance. However, only a fraction of all attributes contributes to the results. Thus, in this example, a vertical (column-based) partitioning of hot and cold attributes is likely to improve system performance significantly. Further, the analysis of accessed and manipulated nodes in the structural provenance reveals that the attributes *author* and *title* are frequently processed together. Thus, system performance benefits from storing these items next to each other.

In comparison, lineage solutions and PROVision [28] only provide the tuple based counter. Lipstick [2] also identifies attributes. However, Lipstick does not reveal information on access and manipulation and, thus, misses influencing attributes.

Auditing. Pebble identifies sensitive data that has been leaked directly or indirectly over the DBLP scenarios D1 through D5. All data in Fig. 10 are leaked whose count is bigger than zero. Data with count zero (blue) is not leaked. Since Pebble distinguishes access and manipulation of items, it further reveals the usage of the *year* item whose count equals one. It is marked as influencing since it does not contribute to any result item in D1 to D5. However, knowing that the *year* item is accessed is important to assess the risk of reconstruction attacks.

In comparison, lineage solutions and PROVision [28] only provide full tuples. Thus, they mark too much data as leaked. This is costly for a company, e.g., if a non-leaked (blue) attribute holds credit card numbers. Then, the company has to issue new credit cards to all marked customers, even though the information is not leaked. Lipstick [2] potentially misses leaked information, since it misses influencing attributes like the *year*. Thus, neither of the mentioned solutions allows for proper risk assessment.

8 CONCLUSION AND OUTLOOK

This paper introduced structural provenance, for which we provided a formal data model and execution semantics for operators frequently used in DISC systems. Further, we showed how to capture the structural provenance in an efficient and scalable way. Based on the captured provenance, we formalized an algorithm to backtrace structural provenance at attribute level for nested data at provenance query time. Our experimental evaluation using the Pebble system showed that our contributions result in the first DISC system integrated provenance solution for nested data that is efficient, scalable, and accurate enough to support novel provenance use-cases, such as auditing and data-usage patterns.

Future work includes extending Pebble with a user-friendly front-end to interact with structural provenance. We also intend to optimize provenance querying.

ABSTRACT

Given a set of points, the *Best Region Search* problem finds the optimal location of a rectangle of a specified size such that the value of a user-defined scoring function over its enclosed points is maximized. A recently proposed top-k algorithm for this problem returns results progressively, while also incorporating additional constraints, such as taking into consideration the overlap between the set of selected top-k rectangles. However, the algorithm is designed for a centralized setting and does not scale to very large datasets. In this paper, we overcome this limitation by enabling parallel and distributed computation of the results. We first propose a strategy that employs multiple rounds to progressively collect partial top-k results from each node in the cluster, while a coordinator handles the aggregation of the global top-k list, dealing with overlapping results. We then devise a single-round strategy, where the algorithm executed by each node is enhanced with additional conditions that anticipate potential overlapping solutions from neighboring nodes. Additional optimizations are proposed to further increase performance. Our experiments on real-world datasets indicate that our proposed algorithms are efficient and scale to millions of points.

1 INTRODUCTION

The amount of geospatial data generated from social networks, sensors, smart phone applications, tracking devices and so on is constantly increasing [9]. Analyzing big geospatial data at scale is of paramount importance for numerous applications in various areas such as geomarketing, mobile advertisement, urban planning, tourism and logistics. In many cases, the analysis involves identifying areas where the intensity of a studied phenomenon is maximized. This involves, for example, finding *hot spots* of user check-ins, commercial activities, crime incidents, etc. Various traditional methods exist and have been used for such purposes, such as computing global and local spatial autocorrelation [2] or finding density-based clusters [10], while several recent studies have also focused on problems related to finding areas of interest according to certain keyword-based and size-based criteria and constraints [3, 4, 7, 8, 15].

In this context, several types of *optimal location selection* problems have been studied. Range aggregate queries [18] have been proposed for scenarios where users are interested in summarized information about objects in a given region. Such queries return an aggregate score over the objects enclosed within a given region, and can be efficiently processed using aggregate spatial indices. However, these methods can not be efficiently applied when the problem is to find where the best regions are located. A typical and widely studied formulation of this problem is the *MaxRS* (Maximizing Range Sum) problem [6], which, given a set of 2-dimensional weighted points, aims at finding the optimal location of a fixed-size rectangular region that maximizes the sum of weights of the points enclosed in it.

In this paper, we focus on the *Best Region Search* (BRS) problem [11], which is a generalization of the *MaxRS* problem. Similarly, the input is a dataset $\mathcal{D}$ of spatial objects represented as weighted points in a 2-dimensional space, and two parameters $a, b \in \mathbb{R}^+$, denoting the width and height of the region to be found. The goal is to identify the optimal location of an axis-aligned $a \times b$ rectangular region R that maximizes the value of a scoring function f computed over the enclosed points. Hence, the difference lies in the fact that in *MaxRS*, f is restricted to the sum of weights of the points within R, while in *BRS* it can be any submodular monotone function. The *MaxRS* problem and its extensions and variants have their roots in problems studied in the past by the computational geometry community [14, 16], and have received much attention recently by the database community [1, 4, 6, 11, 12, 20, 21].

The *BRS* problem has numerous applications related to location planning. For instance, assume a company that is searching for the optimal location to open a new store. In that case, an $a \times b$ region R can be used to approximate the area from which the new store is expected to draw its potential customers. Assuming that a suitable scoring function f is provided, which computes a utility score for each candidate region R based on its contents, the solution to the *BRS* problem indicates the optimal location for placing this new store. Similar examples can also be found, for instance, when recommending regions to travelers. Given the size of the region that a user is willing to explore, modeled by an $a \times b$ rectangle, and a function f quantifying the utility of a region with respect to the user's preferences (e.g., presence of museums, restaurants, shops, etc.), the *BRS* problem computes the best region to be recommended.

The k-*BRS* problem has been introduced in [19], presenting an algorithm that can compute top-k best regions *progressively*. While doing so, we have also observed that in many real-world datasets, where spatial objects are typically not uniformly distributed in space, these top-k results tend to highly overlap, even for very large values of k. This is expected, since by slightly shifting a region R horizontally and/or vertically it is possible to obtain a new region R' that covers almost the same area as R and thus achieves very similar utility score to it. Yet, results of such type offer essentially no new insight over the explored data. Hence, to tackle this problem, we have introduced an additional constraint that either completely prohibits overlaps among the

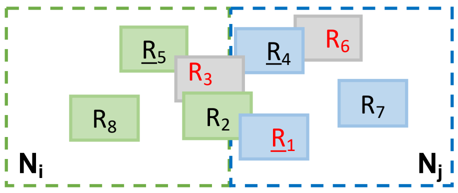

Figure 1: Illustrative example. The green and blue regions are those returned by N_i and N_j, respectively. The underlined results are those finally selected by the coordinator. The red ones are the correct top-3 results.

returned results or reduces the degree of overlap by allowing but penalizing partial overlaps among the returned top-k regions.

Being able to retrieve top-k results progressively, instead of simply computing the overall best region, as well as avoiding overlapping results that provide near-duplicate information, has many advantages in data exploration scenarios. Still, the state-of-the-art solution proposed in [19] operates in a centralized setting and cannot scale as the input dataset size grows; indicatively, it needs around 30 seconds to identify the top-10 non-overlapping regions of size 200×200 m^2 even on moderate-size datasets – around 100 thousand points.

To efficiently address the *k-BRS* problem when dealing with big geospatial data, an approach is needed that can scale out, i.e., distribute and parallelize the computation over multiple workers (computing nodes) in a cluster. In this paper, we address this problem by proposing different methods for parallel and distributed top-k best region search while taking into account the criterion of overlap among the returned results. In particular, we consider a setting where the input dataset is partitioned across several workers that perform local computations in parallel, while a coordinator node is assigned the task to coordinate the execution and merge local results to produce the global top-k result list. Most contemporary Big Data platforms, e.g., Spark, are naturally represented by the aforementioned setting.

Before we describe our approach, we explain the main challenge to this problem, which arises when non-overlapping (or only partially overlapping) results are requested. Specifically, the challenge arises from the fact that, under this constraint, the global top-k results are not contained in the union of the local top-k results computed at each node. Therefore, simply computing the local top-k results at each node and merging these top-k lists at the coordinator can lead to incorrect results in many cases. We illustrate this with the following example.

Example 1. *Consider the example illustrated in Fig. 1, assuming that the data is split in two partitions, each one assigned to a different worker, represented as N_i and N_j. Assume that the top-8 regions with highest scores in both partitions (regardless of overlaps) are those shown in the figure, with the index of each region indicating its rank (i.e., R_1 having the highest score). Suppose that each region belongs to (i.e., is computed by) the worker that contains its center.*

Assume that the user requests the top-3 non-overlapping results. Node N_i will progressively compute its results, and will return to the coordinator the regions R_2, R_5 and R_8. R_3 is skipped since it overlaps with R_2 which has a higher rank. Similarly, N_j will return to the coordinator the results R_1, R_4 and R_7. Again, R_6 is skipped as it overlaps with R_4. Based on these two sets of local top-3 results, the coordinator will compute the global top-3 list excluding overlapping regions, thus returning R_1, R_4 and R_5.

However, the above result is incorrect. The correct global top-3 results should have been R_1, R_3 and R_6. As we can see, R_3 is a false negative – it was missed because N_i skipped it, as it was overlapping with R_2; however, R_2 was eventually discarded by the coordinator because it was overlapping with a better result R_1 from the neighboring node. R_4 and R_5 are false positives – their respective nodes considered them as valid results; however they should have been discarded because eventually a better result R_3 that overlaps with both of them should have been present. R_6 is again a false negative, for reasons similar to R_3.

As revealed by the above example, the root cause of false results is the fact that the admission of a *local* top-k region in the *global* top-k list is precluded by the existence of a higher ranked region that overlaps with it. Since the latter may arise from a different worker than the former, a worker cannot independently reason regarding the validity of its own results, i.e., which of these results will eventually "survive" at the coordinator. To make matters worse, candidates that were rejected locally due to the existence of a better local overlapping result R, may actually have a place in the global top-k list if R is later dismissed at the coordinator.

Since overlapping regions between two neighboring workers occur at the borders, an intuitive – yet insufficient – approach to overcome this problem would be to replicate the contents of two neighboring nodes around the borders. In that case, in the example of Fig. 1, it could be possible for N_i to know, for instance, that R_1 overlaps with R_2 and has higher score than it. However, it may turn out that R_1 is disqualified in N_j, if it overlaps with an even better result not located in the border with N_i, in which case N_i would still have no knowledge of this. Even replicating the whole contents of N_j to N_i would not suffice, since the results of N_j may similarly be affected by its other neighbors as well.

In this paper, we explore different solutions to overcome this problem. First, we propose a *multi-round* algorithm (*MR*), where the problem of dealing with conflicts is mainly handled by the coordinator. The advantage of *MR* is that workers can readily exploit the local *k-BRS* algorithm with minor adaptations, since the decisions for forming the global top-k list are made at the coordinator level. The downside is that when overlapping results are identified, and hence discarded, at the coordinator, a new round has to be executed, where the relevant workers are informed about these results and are requested to compute new results accordingly. To overcome this drawback, we devise a *single-round* algorithm (*SR*). This requires formulating appropriate conditions to reason about the uncertainty of the validity of the local results. In *SR*, each worker proactively anticipates which results may be disqualified because of overlaps with regions from other nodes, and what the respective effects are in each case, and produces a *sufficiently extended* local set of results to guarantee a single round of communication. However, the computation of these extended results imposes additional overhead on each worker, implying potentially significantly higher execution time of the local processes. Eventually, we propose a hybrid algorithm (*HY*), which strikes a balance between the pros and cons of the multi-round and single-round strategies.

In the example described above, we assumed that the proposed regions must not overlap. Other conditions are also possible, e.g., the user might accept overlapping regions as long as their overlap is below a threshold, or even score the overlapping regions differently. Our methods support arbitrarily complex scoring functions, enabling different configurations concerning the overlap.

Summarizing, the paper makes the following contributions:

- We study the top-k best region search problem, identifying and pointing out the challenges that arise when attempting to compute non-overlapping (or partially overlapping) top-k results in a distributed and parallel setting.
- We explore the solution space of the problem, and propose two different distributed algorithms for efficiently solving it. The first is a multi-round algorithm, with the number of rounds bounded by the value of parameter k. The second is a single-round algorithm, which guarantees that the top-k best regions can be identified within a single round of interactions.
- The above two algorithms represent the two extremes in terms of number of rounds, and come with different performance tradeoffs. We thus proceed to explore the configuration space between them, leading to different optimizations, and to a hybrid, fixed-rounds algorithm that combines the benefits of the two.
- We implement all proposed algorithms in Spark and we thoroughly evaluate them using real-world datasets. Our evaluation results demonstrate the scalability and benefits of the proposed algorithms, and analyze their tradeoffs on queries and datasets of different properties.

The rest of the paper is structured as follows. Section 2 summarizes related work. Section 3 presents the problem definition and background. We introduce the multi-round and single-round algorithms in Sections 4 and 5, respectively. Section 6 presents our experimental evaluation, and Section 7 concludes the paper.

2 RELATED WORK

The *Best Region Search* problem has its roots in computational geometry problems relating to intersecting rectangular regions. An intersection graph of rectangles in the 2-dimensional space with sides parallel to the axes is defined in [14]. It is constructed by representing each rectangle with a vertex and connecting two vertices by an edge if the corresponding rectangles intersect. Then, finding the connected components and the maximum clique on this graph is investigated. Moreover, given a set of points in a 2-dimensional space, the problem of finding the placement of a rectangular region P of specified size such that it encloses the maximum or minimum number of points is investigated in [16]. The proposed algorithm is based on an interval tree.

More recently, the problem has attracted interest in spatial databases. Specifically, the *MaxRS* problem has been defined in [6] as follows: given a set of *weighted* points, and a rectangular region R of specified size, find the placement of R that maximizes the *sum of the weights* of all enclosed points. An external-memory algorithm is proposed that is optimal in terms of I/O complexity, based on an external version of the plane-sweep algorithm [13]. Furthermore, the (1-ϵ)-approximate *MaxRS* problem has been studied in [20], which returns a rectangle whose covered weight is at least(1-ϵ) m^*, where m^* is the optimal covered weight and ϵ is an arbitrarily small constant between 0 and 1.

The *MaxRS* problem has also been investigated in a streaming setting. In [1], an algorithm that exploits a graph in a grid index is proposed, using also an upper-bounding technique to avoid unnecessary update computation. A sweep-line based algorithm has also been proposed for the continuous detection of *Bursty Regions* [12]. This is a variation of the continuous *MaxRS* problem, where the burst score of a region is defined over two consecutive sliding windows, and spatial objects in different windows contribute differently to the burst score. Moreover, the continuous maintenance of *range-sum heat maps* over dynamically updating data objects has been studied in [17].

The *Best Region Search* problem generalizes the *MaxRS* problem by allowing the objective score function used to quantify a rectangle's score to be any submodular monotone function over the enclosed points, instead of the sum of their weights [11]. Each point is represented by a fixed-size rectangle centered at it. Then, the best region is identified by finding the maximal intersections of these rectangles. To this end, the input space is partitioned in vertical *slices* that run parallel to the y-axis. Each slice is processed by executing a bottom-up scan over it using a horizontal sweep line to identify so-called *maximal slabs.* The maximal slabs are then processed using a vertical sweep line to identify *maximal regions.* The best region is guaranteed to be centered inside one of those maximal regions. A progressive algorithm for top-k Best Region Search has been proposed in [19]. This algorithm is used in this paper to retrieve local top-k results at each node; hence, it is described in more detail in Section 3.2.

Variants of the *MaxRS* problem have also been considered in road networks. The *length-constrained maximum-sum region* query is introduced in [4]. An approximation algorithm is proposed, utilizing a technique that scales node weights into integers, as well as a heuristic and a greedy algorithm. A unified framework that addresses three variants of *optimal location* queries in road networks is presented in [22]. Given a set of existing facilities and a set of clients, these queries compute the location for a new facility that optimizes a certain cost metric defined based on the distances between the clients and the facilities. Finally, continuous *Best Region Search* in spatial data streams in road networks has been addressed in [5], proposing several pruning strategies and a branch-and-bound algorithm.

3 PRELIMINARIES

In this section, we first provide a formal definition of the problem addressed in this paper, and then we briefly outline the k-BRS algorithm [19], which is exploited in our algorithms to compute the local results at each node.

3.1 Problem definition

Assume a set $\mathcal{D}$ of points in a 2-dimensional space. Let f be a scoring function that assigns a score $f(R)$ to any axes-aligned rectangle R, based on its enclosed points. We assume monotone scoring functions, such that if the contents of a rectangle R' are a superset of those of R, then $f(R') \geq f(R)$. Based on these, the problem of computing the *top-k overlap-aware best regions* can be formally defined as follows:

PROBLEM 1 (TOP-k OVERLAP-AWARE BEST REGIONS). *Given a two-dimensional point dataset $\mathcal{D}$, a monotone scoring function f, width and height parameters w, h, and an integer k, the goal is to compute a ranked list of k axis-aligned rectangles R_i with dimensions $w \times h$, such that for each i, j, $1 \leq i < j \leq k$, it holds that:*

- *$f(R_i) \geq f(R_j)$, i.e., the rectangles are ranked in decreasing order of their score,*
- *$R_i \cap R_j = \emptyset$, i.e., R_j does not overlap with any higher ranked result R_i, and*
- *any other rectangle R' either has score $f(R') \leq f(R_k)$, or there exists another rectangle R_i in the top-k list such that $f(R_i) \geq f(R')$ and R' overlaps with R_i.*

Note that this definition can be relaxed to allow results that *partially* overlap, up to a user-specified threshold. In fact, this boolean condition can be generalized even further, by allowing overlaps but penalizing the score of a region by a factor depending on its degree of overlap with a higher-ranked region, as described in [19] using the notion of *marginal gain*. To simplify presentation, in this paper we focus on the boolean case, but it is straightforward to adapt the proposed algorithms to handle cases where the score of a region is penalized based on its degree of overlap with previous results.

Our goal is to compute top-k overlap-aware best regions in a *parallel and distributed* setting. A progressive algorithm for top-k overlap-aware best regions has been presented in [19]. However, it operates in a centralized setting and does not scale to big geospatial datasets containing millions of points. Transferring this solution to a distributed environment is not straightforward, because, as shown in Section 1, deriving global top-k results from the union of local top-k ones leads to incorrect answers. Hence, in this paper, we focus on overcoming this problem.

Algorithm 1: Local *k-BRS* algorithm.

```
1  Function Local($k$)
2      $\mathcal{L} \leftarrow \emptyset$ ; $\mathcal{G} \leftarrow$ ConstructGrid()
3      $Q \leftarrow$ InitializePriorityQueue($\mathcal{G}$)
4      while $|\mathcal{L}| < k$ & $|Q| > 0$ do
5          $E \leftarrow Q.nextEntry()$
6          if $E.type$ = "Cell" then
7              $\mathcal{S} \leftarrow$ GenerateSlabs($E$)
8              $Q$.addAll($\mathcal{S}$)
9          else if $E.type$ = "Slab" then
10             $\mathcal{R} \leftarrow$ GenerateRegions($E$)
11             $\mathcal{S} \leftarrow$ GetNextSlabs($E.slabTree$)
12             $Q$.addAll($\mathcal{R} \cup \mathcal{S}$)
13         else if $E.type$ = "Region" then
14             if $overlapAcceptable(\mathcal{L}, E)$ then $\mathcal{L}$.add($E$)
15             $\mathcal{R} \leftarrow$ GetNextRegions($E.regionTree$)
16             $Q$.addAll($\mathcal{R}$)
17     return $\mathcal{L}$
```

3.2 The k-BRS algorithm

Next, we briefly outline the *k-BRS* algorithm [19], which is used in this paper as the basis for retrieving local top-k results in each partition. The process is summarized in Alg. 1.

The algorithm starts (Lines 2–3) by constructing a grid with cells of size $w \times h$, i.e., with the same dimensions as the regions to be discovered. For each cell C, an upper bound $UB(C)$ is computed for the score of any region R centered inside C. This is based on the fact that R can enclose at most those points located within C or its neighboring cells. The cells are then inserted into a priority queue Q in decreasing order of their upper bound.

Whenever a cell is extracted from Q (Lines 6–8), it is scanned bottom-up using a horizontal sweep line. This generates a series of *maximal slabs*, each one associated with a respective upper bound, according to which they are inserted into Q. Moreover, the series of slabs leading up to a maximal slab are organized in a *slab tree*, so that these sub-maximal slabs can be visited later if needed. This permits the algorithm to backtrack and explore other results in case the one found is inadmissible due to overlap.

Whenever a maximal slab is extracted from Q (Lines 9–12), it is scanned from left to right using a vertical sweep line. This generates a series of *maximal regions*, each one associated with an upper bound, according to which they are added to Q. In addition, one level of the associated slab tree is traversed, generating one or two new slabs, which now become maximal, and are thus inserted in Q, along with the reduced slab tree, to be processed accordingly. Maximal regions are also associated with a corresponding *region tree*, operating similarly to the slab tree.

Finally, whenever a maximal region is extracted from Q (Lines 13–16), a result is produced, comprising the next region with the highest utility score in the local top-k list. At this point, a check is performed to determine whether this result overlaps with a previously accepted result, and thus determine whether it is admissible or not. New maximal regions are also generated from the region tree and added to Q for future consideration.

4 MULTI-ROUND ALGORITHM

Our first method is an incremental, multi-rounds algorithm (*MR*) that gradually builds the global top-k list of results by retrieving local top-k results from each worker at each round. While aggregating the local top-k results received at the end of each round, the coordinator resolves overlaps, and, if needed, contacts again the affected workers, informing them about the occurred overlaps and asking them for accordingly revised top-k results. This process may take up to k rounds to complete. The steps are outlined in Alg. 2. We start our discussion with data partitioning, and then we explain the querying algorithm.

Data partitioning. Data points are spatially partitioned by a uniform grid with partition width w_p and height h_p (Lines 2–3). Each point with coordinates (x, y) is mapped to partition $P_{i,j}$, with $i = \lceil x/w_p \rceil$ and $j = \lceil y/h_p \rceil$. Data partitioning is performed offline. In Spark, this entails a simple map and groupByKey sequence that parses the original data and generates a new pair RDD with key being the partition id, and value the list of points belonging to this partition. Partitions are held by N nodes (in our case, the Spark workers). Typically, the number of nodes is much less than the number of partitions. It is assumed that $w_p >> w$ and $h_p >> h$, where w and h denote the width and height of the query rectangle.

The node holding each partition is responsible for processing the partition to identify the top-k regions with a top-left corner[1] within the partition. The border cells of the partitions are of particular interest. Notice that a candidate region may intersect two neighboring partitions (e.g., r_8 in Fig. 2). To enable detection of these regions from exactly one partition, and to be able to compute their score, border cells belonging to the top and left borders of each partition are replicated to all partitions they share a border with (for example, the blue-colored cells of $P_{2,3}$, $P_{3,3}$ and $P_{3,2}$ of Fig. 2 are the ones replicated to the node holding $P_{2,2}$). This replication may happen either at query time, when w and h are determined, or may occur offline, assuming that a maximum value for w and h is supported.

Query execution. Upon receiving the query, each partition P is processed in parallel to compute local top-k results (Line 6). The local top-k algorithm (Alg. 1) is used for this purpose, with a

[1]An implementation detail is that, in the *k-BRS* algorithm [19], each input point p is represented by a $w \times h$ rectangle R_p centered at it. The rationale is that any region centered inside R_p encloses p. Now, identifying a result by its top-left corner instead of its center involves a minor adaptation: R_p must have its bottom-right corner (instead of its center) at p. In this way, it still holds that any result R having its top-left corner inside R_p will enclose p.

Algorithm 2: MapReduce implementation of the Multi-round algorithm.

```
1  Function AtCoordinator(k)
       /* Data partitioning */
2      data ← input.map(poi to <partitionIndex, poi>)
3      data ← data.groupByKey(partitionIndex)
4      list globalAns ← ∅
       /* Querying */
5      while |Ans| ≤ k do
6          localAns ← data.map(Local(k, globalAns))
7          roundAns ← localAns.reduce((a, b) ⟹
             AggFunc(a, b, k))
8          globalAns ← globalAns ∪ roundAns
   /* Reduce-based aggregation of results */
9  Function AggFunc(res_1, res_2, k)
10     minAcceptableScore ←
         max(min(res_1 scores), min(res_2 scores))
11     localAns ← res_1 ∪ res_2
12     localAns ← SortDesc(localAns)
13     output ← ∅
14     for pos=1 to k do
15         if overlapAcceptable(localAns[pos], roundAns) &
             sc(localAns[pos]) > minAcceptableScore then
16             output ← output ∪ localAns[pos]
17         else
18             break
19     return output
```

minor tweak such that it accepts as input the list of global results computed so far (*globalAns*). This list is taken into consideration in Alg. 1 (Line 14), so that now the overlap condition is checked with respect to $\mathcal{L} \cup globalAns$ instead of $\mathcal{L}$.

The local results per partition are then passed to an aggregation function *AggFunc*, such that a single list of top-k results ends up at the coordinator. The function takes as input two local results, constructs their union, sorts it, and retains the top-k of them, as long as these do not overlap each other. If a non-acceptable overlap is found, or if the minimum score of the two lists surpasses the score of the current region, then the aggregation interrupts and retains only the output produced so far. The logic behind this is that, after any of these cases is observed, any further results returned by the aggregation process are not guaranteed to be correct or complete. This aggregation is associative and commutative. Therefore, it is executed as a reduction in Spark (Line 7), which means that the whole processing (both maps and reductions) is fully parallelized, and the coordinator never constitutes a bottleneck for the algorithm's performance. Finally, after the reduced results are returned to the coordinator, the coordinator merges them with the results of the previous rounds (if any), and loops through the previous map/reduce steps until it collects a total of k results.

As explained previously, we focus on the case that a boolean condition is used to check whether a new result is admissible with respect to existing results based on potential overlap. In the algorithm, this condition is checked by the *overlapAcceptable* function (Line 15). A generalization of this is to penalize the score of overlapping regions using a marginal gain function, as described in [19].

The above algorithm is amenable to configurations and optimizations. First, the size of partitions is a system parameter, which involves the following tradeoff. Very large partitions reduce the area covered by border cells, thereby reducing the probability that overlapping regions of two partitions require more rounds. However, they also lead to scalability problems of the local algorithm (the workers that hold dense partitions run out of memory, swap aggressively, and eventually crash).

Also notice that the algorithm asks for k results per round, per partition. It is however unlikely that the global top-k results come from the same partition, which means that the local nodes (the Spark workers) are likely producing many more results than needed. To reduce this extra effort, the coordinator can instead ask for the top-k' results per partition at each round, with $k' < k$ set either at the beginning, or progressively at each round, in order to fine-tune the tradeoff between the number of rounds and the local effort at the nodes: a high k' value favors towards a lower number of rounds, whereas a lower k' reduces the effort spent by the workers on computing results that are not really useful, because of yet-unknown overlaps. The following lemma formalizes this tradeoff.

LEMMA 4.1. *The multi-round algorithm requires at least* $\lceil k/k' \rceil$ *rounds and at most* k *rounds.*

PROOF. For the lower bound, consider the case where answers are contained in a single partition. Since each partition generates k' answers at each round, it is not possible to retrieve all results in less than $\lceil k/k' \rceil$ rounds. For the upper bound, consider the top-1 region among all collected local results at a given round. This is guaranteed to be admissible, since it has already been checked locally against the currently existing results (*globalAns*). Hence, at each round, at least one more result is produced. Consequently, the process will terminate after k rounds. □

5 SINGLE-ROUND ALGORITHM AND EXTENSIONS

The multi-round algorithm enables processing of datasets with sizes that could not be practically processed by the centralized algorithm. Still, the iterative nature of the algorithm (and overlapping regions from different partitions) may lead to a potentially high overhead and poor performance. To overcome this drawback, we now introduce a *single-round* algorithm. The algorithm maintains auxiliary information per region that is used during the reduction phase for handing overlapping regions from different partitions. We will then explore the space between the single-round and the multi-round algorithm, proposing a *hybrid* algorithm, and discussing additional optimizations.

5.1 Single-round algorithm

The intuition for the single-round algorithm (*SR*) is the following. When processing each partition, a sufficient number of regions (typically larger than k) will be computed and sent to the coordinator, such that it is guaranteed that the coordinator will have all candidates needed to assemble the global top-k results (discarding non-admissible ones) without further communication to the workers. The challenge is to determine how many, and which, additional regions need to be sent, such that the coordinator is guaranteed to hold sufficient information for extracting the final answer. This challenge arises from the presence of overlaps between candidate regions that are detected in different partitions. For example, in Fig. 2, region r_1 of partition $P_{2,2}$ overlaps with the

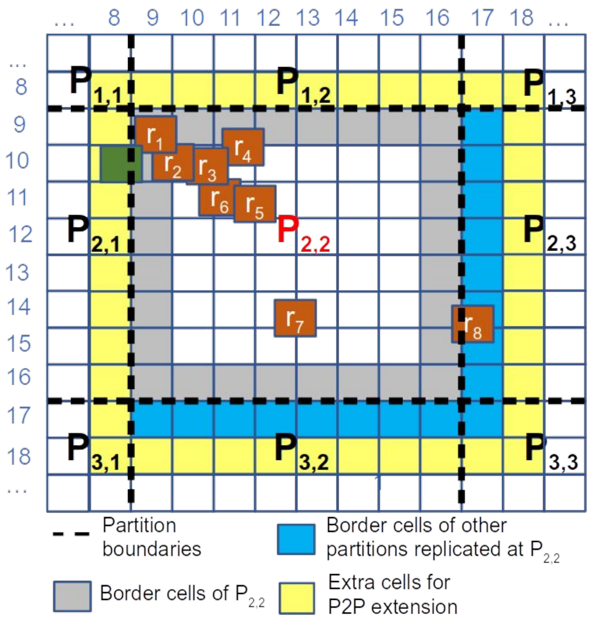

Figure 2: Identified regions within a node's partition. The regions are labeled in decreasing score, i.e., $sc(r_1) > sc(r_2)$.

green region of partition $P_{2,1}$, which has a higher score. Therefore, r_1 will not be in the final results (unless the green region of $P_{2,1}$ intersects with another region of $P_{2,1}$ with higher score), which will make r_2 a possible result. Unfortunately, existence of long chains of such overlaps prohibit local solutions that rely on data replication (e.g., replicating the border cells).

The single-round algorithm addresses this issue by forming a *dependency graph* of the identified candidate regions at each partition. These graphs allow each node to establish a lower bound on the number of regions contained in the local results that will be accepted by the coordinator, if their score is sufficiently high. We start by describing two core components of the algorithm, the *dependency graph* and the *extended dependency graph*.

Definition 5.1 (Dependency graph). Let $\mathcal{R} = r_1, r_2, \ldots$ denote the list of candidate regions detected at a partition P, ordered by their score, i.e., $sc(r_i) \geq sc(r_{i+1})$. Dependency graph $G(\mathcal{R})$ is a directed acyclic graph that contains all candidate regions from $\mathcal{R}$ as vertices, and has an edge between any two regions r_i and r_j if these overlap. The direction of the edge is from the region with the higher score towards the region having the lower score (ties between regions are broken in a consistent manner, by preferring the region with the lowest x coordinate, and then the region with the lowest y coordinate).

As an example, Fig. 3 depicts the dependency graph for the detected regions (r_1 to r_8) in Fig. 2.

Constructing the dependency graph for each partition $P_{x,y}$ is a local process, since it utilizes only the partition's data and the data in the border cells of the neighboring partitions $P_{x+1,y}$, $P_{x,y+1}$, and $P_{x+1,y+1}$ which is replicated in the node holding the partition. Recall, however, that the regions that overlap the border cells of each partition (gray-shaded cells in Fig. 2) may overlap with candidate regions detected in adjacent partitions (e.g., the green region from $P_{2,1}$ which overlaps with r_1 of $P_{2,2}$). The dependencies induced by these regions cannot be depicted in the dependency graph. Thus, to represent these dependencies,

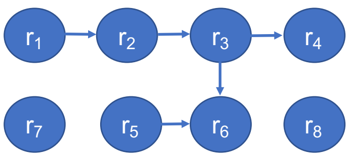

Figure 3: Dependency graph.

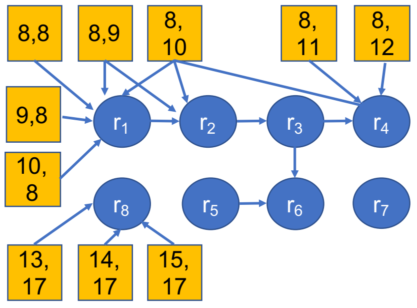

Figure 4: Extended dependency graph.

the dependency graph is extended by adding *artificial* dependencies for all (locally unknown) candidate regions that potentially overlap with regions detected at neighboring partitions.

Definition 5.2 (Extended dependency graph). The extended dependency graph $\mathcal{X}(\mathcal{R})$ of a partition is a DAG containing: (a) $G(\mathcal{R})$, and (b) for each vertex $v \in G(\mathcal{R})$ with an upper-left corner contained in a border cell (i, j), one vertex v' for each one of the cells adjacent to (i, j) that belongs to a different partition, and an edge pointing from v' to v.

Intuitively, the extended dependency graph encodes the possible dependencies from regions detected at other partitions. Since these regions are unknown at the node constructing the graph, they are represented with the coordinates of the cell that would contain their upper-left corner. For example, region r_1 of partition $P_{2,2}$ has an upper-left corner at cell $(9, 9)$. The adjacent cells of $(9, 9)$ belonging in other partitions are the cells $(8, 8)$, $(8, 9)$, $(8, 10)$, $(9, 8)$, and $(10, 8)$ of partitions $P_{1,1}$, $P_{1,2}$, and $P_{2,1}$. Any region from another partition that has a non-empty overlap with r_1 will have its upper-left corner at one of these cells. Figure 4 depicts the extended dependency graph of partition $P_{2,2}$.

The significance of the extended dependency graph is that it allows to establish an upper bound on the number of regions in the partition that may be excluded from the results due to (chains of) overlapping regions contained in other partitions. Conversely, it allows each partition to derive a lower bound on the number of *safe regions*, i.e., the regions that will not be invalidated from the contents of other partitions, even by long chains of overlaps.

The progressive construction of the extended dependency graph takes place alongside the local algorithm introduced in Alg. 1, and is summarized in Alg. 3. Precisely, we slightly modify the local algorithm in two ways: (a) for every identified region that passes the filter of acceptable overlap (Line 14), the modified algorithm invokes a function *addRegion*, to add the region and its dependencies in the extended dependency graph, (b) it terminates when *addRegion* has detected sufficient safe regions.

In more detail, before processing a partition, the node initializes an empty extended dependency graph $\mathcal{G}$, three sets *Safe*, *Unsafe*, and *detectedRegions* for keeping the regions, a set $\mathcal{M}$ for keeping the identified dependencies, and a counter for the number of identified safe regions *safeCnt*. Upon invocation, *addRegion* checks the new region to decide whether it is safe, unsafe, or inadmissible, and to maintain a lower bound for the number of safe regions (variable *safeCnt*).[2] This process is governed by a set of rules. Precisely, for a candidate region r_x, the node checks for three different cases:

Case 1: r_x does not overlap with other identified regions (either safe or unsafe), or with the border cells. r_x is a safe region, i.e., it will be included in the final answer if its score is sufficiently high. We increase *safeCnt* by one, and add it in the *Safe* set and in the extended dependency graph with no dependencies. r_7 is one such example from Fig. 2.

Case 2: r_x overlaps with a safe region r_y, which is already included in the Safe *set.* Since r_y is already identified, its score is higher than the score of r_x. Therefore, node discards r_x and continues. As an example, consider r_5 and r_6 from Fig. 2 – since r_5 is safe and has a higher score than r_6, the latter will be discarded.

Case 3: r_x overlaps with a border cell, or with an unsafe region r_y included in the Unsafe *set.* In this case, r_x is also unsafe. r_x is added in the *Unsafe* set, and in the extended dependency graph, with dependency from r_y and/or the adjacent cells of the other partitions. Let $\mathcal{D}(r_x)$ denote the set of all dependencies for r_x contained in the dependency graph after this process. We have two further sub-cases:

Case 3a: If none of the regions contained in $\mathcal{D}(r_x)$ is included in $\mathcal{M}$, none of these has been considered before. Therefore, either r_x or a region from $\mathcal{D}(r_x)$ will be part of the top-k regions, assuming that their score is sufficiently high. To capture this, r_x and the regions in $\mathcal{D}(r_x)$ are added to $\mathcal{M}$, and counter *safeCnt* is increased by one. From Fig. 2, r_1 and r_8 will belong in this category. Out of these, the coordinator will later detect that r_1 has an overlap with the green-marked region detected at partition $P_{2,1}$ (i.e., the green region will be included in the results instead), whereas r_8 will be included in the results if is score is sufficiently high (hence the increase on *safeCnt* for both of them). Another example is region r_3, which depends on r_2: since r_2 overlaps with r_1 which will be included in $\mathcal{M}$, r_2 will not be included in $\mathcal{M}$. This means that r_3 and its dependencies will be included in $\mathcal{M}$, and *safeCnt* will be increased by one.

Case 3b: If any of the regions contained in $\mathcal{D}(r_x)$ is already included in set $\mathcal{M}$, then *safeCnt* is not increased and r_x is not added in $\mathcal{M}$. As an example, consider regions r_2 and r_1 from Fig. 2. Region r_1 will be identified first, and already contained in $\mathcal{M}$ when r_2 is identified. Therefore, identification of r_2 will not lead to an increase of *safeCnt*.

After completion of *addRegion*, the control returns to the modified local algorithm, which breaks the loop when *safeCnt* reaches k. The local results for the partition are contained in *detectedRegions*, and the extended dependency graph is saved in $\mathcal{G}$.

Similar to the case of the multi-round algorithm, implementation of the single-round algorithm over Spark requires a way to hierarchically merge/reduce the local results (the dependency graphs) in order to get a final dependency graph with no further artificial dependencies in the coordinator, for extracting the final answer. Conceptually, the required merging involves the following steps: (1) we form the union of the two graphs, (2) if the two graphs share a border, we identify the artificial dependencies in the union graph that can now be eliminated, or replaced by dependencies on real regions, (3) we propagate the effect of each dependency elimination or replacement (e.g., switching a region from unsafe to safe), by performing a depth-first traversal of the graph starting from the affected region, and, (4) we reduce the graph by finding the score of the top-k safe region, and removing all regions with a lower score.

[2]The problem of counting the number of safe regions is not equivalent to the problem of actually detecting the safe regions. Addressing the latter problem typically leads to less regions marked as safe, which translates to larger dependency graphs and degradation of the algorithm's performance.

Algorithm 3: Single-round algorithm – progressive construction of extended dependency graph.

```
1  $\mathcal{G} \leftarrow \emptyset$ , $Safe \leftarrow \emptyset$ , $Unsafe \leftarrow \emptyset$ , $detectedRegions \leftarrow \emptyset$ ,
     $M \leftarrow \emptyset$ , $safeCnt \leftarrow 0$
2  Function addRegion(region)
3      if region does not overlap with any region in Safe,
         Unsafe, and border cells then
4          $\mathcal{G}$.addNode(region)
5          $Safe \leftarrow Safe \cup region$
6          $safeCnt \leftarrow safeCnt + 1$
7      else if region overlaps with a region in Safe then
8          continue
9      else if region overlaps with a region in Unsafe or
         border cells then
10         $\mathcal{G}$.addNode(region)
11         $\mathcal{G}$.addDependencies(region)
12         $Unsafe \leftarrow Unsafe \cup region$
13         if region dependencies is included in $\mathcal{M}$ then
14             continue
15         else
16             $safeCnt \leftarrow safeCnt + 1$
17             $M \leftarrow M \cup$( region dependencies)
18     $detectedRegions \leftarrow Safe \cup Unsafe$
```

Notice that the effect of the propagation step (step 3) relies on the same rules that we introduced earlier to determine whether a region is safe, unsafe, or can be safely removed. Therefore, a simple way to implement the above process is to initialize an empty graph, and keep adding the regions of the two partitions in descending order of score by invoking *addRegion* function of Alg. 3. The adding process can stop when *safeCnt* exceeds k.

THEOREM 5.3. *The final dependency graph produced by the algorithm only contains safe regions, which are the answer to the user's query.*

Proof sketch: Since the final dependency graph contains the input from all partitions, it will no longer contain artificial dependencies, which cause the unsafe regions (notice that inadmissible regions are not included in the graph – see lines 7-8 of Alg. 3). Also, regions are added in this graph in order of descending score, and the graph is completed as soon as the graph contains k nodes. The proof can be formalized with induction. □

The discussed algorithm is amenable to several optimizations and extensions for reducing network load and/or wallclock time. We present these in the following.

5.2 Spatial-aware tree-based aggregation

The aggregation function at the single-round algorithm is commutative and associative, similar to the multi-round algorithm. Therefore, it can be expressed in Spark as a reduction, enabling the Spark engine to fully distribute this part of the algorithm as well. Notice however that Spark does not take spatial proximity of partitions into account when executing the reducers. As

Algorithm 4: MapReduce implementation of Single-round algorithm. Parameters res_1, res_2, res_3, ... represent the results grouped by the same key.

```
Function AtCoordinator($k$)
    $data \leftarrow input.map$(poi to <$partitionIndex, poi$>)
    $data \leftarrow data.groupByKey(partitionIndex)$
    /* first compute the local results per
       partition                                  */
    $localAns \leftarrow data.map$(modified Alg1.$Local(k)$)
    /* recursive hierarchical aggr.               */
    for $i$=1 to $treeHeight$ do
        $localAns \leftarrow$
          $localAns.map(recomputePartitionIndexes(b))$
          $.groupByKey(partitionIndex).map(mergeRegions(k))$
    $Ans \leftarrow localAns$
Function mergeRegions(<$res_1, res_2, res_3, \ldots$>, $k$)
    $\mathcal{G} \leftarrow \emptyset$
    $pos \leftarrow 0$
    $unionRes \leftarrow sortDesc(res_1 \cup res_2 \cup res_3 \ldots)$
    while ($\mathcal{G}.safeCnt < k$) do
        $\mathcal{G}.addRegion(unionRes.get(pos))$
        $pos \leftarrow pos + 1$
    return $\mathcal{G}$
```

such, for a 16-partitions example of Fig. 5, one possible reduction order could be the following (where $\oplus$ denotes the reduction/aggregation function of the results): $(((1 \oplus 16) \oplus (5 \oplus 11)) \oplus (9 \oplus 7)) \oplus (4 \oplus 13) \ldots$. This random-order reduction precludes a core optimization, since merging distant partitions (e.g., partitions 1 and 16) does not help the reduction function to increase the per-partition number of safe regions. Ideally, we could reduce partition results in a proximity-aware hierarchical approach (i.e., order $((1 \oplus 2) \oplus (3 \oplus 4))\ldots$). Then, the merging process would, for example, exploit the partial results of partition 1 to mark the partial results of partition 2 that border with partition 1 as safe, or to exclude them, depending on their overlap and scores.

To exploit this observation, we enforce an explicit reduction order to Spark by introducing a hierarchical structure of aggregations. Fig. 5 depicts a small example with a hierarchical aggregation of 16 partitions. First, we apply a Z-order curve to assign an id to all partitions. Notice that close-by ids now mostly have spatial proximity. Then, each partition with id id assumes place in the hierarchy as the child of parent with id $\lceil id/b^2 \rceil$, where b^2 is the desired fan-out of our hierarchy. In our example, partitions with id 1 to 4 become children of a parent with id 1, i.e., their results will be merged together with a reduction in order to receive their parent node 1. The aggregation process continues recursively, until we reach to a single parent.

In concrete terms, let P denote the total number of partitions, and $p = b^i$ be the smallest power of $b \in \mathbb{N}^+$ that is greater than or equal to P, for a user-configured value of b. The space is recursively partitioned to p tiles of equal size ($b \times b$ tiles at each recursion), giving rise to a (b^2)-ary aggregation tree. This aggregation tree is represented in Spark with a chain of *map* and *groupByKey* sequences (Alg. 4, lines 5-7). The *map* functions determine the place of the tile in the hierarchy (essentially the id of the parent reducer), and the *groupByKey* functions bring together the results of the neighboring partitions, for the merging algorithm to run (function *mergeRegions*). The process continues until the root of the hierarchy, and the results are finally collected by the coordinator. Again, this whole process is executed in a decentralized fashion, and the coordinator only receives the final results. The value b that determines the number of levels in the tree hierarchy is important. A very small value of b, e.g., 2, leads to many levels, introducing significant synchronization overhead in Spark. At the other extreme, very large b values lead to low parallelism and large memory requirements at the nodes.

5.3 Peer-to-peer communication

Up to now, construction of the extended dependency graph did not exploit information regarding the neighboring partitions. As such, all artificial dependencies from neighboring partitions were set in a pessimistic way to dominate the local regions, leading to potentially long dependency chains (e.g., Fig. 6 contains a dependency chain that includes r_1 to r_4, because r_1 is unsafe). To alleviate this issue, we introduce moderate communication between the nodes, for exchanging key statistics regarding their neighboring partitions (e.g., the exact highest score of any region within all border cells, the maximum score of all regions in the border cells, or even the individual regions identified in the border cells and their scores). These statistics or results can then be used during the local algorithm to replace or tighten the artificial dependencies, i.e., to upper-bound the score of the artificial vertices in the extended dependency graph. The amount and type of data to exchange between nodes can lead to a spectrum of configurations that enable a tradeoff between the number of safe regions and the computational overhead and network volume.

This P2P-style communication, though, is not natural in Spark's MapReduce paradigm. One way to simulate it within Spark is by introducing a preliminary round, where each node runs a fast preparation step on each of its partitions and computes the desired statistics. However, this extra round introduces a high synchronization overhead for Spark. Instead, we choose to extend the idea of replication of border cells we described earlier, and assign to each node the additional task of first extracting coarse-grained statistics for the border cells of its eight neighboring partitions, prior to analyzing its own partition. In this way, the code for statistics extraction can be fully integrated in the map process of the single-round algorithm, without requiring an additional round of synchronization.

Particularly, we extend the data held for each partition by one row/column in each direction. In the example of Fig. 2, the yellow-colored cells of the neighboring partitions will also be copied to the node holding $P_{2,2}$, in addition to the blue-colored cells.[3]. When the processing for $P_{2,2}$ is initiated, the first task of the node is to process these replicated border cells and extract these statistics that will be subsequently used for constructing the extended dependency graph. We examined two levels of granularity for these statistics (in decreasing granularity):

- Executing the local algorithm on these cells to extract all contained regions – possibly overlapping each other. The scores of these regions will be an upper bound of the true scores. Therefore, these scores can be used to remove some of the dependency relations of the artificial dependencies in the extended dependency graph, i.e., if the region of the local partition has a higher score than the region in the replicated area (Fig. 6 (left)).

[3]Notice the asymmetry between the replicated cells from the left and the replicated cells from the right of $P_{2,2}$ (similarly for the cells above and below) This happens because the node holding $P_{2,2}$ is also responsible for finding the regions that overlap $P_{2,3}$, but not the ones overlapping $P_{2,1}$

Algorithm 5: Hybrid algorithm – region merging. Parameters $res_1, res_2, res_3, \ldots$ represent the results grouped by the same key.

```
1 Function mergeRegions(<$res_1$, $res_2$, $res_3$, ...>, $k$)
2     $minAcceptableScore \leftarrow$
        $\max(\min(sc(res_1)), \min(sc(res_2)), \min(sc(res_3)), \ldots)$
3     $\mathcal{G} \leftarrow \emptyset$ , $pos \leftarrow 0$
4     $unionRes \leftarrow sortDesc(res_1 \cup res_2 \cup res_3 \ldots)$
5     while $\mathcal{G}.safeCnt < k$ & $sc(unionRes.get(pos)) >$
        $minAcceptableScore$ do
6         $\mathcal{G}.addRegion(unionRes.get(pos))$
7         $pos \leftarrow pos + 1$
8     return $\mathcal{G}$
```

- For each border cell of a neighboring partition with coordinates (i, j), compute the score of the $2\epsilon \times 2\epsilon$ region consisting of cells $(i, j), (i + 1, j), (i, j + 1), (i + 1, j + 1)$. This does not require executing the local algorithm, since the exact region boundaries are known. We only need to compute the score function for the region, and use it as an upper bound for the cell. (Fig. 6 (right)).

The first approach produces the tightest upper bounds, but preludes execution of the full local algorithm on the border cells, thereby adding non-negligible time overhead. The second approach produces weaker upper bounds for the scores, but it is much more efficient. In our experiments, the second approach provided the best tradeoff in terms of overall execution time (and, thus, is the only one reported).

5.4 Hybrid algorithm

The single-round algorithm is very conservative, requiring k safe regions to be obtained from every partition. In practice, this leads to additional load for extending the local graphs, that could otherwise be avoided. We next describe a hybrid algorithm (*HY*), which covers the space between the single-round and multi-round algorithms, balancing the number of rounds and the number of results expected from each round. The intuition is that we can execute the single-round algorithm, but now requesting a smaller number of safe regions $k' << k$ per partition, aggregate the partial results, and then progressively ask for more results only from the partitions from which we already consumed at least one safe region. The partial results collected per round are a sorted subset of the final results (at least the next k' answers, but typically much more), and can be presented progressively to the user.

Similar to the case of the multi-round algorithm, the aggregation function (see Alg. 5) needs to stop accepting more data when it can no longer guarantee correctness of results. Correctness of results is guaranteed by establishing a bound for the region scores, above which all regions are guaranteed to be complete. When aggregating partial results of two partitions, say, res_1 and res_2, this score bound is simply the maximum of the two minimum scores in each of the partial results (Line 2). The intuition behind this bound is that the reducer does not have sufficient information about regions with lower score for one of the two, but all possible solutions (safe and unsafe regions) for higher scores are already included in the individual dependency graphs. Notice that this bound is naturally moved up in the hierarchy, as the aggregate results are pushed to parent reducers, and regions with lower scores are filtered out.

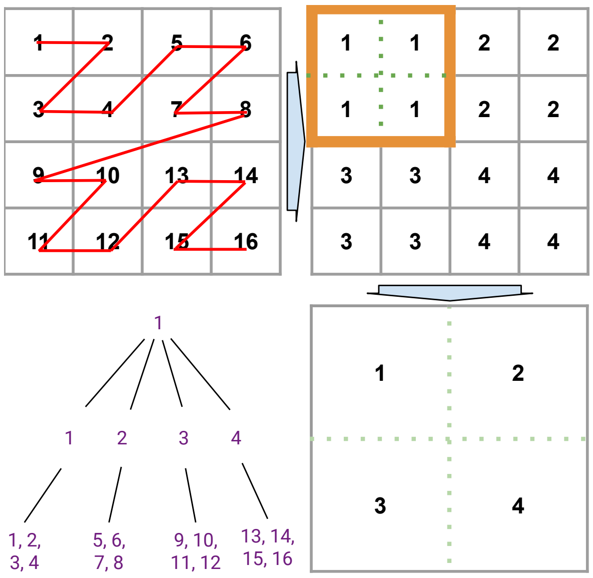

Figure 5: Hierarchical aggregation in 4×4 partitions with $b = 2$ by applying Z-order. The tree depicts the aggregation hierarchy, from 16 partitions to a single result.

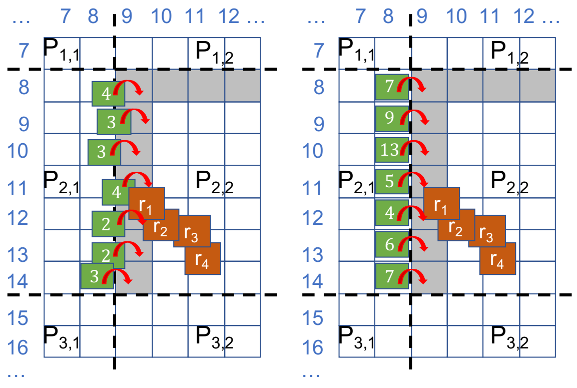

Figure 6: Exchanging region scores (left) or upper bounds for border cells (right).

6 EXPERIMENTAL EVALUATION

We have conducted an experimental evaluation to compare the performance of our proposed algorithms, investigate their scalability, and explore the impact of the various parameters.

6.1 Experimental setting

Datasets. We conducted our experiments using a real-world dataset comprising 64 million records representing Points of Interest from OpenStreetMap[4] and geolocated photos from Flickr[5] worldwide. We have mapped these to 26 million distinct locations (points). We have assigned a weight (score) to each point denoting the number of records (POIs or photos) mapped to it.

Experimental setup. The experiments are executed on a cluster of 11 nodes, each with 30 GB of RAM. Ten of the nodes are configured as workers, and the eleventh is indicated as the master/coordinator. The cluster runs Spark 2.4.3, and Hadoop HDFS

[4] https://www.openstreetmap.org

Parameters	Values
number of points $\|\mathcal{D}\|$	5, 10, 15, 20, **26** million
number of nodes $\|\mathcal{N}\|$	1, 2, 4, 6, 8, **10**
top-k regions	50, 100, 200, **300**, 400, 500
region width and height ϵ	0.00025, 0.0005, 0.00075, **0.001**, 0.00125, 0.0015 (from approximately $27x27m^2$ to $162x162m^2$)
k' – Multi-round	3, 5, 10, 20, 30, 40, 50, 60, **300**
k' – Hybrid	3, 4, 5, 6, **10**, 15

Table 1: Experimental parameters (default value is bold).

2.9.1. The input file is distributed across the 10 workers, with replication factor set to one.

Implementation and configuration. All algorithms are implemented in Scala. Our implementations include by default the hierarchical aggregation for the hybrid algorithm and the corresponding commutative and associative reduction function for the single-round algorithm, since the coordinator becomes a bottleneck (and crashes for some parameters) otherwise.

We partitioned the input points into a uniform grid with dimensions 20,000 × 20,000, leading to partitions of size approximately $2km \times 2km$. The most densely populated partition contains approximately 18,000 points. The value of b in the tree-based aggregation was set to 8. We found these values to provide consistently good performance without creating bottlenecks. Using larger partitions creates bottlenecks during the local execution of the algorithm to the workers, whereas a significantly larger base leads to bottlenecks during the aggregation step (the reducer needs to aggregate too many partial results, which may lead to crashes around dense areas). With respect to all other parameters, unless otherwise mentioned, we use the default values shown in Table 1. The region width and height ϵ is measured in degrees.

6.2 Multi-round vs Single-round

We start by comparing the performance of the multi-round (*MR*) and the single-round (*SR*) algorithms.

We first vary the number of requested top-k regions from 50 to 500. Fig. 7 shows the results – wallclock time for both algorithms on the left Y axis and number of rounds for *MR* on the right Y axis. We see that the value of k has only a minor influence on the performance of *SR*. Conversely, the execution time of *MR* increases as k increases, eventually becoming around 40 times higher than that of *SR*. This stark difference is attributed to the number of rounds required by *MR*. Indicatively, for $k = 500$, *MR* requires 58 rounds, while *SR* only requires one. Of course, one round of execution for *SR* is more time consuming than for *MR* due to the extra time spent on creating and maintaining the dependency graph and continuing the computation of results until k safe ones are found. Indeed, we can observe that the one round of *SR* takes around 700 seconds to complete, whereas each round of *MR* takes on average 400 seconds. Yet, this difference is very small to compensate the extra overhead incurred by the high number of rounds required by *MR*.

In our second experiment (Fig. 8), we fix k to 300 and vary the width and height ϵ of the regions to be discovered. We see that the performance of both algorithms is affected by ϵ. These results are consistent to [19], which shows that the centralized algorithm (being used to retrieve the local top-k results in each partition) becomes slower as ϵ increases. Thus, they also exemplify the importance of having a parallel and distributed solution to achieve scalability. Still, since *SR* only needs to run the local algorithm once, it scales much better than *MR*, which is again affected by

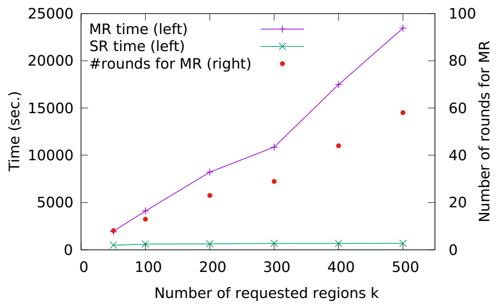

Figure 7: Performance of *MR* and *SR* for varying k.

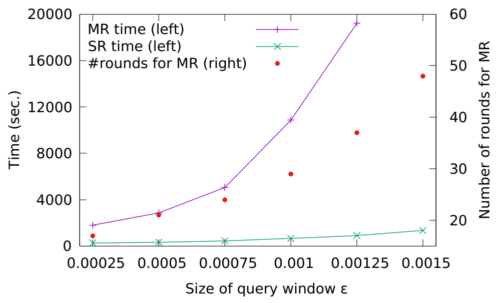

Figure 8: Performance of *MR* and *SR* for varying ϵ (region width and height).

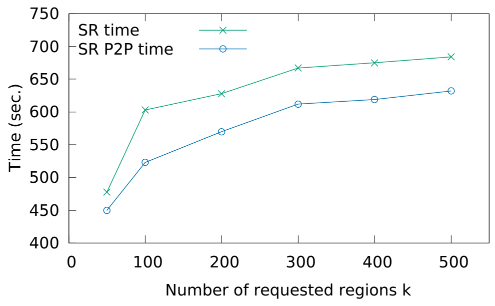

Figure 9: Effect of P2P extension on *SR* for varying k.

the need to execute multiple rounds, eventually requiring one order of magnitude more time compared to *SR*. Indicatively, for $\epsilon = 0.0015°$, *SR* takes 1352 seconds, while *MR* requires 44383 (for illustration reasons, the latter point is omitted in the plot).

We also evaluate the impact of the P2P extension on the performance of *SR*. Figure 9 plots the execution time of the algorithm with and without this extension. As expected, the extension always saves time, since it enables each node to create smaller dependency graphs per partition, and it has very low overhead. Indicatively, the average size of the dependency graph per partition with the P2P extension was reduced by approximate 40% for $k = 50$ and by 55% for $k = 500$. Since P2P consistently improves the performance of *SR*, it is applied in all remaining results.

6.3 Limiting the number of local results

We now examine how limiting the number of local results affects the performance of the algorithms. Recall that both *MR* and the Hybrid algorithm (*HY*) support requesting $k' < k$ results or safe regions from each partition at each round.

Figure 10 plots the execution time (left Y axis) and number of rounds (right axis) for *MR* for various k' values. Clearly, the

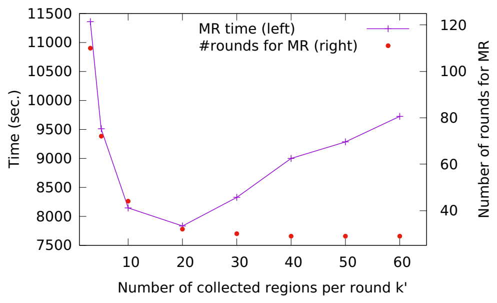

Figure 10: Execution time of *MR* for varying k'.

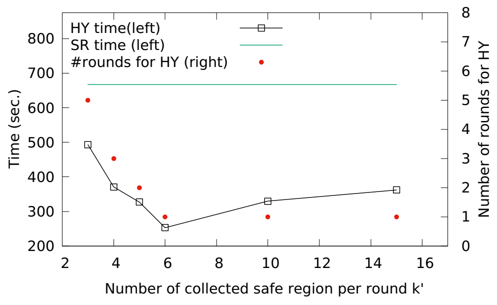

Figure 11: Execution time of *HY* for varying k' (with *SR* included for reference).

value of k' has significant influence on performance. As expected, setting a very low k' leads to a high number of rounds, which translates to excessive synchronization overhead and to longer execution times. Increasing k' until 20 reduces total time by limiting the time spent by the workers on computing the local results (which, in most cases, are anyway not needed by the coordinator). Since this time reduction is per round, and many rounds are required, the overall performance increase is significant. On the other hand, increasing k' beyond a certain point no longer reduces the number of rounds, but increases the average execution time per round, and consequently, the total execution time of the algorithm. Interestingly, already for $k' > 20$, execution time increases with the value of k', i.e., the performance gain because of reduction of the number of rounds is overshadowed by the additional time required for computing more local results, and merging them in the reduction phase.

Figure 11 depicts the influence of the respective parameter k' for *HY*. In this case, k' denotes the number of safe regions requested per partition. We see that a very low value of k' raises the need for additional rounds, since the appearance of non-admissible results prevents the coordinator from obtaining a valid top-k at the first place. However, with k' equal to 6, *HY* already completes in a single round and achieves the optimal performance, which is around one third of the baseline performance of *SR* (this would correspond to the worst performance of *HY*). It is also worth noticing that, in absolute time difference, *HY* is not as sensitive as *MR* with respect to a higher-than-optimal number of local results (cf., a high k' value in Fig 10). For example, even when collecting 15 safe regions per round (2.5 times more than the optimal), the difference in time is only around 100 seconds, compared to around 2000 seconds for *MR*. This is attributed to the fact that a sub-optimal value of k' affects much fewer rounds in *HY*, compared to a sub-optimal value of k' for *MR*. Thus, when tuning *HY*, it is relatively easier to find a good value for k'.

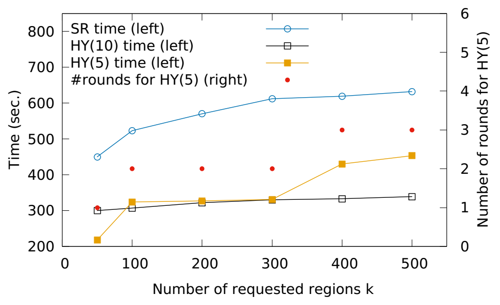

Figure 12: Comparison of *SR* and *HY* for varying k. *HY*(5) and *HY*(10) correspond to *HY* with $k' = 5$ and $k' = 10$, respectively. *HY*(10) always completes in a single round.

6.4 Comparing *SR* and *HY*

We now evaluate the performance of *SR* and *HY* for varying k and ϵ. We omit *MR* in these experiments since, as already indicated in previous results, it is always outperformed significantly by *SR*.

Figure12 presents the execution time of both algorithms, for different values of k, and for two hybrid executions with $k' = 5$ and $k' = 10$, noted as *HY*(5) and *HY*(10), respectively. The plot also includes the number of rounds for *HY*(5) (right Y axis). The number of rounds for *HY*(10) (and for *SR*) is always 1, and therefore it is omitted. As expected, the value of k brings a noticeable increase on the cost of *SR*, since it leads to larger dependency graphs. For *HY*(5), a higher k leads to more rounds, which also causes an increase in execution time. Nevertheless, *HY*(5) still outperforms *SR*, because due to the low value of k' the additional rounds are much faster compared to one round of *SR*. Also, *HY*(10) exhibits a very mild increase of the execution time (300 seconds for $k = 50$, compared to 339 seconds for $k = 500$). Since Hybrid(10) always takes 1 round, even for k=500, this increase is solely attributed to the extra cost during the hierarchical reduction: reducers need to maintain longer lists, and pass these lists to their parent nodes in the tree hierarchy. Still, this increase is negligible. Therefore, it is better to opt for a slightly higher value of k', in order to avoid the risk of running multiple rounds.

Figure 13 shows the execution time of *SR* and *HY*(10) for varying ϵ. Both algorithms exhibit a similar trend, but with *HY* consistently outperforming *SR*, and with the absolute difference between the execution time growing as ϵ increases. Detailed profiling on this result reveals that the additional time is exclusively spent on the local algorithm. As ϵ increases, the local algorithm spends more time for generating *each* result. Since *SR* has to compute 300 results in each partition, whereas *HY*(10) only 10, the total difference between the execution time of the two algorithms increases when the time spent per result is higher.

6.5 Scalability

Our last set of experiments focuses on investigating the scalability of the three algorithms, when varying the size of the dataset or number of executor nodes.

Given the original dataset, containing 26 million distinct points, we derive datasets of size from 5 to 20 million points by applying uniform sampling. Fig. 14 plots the execution time of the three algorithms. We observe that *MR* is the slowest algorithm in all cases, while *HY* performs better than *SR*. Moreover, *MR* demonstrates poor scalability compared to the other two, which exhibit similar performance, with *HY* scaling slightly better.

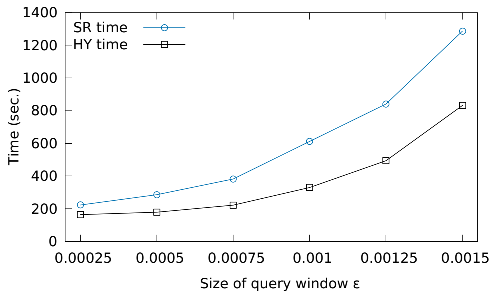

Figure 13: Comparison of *SR* and *HY* for varying ϵ. The number of rounds for *HY* is always one in this set of experiments (for k' set to 10).

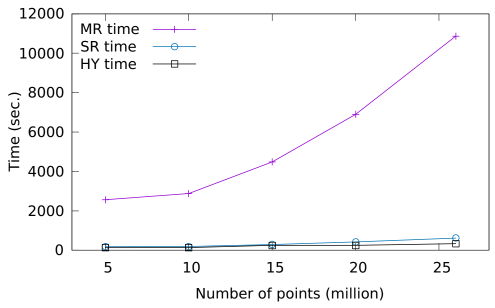

Figure 14: Execution time of *MR*, *SR*, *HY* for varying the number of points.

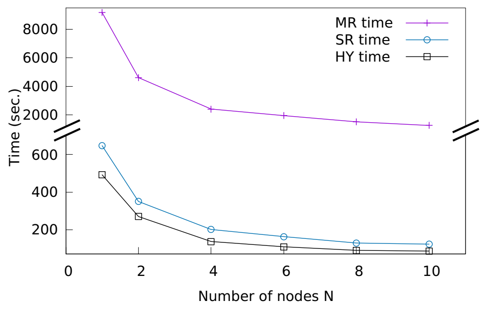

Figure 15: Execution time of *MR*, *SR*, *HY* for varying the number of nodes.

In our second experiment (Fig. 15), we vary the number of nodes from 1 to 10. Since it is not possible to process the whole dataset (26 million points) in a single node due to memory limitations, we sample 5 million points as input (i.e., the largest dataset size executable in a single node). As shown, addition of extra nodes decreases overall execution time for all algorithms, with *SR* and *HY* exhibiting linear speedup.

6.6 Summary

The experiments show that *SR* substantially outperforms *MR* in all cases, indicating that the extra cost incurred by multiple rounds dominates that for retrieving a sufficiently larger number of local results to ensure the construction of the global top-k in a single round. Overall, *HY* is the most efficient algorithm, indicating that in practice it suffices to compute just a few more than k local results to ensure that the coordinator can assemble the correct top-k list, despite any inadmissible local results.

Moreover, both algorithms *MR* and *HY* can benefit from setting the parameter k' to a much lower value than k (e.g., around 0.1 $\times$ k). This significantly increases the efficiency of *HY* due to the drastic reduction of the cost of local processing, while still obtaining the global top-k results in one or two rounds.

7 CONCLUSIONS

We have presented the first scalable algorithms for addressing the *top-k Best Region Search* problem. Our approach relies on distributing the dataset and the expensive computational part over cluster resources, thereby allowing the processing of large datasets in parallel. Starting from a multi-round algorithm, we proceed to devise one that requires a single round and is more efficient by one order of magnitude. Then, we also propose a hybrid algorithm, which further reduces computational time by a factor of two. Our future work focuses on continuous algorithms, for maintaining the answer in dynamic datasets, as well as approximation techniques, for further reducing the computational cost when small, bounded errors can be tolerated.

ABSTRACT

Data curation – the process of discovering, integrating, and cleaning data – is one of the oldest, hardest, yet inevitable data management problems. Despite decades of efforts from both researchers and practitioners, it is still one of the most time consuming and least enjoyable work of data scientists. In most organizations, data curation plays an important role so as to fully unlock the value of big data. Unfortunately, the current solutions are not keeping up with the ever-changing data ecosystem, because they often require substantially high human cost. Meanwhile, deep learning is making strides in achieving remarkable successes in multiple areas, such as image recognition, natural language processing, and speech recognition. In this vision paper, we explore how some of the fundamental innovations in deep learning could be leveraged to improve existing data curation solutions and to help build new ones. We identify interesting research opportunities and dispel common myths. We hope that the synthesis of these important domains will unleash a series of research activities that will lead to significantly improved solutions for many data curation tasks.

1 INTRODUCTION

Data Curation (DC) [32, 44] – the process of discovering, integrating [46] and cleaning data (Figure 1) for downstream analytic tasks – is critical for any organization to extract real business value from their data. The following are the most important problems that have been extensively studied by the database community under the umbrella of data curation: *data discovery*, the process of identifying relevant data for a specific task; *schema matching and schema mapping*, the process of identifying similar columns and learning the transformation between matched columns, respectively; *entity resolution*, the problem of identifying pairs of *tuples* that denote the same entity; and *data cleaning*, the process of identifying errors in the data and possibly repairing them. These are in addition to problems related to outlier detection, data imputation, and data dependencies.

Due to the importance of data curation, there has been many commercial solutions (for example, Tamr [45] and Trifacta [23]) and academic efforts for all aspects of DC, including data discovery [8, 19, 33, 36], data integration [12, 27], and data cleaning [7, 16, 42]. An oft-cited statistic is that data scientists spend 80% of their time curating their data [8]. Most DC solutions cannot be fully automated, as they are often *ad-hoc* and require substantial effort to generate things, such as features and labeled data, which are used to synthesize rules and train machine learning models. Practitioners need practical and usable solutions that can significantly reduce the human cost.

Deep Learning (DL) is a successful paradigm within the area of machine learning (ML) that has achieved significant successes in diverse areas, such as computer vision, natural language processing, speech recognition, genomics, and many more. The trifecta of big data, better algorithms, and faster processing power has resulted in DL achieving outstanding performance in many areas. Due to these successes, there has been extensive new research seeking to apply DL to other areas both inside and outside of computer science.

Data Curation Meets Deep Learning. In this article, we investigate intriguing research opportunities for answering the following questions:

- What does it take to significantly advance a challenging area such as DC?
- How can we leverage techniques from DL for DC?
- Given the many DL research efforts, how can we identify the most promising leads that are most relevant to DC?

We believe that DL brings unique opportunities for DC, which our community must seize upon. We identified two fundamental ideas with great potential to solve challenging DC problems.

Feature (or Representation) Learning. For ML- or non-ML based DC solutions, domain experts are heavily involved in feature engineering and data understanding so as to define data quality rules. *Representation learning* is a fundamental idea in DL where appropriate features for a given task are automatically learned instead of being manually crafted. Developing DC-specific representation learning algorithms could dramatically alleviate many of the frustrations domain experts face when solving DC problems. The learned representation must be generic such that it could be used for multiple DC tasks.

DL Architectures for DC. So far, no DL architecture exists that is cognizant of the characteristics of DC tasks, such as representations for tuples or columns, integrity constraints, and so on. Naively applying existing DL architectures may work well for some, but definitely not all, DC tasks. Instead, designing new DL architectures that are tailored for DC and are cognizant of the characteristics of DC tasks would allow efficient learning both in terms of training time and the amount of required training data. Given the success of domain specific DL architectures in computer vision and natural language processing, it behooves us to design an equivalent of such a DL architecture customized for DC task(s).

Contributions and Roadmap. The major elements of our proposed approach to exploiting the huge potential offered by DL to tackle key DC challenges include:

- **Representation Learning for Data Curation.** We describe several research directions for building representations that are explicitly designed for DC. Developing algorithms for representation learning that can work on multiple modalities of data (structured, unstructured, graphical),

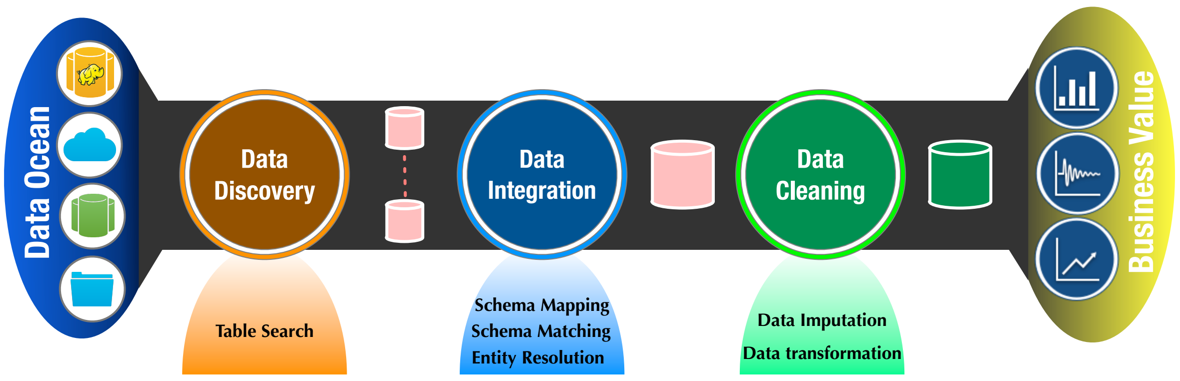

Figure 1: A Data Curation Pipeline

and can work on diverse DC tasks (such as deduplication, error detection, data repair) is challenging.

- **Deep Learning Architectures for Data Curation Tasks.** We identify some of the most common tasks in DC and propose preliminary solutions using DL. We also highlight the importance of designing DC specific DL architectures.
- **Early Successes of DL for DC.** In the last couple of years, there has been some promising developments in applying DL to some DC problems such as data discovery [19] and entity resolution [14, 35]. We provide a brief overview of these work and the lessons learned.
- **Taming DL's Hunger for Data.** DL often requires a large amount of training data. However, there are multiple promising techniques, which when adapted for DC, could dramatically reduce the required amount of labeled data.
- **Myths and Concerns about DL.** DL is still a relatively new concept, especially for database applications and is not a silver bullet. We thus identify and address a number of myths and concerns about DL.

2 DEEP LEARNING FUNDAMENTALS

We provide a quick overview of relevant DL concepts needed for the latter sections. Please refer to [5, 20, 29] for additional details.

Deep learning is a subfield of ML that seeks to learn meaningful representations from the data using computational models that are composed of multiple processing layers. The representations could be then used to solve the task at hand effectively. The most commonly used DL models are neural networks with many hidden layers. The key insight is that successive layers in this "deep" neural network can be used to learn increasingly useful representations of the data. Intuitively, the input layer often takes in the raw features. As the data is forwarded and transformed by each layer, an increasingly sophisticated and more meaningful information (representation) is extracted. This incremental manner in which increasingly sophisticated representations are learned layer-by-layer is one of the defining characteristic of DL.

2.1 Deep Learning Architectures

Fully-connected Neural Networks. The simplest model is a neural network with many hidden layers – a series of layers where each node in a given layer is connected to every other node in the next layer. They are also called feed-forward neural network. It can learn relationships between any two input features or intermediate representations. Its generality however comes with a cost; one has to learn weights and parameters which requires a lot of training data.

Domain Specific Architectures. There are a number of neural network architectures that are designed to leverage the domain specific characteristics. For example, Convolutional Neural Networks (CNNs) are widely used by the computer vision community. The input is fed through convolutions layers, where neurons in convolutional layers only connect to close neighbors (instead of all neurons connecting to all neurons). This method excels in identifying spatially local patterns and use it to learn spatial hierarchies such as nose → face → human. Recurrent Neural Networks (RNNs) are widely used in Natural Language Processing (NLP) and Speech recognition. RNN processes inputs in a sequence one step at a time. For example, given two words "data curation", it first handles "data" and then "curation". Neurons in an RNN are designed by being fed with information not just from the previous layer but also from themselves from the previous pass that are relevant for NLP.

2.2 Distributed Representations

Deep learning is based on learning data representations, and the concept of distributed representations (*a.k.a.* embeddings) is often central to DL. *Distributed representations* [24] represent one object by many representational elements (or many neurons). Each neuron is associated with more than one represented object. That is, the neurons represent features of objects. Distributed representations are very expressive and can handle semantic similarity. These advantages become especially relevant in domains such as DC. There has been extensive work on developing algorithms for learning distributed representations for different types of entities such as words and nodes.

Distributed Representations of Words (*a.k.a.* word embeddings) seek to map individual words to a vector space, which helps DL algorithms to achieve better performance in NLP tasks by grouping similar words. The dimensionality is often fixed (such as 300) and the representation is often *dense*. Word embeddings are often learned from the data in such a way that semantically related words are often close to each other. The geometric relationship between words often also encodes a semantic relationship between them. An oft-quoted example shows that by adding the vector corresponding to the concept of *female* to the distributed representation of *king*, we (approximately) obtain the distributed representation of *queen*.

Distributed Representations of Graphs (*a.k.a.* network embeddings) are a popular mechanism to effectively learn appropriate features for graphs (see [6] for a survey). Each node is represented as a dense fixed length high dimensional vector. The optimization objective is neighborhood-preserving whereby two nodes that are in the same neighborhood will have similar representations. Different definitions of neighborhood results in different representations for nodes.

Distributed Representations for Sets. Sets are a fundamental data structure where the order of items does not matter. Sets are extensively used in the Codd model where each tuple is a set of atomic units and a relation is a set of tuples. Algorithms for learning set embeddings must ensure that they have permutation invariance so that any permutation of the set should obtain the same embedding. There has been a number of popular algorithms for processing sets to produce such embeddings such as [41, 52].

Compositions of Distributed Representations. One can then use these to design distributional representations of atomic units – words in NLP, or nodes in a graph – for more complex units. For NLP, these could be sentences (*i.e.,* sentence2vec), paragraphs or even documents (*i.e.,* doc2vec) [28]. In the case of graphs, it can be subgraphs or entire graph.

3 REPRESENTATION LEARNING FOR DATA CURATION

In this section, we discuss potential research opportunities for designing DL architectures and algorithms for learning DC specific representations.

3.1 The Need for DC Specific Distributed Representations

Data curation is the process of discovering, integrating and cleaning data for downstream tasks. There are a number of challenging sub-problems in data curation. However, a number of problems could be unified through the prism of "matching".

Data Discovery is the process of identifying relevant data for a specific task. In most enterprises, data is often scattered across a large number of tables that could range in the tens of thousands. As an example, the user might be interested in identifying all tables describing user studies involving insulin. The typical approach involves asking an expert or performing manual data exploration [8]. Data discovery could be considered as identifying tables that *match* a user specification (*e.g.,* a keyword or an SQL query).

Schema Matching is the problem of identifying a pair of *columns* from different tables that are (semantically) related and provide comparable information about an underlying entity. For example, two columns *wage* and *salary* could store similar information. The problem of **schema mapping** seeks to learn the transformation between matched columns such as *hourly wage* and *monthly salary.* One can see that this problem seeks to identify *matching* columns.

Data Cleaning is the general problem of detecting errors in a dataset and repairing them in order to improve the quality of the data. This includes qualitative data cleaning which uses mainly integrity constraints, rules, or patterns to detect errors and quantitative approaches which are mainly based on statistical methods. Many sub-problems in data cleaning fall under the ambit of matching. These include:

- **Entity Resolution** is the problem of identifying pairs of *tuples* that denote the same entity. For example, the tuple ⟨Bill Gates, MS⟩ and ⟨William Gates, Microsoft⟩ refer to the same person. This has a number of applications such as identifying duplicate tuples between two tables. Once again, we can see that this corresponds to discovering *matching* entities (or tuples), *i.e.,* those that refer to the same real-world objects.
- **Data Dependencies** specify how one attribute value depends on other attribute values. This is widely used as integrity constraints for capturing data violations. For example, the social security number determines a person's name while the country name typically determines its capital. We can see that this could be treated as an instance of *relevance matching*.
- **Outlier Detection** identifies anomalous data that *does not match* a group of values, either syntactically, semantically, or statistically. For example, the phone number $123-456-7890$ is anomalous when the other values are of the form *nnnnnnnnnn*.
- **Data Imputation.** is the problem of guessing the missing value that should *match* its surrounding evidence.

The main drawback of traditional DC solutions is that they typically use syntactic similarity based features. The syntactic approach is often ad-hoc, heavily reliant on domain experts and thus not extensible. While they are effective, they cannot leverage semantic similarity. A different approach is needed.

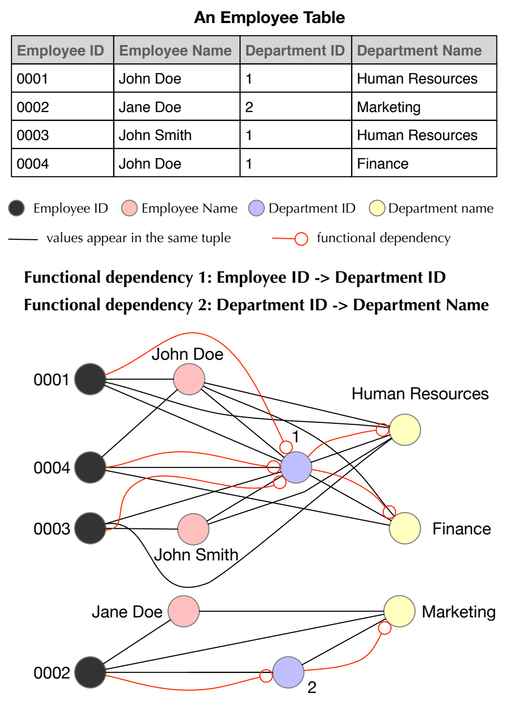
Intuitively, distributed representations, which can interpret one object in many different ways, may provide great help for various DC problems. However, there are a number of challenges before they could be used in DC. In domains such as NLP, simple co-occurrence is a sufficient approximation for distributional similarity. In contrast, domains such as DC require much more complex syntactic and semantic relationships between (multiple) attribute values, tuples, columns, and tables. Furthermore, the data itself could be noisy and the learned distributions should be resilient to errors.

3.2 Distributed Representation of Cells

A *cell*, which is an attribute value of a tuple, is the atomic data element in a relational database. Learning distributed representation for cells is already quite challenging and requires synthesis of representation learning of words and graphs.

Word Embeddings based Approaches. An initial approach inspired by word2vec [31] treats this as equivalent to the problem of learning word embeddings. Each tuple corresponds to a document where the value of each attribute corresponds to words. Hence, if two cell values occur together often in a similar context, then their distributed representation will be similar. For example, if a relation has attributes Country and Capital with many tuples containing *(USA, Washington DC)* for these two attributes, then their distributed representations would be similar.

Limitations of this Approach. The embeddings produced by this approach suffer from a number of issues. First, databases are typically well normalized to reduce redundancy, which also minimizes the frequency that two semantically related attribute values co-occur in the same tuples. Databases have many data dependencies (or integrity constraints), within tables (*e.g.,* functional dependencies [2], and conditional functional dependencies [17])



An Employee Table

Employee ID	Employee Name	Department ID	Department Name
0001	John Doe	1	Human Resources
0002	Jane Doe	2	Marketing
0003	John Smith	1	Human Resources
0004	John Doe	1	Finance

Functional dependency 1: Employee ID -> Department ID
Functional dependency 2: Department ID -> Department Name

Figure 2: A Heterogeneous Graph of A Table

or across tables (*e.g.,* foreign keys, and matching dependencies). These data dependencies are important hints about semantically related cells that should be captured by learning distributed representations of cells.

Combining Word and Graph Embeddings. To capture the relationships (*e.g.,* integrity constraints) between cells, a more natural way is to treat each relation as a *heterogeneous network.* Each relation D is modeled as a graph $G(V, E)$, where each node $u \in V$ is a unique attribute value, and each edge $(u, v) \in E$ represents multiple relationships, such as (u, v) co-occur in one tuple, there is functional dependency from the attribute of u to the attribute of v, and so on. The edges could be either directed or undirected, have labels and weights. This enriched model might provide a more meaningful distributed representation that is cognizant of both content and constraints.

A sample table and our proposed graph representation of the table is shown in Figure 2. There are four distinct Employee ID values (nodes), three distinct Employee Name values, two distinct Department ID values, and three Department Name values. There are two types of edges: undirected edges indicating values appearing in the same tuple, *e.g.,* 0001 and John Doe, and directed edges for functional dependencies, *e.g.,* Employee ID 0001 implies DepartmentID 1.

Research Opportunities.

- *Algorithms.* How can we design an algorithm for learning cell embeddings that take values, integrity constraints, and other metadata (*e.g.,* a query workload) into consideration?
- *Global Distributed Representations.* We need to learn distributed representations for the cells over the entire data lake, not only on one relation. How can we "transfer" knowledge gained from one relation to another to improve the representations?
- *Handling Rare Values.* Word embeddings often provide inadequate representations for rare values. How can we ensure that primary keys and other rare values have a meaningful representation?

3.3 Hierarchical Distributed Representations

Many DC tasks are often performed at a higher level of granularity than cells. The next fundamental question to solve is to design an algorithm to *compose* the distributed representations of more abstract units from these atomic units. As an example, how can one design an algorithm for tuple embeddings assuming one already has a distributed representation for each of its attribute values? A common approach is to simply *average* the distributed representation of all its component values.

Research Opportunities.

- *Tuple, Column and Table Embeddings (Tuple2Vec, Column2Vec, Table2Vec):* Are there any other elegant approaches to compose representations for tuples than averaging? Can it be composed from representations for cells? Or should it be learned directly? How can one extend this idea to learn representations for columns that are often useful for tasks such as schema matching? Finally, how can one learn a representation for the entire relation that can benefit a number of tasks such as copy detection or data discovery (finding similar relations)?
- *Compositional or Direct Learning*: Different domains require different ways to create hierarchical representations. For the computer vision domain, hierarchical representations such as shapes are learned by composing simpler individual representations such as edges. On the other hand, for NLP, hierarchical representations are often learned directly [28]. What is an appropriate mechanism for DC?
- *Contextual Embeddings for DC.* There has been increasing interest in the NLP community in contextual embeddings [10, 38] that can provide different embeddings for a word (such as apple) based on the surrounding context. This is often helpful for tasks requiring word disambiguation. Often, DC tasks require a number of contextual information and hence any learned representation must take that into account. What is an appropriate formalization of context and algorithms for contextual embeddings in DC?
- *Multi Modal Embeddings for DC.* Enterprises often possess data across various modalities, such as structured data (*e.g.,* relations), unstructured data (*e.g.,* documents), graphical data (*e.g.,* enterprise networks), and even videos, audios, and images. An intriguing line of research is *cross modal representation learning* [25], wherein two entities that are similar in one or more modalities, *e.g.,* occurring in the same relation, document, image, and so on, will have similar distributed representations.

4 DEEP LEARNING ARCHITECTURES FOR DATA CURATION TASKS

Representation learning and domain specific architectures are the two pillars that led to the major successes achieved by DL in various domains. While representation learning ensures that the input to the DL model contains all relevant information, the domain specific architecture often processes the input in a meaningful way requiring less training data than generic architectures.

In this section, we motivate the need for designing DC specific architecture and provide a promising design space to explore.

4.1 Need for DC Specific DL Architectures

Recall from Section 2 that a fully connected architecture is the most generic one. It does not make any domain specific assumptions and hence can be used for arbitrary domains. However, this generality comes at a cost: a lot of training data. One can argue that a major part of DL's success in computer vision and NLP is due to the design of specialized DL architectures – CNN and RNN respectively. CNN leverages spatial hierarchies of patterns where complex/global patterns are often composed of simpler/local patterns (*e.g., curves → mouth → face*). Similarly, RNN processes an input sequence one step at a time while maintaining an internal state. These assumptions allows one to design effective neural architectures for processing images and text that also require less training data. This is especially important in data curation where there is a persistent scarcity of labeled data. There is a pressing need for new DL architectures that are tailored for DC and are cognizant of the characteristics of DC tasks. This would allow them to do the learning efficiently both in terms of training time and the amount of required training data.

Desiderata for DC-DL Architectures.

- *Handling Heterogeneity.* In both CNN and RNN, the input is homogeneous – images and text. However, a relation can contain a wide variety of data, such as categorical, ordinal, numerical, textual, and image.
- *Set/Bag Semantics.* While an image can be considered as a sequence of pixels and a document as a sequence of words, such an abstraction does not work for relational data. Furthermore, the relational algebra is based on set and bag semantics with the major query languages specified as set operators. DL architectures that operate on sets are an under explored area in DL.
- *Long Range Dependencies.* The DC architecture must be able to determine long range dependencies across attributes and sometimes across relations. Many DC tasks rely on the knowledge of such dependencies. They should also be able to leverage additional domain knowledge and integrity constraints.

4.2 Design Space for DC-DL Architectures

Broadly speaking, there are two areas in which DL architectures could be used in DC. First, novel DL architectures are needed for learning effective representations for downstream DC tasks. Second, we need DL architectures for common DC tasks such as matching, data repair, imputation, and so on. Both are challenging on their own right and require significant innovations.

Architectures for DC Representation Learning. In a number of fields such as computer vision, deep neural networks learn general features in early layers and transition to task specific features in the latter layers. Initial layers learn generic features such as edges (which can be used in many tasks) while latter layers learn high level concepts such as a cat or dog (which could be used for task for recognizing cats from dogs). Models trained on large datasets such as ImageNet could be used as feature extractors followed by specific task specific models. Similarly, in NLP there has been a number of pretrained language models such as word2vec [31], ELMo [38], and BERT [10] that could then be customized for various tasks such as classification, question answering, semantic matching, and coreference resolution. In other words, the pre-trained DL models act as a set of Lego bricks that could be put together to perform the required functionality. It is thus important that the DL architecture for DC follows this property by learning features that are generic and could readily generalize to many DC tasks.

While there has been extensive work in linguistics about the hierarchical representations of language, a corresponding investigation in data curation is lacking. Nevertheless, we believe that a generic DC representation learning architecture must be inspired based on the pretrained language models. Once such an architecture is identified, the learned representations could be used for multiple DC tasks.

DL Architectures for DC Tasks. While the generic approach is often powerful, it is important that we must also work on DL architectures for specific DC tasks. This approach is often much simpler and provides incremental gains while also increasing our understanding of DL-DC nexus. In fact, this has been the approach taken by the NLP community - they worked on DL architectures for specific tasks (such as text classification or question answering) even while they searched for more expressive generative language models.

A promising approach is to take specific DC tasks and break them into simpler components and evaluate if there are existing DL architectures that could be reused. Often, it is possible to "compose" individual DL models to create a more complex model for solving a specific DC task. Many of the DC tasks could be considered as a combination of tasks such as matching, error detection, data repair, imputation, ranking, discovery, and syntactic/semantic transformations. An intriguing research question is to identify DL models for each of these and investigate how to instantiate and compose them together.

4.3 Pre-Trained DL Models for DC

In domains such as computer vision and NLP, there is a common tradition of training a DL model on a large dataset and then reusing it (after some tuning) for tasks on other smaller datasets. One example include ImageNet [9] which contains almost 14M images over 20k categories. The spatial hierarchy learned from this dataset is often a proxy for modeling the visual world [5] and can be applied on a different dataset and even different categories [5]. Similarly, in NLP, word embeddings are an effective approximation for language modeling. The embeddings are often learned from large diverse corpora such as Wikipedia or PubMed and could be used for downstream NLP tasks. These pre-trained models can be used in two ways: (a) *feature extraction* where these are used to extract generic features that are fed to a separate classifier for the task at hand; (b) *fine-tuning* where one adjusts the abstract representations from the last few hidden layers of a pre-trained model and make it more relevant to a targeted task. A promising research avenue is the design of pre-trained DL models for DC that could be used by others with comparatively less resources.

5 EARLY SUCCESSES OF DL FOR DC

In this section, we describe the early successes achieved by the DC community on using DL for major DC tasks such as data discovery and entity matching.

5.1 Data Discovery

Large enterprises typically possess hundreds or thousands of databases and relations. Data required for analytic tasks is often scattered across multiple databases depending on who collected the data. This makes the process of finding relevant data for a particular analytic task very challenging. Usually, there is no domain expert who has complete knowledge about the entire data repository. This results in a non-optimal scenario where the data analyst patches together data from her prior knowledge or limited searches – thereby leaving out potentially useful and relevant data.

As an example of applying word embeddings for data discovery, [19] shows how to discover semantic links between different data units, which are materialized in the *enterprise knowledge graph* (EKG)[1]. These links assist in data discovery by linking tables to each other, to facilitate navigating the schemas, and by relating data to external data sources such as ontologies and dictionaries, to help explain the schema meaning. A key component is a semantic matcher based on word embeddings. The key idea is that a group of words is similar to another group of words if the average similarity in the embeddings between all pairs of words is high. This approach was able to surface links that were previously unknown to the analysts, *e.g., isoform*, a type of protein, with *Protein* and *Pcr* – polymerase chain reaction, a technique to amplify a segment of DNA – with *assay*. We can see that any approach using syntactic similarity measures such as edit distance would not have identified these connections.

5.2 Entity Matching

Entity matching is a key problem in data integration, which determines if two tuples refer to the same underlying real-world entity [15].

DeepER. A recent work [14], DeepER, applies DL techniques for ER, whose overall architecture is shown in Figure 3. DeepER outperforms existing ER solutions in terms of accuracy, efficiency, and ease-of-use. For accuracy, DeepER uses sophisticated compositional methods, namely uni- and bi-directional recurrent neural networks (RNNs) with long short term memory (LSTM) hidden units to convert each tuple to a distributed representation, which are used to capture similarities between tuples. DeepER uses a locality sensitive hashing (LSH) based approach for blocking; it takes all attributes of a tuple into consideration and produces much smaller blocks, compared with traditional methods that consider only few attributes. For ease-of-use, DeepER requires much less human labeled data, and does not need feature engineering, compared with traditional machine learning based approaches which require handcrafted features, and similarity functions along with their associated thresholds.

DeepMatcher [35] proposes a template based architecture for entity matching. Figure 4 shows an illustration. It identifies four major components: attribute embedding, attribute summarization, attribute similarity and matching. It proposes various choices for each of these components leading to a rich design space. The four most promising models differ primarily in how the attribute summarization is performed and are dubbed as SIF, RNN, Attention, and Hybrid. SIF model is the simplest and computes a weighted average aggregation over word embeddings to get the attribute embedding. RNN uses a bi-directional

[1]An EKG is a graph structure whose nodes are data elements such as tables, attributes, and reference data such as ontologies and mapping tables, and whose edges represent different relationships between nodes.

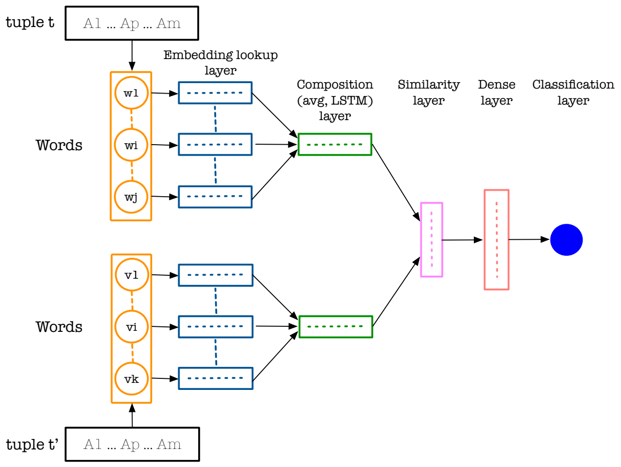


Figure 3: DeepER Framework (Figure from [14])

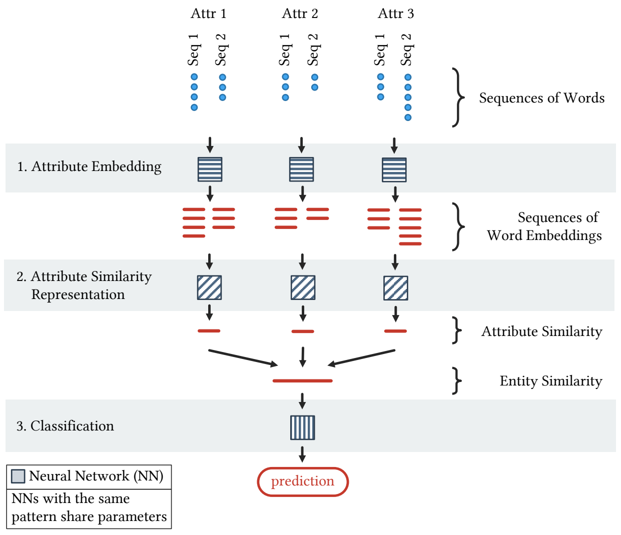

Figure 4: DeepMatcher Framework (Figure from [35])

GRU for summarizing an attribute for efficiency. Attention uses a decomposable attention model that can leverage information from aligned attributes of both tuples to summarize the attribute. Finally, the hybrid approach combines RNN and attention. DeepMatcher was evaluated on a diverse set of datasets such as structured, unstructured and noisy and provides useful rule of thumb on when to use DL for ER.

5.3 Representation Learning

A number of recent works such as DeepER [14], DeepMatcher [35] have applied a compositional approach using averaging or RNN/LSTMs for obtaining tuple embeddings from pre-trained word embeddings. For a number of benchmark datasets in entity resolution, this provides good results. There has been a number of recent efforts for learning distributed representations for data curation directly. Freddy [22] incorporated support for semantic similarity based queries by using pre-trained word embeddings inside Postgres. Termite [18] proposed an effective technique to learn a *common* (distributed) representation for both structured and unstructured data in an organization. In this approach, various entities such as rows, columns, and paragraphs are all represented as a vector. This unified representation allows Termite to identify related concepts even if they are spread across structured and unstructured data. Finally, EmbDC [4] proposed an interesting approach to learn embeddings for cells that combine ideas from word and node embeddings. It constructs a tripartite graph and performs random walks over them. The walks correspond to sentences that are passed to an algorithm that computes word embeddings. This allows for different permutations of the same data being outputted thereby partially incorporating the set semantics. The authors show that this two step approach provides promising results for unsupervised DC tasks such as schema matching and entity resolution.

5.4 Understanding the Success and What is Missing?

Both DeepER and DeepMatcher provide a mechanism to obtain tuple embeddings from pre-trained word embeddings. The similarity between the embeddings of two tuples is then used to train a DL classifier. In both cases, the classifier was generic and hence the state-of-the-art performance of these approaches could be attributed to learning effective representations for the tuples. A follow-up work [50] showed that such learned representations could improve the performance of even non-DL classifiers. [35] performed extensive empirical evaluation and found that deep learning based methods were especially effective for entity resolution involving textual and dirty data. For example, the use of word embeddings allowed the DL based approach to identify that 'Bill' and 'William' are semantically similar while no string similarity metric could do that. Learning such representations could result in some unexpected applications such as performing entity resolution between relations that are in different languages [3].

Something analogous happens in the data discovery scenario as well. The word embedding based approach learned effective representations that could show that certain concepts were relevant (*isoform* and *Protein* or *Pcr* and *assay* as mentioned above) that could not have been identified by any syntactic similarity measures such as edit distance. This ability to learn representations that could identify similar pair of words even if they are syntactically dissimilar explains the success of DL for schema matching in [34, 43].

From the above discussion, it is clear that learning effective representations was the cornerstone of improved performance of DL based methods. Such representations learn relationships that are hard to pull off using non-DL methods. However, these early works are only scratching the surface as they do not yet leverage powerful techniques such as task specific architectures or transfer learning. As an example, DeepMatcher proposed a template based architecture that has two key layers – composition/aggregation and similarity computation. This could be considered as a rudimentary task specific architecture that resulted in reduced training data. Recent work such as [50] and [26] seek to use transfer learning to improve ER. However, the days of using pre-trained ER models for multiple datasets is still far off. Even within representation learning, works have not yet explored the use of contextual embeddings such as ELMO or BERT.

6 TAMING DL'S HUNGER FOR DATA

Deep learning often requires a large amount of training data. Unfortunately, in domains such as DC, it is often prohibitively expensive to get high quality training data. In order for DL to be widely used to solve DC problems, we must overcome the problem of obtaining training data. Fortunately, there are a number of exciting innovations from DL that can be adapted to solve this issue. We highlight some of these promising ideas and discuss some potential research questions.

6.1 Unsupervised Representation Learning

While the amount of *supervised* training data is limited, most enterprises have substantial amount of *unsupervised* data in various relations and data lakes. These unlabeled data could be used to learn some generic patterns and representations that are then used train a DL model with relatively less labeled data. This technique is widely used in NLP where word embeddings are learned on large unlabeled corpus data such as Wikipedia and provide good performance for many downstream NLP tasks.

Research Opportunities.

- How can we perform a *holistic representation learning* over the enterprise data? How can the learned representations be used as features for downstream DC tasks such as entity matching, schema matching, etc? While there are some promising start in recent work such as [4, 51], more needs to be done.

6.2 Data Augmentation

Data augmentation increases the size of labeled training data without increasing the load on domain experts. The key idea is to apply a series of *label preserving transformations* over the existing training data. For an image recognition task, one can apply a transformations such as translation (moving the location of the dog/cat within the image), rotation (changing the orientation), shearing, scaling, changing brightness/color, and so on. Each of these operations does not change the label of the image (cat or dog) – yet generate additional synthetic training data.

Research Opportunities.

- *Label Preserving Transformations for DC.* What does label preserving transformations mean for DC? Is it possible to design an algebra of such transformations?
- *Domain Knowledge Aware Augmentation.* To avoid creating erroneous data, we could integrate domain knowledge and integrity constraints in the data augmentation process. This would ensure that we do not create tuples that say New York City is the capital of USA.
- *Domain Specific Transformations.* There are some recent approaches such as Tanda [40] that seek to learn domain specific transformations. For example, if one knows that *Country* $\rightarrow$ *Capital*, we can just swap the (Country, Capital) values of two tuples to generate two new tuples. In this case, even if the new tuple is not necessarily real, its label will be the same as the original tuple. Is it possible to develop an algebra for such transformations?

6.3 Synthetic Data Generation for DC

A seminal event in computer vision was the construction of ImageNet dataset [9] with many million images over thousands of categories. This was a key factor in the development of powerful DL algorithms. We believe that the DC community is in need of such an ImageNet moment.

Research Opportunities.

- *Benchmark for DC.* It is paramount to create a similar benchmark to drive research in DC (both DL and non-DL). While there has been some work for data cleaning such as BART [1], it is often limited to specific scenarios. For example, BART can be used to benchmark data repair algorithms where the integrity constraints are specified as denial constraints.
- *Synthetic Datasets.* If it is not possible to create an open-source dataset that has realistic data quality issues, a useful fall back is to create synthetic datasets that exhibit representative and realistic data quality issues. The family of TPC benchmarks involves a series of synthetic datasets that is somehow realistic and widely used for benchmarking database systems. A recent work [48] proposed a variational autoencoder based model for generating synthetic data that has similar statistical properties as the original data. Is it possible to extend that approach to encode data quality issues as well?

6.4 Weak Supervision

A key bottleneck in creating training data is that there is often an implicit assumption that it must be accurate. However, it is often infeasible to produce sufficient hand-labeled and accurate training data for most DC tasks. This is especially challenging for DL models that require a huge amount of training data. However, if one can relax the need for the veracity of training data, its generation will become much easier for the expert. The domain expert can specify a high level mechanism to generate training data without endeavoring to make it perfect.

Research Opportunities.

- *Weakly Supervised DL Models.* There has been a series of research (such as Snorkel [39]) that seek to *weakly supervise* ML models and provide a convenient programming mechanism to specify "mostly correct" training data. What are the DC specific mechanisms and abstractions for weak supervision? Can we automatically create such a weak supervision through data profiling?

6.5 Transfer Learning

Another trick to handle limited training data is to "transfer" representations learned in one task to a different yet related task. For example, DL models for computer vision tasks are often trained on ImageNet [9], a dataset that is commonly used for image recognition purposes. However, these models could be used for tasks that are not necessarily image recognition. This approach of training on a large diverse dataset followed by tuning for a local dataset and tasks has been very successful.

Research Opportunities.

- *Transfer learning.* What is the equivalent of this approach for DC? Is it possible to train on a single large dataset such that it could be used for many downstream DC tasks? Alternatively, is it possible to train on a single dataset and for a single task (such as entity matching) such that the learned representations could be used for entity matching in similar domains? How can we train a DL model for one task and tune the model for new tasks by using the limited labeled data instead of starting from scratch?
- *Pre-trained Models.* Is it possible to provide pre-trained models that have been trained on large, generic datasets? These models could then be tuned by individual practitioners in different enterprises.

7 DEEP LEARNING: MYTHS AND CONCERNS

In the past few years, DL has achieved substantial successes in many areas. However, DC has a number of characteristics that are quite different from prior domains where DL succeeded. We anticipate that applying DL to challenging real-world DC tasks can be messy. We now describe some of the concerns that could be raised by a pragmatic DC practitioner or a skeptical researcher.

7.1 Deep Learning is Computing Heavy

A common concern is that training DL models requires exorbitant computing resources where model training could take days even on a large GPU cluster. In practice, training time often depends on the model complexity, such as the number of parameters to be learnt, and the size of training data. There are many tricks that can reduce the amount of training time. For example, a task-aware DL architecture often requires substantially less parameters to be learned. Alternatively, one can "transfer" knowledge from a pre-trained model from a related task or domain and the training time will now be proportional to the amount of fine-tuning required to customize the model to the new task. For example, DeepER [14] leveraged word embeddings from GloVe (whose training can be time consuming) and built a light-weight DL model that can be trained in a matter of minutes even on a CPU. Finally, while training could be expensive, this can often be done as a pre-processing task. Prediction using DL is often very fast and comparable to that of other ML models.

7.2 Data Curation Tasks are Too Messy or Too Unique

DC tasks often require substantial domain knowledge and a large dose of "common sense". Current DL models are very narrow in the sense that they primarily learn from the correlations present in the training data. However, it is quite likely that this might not be sufficient. Unsupervised representation learning over the entire enterprise data can only partially address this issue. Current DL models are often not amenable to encoding domain knowledge in general as well as those that are specific to DC such as data integrity constraints. As mentioned before, substantial amount of new research on DC-aware DL architectures is needed. However, it is likely that DL, even in its current form, can reduce the work of domain experts.

DC tasks often exhibit a *skewed label distribution.* For the task of entity resolution (ER), the number of non-duplicate tuple pairs are orders of magnitude larger than the number of duplicate tuple pairs. If one is not careful, DL models can provide inaccurate results. Similarly, other DC tasks often exhibit *unbalanced cost model* where the cost of misclassification is not symmetric. Prior DL work utilizes a number of techniques to address these issues such as (a) cost sensitive models where the asymmetric misclassification costs are encoded into the objective function, and (b) sophisticated sampling approach where we under or over sample certain classes of data. For example, DeepER [14] samples non-duplicate tuple pairs that are abundant at a higher level than duplicate tuple pairs.

7.3 Deep Learning Predictions are Inscrutable

Domain experts could be concerned that the predictions of DL models are often uninterpretable. Deep learning models are often very complex and the black-box predictions might not be explainable by even DL experts. However, explaining why a DL model made a particular data repair is very important for a domain expert. Recently, there has been intense interest in developing algorithms for explaining predictions of DL models or designing interpretable DL models in general. Please see [21] for an extensive survey. Designing algorithms that can explain the prediction of DL models for DC tasks is an intriguing research problem. While there are some promising approaches exist for specific tasks such as Entity resolution [11, 13, 49], more research remains.

7.4 Deep Learning can be Easily Fooled

There exist a series of recent works which show that DL models (especially for image recognition) can be easily fooled by perturbing the images in an adversarial manner. The sub-field of adversarial DL [37, 47] studies the problem of constructing synthetic examples by slightly modifying real examples from training data such that the trained DL model (or any ML model) makes an incorrect prediction with high confidence. While this is indeed a long term concern, most DC tasks are often collaborative and limited to an enterprise. Furthermore, there are a series of research efforts that propose DL models that are more resistant to adversarial training such as [30].

7.5 Building Deep Learning Models for Data Curation is "Just Engineering"

Many DC researchers might look at the process of building DL models for DC and simply dismiss it as a pure engineering effort. And they are indeed correct! Despite its stunning success, DL is still at its infancy and the theory of DL is still being developed. To a DC researcher used to purveying a well organized garden of conferences such as VLDB/SIGMOD/ICDE, the DL research landscape might look like the wild west.

In the early stages, researchers might *just apply* an existing DL model or algorithm for a DC task. Or they might slightly tweak a previous model to achieve better results. We argue that database conferences must provide a safe zone in which these DL explorations are conducted in a principled manner. One could take inspiration from the computer vision community. They created a large dataset (ImageNet [9]) that provided a benchmark by which different DL architectures and algorithms can be compared. They also created one or more workshops focused on applying DL for specific tasks in computer vision (such as image recognition and scene understanding). The database community has its own TPC series of synthetic datasets that have been influential in benchmarking database systems. Efforts similar to TPC are essential for the success of DL-driven DC.

7.6 Deep Learning is Data Hungry

Indeed, this is one of the major issues in adopting DL for DC. Most classical DL architectures often have many hidden layers with millions of parameters to learn, which requires a large amount of training data. Unfortunately, the amount of training data for DC is often small. The good news is, there exist a wide variety of techniques and tricks in the DL's arsenal that can help address this issue. We could leverage the techniques described in Section 6 for addressing these issues.

8 A CALL TO ARMS

In this paper, we make two key observations. Data Curation is a long standing problem and needs novel solutions in order to handle the emerging big data ecosystem. Deep Learning is gaining traction across many disciplines, both inside and outside computer science. The meeting of these two disciplines will unleash a series of research activities that will lead to usable solutions for many DC tasks. We identified research opportunities in learning distributed representations for database aware objects such as tuples or columns and designing DC-aware DL architectures. We described a number of promising approaches to tame DL's hunger for data. We discuss the early successes in using DL for important DC tasks such as data discovery and entity matching that required novel adaptations of DL techniques. We make a call to arms for the database community in general, and the DC community in particular, to seize this opportunity to significantly advance the area, while keeping in mind the risks and mitigation that were also highlighted in this paper.

ABSTRACT

A clustering may be considered as fair on pre-specified sensitive attributes if the proportions of sensitive attribute groups in each cluster reflect that in the dataset. In this paper, we consider the task of fair clustering for scenarios involving multiple multi-valued or numeric sensitive attributes. We propose a fair clustering method, *FairKM* (Fair K-Means), that is inspired by the popular K-Means clustering formulation. We outline a computational notion of fairness which is used along with a cluster coherence objective, to yield the FairKM clustering method. We empirically evaluate our approach, wherein we quantify both the quality and fairness of clusters, over real-world datasets. Our experimental evaluation illustrates that the clusters generated by FairKM fare significantly better on both clustering quality and fair representation of sensitive attribute groups compared to the clusters from a state-of-the-art baseline fair clustering method.

1 INTRODUCTION

Clustering is the task of grouping a dataset of objects in such a way that objects that are assigned to the same group, called a *cluster*, are more similar to each other than those in other groups/clusters. Clustering [10] is a well-studied and fundamental task, arguably the most popular task in unsupervised or exploratory data analytics. A pragmatic way of using clustering within analytics pipelines is to consider objects within the same cluster as being indistinguishable. Customers in the same cluster are often sent the same promotional material in a targeted marketing scenario in retail, whereas candidates clustered using their resumes may be assigned the same shortlisting decision in a hiring scenario. Clustering provides a natural way to tackle the infeasibility of doing manual per-object assessment or appreciation, especially in cases where the dataset in question encompasses more than a few hundreds of objects. Central to clustering is the notion of similarity which may need to be defined in a task-oriented manner. As an example, clustering to aid a task on identifying tax defaulters may use a similarity measure that focuses more on the job and income related attributes, whereas that for a health monitoring task may more appropriately focus on a very different set of attributes.

Usage of clustering algorithms in analytics pipelines for making important decisions open up possibilities of unfairness. Among two high-level streams of fairness constructs, viz., individual fairness [8] and group fairness [12], we focus on the latter. Group fairness considers fairness from the perspective of *sensitive attributes* such as gender and ethnicity and groups defined on the basis of such sensitive attributes. Consider a clustering algorithm that targets to group records of individuals to clusters; it is possible and likely that certain clusters have highly skewed distributions when profiled against particular sensitive attributes. As an example, clustering a dataset with broad representation across gender groups based on exam scores could lead to clusters that are highly gender-homogeneous due to statistical correlations[1]; this would happen even if the gender attribute were not explicitly considered within the clustering, since such information could be held implicitly across one or more other attributes. Choosing a cluster with a high gender or ethnic skew for positive (e.g., interview shortlisting) or negative (e.g., higher scrutiny or checks) action entails differentiated impact across gender and ethnic groups. This could also lead to reinforcement of societal stereotypes. For example, consistently choosing individuals from particular ethnic groups for pro-active surveillance could lead to higher reporting of violations from such ethnic groups since enhanced surveillance translates to higher crime visibility, resulting in higher reporting rates. This reporting skew results thus manifests as a data skew which provides opportunities for future invocations of the same analytics to exhibit higher ethnic asymmetry. In modern decision making scenarios within a liberal and democratic society, we need to account for a plurality of sensitive attributes within analytics pipelines to avoid causing (unintended) discrimination; these could include gender, race, religion, relationship status and country of origin in generic decision-making scenarios, and could potentially include attributes such as age and income in more specific ones. There has been much recent interest in the topic of fair clustering [1, 6].

Our Contribution. In this paper, we consider the task of fair clustering in the presence of multiple sensitive attributes. As will be outlined in a later section, this is a direction that has received less attention amidst existing work on fair clustering that has been designed for scenarios involving a single binary sensitive attribute [3, 6, 14, 17], single multi-valued/categorical sensitive attribute [1, 20–22], or multiple overlapping groups [4]. We propose a clustering formulation and algorithm to embed group fairness in clustering that incorporates multiple sensitive attributes that may include numeric, binary or multi-valued (i.e., categorical) sensitive ones. Through an empirical evaluation over multiple datasets, we illustrate the empirical effectiveness of our approach in generating clusters with fairer representations of sensitive groups, while preserving cluster meaningfulness.

2 RELATED WORK

Fairness in machine learning has received significant attention over the last few years. Our work contributes to the area of fair methods for unsupervised learning tasks. We now briefly survey the area of fairness in unsupervised learning, with a focus

[1]https://www.compassprep.com/new-sat-has-disadvantaged-female-testers/

on clustering, our task of interest. We interchangeably refer to groups defined on sensitive attributes (e.g., *ethnic groups*, *gender groups* etc.) as *protected classes* for consistency with terminology in some referenced papers. Towards developing a systematic summary, we categorize prior work into three types depending on whether the fairness modelling appears as a (i) pre-processing step, (ii) during the task of clustering, or (iii) as a post-processing step after clustering. These yield the three technique families.

2.1 Space Transformation Approaches

The family of fairness pre-processing techniques work by first representing the data points in a *'fair'* space followed by applying any existing clustering algorithm upon them. This is the largest family of techniques, and most approaches in this family seek to achieve theoretical guarantees on representational fairness. This family includes one of the first works in this area of fair clustering [6]. The work proposes a fair variant of classical clustering for scenarios involving a single sensitive attribute that can take binary values. Let each object be colored either x or y depending on its value for the binary sensitive attribute. [6] defines fairness in terms of *balance* of a cluster, which is $min\{\#x/\#y, \#y/\#x\}$. They go on and outline the concept of (b, r)*-fairlet decomposition*, where the points in the dataset are grouped into small clusters called fairlets, such that each fairlet would have a balance of b/r, where $b < r$. The clustering is then performed on these fairlets. The fairness guarantees that are provided by the clustering is based on the balance in the underlying fairlets. Fairlet decomposition turns out to be NP-hard, for which an approximation algorithm is provided. Later, [3] proposed a faster fairlet decomposition algorithm offering significant speedups. The work in [20] extends the fairlet idea to K-means for scenarios with a single multi-valued sensitive attribute. They define fair-coresets which are smaller subsets of the original dataset, such that solving fair clustering over this subset also results in giving an approximate solution for the entire dataset.

Another set of fair space transformation approaches build upon methods for dimensionality reduction and representation learning. A recent such work [2] considers the bias in the dataset (that is, representational skew) as a form of noise and uses spectral de-noising techniques to project the original points in the dataset to a new fair projected space. [17] describes a fair version of PCA (Principal Component Analysis) for data with a single binary sensitive attribute. A representation learning method may be defined as fair if the information about the sensitive attributes cannot be inferred from the learnt representations. The method uses convex optimization formulations to embed fairness within PCA. The fairness is specified in terms of failure of the classifiers in predicting the sensitive class of the dimensionality-reduced data points obtained from fair PCA. The method is fair*er* if the data points are less distinguishable with respect to their values of the sensitive attribute in this lower dimension space. Another work that projects the original data points into a fair space is the one described in [21]. This method, which is for cases involving a single multi-valued sensitive attribute, defines a clustering to be fair when there is an equal number of data points of each protected class in each cluster. They define the concept of *fairoids* (short for *fair centroids*) which are formed by grouping together all points belonging to the same protected class. The task is then to learn a latent representation of the data points such that the cluster centroids obtained after clustering on this latent representation are equi-distant from every fairoid.

2.2 Fairness Modelling within Optimization

Methods in this family incorporate the fairness constraints into the clustering step, most usually within the objective function that the clustering method seeks to optimize for. It may be noted that the method we propose in this paper, *FairKM*, also belongs to this family. Approaches within this family define a clustering to be fair if the proportional representation of the protected class in a cluster reflects that in the dataset. One of the techniques [14] describes a fair variant of spectral clustering where a linear fairness constraint is incorporated into the original ratio-cut minimization objective of spectral clustering. Another recent technique [22], the method that comes closest to ours in construction, modifies K-means clustering to add a fairness loss term. The fairness loss is computed as the KL-divergence between the probability distribution across the different values for the sensitive attribute in a cluster, and the corresponding distribution for the whole dataset. This method is designed for a single multi-valued sensitive attribute and does not generalize to multiple such sensitive attributes. *Being closest to our proposed method in spirit, we use this method as our primary baseline, in the experiments.*

In contrast to the above, another recent work [5] outlines a different notion of fairness, one that is independent of (and agnostic to) sensitive attributes. They define fairness as proportionality wrt spatial distributions, to mean that any (n/k) points can form their own cluster if there exists another center that is closer to each of these (n/k) points. This proportionality constraint is incorporated into the objective function of k-median clustering and is optimized to find a clustering that satisfies this constraint.

2.3 Cluster Perturbation Techniques

In this third family of techniques, vanilla clustering is first applied on the original set of data points, after which the generated clusters are perturbed to improve fairness of the solution. In [4], fairness is defined in terms of a lower and upper bound on the representation of a protected class in a cluster. This method is for cases with multiple binary sensitive attributes, referred to as *overlapping groups* in the paper. The k-centers generated from vanilla clustering on the data points are used to perform a fair partial assignment between points and the centers. The fair partial assignment is formulated as a linear program with constraints that ensures that the sum of the weights associated with a point's partial assignments is one, and, the representation of a protected class in a cluster is within the specified upper and lower bounds. The partial assignments are then converted to integral assignments by framing it as another linear programming problem. [1] also uses a similar idea, but it just enforces an upper bound, consequently preventing over-representation of specific groups in a cluster. The work described in [13] proposes a simple approximation algorithm for k-center clustering under a fairness constraint, for scenarios with a single multi-valued sensitive attribute. The method targets to generate a fair summary of a large set of data points, such that the summary is a representative subset of the original dataset. For example, if the original dataset has a 70:30 male:female distribution, then a fair summary should also have the same distribution.

2.4 Summary

Table 1 summarizes the different approaches in literature and our proposed approach *FairKM*, in terms of the number and type of sensitive attributes they handle and their definition for fairness. As it may be seen from the table, there has been very limited

Paper	Number	Type	Fairness Definition
[6],[3],[2]	Single	Binary	Preserve proportional representation of protected classes within clusters.
[20]	Single	Multi-valued	Preserve proportional representation of protected classes within clusters.
[17]	Single	Binary	The accuracy of the classifier predicting the protected class of a data point should be within a specified bound.
[21]	Single	Multi-valued	Each cluster should have an equal number of data points from each protected class.
[4]	Multiple	Binary	The proportional representation of a protected class in a cluster should be within the specified lower and upper bounds.
[1]	Single	Multi-valued	The proportional representation of a protected class in a cluster should not go beyond a specified upper bound.
[13]	Single	Multi-valued	The clustering should produce pre-specified number of cluster centers belonging to each specific protected class.
[14], [22]	Single	Multi-valued	Preserve proportional representation of protected classes within clusters.

Table 1: Fair Unsupervised ML Methods indicating the Number and Type of Sensitive Attributes they are designed for.

exploration into methods that admit multiple multi-valued (*aka* categorical or multi-state) sensitive attributes, the space that *FairKM* falls in. While multiple multi-valued attributes can be treated as together forming a giant multi-valued attribute taking values that are combinations of the component attributes, this results in a large number of very fine-grained groupings. These make it infeasible to both (i) impose fairness constraints over, and (ii) ensure parity in treatment of different sensitive attributes independent of the differences in the number of values they take. Considering the fact that real-life scenarios routinely present with multiple sensitive attributes, *FairKM*, we believe addresses an important line of inquiry in the backdrop of the literature. We will empirically evaluate *FairKM* against [22], the latter coming from the same technique family and having similar construction.

3 PROBLEM DEFINITION

Let $\mathcal{X} = \{\ldots, X, \ldots\}$ be a dataset of records defined over two sets of attributes $\mathcal{N}$ and $\mathcal{S}$. $\mathcal{N}$ stands for the set of attributes that are relevant to the task of interest, and thus may be regarded non-sensitive. As examples, this may comprise experience and skills in the case of screening applicants for a job application, and attributes from medical wearables' data to inform decision making for pro-active screening. $\mathcal{S}$ stands for the set of *sensitive attributes*, which would typically include attributes such as those identifying *gender*, *race*, *religion*, *relationship status* in a citizen database and any other sensitive attribute over which fairness is to be ensured. In other scenarios such as NLP for education, representational fairness may be sought over attributes such as types of problems in a word problem database; this forms one of the scenarios in our empirical evaluation.

The (vanilla) clustering objective would be to group $\mathcal{X}$ into clusters such that it maximizes intra-cluster similarity and minimizes inter-cluster similarity, similarity gauged using the task-relevant attributes in $\mathcal{N}$. Within a fair clustering, we would additionally like the output clusters to be *fair* on attributes in $\mathcal{S}$. A natural way to operationalize fairness within a clustering that covers all objects in $\mathcal{X}$ would be to ensure that the distribution of groups defined on sensitive attributes within each cluster approximates the distribution across the dataset; this correlates with the well-explored notion of *statistical parity* [8] in fair supervised learning. For example, suppose the sex ratio in $\mathcal{X}$ is 1:1; we would ideally like each cluster in the clustering output to report a sex ratio of 1:1, or very close to it. In short, we would like a fair clustering to produce clusters, each of which are both:

- coherent when measured on the attributes in $\mathcal{N}$, *and*
- approximate the dataset distribution when measured on the attributes in $\mathcal{S}$.

It may be noted that simply *hiding* the $\mathcal{S}$ attributes from the clustering algorithm does not suffice. A *gender blind* clustering algorithm may still produce clusters that are highly gender-homogeneous, since some attributes in $\mathcal{N}$ could implicitly encode gender information. Indeed, we would like a fair clustering to surpass $\mathcal{S}$-blind clustering by significant margins on fairness.

4 FAIRKM: OUR METHOD

We now describe our proposed technique for fair clustering, code-named *FairKM*, short for Fair K-Means, indicating that it draws inspiration from the classical K-Means clustering algorithm [9, 16]. FairKM incorporates a novel fairness loss term that nudges the clustering towards fairness on attributes in $\mathcal{S}$. The FairKM objective function is as follows:

$$O = \underbrace{\sum_{C \in \mathcal{C}} \sum_{X \in C} dist_{\mathcal{N}}(X, C)}_{\text{K-Means Term over attributes in } \mathcal{N}} \quad + \lambda \quad \underbrace{deviation_{\mathcal{S}}(\mathcal{C}, \mathcal{X})}_{\text{Fairness Term over attributes in } \mathcal{S}} \tag{1}$$

As indicated, the objective function comprises two components; the first is the usual K-Means loss for the clustering $\mathcal{C}$, $dist_{\mathcal{N}}(X, C)$ computing the distance between X and prototype of cluster C, distance computed only over attributes in $\mathcal{N}$. The second is a fairness loss term we introduce, which is computed over attributes in $\mathcal{S}$. λ is a parameter that may be used to balance the relative strength of the two terms. As in K-Means, this loss is computed over a given clustering; the task is thus to identify a clustering that minimizes O as much as possible. We now describe the details of the second term, and the intuitions behind its construction.

4.1 The Fairness Term in FairKM

While the K-Means term in the *FairKM* objective tries to ensure that the output clusters are coherent in the $\mathcal{N}$ attributes, the fairness term performs the complementary function of ensuring that the clusters manifest fair distributions of groups defined by sensitive attributes in $\mathcal{S}$. We outline the motivation and construction of the fairness term herein.

Attribute-Specific Deviation for a Cluster: Consider a single sensitive attribute S (e.g., gender) among the set of sensitive attributes $\mathcal{S}$. For each data object X, S may take on one value from a set of permissible values. Let s be one such value (e.g., female, for the choice of S as gender). For an ideally fair cluster C, one would expect that the fractional representation of s in C - the fraction of objects in C that take the value s for S - to be close to the fractional representation of s in $\mathcal{X}$. With our intent of generating clusters that are as fair as possible, we seek to generate clusterings such that the deviation between the fractional representations of s in C and $\mathcal{X}$ are minimized for each cluster C. For a given cluster C and a choice of value s for S, we model the deviation as simply the square of the absolute differences between the fractional representations in C and $\mathcal{X}$:

$$D_C^S(s) = \left(\frac{|\{X | X \in C \wedge X.S = s\}|}{|C|} - \frac{|\{X | X \in \mathcal{X} \wedge X.S = s\}|}{|\mathcal{X}|} \right)^2 \tag{2}$$

The deviation, when aggregated over all values of S, yields:

$$D_C^S = \begin{cases} \sum_{s \in Values(S)} D_C^S(s) & |C| \neq 0 \\ 0 & |C| = 0 \end{cases} \tag{3}$$

The above aggregation accounts for the fact that $D_C^S(s)$ is undefined when C is an empty cluster.

Domain Cardinality Normalization: Different sensitive attributes may have different numbers of permissible values (or domain cardinalities). For example, *race* and *gender* attributes typically take on much fewer values than *country of origin*. Those attributes with larger domains are likely to yield larger D_C^S scores because, (i) the deviations are harder to control within (small) clusters given the higher likely scatter, and (ii) there are larger numbers of $D_C^S(s)$ terms that add up to D_C^S. In order to ensure that attributes with larger domains do not dominate the fairness term, we normalize the deviation by the number of different values taken by an attribute, yielding ND_C^S, a normalized attribute-specific deviation:

$$ND_C^S = \frac{D_C^S}{|Values(S)|} \tag{4}$$

This is then summed up over all attributes in $\mathcal{S}$ to yield a single term for each cluster:

$$ND_C = \sum_{S \in \mathcal{S}} ND_C^S \tag{5}$$

Cluster Weighting: Observe that ND_C deviation loss would tend towards 0.0 for very large clusters, since they are obviously likely to reflect dataset-level distributions better; further, an empty cluster would also have $ND_C^S = 0$ by definition. Considering the above, a clustering loss term modelled as a simple sum over its clusters, $\left(\sum_{C \in \mathcal{C}} ND_C\right)$ or a cardinality weighted sum, $\left(\sum_{C \in \mathcal{C}} |C| \times ND_C\right)$, can both be driven towards 0.0 by keeping a lot of clusters empty, and distributing the dataset objects across very few clusters; the boundary case would be a single non-empty cluster. Indeed, this propensity towards the boundary condition is kept in check by the K-Means term; however, we would like our fairness term to drive the search towards more reasonable fair clustering configurations in lieu of simply reflecting a propensity towards highly skewed clustering configurations.

Towards achieving this, we weight each cluster's deviation by the square of it's fractional cardinality of the dataset. This leads to an overall loss term as follows:

$$\sum_{C \in \mathcal{C}} \left(\frac{|C|}{|\mathcal{X}|} \right)^2 \times ND_C \tag{6}$$

The squared term in the weighting enlarges the ND_C terms of larger clusters much more than smaller ones, making it unprofitable to create large clusters; this compensates for the propensity towards skewed clusters as embodied in the loss construction.

Overall Loss: The overall fairness loss term is thus:

$$deviation_{\mathcal{S}}(\mathcal{C}, \mathcal{X}) =$$

$$\sum_{C \in \mathcal{C}} \left(\frac{|C|}{|\mathcal{X}|} \right)^2 \times \sum_{S \in \mathcal{S}} \frac{\sum_{s \in Values(S)} \left(Fr_C^S(s) - Fr_{\mathcal{X}}^S(s) \right)^2}{|Values(S)|} \tag{7}$$

where $Fr_C^S(s)$ and $Fr_{\mathcal{X}}^S(s)$ are shorthands for the fractional representation of $S = s$ objects in C and $\mathcal{X}$ respectively.

4.2 The Optimization Approach

Having defined the objective function, we now outline the optimization approach. It is easy to observe that there are three sets of parameters, the clustering assignments for each data object in $\mathcal{X}$, the cluster prototypes that are used in the first term of the objective function, and the fractional representations, i.e., $Fr_C^S(s)$s, used in the fairness term. Unlike K-Means, given the more complex construction, it is harder to form a closed-form solution for the cluster assignments. Thus, from a given estimate of all three sets of parameters, we step over each data object $X \in \mathcal{X}$ in round-robin fashion, updating its cluster assignment, and making consequent changes in cluster prototypes and fractional representations. One set of round-robin updates forms an iteration, with multiple such iterations performed until convergence or until a maximum threshold of iterations is reached.

4.2.1 *Cluster Assignment Updates.*

At $\lambda = 0$, *FairKM* defaults to K-Means where the cluster assignments are determined only by proximity to the cluster prototype (over attributes in $\mathcal{N}$). At higher values of λ, *FairKM* cluster assignments are increasingly swayed by considerations of representational fairness of $\mathcal{S}$ attributes within clusters.

It may be noted that the cluster assignments are used in both the terms of the *FairKM* objective, in different ways. This makes a closed form estimation of cluster assignments harder to arrive at. This leads us to a round-robin approach of determining cluster assignments. When each X is considered, the cluster prototypes as well as the current cluster assignments of all other objects, i.e. $\mathcal{X} - \{X\}$, are kept unchanged. The cluster assignment for X is then estimated as:

$$Cluster(X) = \arg\min_{C} \; O_{\mathcal{C}+(X \in C)} \tag{8}$$

For the candidate object X, we evaluate the value of the objective function by changing X's cluster membership from the present one to each cluster, $C + (X \in C)$ indicating a corresponding change in the clustering configuration retaining all other objects' present cluster assignments. X is then assigned to the cluster for which the minimum value of O is achieved. While this may look as a simple step, implementing it naively is computationally expensive. However, easy optimizations are possible when one observes the dynamics of the change and how it operates across the two terms. We now outline a simple way of affecting the cluster assignment decision. First, let X's current cluster assignment be C'; the cluster assignment step can be equivalently written as:

$$Cluster(X) = \arg\min_{C} \delta(O)_{X \in C' \rightarrow X \in C} \tag{9}$$

where δO indicates the change in O when the respective cluster assignment change is carried out. This can be expanded into the changes in the two terms in the objective function as follows:

$$\delta(O)_{X \in C' \rightarrow X \in C} = \\ \delta(\text{K-Means term})_{X \in C' \rightarrow X \in C} + \lambda \times \delta(\text{deviation term})_{X \in C' \rightarrow X \in C} \tag{10}$$

We now detail the changes in the respective terms separately. **Change in K-Means Term:** We now outline the change in the K-Means term by moving X from C' to C. As may be obvious, this depends only on attributes in $\mathcal{N}$. We model the cluster prototypes as simply the average of the objects within the cluster. The change in the K-Means term is the sum of (i) the change in the K-Means term corresponding to C' brought about by the exclusion of X from it, and (ii) the change in the K-Means term corresponding to C brought about by the inclusion of X within it. We discuss them below.

Consider a single numeric attribute $N \in \mathcal{N}$, for simplicity. Through excluding X from C', the N attribute value of the cluster prototype of C' undergoes the following change:

$$C'.N \rightarrow \left[\left(C'.N - \frac{X.N}{|C'|}\right) \times \frac{|C'|}{|C' - 1|}\right] \tag{11}$$

where C' is overloaded to refer to the cluster and the cluster prototype (to avoid clutter), all values referring to those prior to exclusion of X. The term after the $\rightarrow$ stands for the N attribute value for the new cluster prototype. As indicated, it is computed by the removal of the contribution from X from the cluster prototype, followed by re-normalization, now that C' has one fewer object within it. The change in the K-Means term for N corresponding to C' is then as follows:

$$\delta_{X_{out}} KM(C', N) = \left(\sum_{X' \in C', X' \neq X} (X'.N - New(C'.N))^2\right) - \\ \left[\left(\sum_{X' \in C', X' \neq X} (X'.N - C'.N)^2\right) + (X.N - C'.N)^2\right] \tag{12}$$

where $New(C'.N)$ is the new estimate of $C'.N$ as outlined in Eq. 11. The first term corresponds to the K-Means loss in the new configuration (after exclusion of X), whereas the sum of the second and third terms correspond to that prior to exclusion of X. Analogous to the above, the new centroid computation for C and the change in the K-Means terms are outlined below:

$$C.N \rightarrow \left[\left(C.N \times \frac{|C|}{|C+1|}\right) + \frac{X.N}{C+1}\right] \tag{13}$$

$$\delta_{X_{in}} KM(C, N) = \left[\left(\sum_{X' \in C, X' \neq X} (X'.N - New(C.N))^2\right) + \\ (X.N - New(C.N))^2\right] - \left(\sum_{X' \in C, X' \neq X} (X'.N - C.N)^2\right) \tag{14}$$

It may be noticed that the computation of the changes above only involve X and other objects in C and C'. In particular, the other clusters and their objects do not come into play. So far, we have computed the changes for only one attribute N. The overall change in the K-Means term is simply the sum of these changes across all attributes in $\mathcal{N}$.

$$\delta(\text{K-Means term})_{X \in C' \rightarrow X \in C} = \\ \sum_{N \in \mathcal{N}} \left(\delta_{X_{out}} KM(C', N) + \delta_{X_{in}} KM(C, N)\right) \tag{15}$$

Change in Fairness Term: We now outline the construction of the change in the fairness term. As earlier, we start by considering a single cluster C^*, a single attribute S, and a single value s within it. The fairness term from Eq. 7 can be written as follows:

$$dev(C^*, S = s) = \frac{C^{*2} \times \left(\left(\frac{C^*_s}{C^*}\right)^2 + \left(\frac{\mathcal{X}_s}{\mathcal{X}}\right)^2 - 2\frac{C^*_s}{C^*}\frac{\mathcal{X}_s}{\mathcal{X}}\right)}{\mathcal{X}^2 \times |Values(S)|} \tag{16}$$

where each set (C^* and $\mathcal{X}$) is overloaded to represent both itself and its cardinality (to avoid notation clutter), and their suffixed versions (C^*_s and $\mathcal{X}_s$) are used to refer to their subsets containing their objects which take the value $S = s$. The above equation follows from the observation that $Fr^S_{C^*}(s) = \frac{C^*_S}{C^*}$ and analogously for $\mathcal{X}$. When an object changes clusters from C' to C, there is a change in the terms associated with both clusters, as in the previous case. The change in the origin cluster C' works out to be the follows:

$$\delta_{X_{out}} dev(C', S = s) = \frac{1}{\mathcal{X}^2 \times |Values(S)|} \times \left[\left(\frac{\mathcal{X}_s}{\mathcal{X}}\right)^2 (1 - 2C') + \\ \mathbb{I}(X.S = s)(1 - 2C'_s) - 2\left(\frac{\mathcal{X}_s}{\mathcal{X}}\right)\left(\mathbb{I}(X.S = s)(1 - C') - C'_s\right)\right] \tag{17}$$

where $\mathbb{I}(.)$ is an indicator function, and C' and C'_s denote the cardinalities before X is taken out of C'. We omit the derivation for space constraints. Intuitively, to nudge clusters towards fairness, we would like to incentivize removal of objects with $S = s$ from C' when C' is overpopulated with such objects (i.e., C'_s is high). This is evident in the $-(C'_s \times \mathbb{I}(X.S = s))$ component; when C'_s is high, removal of an object with $S = s$ entails a bigger reduction in the objective. The analogous change in the target cluster C, is as follows:

$$\delta_{X_{in}} dev(C, S = s) = \frac{1}{\mathcal{X}^2 \times |Values(S)|} \times \left[\left(\frac{\mathcal{X}_s}{\mathcal{X}}\right)^2 (1 + 2C) + \\ \mathbb{I}(X.S = s)(1 + 2C_s) - 2\left(\frac{\mathcal{X}_s}{\mathcal{X}}\right)\left(\mathbb{I}(X.S = s)(1 + C) + C_s\right)\right] \tag{18}$$

where C and C_s denote the cardinalities before X is inserted into C. Given that we are inserting X into C, the fairness intuition suggests that we should disincentivize addition of objects with s when C already has too many of such objects. This is reflected in the $(C_s \times \mathbb{I}(X.S = s))$ term; notice that this is exactly the same term as in the earlier case, but with a different sign.

Thus, the overall fairness term change is as follows:

$$\delta(\text{deviation term})_{X \in C' \to X \in C} = \sum_{S \in \mathcal{S}} \sum_{s \in Values(S)} \left(\delta_{X_{out}} dev(C', S = s) + \delta_{X_{in}} dev(C, S = s) \right) \tag{19}$$

This completes all the steps required for Eq. 9. Based on the change in the cluster assignment, the cluster prototypes and fractional representations are to be updated.

4.2.2 Cluster Prototype Updates. Once a new cluster has been finalized for X, the origin and target cluster prototypes are updated according to Eq. 12 and Eq. 14 respectively.

4.2.3 Fractional Representation Updates. The $Fr^S_{C'}(s)$s and $Fr^S_C(s)$s need to be updated to reflect the change in the cluster assignment of X. These are straightforward and given as follows:

$$\forall S \forall s \in Values(S), Fr^S_{C'}(s) = \begin{cases} \frac{C'_s - 1}{C' - 1} & \text{if } X.S = s \\ \frac{C'_s}{C' - 1} & \text{if } X.S \neq s \end{cases} \tag{20}$$

$$\forall S \forall s \in Values(S), Fr^S_{C}(s) = \begin{cases} \frac{C_s + 1}{C + 1} & \text{if } X.S = s \\ \frac{C_s}{C' + 1} & \text{if } X.S \neq s \end{cases} \tag{21}$$

where the C, C', C_s and C'_s values above are cardinalities of the respective sets prior to the update to X's cluster assignment.

Alg. 1 *FairKM*

```
Input. Dataset $\mathcal{X}$, attribute sets $\mathcal{S}$ and $\mathcal{N}$, number of clusters $k$
Hyper-parameters: Fairness Weighting $\lambda$
Output. Clustering $\mathcal{C}$
1. Initialize k clusters randomly
2. Set cluster prototypes as Cluster Centroids
3. while(not yet converged and max. iterations not reached)
4.     $\forall X \in \mathcal{X}$,
5.         Set Cluster(X) using Eq. 9 (and Eq. 10 through Eq. 19)
6.         Update cluster prototypes as outlined in Sec 4.2.2
7.         Re-estimate the $Fr^S_C(s)$ using Eq. 20 and Eq. 21
8. Return the current clustering assignments as $\mathcal{C}$
```

4.3 FairKM Algorithm

Having outlined the various steps, the *FairKM* algorithm can now be summarized in Algorithm 1. The method starts with a random initialization of clusterings (Step 1) and proceeds iteratively. Within each iteration, each object is considered in round-robin fashion, executing three steps in sequence: (i) updating the cluster assignment of X (Step 5), (ii) updating the cluster prototypes to reflect the change in cluster assignment of X (Step 6), and (iii) updating the fractional representations correspondingly (Step 7). The significant difference in construction from K-Means is due to the inter-dependency in cluster assignments; the cluster assignment for X depends on the current cluster assignments for all other objects $\mathcal{X} - \{X\}$, due to the construction of the *FairKM* objective as reflected in the update steps. The updates proceed as long as the clustering assignments have not converged or a pre-specified maximum number of iterations have not reached.

4.3.1 Complexity: The time complexity of *FairKM* is dominated by the cluster assignment updates. Within each iteration, for each X ($|\mathcal{X}|$ of them) and each cluster it could be re-assigned to (k of them), the deviation needs to be computed for both the (i) K-Means term, and the (ii) fairness term. First, considering the K-Means term, it may be noted that each other object in $\mathcal{X}$ would come into play once, either as a member of X's current cluster (in Eq. 12) or as a member of a potential cluster to which X may be assigned (in Eq. 14). This yields an overall complexity of each K-Means deviation computation being in $O(|\mathcal{X}||\mathcal{N}|)$. Second, considering the fairness deviation computation, it may be seen as a simple computation (Eq. 17 and 18) that can be completed in constant time. This computation needs to be performed for each attribute in $\mathcal{S}$ and each value of the attribute (consider m as the maximum number of values across attributes in $\mathcal{S}$), yielding a total complexity of $O(|\mathcal{S}|m)$ for each fairness update computation. With the updates needing to be computed for each new candidate cluster, the overall complexity of Step 5 would be $O(|\mathcal{X}||\mathcal{N}|k + |\mathcal{S}|mk)$. Step 6 is in $O(|\mathcal{X}||\mathcal{N}|)$ whereas Step 7 is simply in $O(|\mathcal{S}|m)$. With the above steps having to be performed for each X and for each iteration, the overall *FairKM* complexity works out to be in $O(|\mathcal{X}|^2|\mathcal{N}|kl + |\mathcal{X}||\mathcal{S}|mkl)$ where l is the number of iterations. While the quadratic dependency on the dataset size makes *FairKM* much slower than simple K-Means (which is linear on dataset size), *FairKM* compares very favorably against other fair clustering methods (e.g., exact fairlet decomposition [6] is NP-hard, and even the proposed approximation is super-quadratic) which are computationally intensive.

4.4 FairKM Extensions

We outline two extensions to the basic *FairKM* outlined earlier which was intended towards handling numeric non-sensitive attributes and multi-valued sensitive attributes.

4.4.1 Extension to Numeric Sensitive Attributes. *FairKM* is easily adaptable to numeric sensitive attributes (e.g., *age* for cases where that is appropriate). If all attributes in $\mathcal{S}$ are numeric, the fairness loss term in Eq. 7 would be written out as:

$$deviation_{\mathcal{S}}(\mathcal{C}, \mathcal{X}) = \sum_{C \in \mathcal{C}} \left(\frac{|C|}{|\mathcal{X}|} \right)^2 \times \sum_{S \in \mathcal{S}} (C.S - \mathcal{X}.S)^2 \tag{22}$$

where $C.S$ and $\mathcal{X}.S$ indicate the average value of the numeric attribute S across objects in C and $\mathcal{X}$ respectively. When there are a mix of multi-valued and numeric attributes, the inner term would take the form of Eq. 7 and Eq. 22 for multi-valued and numeric attributes respectively. These entail corresponding changes to the update equations which we do not describe here for brevity.

4.4.2 Extension to allow Sensitive Attribute Weighting. In certain scenarios, some sensitive attributes may need to be considered more important than others. This may be due to historical reasons based on a legacy of documented high discrimination on certain attributes, or due to visibility reasons where discrimination on certain attributes (e.g., *gender, race* and *sexual orientation*) being more visible than others (e.g., *country of origin*). The *FairKM* framework could easily be extended to allow for differential attribute-specific weighting by changing the deviation term to be as follows:

$$deviation_{\mathcal{S}}(\mathcal{C}, \mathcal{X}) = \sum_{C \in \mathcal{C}} \left(\frac{|C|}{|\mathcal{X}|}\right)^2 \times \sum_{S \in \mathcal{S}} w_S \times \frac{\sum_{s \in Values(S)} \left(Fr_C^S(s) - Fr_{\mathcal{X}}^S(s)\right)^2}{|Values(S)|} \tag{23}$$

Attributes that are more important for fairness considerations can then be assigned a higher weight, i.e. w_S, which would lead to their loss being amplified, thus incentivizing *FairKM* to focus more on them for fairness, consequently leading to a higher representational fairness over them, within the clusters in the output. The w_S terms would then also affect the update equations.

5 EXPERIMENTAL STUDY

We now detail our experimental study to gauge and quantify the effectiveness of *FairKM* in delivering good quality and fair clusterings against state-of-the-art baselines. We first outline the datasets in our experimental setup, followed by a description of the evaluation measures and baselines. This is then followed by our results and an analysis of the results.

5.1 Datasets

We use two real-world datasets in our empirical study. The datasets are chosen to cover very different domains, attributes and dataset sizes, to draw generalizable insights from the study. First, we use the popular *Adult* dataset from UCI repository [7]; this dataset is sometimes referenced as the *Census Income* dataset and contains information from the 1994 US Census. The dataset has 32561 instances, each instance represented using 13 attributes. Among the 13 attributes, 5 are chosen to form the set of sensitive attributes, $\mathcal{S}$. These are {*marital status*, *relationship status*, *race*, *gender*, *native country*}. The number of values taken by each of the sensitive attributes are shown in Table 3. The set of non-sensitive attributes, $\mathcal{N}$, pertain to *age*, *work class* (2 attributes), *education* (2 attributes), *occupation*, *fiscal information* (2 attributes) and *number of working hours*. The dataset has been widely used for predicting income as belonging to one of $> 50k\$$ or $<= 50k\$$. We first undersample the dataset to ensure parity across this income class attribute that we do not use in the clustering process. The total number of instances after undersampling is 15682. Second, we use a dataset[2] of 161 word problems from the domain of kinematics. Kinematics is the study of motion without considering the cause of motion. The problems in this dataset is categorized into various types as indicated in Table 2. The complexity of a word problem typically depends on the type. For example, Type 1 problems are easier to solve (in terms of the equations required) compared to Type 5 problems. Table 4 shows the number of problems of each of the above types in the dataset. Given such a dataset of word problems from kinematics domain, we are interested in the task of clustering the word problems such that the proportional representation of problems of a particular type in a cluster reflects its representation in the entire dataset. In the application scenario of automatic construction of multiple questionnaires (one from each cluster) from a question bank, the fair clustering task corresponds to ensuring that each questionnaire contains a reasonable mix of problem types. This ensures that there is minimal asymmetry between the different questionnaires generated by a clustering, in terms of overall hardness. For the fair clustering formulation, thus, the problem types form the set of 5 sensitive binary attributes, $\mathcal{S}$. The lexical representation of each word problem, as a 100 dimensional vector using Doc2Vec models [15], forms the set of numeric attributes in $\mathcal{N}$. Given our fairness consideration, we consider achieving a fair proportion of word problem types within each cluster that reflects their proportion across the dataset.

It may be noted that the *Adult* and *Kinematics* datasets come from different domains (Census and Word Problems/NLP respectively), have different sizes of non-sensitive attribute sets (8 and 100 attributes in $\mathcal{N}$ respectively), different kinds of sensitive attribute sets (multi-valued and binary respectively) and have widely varying sizes ($15k$ and 161 respectively). An empirical evaluation over such widely varying datasets, we expect, would inspire confidence in the generalizability of empirical results.

[2]https://github.com/savithaabraham/Datasets

5.2 Evaluation

Having defined the task of fair clustering in Section 3, it follows that a fair clustering algorithm would be expected to perform well on two sets of evaluation metrics, those that relate to clustering quality over $\mathcal{N}$ and those that relate to fairness over $\mathcal{S}$. We now outline such evaluation measures below, in separate subsections.

5.2.1 *Clustering Quality.*

These measure how well the clustering fares in generating clusters that are coherent on attributes in $\mathcal{N}$, and do not depend on attributes in $\mathcal{S}$. These could include:

- *Silhouette Score* **(SH):** Silhouette [19] measures the separatedness of clusters, and quantifies a clustering with a score in $[-1, +1]$, higher values indicating well-separated clusters.
- *Clustering Objective* **(CO):** Clustering objective functions such as those employed by K-Means [16] measure how much observations deviate from the centroids of the clusters they are assigned to, where lower values indicate coherent clusters. In particular, the K-Means objective function is:

$$\sum_{C \in \mathcal{C}} \sum_{X \in C} dist_{\mathcal{N}}(X, C) \tag{24}$$

  where C stands for both a cluster in the clustering $\mathcal{C}$ as well as the prototype object for the cluster, and $dist_{\mathcal{N}}(.,.)$ is the distance measure computed over attributes in $\mathcal{N}$.
- *Deviation from $\mathcal{S}$-blind Clusterings:* $\mathcal{S}$-blind clusterings may be thought of achieving the best possible clusters for the task when no fairness considerations are imposed. Thus, among two clusterings of similar fairness, that with lower deviation from $\mathcal{S}$-blind clusterings may be considered desirable. A fair clustering can be compared with a $\mathcal{S}$-blind clustering using the following two measures:
  - *Centroid-based Deviation* **(DevC):** Consider each clustering to be represented as a set of cluster centroids, one for each cluster within the clustering. The sum of pair-wise dot-products between centroid pairs, each pair constructed using one centroid from the fair clustering and one from the $\mathcal{S}$-blind clustering, would be a measure of deviation between the clusterings. Such measures have been used in generating disparate clusterings [11].
  - *Object pair-wise Deviation* **(DevO):** Consider each pair of objects from $\mathcal{X}$, and one clustering (either of $\mathcal{S}$-blind and fair); the objects may belong to either the *same* cluster or to *different* clusters. The fraction of object pairs from $\mathcal{X}$ where the same/different verdicts from the two clusterings disagree provide an intuitive measure of deviation between clusterings.

Type	Description
1:Horizontal Motion	The object involved is in a horizontal straight line motion.
2:Vertical motion with an initial velocity	The object is thrown straight up or down with a velocity.
3:Free fall	The object is in a free fall.
4:Horizontally projected	The object is projected horizontally from a height.
5:Two-dimensional	The body is projected with a velocity at an angle to the horizontal.

5.2.2 Fairness. These measure the fairness of the clustering output from the (fair) clustering algorithm. Analogous to clustering quality measures that depend only on $\mathcal{N}$, the fairness measures we outline below depend only on $\mathcal{S}$ and are independent of $\mathcal{N}$. As outlined earlier, we quantify unfairness as the extent of deviation between representations of groups defined using attributes in $\mathcal{S}$ in the dataset and each cluster in the clustering output. Consider a multi-valued attribute $S \in \mathcal{S}$, which can take on t values. The normalized distribution of presence of each of the t values in $\mathcal{X}$ yields a t-length probability distribution vector $\mathcal{X}_S$. A similar probability distribution can then be computed for each cluster C in the clustering $\mathcal{C}$, denoted C_S. Different ways of measuring the cluster-specific deviations $\{\ldots, dev(C_S, \mathcal{X}_S), \ldots\}$ and aggregating them to a single number yield different quantifications of fairness, as below:

- *Average Euclidean* **(AE):** This measures the average of cluster-level deviations, deviations quantified using euclidean distance between representation vectors (i.e., $\mathcal{X}_S$ and C_Ss). Since clusters may not always be of uniform sizes, we use a cluster-cardinality weighted average.
$$AE_S = \frac{\sum_{C \in \mathcal{C}} |C| \times ED(C_S, \mathcal{X}_S)}{\sum_{C \in \mathcal{C}} |C|} \tag{25}$$
where $ED(.,.)$ denotes the euclidean distance.
- *Average Wasserstein* **(AW):** In this measure, the deviation is computed using Wasserstein distance in lieu of Euclidean, as used in [21], with other aspects remaining the same as above.
- *Max Euclidean* **(ME):** Often, just optimizing for average fairness across clusters is not enough since there could be a very skewed (small) cluster, whose effect may be obscured by other clusters. It is often the case that one or few clusters get picked from a clustering to be actioned upon. Thus, the maximum skew is of interest as an indicative upper bound on the unfairness the clustering could cause if *any* one of its clusters is chosen for further action.
- *Max Wasserstein* **(MW):** This uses Wasserstein instead of Euclidean, using the same formulation as *Max Euclidean.*

When there are multiple attributes in $\mathcal{S}$, as is often the case, the average of the above measures across attributes in $\mathcal{S}$ provides aggregate quantifications. As may be evident, the above constructions work only for categorical attributes; however, a similar set of measures can be readily devised for numeric attributes in $\mathcal{S}$. With our datasets containing only categorical attributes among $\mathcal{S}$, we do not outline the corresponding metrics for numeric attributes, though they follow naturally. We are unable to apply some popular fairness evaluation metrics such as *balance* [6] due to them being devised for binary attributes.

5.3 Baselines

We compare our approach against two baselines. The first is that of $\mathcal{S}$-blind K-Means clustering, that performs K-Means clustering on data using the attributes in $\mathcal{N}$ alone. This baseline is code-named K-Means ($\mathcal{N}$). K-Means ($\mathcal{N}$) will produce the most coherent clusters on $\mathcal{N}$ as its objective function just focuses on maximizing intra-cluster similarity and minimizing inter-cluster similarity over $\mathcal{N}$, unlike *FairKM* that has an additional fairness constraint which may result in compromising the coherence goal. Comparing the two enables us to evaluate the extent to which cluster coherence is traded off by *FairKM* in generating fairer clusters. The second baseline is the approach described in [22] which is a fair version of K-Means clustering for scenarios involving a single multi-valued sensitive attribute. We will refer to this baseline as *ZGYA* from here, based on the names of the authors. Since it is designed for a single multi-valued sensitive attribute and cannot handle multiple sensitive attributes within its formulation, we invoke *ZGYA* multiple times, separately for each attribute in $\mathcal{S}$. Each invocation is code-named *ZGYA*(S) where S is the sensitive attribute used in the invocation. We also report results for similar runs of *FairKM*, where we consider just one of the attributes in $\mathcal{S}$ as sensitive at a time. The comparative evaluation between *FairKM* and *ZGYA* enables studying the effectiveness of FairKM formulation over that of *ZGYA* in their relative effectiveness of trading off coherence for fairness.

5.4 Setting λ in *FairKM*

From Eq. 1, it may be seen that the K-Means term has a contribution from each object in $\mathcal{X}$, whereas the fairness term (Eq. 7) aggregates cluster level contributions. This brings a disparity in that the former has $|\mathcal{X}|/k$ times as many terms as the latter. Further, it may be noted that the fairness term aggregates deviations between cluster level fractional representations and dataset level fractional representation. The fractional representation being an average across objects in the cluster, each object can only influence $1/|C|$ of it, where $|C|$ is the cluster cardinality. On an average, across clusters, $|C| = |\mathcal{X}|/k$. Thus, the fairness term has $|\mathcal{X}|/k$ fewer terms, each of whom can be influenced by an object to a fraction of $1/(|\mathcal{X}|/k)$. To ensure that the terms are of reasonably similar sizes, so the clustering quality and fairness concerns be given similar weighting, the above observations suggest that λ be set to $(\frac{|\mathcal{X}|}{k})^2$. From our empirical observations, we have seen that the *FairKM* behavior varies smoothly around this setting. Based on the above heuristic, we set λ to 10^6 for the Adult dataset, and 10^3 for the Kinematics dataset, given their respective sizes. We will empirically analyze sensitivity to λ in Section 5.7. We set max iterations to 30 in *FairKM* instantiations.

5.5 Clustering Quality and Fairness

5.5.1 Evaluation Setup. In each of our datasets, there are five sensitive (i.e., $\mathcal{S}$) attributes. *FairKM* can be instantiated with all of them at once, and we do so with appropriate values of λ (10^6 or 10^3, as mentioned in Section 5.4). We perform 100 such instantiations, each with a different random seed, and measure the *clustering quality* and *fairness* evaluation measures (fairness measures computed separately for each attribute in $\mathcal{S}$ as well as the average across all attributes in $\mathcal{S}$) outlined in Section 5.2. We take the mean values across the 100 instantiations to arrive at a single robust value for each evaluation measure for *FairKM*. An analogous setting is used for our first baseline, the $\mathcal{S}$-blind K-Means (denoted K-Means ($\mathcal{N}$)), as well. Our second baseline, *ZGYA*, unlike *FairKM*, needs to be instantiated with one $\mathcal{S}$ attribute at a time. Given this setting, we adopt different mechanisms to compare *FairKM* against *ZGYA* across clustering quality and fairness evaluation measures. First, for *clustering quality*, we instantiate *ZGYA* separately with each attribute in $\mathcal{S}$ and compute an average value for each evaluation measure across random initializations as described previously. This yields one value for each evaluation measure for each attribute in $\mathcal{S}$, which we take an average of, and report as the *clustering quality* of *Avg. ZGYA*. Second, for *fairness*, we adopt a synthetic favorable setting for *ZGYA* to test *FairKM* against. For each attribute $S \in \mathcal{S}$, we consider the fairness metrics (AE, AW, ME, MW) obtained by the instantiation of *ZGYA* over *only* that attribute (averaged across random initializations, as earlier). This is compared to the fairness metrics obtained for S by the *FairKM* instantiation that considers *all* attributes in $\mathcal{S}$. In other words, for each $S \in \mathcal{S}$, we benchmark the single cross-$\mathcal{S}$ instantiation of *FairKM* against separate S-targeted instantiations of *ZGYA*. We also report the average across these separate comparisons across attributes in $\mathcal{S}$. For K-Means style clustering formulations, the number of clusters k, is an important parameter. We experiment with two values for k, viz., 5 and 15, for the Adult dataset, whereas we use $k = 5$ for the Kinematics dataset, given its much smaller size.

5.5.2 Clustering Quality. The clustering quality results appear in Table 5 (Adult dataset) and Table 7 (Kinematics dataset), with the direction against each evaluation measure indicating whether lower or higher values are more desirable. For clustering quality metrics that depend only on attributes in $\mathcal{N}$, we use K-Means ($\mathcal{N}$) as a reference point since that is expected to perform well, given that it does not need to heed to $\mathcal{S}$ and is not held accountable for fairness. Thus, *FairKM* is not expected to beat K-Means ($\mathcal{N}$); the lesser the degradation from K-Means ($\mathcal{N}$) on various clustering quality metrics, the better it may be regarded to be. We compare *FairKM* and *Avg. ZGYA* across the results tables, highlighting the better performer on each evaluation measure by boldfacing the appropriate value. On the Adult dataset (Table 5), it may be seen that *FairKM* performs better than *Avg. ZGYA* on seven out of eight combinations, with it being competitive with the latter on the eighth. *FairKM* is seen to score significantly better than *Avg. ZGYA* on clustering objective (CO) and silhoutte score (SH), with the gains on the deviation metrics (DevC and DevO) being more modest. It may be noted that *CO* and *SH* may be regarded as more reliable measures, since they evaluate the clustering directly. In contrast, *DevO* and *DevC* evaluate the deviation against reference K-Means ($\mathcal{N}$) clusterings; these deviation measures penalize deviations even if those be towards *other* good quality clusterings that may exist in the dataset. The trends from the Adult dataset hold good for the Kinematics dataset as well (see Table 7), confirming that the trends generalize well across datasets of widely varying character. Overall, our results indicate that *FairKM* is able to generate much better quality clusterings than *Avg. ZGYA*, when gauged on attributes in $\mathcal{N}$.

5.5.3 Fairness. The fairness evaluation measures for the Adult and Kinematics datasets appear in Tables 6 and 8 respectively; it may be noted that lower values are desirable on all evaluation measures, given that they all measure deviations. In these results, which include a synthetically favorable setting for *ZGYA* (as noted earlier), the top block indicates the average results across all attributes in $\mathcal{S}$, with the following result blocks detailing the results for the specific parameters in $\mathcal{S}$. The overarching summary of this evaluation suggests, as indicated in the top-blocks across the two tables, that *FairKM* surpasses the baselines with significant margins. The *% impr* column indicates the gain achieved by *FairKM* over the next best competitor. The percentage improvements recorded are around 35 + % on an average for the Adult dataset, whereas the corresponding figure is higher, at around 60 + % for the Kinematics dataset. We wish to specifically make a few observations from the results. *First*, the closest competitor to *FairKM* is *ZGYA* on the Kinematics dataset, whereas K-Means ($\mathcal{N}$) curiously outperforms *ZGYA* quite consistently on the Adult dataset. This indicates that *ZGYA* is likely more suited to settings where the number of values taken by the sensitive attribute is less. In our case, the Kinematics dataset has all binary attributes in $\mathcal{S}$, whereas Adult dataset has sensitive attributes that take as many as 41 different values. *Second*, while *FairKM* is designed to accommodate $\mathcal{S}$ attributes that take many different values, the fairness deviations appear to degrade, albeit at a much lower pace than *ZGYA*, as attributes take on very many values. This is indicated by the lower performance (with small margins) on the *native country* (41 values) attribute at $k = 5$ in Table 6. However, promisingly, it is able to utilize the additional flexibility that is provided by larger ks to ensure higher rates of fairness on them. As may be seen, *FairKM* recovers well to perform significantly better on *native country* at $k = 15$. This indicates that *FairKM* will benefit from a higher flexibility in cluster assignment (with higher k) when there are a number of (high cardinality) attributes to ensure fairness over. *Third*, the *FairKM* formulation targets to minimize overall fairness and does not specifically nudge it towards ensuring good performance on the *max* measures (ME and MW) that quantify the worst deviation across clusters. Thus, it's design allows to choose higher fairness in multiple clusters even at the expense of disadvantaging fairness in one or few clusters, which is indeed undesirable. The performance on ME and MW

suggest that such trends are not widely prevalent, with *FairKM* recording reasonable gains on ME and ME. However, cases such as *marital status* in Table 6 and Type-3 in Table 8 suggest that is a direction in which *FairKM* could improve. *Finally*, the overall summary from Tables 6 and 8 suggest that *FairKM* delivers much fairer clusters on $\mathcal{S}$ attributes, and records significant gains over the baselines, in our empirical evaluation.

5.6 *FairKM* vs. *ZGYA*

Having compared *FairKM* against *ZGYA* for fairness in a synthetic setting that was favorable to the latter in the previous section, we now do a more direct comparison here. In particular, we consider comparing the *FairKM* and *ZGYA* instantiations with each sensitive attribute separately, which offers a more level

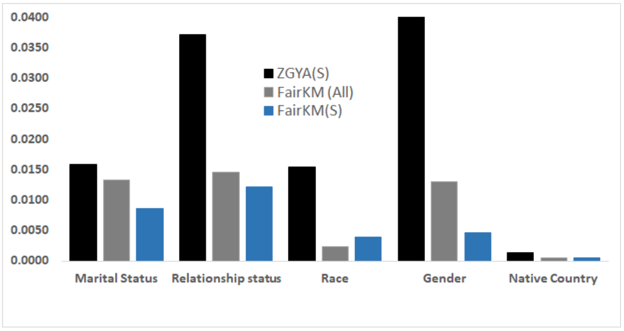

Figure 1: Adult Dataset: AW Comparison

setting. Figure 1 illustrates the comparison on the AW evaluation measure over the Adult dataset for each $\mathcal{S}$ attribute with *ZGYA(S)* and *FairKM(S)* values shown separated by the *FairKM (All)* value in between them; all these are values obtained with $k = 5$. The *FairKM (All)* is simply *FairKM* instantiated with all attributes in $\mathcal{S}$, which was used in the comparison in the previous section. As may be seen, with *FairKM(S)* focusing on just the chosen attribute (as opposed to *FairKM (All)* that needs to spread attention across all attributes in $\mathcal{S}$), *FairKM(S)* is able to achieve better values for AW. Thus, *FairKM(S)* is seen to beat *ZYGA(S)* by larger margins than *FairKM (All)*, as expected. The *Race* attribute shows

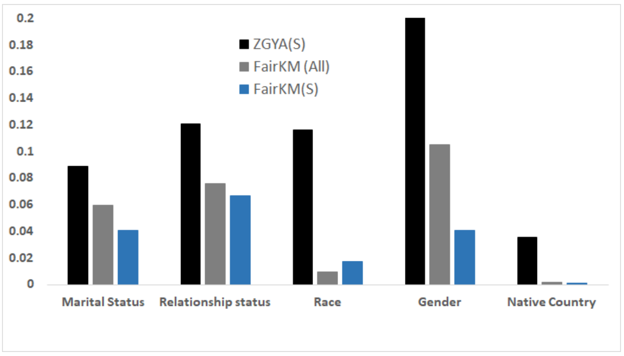

Figure 2: Adult Dataset: MW Comparison

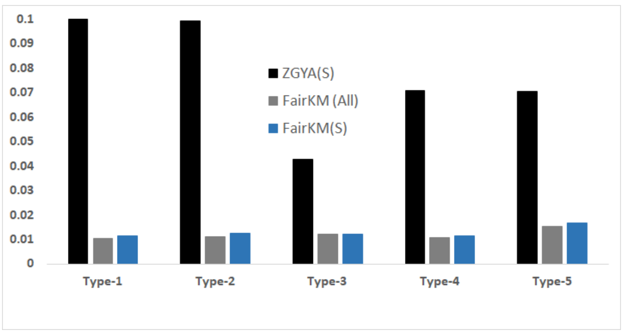

Figure 3: Kinematics Dataset: AW Comparison

a different trend, with *FairKM(S)* recording a slightly higher AW than *FairKM(S)*. While we believe this is likely to be due to an

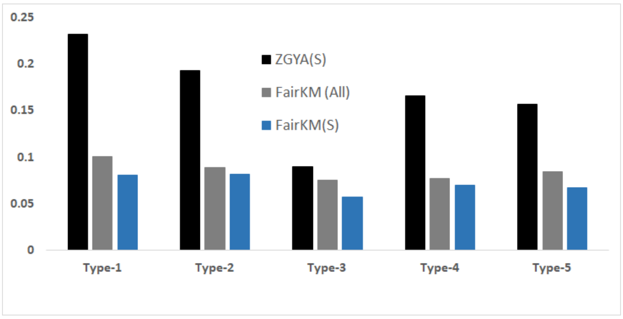

Figure 4: Kinematics Dataset: MW Comparison

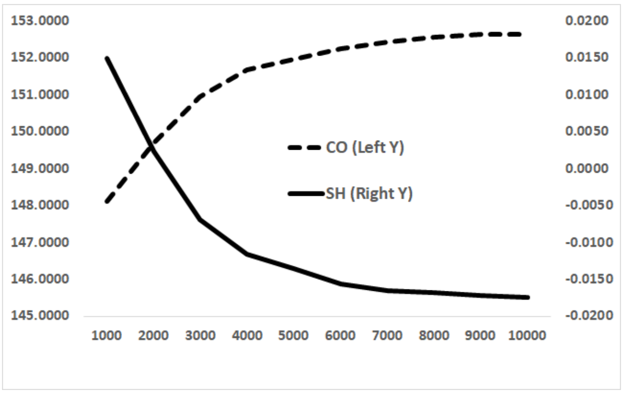

Figure 5: Kinematics Dataset: (CO and SH) vs. λ

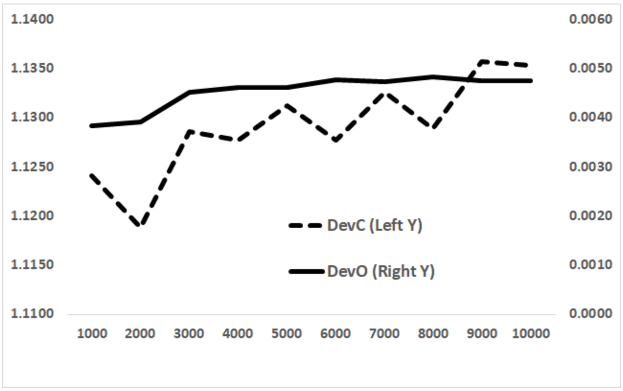

Figure 6: Kinematics Dataset: (DevC and DevO) vs. λ

unusually high skew in the *race* attribute where 87% of objects take the same single value, this warrants further investigation. Figure 2 presents the corresponding chart for MW evaluation measure, and offers similar high-level trends as was observed for AW. The corresponding charts for the Kinematics dataset appear in Figures 3 and 4 respectively. Over the much smaller Kinematics dataset, the gains by *FairKM(S)* over *FairKM (All)* are more pronounced in MW with both techniques recording reasonably similar AW numbers. The observed trends were seen to hold for AE and ME evaluation measures as well, those charts excluded for brevity. To summarize the findings across the datasets, it may be seen that *FairKM(S)* may be seen to beat the *ZGYA(S)* baseline with larger margins than *FairKM (All)* on an average, as desired.

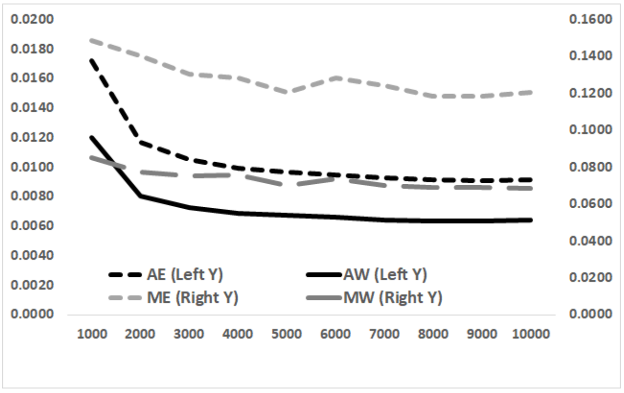

Figure 7: Kinematics Dataset: Fairness Metrics vs. λ

5.7 *FairKM* Sensitivity to λ

We now study *FairKM*'s sensitivity to it's only parameter λ, the weight for the fairness term. With increasing λ, we expect *FairKM* to fare better on fairness measures with corresponding degradations in the clustering quality measures. The vice versa is expected to hold with decreasing λ. We observed such desired trends across Adult and Kinematics datasets, with changes being slower and steadier for the larger Adult dataset. This is on expected lines with the number of parameters such as clustering assignments being larger on the Adult dataset. In the interest of focusing on the smaller dataset, we outline the changes with λ on clustering quality and fairness measures on the Kinematics dataset, when λ is varied from 1000 to 10000. The variations on the CO and SH measures are illustrated in Figure 5, whereas the variations on DevC and DevO are plotted in Figure 6. We use both sides of the Y-axis to plot the measures which widely vary in terms of their ranges; the axis used is indicated in the legend. As may be seen from them, CO, SH and DevO record slow and steady degradation (the Y-axis is stretched to highlight the region of the change; it may be noted that the quantum of change is very limited) with increasing λ. The degradation in DevC, however, is more jittery, while the direction of change remains on expected lines. The fairness deviation measures are plotted against varying λ (once again, on both Y-axes) in Figure 7. They record gradual but steady improvements (being deviations, they are better when low) with increasing λ, on expected lines. Overall, it may be seen that *FairKM* moves steadily but gradually towards fairness with increasing λ, as desired.

6 CONCLUSIONS AND FUTURE WORK

We considered the problem of ensuring representational fairness in clustering for scenarios comprising multiple sensitive attributes. We proposed a novel clustering method, *FairKM*, to accomplish the fair clustering task. In particular, *FairKM* comprises the optimization of the classical clustering objective in tandem with a novel fairness loss term, towards achieving a trade-off between clustering quality (on the non-sensitive attributes) and cluster fairness (on the sensitive attributes). We outline a series of evaluation metrics for both the above criteria, and perform a rigorous empirical evaluation of *FairKM* over two real-world datasets of widely varying character, pitching *FairKM* against other available methods. Our empirical evaluation illustrates that *FairKM* outperforms the baseline *ZGYA* even over synthetic settings that are artificially favorable to the latter. This illustrates the effectiveness of the *FairKM* formulation.

6.1 Future Work

We are exploring three directions of future work towards enhancing *FairKM*. First, we are studying the performance trends of *FairKM* with increasing number of sensitive attributes as well as increasing number of values per sensitive attribute. Second, drawing cue from the observation in Section 5.6, we are looking at how *FairKM* can be improved to ensure good performance even on attributes with highly skewed distributions. Third, the main computational bottleneck in *FairKM* is the cluster centroid update while doing cluster assignments. We are considering approximation heuristics such as mini-batch updates where centroid updates are done only once every mini-batch of clustering assignment updates, to speed up *FairKM* for scalability.

Ontology-Based RDF Integration of Heterogeneous Data

ABSTRACT

The proliferation of heterogeneous data sources in many application contexts brings an urgent need for expressive and efficient data integration mechanisms. There are strong advantages to using RDF graphs as the integration format: being schemaless, they allow for flexible integration of data from heterogeneous sources; RDF graphs can be interpreted with the help of an ontology, describing application semantics; last but not least, RDF enables joint querying of the data and the ontology.
To address this need, we formalize *RDF Integration Systems (RIS)*, Ontology Based-Data Access mediators, that go beyond the state of the art in the ability to expose, integrate and flexibly query data from heterogeneous sources through GLAV (global-local-as-view) mappings. We devise several *query answering strategies*, based on an innovative integration of LAV view-based rewriting and a form of mapping saturation. Our experiments show that one of these strategies brings strong performance advantages, resulting from a balanced use of mapping saturation and query reformulation.

1 INTRODUCTION

The proliferation of digital data sources across all application domains brings a new urgency to the need for tools which allow to query heterogeneous data (relational, JSON, key-values, graphs etc.) in a flexible fashion. Traditional data integration systems fall into two classes: *data warehousing*, where all data source content is materialized in a single centralized source, respectively, *mediation*, where data remains in their original stores and all data can be queried through a single module called *mediator*. Data warehousing simplifies query evaluation, but requires potentially costly maintenance operations when the content of data sources changes; mediation does not suffer from these drawbacks, but requires more intricate query evaluation algorithms to distribute the work between the sources and the mediator.
Below, we classify prior mediator-based approaches according to two main dimensions, and illustrate this classification in Table 1. Note that we also include in this table theoretical frameworks that did not necessarily lead to implementations.
A first dimension concerns the **data model and query language** provided by the mediator to its applications.
(*i*) The earliest goal of a mediator system was to mimic a single, integrated database. Thus the mediator supports one data model and its query language, e.g., relational and SQL, or XML and XPath/XQuery. More recent polystore systems support side-by-side different (data model, query language) pairs. These database-style mediators appear in the row we label **DB** in Table 1.
(*ii*) Mediators studied in knowledge representation and management research provide a view of the data sources as a set of classes and relationships, also endowed with a set of semantic

		Mappings		
		GAV	**LAV**	**GLAV**
Model	**DB**	[22, 24, 27]	[4, 5, 22, 38]	[19]
	CQ	[40, 41, 43]	[1, 28, 30, 36]	[18]
	SPARQL-data	[11, 17, 32, 34]	[45]	[21]
	SPARQL	[16, 33, 44]		this work

Table 1: Outline of the positioning of our work.

constraints, or ontology. In such systems, users formulate conjunctive (relational) queries; answering them involves not only evaluation over the data (as done in DB mediators), but also reasoning on the data with the help of ontologies. This mediation approach is also commonly termed *Ontology-Based Data Access* (OBDA) [41], with ontologies expressed in Description Logics (DL, in short). Work following this approach are listed in the row we label **CQ** in Table 1.
(*iii*) RDF [47] is naturally suited as an integration model, thanks to its flexibility, its wide adoption in the Open Data community, its close relationship with ontology languages such as RDFS and OWL, and the presence of its associated standard SPARQL query language. Accordingly, several mediators from the CQ group have been extended to support RDF as an integration model and SPARQL query answering. However, while SPARQL allows *querying the data together with the ontology*, e.g., "find the properties of node *n*, as well the classes to which the values of these properties belong", a DL-based mediation approach shares with all logic-based query languages, e.g., Datalog, SQL etc., the inability to do so. RDF mediators which support SPARQL but limited to querying the data only (not the ontology) appear in the row we label **SPARQL-data** in Table 1.
(*iv*) Recent RDF mediators lift this limitation to support joint querying of the data and ontology; we list them in the **SPARQL** row in Table 1.
