Foreword by the PC Chair

The International Conference on Extending Database Technology (EDBT) is an established forum for researchers and practitioners alike to disseminate knowledge and research results related to data management. This year, the 24th edition of EDBT, scheduled to take place between March 23rd and March 26, 2021 in Nicosia, Cyprus, has instead been held entirely online, due to the circumstances and the travel restrictions imposed by the 2020/2021 pandemic. It has been jointly organized with the International Conference on Database Theory (ICDT).

The organizing committee solicited contributions in many different areas, including, but not limited to, Data Preparation, Data Privacy, Database Engines, Distributed Data Systems, Graph Management, Reasoning over Data, Machine Learning and AI in Databases, Novel Database Architectures, Semi-structured Data Management, and User Interfaces for Data. Novel in this year's edition is the solicitation of contributions in the area of Applied Database Systems for Data Science. The goal is to give the opportunity to researchers from different areas dealing with interesting data management challenges in the context of Data Science, to disseminate them to the data management community, and at the same time to give database researchers working on interesting data science scenarios to publish their works.

The main Research track, the Industrial & Application track, as well as the Demonstration track have remained as in previous years, while the Short paper track has been slightly extended to accommodate papers of 6 pages, to allow more technical content.

With some rare exceptions, research papers were reviewed by 4 reviewers. Discussions and decisions were taken under the coordination of a senior PC member, with expertise in the respective area of the paper under review. The reviewing phase involved two cycles: resulting in a number of papers being revised and having their qualify improved significantly.

Consistent with the tradition, the program included two keynotes, one on Data Profiling by Felix Naumann (Hasso Plattner Institute, Germany), and one on Knowledge Management by Katja Hose (Aalborg University, Denmark). These keynotes were complemented by the two additional keynotes of the co-organized ICDT. Last but not least, the program had the traditional tutorial track, featuring four tutorials on topics related to knowledge graphs, blockchains, text-to-SQL, and time series management. The overall program was accompanied by 6 Workshops.

The Program committee reviewed 108 full research papers, of which 27 were accepted. For short papers, 34 papers out of 113 were selected. The Industry and Application track received 22 submissions of which it selected 11 for publication, while the demo track received 24 works of which 15 were accepted.

Given that this year the conference took place online, it was a good opportunity to exploit at the maximum the opportunities that digital technologies can offer. Furthermore, it was our intention to make sure that the paper contributions are disseminated to a broader audience, especially outside the conference participants. For this reason, the authors were asked to provide a pre-recorded presentation of 10 min that will remain in the proceedings, a 30 sec pitch video that advertises the results of the contribution and a graphics ad.

In order to recognize significant contributions and give credits to the authors, the technical program committee awarded the Best Paper award to one of the research papers and the Best Demonstration award to one of the demos. Furthermore, following the EDBT tradition, it awarded the Test-of-Time award to a paper from the EDBT 2011 proceedings that has been deemed to have the greatest impact among those of that year. A novelty in this year's EDBT edition is the additional recognition of the Best Short Paper.

The realization of EDBT 2021 is a result of a collaborative effort of the different chairs and program committee members. Congratulations are in place to the senior PC members for guiding the discussions in such a professional and timely manner, ensuring the selection of the best quality papers. Special thanks for the excellent collaboration and quality of work go to the Industrial and Application Chair Eric Simon, the Demonstration Chair Sihem Amer-Yahia, the tutorial chairs Stefan Manegold and Wang-Chiew Tan, and the Workshop Chair Evaggelia Pitoura. A great deal of credits go to the Proceedings Chair Francesco Guerra for all the extra work he has put in organizing the material and making sure that all the proceedings information is in place. My appreciation goes also to the members of the paper award committees for the effort they put in evaluating the candidate papers and providing the decisions in a timely manner. I find it impossible to describe the passion, professionalism, consistency and collaborative attitude the general chairs Demetris Zeinalipour and Panos K. Chrysanthis have demonstrated. It was great working with them. I would also like to thank all the program committee members since due to them the high quality program became possible, the award committees, as well as Angela Bonifati and Marc H. Scholl from the EDBT Board for the their numerous advices and support. Last but not least, I would like to thank all the authors for the works they submitted to the conference, the keynote speakers, the tutorial presenters, and the demonstration presenters.

Yannis Velegrakis, EDBT 2021 PC Chair

Message from the General Chairs

The 24th edition of the International Conference on Extending Database Technology (EDBT) was held between the 23rd and 26th of March 2021, despite the COVID-19 worldwide pandemic. Continuing its longstanding tradition as a premier data management research forum taking place in a European location, EDBT 2021, jointly organized with the International Conference on Database Theory (ICDT), was held virtually in Nicosia, the capital of the beautiful island of Cyprus.

At the onset, our aim has been to offer as close to an in-person, face-to-face experience as possible, maximizing the dissemination of knowledge and sharing of research results among the EDBT/ICDT participants at no health risk to them, and together discover the Cypriot culture and hospitality. EDBT/ICDT 2021 was initially planned to become the first hybrid EDBT/ICDT conference, combining physical presentations with an extended online audience, although this plan later evolved into an online format due to the ongoing situation with COVID-19. To this end, we have been committed to offering the best possible online experience to attendees by capitalizing and expanding on the success of earlier conferences.

Particularly, we decided on a number of novelties compared to previous conferences. Firstly, given that an optimal online experience cannot be achieved with pre-recorded presentations, but only with live presentations and direct interactions between the speakers and the audience, we decided in coordination with the Program Chairs on the online synchronous delivery of all events, including all research presentations, tutorials and live demonstrations. The next challenge was to select the appropriate conference management platform. Our personal experience as participants in several online conferences during the past year, and our evaluation of a number of popular web socializing platforms, led us to the decision that a custom conference attendance experience can only be delivered by an in-house platform that relies on a reliable teleconferencing channel, an intuitive interface, and a low learning curve.

To this end, the Data Management Systems Laboratory at the University of Cyprus, under the leadership of Demetris Zeinalipour developed and hosted a novel web-based platform named VGATE (Virtual Gate) to online conferences. VGATE allowed the Organizing Committee to collaborate over a Web-based Sheet interface (like Google Sheets) to plan and manage the organization. VGATE provided numerous helpful building-blocks in the online organization, namely, zoom license management and user status integration, integration of proceedings and multimedia content, industry booths, live sessions, social rooms, and for the first time an online helpdesk supported by Easy-Conferences Ltd. Special thanks to Paschalis Mpeis (University of Cyprus, Cyprus), Soteris Constantinou (University of Cyprus, Cyprus) and Constantinos Costa (University of Pittsburgh, USA) for their support and code contributions to the project under an extremely tight schedule. Special thanks also to Zoom Video Communications, Inc., for facilitating and sponsoring EDBT/ICDT 2021.

Novel this year is the participation of EDBT/ICDT to the newly founded Diversity and Inclusion (D&I) initiative of the Data Management community. EDBT/ICDT (alongside SIGMOD, VLDB, SoCC, and ICDE) celebrates the diversity in our community and welcomes everyone regardless of age, sex, gender identity, race, ethnicity, socioeconomic background, country of origin, religion, sexual orientation, physical ability, education, work experience, etc. To introduce this initiative, Panos K. Chrysanthis, the EDBT/ICDT D&I Chair, together with Sihem Amer-Yahia (CNRS, University Grenoble Alpes, France), a D&I Core Member, organized a panel as part of the Reception on DAY1 of the conference.

With D&I and broad participation in mind, the conference program was structured in a way that is convenient to at least half of the world at any given time. Specifically, the program was split into morning sessions (CET), which were convenient for EU-ASIA participants, on DAY1 and DAY3, and the afternoon sessions (CET), which were convenient for EU-America participants on DAY2 and DAY4. The Workshops were scheduled on DAY1 in the morning or afternoon based on the geographical location of their presenters. Social events were split along the same lines, presenting the host country, Cyprus, through music and videos on culture, geography, food, leisure, and other enjoyable aspects of Cyprus. Virtual corridor and hallway discussions were supported by a number of unmoderated and dynamic social rooms on VGATE at all times.

This year we also introduced some additional novelties, namely: (i) We introduced a special ceremony during Reception on DAY2, titled "*Pandemic Greetings from the Pioneers and the Next Data Management Challenge*", with greetings by Philip A. Bernstein (Microsoft Research, WA, USA), Laura M. Haas (University of Massachusetts – Amherst, MA, USA), Yannis Ioannidis (University of Athens, Greece) and Jeffrey D. Ullman (Stanford, CA, USA); (ii) we introduced the concept of a sponsored industry talk during Dinner on DAY3, with title "*Behind the Scenes of Snowflake's new Search Optimization Service*", by Ismail Oukid (Snowflake, Germany) and Stefan Richter (Snowflake, Germany); (iii) we introduced a dedicated "*Demos in Action: Meet the Authors!*" session during Dinner on DAY3, which allowed Demo presenters to individually showcase their demos to participants in their private presentation space through

VGATE. Finally, we also continued to support the Climate Change discussion with a session on DAY4, led by Antoine Amarilli (Télécom Paris, France), with guest Benjamin Pierce (University of Pennsylvania, USA).

In all above endeavors, we had the support and encouragement of our incredible Organization Committee and the EDBT Executive Board, in particular, the President of EDBT Executive Board Angela Bonifati (Lyon 1 University, France), as well as the Chair of the ICDT Council Wim Martens (University of Bayreuth, Germany).

We are grateful to the entire Technical Program Committees, which, under the excellent leadership of the EDBT Program Chair Yannis Velegrakis (University of Trento, Italy and Utrecht University, Netherlands) and the ICDT Program Chair Ke Yi (Hong Kong University of Science and Technology, Hong Kong), brought forward an exciting technical program with a rich production of technical content (proceedings, videos, pitches, ads, etc.). Our gratitude also extends personally to the EDBT Demonstration Chair Sihem Amer-Yahia (CNRS, University Grenoble Alpes, France), the EDBT Workshop Chair Evaggelia Pitoura (University of Ioannina, Greece), the Climate Chair Antoine Amarilli (Télécom Paris, France), the EDBT Applied Database Systems for Data Science Vice-Chair Paul Groth (University of Amsterdam, Netherlands), the EDBT Industrial/Application Chair Eric Simon (SAP, France), the Tutorial Chairs Stefan Manegold (CWI, Netherlands) and Wang-Chiew Tan (Megagon Labs, USA), for the excellent collaboration, and exchange of ideas and insightful discussions. We would also like to highlight EDBT Demonstration Chair Sihem Amer-Yahia's success in putting together EDBT's first all-women Demonstration Track Committee. We would also like to thank the organizers of the six, co-located workshops DOLAP, BigVis, BMDA, DARLI-AP, SIMPLIFY and PIE+Q for enriching the scope of the technical program.

Several people contributed to the successful organization of the EDBT/ICDT 2021 conference. Special thanks to the following valued collaborators for their passion in organizing a memorable event: the Sponsorship Chair Divyakant Agrawal (University of California-Santa Barbara, USA), the Publicity Chair Herodotos Herodotou (Cyprus University of Technology, Cyprus), the Finance Chair George Pallis (University of Cyprus, Cyprus), the EDBT Proceedings Chair Francesco Guerra (University of Modena and Reggio Emilia, Italy), the ICDT Proceedings Chair Zhewei Wei (Renmin University, China), the Workshops Proceedings Chair Constantinos Costa (University of Pittsburgh, USA) and the Website support by Nicolas Kantzilaris (Easy Conferences, Cyprus).

Our sincere gratitude to our platinum sponsor, Snowflake, and our bronze sponsors, Oracle and Zoom, as well as the contact persons behind the support, namely Martin Hentschel (Snowflake), Ann Brisson (Oracle) and Alberto Colautti (Zoom).

Organizing EDBT 2021 at the University of Cyprus was Prof. George Samaras†' passion. After his unexpected passing two years ago, his friends and colleagues at the University of Cyprus volunteered to make his passion a reality. We are grateful to the EDBT Executive Board for giving us this opportunity and trusting us to organize EDBT 2021 alongside ICDT 2021 in Cyprus, as proposed by George in 2018. We dedicate the EDBT/ICDT 2021 in honor of the memory of Prof. George Samaras† (1959–2018).

We hope you enjoyed EDBT/ICDT 2021's exciting technical program and your virtual visit to Cyprus!

Test-of-Time Award

Established in 2014, the Test-of-Time Award of the Extended Database Technology (EDBT) Conference recognizes papers presented at the EDBT Conferences that have had the most impact in terms of research, methodology, conceptual contribution, or transfer to practice over the past ten years. The 2021 Test-of-Time Award committee looked and evaluated the impact of the papers in the EDBT 2011 proceedings, and selected

SeMiTri: a framework for semantic annotation of heterogeneous trajectories

by Zhixian Yan, Dipanjan Chakraborty, Christine Parent, Stefano Spaccapietra, and Karl Aberer

published in the EDBT 2011 Proceedings, pp. 259–270, DOI: 10.1145/1951365.1951398,

because it is one of the earliest papers to propose a general method for enriching moving object trajectories with semantics useful for supporting location-based services, which have been and still are in high demand across several application sectors. Since its publication, SeMiTri has generated significant interest, and follow-up work on semantic processing of mobile data and trajectories.

The EDBT 2021 Test of Time Award committee was formed by Barbara Catania, University of Genova, Italy, Gautam Das, University of Texas at Arlington, USA, Beng Chin OOI, National University of Singapore, Singapore, Themis Palpanas, University of Paris, France, and Yufei Tao, Chinese University of Hong Kong, China.

The EDBT Test-of-Time award for 2021 will be presented during the EDBT/ICDT 2021 Conference in Nicosia, Cyprus, as part of the Awards session on March 24, 2021.

Best Paper Award

The Best Paper Award Committee has looked at the papers accepted in the conference and selected one that was distinguishing itself in terms of research quality, presentation, technical challenges, and novelty. The selected paper is

DomainNet: Homograph Detection for Data Lake Disambiguation

by Aristotelis Leventidis, Laura Di Rocco, Wolfgang Gatterbauer,
Renée J. Miller and Mirek Riedewald.
DOI: 10.5441/002/edbt.2021.03

The paper presents DomainNet, a system that disambiguates values from heterogeneous datasets by creating a network representing co-occurring values and computing their graph centrality. The system is unsupervised, its accuracy outperforms the state-of-the-art, and it is accompanied by an open benchmark. The paper is of high significance: the problem is important, the proposed solution is effective, and the benchmark facilitates further research.

Abstract: Modern data lakes are deeply heterogeneous in the vocabulary that is used to describe data. We study a problem of disambiguation in data lakes: how can we determine if a data value occurring more than once in the lake has different meanings and is therefore a homograph? While word and entity disambiguation have been well studied in computational linguistics, data management and data science, we show that data lakes provide a new opportunity for disambiguation of data values since they represent a massive network of interconnected values. We investigate to what extent this network can be used to disambiguate values.
DomainNet uses network-centrality measures on a bipartite graph whose nodes represent values and attributes to determine, without supervision, if a value is a homograph. A thorough experimental evaluation demonstrates that state-of-the-art techniques in domain discovery cannot be re-purposed to compete with our method. Specifically, using a domain discovery method to identify homographs has a precision and a recall of 38% versus 69% with our method on a synthetic benchmark. By applying a network-centrality measure to our graph representation, DomainNet achieves a good separation between homographs and data values with a unique meaning. On a real data lake our top- 200 precision is 89%.

The EDBT 2021 Best Paper Award committee was formed by Avigdor Gal, Technion Israel Institute of Technology, Israel, Lucasz Golab, University of Waterloo, Canada, Christian Jensen, Aalborg University, Denmark, and Qiong Luo, HKUST, China.

The EDBT Best Paper Award for 2021 will be presented during the EDBT/ICDT 2021 Conference in Nicosia, Cyprus, on March 24, 2021.

Best Short Paper Award

The Best Short Paper Award Committee has looked at the papers accepted in the conference and selected one that was distinguishing itself in terms of research quality, presentation, technical challenges, novelty, and potential impact to the broader research community and industry. The selected paper is

Answer Graph: Factorization Matters in Large Graphs

by Zahid Abul-Basher, Nikolay Yakovets, Parke Godfrey, Stanley Clark, and Mark Chignell.
DOI: 10.5441/002/edbt.2021.56

The paper proposes a two-step method for answering SPARQL conjunctive queries. The first step constructs an answer graph consisting only of node-edge-node triples that are answers to the query (a factorized answer set). In the second step, this answer graph is used to compute the actual embeddings for the query. The authors present detailed implementations for generating answer graphs and computing the final embedding, particularly in the case of cyclic conjunctive queries. Some first results from an experimental evaluation are also provided.

The EDBT 2021 Best Short Paper Award committee was formed by Manos Athanasoulis, Boston University, USA, Johann Gamper, Free University of Bozen-Bolzano, Italy, Ioana Manolescu, INRIA, France, Letizia Tanca, University of Milan, Italy, and Yannis Kotidis, Athens University of Economics and Business, Greece

The EDBT Best Short Paper Award for 2021 will be presented during the EDBT/ICDT 2021 Conference in Nicosia, Cyprus.

Best Demonstration Award

The Best Demonstration Award Committee has reviewed the video recordings of the 15 demos accepted at EDBT/ICDT and selected the most engaging demonstration that serves as an example of a structured and well illustrated demonstration and showcases an end-to-end system on a state-of-the-art topic that promotes data management beyond its boundaries. The selected demo is

Conversational OLAP in Action

by Matteo Francia, Enrico Gallinucci, and Matteo Golfarelli
(DISI – University of Bologna)
DOI: 10.5441/002/edbt.2021.74

For demonstrating COOL, a tool supporting natural language COnversational OLap sessions. COOL interprets and translates a natural language dialogue into an OLAP session that starts with a GPSJ query. The demonstration is engaging and showcases the usability of COOL and its capabilities in assisting query formulation and ambiguity resolution.

The EDBT 2021 Best Demonstration Award committee was formed by Sihem Amer-Yahia, CNRS Univ. Grenoble Alpes, France, Elena Baralis, Politecnico di Torino, Italy, Maria Luisa Damiani, University of Milan, Italy, Anna Fariha, UMass Amherst, USA, Irini Fundulaki, FORTH, GRnet, Greece, Zoi Kaoudi, TU Berlin, Germany, Georgia Koutrika, ATHENA, Greece, Esther Pacitti, University of Montpellier (Inria&CNRS), France, and Agma Traina, ICMC-USP, Brazil.

The EDBT Best Demonstration Award for 2021 will be presented during the EDBT/ICDT 2021 Conference in Nicosia, Cyprus, on March 24, 2021.

ABSTRACT

Exchanging data between data sources is a fundamental problem in many data science and data integration tasks. In this paper, we focus on the data exchange problem in the presence of privacy constraints on the source data, which has been disregarded in the literature to date. By leveraging a logical privacy-preservation paradigm, the privacy restrictions are expressed as a set of *policy views* representing the information that is safe to expose over *all* instances of the source in order to exchange them with the target. We introduce a protocol that provides formal privacy guarantees and is *data-independent*, i.e., under certain criteria, it guarantees that the mappings leak no sensitive information independently of the instances lying in the source. Moreover, we design an algorithm for *repairing* an input mapping w.r.t. a set of policy views, in cases where the input mapping leaks sensitive information. We show that the repairing can build upon hard-coded and learning-based user preference functions and we show the trade-offs. Our empirical evaluation shows that repairing mappings is quite efficient, leading to repairing sets of 300 s-t tgds in an average time of 5s on a commodity machine. It also shows that the repairing based on learning is robust and has comparable runtimes with the hard-coded one.

KEYWORDS

privacy-preserving data integration, data exchange, mapping repairs

1 INTRODUCTION

Data exchange is a key process in data science and data integration pipelines, leading to translating data compliant with a source schema S and lying in a source database to a target database with a non-overlapping target schema T [1, 4, 17]. Data exchange is also part of metadata management operations [6], since the schema mappings between source and target also known as *source-to-target* (s-t) dependencies Σ_{st} (s-t tgds) are declarative expressions manipulating schema elements, i.e. metadata rather than data.

Despite a wealth of research on the topic, the privacy-aware variant of the data exchange problem has received little attention to date. However, recent data protection regulations such as EU GDPR or CCPA in the US bring the attention to the problem of protecting personal data when transferring data across countries and institutions, thus motivating our work. In a privacy-aware data exchange scenario (as exemplified in Figure 1), the source schema comes with a set of constraints called policy views $\mathcal{V}$ representing the data that is *safe* to expose to the target over *all instances* of the source. The policy views can be considered as user views on the data of the source and can encode possible formulations of the different purposes the data will undergo during the exchange process as in many data protection regulations.

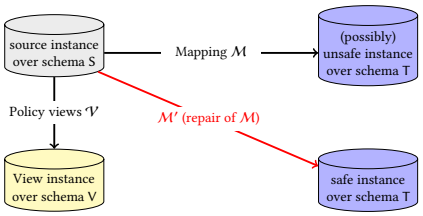

Figure 1: A privacy-aware data exchange setting with mappings and policy views.

This process entails the repairing of the original mapping $\mathcal{M}$ into a mapping $\mathcal{M}'$ in order to make the exported target instance safe. However, in order to realize such a data exchange scenario, one needs to address the following issues: (1) given a set of privacy restrictions on the source schema, what would it mean for a data exchange setting to be safe under the proposed privacy restrictions?; (2) assuming that the privacy-preservation protocol is fixed, how could we assess the safety of a data exchange setting w.r.t. the privacy restrictions and provide *strong guarantees* of no privacy leakage?; finally, in case of privacy violations, (3) how could we *repair* the s-t tgds (and transform the mapping $\mathcal{M}$ into a repaired mapping $\mathcal{M}'$)?

To address the first issue, we build upon prior work on the logical foundations of privacy-preserving data integration [5, 21], and we tailor them to a data exchange setting. Hence, we define a set of s-t tgds to be safe w.r.t. the policy views if *every positive information* that is kept secret by the policy views is also kept secret by the s-t tgds. As we will see in subsequent sections and contrarily to previous work, our proposed privacy-preservation protocol is *data-independent* allowing us to provide strong privacy-preservation guarantees over all instances of the sources. As such, our work leads to the first practical framework establishing privacy-conscious data exchange. The above addresses the second aforementioned issue in that it enables a schema-level enforcement of the privacy-preserving protocol with strong guarantees. Regarding the third issue, we propose a repairing algorithm for the proposed privacy-preservation protocol in case of detected unsafety. Since multiple repairs are possible, such an algorithm might leverage techniques for learning the user preferences during the repairing process, which is also a desirable feature in privacy enforcement over sensitive data. In order to further illustrate the relevance of our problem, we illustrate a running example inspired by a real-life data exchange process between two different hospitals in the UK[1].

1.1 Illustrative example

Consider the source schema S of NHS consisting of the following relations: P, H_N, H_S, O and S as illustrated in Figure 2 (a). Relation P stores for each person registered with the hospital, his insurance number, his name, his ethnicity group and his county. Relations H_N and H_S store for each patient who has been admitted to some hospital in the north or the south of UK, his

[1] https://www.nhs.uk/

Source schema $S = \{P(i, n, e, c); H_N(i, d); H_S(i, d); O(i, t, p); S(i, n, e, c)\}$

Target schema $T = \{EthDis(e, d); CountyDis(c, d); SO(e)\}$

View schemas $V = \{V_1(e, d); V_2(c, d); V_3(t, p); V_4(e)\}$

(a) Schemas S, T and V

$$P(i, n, e, c) \wedge H_N(i, d) \rightarrow V_1(e, d) \quad (1)$$

$$P(i, n, e, c) \wedge H_S(i, d) \rightarrow V_2(c, d) \quad (2)$$

$$O(i, t, p) \rightarrow V_3(t, p) \quad (3)$$

$$S(i, n, e, c) \rightarrow V_4(e) \quad (4)$$

(b) Policy views $\mathcal{V}$

$$P(i, n, e, c) \wedge H_N(i, d) \rightarrow EthDis(e, d) \quad (5)$$

$$P(i, n, e, c) \wedge H_N(i, d) \rightarrow CountyDis(c, d) \quad (6)$$

$$S(i, n, e, c) \wedge O(i, t, p) \rightarrow SO(e) \quad (7)$$

(c) Mapping from S to T.

Figure 2: Schema and tgds in our illustrative example

insurance number and the reason for being admitted to the hospital. Relation O stores information related to patients in oncology departments and, in particular, their insurance numbers, their treatment and their progress. Finally, relation S stores for each student in UK, his insurance number, his name, his ethnicity group and his county.

Consider also the set $\mathcal{V}$ comprising the policy views (1)–(4). The policy views define the information that is safe to make available to the public. View (1) projects the ethnicity groups and the hospital admittance reasons for patients in the north of UK; view (2) projects the counties and the hospital admittance reasons for patients in the south of UK; view (3) projects the treatments and the progress of patients of oncology departments; view (4) projects the ethnicity groups of the school students. The policy views are compliant with the NSS privacy preservation protocol that is adopted at the hospital. Precisely, the NSS privacy preservation protocol considers as unsafe any non-evident piece of information that can potentially de-anonymize an individual. For example, views (1) and (2) do not leak any sensitive information concerning the precise address of patients. Indeed, they include patients from a very large geographical area thus implying that the probability of de-anonymizing a patient is significantly small. Similarly, views (3) and (4) are considered to be safe: the probability of de-anonymizing patients of the oncology department from view (3) is zero, since there is no way to link a patient to his treatment or his progress, while view (4) projects information which is already evident to public.

Finally, consider the following set of source-to-target dependencies Σ_{st}. Dependencies (5) and (6) project similar information with the views (1) and (2), respectively. However, contrarily to the views, they solely focus on patients in the north of UK. Finally, dependency (7) projects the ethnicity groups of students who have been in some oncology department, whereas view V_4 aims at concealing the information about the department in which a student has been admitted.

The above example shows that the policy views defined within one hospital might be in stark contrast with the mappings used to export patient's information to another hospital. This motivates the aforementioned questions (1), (2) and (3) about establishing formal guarantees for privacy preservation as well as enabling repairing of the mappings in order to make them safe. To the best of our knowledge, our work is the first to provide practical algorithms for a logical privacy-preservation paradigm effective in a real system [10], described as an open research challenge in [5, 21]. Our technique is inherently data-independent thus bringing the advantage that both the safety test and the repairing operations are executed on the metadata provided through the mappings and not on the underlying data instances.

The paper is organized as follows. Section 2 discusses the related work. Section 3 presents the basic concepts and notions. Section 4 lays our privacy preservation protocol. Section 5 presents our repairing algorithms and their properties. mechanism. Section 6 outlines the experimental results, while Section 7 concludes our work. The code base along with the experimental data are publicly available at [12].

2 RELATED WORK

Privacy in data integration. Safety of secret queries formulated against a global schema and adhering to the certain answers semantics has been tackled in previous theoretical work [21]. They define the optimal attack that characterizes a set of queries that an attacker can issue to which no further queries can be added to infer more information. They then define the privacy guarantees against the optimal attack by considering the static and the dynamic case, the latter corresponding to modifications of the schemas or the GLAV mappings. The same definition of secret queries and privacy setting is adopted in [5], which instead focuses on boolean conjunctive queries as policy views and on the notion of safety with respect to a given mapping. An ontology-based integration scenario is assumed in which the target instance is produced via a set of mappings starting from an underlying data source. Whereas they study the complexity of the view compliance problem in both data-dependent and data-independent setting, we focus on the latter and extend it to non-boolean conjunctive queries as policy views. We further consider multiple policy views altogether in the design of a practical algorithm for checking the safety of schema mappings and for repairing the mappings in case of violations.

Privacy in data publishing. Data publishing accounts for the settings in which a view exports or publishes the information of an underlying data source. Privacy and information disclosure in data publishing linger over the problem of avoiding the disclosure of the content of the view under a confidential query. A probabilistic formal analysis of the query-view security model has been presented in [20], where they offer a complete treatment of the multi-party collusion and the use of external adversarial knowledge. Access control policies using cryptography are used in [20] to enforce the authorization to an XML document. Our work differs from theirs on both the considered setting, as well as the adopted techniques and the adopted privacy protocol. Striking the balance between utility and privacy in a logic-based framework has been the object of investigation in recent studies focusing on data publishing for Linked Data [13, 14, 19]. The problem there is remarkably different from ours since they focus on publishing a single RDF dataset by applying privacy and utility queries in SPARQL, checking for their compatibility, and for update operations realizing the privacy and utility constraints.

Controlled Query Evaluation. Controlled Query Evaluation is a confidentiality enforcement framework introduced in [23] and refined in [9],[7] and [8], in which a policy declaratively specifies sensitive information and confidentiality is enforced by a censor. Provided a query as input, a censor verifies whether the

query leads to a violation of the policy and in case of a violation it returns a distorted answer. It has been recently adopted in ontologies expressed with Datalog-like rules and in lightweight Description Logics [18]. They assume that the policies are only known to database administrators and not to ordinary users and that the data has protected access through a query interface. Our assumptions and setting are quite different, since our multiple policy views are accessible to every user and our goal is to render the s-t mappings safe with respect to a set of policies via repairing and rewriting.

Data privacy. Previous work has addressed access control to protect database instances at different levels of granularity [22], in order to combine encrypted query processing and authorization rules. Our work being logic-based and declarative does not deal with these authorization methods, as well as does not consider any concrete privacy or anonymization algorithms operating on data instances, such as differential privacy [15] and k-anonymity [24]. Further exploring the connection between concrete privacy enforcement and logic-based privacy formalisms is the subject of future investigation.

Data exchange. The vast literature on data exchange [17] has inspired our work. In the considered scenarios, the source and target schema are considered along with s-t mappings and target dependencies, the latter being both egds and tgds. Similarly, past work on degugging schema mappings [11] has focused on all possible routes generated by the exchange process when incomplete or undefined values in one or more variables are exported from the source instance. By opposite, we focus in this paper on the case in which s-t mappings are coupled with source dependencies under the form of policy views, the latter being typical in privacy scenarios and unexplored in the classical data exchange setting.

3 PRELIMINARIES

Relational symbols and critical instances. Let Const, Nulls, and Vars be mutually disjoint, infinite sets of *constant values*, *labeled nulls*, and *variables*, respectively. A *schema* is a set of *relation names* (or just *relations*), each associated with a nonnegative integer called *arity*. A *relational atom* has the form $R(\vec{t})$ where R is an n-ary relation and $\vec{t}$ is an n-tuple of *terms*, where a term is either a constant, a labelled null, or a variable. An *equality atom* has the form $t_1 = t_2$ where t_1 and t_2 are terms. An atom is called ground or fact, when it does not contain any variables. A position in an n-ary atom A is an integer $1 \leq i \leq n$. We denote by $A|_i$, the i-th term of A. An instance I is a set of relational facts. An atom (resp. an instance) is *null-free* if it does not contain labelled nulls. The *critical instance* of a schema S, denoted as Crt_S, is the instance containing a fact of the form $R(\vec{*})$, for each n-ary relation $R \in \mathsf{S}$, where $*$ is called the *critical constant* and $\vec{*}$ is an n-ary vector. A *substitution* σ is a mapping from variables into constants or labelled nulls.

Dependencies and queries A *dependency* describes the semantic relationship between relations. A *Tuple Generating Dependency* (tgd) is a formula of the form $\forall \vec{x}\ \lambda(\vec{x}) \rightarrow \exists \vec{y}\ \rho(\vec{x}, \vec{y})$, where $\lambda(\vec{x})$ and $\rho(\vec{x}, \vec{y})$ are conjunctions of relational, null-free atoms. An *Equality Generating Dependency* (egd) is a formula of the form $\forall \vec{x}\ \lambda(\vec{x}) \rightarrow x_i = x_j$, where $\lambda(\vec{x})$ is a conjunction of relational, null-free atoms. We usually omit the quantification for brevity. We refer to the left-hand side of a tgd or an egd δ as the *body*, denoted as $\mathsf{body}(\delta)$, and to the right-hand side as the *head*, denoted as $\mathsf{head}(\delta)$. An instance I satisfies a dependency δ, written $I \models \delta$ if each homomorphism from $\mathsf{body}(\delta)$ into I can be extended to a homomorphism h' from $\mathsf{head}(\delta)$ into I. An instance I satisfies a set of dependencies Σ, written as $I \models \Sigma$, if $I \models \delta$ holds, for each $\delta \in \Sigma$. The *solutions* of an instance I w.r.t. Σ is the set of all instances J such that $J \supseteq I$ and $J \models \Sigma$. A solution is called *universal* if it can be homomorphically embedded to each solution of I w.r.t. Σ.

A *conjunctive query* (CQ) is a formula of the form $\exists \vec{y}\ \bigwedge_i A_i$, where A_i are relational, null-free atoms. A CQ is boolean if it does not contain any free variables. A substitution σ is an *answer* to a CQ Q on an instance I if the domain of σ is the free variables of Q, and if σ can be extended to a homomorphism from $\bigwedge_i A_i$ into I. We denote by $Q(I)$, the answers to Q on I.

Let S be a source schema and let T be a target schema. A *mapping* $\mathcal{M}$ from S to T is defined as a triple $(\mathsf{S}, \mathsf{T}, \Sigma)$, where $\Sigma = \Sigma_{st}$;, i.e. the set of the s-t dependencies over S and T. We usually refer to the dependencies in Σ_{st} as *mappings*. A variable x of a mapping $\mu \in \Sigma_{st}$ is called exported if it occurs both in the body and the head of μ. We denote by $\mathsf{exported}(\mu)$, the set of exported variables of μ. The inverse of set of s-t dependencies Σ_{st}, denoted as Σ_{st}^{-1} is the set consisting, for each mapping μ in Σ_{st} of the form $\lambda(\vec{x}) \rightarrow \rho(\vec{x}, \vec{y})$, a mapping μ^{-1} of the form $\rho(\vec{x}, \vec{y}) \rightarrow \lambda(\vec{x})$. We focus on *GAV* mappings in this paper, thus assuming that $\vec{y}$ is empty. Moreover, we consider the setting in which Σ only consists of Σ_{st} thus not including Σ_t. This implies that target egds and target tgds are excluded, since, despite their usage in data exchange, their role is less understood in the privacy-preserving variant considered in this paper.

4 PRIVACY PRESERVATION

In this section, we introduce our notion of privacy preservation. Let $\mathcal{V}$ be a set of *policy views* over S, representing the information that is safe to expose for instances I of S. Our goal is to verify whether a user-defined mapping $\mathcal{M} = (\mathsf{S}, \mathsf{T}, \Sigma)$ is safe w.r.t. the views in a set $\mathcal{V}$. Below, we will introduce a notion for assessing the safety of a GAV mapping $\mathcal{M}_2$ with respect to a GAV mapping $\mathcal{M}_1$, when both make use of the same source schema S. Moreover, let $\Sigma_i = \Sigma_{st_i}$ be the dependencies associated with $\mathcal{M}_i$.

4.1 A formal privacy-preservation protocol

Our notion of privacy preservation builds on the logical foundations introduced in [5] for ontology-based data integration for boolean queries. However, we extend the notion of privacy preservation from [5] to a relational data exchange setting in the presence of non-boolean conjunctive queries. First, we define the notion of disclosure of a CQ by a mapping as follows:

Definition 4.1. A mapping $\mathcal{M} = (\mathsf{S}, \mathsf{T}, \Sigma)$ *does not disclose a CQ* p *over* S *on any instance of* S, if for each instance I of S there exists an instance I' such that $I \equiv_{\mathcal{M}} I'$ and $p(I') = \emptyset$.

The problem of checking whether a mapping $\mathcal{M}$ over S does not disclose a boolean and constants-free CQ p on any instance of S is decidable for GAV mappings consisting of CQ views [5]. In particular, $\mathcal{M}$ does not disclose p on any instance of S if and only if there does not exist a homomorphism from p into the *unique* instance computed by the *visible chase* $\mathsf{visChase}_\mathsf{S}(\Sigma)$ of Σ under the critical instance Crt_S of S. The visible chase computes a *universal source instance* defined as follows:

Definition 4.2. 7 Given a mapping $\mathcal{M} = (\mathsf{S}, \mathsf{T}, \Sigma)$, an instance I is a *universal source instance* over S if for any instance J over the source schema S, there exists an homomorphism h from J into I

such that for any constant c from J that is made visible through $\mathcal{M}$, $h(c) = *$.

The only constant occurring in the instance computed by $\text{visChase}_S(\Sigma)$ is the critical constant $*$ and it represents any other constant that can occur in the source instance.

We introduce our own variant of the visible chase, which organizes the facts derived during chasing into subinstances called *bags*. Algorithm 1 describes the steps of the proposed variant. Please note that Algorithm 1 derives the same set of facts with the algorithm from [5]. However, instead of keeping these facts in a single set, we keep them in separate bags. Before presenting Algorithm 1, we will introduce a couple of useful new notions. The first notion serves the need of defining derived egds that allow to unify as many labeled nulls as possible with the critical constant in the target instance. The second notion allows to define relevant bags for which this unification must hold. Both notions are exploited by the visible chase (Algorithm 1) whose last step triggers the obtained egds.

Definition 4.3. Consider an instance I. Consider also a s-t tgd δ and a homomorphism h from $\text{body}(\delta)$ into I, such that $h(x) \in \text{Nulls}$, for some $x \in \text{exported}(\delta)$. Then, we say that the egd

$$\text{body}(\delta) \rightarrow \bigwedge_{\forall x \in \text{exported}(\delta): h(x) \in \text{Nulls}} x \approx * \qquad (8)$$

is *derived* from δ in I. For an egd ϵ that is derived from a s-t tgd δ in I, $\text{tgd}(\epsilon)$ denotes δ. For a set of s-t tgds Σ and an instance I, $\Sigma_\approx$ is the set comprising for each $\delta \in \Sigma$, the egd that is derived from δ in I.

Definition 4.4. Consider an instance I, whose facts are organized into the bags $\beta_1, \ldots, \beta_m$. Consider also a derived egd δ of the form (8) and an active trigger h for δ in I. A bag β_i is *relevant* for δ and h in I, where $1 \leq i \leq m$, if some fact $F \in h(\text{body}(\delta))$ occurs in β_i and if some $h(x)$ is a labeled null occurring in β_i, where $x \in \text{exported}(\delta)$.

Let $\beta_{j_1}, \ldots, \beta_{j_k} \subseteq \beta_1, \ldots, \beta_m$ be the set of bags that are relevant for δ and h in I. Let $\nu = \{h(x_j) \mapsto h(x_i)\}$ if $h(x_i) = *$, and $\nu = \{h(x_i) \mapsto h(x_j)\}$ if $h(x_i) \notin \text{Const}$, where x_i, x_j are variables from $\text{exported}(\delta)$. Then, the *derived* bag β for δ and h in I consists of the facts in $\bigcup_{l=1}^{k} \nu(\beta_{j_l})$. The bags $\beta_{j_1}, \ldots, \beta_{j_k}$ are called the *predecessors* of β. We use $\beta_{j_l} \prec \beta$ to denote that β_{j_l} is a predecessor of β, for $1 \leq l \leq k$.

We are now ready to proceed with the description of Algorithm 1. Given a s-t mapping, Algorithm 1 computes a universal source instance whose facts are organized into bags. Algorithm 1 first computes the instance I_0 by chasing Crt_S using the s-t tgds, line 1. It then chases I_0 with the inverse s-t tgds Σ^{-1}, line 2. and proceeds by chasing I_1 with the set of all derived egds $\Sigma_\approx$, for each $\delta \in \Sigma$ in I_1, line 4. Algorithm 1 computes a fresh bag at each chase step. In particular, for each active trigger h for δ in I, Algorithm 1 adds a fresh bag with facts $h'(\text{head}(\delta))$, if $\delta \in \Sigma \cup \Sigma^{-1}$, line 9; otherwise, if $\delta \in \Sigma_\approx$, then it adds the derived bag for δ and h in I, see Definition 4.4, line 20.

Note that, $\Sigma_\approx$ aims at "disambiguating" as many labeled nulls occurring in I_1 as possible, by unifying them with the critical constant $*$. Since $*$ represents the information that is "visible" to a third-party, chasing with $\Sigma_\approx$ computes the *maximal information* from the source instance a third-party has access to. Note that Algorithm 1 always terminates [5]. Let $B = \text{visChase}_S(\Sigma)$. We will denote by $I_S(\Sigma)$, the instance $\bigcup_{\beta \in B} \beta$.

Algorithm 1 $\text{visChase}_S(\Sigma)$

1: $B_0 := \text{bagChaseTGDs}(\Sigma, \text{Crt}_S)$
2: $B_1 := \text{bagChaseTGDs}(\Sigma^{-1}, \bigcup_{\beta \in B_0} \beta \setminus \text{Crt}_S)$
3: Let $\Sigma_\approx$ be the set of all derived egds $\Sigma_\approx$, for each $\delta \in \Sigma$ in I_1
4: **return** $\text{bagChaseEGDs}(\Sigma_\approx, B_0 \cup B_1)$

5: **procedure** $\text{bagChaseTGDs}(\Sigma, I)$
6: $B := \emptyset$
7: **for each** $\delta \in \Sigma$ **do**
8: **for each** active trigger $h : \text{body}(\delta) \rightarrow I$ **do**
9: **create** a fresh bag β with facts $h'(\text{head}(\delta))$
10: **add** β to B
11: **return** B

12: **procedure** $\text{bagChaseEGDs}(\Sigma_\approx, B)$
13: $i := 0$; $I_i := \bigcup_{\beta \in B} \beta$
14: **do**
15: $i := i + 1$
16: **for each** ($\delta \in \Sigma_\approx$ of the form (8) **do**
17: **for each** active trigger $h : \text{body}(\delta) \rightarrow I_{i-1}$ **do**
18: **if** $h(x) \neq *$, for some $x \in \text{exported}(\delta)$ **then**
19: Let β be the derived bag for δ and h in I_{i-1}
20: **add** β to B
21: $I_i := I_i \cup \beta$
22: **while** $I_{i-1} \neq I_i$
23: **return** B

Example 4.5. We demonstrate the visible chase algorithm over the policy views and the s-t dependencies from Example 1.1. We show how the algorithm runs first on the policy views $\mathcal{V}$ and then show the computation on Σ_{st}.

We first present the computation of $I_S(\mathcal{V}) = \bigcup_{\beta \in \text{visChase}_S(\mathcal{V})} \beta$.

The critical instance Crt_S of S consists of the facts shown in the following Eq. (9)

$$\text{P}(*,*,*,*) \quad \text{H}_\text{N}(*,*) \quad \text{H}_\text{S}(*,*) \quad \text{O}(*,*,*) \quad \text{S}(*,*,*,*) \qquad (9)$$

where $*$ is the critical constant.

The instance I_1 computed by chasing the output of line 1 using $\mathcal{V}^{-1}$ will consist of the facts

$$\begin{array}{lll} \text{P}(\text{n}_\text{i}, \text{n}_\text{n}, *, \text{n}_\text{c}) & \text{H}_\text{N}(\text{n}_\text{i}, *) & \text{O}(\text{n}''_\text{i}, *, *) \\ \text{P}(\text{n}'_\text{i}, \text{n}'_\text{n}, \text{n}_\text{e}, *) & \text{H}_\text{S}(\text{n}'_\text{i}, *) & \text{S}(\text{n}'''_\text{i}, \text{n}'''_\text{n}, *, \text{n}'''_\text{c}) \end{array} \qquad (I_1)$$

where the constants prefixed by n are labeled nulls created while chasing Crt_S with the inverse mappings. Since there exists no homomorphism from the body of any s-t tgd into I_1 mapping an exported variable into a labeled null, $\Sigma_\approx$ will be empty, see Definition 4.3. Thus, $I_S(\mathcal{V}) = I_1$.

We next present the computation of $I_S(\Sigma_{st}) = \bigcup_{\beta \in \text{visChase}_S(\Sigma_{st})} \beta$. The instance I'_1 computed by chasing the output of line 1 by Σ_{st}^{-1} will consist of the facts

$$\begin{array}{lll} \text{P}(\text{n}_\text{i}, \text{n}_\text{n}, *, \text{n}_\text{c}) & \text{H}_\text{N}(\text{n}_\text{i}, *) & \text{S}(\text{n}''_\text{i}, \text{n}''_\text{n}, *, \text{n}'_\text{c}) \\ \text{P}(\text{n}'_\text{i}, \text{n}'_\text{n}, \text{n}_\text{e}, *) & \text{H}_\text{N}(\text{n}'_\text{i}, *) & \text{O}(\text{n}''_\text{i}, \text{n}''_\text{t}, \text{n}''_\text{p}) \end{array} \qquad (I'_1)$$

Since there exists a homomorphism from the body of μ_e into I'_1 mapping the exported variable e into the labeled null n_e, and since there exists another homomorphism from the body of μ_c into I'_1 mapping the exported variable c into the labeled null n_c, $\Sigma_\approx$ will comprise the egds ϵ_1 and ϵ_2 shown below

$$\text{P}(\text{i}, \text{n}, \text{e}, \text{c}) \wedge \text{H}_\text{N}(\text{i}, \text{d}) \rightarrow \text{e} \approx * \qquad (\epsilon_1)$$

$$\text{P}(\text{i}, \text{n}, \text{e}, \text{c}) \wedge \text{H}_\text{N}(\text{i}, \text{d}) \rightarrow \text{c} \approx * \qquad (\epsilon_2)$$

The last step of the visible chase involves chasing I_1' using $\Sigma_{\approx}$. W.l.o.g, assume that the chase considers first ϵ_1 and then ϵ_2. During the first step of the chase, there exists a homomorphism from body(ϵ_1) into I_1'. Hence, $n_e = *$. During the second step of the chase, there exists a homomorphism from body(ϵ_2) into I_1' and, hence, $n_c = *$. The instance computed at the end of the second round of the chase will consist of the facts

$$\begin{array}{llll} P(n_i, n_n, *, *) & H_N(n_i, *) & H_N(n_i', *) & (10) \\ S(n_i'', n_n'', *, n_c') & O(n_i'', n_t'', n_p'') & & \end{array}$$

Since there exists no active trigger for ϵ_1 or ϵ_2 in the above instance (Eq (10)), the chase will terminate.

The facts in $I_S(\Sigma_{st})$ will be organized into the following bags β_1–β_5 (one bag per line)

$$\begin{aligned} SO(e) &\xrightarrow{\langle \mu_s^{-1}, h_1 \rangle} S(n_i'', n_n'', *, n_c'), O(n_i'', n_t'', n_p'') \\ CountyDis(c, d) &\xrightarrow{\langle \mu_c^{-1}, h_2 \rangle} P(n_i', n_n', n_e, *), H_N(n_i', *) \\ EthDis(e, d) &\xrightarrow{\langle \mu_e^{-1}, h_3 \rangle} P(n_i, n_n, *, n_c), H_N(n_i, *) \\ P(n_i', n_n', n_e, *), H_N(n_i', *) &\xrightarrow{\langle \epsilon_1, h_4 \rangle} P(n_i', n_n', *, *), H_N(n_i', *) \\ P(n_i, n_n, *, n_c), H_N(n_i, *) &\xrightarrow{\langle \epsilon_2, h_5 \rangle} P(n_i, n_n, *, *), H_N(n_i, *) \end{aligned}$$

$$\begin{aligned} h_1 &= \{i \mapsto n_i', n \mapsto n_n', e \mapsto n_e, c \mapsto *, d \mapsto *\} \\ h_2 &= \{c \mapsto *, d \mapsto *\} \\ h_3 &= \{e \mapsto *, d \mapsto *\} \\ h_4 &= \{i \mapsto n_i', n \mapsto n_n', e \mapsto n_e, c \mapsto *, d \mapsto *\} \\ h_5 &= \{i \mapsto n_i, n \mapsto n_n, e \mapsto *, c \mapsto n_c, d \mapsto *\} \end{aligned}$$

The contents of the bags correspond to the right-hand side of the arrows. However, for presentation purposes, we also show the related dependency δ and the homomorphism h that lead to the derivation of each bag (shown at the top of each arrow), as well as, the facts in h(body(δ)) (left-hand side of each arrow). The obtained bags will be part of the universal source instance $I_S(\Sigma_{st})$. Such an instance will be used in Section 5 in order to apply the notion of safety in the repairing of the underlying mappings Σ_{st}.

4.2 Preserving the privacy of policy views

We consider a mapping $\mathcal{M} = (S, T, \Sigma)$ to be safe w.r.t. a view mapping $\mathcal{M}_V = (S, V, \mathcal{V})$ (with $\mathcal{V}$ being the set of policy views and V being the schema of the views as shown in Figure 1), if $\mathcal{M}$ does not disclose the information that is also not disclosed by $\mathcal{M}_V$. Definition 4.6 and Theorem 4.7 presented below formalize our notion of privacy preservation and show that there exists a simple process for verifying whether $\mathcal{M}$ is safe w.r.t. $\mathcal{M}_V$.

Definition 4.6. A mapping $\mathcal{M}_2 = (S, T_2, \Sigma_2)$ *preserves the privacy of a mapping* $\mathcal{M}_1 = (S, T_1, \Sigma_1)$ *on all instances of* S, if for each constants-free CQ p over S, if p is not disclosed by $\mathcal{M}_1$ on any instance of S, then p is not disclosed by $\mathcal{M}_2$ on any instance of S.

Theorem 4.7. *A mapping* $\mathcal{M}_2 = (S, T_2, \Sigma_2)$ preserves the privacy of a mapping $\mathcal{M}_1 = (S, T_1, \Sigma_1)$ on all instances of S, *if and only if there exists a homomorphism* h *from* $I_S(\Sigma_2)$ *into* $I_S(\Sigma_1)$, *such that* $h(*) = *$.

Proof. (Sketch) First we show that the following holds:

Lemma 4.8. *A mapping* $\mathcal{M} = (S, T, \Sigma)$ does not disclose a constants-free CQ p over S on any instance of S, *iff* $\vec{*} \notin p(J)$, *where* $J = I_S(\Sigma_{st})$.

Proof. By adapting the proof technique of Theorem 16 from [5], we can show that $J = I_S(\Sigma_{st})$ is a *universal* source instance $I_S(\Sigma)$ satisfying the following property: for each pair of source instances I and I', such that I' is indistinguishable from I w.r.t. the mapping $\mathcal{M}$, there exists a homomorphism h from I' into $I_S(\Sigma)$ mapping each schema constant into the critical constant $*$. Due to the existence of a homomorphism h from I' into $I_S(\Sigma)$, for each pair of indistinguishable source instances I and I', we can see that if $\vec{*} \notin p(J)$ for a constants-free CQ p, then $p(I') = \emptyset$. Due to the above and due to Definition 4.1, it follows that $\mathcal{M} = (S, T, \Sigma)$ does not disclose a constants-free CQ p over S on any instance of S. □

Lemma 4.8 states that, in order to check if a constants-free CQ is safe according to Definition 4.1, we need to check if the critical tuple is among the answers to p over the instance computed by visChase$_S(\Sigma)$. Next, we show the following lemma.

Lemma 4.9. *Given two instances* I_1 *and* I_2, *the following are equivalent*

(1) for each CQ p, *if* $\vec{u} \in p(I_1)$, *then* $\vec{u} \in p(I_2)$, *where* $\vec{u}$ *is a vector of constants*
(2) there exists a homomorphism from I_1 *to* I_2 *preserving the constants of* I_1

Proof of Lemma 4.9. (2)⇒(1). Suppose that there exists a homomorphism h from I_1 to I_2 preserving the constants of I_1. Suppose also that $\vec{u} \in p(I_1)$, with p being a CQ. This means that there exists a homomorphism h_1 from p into I_1 mapping each free variable x_i of p into u_i, for each $1 \leq i \leq n$, where n is the number of free variables of p. Since the composition of two homomorphisms is a homomorphism and since h preserves the constants of I_1 due to the base assumptions, this means that $h \circ h_1$ is a homomorphism from p into I_2 mapping each free variable x_i of p into t_i, for each $1 \leq i \leq n$. This completes this part of the proof.

(1)⇒(2). Let p_1 be a CQ formed by creating a non-ground atom $R(y_1, \ldots, y_n)$ for each ground atom $R(u_1, \ldots, u_n) \in I_1$, by taking the conjunction of these non-ground atoms and by converting into an existentially quantified variable every variable created out of some labelled null. Let $\vec{x}$ denote the free variables of p_1 and let $n = |\vec{x}|$. From the above, it follows that there exists a homomorphism h_1 from p_1 into I_1 mapping each $x_i \in \vec{x}$ into some constant occurring in I_1. Let $\vec{u} \in p_1(I_1)$. From (1), it follows that $\vec{u} \in p_1(I_2)$ and, hence, there exists a homomorphism h_2 from p_1 into I_2 mapping each $x_i \in \vec{x}$ into u_i, for each $1 \leq i \leq n$. Since h_1 ranges over all constants of I_1 and since $h_1(x_i) = h_2(x_i)$ holds for each $1 \leq i \leq n$, it follows that there exists a homomorphism from I_1 to I_2 preserving the constants of I_1. This completes the second part of the proof. □

Lemma 4.9 can be restated as follows:

Lemma 4.10. *Given two instances* I_1 *and* I_2, *the following are equivalent*

(1) for each CQ p, *if* $\vec{t} \notin p(I_2)$, *then* $\vec{t} \notin p(I_1)$
(2) there exists a homomorphism from I_1 *to* I_2

We are now ready to return to the main part of the proof. Given a CQ p over a source schema S, and a mapping $\mathcal{M}$ defined as the triple (S, T, Σ), where T is a target schema and Σ is a set of s-t dependencies, we know from Proposition 4.8 that if $\mathcal{M}$ discloses p on some instance of S, then there exists a homomorphism of p into visChase$_S(\Sigma)$ mapping the free variables of p into the critical constant $*$.

From the above, we know that $\mathcal{M}_2$ does not preserve the privacy of $\mathcal{M}_1$ if there exists a CQ p over S, such that $\vec{*} \notin J_1$ and $\vec{*} \in J_2$, where $J_1 = I_S(\Sigma_1)$ and $J_2 = I_S(\Sigma_2)$. We will now prove that $\mathcal{M}_2$ preserves the privacy of $\mathcal{M}_1$ iff there exists a homomorphism from J_2 into J_1 that preserves the critical constant $*$. This will be referred to as conjecture (C).

($\Rightarrow$) If $\mathcal{M}_2$ preserves the privacy of $\mathcal{M}_1$, then for each CQ p, if $\vec{*} \notin p(J_1)$, then $\vec{*} \notin p(J_2)$. From the above and from Lemma 4.10, it follows that there exists a homomorphism $\phi : J_2 \rightarrow J_1$, such that $\phi(*) = *$.

($\Leftarrow$) The proof proceeds by contradiction. Assume that there exists a homomorphism h from J_2 into J_1 preserving $*$, but $\mathcal{M}_2$ does not preserve the privacy of $\mathcal{M}_1$. We will refer to this assumption as assumption (A_1). From assumption (A_1) and the discussion above it follows that there exists a CQ p over S such that $\vec{*} \notin p(J_1)$ and $\vec{*} \in p(J_2)$. Let h_2 be the homomorphism from p into J_2 mapping its free variables into $*$. Since the composition of two homomorphisms is a homomorphism, this means that $h \circ h_2$ is a homomorphism from p into J_1 mapping its free variables into $*$, i.e., $\vec{*} \in p(J_1)$. This contradicts our original assumption and hence concludes the proof of conjecture (C). Conjecture (C) witnesses the decidability of the instance-independent privacy preservation problem: in order to verify whether $\mathcal{M}_2$ preserves the privacy of $\mathcal{M}_1$ we only need to check if there exists a homomorphism $\phi : I_S(\Sigma_2) \rightarrow I_S(\Sigma_1)$, such that $\phi(*) = *$. □

Theorem 4.7 states that in order to verify whether $\mathcal{M}_2$ is safe w.r.t. $\mathcal{M}_1$, we need to compute $I_S(\Sigma_1)$ and $I_S(\Sigma_2)$ and check if there exists a homomorphism from the second instance into the first one that maps $*$ into itself. If there exists such a homomorphism, we say that $I_S(\Sigma_1)$ is *safe* w.r.t. $I_S(\Sigma_2)$, or simply safe, and we say that it is unsafe otherwise.

Example 4.11. Continuing with Example 1.1, we can see that the s-t tgds are not safe w.r.t. the policy views according to Theorem 4.7, since there does not exist a homomorphism from the instance $I_S(\Sigma_{st})$ into the instance $I_S(\mathcal{V})$. This means that there exists information which is disclosed by Σ_{st} in some instance that satisfies Σ_{st}, but it is not disclosed by $\mathcal{V}$. Indeed, from $S(n_i'', n_n'', *, n_c')$ and $O(n_i'', n_t'', n_p'')$, we can see that we can potentially leak the identity of a student who has been to an oncology department. This can happen if there exists only one student in the school coming from a specific ethnicity group and this ethnicity group is returned by μ_s. Please note that the policy views are safe w.r.t. this leak. Indeed, it is impossible to derive this information through reasoning over the returned tuples under the input instance and the views V_3 and V_4.

Furthermore, by looking at the facts $P(n_i, n_n, *, *)$ and $H_N(n_i, *)$, we can see that we can potentially leak the identity and the disease of a patient who has been admitted to some hospital in the north of UK. This can happen if there exists only one patient who relates to the county and the ethnicity group returned by μ_e and μ_c. Note that the policy views V_1 and V_2 do not leak this information, since it is impossible to obtain the county and the ethnicity group of an NHS patient at the same time.

5 REPAIRING UNSAFE MAPPINGS

In Section 4, we presented our privacy preservation protocol and a technique for verifying whether a mapping is safe w.r.t. another one, over all source instances. This section presents an algorithm for repairing an unsafe mapping $\mathcal{M}$ w.r.t. a set of policy views $\mathcal{V}$. This is a fundamental operation needed to amend mappings whenever the policy views are modified and become unsafe (e.g. in the presence of data protection regulations).

Algorithm 2 repair$(\Sigma, \mathcal{V}, \text{prf}, n)$

1: $\Sigma_1 :=$ frepair$(\Sigma, \mathcal{V}, \text{prf})$
2: $\Sigma_2 :=$ srepair$(\Sigma_1, \mathcal{V}, \text{prf}, n)$
3: **return** Σ_2

Algorithm 2 summarizes the steps of the proposed algorithm. The inputs to it are, apart from Σ and $\mathcal{V}$, a positive integer n which will be used during the second step of the repairing process and a preference mechanism prf for ranking the possible repairs. In the simplest scenario, the preference mechanism implements a fixed function for ranking the different repairs. However, it can also employ supervised learning techniques in order to progressively learn the user preferences by looking at his prior decisions.

Since a mapping $\mathcal{M}$ is safe w.r.t. $\mathcal{V}$ if the instance $I_S(\Sigma)$ is safe according to Theorem 4.7, Algorithm 2 rewrites the tgds in $\mathcal{M}$, such that the derived visible chase instances are safe. The rewriting takes place in two steps. The first step rewrites Σ into a *partially-safe* set of s-t dependencies Σ_1, while the second step rewrites the output of the first one into a new set of s-t dependencies Σ_2, such that $I_S(\Sigma_2)$ is safe. As we will explain later on, partial-safety ensures that the intermediate instance I_1 produced by visChase$_S(\Sigma_1)$ at line 2 of Algorithm 1 is safe, but it does not provide strong privacy guarantees. The benefit of this two-step approach is that it allows repairing one or a small set of dependencies at a time.

5.1 Computing partially-safe mappings

Since the problem of safety is reduced to the problem of checking for a homomorphism from $I_S(\Sigma)$ into $I_S(\mathcal{V})$, a first test towards checking for such a homomorphism is to look if the mappings in Σ would lead to such a homomorphism or not. For instance, by looking at μ_s in Example 1.1 it is easy to see that it leaks sensitive information, since it involves a join between students and oncology departments, which does not occur in $I_S(\mathcal{V})$.

Definition 5.1. A mapping $\mathcal{M} = (S, T, \Sigma)$ is *partially-safe w.r.t.* $\mathcal{M}_V = (S, V, \mathcal{V})$ *on all instances of* S, if there exists a homomorphism from chase$(\Sigma^{-1}, \text{Crt}_T) \setminus \text{Crt}_T$ into $I_S(\mathcal{V})$.

From Algorithm 1, it follows that Σ is partially-safe iff the intermediate instance I_1 computed by visChase$_S(\Sigma)$ is safe.

Proposition 5.2. *A mapping* $\mathcal{M} = (S, T, \Sigma)$ *is* partially-safe w.r.t. $\mathcal{M}_V = (S, V, \mathcal{V})$ on all instances of S, *if for each* $\mu \in \Sigma$, *there exists a homomorphism from* body(μ) *into* $I_S(\mathcal{V})$ *mapping each* $x \in$ exported(μ) *into the critical constant* $*$.

Note that according to Proposition 5.2, in our running example Σ_{st} would be partially-safe, if $\mu_s \notin \Sigma_{st}$, then since there exist homomorphisms from the bodies of μ_s and μ_c into $I_S(\mathcal{V})$, mapping their exported variables into $*$. It is also easy to show the following

Remark 1. *A mapping* $\mathcal{M} = (S, T, \Sigma)$ *is* safe w.r.t. $\mathcal{M}_V = (S, V, \mathcal{V})$ on all instances of S, *only if it is partially-safe w.r.t.* $\mathcal{M}_V$ *on all instances of* S. □

Proposition 5.2 presents a quite convenient, yet somewhat expected, finding: in order to obtain a partially-safe mapping, it suffices to repair each s-t dependency *independently of the others*. Furthermore, the repair of each $\mu \in \Sigma$ involves breaking joins

and hiding exported variables, such that the repaired dependency μ_r satisfies the criterion in Proposition 5.2.

We make use of the result of Proposition 5.2 in Algorithm 3. Algorithm 3 obtains, for each $\mu \in \Sigma$, a set of rewritings $\mathcal{R}_\mu$, out of which we will choose the best rewriting according to prf. The set $\mathcal{R}_\mu$ consists of *all* rewritings that differ from μ w.r.t. the variable repetitions in the bodies of the rules and the exported variables. Below, we present the steps of Algorithm 3.

For each s-t tgd μ and for each atom $B \in \text{body}(\mu)$, Algorithm 3 constructs a fresh atom C and adds C to a set $\mathcal{C}$. The set of atoms $\mathcal{C}$ provides us with the means to identify all repairs of μ that involve breaking joins and hiding exported variables. In particular, each homomorphism ξ from $\mathcal{C}$ into $I_S(\mathcal{V})$ corresponds to one repair of μ. In lines 12–25, Algorithm 3 modifies each atom $B \in \text{body}(\mu)$ by taking into account prior body atom modifications. The prior modifications are accumulated in the relation ρ and the mapping ψ. The relation ρ keeps for each variable x from $\text{body}(\mu)$, the fresh variables that were used to replace x during prior steps of the repairing process, while ψ is a substitution from the partially repaired body into $I_S(\mathcal{V})$. In particular, at the end of the i-th iteration of the loop in line 12, ψ holds the substitution from the first repaired i atoms from $\text{body}(\mu)$ into $I_S(\mathcal{V})$. We adopt this approach instead of replacing variable x in position p always by a fresh variable, in order to minimize the number of the joins we break.

Below, we describe how Algorithm 3 modifies each body atom of μ, w.r.t. a homomorphism ξ, lines 9–27. Let $C = \nu(B)$ be the fresh body atom that was constructed out of B in line 5. For each atom $B \in \text{body}(\mu)$ and for each $p \in \text{pos}(B)$, if the variable y in position p of C is not mapped to the critical constant $*$ via ξ and $B|_p$ is an exported variable, this means that *the variable sitting in position p of B should not be exported* (see first condition in line 16). Similarly, if the variable sitting in position p of B is mapped to a different constant than the one that y maps via ξ, then this means that *the variable sitting in position p of B introduces an unsafe join* (see second condition in line 16). In the presence of these violations, we must replace variable x in position p of B, either by a variable that was used in a prior step of the repairing process, line 17–18), or by a fresh variable, lines 19–23. Otherwise, if there is no violation so far, then we add the mapping $\{x \mapsto \xi(y)\}$ to ψ, if it is not already there, lines 24–25. Finally, the algorithm chooses the best repair according to the preference function, lines 28–31.

Algorithm 3 frepair$(\Sigma, \mathcal{V}, \text{prf})$

```
1:  for each μ ∈ Σ do
2:      ν := ∅, C := ∅
3:      for each B ∈ body(μ), where B = R(x⃗) do
4:          create a vector of fresh variables y⃗
5:          create the atom C = R(y⃗)
6:          add (B, C) to ν
7:          add C to C
8:      R_μ := ∅
9:      for each homomorphism ξ : C → I_S(V) do
10:         ρ := ∅, ψ := ∅
11:         μ_r := μ
12:         for each B ∈ body(μ_r) do
13:             C = ν(B)
14:             for each p ∈ pos(B) do
15:                 x = B|_p, y = C|_p
16:                 if x ∈ exported(μ) and * ≠ ξ(y) or x ∈
    dom(ψ) and ψ(x) ≠ ξ(y) then
17:                     if ∃x' s.t. (x, x') ∈ ρ and ψ(x') = ξ(y)
    then
18:                         B|_p = x'
19:                     else
20:                         create a fresh variable x'
21:                         add (x, x') to ρ
22:                         add {x' ↦ ξ(y)} to ψ
23:                         B|_p = x'
24:                 else if x ∉ dom(ψ) then
25:                     add {x ↦ ξ(y)} to ψ
26:         if μ_r ≠ μ then
27:             add μ_r to R_μ
28:     if R_μ ≠ ∅ then f
29:         choose the best repair μ_r of μ from R_μ based on prf
30:         remove μ from Σ
31:         add μ_r to Σ
32: return Σ
```

Proposition 5.3. *For any $\mathcal{M} = (S, T, \Sigma)$, any $\mathcal{M}_V = (S, V, \mathcal{V})$ and any preference function* prf*, Algorithm* frepair *returns a mapping $\mathcal{M}' = (S, T, \Sigma')$ that is partially-safe w.r.t. $\mathcal{M}_V$ on all instances of S.*

Proof. (Sketch) From Proposition 5.2, a mapping $\mathcal{M} = (S, T, \Sigma)$ is partially-safe w.r.t. $\mathcal{M}_V = (S, V, \mathcal{V})$ on all instances of S, if for each $\mu \in \Sigma$, there exists a homomorphism from $\text{body}(\mu)$ into $I_S(\mathcal{V})$ mapping each $x \in \text{exported}(\mu)$ into the critical constant $*$. Since for each $\mu \in \Sigma$ frepair computes a set of repaired tgds $\mathcal{R}_\mu$, it follows that Proposition 5.3 holds, if such a homomorphism exists, for each repaired tgd in $\mathcal{R}_\mu$. The proof proceeds as follows. Let μ_r^i and ψ^i denote the repaired s-t tgd and the homomorphism ψ computed at the end of each iteration i of the steps in lines 12–25 of Algorithm 3. Let also B^i denote the i-th atom in $\text{body}(\mu_r)$. Since each $C \in \mathcal{C}$ is an atom of distinct fresh variables, since ξ is a homomorphism from $\mathcal{C}$ to $I_S(\mathcal{V})$ and since $\psi(B^i) = \mu_r|_i$, it follows that in order to prove Proposition 5.2, we have to show that the following claim holds, for each $i \geq 0$:

- ϕ. ψ^i is a homomorphism from the first i atoms in the body of μ_r into $I_S(\mathcal{V})$ mapping each exported variable occurring in $B^0, \ldots, B^i$ into the critical constant $*$.

For $i = 0$, ϕ trivially holds. For $i + 1$ and assuming that ϕ holds for i let $C^{i+1} = \nu(B^{i+1})$, line 13. The proof of claim ϕ depends upon the proof of the following claim, for each iteration $p \geq 0$ of the steps in lines 14–25:

- θ. $\psi^{i+1}(B^{i+1}|_p) = \xi(y)$, where $y = C^{i+1}|_p$.

The claim θ trivially holds for $p = 0$, while for $p > 0$, it directly follows from the steps in lines 16–25. Since ϕ holds for i, since the steps in lines 16–25 do not modify the variable mappings in ψ^i and due to θ, it follows that ϕ holds for $i + 1$, concluding the proof of Proposition 5.3. □

Example 5.4. We demonstrate an example of Algorithm 3.

Since Algorithm 3 focuses on $I_S(\mathcal{V})$ overlooking the actual views in $\mathcal{V}$, we will not explicitly define $\mathcal{V}$. Instead, we will only assume that the visible chase computes the instance

$$I_S(\mathcal{V}) = \{R_1(*, n_1, n_2), S_1(n_1, n_2, n_2), S_1(n_1, n_3, *), S_1(n_1, *, *)\}$$

where n_1–n_3 are labeled nulls. Consider also the mapping $\mathcal{M}$ consisting of the following s-t dependency

$$R_1(x, y, z) \wedge S_1(y, z, z) \rightarrow T_1(x, z) \qquad (\mu_1)$$

Note that $\mathcal{M}$ is not partially-safe. Algorithm 3 computes two repairs for μ_1 by applying the steps described below. First, it computes the atoms $\mathsf{R}_1(x_1, x_2, x_3)$ $\mathsf{S}_1(x_4, x_5, x_6)$ and adds them to C, lines 3–7. Then, it identifies the following three homomorphisms from C into $I_{\mathsf{S}}(\mathcal{V})$:

$$\xi_1 = \{x_1 \mapsto *, x_2 \mapsto \mathsf{n}_1, x_3 \mapsto \mathsf{n}_2, x_4 \mapsto \mathsf{n}_1, x_5 \mapsto \mathsf{n}_2, x_6 \mapsto \mathsf{n}_2\}$$
$$\xi_2 = \{x_1 \mapsto *, x_2 \mapsto \mathsf{n}_1, x_3 \mapsto \mathsf{n}_2, x_4 \mapsto \mathsf{n}_1, x_5 \mapsto \mathsf{n}_3, x_6 \mapsto *\}$$
$$\xi_3 = \{x_1 \mapsto *, x_2 \mapsto \mathsf{n}_1, x_3 \mapsto \mathsf{n}_2, x_4 \mapsto \mathsf{n}_1, x_5 \mapsto *, x_6 \mapsto *\}$$

From ξ_1, we can see that the joins in the body of μ_1 are safe; however, it is unsafe to export z. From ξ_2, we can see that is safe to reveal the third position of S_1; however, it is unsafe to join the second and the third position of S_1. Algorithm 3 then iterates over ξ_1 and ξ_2, line 9. When $B = \mathsf{R}_1(x, y, z)$ and $p < 3$, Algorithm 3 computes ψ to $\{x \mapsto *, y \mapsto \mathsf{n}_1\}$, since there is no violation according to line 16. When $B = \mathsf{R}_1(x, y, z)$ and $p = 3$, however, a violation is detected. This is due to the fact that z is an exported variable and $\xi(x_3) = \mathsf{n}_2$. Algorithm 3 tackles this violation by creating a fresh variable z_1. Then, it adds the relation (z, z_1) to ρ, replaces z in $B|_3$ by z_1 and adds the mapping $\{z_1 \mapsto \mathsf{n}_2\}$ to ψ, lines 19–23. Algorithm 3 then considers $\mathsf{S}_1(y, z, z)$. When $p = 1$, no violation is encountered, since $\psi(y) = \xi_1(x_4)$. However, when $p = 2$, a homomorphism violation is encountered, since z is an exported variable and since $\xi(x_3) = \mathsf{n}_2$. Since $(z, z_1) \in \rho$ and $\psi(z_1) = \xi_1(x_5)$, Algorithm 3 replaces z in the second position of $\mathsf{S}_1(y, z, z)$ by z_1, line 19. By applying a similar reasoning, we can see that the variable z siting in $\mathsf{S}_1(y, z, z)|_3$ is also replaced by z_1. Hence, the first repair of μ is

$$\mathsf{R}_1(x, y, z_1) \wedge \mathsf{S}_1(y, z_1, z_1) \rightarrow \mathsf{T}_1(x) \qquad (r_1)$$

Algorithm 3, then proceeds by repairing μ_1 based on ξ_2. When $B = \mathsf{R}_1(x, y, z)$, Algorithm 3 proceeds as described above and computes ψ to $\{x \mapsto *, y \mapsto \mathsf{n}_1, z_1 \mapsto \mathsf{n}_2\}$. When $B = \mathsf{S}_1(y, z, z)$ and $p = 1$, then no violation is encountered since $\psi(y) = \xi_1(x_4)$, while when $B = \mathsf{S}_1(y, z, z)$ and $p = 2$, there is a violation. Since the condition in line 18 is not met, Algorithm 3 creates a fresh variable z_2 and adds the mapping $\{z_2 \mapsto \mathsf{n}_3\}$ to ψ. When $B = \mathsf{S}_1(y, z, z)$ and $p = 3$, then no violation is met, since $z \in \text{exported}(\mu)$ and $\xi_2(x_6) = *$. Hence, the second repair of μ_1 is

$$\mathsf{R}_1(x, y, z_1) \wedge \mathsf{S}_1(y, z_2, z) \rightarrow \mathsf{T}_1(x, z) \qquad (r_2)$$

Finally, we can see that the repair for μ_1 w.r.t. ξ_3 is

$$\mathsf{R}_1(x, y, z_1) \wedge \mathsf{S}_1(y, z, z) \rightarrow \mathsf{T}_1(x, z) \qquad (r_3)$$

5.2 Computing safe mappings

Unifications of one or more labeled nulls occurring in I_1 with the critical constant $*$, might lead to unsafe instances. Consider, for instance, a simplified variant of Example 1.1, where Σ_{st} comprises only μ_e and μ_c. Both μ_e and μ_c are partially-safe, as we have explained above. However, the unification of the labeled nulls n_n and n_c produces an unsafe instance. Algorithm 4 aims at repairing the output of the previous step, such that no unsafe unification of a labeled null with $*$ takes place.

Consider again the simplified variant of Σ_{st} from above. Since Σ_{st} is partially-safe, it suffices to look for homomorphism violations in I_i, for $i \geq 1$. A first observation is that the homomorphism violations are "sitting" within the bags. This is due to the fact that each bag stores *all* the facts associated with the bodies of one or more s-t tgds from Σ_{st}. A second observation is that one way for preventing unsafe unifications is to hide exported variables. For example, let us focus on the unsafe unification of n_e with $*$. This unification takes place due to ϵ_1, which in turn has been created due to the fact that e is an exported variable in μ_e. By hiding the exported variable e from μ_e, we actually prevent the creation of ϵ_1 and hence, we block the unsafe unification of e with $*$. Hiding exported variables is one way for preventing unsafe unifications with the critical constant. Another way for preventing unsafe unifications is to break joins in the bodies of the rules.

Example 5.5. This example demonstrates a second approach for preventing unsafe labeled null unifications.

Consider a set of policy views $\mathcal{V}$ leading to the following instance $I_{\mathsf{S}}(\mathcal{V}) = \{\mathsf{R}_1(\mathsf{n}_1, \mathsf{n}_1, *), \mathsf{R}_1(*, *, \mathsf{n}_2), \mathsf{S}_1(*)\}$, where n_1 and n_2 are labelled nulls. Consider also the mapping $\mathcal{M}$ consisting of the following s-t dependencies:

$$\mathsf{R}_1(x, x, y) \wedge \mathsf{S}_1(y) \rightarrow \mathsf{T}_1(y) \qquad (\mu_2)$$
$$\mathsf{R}_1(x, x, y) \rightarrow \mathsf{T}_2(x) \qquad (\mu_3)$$

It is easy to see that $\mathcal{M}$ is partially-safe, but unsafe in overall. Indeed, $I_{\mathsf{S}}(\Sigma)$ will consist of the following bags (for presentation purposes, we adopt the notation from Example 4.5):

$$\mathsf{T}_1(*) \xrightarrow{\langle \mu_2^{-1}, \theta_1 \rangle} \mathsf{R}_1(\mathsf{n}_3, \mathsf{n}_3, *), \mathsf{S}_1(*)$$
$$\mathsf{T}_2(*) \xrightarrow{\langle \mu_3^{-1}, \theta_2 \rangle} \mathsf{R}_1(*, *, \mathsf{n}_4)$$
$$\mathsf{R}_1(\mathsf{n}_3, \mathsf{n}_3, *), \mathsf{S}_1(*) \xrightarrow{\langle \epsilon_3, \theta_3 \rangle} \mathsf{R}_1(*, *, *), \mathsf{S}_1(*)$$

where $\epsilon_3 := \mathsf{R}_1(x, x, y) \rightarrow x = *, \theta_1 = \{y \mapsto *\}, \theta_2 = \{x \mapsto *\}$ and $\theta_3 = \{x \mapsto \mathsf{n}_3, y \mapsto *\}$. Note that ϵ_3 has been created out of μ_3, since there exists a homomorphism from $\text{body}(\mu_3)$ into $\mathsf{R}_1(\mathsf{n}_3, \mathsf{n}_3, *)$ mapping the exported variable x into n_3.

One approach for preventing the unsafe unification of n_3 with $*$ is to hide the exported variable x from μ_3. By doing this, we block the creation of ε, and hence the unsafe unification.

A second approach is to keep x as an exported variable in μ_3, but modify the body of μ_2 by breaking the join between the first and the second position of R_1

$$\mathsf{R}_1(x, z, y) \wedge \mathsf{S}_1(y) \rightarrow \mathsf{T}_1(y) \qquad (\mu_2')$$

By doing this, we prevent the creation of ε, since the instance computed at line 2 of Algorithm 1 would consist of the facts $\mathsf{R}_1(\mathsf{n}_3, \mathsf{n}_5, *)$, $\mathsf{R}_1(*, *, \mathsf{n}_4)$, $\mathsf{S}_1(*)$ and, hence, there would be no homomorphism from $\text{body}(\mu_3)$ into it. Note that the modification of μ_2 to μ_2' is safe. Intuitively, this holds, since we break joins, and thus, we export less information.

Before presenting Algorithm 4, we will introduce some new notation. The *depth* of each bag β, denoted as $\text{depth}(\beta)$, coincides with the highest derivation depth of the facts in β. The *support* of a bag β, denoted as $\beta^{\prec}$, is inductively defined as follows: if $\text{depth}(\beta) = 1$, then $\beta^{\prec} = \beta$; otherwise, if $\text{depth}(\beta) > 1$, then $\cup_{\beta' \prec \beta} \beta'^{\prec}$. Consider an active trigger h for δ in I leading to the creation of a bag β. We use the following notation: $\text{dependency}(\beta) = \delta, \text{trigger}(\beta) = h$ and $\text{premise}(\beta) = h(\text{body}(\delta))$. Two bags β_1 and β_2 are candidates for modifyBody if $\beta_1 \prec \beta_2$, $\text{depth}(\beta_1) = 1$, $\text{depth}(\beta_2) = 2$ and there exists at least one repeated variable in the body of $\text{tgd}(\beta_1)$.

Algorithm 4 presents an iterative process for repairing a partially-safe Σ, by employing the three ideas we described above: checking for homomorphism violations within each bag and preventing unsafe unifications either by hiding exported variable, or by modifying the bodies of the s-t tgds. In brief, at each iteration $i \geq 0$, the algorithm repairs one or more dependencies from Σ_i, where $\Sigma_0 = \Sigma$, and incrementally computes the visible chase of the new

set of dependencies, lines 4–25. Algorithm 4 terminates either when the dependencies are safe, or when the maximum number of iterations n is reached, line 25, in which case it repairs all unsafe dependencies by hiding their exported variables. The algorithm starts by initializing Σ_0 to Σ, lines 1. Then, at each iteration i, it first identifies the lowest depth unsafe bag, line 7, and attempts to repair the dependencies from Σ_i that lead to its creation, lines 7–22. If $i < n$, it proposes two different repairs for Σ_i, one based on hiding exported variables through hideExported (Algorithm 5), and the second based on eliminating joins through modifyBody (Algorithm 6), lines 10–19. Algorithm 4 applies the modifyBody if there exist two bags in the support of β that are candidates for modifyBody. Informally, Algorithm 4 tries to apply modifyBody as early as possible (condition depth$(\beta_1) = 1$, depth$(\beta_2) = 2$) and when there are one or more repeated variables in the body of tgd(β_1) (recall Example 5.5). Otherwise, if $i = n$, it either applies the function hideExported, or it eliminates the s-t tgds that are responsible for unsafe unifications.

Note that when we reach the maximum number of iterations we do not apply modifyBody. This is due to the fact that modifyBody might lead to unsafe unification of labeled nulls to $*$ that were not taking place before the modifying the s-t tgd through modifyBody. In contrast, hideExported is a safe modification, since it does not lead to new unsafe unifications.

Theorem 5.6. *For any partially-safe* $\mathcal{M} = (S, T, \Sigma)$, *any* $\mathcal{M}_V = (S, V, \mathcal{V})$, *any preference function* prf *and* $n \geq 0$, *Algorithm* srepair *returns a mapping* $\mathcal{M}' = (S, T, \Sigma')$ *that* preserves the privacy of $\mathcal{M}_V$ on all instances of S.

Proof. (Sketch) Since srepair takes as input a partially-safe mapping $\mathcal{M} = (S, T, \Sigma)$, it follows from Definition 5.1 that there

exists a homomorphism from chase$(\Sigma^{-1}, \text{Crt}_T) \setminus \text{Crt}_T$ into $I_S(\mathcal{V})$. Furthermore, from Proposition 5.2, we know that for each $\mu \in \Sigma$, there exists a homomorphism from body(μ) into $I_S(\mathcal{V})$ mapping each $x \in$ exported(μ) into the critical constant $*$. Due to the above, since the steps in lines 16–20 of Algorithm 1 do not introduce new labeled nulls and since srepair applies the procedure hideExported to each unsafe bag β in B_n, if there does not exist a bag $\beta' \in B_n$, such that $\beta \prec \beta'$, it follows that $\mathcal{M}'$ preserves the privacy of $\mathcal{M}_V$ on all instances of S, if hideExported prevents dangerous unifications of labeled nulls with the critical constant in line 4 of Algorithm 1. In particular, assume that we are in the n-th iteration of the steps in lines 4–25 of Algorithm 4. Let $\beta_n^0, \ldots, \beta_n^M$ be the unsafe bags in B_n. Assume also that for each $1 \leq l \leq M$, β_n^l, was derived due to some active trigger h^l, for some derived egd $\varepsilon^l \in \Sigma_{\approx}$ in I_j, where $j \geq 0$, line 17 of Algorithm 1. Let $\mu^l =$ tgd(ε^l), for each $0 \leq l \leq M$ and let μ_r^l be the repaired s-t tgd. Finally, let $\beta_{n+1}^0, \ldots, \beta_{n+1}^N$ be the bags in B_{n+1}, line 23 of Algorithm 4. Based on the above, in order to show that Theorem 5.6 holds, we need to show that (i) the number of bags in B_{n+1} is $\leq$ the number of bags in B_n and that (ii) the s-t tgds in $\left(\Sigma \setminus \bigcup_{l=0}^{M} \mu^l\right) \cup \bigcup_{l=0}^{M} \mu_r^l$ are safe. In order to show (i) and (ii), we consider the steps in Algorithm 5: for each $1 \leq l \leq M$, each exported variable y occurring in μ^l, which leads to an unsafe

	min	max	step
# s-t tgds per scenario (n_{dep})	100	300	50

# exported variables per s-t tgds (n_{vars})	5	8	–

Table 1: Properties of the generated iBench scenarios.

unification, line 11 of Algorithm 5, is turned into a non-exported variable. □

By combining Proposition 5.3 and Theorem 5.6 we can prove the correctness of Algorithm 2. Furthermore, if the preference function always prefers the repairs computed by hideExported from the repairs computed by modifyBody, we can show the following:

Proposition 5.7. *For each mapping* $\mathcal{M} = (\mathbf{S}, \mathbf{T}, \Sigma)$*, each* $\mathcal{M}_\mathbf{V} = (\mathbf{S}, \mathbf{V}, \mathcal{V})$ *and each preference function* prf *that always prefers the repairs computed by* hideExported *from the repairs computed by* modifyBody*, Algorithm 2 returns a non-empty mapping that is safe w.r.t.* $\mathcal{M}_\mathbf{V}$*, if such a mapping exists.*

Proof. (Sketch) From Algorithm 3, we can see that frepair always computes a non-empty partially-safe mapping, if such a mapping exists. Note that a mapping, where no variable is exported and no repeated variables occur in the body of the s-t tgds is always partially-safe as long as, the predicates in the bodies of the s-t tgds are the same with the ones occurring in the policy views. Please also note that such a mapping is always considered by frepair. The above argument, along with the fact that a partially-safe mapping can be transformed into a safe one by turning exported variables into non-exported ones by means of the function hideExported, shows that Proposition 5.7 holds. □

6 EXPERIMENTS

We gauge the efficiency of our repairing algorithm on two types of preference function: a hardcoded one and a learning-based preference function.

We evaluated our algorithm using a set of 3.6K diverse mapping scenarios each of which consisting of a set of policy views and a set of s-t tgds. The characteristics of the scenarios are summarized in Table 1. In each scenario, we used a different number of s-t tgds n_{dep}, a different number of body atoms n_{atoms} and a different number of exported variables n_{vars}. The source schemas and the policy views have been synthetically generated using `iBench`, the state-of-the-art data integration benchmark [2]. We considered relations of up to five attributes and we created mappings using the `iBench` configuration recommended by the authors of [2]. We generated a set of varied policy views by applying the `iBench` operators copy, merge, deletion of attributes and self-join, each of which has been applied 10 times.

We implemented our algorithm in `Java` and we used the `Weka` library [16] that provides an off-the-shelf implementation of the k-NN algorithm for the learning-based preference function. We ran our experiments on a laptop with one 2.6GHz 2-core processor, 16Gb of RAM, running Debian 9.

In the remainder, all data points have been computed as an average on a total of 5 runs preceded by one discarded cold run.

Running time of repair**.** First, we study the impact of the number of s-t tgds and body atoms on the running time of repair. We adopt a fixed preference function that chooses the repair with the maximum number of exported variables. In case of ties, the repair with the maximum number of joins is preferred. We vary the number of s-t tgds from 100 to 300 by steps of 50 and the number of body atoms from 3 to 5, respectively. The obtained results are shown in Figure (3a), illustrating the fact that the median repairing time is less than 1.5s in most cases. For the most complex scenario containing up to five body atoms per s-t tgd, the median running time is less than 8s with 71s being the maximum. These results clearly show the high performance of our repair method along with its scalability. The reader should keep in mind that the repairing process is triggered prior to exchanging the data between source and target and might be rerun each time a mapping (set of s-t tgds) is modified or each time a policy view is modified, thus bringing the overhead to be quite reasonable in both cases.

prediction	golden standard μ_1	golden standard μ_2
μ_1	230	0
μ_2	0	395680

(a) P_{max} **confusion matrix.**

prediction	golden standard μ_1	golden standard μ_2
μ_1	290	1
μ_2	42	395577

(b) P_{avg} **confusion matrix.**

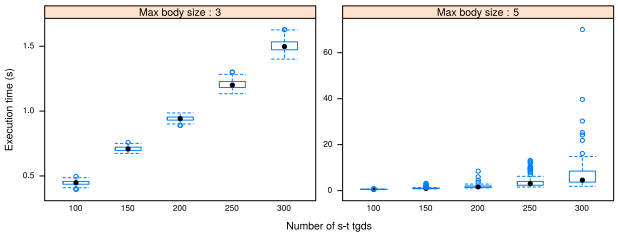
Table 2: Confusion matrix for the golden standards.

Figure (3b) shows the time breakdown for repair. The first bar shows the average running time to run the visible chase over the input s-t mappings, the second one shows the average running time for checking the safety of the computed bags and the third one shows the average running time for repairing the s-t tgds. The results show that the repairing time is $32x$ greater than the time to compute the visible chase and $40x$ greater than the time to check the safety of the chase bags for scenarios with 300 s-t tgds. In the simplest scenarios, these numbers are much lower (reduced to $5x$ and $9x$, respectively). Overall, the absolute values of the rewriting times are kept low (of the order of few seconds) for all these scenarios and gracefully scale while increasing the number of s-t tgds and the number of atoms in their bodies.

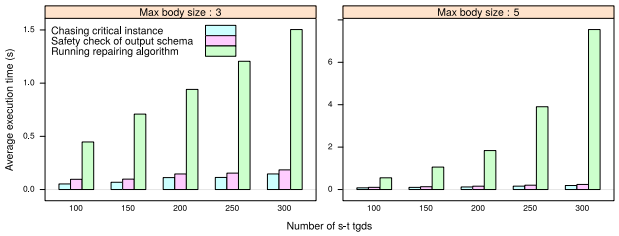
Time breakdown between frepair **and** srepair**.** Figure (3c) shows the average running time for frepair and srepair for the considered scenarios. We can see that srepair is the most time-consuming step of our algorithm. We can also see that the running time of srepair increases more in comparison to the running time of frepair when increasing the number of the s-t tgds and the number of atoms in their bodies. This is due to the incurred overhead during the incremental computation of the visible chase after repairing a s-t tgd (line 23 of Algorithm 4). Figure (3d) shows the correlation between the number of active triggers detected while incrementally computing the visible chase and the running time of srepair for scenarios with 100 s-t tgds using the ANOVA method ($p\text{-}value < 2.2e^{-16}$). Figure (3d) shows that the most complex scenarios lead to the detection of more than 45,000 active triggers. Despite the high number of the detected active triggers, the running time of srepair is kept low thus confirming its efficiency.

Leveraging learning-based preferences. We adopted the following steps in order to evaluate the performance of our learning approach. First, we defined the following two golden standard preference functions that we will try to learn:

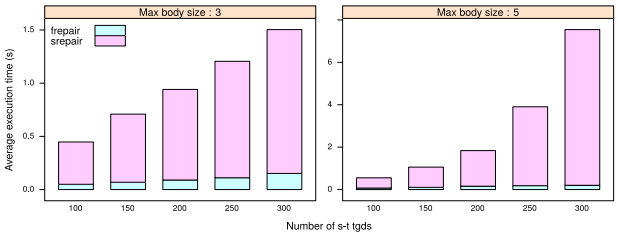
- P_{max}, which chooses the repair with the maximum number of exported variables and in case of ties, it chooses the repair with the maximum number of joins.
- P_{avg}, which computes the average number of exported variables and joins for each repair, and choose the one with the maximum average value.



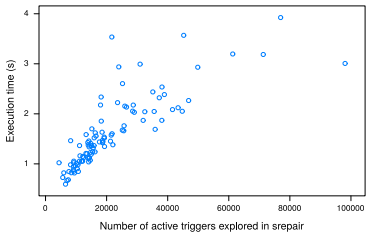
(a) Repairing times.



(b) Time comparisons.



(c) Time breakdown between frepair and srepair.



(d) Running time of srepair over 100 s-t tgds.

Figure 3: Summary of the performance-related experimental results.

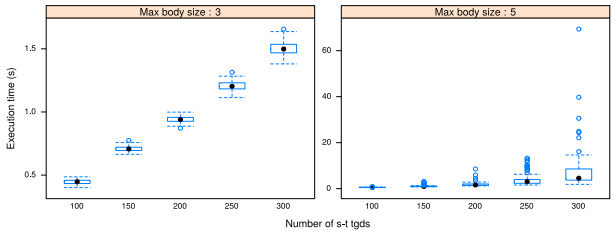


Figure 4: Repairing times with ML classifiers.

For both preference functions, we created a training set of 10,000 measurements for the k-NN classifier by running the repairing algorithm on fresh scenarios of 50 s-t tgds and five body atoms per s-t tgd. For each input vector $\langle \delta_{FV}, \delta_J \rangle$ whose repair we wanted to predict, we computed the Euclidean distance between $\langle \delta_{FV}, \delta_J \rangle$ and the vectors of the training set. We also set the value of parameter k to 1. This parameter controls the number of neighbors used to predict the output. Higher values of this parameter led to comparable predictions and are omitted for space reasons. Finally, we used the trained k-NN classifier as a preference function in srepair, rerun the above scenarios and compared the returned repairs with the ones returned when applying the golden standards P_{max} and P_{avg} as preference functions.

Learning P_{max}. Table (2a) (left) reports the confusion matrix associated to learning P_{max}, including the choices made by the k-NN classifier during its iterations.

Let us call μ_1 and μ_2 two possible repairs of an s-t tgd as evaluated by the k-NN classifier. We can observe that the prediction of μ_1 was correct (and equal to the golden standard in the training set) in 230 cases, while the prediction of μ_2 was correct in 395,680 cases.

This confirms the fact that μ_2 is the best repair across the iterations of the k-NN algorithm and is also chosen in case μ_1 and μ_2 are equally weighed by the preference function.

Furthermore, we also report the accuracy of learning the preference function, obtained by measuring the closeness of the learned mapping to the golden standard mapping.

We used the Matthews Correlation Coefficient metric (MCC) [3] to compare the repairs returned by the trained k-NN classifier and the ones returned when applied P_{max}. This is a classical measure that allows to evaluate the quality of ML classifiers when ranking is computed between two possible values (in our case, the choice between μ_1 and μ_2). This measure has been computed using the following formula:

$$MCC = \frac{N_{1,1} \times N_{2,2} - N_{1,2} \times N_{2,1}}{\sqrt{(N_{1,1} + N_{1,2})(N_{1,1} + N_{2,1})(N_{2,2} + N_{1,2})(N_{2,2} + N_{2,1})}}$$

where $N_{i,j}$ is the number of predictions of μ_i when μ_j is expected. The results of MCC range from -1 for the cases where the model perfectly predicts the inverse of the expected values, to 1 for the cases where the model predicts the expected values. The value $MCC = 0$ means that there is no correlation between the predicted value and the expected one. By applying MCC to the learning of P_{max}, we observed that the data are clearly discriminated, thus leading to high-quality of our prediction in this case ($MCC = 1$).

Learning P_{avg}. Table (2b) (right) shows the confusion matrix associated to learning P_{avg}. We can see that the predictions are less accurate in this case. The data is not as clearly discriminated as before, leading to a fairly negligible error rate ($< 0.02\%$). However, the latter is still acceptable for learning, since only $< 0.02\%$ of the predictions are erroneous. This is corroborated by an MCC value equal to 0.93, thus leading to a fairly acceptable quality of the prediction in this case too.

Running time of repair with ML classifiers. In the last experiment, we want to measure the impact of learning on the performance of our algorithm. To this end, we compare the running time of repair when adopting a hard-coded preference function (as in the results reported in Figure 3) and when adopting a learned preference function. Figure 4 shows the running times for the same scenarios used in Figure 3. We can easily observe that the runtimes are rather similar with and without learning and the difference amounts to a few milliseconds. This further corroborates the utility of learning the preference function and shows that the learning is robust and does not deteriorate the performances of our algorithm.

Qualitative study. In order to illustrate the utility of our approach, in this experiment we study possible rewritings of a mapping defined over the NHS schema.The NHS schema focuses on storing information concerning patients admitted in hospitals. Here, we consider the dependencies involving general information on patients. This includes administrative information

Table 4: Properties of the repairing process.

(relation patient in the source schema), social and medical information on the patient himself (relations birth and death), social data on patients' mothers (relation mother_social_data) and information on drugs prescriptions (relation pis_e_prescribing).

The characteristics of the source schema are summarized in Table 3a. The mapping to rewrite and the characteristics of its target schema are summarized in Tables 3d and 3b, respectively. The set of policy views and the characteristics of their target schema are reported in Tables 3e and 3c, respectively.

The link_death_drugs_data view allows to link the prescribed drugs with patient pathology, but no personal information is exported to prevent the identification of the patient. The death_causes view gives access to the causes of death of the admitted patients. The prescribed_drugs_evolution view gives access to drug prescriptions information without any identifying information. The mother_social and fathers_social views give access to patients' mothers and fathers social information.

In Table 4, we show the number of possible repairs for each tgd in Table 3d. It can be seen that the tgd (1) has three possible repairs, exporting from 25 to 29 variables, respectively. Analogously, the tgd (2) leads to two possible repairs, allowing to export from 13 to 14 variables each. Both tgds (3) and (4) lead to two possible repairs, with a constant number of exported variables for each tgd. These rewritings are distinguished by the exported variables, and one can decide to choose which repairing fits best her needs either visually or by leveraging the user preference function, as shown in our previous experiment.

7 CONCLUSION

We have studied the problem of data exchange in the presence of privacy restrictions expressed as policy views on the source schema. We have proposed a repairing process for the mappings that are unsafe under the source policy views. Our approach is inherently data-independent and leads to repairing the mappings guaranteeing privacy preservation at a schema level. As such, our approach is orthogonal to several data-dependent privacy-preservation methods (such as differential privacy methods), that can be used on the source and target instances to further corroborate the privacy guarantees. The study of such fruitful combinations of methods is devoted to future work.

We also envision several other extensions of our work, such as the study of more expressive GLAV mappings and the interplay between data-independent and data-dependent privacy methods as well as the usage of other learning methods.

ABSTRACT

Modern data lakes are deeply heterogeneous in the vocabulary that is used to describe data. We study a problem of disambiguation in data lakes: *how can we determine if a data value occurring more than once in the lake has different meanings and is therefore a homograph?* While word and entity disambiguation have been well studied in computational linguistics, data management and data science, we show that data lakes provide a new opportunity for disambiguation of data values since they represent a massive network of interconnected values. We investigate to what extent this network can be used to disambiguate values.

`DomainNet` uses network-centrality measures on a bipartite graph whose nodes represent values and attributes to determine, without supervision, if a value is a homograph. A thorough experimental evaluation demonstrates that state-of-the-art techniques in domain discovery cannot be re-purposed to compete with our method. Specifically, using a domain discovery method to identify homographs has a precision and a recall of 38% versus 69% with our method on a synthetic benchmark. By applying a network-centrality measure to our graph representation, `DomainNet` achieves a good separation between homographs and data values with a unique meaning. On a real data lake our top-200 precision is 89%.

1 INTRODUCTION

Data lakes are large repositories where the metadata, including table names, attribute names, and attribute descriptions may be incomplete, ambiguous, or missing [32]. Modern data lakes are heterogeneous in many different ways: semantics, metadata, and data values. We consider the problem of determining if a data value (i.e., the value of an attribute in a table) that appears more than once in the data lake has a single meaning. A data value with more than one meaning is a *homograph*. We illustrate the data lake disambiguation problem through an example.

Example 1.1. *Consider the small sample of a data lake in Figure 1, showing four tables about different topics. T1 is about corporate sponsorship for efforts to save at-risk species, T2 is about populations in zoos, T3 is about car imports, and T4 is about corporate sales. Without disambiguation, a simple keyword search for Jaguar will return a very heterogeneous set of tuples.*

One approach to tackle this problem would be to apply document disambiguation by treating tables as documents. Such techniques are excellent at discerning topics in natural language documents and using this information to further disambiguate the words. However, because of the nature of tables that are often used to express relationships between different types of entities and values, distinguishing between a donor table T1 and a zoo table T2 that contain within them synonyms for animals while also being about very different topics (donations and zoos) is a difficult task. Distinguishing between car manufacturers T3 and corporations T4 can be even harder because of the prevalence of numerical values.

Entity resolution and disambiguation methods commonly assume a small set of tables about a small number of entity types (which may have the same or different schemas). In contrast, in a data lake the values to be disambiguated may appear in hundreds of tables about very different entity types and relationships between them. The ambiguous values need not be named entities, but may be descriptors or any data value in a table. This makes entity resolution inapplicable, but opens up new opportunities to use the large network of values and co-occurrences of values in the lake in new ways.

T1

Donor	At Risk	Donation
Google	Panda	1M
Volkswagen	Puma	2M
BMW	Jaguar	0.9M
Amazon	Pelican	1.5M

T2

name	locale	num
Panda	Memphis	2
Panda	Atlanta	2
Lemur	National	20
Jaguar	San Diego	8

T3

C1	C2	C3
XE	Jaguar	UK
Prius	Toyota	Japan
500	Fiat	Italy

T4

Name	Revenue	Total
Jaguar	25.80	43224
Puma	4.64	13000
Apple	456	370870
Toyota	123	123456

Figure 1: Running example with Jaguar and Puma having multiple meanings. How can we use co-occurrence information across a data lake to discern different meanings?

In entity resolution (ER) [9], the idea is to determine if two (or a set of) tuples refer to the same real-world entity or not. An important assumption in ER is that the tables being resolved are about the same (known) entity types. As an example, given a set of tables about papers that include authors as data values, we can determine if two tuples refer to the same paper (have the same meaning). As a by-product of entity resolution, a data value, for example "X. Wang," may be identified as an ambiguous data value that refers to more than one real-world entity. Schema-agnostic ER techniques have been proposed that do not assume the entities are represented by the same schema [37]. However, these approaches still assume the tables being resolved represent entities of the same type.

In our problem, we are not starting with a small set of tables that are known to refer to the same type of real-world entities, e.g., customers or research papers. We want to understand in a data lake with a massive number of tables if the value "Puma"

in T1 (see Figure 1), Attribute `At Risk` refers to the same real-world concept (not necessarily an entity) as "Puma" in Table T4, Attribute `Name`.

Disambiguation of words in documents has also been heavily studied [4, 24, 43, 49]. Solutions often rely on language structures or labeled training data. In contrast to documents, which are free text, tables are structured and lack the same intuitive notion of *context*. While plenty of research has explored disambiguation of documents, to the best of our knowledge there is no work on disambiguation of data lakes. This is of importance because data lakes can contain many data values that have different meanings. As an example, "Not Available" is a well known way to represent NULL values in a table. "Not Available" is not ambiguous from a natural-language point of view. However in a data lake it may appear in multiple attributes corresponding to names, telephone numbers, IDs etc., making "Not Available" a homograph meaning "unknown name" or "unknown number," etc.

Determining if a value in a data lake has a single or multiple meanings is unexplored territory. We define data lake disambiguation as follows:

Definition 1 (Data lake Disambiguation). *Given a data lake containing a collection of tables with possibly missing, incomplete, or heterogeneous table and attribute names. For any data value v that appears in more than one attribute (column) or table, determine if it has a single meaning or more than one meaning. The latter are called homographs.*

A homograph is not necessarily a single word from a dictionary or a vocabulary. In a data lake, a homograph can be a phrase, initialism (e.g., "NA"), identifier, or any blob (data value). We do not assume homographs to be named entities; they can be adjectives or another part of speech. Homographs arise naturally from words used in different contexts, e.g., the classic example of *Apple* as a fruit or a company, or *Jaguar* in Example 1.1. They can also arise due to errors, e.g., when animal color "yellow" is accidentally entered in the habitat column. We consider this now ambiguous value a homograph. Notice that updates to the data lake can change a homograph to a value with a single meaning, e.g., when the table with the only alternative meaning is removed; and vice versa.

In this work, we examine the global co-occurrence of data values within a data lake and how such information can be used to disambiguate data values. We show that a local measure is not sufficient and motivate why and how the full network of value co-occurrences enables effective disambiguation. This network exploits table structure and had not been considered in the most commonly studied disambiguation problems such as named-entity disambiguation and entity resolution. Its disambiguation power comes at a price: The value co-occurrence information is massive and it is not obvious how to process it efficiently for disambiguation.

Contributions. We address the data lake disambiguation problem using a network-based approach called `DomainNet`. Our main contributions are as follows.

- We define the problem of homograph detection in data lakes. Homographs may arise in tables that do not represent the same (or even similar) types of entities, and hence cannot be identified using entity resolution and disambiguation. They may not even be words in natural language and do not appear in natural-language contexts, making language models ineffective.
- We present `DomainNet`, a network-based approach to determine if a data value appearing in multiple attributes or tables is a homograph. `DomainNet` is motivated by work on community detection where a community represents a meaning for a value (e.g., animal or car model). A homograph is then a value that occurs in multiple communities. However, in the homograph detection problem (*i*) there are an *unknown* and possibly *large* number of meanings for a value and (*ii*) our goal is to find *values* that span communities, not the communities. We identify two measures for finding such community-spanning values, the *local clustering coefficient* [48] and the *betweenness centrality* [16], and empirically evaluate their usefulness in homograph detection.
- We present an evaluation on a synthetic dataset (with ground truth), studying the performance of both centrality measures and motivating the use of the more computationally expensive betweenness centrality. We compare `DomainNet` to a recent unsupervised domain detection algorithm D^4 [36] (any value belonging to multiple domains is a homograph). D^4 achieves a precision and a recall of 38% whereas `DomainNet` reaches 69%.
- We create a disambiguation benchmark from the real data used in a recent table-union benchmark [33] and show that we can effectively find naturally occurring homographs in this data (89% of the first 200 retrieved values are homographs based on ground truth). We also systematically introduce homographs into real data and show that betweenness centrality achieves 85% accuracy when homographs are injected into both small and large attributes, and over 97% accuracy when homographs are all injected into attributes with at least 500 distinct values. We show that `DomainNet` is effective even when there is high variance in the number of meanings of different homographs.
- To illustrate the importance of homograph discovery, we show the impact that as few as 50 homographs (injected into a clean unambiguous real data lake) can have on a domain discovery algorithm [36]. As the number of of homographs increases, the accuracy of the domain discovery algorithm deteriorates.
- The scalability of our approach depends on the size of the data lake vocabulary (the number of values) and on the density of the network (number of edges). We use real data (from NYC open data) with a vocabulary size of 1.5M to show that we can compute the `DomainNet` network in 3.5 min and find homographs in 27 min using an approximation of betweenness centrality based on sampling.

The remainder of this paper is organized as follows. In Section 2 we discuss existing work in disambiguation. In Section 3 we introduce our approach and describe how applying centrality measures on a graph representation of the data lake can be used to identify homographs. Section 4 summarizes the datasets used in our experimental evaluation presented in section 5. We conclude and outline possible future directions of our work in Section 6. 2 FOUNDATIONS OF DISAMBIGUATION

Disambiguation has been studied in several contexts in NLP, data management and broadly in AI and data science. We analyze how this work can be applied to disambiguation in data lakes.

2.1 Entity Resolution

Entity Resolution (ER) identifies records (also called tuples) across different datasets (or sometimes corpora) that represent the same

real-world entities. ER is generally applied to structured and semi-structured data including tables and RDF triples [18]. Some ER approaches also identify ambiguous values as part of the resolution process. For example, using collective entity resolution over two types of tables (e.g., papers and authors) one can identify if a value, say "X. Wang," refers to different authors [3]. Similarly in familial networks, one can resolve synonyms (different values that refer to the same person) and identify homographs (same value used to refer to different people) [26].

ER assumes that the information to be resolved or disambiguated is of a single known type (e.g., resolving customer tuples or patient records) or a small set of types (e.g., authors, their papers, and publishing venues). Some work, called schema-agnostic ER, does not require that all data be represented using the same schema [9]. However, all these approaches start with the assumption that two or more tables (or corpora) are describing the same type of entities [37, 38, 42].

In data lake disambiguation, we seek to find ambiguous values even when we do not know what type of entities a table is describing. We also do not know if different tables are describing the same or different entities. Hence, we cannot apply collective models or other resolution models that rely on this knowledge.

Example 2.1. *Given the four tuples with* `Jaguar`*:* `[BMW, Jaguar, 0.9M]`, `[Jaguar, San Diego, 8]`, `[XE, Jaguar, UK]`, *and* `[Jaguar, 25.8, 43224]`, *does* `Jaguar` *have the same meaning? These four tuples correspond to four different types of facts: donors and the amount they contribute to protect an endangered species, animals in zoos, car models, and economic information about companies. ER schema-agnostic algorithms are insufficient in resolving (or disambiguating) values within these heterogeneous tables because they rely on the hypothesis that the tables they examine refer to the same type of real-world entity.*

2.2 Semantic Type Detection

A possible approach to data lake disambiguation is to discover semantic types for all attributes (columns) and then label a value appearing in different semantic types a homograph. In the running example, identifying the semantic type of `T1.At Risk` and `T2.name` as animal and mammal, respectively, and knowing that mammals are animals, one can infer that Jaguar is not a homograph there. In contrast, recognizing `T3.C2` is of type "Car Manufacturer," which is neither a sub- nor super-type of animals, implies that Jaguar in `T3` and `T1` represents a homograph. Here, we discuss different approaches to semantic type discovery and to what extent they could be used for homograph detection.

Knowledge-based Techniques. There has been considerable work on semantic type detection in the Semantic Web community that uses external knowledge from well-known ontologies including DBpedia [28], Yago [46] and Freebase [5]. Most solutions have been applied to Web tables [11, 12, 29] that are small (in comparison to other data lakes) and have rich metadata (table and attribute names).

Hassanzadeh et al. [20] use a map-reduce approach to find similarity between a (column, data value) pair from a table with a (class, instance label) pair from the Knowledge Base (KB). Ritze et al. [41] match Web tables to DBpedia to profile the potential of Web tables for augmenting knowledge bases with missing information. These approaches cannot infer type information for an attribute that it is not part of the KB. Unfortunately, the coverage of values from data lakes in Open KBs is low (a recent study reports about 13% [33]), limiting their applicability.

Supervised Techniques. An alternative are machine learning (ML) techniques that infer the semantic type of attributes. ML solutions utilize a variety of graphical models (Conditional Random Fields [19], Markov Random Fields [31]), as well as Multi-level Classification [47], and Deep Learning [23]. Sherlock [23] uses features about the values in an attribute to classify some of the attributes in a data lake into one of 78 semantic types (like address or horse jockey) [23]. A recent solution, called SATO [51], augments this approach and shows that using row information can improve the classification accuracy for the same 78 semantic types. These approaches require large amounts of labeled training data and are limited by the set of pre-defined types.

Unsupervised Techniques. Unsupervised semantic type discovery algorithms have only recently started to be studied. We discuss two unsupervised algorithms, one for semantic type discovery, D^4 [36], and one for table unionability search [33].

D^4 provides an unsupervised approach with a focus on assembling all the values of each semantic type in a data lake [36] (these values are called a "domain"). They propose a data-driven approach that leverages value co-occurrence information to cluster values that are from the same domain. Heuristics attempt to deal with ambiguous values that may appear in multiple domains. In our context, D^4 can be used to label values that appear in multiple domains as homographs. This indeed serves as a baseline in our experiments.

Table Union Search [33] solves a different problem. Given a query table, they find a set of tables from the lake that are most unionable with it. In order to do so, they provide several similarity measures that are used collectively to calculate how unionable two attributes are. This work can use both ontological and semantic (word embedding) signals when present to determine unionability over heterogeneous attributes, but does not attempt to find or label homographs.

2.3 Disambiguation in Related Areas

Word-sense disambiguation (WSD) [24, 34], i.e., the task of identifying which meaning of a word is used in a sentence, is an important problem in computational linguistics. Although a human can proficiently perform this task on a document, constructing algorithms that perform this task effectively is still an open research problem. Techniques proposed so far range from dictionary-based methods, which use the knowledge encoded in lexical resources (e.g., WordNet) [34], to more recent solutions in which a classifier is trained for each distinct word on a corpus of manually sense-annotated examples [39]. Additionally, completely unsupervised methods have also been proposed that cluster occurrences of words, thereby inducing word senses, i.e, word embeddings [24]. The aforementioned solutions rely on information (or latent information) about the structure of sentences including grammatical rules. Finally, while solutions that do not rely on grammar also exist, they only operate on documents and not tables [4, 43].

Another relevant sub-task in Natural Language Processing is Named-Entity Recognition (NER), which has been proposed as a possible solution for disambiguation [49]. NER seeks to locate and classify named entities mentioned in unstructured text into predefined categories such as person names, organizations, locations, etc. NER systems have been created that use linguistic grammar-based techniques as well as statistical models [1].

A special case of the NER problem is the author name disambiguation problem [14, 44] Authors of scholarly documents often share names which makes it hard to distinguish each author's

work. Hence, author name disambiguation aims to find all publications that belong to a given author and distinguish them from publications of other authors who share the same name. Different solutions have been proposed using graphs [30]. However, the graph structure proposed is largely domain specific. The graph contains not only the information about the co-authorship and published papers, but also venue of the paper published, year of research activities and so on.

3 DISAMBIGUATION USING DOMAINNET

We now present our proposed solution, DomainNet[1], for finding homographs in a data lake.

3.1 Problem Definition

Recall from Definition 1 that a *homograph* is a data value that appears in at least two attributes with more than one meaning. Values that are not homographs are *unambiguous values*. In data lakes, attribute and table names can be missing or misleading (with many ambiguous terms like "name," "column 2," or "detail") [32]. Well-curated enterprise lakes may have more complete metadata, but even they do not follow the unique name assumption—which states that different attribute names always refer to different things. As a result, many data lake search approaches rely solely on the table contents [10, 13, 52, and others]. In a similar vein, in DomainNet, we investigate to what extent data values and the co-occurrence of data values within attributes can be used to determine if a value is a homograph.

Example 3.1. *In Figure 1, the data value* Jaguar *is a homograph because it refers to the animal in Tables T1 and T2 and refers to the car manufacturer in Tables T3 and T4. Other values such as* Panda *and* Toyota *are unambiguous since they only have a single meaning across* all *tables.* Puma *is also a homograph, appearing as an animal and a company. Figure 2 displays which values co-occur with* Jaguar *in the same column using an incidence matrix: the vertical axis shows the different values, and the horizontal axis the different attributes occurring in the data lake.*

Note that homographs need not be values from a dictionary. They can be any data value that appears in a table. Another example of a homograph is the data value 01223 *which in some attributes may refer to a Massachusetts zip code and in others to an area code near Cambridge, UK, and in yet others to the suffix of an Oil Filter Element Replacement product code.*

	Fiat	Toyota	Apple	Puma	Jaguar	Pelican	Panda	Lemur
T2.name					1		1	1
T1.At Risk				1	1	1	1	
T4.Name		1	1	1	1			
T3.C2	1	1			1			

Figure 2: Incidence matrix: vertical axis attributes, horizontal axis data values.

In a well-curated database or warehouse, we may know the semantic meaning of each attribute (e.g., "Animal Name" vs. "Company Name") and can leverage it to identify homographs. However, in a dynamic, non-curated data lake, we cannot rely on this information to be available.

[1]The code for DomainNet and our benchmarks is available at https://github.com/northeastern-datalab/domain_net.

3.2 DomainNet: Viewing Values as a Network

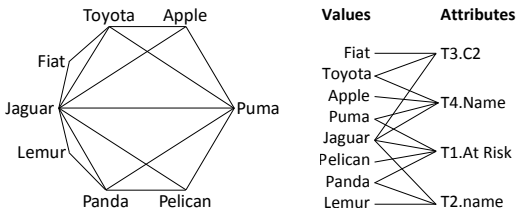
In data lakes, without *a priori* knowledge of table semantics or types, we take a network-based approach to understanding the meaning of repeated data values. We propose to detect homographs using network measures. For that purpose, we can interpret the co-occurrence information about values across different attributes using a network representation in which nodes represent data values and edges represent the fact that two values co-occur in at least one column (attribute) in the data lake.

Example 3.2. *In Figure 3, we depict the values from the same four attributes shown in Example 3.1. Figure 3a shows the value co-occurrence network. Notice that by removing both "Puma" and "Jaguar" the remaining nodes become* disconnected *into two components. This captures the intuition that those two values are pivotal in that they bridge two otherwise disconnected meanings or graph components.*

Whereas this representation allows us to apply straightforward metrics from community detection, it comes at a high cost: the representation uses more space than the original data lake. The incidence matrix is sparse and has as many entries as there are cells in the data lake (Figure 2). In contrast, the co-occurrence graph increases quadratically in size with respect to the cardinality of attributes (the size of the vocabulary) in the data lake (Figure 3a). Consider a single column with 100 values. The incidence matrix represents this information with 100 rows, 1 column, and 100 entries. The co-occurrence graph represents this with 100*99/2=4950 edges across 100 nodes.

Thus, we use a more compact network representation that allows us (after some modifications) to apply network metrics to discover pivotal points (Figure 3b). DomainNet uses a bipartite graph composed of (data) value nodes and attribute nodes. The attribute nodes represent the set of attributes and the value nodes the set of data values across all attributes in the lake. Every data value is treated as a single string, it is capitalized and has its leading and trailing white-space removed to ensure consistent comparison of data values across the lake. Notice that each data value, even if found in multiple attributes, is represented by one single value node in the graph. An edge is placed between a value node and an attribute node if the data value appears in the attribute (column) corresponding to that attribute node. Data values that appear in more than one attribute are candidates for being homographs.

Example 3.3. *Figure 3b, shows a portion of the* DomainNet *representation for Figure 1 using only the four attributes of Example 3.1.*



(a) Co-occurrence graph **(b) Bipartite graph**

Figure 3: Two graph representations of a portion of Figure 1.

In the DomainNet bipartite graph, we call two data values *neighbors* if they both appear in the same attribute (and hence there is a path of length two between them in the graph). Similarly,

two attributes are *neighbors* if they have at least one data value in common (and hence there is a path of length two between them). For a data value node v, $N(v)$ denotes the set of all its value neighbors. We also define the *cardinality of a data value* node v as the number of neighbors $|N(v)|$, which is the number of unique data values that co-occur with v. If n is the number of value nodes and a the number of attribute nodes, the number of edges in a DomainNet graph over real data tends to be much less than $n \cdot a$.

Tables to Graph. Recent work on embedding algorithms in relational databases [2, 7, 27] use a graph representation of tables. Like DomainNet, they model values and columns as nodes. Depending on the problem addressed, some approaches also include nodes for rows and tables. Like in our approach, column names are not assumed to be present or unambiguous.

Koutras et al. [27] and Capuzzo et al. [7] use a tripartite graph representation in which every value node is connected with its column node and its row node. Such an approach works well for the tasks of tuple-level entity resolution and for schema matching (a similar task to semantic type discovery). We experimented using both row and table information in DomainNet and found it was not useful in disambiguating values. In our example, Panda in $T1$ and $T2$ are not homographs, but the row information makes them seem quite different and we did not find it helpful.

In contrast, Arora and Bedathur [2] use a homogeneous graph using only data value nodes that are connected with each other if they appear in the same row of the table. They do not use the value co-occurrence information within a column, making homograph detection using solely row context inappropriate in large heterogeneous datasets.

3.3 Homograph-Disambiguation Methodology

Intuitively, data values that frequently co-occur with each other will form a latent semantic type or community in DomainNet, with many paths of varying length between them. Homographs will span two or more communities. Notice however that we do not know *a priori* what the communities are or even how many there are. While there is a rich literature on community detection, many approaches require knowledge of the possible communities such as the number of communities [8]. Others are parameter-free, meaning they can learn the number of communities [21, and others]. However, in our problem the number is not only unknown, it may be massive. A data lake with just a modest number of tables may have many attributes representing a multitude of different semantic types (communities of values) [8, 15].

What we propose in this paper is to use network centrality measures that can be defined without prior knowledge of how many communities exist, their overlap, or the distribution of attribute cardinalities. The intuition behind centrality measures is to capture how well connected the neighbors of a given node are. We define variants of these measures appropriate for the DomainNet bipartite graph. We then discuss to what extent these measures may distinguish whether a data value has a single meaning or multiple meanings (the latter being a homograph).

Local Clustering Coefficient as a homograph score. The local clustering coefficient (LCC) [48] for a given value node measures the average probability that a pair of the node's neighbors are also neighbors with each other, i.e., the fraction of value-neighbor triangles that actually exist over all possible triangles.

The LCC metric is usually defined over unipartite graphs (such as the co-occurrence graph in Figure 3(a)). We use the definition of value-neighbors (recall the set of all value neighbors of a value node u is $N(u)$) to generalize LCC to our bipartite graph.

The pairwise clustering coefficient of two data value nodes v and w is defined as the Jaccard similarity between their neighbors

$$c_{vw} = \frac{N(v) \cap N(w)}{N(v) \cup N(w)}.$$

Given a graph G and a value node u, the LCC is defined as the average pairwise clustering coefficient among all the node's value neighbors:

$$c_u = \frac{\sum_{v \in N(u)} c_{vu}}{|N(u)|}. \quad (1)$$

The LCC of a node u can be computed in time $O(N(u)^2)$ and provides a notion of the importance of a node in connecting different communities.

Hypothesis 3.4 (Homographs using LCC). *A value node corresponding to a value that is a homograph will have a lower local clustering coefficient than a value node with a single meaning.*

Intuitively, we expect unambiguous values to appear with a set of values that co-occur often and thus have high LCC scores. This behavior should be less common for homographs, which may span values from different communities as they appear in various contexts depending on their meaning.

Despite LCC's computational simplicity, the measure as defined in Equation (1) is no more than the average Jaccard similarity between the set of attributes that a value co-occurs with. Unfortunately, it is well-known that *Jaccard similarity is biased to small sets.* As consequence, *the measure is not as effective in real data lakes* where attribute sizes are often considerably skewed. Our experiments will confirm this downside of LCC.

Betweenness Centrality as a homograph score. The LCC of a node is fast to compute, but it only considers the local neighborhood of a value. In a data lake, the local neighborhood may not be sufficient. In particular, the local neighborhood may not include values that are members of the same community but happen to not co-occur. In order to overcome these two problems (missing values in the neighborhood and attributes with very different cardinalities) we look at metrics that take a more global perspective on the network.

The *betweenness centrality* (BC) of a node measures how often a node lies on paths between *all other nodes* (not just the neighbors) in the graph [16]. One way to think of this measure is in a communication network setting where the nodes with highest betweenness are also the ones whose removal from the network will most disrupt communications between other nodes in the sense that they lie on the largest number of paths [35].

Consider two nodes v and w. Let σ_{vw} be the total number of shortest paths between v to w, and let $\sigma_{vw}(u)$ be the number of shortest paths between v to w that pass through u (where u can be any node).[2] The betweenness centrality of a node u is defined as follows, where v and w can be any node in the graph:

$$BC(u) = \sum_{v \neq u, w \neq u} \frac{\sigma_{vw}(u)}{\sigma_{vw}}. \quad (2)$$

[2] Since the bipartite graph used in DomainNet is not homogeneous we also examined other variations of BC such as considering only values nodes as end points for the examined shortest paths. We found that using all nodes in the BC definition provided empirically the best results for finding homographs.

By convention $\frac{\sigma_{vw}(u)}{\sigma_{vw}} = 0$ if σ_{vw} (and therefore $\sigma_{vw}(u)$) is 0.

Intuitively, a homograph appears with sets of values that do not or rarely co-occur across those sets, and thus the shortest paths between such non-co-occurring nodes would have to go through the homograph node. Conversely, unambiguous values appear with a set of values that also co-occur a lot, and thus the shortest path between them does not unnecessarily have to go through one or a few nodes.

Hypothesis 3.5 (Homographs using BC). *A value node corresponding to a homograph will have a higher betweenness centrality than a value node with a single meaning.*

Example 3.6. *The LCC scores of the* Jaguar *and* Puma *data value nodes in Figure 1 are 0.36 and 0.43 respectively. The LCC scores of the other data value nodes that appear more than once,* Toyota *and* Panda*, are somewhat higher at 0.46. The BC scores of the* Jaguar *and* Puma *value nodes in Figure 1 are 0.025, 0.003 respectively. The BC of the other value nodes that appear more than once,* Toyota *and* Panda*, are at 0.002. Since this example only uses four small tables it does not expose the possibly different rankings between LCC and BC scores but suggests that BC, even on small graphs is more discerning.*

Complexity of BC. Calculating the BC for all nodes in a graph is an expensive computation. A naive implementation takes $O(n^3)$ time and $O(n^2)$ space (n denotes the number of nodes in the graph). The most efficient algorithm to date is Brandes' algorithm [6] that takes $O(nm)$ time and $O(n+m)$ space (for unweighted networks) where m is the number of edges in the graph. Notice that this algorithm is still expensive if the graph is dense (i.e., $m >> n$).

The high time complexity of BC motivated approximations, which usually sample a subset of nodes from the graph and thus do not calculate all shortest paths. One common sampling strategy is to pick nodes with a probability that is proportional to their degree (nodes with high degree are more likely to appear in shortest paths). Riondato and Kornaropoulos [40] provide an approximation algorithm via sampling with offset guarantees. Geisberger, Sanders, and Schultes [17] provide an approximation algorithm without guarantees that performs very well in practice. The complexity of the approximate BC is $O(sm)$ where s is the number of nodes sampled. We chose Geisberger, Sanders, and Schultes [17] to approximate betweenness centrality to benefit most from its short run-time on large graphs.

3.4 Disambiguation Using DomainNet

In this section, we describe the implementation of an end-to-end system which allows users to disambiguate data lakes using our proposed methodology. Our system has three steps as illustrated in Figure 4: (1) construct DomainNet graph; (2) calculate measures; and (3) rank measures.

DomainNet *graph construction.* The input is a set of raw data tables from relational databases, CSV files, or any other open data format. It is important to note that we do not require any information in regards to types, attribute names, or the semantics of relationships between tables. We build our bipartite graph as described in Section 3.2.

Graph measure computation. Using the DomainNet graph constructed in the previous step, our system computes both LCC and BC scores for each value node (Section 3.3). We show empirically in Section 5.1 that BC outperforms LCC in homograph detection.

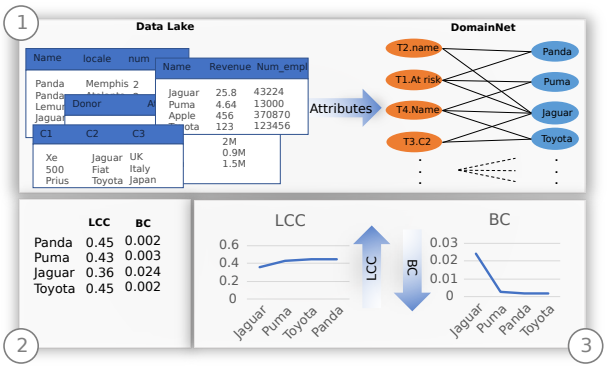


Figure 4: Disambiguation system on DomainNet. (1) Construct a DomainNet graph from a data lake. (2) Calculate BC and LCC scores for each value node in the graph. (3) Rank the scores accordingly.

Graph measure ranking. Nodes are ranked by their centrality score (ascending order for LCC measures, and descending order for BC measures) the top ranked data values present to a user.

4 DATASET DESCRIPTION

Homograph detection in data lakes is a new problem and no benchmarks are available for it. While many data lakes exist, they do not contain labels that identify the homographs. In addition to being a hugely expensive task when done manually, homograph labeling is not a one-time effort: when the content of the data lake changes, an unambiguous value can become a homograph or vice versa. Hence, benchmark design in this context constitutes a non-trivial contribution in itself.

We introduce the four datasets used for the evaluation of DomainNet. The first is a new synthetic benchmark and the other three contain real data. The second is an adaptation of the Table Union Search (TUS) Benchmark [33] that uses real tables from UK and Canadian open-data portals and which we adapt for our problem. The third is a modified version of TUS, called TUS-I, where we systematically inject homographs. The fourth, used to evaluate scalability, is a real data set from NYC Education Open Data, which was also used to evaluate a domain discovery approach [36].

Table 1 summarizes detailed statistics about the datasets. For each, we list the number of tables, the total number of attributes (columns) across all tables, the number of unique values in the data lake, the total number of homographs, the range of cardinalities of any homograph[3] (Card(H)), and the range of the number of distinct meanings, #M, (based on ground truth) the different homographs have across the data lake. All datasets can be found at https://github.com/northeastern-datalab/DomainNet-Datasets

Table 1: Four datasets and their statistics.

	#Tables	#Attr	#Val	#Hom	Card(H)	#M
SB	13	39	17,633	55	151-1,966	2
TUS - I	1,253	5020	163,860	N/A	N/A	N/A
TUS	1,327	9859	190,399	26,035	3-22,703	2-100
NYC-EDU	201	3496	1,469,547	N/A	N/A	N/A

[3]Recall the definition of the cardinality of a homograph node v as $|N(v)|$, which is the number of unique data values that v co-occurs with.

4.1 Synthetic Benchmark (SB)

We designed a small fully synthetic, but real-world inspired, data lake for a systematic validation of our approach. It consists of 13 tables generated using Mockaroo[4], which lets the data creator specify data sources from various categories.

Each table has 1000 rows, except for two tables that contain countries and states. We used the real numbers of countries and US states of 193 and 50, respectively. There are 55 data values that are homographs, e.g., Sydney (city or name), Jamaica (city or country), Lincoln (car or city), CA (country or state abbreviation), and Pumpkin (grocery product or movie title). The benchmark along with its metadata (full list of tables and their schemas and stats) are in our github.

4.2 Table Union Search Benchmark (TUS)

In the absence of homograph-labeled large real data lakes, we set out to find a closely related benchmark that we could adapt to our purposes. Unfortunately, while there are many table-based benchmarks, even those for data-semantics-related problems generally proved hard to adapt. For example, the VizNet corpus [22] used in semantic type detection in tables [23, 51] provided ground-truth labels for only a small fraction of the columns in the repository, making ground-truth discovery of all homograph labels practically impossible. We therefore selected the Table Union Search (TUS) benchmark [33], which contains real data and provides a ground-truth mapping for *each* column to the set of columns in the repository that it is unionable with. This enables us to automatically label all homographs. Let $U(a)$ denote the set of columns (attributes) a given column a is unionable with and notice that a is always unionable with itself, hence $a \in U(a)$. Let $A(n)$ be the set of columns (attributes) a data value n appears in. Converting the TUS benchmark into our bipartite graph representation, we can automatically label data values as "unambiguous" or "homograph" based on the unionability ground truth.

Definition 2 (Homograph in the table union search benchmark). *A data value n is a homograph if there exist two attributes a and a' in $A(n)$ such that $U(a) \neq U(a')$; otherwise n is an unambiguous value.*

Intuitively, a data value is a homograph if it appears in at least two different columns that are not unionable (and hence have different types). For instance, assume value `USA` appears in columns `country_x1` and `location_x2` in tables X1 and X2, respectively. If the corresponding two columns are unionable, i.e., $U(\texttt{country\_x1}) = U(\texttt{location\_x2}) = \{\texttt{country\_x1}, \texttt{location\_x2}\}$, then we can conclude that `USA` is an unambiguous value. In contrast, the columns containing the value `jaguar` in the zoo or donor tables are not unionable with either the company or car model tables and hence `jaguar` would be labeled a homograph.

Based on Definition 2 there are 164,364 unambiguous values and 26,035 homographs in the TUS benchmark, suggesting homographs are very abundant in real data lakes. Notice that attribute cardinalities in TUS have high skew, a common phenomenon in data lakes for open-data repositories [32]. Hence, this benchmark provides a "stress-test" for our approach. How well can it deal with both small and large cardinalities of attributes containing a homograph (in TUS these cardinalities range from 3 to 22,703).

[4] https://www.mockaroo.com/

4.3 TUS with Injected Homographs (TUS-I)

Having real data is important, but we also need to understand the performance of our solution as the number of homographs in a data lake changes. To this end, we modified the TUS benchmark as follows. First, we removed all 26,035 homographs. Second, we carefully introduce artificial homographs with different properties. Since the artificial homographs are now the only ones in the data lake, we can measure how their properties affect the detection algorithm.

A homograph is injected by selecting two different data values from two columns that are not unionable. These original values are then replaced by a new unique value such as "InjectedHomograph1". We only replaced string values with at least 3 characters. In our experiments, we vary the minimum allowed cardinality of the attributes containing values replaced with an injected homograph. We also vary the number of meanings of an injected homograph. This allows us to evaluate the effectiveness of our approach in identifying homographs with respect to the cardinality and number of meanings of the homographs.

5 EXPERIMENTAL EVALUATION

The main goal of the experiments is to evaluate how well `DomainNet` performs in terms of precision and recall for identifying the homographs in the benchmark datasets. We are particularly interested in determining if the more expensive betweenness centrality (BC) provides significant improvement over local clustering coefficients (LCC) (Section 3). Since a homograph candidate must appear in at least two different table columns, `DomainNet` pre-processes the input to remove data values that appear only once in the data lake. As a result, the corresponding graph representation has about 3% fewer nodes in the TUS benchmark and 30% fewer nodes in SB. Moreover we examine how our method scales with larger input graphs and how homographs can impact existing data integration tasks such as domain discovery.

Comparison to a baseline. There is no previous work that directly explores homograph detection in data lakes (Section 2), and previous work on the related problem of semantic type detection and domain discovery is generally supervised, i.e., requires labeled training data. Hence, the only suitable algorithm that we could reasonably adapt to solve our problem is the recently proposed state-of-art unsupervised domain-discovery algorithm D^4 [36]. We used the original code provided by the authors[5] with its default parameter settings. When applied to a data lake, D^4 assigns attributes to the discovered domains. A natural way to identify homographs then is to identify data values that appear in more than one of those domains. We compare D^4 to `DomainNet` on the synthetic benchmark as it only contains string values. D^4 discovers domains only for string data, making it ineffective on the TUS benchmark, which contains real data with many numerical attributes.

Measures of success. We generally measure precision and recall, which are reported for the k top-ranked homograph candidates identified by each of the algorithms. By default k is set to the true number of homographs in the data lake.

Software implementation. We implemented `DomainNet` in Python 3.8, using Networkit [6] [45] to calculate exact and approximate BC scores over our bipartite graph. This is a Python library for large-scale graph analysis whose algorithms are written in

[5] The code is available at https://github.com/VIDA-NYU/domain-discovery-d4.
[6] https://networkit.github.io

C++ and support parallelism. All our experiments were run on a commodity laptop with 16GB RAM and an Intel i7-8650U CPU.

5.1 Fully Synthetic Benchmark (SB)

We first use the SB to compare the homograph rankings obtained using the LCC and BC measures (Section 3) in order to study their ability to identify homographs. The bipartite graph for SB is relatively small, consisting of 17,672 nodes (17,633 data-value nodes and 39 attribute nodes) and 19,473 edges. We calculated the local clustering coefficients (LCC) and betweenness centrality (BC) for each node in the graph and examined how these scores differ between homographs and unambiguous values.

Which measure is better at discovering homographs? Figure 5 shows the top-55 data values based on LCC. For LCC, lower scores should in theory indicate a greater probability of being a homograph. Notice how more than 75% of the top-ranked data values are not homographs, meaning that a large number of unambiguous values have smaller LCC scores than the homographs. This is mainly caused by unambiguous values from small domains that do not co-occur often with many values in their domain. This confirms our hypothesis from Section 3 that LCC may not work well when homographs appear in small domains. In fact, the majority of the 55 homographs in the dataset have LCC scores significantly above 0.45 and so it is not necessarily true that homographs have low LCC cores. Overall the results indicate that LCC scores do not provide an effective separation between homographs and unambiguous values.

On the other hand, the BC scores result in a vastly better top-55 result as shown in Figure 6. Here 38 out of the top-55 BC scores correspond to homographs. This is a much improved outcome over the LCC scores in Figure 5. But what happened to the remaining 17 homographs that are not in the top-55? We noticed that the remaining 17 homographs have betweenness scores of nearly zero and they all are values corresponding to homographs that are abbreviations of country and state names. Recall that these are the only two tables in SB with fewer than 1000 tuples, where the state table contains only 50 tuples. This means that the BC score for values in these small domains cannot be very large as there cannot be as many shortest paths that would pass through the homograph in question.

An explanation for the low BC scores for these homographs is the fact that there is considerable intersection between the country and state values which is not the case with other homographs (e.g., the car brands and cities intersect only on the value Lincoln and Jaguar). This relatively large intersection also reduces the BC scores for those homographs as the number of shortest paths connecting two nodes between cities and states is much larger. For example, going from the country code GR to the state code MA, the shortest path could be using the homograph AL (which is for Albania/Alabama) or CA (which is for Canada/California) or any other homograph between countries and states. As a result those homographs receive lower BC scores, because the denominator in Equation (2) becomes large.

How good is previous work at finding homographs? As discussed earlier, we compare `DomainNet` against a competitor based on D^4[36]. When applied to the SB dataset, D^4 discovers four domains corresponding to `Country`, `Country Code`, `Scientific Animal Name`, and `Scientific Plant Name`. It maps the domains on 14 out of 39 table columns (attributes) in SB. Among these 14 attributes, there are 21 of the 55 homographs. Overall, when considering the top-55 results returned, the D^4-based algorithm disambiguates homographs in SB with a precision, recall, and F1-score of 38%. Using the BC score, `DomainNet` achieves for the top-55 results a precision, recall, and F1-score of 69%.

5.2 Experimental Evaluation on TUS-I

We now study the BC-score-based version of `DomainNet` in more detail on the large real-world dataset TUS-I with the injected homographs. Due to the cost of running BC for each node, all BC scores are approximated using 5000 samples. [7]

Table 2: % of the 50 injected homographs appearing in the top-50 results vs. cardinality of the data values replaced by the injected homograph. (Numbers are averages of 4 runs for each threshold.)

Cardinality of replaced values	> 0	≥ 100	≥ 200	≥ 300	≥ 400	≥ 500
% of injected homographs in top 50	85%	93.5%	93.5%	95%	94.5%	97.5%

How does cardinality affect homograph discovery? Recall that after removing all original homographs in TUS, the TUS-I dataset only contains the homographs we methodically injected in order to study a specific effect on betweenness centrality. We ran our experiments by randomly selecting 50 pairs of values from different domains[8] and replaced them with our 50 injected homographs. Each experiment was repeated 4 times with a different seed for selecting the values for replacement. Since the number of homographs in our experiment is always 50, in an ideal scenario the top-50 BC scores would correspond to exactly those injected homographs.

We found that cardinality has the expected impact on BC scores in terms of separating homographs and unambiguous values. If the data values chosen for replacement have a not too small cardinality (i.e., they co-occur with many other values) then the BC score of their injected homograph was notably higher. We confirmed this observation in Table 2 where we varied the cardinality threshold for the data values chosen for replacement. Overall, as we increased the cardinality threshold, a larger percentage of the injected homographs ranked in the top-50. In fact, if the replaced values had a cardinality of 500 or higher, `DomainNet` consistently ranked at least 48 of the 50 injected homographs in the top 50. For reference, the largest attribute in TUS has 25,000 values and over half of all attributes have more than 500 values.

How does the number of meanings of a homograph affect homograph discovery? In addition to varying the cardinality of the replaced values, we also examined how the number of meanings of the injected homographs impacts their BC-based rankings. The number of meanings of an injected homograph is the number of values replaced for each injected homograph. The replaced values are all chosen from different domains to ensure that the injected homographs have consistently the specified amount of meanings. We explored injected homographs with the number of meanings in the range 2 to 8 for replaced data values with a cardinality of 500 or higher. Table 3 shows that as we increase the number of meanings, `DomainNet` becomes better at discovering them. This is consistent with our intuition for betweenness centrality since homographs with more meanings are more likely

[7] A common heuristic for the sample size is about 1-3% of the total number of nodes in the graph. This works well in practice with sparse graphs like `DomainNet` [17]. We will further test the validity of this heuristic in Section 5.4.

[8] Different domains in the TUS benchmark context means values from columns that are not unionable with each other.

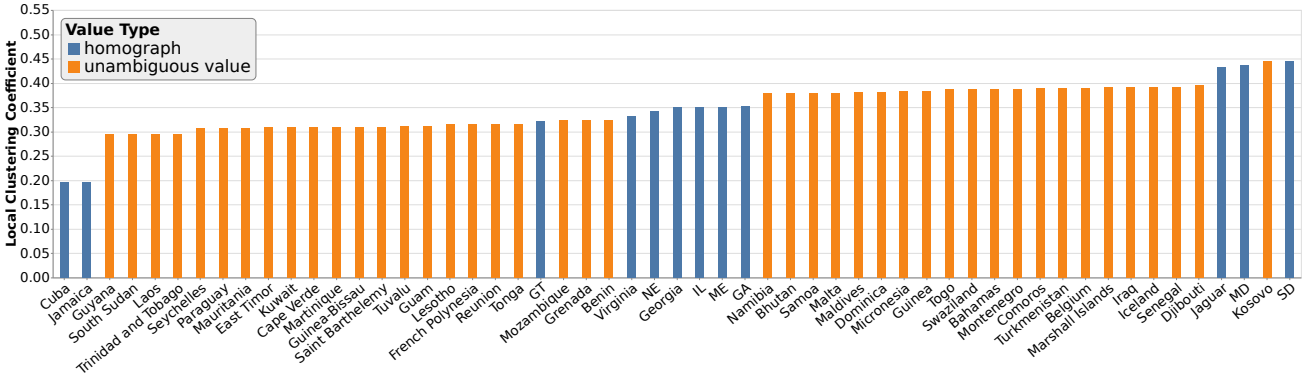

Figure 5: The top-55 data values with the lowest local clustering coefficients. Homographs are scattered throughout and do not necessarily have low LCC coefficients.

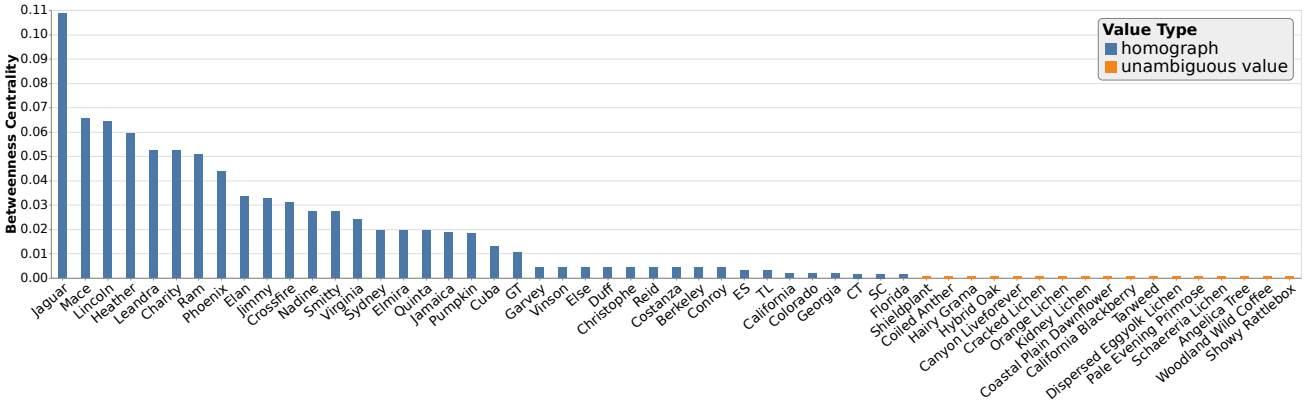

Figure 6: The top-55 data values with the greatest betweenness centrality scores. In the top-55 data values, 38 of them are homographs. The homographs not in the top-55 are country/state abbreviation homographs.

Table 3: % of injected homographs in the top 50 according to betweenness centrality while varying the number of meanings of the injected homographs

# meanings of injected homographs	2	3	4	5	6	7	8
% of homographs in top 50	97.5	97.5	98.5	98.5	100	100	100

to be hub nodes that connect multiple sets of nodes with each other in our bipartite graph representation of the data lake.

5.3 Homographs in TUS Benchmark

Lastly, we explore the performance of `DomainNet` with betweenness centrality on the real TUS dataset with its 26,035 real homographs. Since the number of homographs is large, we not only report precision, recall, and F1-score for the top-26,035 results, but for all top-k with k from 1 all the way to the number of nodes in our graph, i.e., 190,399. We do not compare against the D^4-based algorithm for homographs, because D^4 operates only on string attributes, and given the large number of numerical attributes the D^4 coverage will be even lower than in SB (where it only finds domains for 14 out of 39 attributes).

How does our approach perform on a real open-data benchmark? Figure 7 shows the summary of our top-k evaluation results. Notice that for relatively small values of k such as $k = 200$ our method can identify homograph values with high precision (0.89). Naturally, as we increase k precision decreases and recall

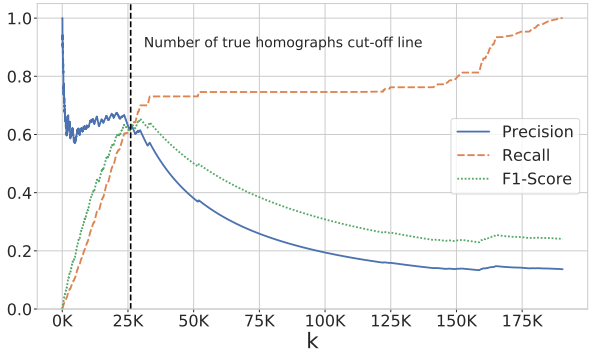

Figure 7: Top-k evaluation on the TUS dataset. The vertical line at k=26,035 denotes the number of true homographs in the dataset.

increases. At $k = 26,035$ (vertical line in Figure 7), which is the number of true homographs in the TUS benchmark, we achieve a precision, recall and F1-score of 0.622. The highest F1-score occurs at $k = 29,633$ where precision, recall, and F1-score are 0.615, 0.7 and 0.655, respectively.

It is important to emphasize that our approach is completely unsupervised and does not assume any external knowledge about the tables or their values. Existing state-of-the-art methods that tackle data integration tasks as described in Section 2 cannot be

readily used for homograph identification or their coverage is severely limited (e.g., knowledge-based approaches like AIDA [50]).

Below we report the top-10 values and their BC scores from the TUS benchmark.

- "Music Faculty" → 0.00064
- "Manitoba Hydro" → 0.00045
- "50" → 0.00029
- "1800ZZMALDY2" → 0.00028
- "." → 0.00027
- "Conseil de développement" → 0.00025
- "125" → 0.00023
- "2" → 0.00022
- "Biomedical Engineering" → 0.00022
- "SQA" → 0.00016

All 10 data values are homographs based on the ground truth. Notice that from a natural-language perspective these 10 values do not seem to be homographs, but a closer look at the data revealed good reasons why they were labeled as homographs. For example the value *Music Faculty* appears in two distinct contexts: as a geographic location/landmark in transportation-related tables as well as a department in university-related tables.

The value with the fifth-highest BC score is the period character. This may seem bizarre, but the period is used extensively as a null replacement in a large variety of tables and thus it acts as a homograph with a very large number of meanings. Finally, notice that we identify numerical values such as 50, 125 and 2, which appear in a variety of contexts such as addresses, identification numbers, quantity of products, etc. Numerical values are traditionally difficult to deal with in many data-integration tasks, hence being able to identify some of them in a completely unsupervised manner is a notable step toward better coverage for numerical values.

5.4 Scalability

As discussed in Section 3.4, Step 1 (graph construction) and Step 2 (centrality measure computation) are the most computationally expensive in our approach. In this section, we examine empirically the scalability of these steps.

The time to construct our bipartite graph is dependent on how long it takes to scan all input tables, which is a relatively fast operation. For example, the bipartite graph for the TUS dataset takes about 1.5 minutes to construct, which is how long it takes to read through each table in the dataset.

The runtime of Step 2 depends on the graph measure used. LCC is a local measure that is efficient to compute, but as we demonstrated in section 5.1 it is not as effective in finding homographs as BC is. Computing the LCC score for every node in the TUS dataset takes 4 seconds. For the global measure BC, since we are more interested in the score rankings rather than the scores themselves, approximating BC via sampling can significantly decrease the runtime without compromising quality.

In Figure 8, we examine how precision and runtime vary as we change the number of samples used for the approximate BC algorithm [17] on the TUS benchmark. Even for a small sample size (e.g., 1000), precision stabilises at 0.6. Notice that 1000 samples correspond to around .5% of the nodes in the TUS graph and it takes about 40 seconds for the algorithm to complete. The BC approximation has a complexity of $O(sm)$ where s is the number of nodes sampled and m the number of edges in the graph. Based on the literature and testing on our graphs we found that sampling 1% of the nodes provides a good approximation of BC that is very consistent with the score rankings produced by the exact BC computation.

We also considered a bigger data lake to further test execution times—the NYC education open data dataset as used in D^4 [36]. The bipartite graph representation of that dataset has roughly 1.5M nodes and 2.3M edges which is an order of magnitude larger than the bipartite graph for the TUS dataset. The graph was constructed in 3.5 minutes and the BC scores for every node were computed in 27 minutes using approximate BC on 1% of the nodes (~15K nodes).

To examine how runtime scales with graph size we extracted random subgraphs[9] of various sizes from the bipartite graph used for the NYC education dataset. We ran approximate BC for each graph by sampling 1% of its nodes and measured the runtime. Figure 9 shows that runtime increases linearly with graph size (i.e., number of edges) which is in accordance with the $O(sm)$ complexity of the approximate BC algorithm. .

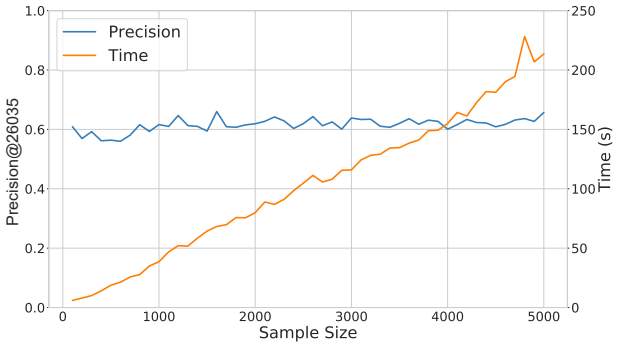

Figure 8: Precision at k (where k is the number of homographs in the dataset) and execution time at various sample sizes for approximate BC on the SB and TUS datasets. Exact BC on TUS took 150 minutes with a precision of 0.631.

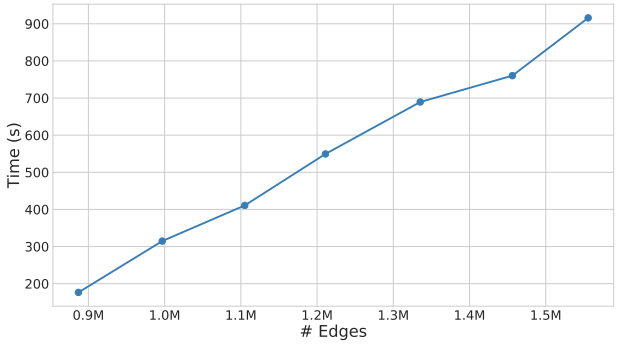

Figure 9: Runtime of approximate BC for various sized subgraphs based on the NYC education dataset.

5.5 Impact of homograph discovery on D^4

As shown in Table 1 the number of homographs in a real data lake can be large. To further understand the impact of homographs on

[9]The subgraphs were constructed by randomly selecting an attribute node and adding all its connecting value nodes. We repeat by selecting another attribute node until the subgraph reaches the desired size (within some margin)

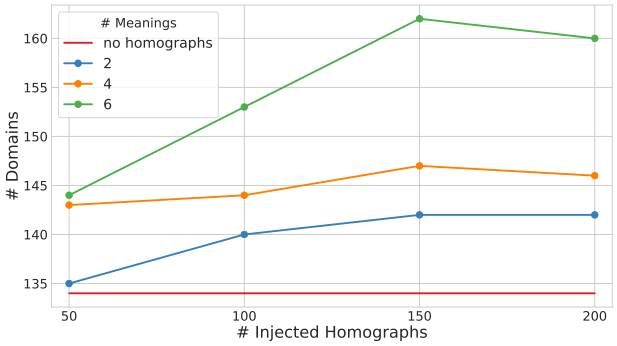

Figure 10: Number of domains found by D^4 over different TUS-injected datasets. The horizontal red line shows the number of domains found when no homographs were present in the dataset.

existing approaches, we consider the task of domain discovery and examine how knowing homographs *a priori* can benefit them.

We report the results of five different runs of D^4 in Figure 10. The plots show the number of domains found by D^4 (y-axis) as we vary the number and meanings of the injected homographs. To be fair in the comparison and to understand the impact of homographs on the domain discovery task, we use the TUS-I benchmark. We first ran D^4 over the dataset without homographs and then over the same dataset with injected homographs. More specifically, we injected 50, 100, 150 and 200 homographs with 2, 4 and 6 meanings. In all the above configurations the dataset always had 68 domains based on the ground truth. The horizontal line in Figure 10 shows that D^4 returns 134 domains for TUS-I with no homographs. The difference in the number of domains based on the ground truth and D^4's results is due to the nature of the TUS benchmark [33] as it is created from a set of large real open data tables that were randomly sliced vertically and horizontally. Consequently, in some cases the columns originating from the same table no longer share any values, causing D^4 to discover more domains than there are based on ground truth.

As we increase the number and meanings of the injected homographs, D^4 returns even more domains leading to lower accuracy. D^4's output provides statistics about the maximum and the average number of domains assigned to a column. In the TUS-I with no homographs, that maximum is 2 and the average is almost 1 (i.e., 1.031) and it increases with the number of homographs. With 200 homographs the maximum is 4 and the average is 1.04. We also ran D^4 on the TUS-I with 5000 injected homographs, to simulate a dataset with a large proportion of homographs as in the TUS benchmark. The maximum domains per column is 22 and the average is 1.7 with a total of 371 domains found. The presence of homographs is negatively affecting D^4 and causing it to erroneously assign larger numbers of heterogeneous domains to attributes as the number of homographs increases. Homograph discovery therefore is an important step that can be executed before domain discovery to improve its performance.

6 CONCLUSION AND FUTURE WORK

We presented `DomainNet`, a method for finding homographs in data lakes. To the best of our knowledge, this is the first solution for disambiguating data values in data lakes. Notably, our approach does not require complete or consistent attribute names.

We showed that a measure of centrality can effectively separate homographs from unambiguous values in a data lake by representing tables as a network of connections between values and attributes.

We compared against an alternative approach using D^4 to identify the semantic domain (type) of attributes [36] and labeling a value a homograph if it appears in more than one domain. Our direct computation of homographs has significantly better precision and recall than the domain-discovery approach. This seems to be due to D^4 at times placing homographs into a domain represented by their most popular meaning and the fact that D^4 does not find domains for every attribute. When we inject homographs into real data, `DomainNet` is robust to the number of meanings of the homographs, reliably finding homographs with even better accuracy as the number of meanings increases. We also demonstrated the importance of homograph detection by showing that the presence of homographs can have considerable impact on existing semantic integration tasks (specifically, domain discovery).

In a benchmark created from real data, our method provides a clear separation with high precision of homographs from values that are repeated, but always with the same meaning. The accuracy is influenced by the cardinality of the homograph (i.e., the number of data values with which the homograph co-occurs). When this number is too small, the bipartite graph representation is not always sufficient to effectively identify all homographs. In our experiments, the accuracy dropped from 97% to 85% as we reduced the cardinality of homographs.

The homographs we discover on real data include phrases with multiple meanings (e.g., `Music Faculty` referring both to a geographic location and to a University unit). They also include null values (e.g., a dot "." can indicate unknown/missing X where X varies in different contexts) and data errors (e.g., `Manitoba Hydro`, an electric company, is placed in the wrong column `Street Name`). In NLP, previous work on disambiguation primarily focuses on the disambiguation of words and named-entities. Our method is purely based on co-occurrence information and does not discriminate between different types of homographs. In fact, we provide the first approach to disambiguate numerical values in tables (e.g. 25 can be a street number or an ID number).

Identifying homographs from tables in a completely unsupervised manner can play an important role in improving other data-lake analysis tasks. Specifically, we are considering how to determine if a homograph is an error, e.g., the value has been placed in the wrong cell. With such knowledge, we can help not only identify such errors, but clean them as well. We also believe that our homograph metrics can improve supervised semantic type detection such as Sherlock [23] or SATO [51].

In this context, it will also be important to determine the number of distinct meanings of a homograph. Our approach is motivated by work on community detection where a community represents a meaning for a value (e.g., animal or car model). Hence we are investigating the role of community detection algorithms on discovery of meanings of values in data lake tables. Notice that in this problem, we do not know *a priori* what the communities are or even how many there are. Non-parameterized community detection algorithms can be used to discern the number of meanings of homographs. However, innovation is needed for homographs with large numbers of meanings (such as null equivalents) [21, and others].

To the best of our knowledge there are no available benchmarks for homograph detection. Our synthetic benchmark (SB)

and our benchmarks TUS and TUS-I (that use real open data tables [33]) are the first open benchmarks in this area.

In order to design a robust and completely unsupervised solution that scales to large data lakes, we have quite deliberately limited `DomainNet` to use only value co-occurrence information in table columns, ignoring additional structural information like co-occurrence of values in the same row. Our goal was to explore how much this information alone reveals about data value semantics. Given our strong positive results, we believe our metrics should become an important feature that could be used in other problems that involve understanding or integrating tables. An important open problem is to extend `DomainNet` to *collectively* resolve ambiguous metadata and data, perhaps using probabilistic graphical models that have been applied to collectively resolving multiple types of entities at once [26] and to collectively resolving data and metadata inconsistency in schema mapping [25].

ABSTRACT

Subspace clustering is the task of grouping objects based on mutual similarity in subspaces of the full-dimensional space. The INSCY algorithm extends the well-known density-based clustering algorithm DBSCAN. It finds dimensionality-unbiased non-redundant subspace clusters using a tree structure to speed up the processing of subspaces. Still, finding density-based clusters in all subspaces implies an exponential search space in the number of dimensions. Thus, the running time of INSCY is still measured in hours on even small datasets of 2000 points. For larger datasets, it becomes prohibitively expensive.

To benefit from INSCY for real-world sized datasets, we propose a novel GPU-parallel approach that runs on standard graphics cards. To utilize the many cores of the GPU, we need new algorithmic strategies that fit the computational model of the GPU. While the GPU provides a large number of threads, traditional algorithms incur diverging threads and poor memory alignment, both of which lead to idle time and poor runtime performance. In INSCY, extracting subspace regions from the SCY-tree structure and the density-based clustering of regions itself are thus unfit for the GPU.

Our novel GPU-friendly algorithm GPU-INSCY computes the same subspace clustering as INSCY at dramatically reduced runtimes. To achieve this, we devise a restructured SCY-tree index-structure and associated operations for the GPU, as well as a GPU-parallel density-based subspace clustering.

We experimentally show that GPU-INSCY scales well with the size of the dataset and the number of dimensions, and improves the running time of INSCY by a factor of several thousand for large datasets of high dimensionality.

1 INTRODUCTION

Clustering, i.e., grouping data points based on mutual similarity, is a widely used data mining task, e.g., for grouping customers to allow for targeted marketing. However, real-world data is often high-dimensional, and a higher number of dimensions means that there are more possibilities for points to seem dissimilar. This is known as the curse of dimensionality. Due to this effect, points tend to group within a subspace of the full-dimensional space, leading to the task of subspace clustering [2, 4, 15], where we search for clusters with all possible subspaces. To search for such clusters, we often employ density-based clustering similar to DBSCAN [12]. Most subspace clustering algorithms, e.g., SUBCLU [15], use a fixed density threshold independent of the subspace's dimensionality. When finding clusters, the density threshold needs to match the expected density such that we can find all points within clusters, but without including everything. However, the expected density is lower for higher-dimensional subspaces than it is for lower-dimensional subspaces. For density-based subspace clustering, this problem implies that density-measures that do not take the subspace's dimensionality into account are biased toward lower subspaces. To address this problem, Assent et al. [6] formulated a dimensionality-unbiased density-measure and utilized this in the algorithm INSCY [8]. INSCY, furthermore, removes redundancy and provides an index-structure called SCY-tree used to partition and prune regions of density-connected data points. A drawback that remains, is that the running time is still measured in hours on even small datasets of a couple of thousands of points.

To reduce the runtime of dimensionality-unbiased density-based subspace clustering, we exploit modern graphics cards (GPUs), capable of general-purpose computations, fast context switches, and parallelizing over many cores, but with a restrictive computational model and limited memory. The high computational throughput of GPUs has been utilized to improve clustering runtimes [1, 5, 10]. However, to our knowledge, there exists no GPU-parallelization of a dimensionality-unbiased index-supported algorithm like INSCY, which is challenging to GPU-parallelize due to index and depth-first subspace search being optimized for (sequential) CPU processing.

Contributions. In this work, we present a novel GPU-parallel algorithm, called GPU-INSCY, which provides the same clusterings as INSCY at substantially reduced runtimes. To achieve this, we restructure several major parts of INSCY, the index-structure SCY-tree, the operations used to partition regions of data, and the clustering of points. INSCY partitions regions represented by SCY-trees through a sequence of operations. We show how to make these operations parallel and combine several partitions into one process. Combining these allows us to avoid many redundant iterations and temporary copies. The clustering step is also GPU-parallelized and improved further by utilizing the density monotonicity for neighborhoods in increasing subspaces.

This paper is organized as follows: Section 2 discusses related work, Section 3 gives the background of subspace clustering and INSCY, Section 4 describes our new parallel algorithm GPU-INSCY, Section 5 presents the experimental comparison of INSCY and GPU-INSCY, and Section 6 concludes our work.

2 RELATED WORK

Subspace clustering is the task of grouping points based on mutual similarity in any possible subspace of the full-dimensional space, hence its worst case complexity is exponential in the number of dimensions.

Algorithms for subspace clustering [2, 4, 6–8, 11, 14, 15, 25] are often categorized into bottom-up or top-down approaches [16, 21, 24, 26]. Bottom-up approaches start with clustering in 1-dimensional subspaces, iteratively combining k-dimensional subspace clusters into $(k+1)$-dimensional subspace clusters. CLIQUE [4] and MAFIA [14] are grid-based approaches that may miss subspace clusters spanning across grid cells. Instead of clustering dense cells, SUBCLU [15] clusters dense points, as in the density-based full space clustering algorithm DBSCAN[12]. An issue with SUBCLU and other density-based subspace clustering approaches is that they use a fixed density-threshold for all subspaces. Therefore, they do not take dimensionality into account and are biased towards lower-dimensional subspace clusters. INSCY is an extension of SUBCLU that mitigates this problem by introducing a density measure normalized by a subspace's expected density.

Top-down approaches start by clustering the full-dimensional space and iteratively refine the subset of dimensions associated with each subspace cluster [2, 3, 29]. These approaches limit subspace clusters by assigning each point in the data to exactly one subspace cluster. Due to the exponential search for subspaces, many of the algorithms take an approximate approach to subspace clustering [2, 14, 20]. They do so using a heuristic to pick the subspaces that are examined or only compute clusterings of dense regions instead of single dense points. These approaches might miss clusters that exact algorithms like INSCY capture.

Even though exact subspace clustering algorithms are time consuming, few algorithms have been proposed to reduce the running time by exploiting the high computational throughput of the GPU. Utilizing the many cores of the GPU is highly challenging because of the distinct and limited computational model, as well as limited memory. There have been proposed several GPU-parallelized full-space clustering algorithms [5, 10, 13, 17, 19]. One of the earliest GPU versions of the full-space clustering algorithm DBSCAN was CUDA-DClust* [10], which starts multiple searches for clusters in parallel. If multiple searches start within the same cluster, they are merged. Multiple other GPU-versions of DBSCAN have been developed [5, 18, 19, 28]. Our assessment of self-reported results suggest that G-DBSCAN[5] and CUDA-DClust*[10] are the best performing options. An experimental evaluation [22] studies three of these GPU-versions and finds that G-DBSCAN is the fastest and CUDA-DClust* uses less memory.

Only one GPU-parallelization of a well-known subspace clustering approach has been proposed [1] for grid-based MAFIA. GPUMAFIA parallelizes one operation at a time, mapping nested for-loops of minor computations directly to parallel threads. Our restructuring of INSCY lets us GPU-parallelize GPU-INSCY even further such that we can even parallelize operations performed at different points of the process. We completely restructure the algorithm and its underlying SCY-tree structure to fit the computational model and the memory structure of the GPU.

To the best of our knowledge, we are the first to develop a GPU-parallelized version of a density-based subspace clustering algorithm, in particular an algorithm that supports dimensionality-unbiased density measures and exploits indexing structures for efficient computation.

3 BACKGROUND

3.1 The graphics processing unit

We give a short introduction to graphics processing units (GPUs) and their computational model. When using a GPU for general-purpose computation, the GPU is *co-processor*, and the CPU is *main processor*. Throughout the paper, we use the term *parallel* to denote parallel execution under the GPU's computational model. The main difference between a multi-core CPU and a GPU is that GPUs can perform fast context switches and that several cores on the GPU uses the same program counter and, therefore, must perform the same operations.

CUDA is NVIDIA's framework for using their line of GPUs. It uses the concept of a kernel, which is a function executed on multiple threads in parallel. Threads are organized into blocks, and all threads within a single block are capable of synchronizing, share fast accessible memory, and use atomic operations. However, there is a physical limit to the number of threads a block can contain, and the communication between threads comes at a time-cost. Each block is further separated into warps. All threads within a warp share a program counter, implying that they must perform the same instructions (SIMD) at all times. In the case of branch-diversion, threads in different branches will remain idle until the other branch has finished.

When parallelizing operations on the GPU, we are not guaranteed any order of executions. Therefore, our goal is to identify *independent* operations, i.e., operations that do not use the partial result of each other and therefore can be run in any order without changing the final result. All allocation of memory and calls to kernels are done by the CPU and executed on the GPU. All communication with the GPU comes with a time-cost due to the large latency of data transfer. Therefore, it is essential to balance where data is processed and how long it takes to transfer.

3.2 INSCY

We describe INSCY briefly. For further details please see [8]. We use the following terminology: let $X \in \mathbb{R}^{n \times d}$ be a d-dimensional dataset with n points, $D = \{0, \ldots, d-1\}$ an index set for the full dimensional space, $S \subseteq D$ a subspace of D, and $N_\varepsilon^S(p)$ the neighborhood with radius ε of a point p in subspace S.

According to INSCY [6], a subspace cluster is a maximal set of points of at least min_C, which are density-connected in a subspace according to some density measure, and which is not redundant w.r.t. a higher dimensional subspace projection:

Definition 3.1. **INSCY Subspace Cluster**
A set of points $C \subseteq X$ in subspace $S \subseteq D$ is a subspace cluster if:

- objects in C are **S-connected**: $\forall p, q \in C : \exists o_1, \ldots, o_m \in C : p = o_1 \wedge q = o_m \wedge \forall i \in \{2, \ldots, m\} : o_i \in N_\varepsilon^S(o_{i-1})$
- all points fulfill the **density criterion**: $\forall p \in C : dc^S(p)$,
- C is **maximal**, i.e., contains all S-connected objects: $\forall p, q \in X : p, q$ S-connected $\Rightarrow p \in C \wedge q \in C$,
- **minimum cluster size**: $|C| \geq min_C$,
- **not redundant**: $\nexists C', S'$ subspace cluster with $C' \subseteq C \wedge S \subset S' \wedge |C'| \geq r \times |C|$

where r is the redundancy parameter, min_C is the minimum size of a cluster, and $dc^S(p)$ is any dimensionality-unbiased density criterion within subspace S.

In this paper, we use the dimensionality-unbiased rectangular density measure for the density criterion $dc^S(p) := |N_\varepsilon^S(p)| \geq \max(F \cdot \alpha(S), \mu)$, where F is the density factor threshold, $\alpha(S) = \mathbb{E}_S\left[|N_\varepsilon^S(p)|\right] = |X| \frac{c(S) \times \varepsilon^{|S|}}{v_S}$ is the expected density, $c(S) = \pi^{\frac{|S|}{2}} / \Gamma\left(\frac{|S|}{2} + 1\right)$ with $\Gamma(n+1) = n \times \Gamma(n), \Gamma(1) = 1, \Gamma(1/2) = \sqrt{\pi}$, v_S is the volume of subspace S, and μ is the minimum number of points required for not just being pseudodense. Other density measures can also be used. For further details see [6]. Note that

Def. 3.1 is similar to density-based clustering in DBSCAN [12], but with an unbiased density notion wrt. subspaces.

SUBCLU [15] uses monotonicity of density-connectivity to prune points that lie outside clusters in a lower-dimensional subspace projection. However, for INSCY's unbiased density measure that scales with the expected density of a subspace, monotonicity is lost. Still, as [6] observes, pruning can be done by discarding points that are not dense w.r.t. the lowest possible density threshold, i.e., for the full-space. INSCY finds such points, called not weak-dense, which can safely be pruned before searching for clusters within superspaces of the current space. A point is weak-dense if $|N_\varepsilon^S(p)| \geq \max(F \times \alpha(D), \mu)$.

3.2.1 The INSCY algorithm. The idea of INSCY is to bound the search for subspace clusters by identifying regions that fully contain potential clusters. INSCY describes such a region by the dimensions it spans and the respective intervals in these dimensions, and call it a subspace region. INSCY performs a depth-first search (DFS) of the subspace regions, i.e., enumerating all possible subspace regions. INSCY does so by recursively extending with one dimension at a time and partitioning the region into intervals along that dimension. When INSCY returns from the recursion, it performs density-based clustering within the current subspace region to obtain the clusters. This implies that INSCY cluster points within all superspaces of the current space first.

Each dimension is partitioned into a fixed number of cells. As a cluster likely spans multiple cells, INSCY register this by having a border between each cell at the size of the neighborhood radius ε. When performing density-based clustering, it follows that if there are no points within this border, the two cells' points cannot be density-connected. Otherwise, a cluster may span both cells. Such connected cells are referred to as S-connected. S-connected cells must be merged into a density-connected interval to ensure that no clusters are split. An interval spanning multiple cells is identified by the first cell. A dimension might have multiple density-connected intervals, and INSCY is called recursively on each interval in a depth-first manner. The whole process of expanding with a new dimension and bounding to a density-connected interval is referred to as restricting w.r.t. a new dimension and the cell identifying the interval. The pair of dimension d and cell c is called a descriptor (d, c). When expanding with a new dimension, we expand one region at a time. Figure 1 shows a 1-dimensional example, and the expansion into two dimensions. On the left, the dimension is split into three cells, where two are S-connected and merged into one interval marked by green. On the right, we see the expansion. The red region is split into cells along the added dimension and connected with any S-connected cells, and likewise for the green region.

To keep track of the possible dimensions and cells that can be restricted, INSCY introduces an index-structure called SCY-tree. The idea of SCY-tree is to precompute the number of points within cells along a dimension such that restricting becomes easier. The

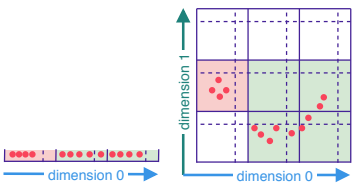

Figure 1: Expansion of 1-d regions into 2-d

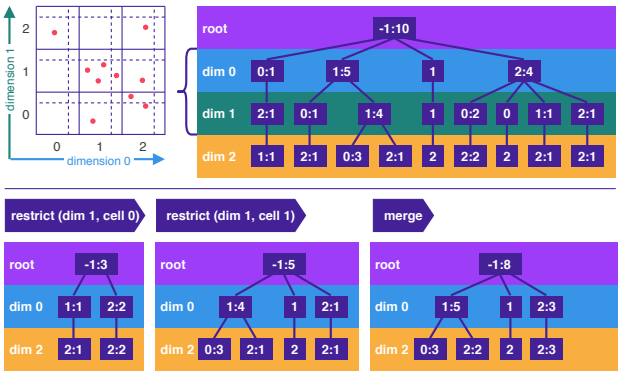

Figure 2: SCY-tree for examples in [8]; node values *cell* : *count*; dimensions and points colored as in later figures

SCY-tree, therefore, represents the dimensions and cells not yet restricted. The SCY-tree is a tree-structure containing nodes that represent a partition of a space along a specific dimension. All nodes regarding a specific dimension are located at the same height in the SCY-tree, which we call a layer. The children of a node represent splits into cells along a dimension, one child per cell. Each node contains its cell number and the count of points within the cell it represents. A cell with an S-connection is represented by adding a sibling with the same cell number, but with the count of points set to -1. Such a node is called an S-connector node. INSCY keeps track of S-connections by continuing the path of S-connector nodes down to the leaf layer. The root node of the SCY-tree represents a restricted subspace region. SCY-trees that represent regions that share a border are called neighboring SCY-trees. For further details, see [8].

Figure 2 (top) shows an example of an initial SCY-tree for the full-dimensional space. In this example, the space is first partitioned along dimension 0, creating three cells noted by the cell number and the count of points in that cell *cell* : *count*. Cell 1 has an S-connection, which is represented by a node without a count of points. Each cell is then further partitioned along dimension 1, discarding cells that do not contain any points.

INSCY proceeds as in Algorithm 1. For each descriptor, create a restricted SCY-tree. If cells in the SCY-tree are S-connected, merge connected restricted SCY-trees into one final restricted SCY-tree. INSCY prune the final restricted SCY-tree for redundancy, call recursively, and cluster the points if there is a possibility for non-redundant clusters.

Restrict. INSCY restricts a SCY-tree by identifying nodes matching the current descriptor, i.e., the nodes residing on the layer of the restricted dimension and with the same cell number as the descriptor. For each matching node, copy the node's path to the root and subtrees below the node into a new restricted

Algorithm 1 INSCY($scytree$, d_f, X, d, r, F, μ, ε, min_C, R)

```
1: for d_re = d_f to d do
2:     for c_re = 0 to n_cells do
3:         scytree' ← restrict(scytree, d_re, c_re)
4:         scytree' ← mergeNeighbors(scytree, scytree', d_re, c_re)
5:         if prune_recursion(scytree', F, μ, ε, min_C) then
6:             INSCY(scytree', d_re + 1, X, d, r, F, μ, ε, min_C, R)
7:             if prune_redundancy(scytree', r, R) then
8:                 R ← R ∪ clustering(scytree', X, F, μ, ε)
```

SCY-tree. Since the SCY-tree keeps track of not yet restricted dimensions, the matching node itself is not copied. The node's children are now children of the node's parent. The count of points is also updated to reflect the number of points in the restricted region. Figure 2 (bottom) contains two restricted SCY-trees for descriptors $(1, 0)$ and $(1, 1)$ and the merged result. For descriptor $(1, 0)$ only 2 nodes match, leading to a small SCY-tree.

Merge. INSCY merges neighboring restricted SCY-trees if there exists an S-connection, i.e. when an S-connector path starts at dimension d and has cell number c that matches the current descriptor (d, c). Merge is done by going through the two restricted SCY-trees and copying the nodes in both. A node can be represented in several SCY-trees. During the merge, nodes with the same cell number and the same parent are merged. Figure 2 (bottom), shows that the descriptor $(1, 0)$ matches an S-connector node, the node represented by only a 0 on dimension 1, and therefore INSCY restricts the neighboring descriptor $(1, 1)$ and merges the two restricted SCY-trees.

Pruning recursion. To reduce the search space, INSCY prunes the final restricted SCY-tree before calling recursively, as follows: Remove non-weak dense points and check if the region's number of points still exceeds min_C. INSCY only proceeds with the recursion if this is the case, as further restrictions will only reduce the number of points.

Pruning redundancy. When returning from the recursive call INSCY has found clusters in all superspaces of the current subspace. The current region can therefore be pruned by redundancy. INSCY prunes by redundancy by checking if the result already contains a cluster covering a factor r of the points in the restricted region. If the number of points in the region is large enough, INSCY computes the density-based clustering on all points in the final restricted SCY-tree and adds all non-redundant clusters to the result.

4 GPU-INSCY ALGORITHM

INSCY is inherently computationally expensive, making it infeasible to run on large real-world datasets. As mentioned in the introduction, GPUs provide computational power that algorithms designed for a different computational model of single-core CPUs, as INSCY, cannot utilize. We design an algorithm for the GPU that reduces the running time of INSCY substantially, making it feasible to run on much larger datasets. To summarize the notation found in this section we provide Table 1 for ease of reading. Recall that threads in a warp must execute the same instructions to fully utilize the GPU's computational power. INSCY does not group similar operations and would perform poorly on the GPU.

The idea of each iteration in INSCY is to bound a subspace region by restricting and merging, prune that region, and perform clustering in that region. This process is repeated until all clusters in all subspace regions are found. This approach is efficient for a sequential algorithm. However, when parallelizing for the GPU, we prefer grouping identical and independent operations to make each kernel call utilize as many cores as possible. Making INSCY run parallel on the GPU is not straightforward since many partial computations depend on previous results. E.g., in the alternation between restricting and merging SCY-trees, we need the previous merged SCY-tree and the neighboring restricted SCY-tree before continuing to merge.

Table 1: Notation

n_{nodes}	number of nodes
n_{pts}	number of points
n_{cells}	number of cells
n_{dims}	number of dimensions
n_{r_dims}	number of restricted dims
$pa \in \mathbb{N}^{n_{nodes}}$	parent array
$ce \in \mathbb{N}^{n_{nodes}}$	cell array
$co \in \mathbb{N}^{n_{nodes}}$	count array
$la \in \mathbb{N}^{n_{dims}}$	layer-indexing array
$dims \in \mathbb{N}^{n_{dims}}$	dimension array
$r\_dims \in \mathbb{N}^{n_{r\_dims}}$	restricted dims array
$po \in \mathbb{N}^{n_{pts}}$	point-id array
$pl \in \mathbb{N}^{n_{pts}}$	point-placement array
$incl \in \{\mathbf{0}, \mathbf{1}\}^{n_{dims} \times n_{cells} \times n_{nodes}}$	node inclusion array
$incl_{pts} \in \{\mathbf{0}, \mathbf{1}\}^{n_{dims} \times n_{cells} \times n_{pts}}$	point inclusion array
$idx \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{nodes}}$	node new-index array
$idx_{pts} \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{pts}}$	point new-index array
$n\_co \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{nodes}}$	new-count array
$is\_S(i)$	is S-connection
$s\_incl(j, i, c)$	should be included
$S \in \{\mathbf{0}, \mathbf{1}\}^{n_{dims} \times n_{cells}}$	S-connection array
$M \in \mathbb{N}^{n_{dims} \times n_{cells}}$	merge map
$n\_pa \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{nodes}}$	new-parent array
$n\_ch \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{nodes} \times n_{cells} \times 2}$	new-children array
$rep(j, c, i)$	representative node

Algorithm 2 GPU-INSCY($scytree'$, d_f, X, d, r, F, μ, ε, min_C, R)

```
1:  L ← GPU_restrict_and_merge(scytree, d_f, d)
2:  precompute_neighborhoods(X, L, ε)
3:  for d_re ← d_f to d − d_f do
4:      C ← 1d array of size |X| initialized to −1
5:      for ∀scytree' ∈ L[d_re] do
6:          if prune_recursion(scytree', F, μ, ε, min_C) then
7:              GPU-INSCY(scytree', d_re + 1, X, d, r, F, μ, ε, min_C, R)
8:              if prune_redundancy(scytree', r, R) then
9:                  L' ← L' ∪ {(scytree', C)}
10: R ← R ∪ GPU_clustering(L', X, F, μ, ε)
```

In this section, we present a new algorithm called GPU-INSCY, in which we tackle the problem of identifying and reorganizing the operations that can be performed in parallel to reduce running time. Contrary to INSCY, GPU-INSCY aims to perform similar and independent operations simultaneously for multiple final restricted SCY-trees to utilize multiple thread blocks. Remember that this allows us to use more cores, but it is only possible if the threads in different blocks do not need to communicate.

We first outline the general order of computations in GPU-INSCY, and we later explain this reordering. These reorderings do not affect the result since the reordered operations are independent of each other as discussed below for each change we introduce. GPU-INSCY can be seen in Algorithm 2. First, compute the set L of all final restricted SCY-trees. Precompute the neighborhoods for all points in all final restricted SCY-trees. For each final restricted SCY-tree, prune the recursion, call GPU-INSCY recursively, and prune for redundancy. All non-pruned final restricted SCY-trees are added to L'. Finally, we cluster all points in each of the final restricted SCY-trees in L'.

Restrict and merge. In GPU-INSCY, we isolate all restrict and merge operations at the beginning of the algorithm, whereas INSCY performs them ad hoc. We isolate the operations such that we can parallelize them in different thread blocks. The result of

each restrict and merge operation only depends on the information parsed to the recursion. Computing all restricted SCY-trees at the beginning does, therefore, not change the final result. Parallelizing within each thread block is not a simple task due to both the alternation between restrict and merge and the fact that INSCY only visits nodes in the SCY-trees one by one when restricting and merging. We discuss how to parallelize restrict and merge in Section 4.1.2, after introducing a representation of the SCY-tree index-structure for the GPU in Section 4.1.1.

Precomputing the neighborhoods. Computing the neighborhoods is an expensive task, and it is used both for the clustering and when computing weak-density while pruning a recursion. In Section 4.2, we describe how to precompute the neighborhoods in parallel and how we take advantage of having direct access to the neighborhoods in a subspace of the current space.

Pruning. In Section 4.3, we parallelize both pruning phases following the same approach as for restrict and merge.

Clustering. In Section 4.2, we change the sequential way of expanding the clusters [12] with one density-connected point at a time, to obtain a more efficient clustering algorithm.

4.1 SCY-tree on the GPU

The SCY-tree representation and the associated operations are not very suited for the GPU. Section 4.1.1 describes how to represent the SCY-tree in a GPU friendly fashion and Section 4.1.2 describes how to perform the restrict and merge operations in parallel.

4.1.1 Representing the SCY-tree on the GPU. Handling memory on the GPU is more restrictive than on the CPU, and allocating memory can only be done from the CPU. Furthermore, it is expensive to alternate between calling kernels, transferring data, and allocating memory. Therefore, we prefer to allocate memory and transfer data as few times as possible. GPU memory is loaded one block at a time to reduce latency, implying that data used close together in time should be placed close together in memory. If the data we use is not placed in the same block, we get cache misses, i.e., not using the loaded data, which we would like to reduce. For ease of reference, we call the GPU friendly representation of the SCY-tree GPU-SCY-tree. A way to represent tree structures on the CPU is to create an object for each node with pointers to its children, parent, and other values in the tree. This structure is very flexible and allows adding nodes on the fly. However, this does not fit well with the restrictions on the GPU.

Remember, all nodes for a particular dimension are placed on the same layer in the SCY-tree. These layers are indexed by j starting with $j = -1$ for the root and incrementing toward the leaf layer $j = n_{dims} - 1$, implying that lower indices are above the higher indices in the SCY-tree. In Section 4.1.2, we describe how we handle all nodes on the same layer simultaneously, and we would therefore like to place these nodes close together in memory. The same is the case for points contained in the tree.

Instead of representing nodes as objects, we choose to represent the GPU-SCY-tree as arrays, with an entry for each node. Each array represents the kind of pointer or values that a node contains. In the arrays, we locate nodes on the same layer in the SCY-tree next to each other and order the layers by their index j. In this way, data for nodes on the same layer is placed close together in memory, making it more likely to avoid cache-misses. We organize points using the same reasoning. To represent the GPU-SCY-tree, we use a total of eight arrays with one entry per node, point, or dimension. An example is given in Figure 3. Besides the arrays we also keep count of the number of nodes

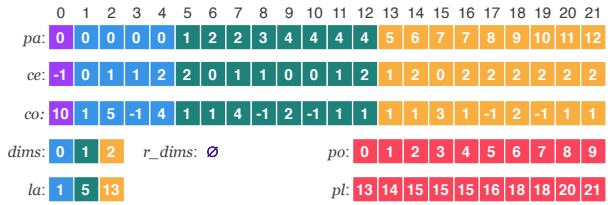

Figure 3: GPU-SCY-tree for SCY-tree in Figure 2.

n_{nodes}, number of points n_{pts}, number of cells n_{cells}, number of dimensions in the SCY-tree n_{dims}, and number of restricted dimensions n_{r_dims}.

The nodes are represented using three arrays: the parent pointer $pa \in \mathbb{N}^{n_{nodes}}$, the cell number $ce \in \mathbb{N}^{n_{nodes}}$, and the count of points $co \in \mathbb{N}^{n_{nodes}}$. Notice that we do not keep pointers to children, see Section 4.1.2 for reasoning. To access each layer j we have an array with the starting index of each layer $la \in \mathbb{N}^{n_{dims}}$ and an array with the dimensions that the layers represent $dims \in \mathbb{N}^{n_{dims}}$. We furthermore keep an array of the restricted dimensions $r\_dims \in \mathbb{N}^{n_{r\_dims}}$, however, for the GPU-SCY-tree in Figure 3 this is empty. To keep track of the points in the GPU-SCY-tree, we have two arrays with an entry for each point. One keeps track of the points' index in the dataset $po \in \mathbb{N}^{n_{pts}}$, and the other keeps track of which leaf-node each point is placed in $pl \in \mathbb{N}^{n_{pts}}$.

4.1.2 Restrict and merge on the GPU. When parallelizing for the GPU, we identify: (i) ways to reorder independent tasks that can be performed in parallel, (ii) similar tasks that can be performed by a warp, and (iii) ways to allocate memory as few times as possible. Restrict and merge for a SCY-tree are sequential operations where we look at one node at a time, check if it should be included, and copy all information to the temporary or final result. Running this in parallel on the GPU requires a substantial restructuring due to two things: The alternation between restrict and merge and a node's inclusion being dependent on the inclusion of either the parent or one of its children. As mentioned before, such a dependency makes the process sequential, which is not suitable for the GPU.

In Section 4, we state that all final restricted SCY-trees can be computed first in the recursion since the computation only requires the descriptors and the SCY-tree parsed to the recursion. But to parallelize the restrict and merge operation, we need several observations and restructuring that we now provide.

Allocating once. To allocate memory only once per restricted GPU-SCY-tree, we first compute which nodes and points are included in the restricted SCY-trees. This information is kept in two temporary binary arrays both initialized to **0**. One for nodes $incl \in \{\mathbf{0}, \mathbf{1}\}^{n_{dims} \times n_{cells} \times n_{nodes}}$ with entries for each descriptor and node combination. And one for points $incl_{pts} \in \{\mathbf{0}, \mathbf{1}\}^{n_{dims} \times n_{cells} \times n_{pts}}$ with entries for each descriptor and point combination. Here **0** and **1** represent false and true, respectively. In Figure 2, we show the restriction for descriptor (1,0). In Figure 4 we show the same restriction in GPU-SCY-tree representation, and the temporary arrays. Here the five included nodes are marked with a **1** in $incl$. Knowing which nodes and points are included allows us to compute the new indices of the nodes and points in the restricted SCY-trees. We compute the indices fornodes and points using inclusive scan (cumulative sum) of $incl$ for each descriptor. The result is kept in $idx \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{nodes}}$

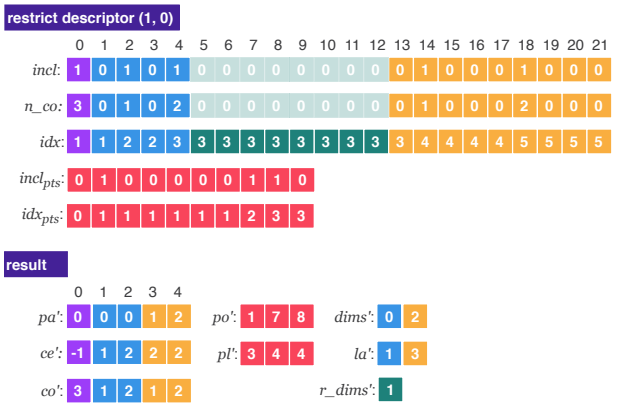

Figure 4: Restrict example before combining with merge.

and $idx_{pts} \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{pts}}$. This is used to determine where each node is placed in the resulting SCY-tree. E.g. in Figure 4, the last included node is placed at entry $4 = idx(18) - 1$. Furthermore, for each descriptor, we use the last index to allocate the needed memory for the restricted SCY-trees.In Figure 4 we need to allocate space for $5 = idx(|idx| - 1)$ nodes. After allocating memory, we copy all included nodes and points to the restricted SCY-trees. To copy, we need the new count of points in the subtrees starting at each node $n\_co \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{nodes}}$ which we compute along side the inclusion of each node.

Restrict is independent. We observe that the restrict operation only requires the SCY-tree parsed to the recursion and the descriptor it is restricting w.r.t.. Both the descriptor and the SCY-tree are not changed during the recursion. Therefore, the restrict operations of each recursion are completely independent of each other and all other operations. Consequently, the final result does not depend on the order of restriction, and we can parallelize the restrict operations over different thread blocks, which allows us to utilize more cores.

Restrict - similar tasks and restructuring. INSCY restricts by identifying all nodes matching a descriptor and then visiting upward and downward in the layers of the SCY-tree from there. INSCY copies all nodes on the path to the root and the subtree below the matching nodes to the new restricted SCY-tree. We take advantage of the SCY-tree being a well-balanced tree with a layer for each dimension. Observe that nodes on layers above the restricted dimension are included if any of its children is included in the restricted SCY-tree. The nodes on layers below are included if their parent is included. Because of the dependency w.r.t. inclusion between parents and children, we have a dependency between layers where we need to compute the inclusion of nodes up- and downwards in the GPU-SCY-tree starting from the restricted dimension. However, observe that computing the inclusion of each node on a layer is independent of the other nodes on that layer. Using this observation, we suggest computing the inclusion of nodes one layer at a time, making the computation of node inclusion parallel over each node on a layer. Since we keep the ordering between parents and children, we do not violate the dependency, and hence we compute the same result as INSCY.

When computing the inclusion of nodes, we have four cases, where the computation is different for each of them. One for nodes directly above the restricted dimension, one for the nodes on the remaining layers above, one for nodes directly below the restricted dimension, and one for the nodes on the remaining layers below. We handle each of the cases in their own kernel, to avoid branch-divergence that would lead to idle threads.

We compute the inclusion array *incl* in parallel with thread blocks for each descriptor $(dims(j), c)$ where j is the layer representing the restricted dimension and c is the cell number.Within each block, we process sequentially over each layer $j + k$ where $-j \leq k < n_{dims} - j$, starting from $k = 0$ and incrementing/decrementing from there. For all nodes i on a given layer we parallelize using threads.

When we compute the inclusion array *incl*, we treat normal nodes and S-connector nodes slightly differently. An S-connection is only used to enforce a merge along the restricted dimension. Therefore, we discard the S-connector path starting at the restricted dimension. Remember, we have an S-connection on the restricted dimension, when an S-connector node i has a normal node as the parent:

$$is\_S(i) := (co(i) < 0) \wedge (co(pa(i)) \geq 0). \tag{1}$$

In Figure 3, node 10 represents an S-connection since it has a negative count and its parent, node 4, has a positive count.

We can now use this when searching for nodes i matching the descriptor $(dims(j), c)$. A node i on layer j matches the descriptor $(dims(j), c)$ if its cell number matches the cell number of the descriptor $ce(i) = c$ and it is not an S-connector node starting at the restricted dimension $\neg is\_S(i)$:

$$s\_incl(j, i, c) := (ce(i) = c) \wedge (\neg is\_S(i)). \tag{2}$$

In Figure 3, for descriptor (1, 0), node 6 should be treated as a match since it is in dimension 1 and has cell number 0 and does not represent an S-connection. Node 10 also matches the descriptor, but it represents an S-connection, so it should not be treated as a match.

We wish to compute inclusion for all nodes on the layers above the restricted dimension. This requires us to look at each child of a given node. As the number of children can vary from node to node, threads in the same warp would stay idle until the other threads have visited all their children. We address this by parallelizing over all children instead and letting the children mark if their parent is included. Observe that now each thread only visits the current node and its parent, instead of a varying number of children.

Starting from layer j we compute inclusion for the nodes on layer $j-1$ just above the restricted dimension $dims(j)$. The parent $pa(i)$ of a node i is marked as included if the node i matches the descriptor $s\_incl(j, i, c)$:

$$\begin{aligned} &\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, \\ &\quad la(j) \leq i < la(j+1), s\_incl(j, i, c) : \\ &\qquad incl(j, c, pa(i)) := \mathbf{1}. \end{aligned} \tag{3}$$

In Figure 4 node 2 is included since node 6 matches the descriptor.

Sequentially moving towards the root, we can now compute inclusion for nodes on layer $j - k$ where $2 \leq k < j$. The parent $pa(i)$ is now included if the node i is marked as included:

$$\begin{aligned} &\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, 1 \leq k < j - 1, \\ &\quad la(j-k) \leq i < la(j-k+1), incl(j, c, i) : \\ &\qquad incl(j, c, pa(i)) := \mathbf{1}. \end{aligned} \tag{4}$$

In Figure 4 the root, node 0, is included since node 2 is included.

Similarly, we include nodes on the layer $j+1$ directly below the restricted dimension $dims(j)$ if the parent matches the descriptor:

$$\forall 0 \le j < n_{dims}, 0 \le c < n_{cells}, la(j+1) \le i < la(j+2) : \\ incl(j,c,i) := s\_incl(j, pa(i), c). \tag{5}$$

In Figure 4 node 14 is included as node 6 matches the descriptor.

Moving towards the leaves, we compute inclusion for nodes on layer $j+k$ where $2 \le k < n_{dims} - j$ by checking if a node's parent is marked as included:

$$\forall 0 \le j < n_{dims}, 0 \le c < n_{cells}, 2 \le k < n_{dims} - j, \\ la(j+k) \le i < la(j+k+1) : \\ incl(j,c,i) := incl(j,c,pa(i)). \tag{6}$$

After we have computed the inclusion of the nodes on the leaf layer, we can compute which points are included. A point p is included if the leaf node where it is located $pl(p)$ is included:

$$\forall 0 \le j < n_{dims}, 0 \le c < n_{cells}, 0 \le p < n_{pts} : \\ incl_{pts}(j,c,p) := \begin{cases} incl(j,c,pl(p)) & \textbf{if } j < n_{dims} - 1 \\ ce(pl(p)) = c & \textbf{else} \end{cases} \tag{7}$$

E.g. in Figure 4 point 1 is included since the leaf node 14 where the point is placed is included. The computation is done in parallel over each descriptor as blocks and each point p as threads. We handle the case of restricting the leaf layer by directly checking if the placement node's cell number matches the descriptor.

Restrict and merge combined. INSCY alternates between restricting and merging as long as S-connections are found. The merge operation only merges restricted SCY-trees that represent subspace regions within the same subspace. Therefore, merges are independent between restricted dimensions in the same recursion. However, remember that the merge operation merges the newly restricted SCY-tree with the previous merged SCY-tree. Instead of this sequential process, we devise a strategy to perform merges and restrictions simultaneously. Implying that we avoid allocating space for the temporary restricted and merged SCY-trees, and by that, save time.

Precomputing SCY-trees to merge. Observe that in INSCY, what makes the merge process sequential, is that we do not know in advance which SCY-trees need to be merged for a given descriptor. However, this only depends on the S-connections along the restricted dimension. A merge is only necessary if there is an S-connection between two cells on the restricted dimension. We suggest precomputing which SCY-trees need to be merged for each descriptor in advance. First, check if there is an S-connection for the given descriptor, then compute from which descriptor the merging process should start. The first check for S-connections can be parallelized as follows. We define $S \in \{\mathbf{0}, \mathbf{1}\}^{n_{dims} \times n_{cells}}$, a table of whether there exists an S-connection for a given descriptor. Each entry of S is initialized to $\mathbf{0}$ and updated in parallel over each layer j as thread blocks and each node i as threads. The update entails writing $\mathbf{1}$ if the node i is the start of an S-connector path.

$$\forall 0 \le j < n_{dims}, la(j) \le i < la(j+1), is\_S(i) : \\ S(j, cells(i)) := \mathbf{1}. \tag{8}$$

We use S to compute from which descriptor each merge sequence starts. This information is saved in $M \in \mathbb{N}^{n_{dims} \times n_{cells}}$, where each entry represents a descriptor. For each entry, we compute which restricted SCY-trees should be merged, denoted by the cell number c of the descriptor associated with the first SCY-tree in that merge sequence. Remember that we start a new sequence

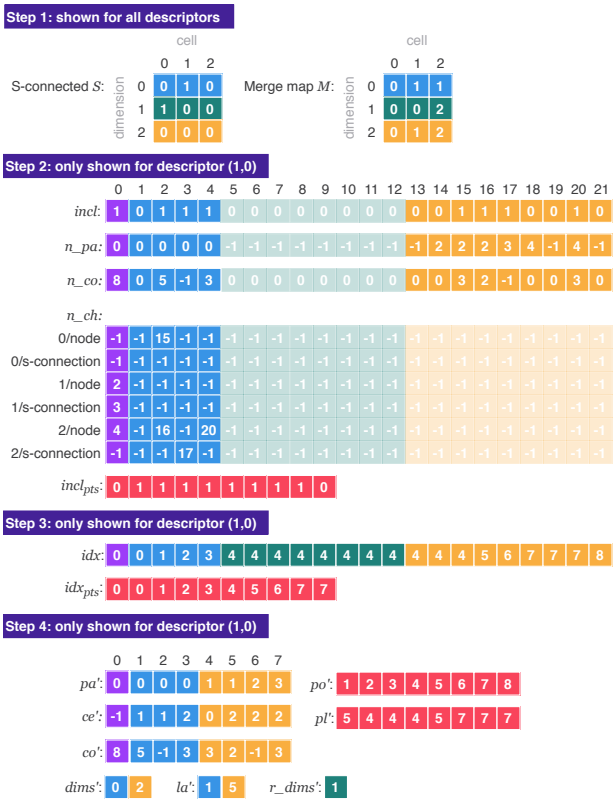

Figure 5: Restrict after combining with merge.

of merges whenever there was no S-connection from the previous cell $S(j, c-1)$. In other words, if there is an S-connection between two cells, we continue the sequence with identifier $M(j, c-1)$. If not, we start a new sequence with the identifier c.

$$\forall 0 \le j < n_{dims}, 0 \le c < n_{cells} : \\ M(j,c) := \begin{cases} M(j,c-1) & \textbf{if } (c > 0) \wedge S(j,c-1) \\ c & \textbf{else} \end{cases} \tag{9}$$

Equation 9 is parallelized over layers j but remains sequential over cell numbers c since we need to know the preceding entry $M(j, c-1)$ to compute $M(j,c)$.

The table with S-connections S and merge map M for the GPU-SCY-tree in Figure 3 are shown in Figure 5. S contains an S-connection in dimension 1, starting at cell 0. Therefore, in M, a merge sequence starts at cell 0, continuing to cell 1.

Avoiding merge sequences. The merge map M allows us to avoid the merge sequence and instead directly include nodes that would be in the final restricted SCY-tree for a given descriptor. More concretely, when checking if a node i on the restricted dimensions $d = dims(j)$ matches the descriptor, we instead look up the restricted dimension and the current node's cell number in the merge map M. We treat node i as a match if $M(j, ce(i))$ matches the cell number c of the descriptor. This changes Equation 2 into:

$$s\_incl(j,i,c) := (M(j, ce(i)) = c) \wedge (\neg is\_S(i)), \tag{10}$$

and Equation 7 into

$$\forall 0 \le j < n_{dims}, 0 \le c < n_{cells}, p < n_{pts} : \\ incl_{pts}(j,c,p) := \begin{cases} incl(j,c,pl(p)) & \textbf{if } j < n_{dims} - 1 \\ M(j,c,ce(pl(p))) = c & \textbf{else} \end{cases} \tag{11}$$

E.g. for descriptor (1, 0), we now also treat node 7 in Figure 3 and 5 as a match, since cell 1 in dimension 1 has a merge sequence starting at cell number 0.

Since nodes on the restricted dimension are not included, nodes directly below that dimension will become their grandparents' children instead. This implies that the grandparent can end up with multiple children with the same cell number. Nodes with the same parent and cell number would have been merged in INSCY and must also be merged in GPU-INSCY to ensure that INSCY and GPU-INSCY still compute the same final restricted SCY-trees. However, INSCY merges these one by one and GPU-INSCY merges them all simultaneously. In Figure 5, nodes 14 and 16 will now both be children of node 2, and they have the same cell number, so they must be merged.

Merging nodes can propagate the problem of children, with the same cell number, down towards the leaves. We merge such nodes during our new restrict phase. We keep track of nodes that need to be merged in the restricted SCY-trees by computing two things: each node's new parent $n\_pa \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{nodes}}$ and the node's new children $n\_ch \in \mathbb{N}^{n_{dims} \times n_{cells} \times n_{nodes} \times n_{cells} \times 2}$. Examples of both arrays are shown in Figure 5. All entries of n_pa and n_ch are initialized to -1. For each descriptor, n_pa holds the new parents of all nodes. Likewise for n_ch, except that we make room for all possible children by $n_{cells} \times 2$. A node can have two types of children: normal or S-connector nodes. For both types, we can have a node for each cell. To look up the type of a node we use:

$$S\_idx(i) := \begin{cases} \mathbf{0} & \textbf{if } co(i) \geq 0 \\ \mathbf{1} & \textbf{else} \end{cases} \tag{12}$$

Merge representatives. When merging nodes in the SCY-tree, we pick one of the nodes to be the representative, which is the node that will actually be included in the final restricted SCY-tree. We will lookup the representative node $rep(j, c, i)$ by

$$rep(j, c, i) := n\_ch(j, c, n\_pa(j, c, i), ce(i), S\_idx(i)).$$

If a node should be represented in the final restricted SCY-tree we say that it is fused into that SCY-tree. We call it fused if it is either merged or included in the SCY-tree. If a node is merged into the SCY-tree, the count of points and children is added to the representative node. In Figure 5, nodes 14 and 16 should be fused, but only node 16 is included as the representative.

We assign a new parent to all nodes that are fused into the final restricted SCY-tree. This implies that iff n_pa has a value that is not -1, the associated node has been fused into the final restricted SCY-tree. Notice that we can use $n\_pa(j, c, i) \geq 0$ to check if the parent has been fused instead of just checking if it has been included $incl(j, c, i)$.

When identifying the new parent of a node i, below the restricted dimension, we look up which node the old parent has been merged into. This will be one of the children of the new grandparent of node i, which is identified as the representative node for the parent:

$$\begin{aligned} &\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, 2 \leq k < n_{dims} - j, \\ &\quad la(j+k) \leq i < la(j+k+1), n\_pa(j, c, pa(i)) \geq 0 : \\ &\qquad n\_pa(j, c, i) := rep(j, c, pa(i)). \end{aligned} \tag{13}$$

When computing the new parent for nodes just below the restricted dimension, we need to skip the nodes on the restricted dimension, since the restricted layer is removed from the result. However, for a node above the restricted dimension, there are no changes. Therefore, no merge of nodes can occur, and we do not need to check which child has been picked:

$$\begin{aligned} &\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, \\ &\quad la(j+1) \leq i < la(j+2), s\_incl(j, pa(i), c) : \\ &\qquad n\_pa(j, c, i) := pa(pa(i)). \end{aligned} \tag{14}$$

E.g., the parent of node 14 is node 6, and the parent of node 6 is node 2. Therefore, the new parent of node 14 is node 2.

For all nodes above the restricted dimension, we do not change the child-parent relationship, and they can be copied in parallel.

$$\begin{aligned} &\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, 1 \leq k < j, \\ &\quad la(j-k) \leq i < la(j-k+1), I(j, c, i) : \\ &\qquad n\_pa(j, c, i) := pa(i), \\ &\qquad n\_ch(j, c, pa(i), ce(i), S\_idx(i)) := i. \end{aligned} \tag{15}$$

Below the restricted dimension, we need to decide which of the merged nodes is the representative. It is not important which of the nodes is picked, but all threads involved in the merge must agree on just one node. We do this by letting each node i, that is fused, write its id as the representative, i.e., the new child:

$$\begin{aligned} &\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, 1 \leq k < n_{dims} - j, \\ &\quad la(j+k) \leq i < la(j+k+1), n\_pa(j, c, i) \geq 0 : \\ &\qquad rep(j, c, i) := i. \end{aligned} \tag{16}$$

We synchronize such that all threads see the same node id, and only include that node as the new child. E.g., in Figure 5 both node 14 and 16 would vote for themselves as the representative. In our example, node 16 was the last to write. Therefore, node 16 becomes the representative. This expands Equation 5 into:

$$\begin{aligned} &\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, la(j+1) \leq i < la(j+2) : \\ &\quad incl(j, c, i) := s\_incl(j, pa(i), c) \wedge (rep(j, c, i) = i), \end{aligned} \tag{17}$$

and Equation 6 into:

$$\begin{aligned} &\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, 2 \leq k < n_{dims} - j, \\ &\quad la(j+k) \leq i < la(j+k+1) : \\ &\qquad incl(j, c, i) := (n\_pa(j, c, i) \geq 0) \wedge (rep(j, c, i) = i). \end{aligned} \tag{18}$$

For a point, the placement can change since nodes are merged. Therefore, we check if the node where the point is placed is fused into the final restricted SCY-tree. This is the case if the node has been assigned a new parent. Equation 11 changes into:

$$\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, p < n_{pts} :$$

$$incl_{pts}(j, c, p) := \begin{cases} n\_pa(j, c, pl(p)) \geq 0 & \textbf{if } j < n_{dims} - 1 \\ M(j, c, ce(pl(p))) = c & \textbf{else} \end{cases} \tag{19}$$

Accumulating count. Now that we know which nodes are fused into the SCY-tree, we can accumulate the count of points in the subtree of each node i. For nodes on the same layer, the entry in n_co might be incremented by different threads. Therefore, we need to use atomic addition, implying that threads handling nodes on the same layer must be in the same thread block. For the layer just above the restricted dimension, we sum the old count of all children that are normal nodes and fused. If the parent is included and an S-connector node, we set the count to -1:

$$\forall 0 \leq j < n_{dims}, 0 \leq c < n_{cells}, la(j) \leq i < la(j+1), s\_incl(j, i, c) :$$

$$n\_co(j, c, pa(i)) := \begin{cases} n\_co(j, c, pa(i)) + co(i) & \textbf{if } co(i) \geq 0 \\ -1 & \textbf{if } co(pa(i)) < 0 \end{cases} \tag{20}$$

For the nodes on the remaining layers above the restricted dimension, we iteratively sum the new count of points of the children:

$$\begin{aligned}&\forall 0 \le j < n_{dims}, 0 \le c < n_{cells}, 1 \le k < j-1,\\ &\quad la(j-k) \le i < la(j-k+1), incl(j,c,i):\\ &\qquad n\_co(j,c,n\_pa(j,c,i)) :=\\ &\qquad\quad + \begin{cases} n\_co(j,c,pa(i)) + n\_co(j,c,i) & \textbf{if } co(i) \ge 0\\ -1 & \textbf{if } co(pa(i)) < 0 \end{cases}\end{aligned} \tag{21}$$

For all layers below the restricted dimension, the new count is a sum of the old counts of all fused nodes:

$$\begin{aligned}&\forall 0 \le j < n_{dims}, 0 \le c < n_{cells}, 1 \le k < n_{dims} - j,\\ &\quad la(j+k) \le i < la(j+k+1), n\_pa(i) \ge 0:\\ &\qquad n\_co(j,c,rep(j,c,i)) := \begin{cases} -1 \textbf{ if } co(i) < 0\\ n\_co(j,c,rep(j,c,i)) + co(i) \textbf{ else} \end{cases}\end{aligned} \tag{22}$$

Overview of restrict and merge operations. To summarize, the restricting and merging for all descriptors is done by

- Initialization: Each entry of $incl$, $incl_{pts}$, idx, idx_{pts}, and n_co is initialized to 0. Each entry of n_ch and n_pa is initialized to -1.
- Step 1: Compute for which descriptors the associated SCY-trees will be merged using two kernels; one that checks for each descriptor if there is an S-connection, using Equation 8, and one that uses this information to compute which SCY-trees will be merged, using Equation 9.
- Step 2: Compute which nodes are included in the final restricted and merged SCY-trees, and accumulate the count of points in the subtrees. We compute the inclusion in the restriction using five kernels. First, directly above the restricted dimension we use Equations 3, 15, and 20, second, for the remaining layers above we use Equations 4, 15, and 21, third, directly below we use Equations 17, 14, 16, and 22, fourth, for the remainder below we use Equations 18, 13, 16, and 22, and at last, we compute inclusion of points by checking if the leaf-node where the point is placed is included using Equation 19.
- Step 3: We now know which nodes and points are included in the final restricted SCY-trees. We do an inclusive scan and decrement each entry with 1 to compute the new indices for nodes idx and points idx_{pts}. This is also used to allocate the arrays for all final restricted SCY-trees.
- Step 4: All needed information has been precomputed, and we now copy all nodes, points, dimensions, and restricted dimensions to the final restricted SCY-trees. Each copy is independent and can be done completely in parallel.

4.2 Density-based clustering on the GPU

In this section, we discuss how to find the subspace clusters for all points in each SCY-tree. For each subspace region, the clustering process of INSCY is similar to that of DBSCAN [12]. The main difference is that INSCY supports different density measures and that clustering is done in a subspace projection. DBSCAN, and other density-based clustering methods, find clusters by expanding chains of density-connected points. This is a sequential process that we would like to replace with a parallelized process.

As discussed in related work, G-DBSCAN [5] is a competitive parallelization of full-space DBSCAN with rectangle kernel for density assessment. To support INSCY subspace clustering and further improve runtime performance, we introduce three major algorithmic solutions: supporting a different unbiased, i.e., subspace-dependent density-measure, reduced neighborhood searches, and expanding several clusters at once.

Precomputing the neighborhoods. To compute the neighborhood without allocating worst-case sizes, G-DBSCAN first computes the neighborhoods' size, then allocates space, and at last populates the neighborhoods with the neighboring points. For GPU-INSCY, the neighborhood of each point in all SCY-trees can be computed independently of other points and can therefore be computed in parallel over different thread blocks.

GPU-INSCY additionally takes advantage of already having computed the neighborhoods in the lower-dimensional subspace projections of the current subspace. Since adding a dimension to a subspace only increases the distance between points, previous neighborhoods can be used to bound the search for neighbors effectively. We demonstrate that this is an efficient strategy in the experiments, see Section 5.

Collecting the clusters. Using the precomputed neighborhoods, G-DBSCAN proceeds as follows. While there are still unclustered points, pick a random point to expand a cluster from. While that cluster is still being expanded, look at all points in parallel. If a point has just been added to the cluster, add its neighbors that have not yet been clustered to the current cluster. Since G-DBSCAN run in parallel for all points, but only a few points actually expand a single cluster each iteration, many threads are left idle. We suggest instead that a point adds itself to a cluster. Furthermore, we expand all clusters simultaneously for each point p in parallel as threads and over each descriptor in parallel as blocks. We precompute for each point if it is dense and only perform the following for dense points. For each descriptor, let $C \in \mathbb{N}^{n_{pts}}$ be clustering labels for each point p in the SCY-tree associated with that descriptor. Start by assigning all points to a singleton cluster, letting the cluster id be the point id, $C(p) := p$. While any cluster is still being expanded, look at all points in parallel. If the point p can reach a cluster with a lower cluster-id through its neighborhood, add the current point to that cluster $C(p) := \min_{q \in N_\varepsilon(p) \cup \{p\}} C(q)$. Between each iteration, we synchronize such that all threads know if any cluster has been expanded. For each iteration we check for all points if they can be expanded, thus we ensure that all density connected clusters have been found.

Clustering of each subspace region (SCY-tree) is independent of each other since the subspace regions are not S-connected, meaning that no density-connected clusters can span multiple subspace regions. Therefore, since no communication is needed, we can compute the clustering in parallel for each SCY-tree using different thread blocks. However, since we want to perform all clusterings in parallel and each SCY-tree must have been pruned first, we can only perform clusterings in parallel at the end.

4.3 Pruning on the GPU

As previously mentioned, we parallelize both pruning phases. In the interest of space, we keep the discussion brief as it follows the same approach as for restricting and merging the GPU-SCY-trees.

When pruning the recursion, we compute in parallel for each point if it is weak-dense. If it is not, mark it as not-included and propagate the count up in the SCY-tree layer by layer. We also parallelize the propagation over all nodes on a layer. If the count in the root is below min_C, then we do not continue with the recursion for this SCY-tree.

Pruning for redundancy is done as follows. For each superspace of the current subspace, we execute three kernels: Find the size of each cluster, find all clusters that overlap with points in the current SCY-tree, and find the smallest cluster that overlaps with the points in the current SCY-tree. Update the largest smallest cluster *max_min_cluster* that overlaps with the current SCY-tree. If the number of points in the SCY-tree scaled by the parameter r is smaller than *max_min_cluster*, we do not perform clustering for this SCY-tree because it can only contain redundant clusters.

4.4 Trading off speed for memory usage

Each recursive call of GPU-INSCY is parallelized over all descriptors simultaneously. This requires that we keep all final restricted SCY-trees, neighborhoods, and clusters in memory for all descriptors. However, memory on the GPU is limited, putting a bound on how large inputs we can process in parallel. There is, therefore, a natural trade-off between memory usage and how many descriptors we efficiently parallelize over simultaneously. To support efficient processing of larger inputs, we devise a version of GPU-INSCY called GPU-INSCY-memory that iterates over subsets of descriptors that we then parallelize over. We study this trade-off experimentally in Section 5.

5 EXPERIMENTS

5.1 Experimental setup

We conduct experiments for comparison of GPU-INSCY with INSCY on synthetic and on real-world data, and study impact of parameters on a workstation with Intel Core i7-9750HF CPU 2.60GHz × 12 cores, 16 GB RAM, GeForce GTX 1660 TI 6 GB dedicated RAM. The large scale experiments in Section 5.4 are executed on NVIDIA TITAN V 12 GB dedicated RAM, Intel Core E5-2687W 3.100GHz × 10 cores, 400 GB RAM.

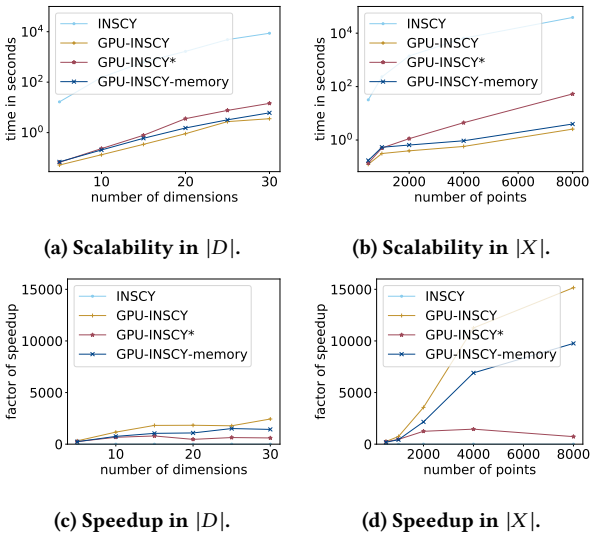
We use a search-tree for efficient neighborhood search in INSCY, which provides a large speedup and makes it a fairer comparison. We have experimentally validated that GPU-INSCY and INSCY produce identical subspace clusterings. Plots and further details have been omitted due to the space limit. We provide our source code at: https://github.com/jakobrj/GPU_INSCY.

5.2 Comparison with INSCY.

For subspace clustering, the dimensionality and size of the dataset are dominating factors regarding runtime. Especially dimensionality since, as the number of dimensions increases, the number of possible subspaces increases exponentially.

To compare INSCY and GPU-INSCY and the impact of input data, we use the data generator provided by [1] to generate synthetic datasets with dense clusters in arbitrary subspaces that may overlap and have a small percentage of noise. As in [7], we generate different datasets with four hidden subspace clusters. All runtimes are averages of three runs on datasets with the same generator settings. All dataset have been min/max-normalized. The default parameters for INSCY and GPU-INSCY in these experiments are $F = 1$, $R = 1$,$\mu = 8$, $\varepsilon = 0.01$, $n_{cells} = 4$, and min_C is set to 5% of the data points.

To analyze components of our algorithm, we also test GPU-INSCY* and GPU-INSCY-memory. GPU-INSCY* is a version of GPU-INSCY that does not bound the neighborhood search, so that we can study the effect of bounding the neighborhood search. GPU-INSCY-memory is described in Section 4.4. For our experiments we group the descriptors by the dimensions such that each iteration of the recursions is only parallel over the cells.



(a) Scalability in $|D|$. (b) Scalability in $|X|$.

(c) Speedup in $|D|$. (d) Speedup in $|X|$.

Figure 6: Scalability in size and dimensionality

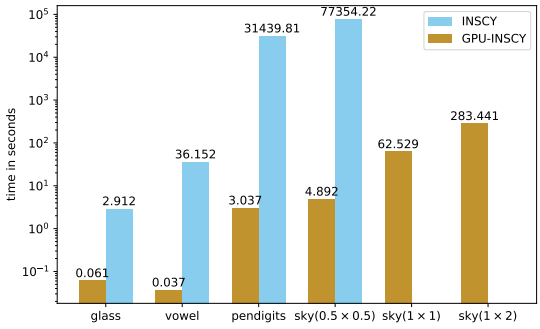


Figure 7: Real world data; INSCY aborted after 24 hours

Comparison of INSCY and GPU-INSCY. In Figure 6a, the running time for INSCY is decent for lower dimensions but increases rapidly for higher dimensions. GPU-INSCY reduces the running time to a point where it is faster to find subspace clusters for 25 dimensions using GPU-INSCY than finding subspace clusters for two dimensions using INSCY. In fact, in Figure 6c, the speedup of GPU-INSCY relative to INSCY keeps increasing. For 30 dimensions we achieve a factor of speedup of more than 2000×. A similar effect is observed for increasing the number of points. In Figure 6b, INSCYs runtime again increases faster than for GPU-INSCY. In Figure 6d, we see that the speedup becomes a factor of several thousand. This speedup is much higher than expected for the relatively low number of 1536 cores on our GPU.

Comparison of versions of GPU-INSCY. As mentioned in Section 4.2, we attribute this dramatic speedup to our bounding of the neighborhood searches. This effect is also clear in Figure 6c and 6d, where we see that GPU-INSCY* achieves a 500-1000× speedup, corresponding to a good use of the cores, and GPU-INSCY achieves a substantially larger speedup of up to 14'000× obtained by our improved neighborhood search. GPU-INSCY-memory allows us to run on larger datasets, with only a slight reduction of factor 2 in speedup, which is a reasonable trade-off.

5.3 Real world datasets

We also demonstrate GPU-INSCY speedups for real-world datasets. We report runtimes on the three datasets (glass, vowel, pendigits) [23] also studied in [7, 8]. The glass dataset $X_{glass} \in \mathbb{R}^{214\times9}$, vowel $X_{vowel} \in \mathbb{R}^{990\times10}$, and pendigits $X_{pendigits} \in \mathbb{R}^{7494\times16}$. Furthermore, we also evaluate on a more sizable higher dimensional real world data set, part of the SkyServer dataset[27] that contains measurements of objects in the sky, e.g., stars and galaxies. We select three different areas of size 0.5×0.5, 1×1, and 1×2, measured in spherical coordinates (RA/Dec): $X_{sky(0.5\times0.5)} \in \mathbb{R}^{7253\times17}$, $X_{sky(1\times1)} \in \mathbb{R}^{29627\times17}$, and $X_{sky(1\times2)} \in \mathbb{R}^{59285\times17}$. Experiments are aborted if they run for more than 24 hours, as INSCY does for larger setups. In Figure 7, we see that we obtain high speedups on all datasets, but much higher for larger datasets up to 15′000× speedup.

5.4 Effect of parameters

In this section, we study the effect of parameters for the density criterion, ε, μ, F and the model parameter n_{cells}.

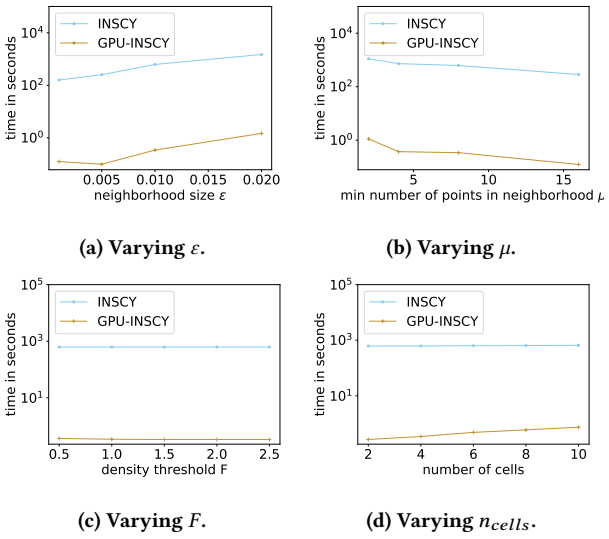
In particular, the parameters for the density criterion are expected to impact the running time. Especially the neighborhood radius ε is interesting since GPU-INSCY uses a strategy for reducing the neighborhood search that INSCY does not employ. The bigger the part of the subspace region that the neighborhood radius covers, the less we save by reducing the search area for the neighborhoods. Therefore, we expect that GPU-INSCY will obtain the greatest speedup for smaller values of ε. In Figure 8a, we study the range of ε between 0 and 0.02, and see that this is the case, but that the speedup remains large for the entire range.

The minimum number of points in the neighborhood μ and density threshold F only affect the number of points that are dense and weak-dense. The fewer points that are dense or weak-dense, the fewer points INSCY and GPU-INSCY need to process. As this is the same fraction of points for both INSCY and GPU-INSCY, we, therefore, expect to see a similar reduction in time for both algorithms. For μ, we study the range between 2 and 16, as this parameter is intended as a cut-off for avoiding tiny subspace clusters in very high-dimensional subspace projections (called pseudodense in INSCY). The factor F that governs the extent to which expected density is exceeded is evaluated in the range between 0.5 and 2.5. A value of 0.5 implies that we only expect a point to be half as dense as the expected density, which is a very low criterion, and 2.5 is more than twice the expected density, which is rather high. In Figure 8b and 8c, we see that the speedup for the density parameters remains stable for both criteria. As expected, we see that the running time decreases equally for both INSCY and GPU-INSCY as μ increases.

The parameter number of cells n_{cells} does not change the result, but only how we partition the subspace into cells and regions. We can, therefore, pick whichever number of cells INSCY or GPU-INSCY perform the best at. In Figure 8d, we study a range between 2 and 10 cells. Here both INSCY and GPU-INSCY perform best at a lower number of cells, especially GPU-INSCY.

5.5 Scalability and different distributions

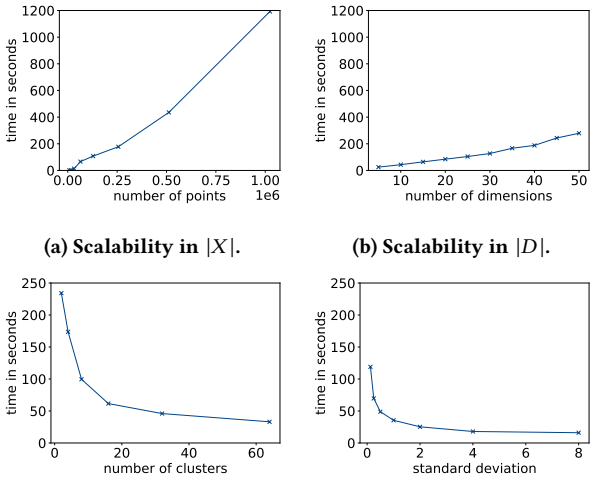
We evaluate scalability and different data distributions for GPU-INSCY alone. The running time of INSCY quickly becomes too high, e.g., more than 10 hours for 8000 points and 15 dimensions, which makes experiments for large inputs infeasible. In this section, we use GPU-INSCY-memory.



(a) Varying ε. (b) Varying μ.

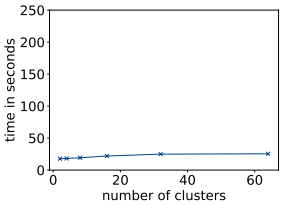
(c) Varying F. (d) Varying n_{cells}.

Figure 8: Runtimes for different parameter values



(a) Scalability in $|X|$. (b) Scalability in $|D|$.

(c) Scalability in number of clusters. (d) Scalability in cluster spread (standard deviation).



(e) Scalability in number of clusters with stable density.

Figure 9: Runtimes for scalability experiments

To test various distributions, we use the generator provided by [9], but modify it to generate clusters in random subspaces and not just the first k dimensions. The default settings used for the dataset generator are 64‘000 points with 4000 points for each cluster, except 1%, which is uniformly distributed noise. The dataset values range from −100 to 100, and the full space consists of 15 dimensions. Each cluster is normally distributed with a

standard deviation of 0.3 in a random 3-dimensional subspace. All datasets have been min/max-normalized. The default parameters for GPU-INSCY in these experiments are $F = 0.1$, $R = 1$, $\mu = 1$, $\varepsilon = 0.0003$, $n_{cells} = 4$, and $min_C = 500$ points.

Scalability. Figure 9a shows runtimes with increasing dataset size $|X|$ up to 1‘024‘000. The figure shows that GPU-INSCY performs subspace clustering on 1‘024‘000 points in less that 20 minutes. We also run experiments for increasing dimensionality $|D|$ up to 50, as shown in Figure 9b. GPU-INSCY can perform subspace clustering in 50 dimensions (and on 64‘000 points) in less than 6 minutes.

Data distribution. We evaluate performance on data with different distributions using the same setting as for scalability. In Figure 9c, we increase the number of clusters, keeping cluster distribution (standard deviation) and total number of points fixed. As we can see, large numbers of clusters further reduce the runtime of GPU-INSCY, as it finds fewer points in each neighborhood when the number of points per cluster decreases. In Figure 9d, we increase the spread of clusters (standard deviation). Again, the runtime of GPU-INSCY further improves, as neighborhoods are again less populated. Finally, we conduct an experiment with stable density. As the number of clusters is doubled, we increase cluster density accordingly by halving standard deviation. As Figure 9e confirms, similar density results in stable runtime when scaling number of clusters.

To summarize, the trend is that a lower density implies fewer points in each neighborhood and, therefore, a lower runtime. This means that GPU-INSCY scales particularly well for large numbers of clusters and clusters that are spread.

Overall, GPU-INSCY outperforms INSCY by two-four orders of magnitude with respect to runtimes for all tested settings. Even on our small GPU, we measure the running time in seconds instead of hours for smaller datasets (< 10‘000 points and 15 dimensions) and minutes instead of days for larger datasets.

6 CONCLUSION

In this paper, we propose GPU-INSCY, a novel GPU-parallel algorithm for dimensionality-unbiased density-based subspace clustering, following INSCY. GPU-INSCY outperforms INSCY by several orders of magnitude. To achieve this, we utilize GPU cores by restructuring both the algorithmic processing and the data structure SCY-tree used in INSCY to fit the GPU computational model. Furthermore, GPU-INSCY proposes a further reduction of the time spent on neighborhood searches. Our experiments show that GPU-INSCY scales well w.r.t. dimensionality and size of the dataset, and compared to INSCY, the gap even continues to grow with the scale of data.

ABSTRACT

Graph databases are used for different applications like analyzing large networks, representing and querying knowledge graphs, and managing master data and complex data structures. Besides graph analytics, the transactional processing of concurrent updates and queries represents a challenging data management task. In this paper, we investigate the usage of persistent memory as a very promising technology for graph processing. We present a novel architecture for transactional processing of queries and updates on a property graph model that exploits and addresses the specific characteristics of persistent memory by hybrid storage and memory management as well as a just-in-time query compilation approach. Our experimental evaluation on interactive short read and update query workloads show that PMem-based systems that are well-designed to exploit PMem characteristics outperform traditional disk-based systems significantly and have only a small overhead compared to DRAM-only systems. Moreover, the evaluation shows that JIT compilation brings performance benefits especially when an adaptive compilation approach is leveraged to hide the overhead of compilation as well as the latency of PMem.

1 INTRODUCTION

Graph databases represent an important class of NoSQL systems with numerous flavors, including systems for analyzing large graphs, systems for querying knowledge bases, and systems supporting updates on graphs and navigational queries. They are designed for different graph data models ranging from RDF triples to property graph models, as well as different processing models from database query processing to approaches like the bulk synchronous parallel (BSP) model.

The numerous available systems mainly adopt the typical architectures of database systems, i.e., traditional disk-based architecture, in-memory architecture or scalable, distributed solutions. Graph data are either stored in disk-based data structures and loaded into memory for processing or kept directly in in-memory structures (without requiring to load data during startup) while using techniques like logging to allow for persistent updates.

In this work, we present a novel architecture for graph databases based on persistent memory (PMem). PMem – also known as non-volatile memory (NVM) or storage-class memory (SCM) – is one of the most promising trends in hardware development which have the potential to hugely impact database system architectures. Characteristics such as byte-addressability, read latency close to DRAM but with read-write asymmetry, and inherent persistence open up new opportunities for database systems. Specifically, Intel's Optane DC Persistent Memory Modules (DCPMMs) are already available on the market and supported by the Persistent Memory Development Kit (PMDK) [17]. Several studies, as well as our experiments, have identified the following characteristics of this technology (we elaborate these in more detail in Section 3):

(C1) PMem has a higher latency and lower bandwidth than DRAM.
(C2) Reads and writes on PMem behave asymmetrically.
(C3) DCPMMs internally work on 256-byte blocks.
(C4) Failure atomicity is only guaranteed for 8-byte aligned writes.

The focus of our work is an architecture for hybrid transactional/analytical processing (HTAP) on a property graph model. Transaction support covers insert/update/delete operations on nodes, relationships, and their properties with ACID guarantees. Furthermore, we support Cypher-like navigational queries. In this paper, we particularly focus on data structures and techniques for query and transaction processing in graph databases exploiting PMem and addressing the characteristics (C1)-(C4) mentioned above. Although we aim for HTAP, we do not consider graph analytics in this paper yet. Exploiting PMem for graph analytics is discussed by other researchers, e.g., in [13]. Our contributions are as follows:

- We present the architecture of an HTAP graph engine with storage structures designed for PMem, primarily taking (C1)-(C3) into account.
- We discuss the implementation of a timestamp ordering-based multiversion concurrency control (MVTO) protocol optimized for PMem addressing (C4).
- We describe our just-in-time (JIT) query compilation approach for compiling graph queries into machine code to hide the higher latency of PMem as described in (C1).

Thus, the novelty of our work lies in the design, adaptation as well as evaluation of transaction and query processing techniques to leverage the idiosyncrasies of persistent memory for graph databases.

2 RELATED WORK

Several of the approaches presented in this paper are based on insights from previous work. In particular, the lessons learned regarding the new concepts of data structures for PMem had a

major impact on the design decisions for our graph engine. There is, to our knowledge, no transactional graph system or JIT query compilation approach targeting persistent memory, yet. Hence, we approach the subject from three directions: general graph management, PMem-aware data structures and storage engines as well as query compilation.

Graph Management. For graph data management, numerous data models and systems have been proposed in the past. Among the several database models for graph data [3], RDF for the Semantic Web and property graph models are the most prominent. On top of these, query languages like SPARQL for RDF triple data, diverse SQL dialects, and dedicated languages like Cypher[1] and Gremlin [36] have been developed. The SQL standardization committee is currently working on standardizing the graph query language GQL.

Depending on the supported data model and query language, graph database systems are either special-purpose systems such as triple stores for RDF like Virtuoso, native stores for property graphs e.g., Neo4j, relationally-backed approaches such as DB2RDF [7] and EmptyHeaded [1]; or extensions of SQL systems like Grail [11] and SAP HANA [37]. Here, standard DBMS implementation techniques are used for data storage, indexing, transaction management, and query processing. Particularly, traversal operations [32], as well as support for graph analytics [29, 38], play an important role. However, only very few approaches try to support HTAP workloads (TigerGraph, Neo4j) and to our best knowledge, no established graph system is utilizing PMem yet [6].

Recently, however, Gill et al. [13] investigated the application of DCPMMs in Memory mode for running graph analytics. They evaluated large scale data sets on existing graph frameworks and demonstrated that their NUMA-aware algorithms on cheaper single machine setups with DCPMMs can outperform more expensive DRAM-only cluster setups. With Sage [9], the authors have shown that the AppDirect mode of DCPMMs in combination with sophisticated algorithms can even achieve a better performance than an unmodified in-memory graph database used on PMem in Memory mode. They especially address the asymmetry of PMem by introducing the parallel semi-asymmetric model. Here, the entire graph is stored as a read-only copy in PMem and a smaller mutable part in DRAM. A volatile auxiliary structure keeps track of deleted edges for graph filtering. Since the focus is on parallel analytical queries, we assume that no transactional updates are possible. In this paper, we want to make the appropriate contribution in this regard.

PMem-aware Storage Designs. Researchers recently started adapting existing data structures to PMem. This includes several variants of the B$^+$-Tree [8, 43], hybrid variants like the FPTree [31], the LB$^+$-Tree [27], DPTree [49], and HiKV [47], as well as LSM-Tree variations [19]. There are also latch-free B$^+$-Tree variants targeting modern hardware, such as the Bw-Tree [26, 45] and the BzTree [4]. While the former addresses multi-core systems with flash storage, the BzTree is explicitly designed for PMem. Apart from the individual data structures, some approaches for PMem-based storage engines have been proposed. SOFORT [30] is a columnar transactional storage engine leveraging PMem by minimizing logging and updating data in place, aiming for mixed OLAP and OLTP workloads. Peloton [33] is another relational DBMS engine already considering PMem by applying write-behind logging [5]. The basic idea is to write and flush all changed entries in-place to PMem during commit. A more recent proposal is the key-value store RStore [25]. It opts for a log-structured design with an index. It utilizes linked and fix-sized append-only blocks in PMem. Once a block is full, it is considered immutable and indexed in a volatile tree which is rebuilt during recovery. Additionally, RStore employs partitions that are owned by only one thread at a time, each having its own log to parallelize recovery.

JIT Query Compilation. Similarly, there are numerous works on query compilation techniques. Neumann [28] presented a query compiler architecture using the LLVM framework[2] to generate and compile code for queries in the HyPer database. Based on this, Kohn et al. [21] proposed an approach to mask the compilation time by compiling the query in the background while interpreting it. They further improve the efficiency by using different execution modes depending on the query type. There are also works that try to provide a lightweight approach, apart from LLVM. An alternative approach, LegoBase, provides a query compiler that generates high-level code in multiple steps, where each step replaces declarative components of the query with imperative code [41]. Funke et al. [12] proposed a lightweight intermediate representation (IR) to reduce compilation times for queries by estimating value lifetimes before code generation. The Voodoo IR [35] is a declarative algebra for utilizing many-core architectures and GPUs by generating OpenCL code. Although these approaches are designed for relational DBMSs, query compilation is also applied in several graph DBMSs, like TigerGraph and Neo4j. However, while JIT query compilation is a broad research topic, there is presently no system that utilizes it to hide the memory access latency of PMem.

3 PERSISTENT MEMORY SPECIFIC DESIGN GOALS

This section aims to summarize the observations of several studies as well as our experiments regarding the characteristics and challenges introduced by PMem – in particular, Intel's Optane DCPMMs. Subsequently, we derive general design goals for systems trying to integrate PMem in their hardware landscape. We hope they help others to avoid common pitfalls when conceiving new efficient systems for modern storage hierarchies.

3.1 Characteristics and Challenges

The first three items presented are specific characteristics of Intel's DCPMM technology, while the remaining are explicit challenges that mostly result from PMem and other system peculiarities.

- **(C1) PMem has a higher latency and lower bandwidth than DRAM.** Random access read latency and the read bandwidth of PMem is worse than DRAM by a factor of about three. Persistent writes are also slower than writes to DRAM. PMem bandwidth is about 7 × lower than that of DRAM [42, 48].
- **(C2) Reads and writes on PMem behave asymmetrically.** This concerns several aspects, namely performance, energy consumption, and cell wear. Asymmetrically slower writes cost more energy and lead to wear.
- **(C3) DCPMMs internally work on 256-byte blocks.** They utilize a write combining buffer that is used to reduce

[1] https://www.opencypher.org

[2] http://llvm.org/

write load by trying to combine four cache lines into one 256-byte block write. Interestingly, read operations also benefit when a multiple of the block size is used [42, 48].

(C4) Failure atomicity is only guaranteed for 8-byte aligned writes. The largest failure-atomic store instruction covers only 8 bytes of data, aligned on an 8-byte boundary. Anything larger has to be implemented in software. This means that inconsistencies of data structures due to partial changes in case of system failures and reordering of instructions by the compiler or the CPU have to be avoided.

(C5) PMem allocations are expensive. Compared to DRAM allocations, PMem allocators such as the PMDK allocator need significantly more time [14, 15, 24]. This is mainly due to the necessity of cache line flushes and recovery measures. In conjunction with the higher latencies of PMem, allocations can be –depending on the number of threads– up to 8× slower than on DRAM [24].

(C6) Dereferencing persistent pointers can prevent optimizations. A persistent pointer is a 16-byte structure consisting of a pool identifier (similar to a file path) and an offset in this pool. It was introduced in PMDK and keeps its validity across application restarts. Since this concept of persistent pointers is not integrated into compilers (yet), their handling cannot be automatically optimized as it is the case for volatile pointers [39].

3.2 Design Goals

From the above characteristics and challenges, we can more or less directly formulate corresponding general design goals as follows. Apart from the generic usability of these goals, we will also use them as a foundation for the design decisions in the next section.

(DG1) Algorithmically save writes (C1 & C2). This was one of the first common goals when PMem came up. The idea is to reduce the number of writes by trading them off for more reads. Furthermore, certain intermediate results can be kept in DRAM instead of PMem. In practice, it has been shown that not the number of writes but rather the number of flushed cache lines is decisive.

(DG2) Opt for a DRAM/PMem hybrid storage design (C1 & C2). It has been shown that a pure PMem-only architecture causes too much performance degradation compared to its DRAM counterpart. A hybrid DRAM/PMem approach is therefore highly recommended when seeking the best performance and still requiring persistence [14, 15].

(DG3) Optimize the access granularity to 256 bytes (C3). Besides, the data structures should be aligned to cache lines. Only then a sequential pattern and correspondingly the peak bandwidth can be reached. Everything else can be considered as random access.

(DG4) Prefer failure-atomic writes over logging or shadowing (C4). For this purpose, flushing of cache lines via the `clwb` (cache line write back) instruction and barriers such as `sfence` (store fence) have to be used. However, the number of such barriers should be minimized for best performance. PMDK transactions can be used to simply and universally achieve failure atomicity. However, for performance-critical sections, the underlying logging and snapshotting approach can lead to excessive overhead. Thus, in the long run, an individual realization of failure atomicity with optimally arranged 8-byte stores, `clwb` instructions, and barriers should be preferred.

(DG5) Use group allocations and reuse blocks of memory instead of deallocating (C5). Not every new record in a system should be associated with an allocation. The less frequent allocation of larger blocks or groups can amortize the overhead. Deallocating can also be replaced by suitable free space management. Since they increase the number of allocations, copy-on-write techniques should be replaced by in-place updates or reuse a preallocated space.

(DG6) Avoid dereferencing of persistent pointers (C6). Persistent pointers should preferably only be used during application (re)start for initialization. Afterward, the current valid virtual pointer or application-specific offsets should rather be used. Alternatively, the external location could be converted to a virtual reference once before using it multiple times. In addition, pointer chasing should be avoided as well, as shown in [14, 15].

4 STORAGE MODEL

Essentially, there are two classes of graph data models, namely RDF triple stores and property graphs. RDF stores express everything as triples (subject-predicate-object) which link two nodes or a node to a property value (also called resources and literals). Predicates can therefore be relationships or property keys. Property graphs, on the other hand, consist of explicit node, relationship, and property structures where the properties are directly assigned to a node or relationship. The RDF model creates a lot of redundancies, which could lead to additional write load, which in turn will most likely have a negative impact on PMem performance. Therefore we decided to opt for the property graph model, which is more compact, more expressive, and more efficient to query.

Data Model Definition. In the following, we adopt a property graph model where a graph $G = (N, R)$ consists of nodes N and directed relationships $R \subseteq N \times N$. Each node $n \in N$ is identified by a unique identifier $id : N \rightarrow ID$. Furthermore, a label (used, e.g., as a type descriptor) is assigned to each node and each relationship via a labeling function $l : \{N \cup R\} \rightarrow L$ where L is the set of labels.

Properties are represented as key-value pairs $(k, v) \in P$ with $P = K \times D$ where K denotes the set of property keys and D the set of possible values including numbers, strings, etc. To each node and relationship, a set of properties can be associated via $p : \{N \cup R\} \rightarrow \mathcal{P}(P)$ where $\mathcal{P}(P)$ denotes the power set of P.

4.1 Design Decisions

The above data model is implemented by storing the graph in node, relationship and property tables maintained in persistent memory. For efficient data access, the specific characteristics of current PMem technology as mentioned in Sections 1 and 3 have to be taken into account. The application of our derived design goals led to the following key design decisions:

(DD1) Each of the tables is managed as a **linked list of chunks** where a chunk is a fixed-sized array (cache-line aligned and a multiple of 256 bytes) of records. To reuse the

space of deleted records, standard free space management using a persistent list is implemented. This way, tables can dynamically and efficiently grow or shrink for updates, by allocating/deallocating chunks (DG3, DG5).

(DD2) A chunk stores **equally-sized records** of the same type (nodes, relationships, properties). Thus, records can be **addressed via their offsets**. Similar to a sparse index, an additional persistent lookup table allows efficient access to chunks based on the record offset (DG1, DG6). Note that we use array offsets because they can be represented as 8-byte integers instead of 16-byte persistent pointers. This not only saves space but also allows for **failure-atomic stores** and avoids costly dereferencing (DG1, DG3, DG6).

(DD3) In order to represent nodes and relationships as equally-sized records, **properties are outsourced** to a separate table. Furthermore, all variable-length values (e.g., strings) are **dictionary encoded**. Both lead to a reduced number of write operations (DG1).

(DD4) The **connections** between nodes and their relationships as well as their properties are represented via array **offsets** instead of (persistent) pointers. Because relationships are directed, each node refers to its list of both outgoing and incoming relationships, also via offsets.

(DD5) The **storage model** is designed **hybrid** both for secondary indexes and for transaction management (DG2). Further details are provided below.

4.2 Key Data Structures

In the following, we give an overview of the key data structures to represent the property graph model and further structures necessary to realize our design decisions and achieve a great performance.

Nodes, Relationships, and Properties. Fig. 1 illustrates the primary storage structures of a persistent graph which we have implemented using Intel's PMDK [17]. The highlighted row illustrates a respective node or relationship record. On top of both the node and relationship table, an additional sparse index is used which maps the identifiers of the first record of each chunk to their corresponding memory location. For each chunk there is a bitmap to indicate free and occupied record slots, enabling an efficient reclamation of deleted entries. The chunks are linked by a persistent pointer to allow the scanning of all data. Node records consist of a label, the offset of the first incoming and first outgoing relationship, as well as the offset to their properties. Relationship records also have a label as well as the offset to their properties. Furthermore, they store the location of the source and destination nodes that they connect. Optionally, relationship records hold offsets to the next relationships of their source and destination node. Note that the records for nodes and relationships contain a few additional fields needed for transaction processing which are described in Section 5. In total, this results in a record size for nodes and relationships of 56 and 72 bytes respectively.

The properties are stored in a separate chunked table as key-value pairs. These are grouped in batches, each belonging to a single node or relationship, to obtain cache-line-sized records. In order to allow variable-length key-value pairs, string types are stored as dictionary codes. If there are more properties for a single node or relationship, the property record links to the next entry. These data structures resemble the typical storage layout

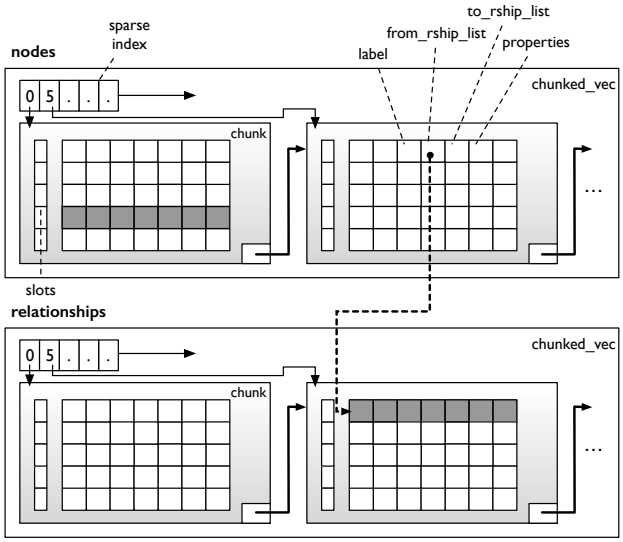

Figure 1: Graph data structures

of disk-based, table-oriented systems such as SQL databases or even graph databases like Neo4j. However, in our case, table chunks are not copied between disk and memory but instead accessed directly in PMem. In addition, nodes, relationships, and associated properties can be addressed individually via their identifiers/offsets.

Dictionary. As mentioned before, to allow for variable-length labels, property keys, and values, a dictionary is used. This compresses strings and, thus, reduces space and write overhead as well as ensures that records remain addressable by offset. Furthermore, the comparison of codes instead of strings speeds up operators such as filters. The dictionary consists of two hash tables for bi-directional translation to make lookups fast. These must be kept persistent, in case of failure, since the codes and strings are not stored elsewhere. An alternative could be to only store one of the hash tables in PMem and rebuild the other DRAM-resident part. Depending on the workload (either more inserts or more queries), the more frequently used table should be kept in DRAM.

Hybrid Indexes. The table-based storage model is useful for lookups on physical node/relationship identifiers (which represent array offsets) as well as scan-intensive processing where large parts of the nodes or relationships are visited. However, for lookup queries on node/relationship properties, scans are too expensive. In order to accelerate these queries, we additionally provide B^+-Tree indexes. An index can be constructed on nodes with a given label and for a property. The values of these properties are used as keys in the index. Since the indexes are secondary data structures that can be rebuilt in the event of a failure, they do not have to be completely persistent. To still have a good compromise between recovery and query performance, we opted for a DRAM/PMem hybrid approach (selective persistence) similar to [18, 31, 47]. In particular, this means that the leaf nodes are stored in PMem and the inner nodes in DRAM, resulting in a maximum of one PMem-resident node being read per lookup (if not already cached by the CPU) and significantly reduced recovery time. This has an additional economic advantage since less DRAM is used, which we expect to be more expensive than

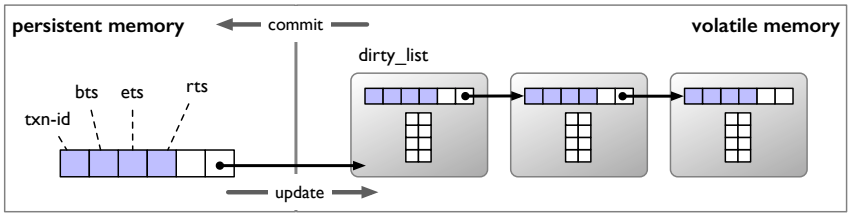

Figure 2: Structure of transactional data

PMem in the near future. In accordance with DG3, all nodes on PMem are cache-line-aligned and a multiple of 256 bytes. For analytical queries, multi-dimensional index structures optimized for PMem could also be used where properties represent the dimensions [18].

5 TRANSACTION PROCESSING

An HTAP architecture requires high-performance concurrency control mechanisms. Several studies in the past [34, 46] have shown that DBMSs with multi-version concurrency control (MVCC) exhibit higher concurrency than their single-version counterparts. Here, transactions can be concurrently executed on different versions of the same object, thus increasing the overall transaction throughput especially when the transactions are long-running and contention is high [22]. This also allows for scalability and efficient utilization of modern multi-core CPUs. MVCC is implemented differently by different DBMSs, each making certain design decisions in order to optimize for its target workloads. The interplay between these design decisions ultimately results in computation and storage overhead trade-offs. Below, we discuss how we implemented these MVCC design decisions in a PMem setting to achieve our design goals presented earlier in Section 3.

5.1 Concurrency Control Protocol

Existing concurrency control (CC) protocols such as two-phase locking (2PL), optimistic concurrency control (OCC), or timestamp ordering (TO) can essentially be used in a multi-version setting. We chose MVTO as our CC protocol. With our MVTO implementation, we support updates of an arbitrary number of objects within a single transaction and achieve snapshot isolation guarantees. Note, that we use MVTO here mainly as an example to evaluate how an MVCC protocol implementation can exploit and address the specifics of PMem. However, in principle, the main concepts should apply to implementations of other protocols too.

There is a transaction identifier (timestamp), `txn-id`, given to each transaction at the beginning of the transaction that uniquely identifies it. Each data object maintains meta-data fields for concurrency control purposes. To this end, we extend the data structures of nodes and relationships, as shown in Fig. 2, by additional *persistent* fields – `txn-id`, begin timestamp `bts`, end timestamp `ets` and read timestamp `rts` – and a volatile field – pointer. The `txn-id`-field is used for write-locking, by way of coordinating which versions are valid for which write-transactions. By default, it is set to zero except if the object is locked by a write-transaction, where it is set to the transaction's `txn-id` using a CaS instruction [22]. The begin timestamp and end timestamp fields mark the validity of an object for access by a read-transaction, while the read timestamp indicates the latest transaction that read it. The pointer field stores a *volatile* pointer to a list of dirty objects (i.e., in DRAM) to address (DG1) and (DG2). Alternatively, the `bts`, `ets`, and `rts` fields and perhaps also the `txn-id` of the current version could be moved to DRAM in order to reduce the persistent record size. These fields could then be re-initialized during recovery (or during the first access after a failure). However, this could also be disadvantageous because the transaction information of the current version would always have to be retrieved with another random read in DRAM.

Write transaction. A transaction T always updates the latest version of an object o. It creates a new version o_{i+1} of the object if no other transaction has a lock on o_i and o_i has not been read by a more recent transaction (i.e., the transaction identifier $id(T) > \texttt{rts}(o_i)$). Otherwise, T aborts. The `txn-id` field of o_{i+1} is set to $id(T)$. In case of an update, o_{i+1} is kept in the dirty list in volatile memory until commit. If the transaction inserts a new object, this object is already stored in the persistent array (i.e., in PMem), but still locked until the end of the transaction.

Read transaction. A transaction T reads version o_i of an object for which $id(T)$ is between the `bts` and `ets`, i.e., $\texttt{bts}(o_i) \leq id(T) < \texttt{ets}(o_i)$, and which is not locked by another active transaction. Thus, the object is accessed in PMem first (representing the most recent committed version) and if this is not the version valid for T then the dirty list in volatile memory is traversed to retrieve the correct version. In case of a lock held by another transaction, the transaction is aborted. Upon reading o_i, the `rts` field is updated to $id(T)$ unless $\texttt{rts}(o_i) \geq id(T)$. In this case, the transaction reads an older version without updating `rts`.

Commit. For commit of a transaction T, the timestamp fields of the updated object version o_{i+1} are set accordingly: `bts` to $id(T)$ and `ets` to `INF` and for the previous version o_i, the field `ets` is set to $id(T)$. In the case of delete, `ets` of the deleted version o_{i+1} is set to $id(T)$ instead. If the object was newly created, however, it is simply unlocked (i.e., resetting `txn-id` to 0). Otherwise, o_{i+1} has to be copied back to PMem. In order to guarantee failure atomicity, this memory copy has to be performed atomically. This can be implemented in different ways. One approach is to rely on the solution provided by the Intel PMDK to atomically update and persist data that is larger than the power-fail atomic size or portions of data that are non-contiguous. PMDK uses transactional operations for memory allocation, freeing, and setting. Internally, these transactions are implemented via redo logging to ensure the atomicity of memory allocations and undo logging for transactional snapshots [40]. Other approaches are, e.g., using Multi-Word CaS instructions such as PMwCAS [44] which allows atomically changing multiple 8-byte words on PMem. In our current implementation, we use the PMDK solution for the sake of simplicity (DG4). However, this comes with a small overhead.

5.2 Version Storage

A transaction updating an object version o_i creates a new version o_{i+1} by making a copy of o_i and appending it to the front of the list of dirty versions (i.e., *version chain*). It then performs all updates on o_{i+1} in DRAM until commit. Keeping all uncommitted data in volatile memory is a design decision we made in order to minimize the number of writes to PMem (DG1, DG2). This hybrid DRAM/PMem approach allows for the creation of all versions by transactions to be a volatile copy instead of the more expensive copy to PMem, and also allows for all the write operations that occur during the lifetime of a transaction to be performed at DRAM latency until the transaction is to commit when the updates are finally persisted in PMem. Note that a dirty object has the same structure as its committed version but with a different validity interval (as specified by the range [bts, ets]).

5.3 Garbage Collection

In our current implementation, we use Transaction-level Garbage Collection (GC), where storage space occupied by dirty versions that are not going to be used anymore is reclaimed at transaction-level granularity [46]. A node or a relationship maintains a volatile dirty list, only if there is a valid dirty version of it. A dirty version is not used anymore if it becomes invalid (i.e., the transaction that created it aborts) or if it is no longer *visible* to any active transaction (i.e., its ets $<$ $id(T)$ of the oldest active transaction T). All empty or unused dirty lists are discarded during a commit. If the storage space to be reclaimed is in PMem, either because a committed transaction deleted the object or the object was inserted by an aborted transaction, we do not deallocate the record slot(s). Rather, we simply mark it with a bitmap as free for later reuse (DG5).

6 QUERY PROCESSING

The characteristics of PMem have several implications for query processing. First of all, data access is no longer block-oriented and, therefore, has to be optimized for sequential access. The direct and byte-addressable access is very similar to in-memory databases. In graph databases, this is particularly useful for traversal operators. However, as mentioned above, reading from PMem is slower than from DRAM. Hiding this higher latency requires efficient cache utilization, multithreaded processing, and various execution modes.

6.1 Push-based Approach

We address these requirements by a multithreaded push-based query engine. Our engine provides a set of graph-specific algebra operators [16] such as NodeScan, RelationshipScan, and ForeachRelationship; as well as standard relational operators like Filter, Project, and several Join variants. As every operator is implemented and ahead-of-time (AOT)-compiled, i.e., available at run-time, the engine is able to interpret queries (given as graph algebra expressions) directly by calling these operators with the required parameters. Processing a typical traversal query (Match in Cypher) is initiated by scans on the node or relationship tables including filters. For each node satisfying the optional filter condition the traversal operation is applied, i.e., the NodeScan operator forwards the current node to the next operator ForeachRelationship, and so on. (Fig. 3).

Though traversals could be also implemented using joins of a standard relational query engine [11], the ForeachRelationship leverages the direct addressability of data in PMem. As described

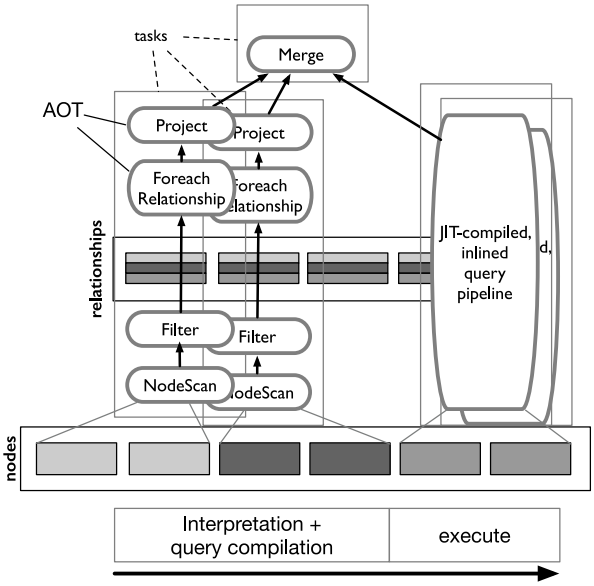

Figure 3: Query execution plan

in Sect. 4.2, node records contain the persistent addresses (offsets) of their relationships, which in turn store the address of the sibling nodes, and are used to traverse the path. This avoids the problem of join escalation during traversals.

For query parallelization, we leverage a task model. Scans are performed as parallel scans: Each task processes a range of the node/relationship tables. Thus, all subsequent operators following the scan are also performed within this task until a pipeline breaker like a join or sort operator is reached. This way, we follow the morsel-driven parallelism approach [23].

For using indexes in query processing, an appropriate IndexScan operator is provided that performs a lookup or range scan on the B$^+$-Tree, extracts the matching nodes from the node tables, and passes them to the subsequent operator pipeline.

6.2 Just-In-Time Query Compilation

Besides the AOT compiled query engine, we implement a JIT query compiler that transforms graph algebra expression into machine code. Traditional query execution engines use a query interpreter to execute query statements. This has several drawbacks that reduce the resulting performance. An interpreter relies on AOT compiled code, which means that the appropriate methods must be available for every possible occurrence of a particular tuple element type. Furthermore, a query interpreter is not able to recognize equal or redundant instructions. Particularly for operators that lead to variable cardinalities, like selections or aggregations, it introduces additional overhead. Query compilation is an approach to tackle these issues. Our approach aims to compile given graph algebra expressions into highly efficient machine code using the JIT compilation technique [20]. As the compiling framework, we chose the LLVM compiler infrastructure because it provides numerous relevant features for the JIT compilation, reliable performance, and portability to several architectures. Moreover, the LLVM IR provides an instruction set suitable for the implementation of all the abstractions needed for our graph query engine. One significant requirement for the JIT query compiler is the fulfillment and compliance with the formulated design goals (DG1-DG6). This is mainly done by reusing

(calling) AOT-compiled code, e.g., access methods to nodes or methods for transaction processing. Thereby, the code generation effort will be reduced because it is already compliant with the design goals and optimized by the AOT compiler.

Similar to the approach presented by [28], we aim to process intermediate tuple results as long as possible in the CPU registers. In order to achieve this, it is necessary to transform the complete query pipeline into a single LLVM IR function. Here it becomes apparent that a transformation from graph algebra to machine code can be easily accomplished with LLVM IR. However, to ensure reliable performance, we identified the following requirements for the IR code generation that must be met.

(1) Minimize stack allocation and avoid heap allocation.
(2) Process initializations only at the first entry point of the IR function.
(3) Process type information at (JIT) compile-time.
(4) Provide full compatibility to the AOT execution engine.

One significant advantage of query compilation over interpretation is that the tuple element type information can be handled at compile-time. The consequence of this is the absence of type conversions at run-time as code can be generated for individual types.

Starting from a graph algebra expression that forms an operator tree, each operator will be transformed into LLVM IR code. Further, each operator provides at least an *entry* and a *consume* IR basic block, representing the operator's start and end points. Complex operators comprise more basic blocks for the actual tuple processing, e.g., Join. Though, the general control flow starts at the entry basic block. After processing in further basic blocks, the control flow branches to the consume basic block to push the results to the next operator. A branching instruction links each consume basic block with the entry basic block of the succeeding operator, forming an inlined query pipeline. Fig. 4 illustrates the transformation process, starting from a query plan in the form of graph algebra. Furthermore, it shows each operator's return path, which is, for most cases, the loop header of the previous operator. The finish operator will be called after the complete scan. Depending on the query, it invokes the function return or the next query pipeline.

The query engine's current implementation provides two access paths for the query pipeline: the NodeScan and Create operator. Code generation for these operators is basically the same as for the normal operators. Both contain at least the entry and consume basic block. As an access path is always the first operator in the pipeline, it must also provide the actual generated

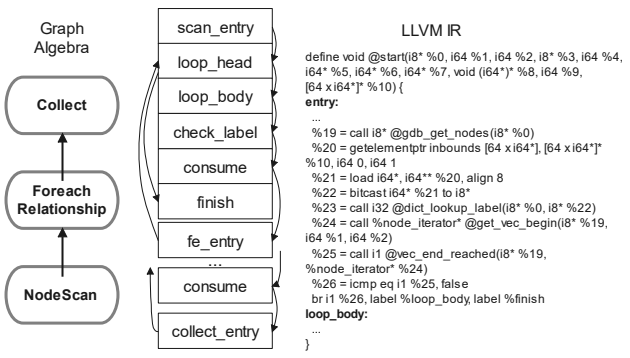

Figure 4: Graph algebra to LLVM IR transformation

function's entry point. Due to the reason that the code generator transforms the complete pipeline into a single IR function, memory allocation must be carefully handled. For this reason, the access path initializes all relevant values for the complete query pipeline, e.g., number of nodes, projection keys, or global constants.

The code generation for joins requires additional work. A join operator comprises two inputs. For now, we consider the right sub-pipeline of the join as the side which will be materialized. Consequently, it requires the prior execution of the right sub-pipeline. However, the actual code generation starts from the left sub-pipeline in order to minimize tree traverses. Whenever the code for an access path is generated, it checks if the current function is already initialized. If this holds, it swaps the function entry basic block with its own and connects the finish basic block of the second access path with the entry basic block of the previous access path. This enables the handling and execution of multiple query pipelines within a single function.

IR Code Generation. We use the *visitor design pattern* to generate the appropriate IR code for each operator. Further, this enables the extension of the query engine in future work. Each operator derives from a base class and implements a `codegen` method for code generation. The query engine calls the *visitor* to start the code generation process, which calls all the operator's `codegen` methods recursively. We implement several IR abstractions that help to generate IR code with more ease. Due to the reason that most operators rely on loops, we provide two IR loop abstractions. The `while_loop` abstraction is used for the iteration through a chunked vector. It receives the vector, the current iterator, the succeeding basic block, and the actual loop body as function arguments. The other loop abstraction is the `while_loop_condition`, used for the iteration as long as a condition is valid. Further, our abstraction set contains methods that generate code to extract label codes or property values. The operator IR code is based on these abstractions and mainly mimicking the push-based processing described previously. An additional structure is built to provide the type of tuple element at code generation and the appropriate register value. The code of the next operators is generated according to the type of the previous tuple element. For example, the projection operator uses the proper node functions if the last result tuple element is a node. This handling allows for generating code without much effort at run-time.

JIT Compilation. We extended the JIT compiler of LLVM to further features. First of all, our JIT query engine can persist already compiled code to PMem. This has the advantage that no further compilation is required for subsequent runs of a query. For that purpose, a persistent and concurrent hash map is used. The compilation output of the JIT is a binary object file that will be linked with the current database instance. Usually, this file is located in a memory buffer in the volatile memory. Before the compilation process, the query engine generates a unique query identifier that comprises the operators' identifiers, which will be used to lookup the persistent hash map for already compiled code. If the code is found, it will be linked with the current database instance. Otherwise, the compilation process of the query starts. The compiled code will be persisted in PMem after its compilation, using the query identifier as a key for the hash map.

A major advantage of JIT compilation is the ability to optimize the IR code at run-time. The LLVM framework provides a convenient approach for IR code optimization. Several LLVM

optimization passes can be used for this purpose. An analysis of the IR code reveals that it comprises mainly of loops and pointer arithmetics. Therefore, our optimization strategy focuses on these constructs. The following optimization pass cascade is used to further optimize the code at run-time:

- *Promote Memory To Register* transforms instructions that allocate stack memory into register values. This makes the IR code generation convenient and compliant with the requirement (1).
- *Control Flow Graph Simplification* merges and deletes basic blocks if they have common or no predecessors.
- *Loop Unrolling* removes the overhead of loops by explicit extraction of the body to multiple instructions.
- *Dead Code Elimination* eliminates unreachable code.
- *Instruction Combining* combines redundant instruction to form smaller and faster code with the same effect.

Additionally, the IR code is optimized with the standard C++ aggressive optimization (-O3).

Adaptive Execution. While the compiled query code itself is fast, the compilation time should also be considered. Notably, when executing short-running queries where only a small portion of data is touched, the compilation time will be longer than the actual execution time. In order to hide the compilation time as well as memory access latency of PMem, we additionally support an adaptive query processing approach, which is illustrated in Fig. 3. In contrast to the approach by [21], the adaptive execution can switch between only two modes, which is currently sufficient for our engine. The interpretation mode is always initiated first at query execution. This mode uses AOT-compiled database code to execute the query. Similarly, the visitor design pattern is used to transform the given algebra query plan into the interpret functions. These functions are then linked together, forming a cascade of functions that execute the actual query. The downside of such an approach is the additional (AOT-compiled) code overhead because every operator and its varieties must be available at compile-time. During adaptive execution, the query engine switches to the JIT mode after compilation.

We take advantage of the morsel-driven parallelism for the actual switching procedure, where morsels are pinned to a single task and pushed into a task pool. The working threads pull a task from the pool and execute the task function (the query) on the pinned morsel.

We implement the task function as a static function. As the execution always starts in the interpretation mode, it will be initialized to the appropriate function, which invokes the interpretation. While the query is executed in the interpretation mode, a background thread compiles the query plan into machine code. The compilation process emits a function that processes the query plan into machine code. As soon as the compilation is done, it redirects the static task function to the compiled function. The next pulled task from the pool will execute the compiled query function.

7 EVALUATION

In this section, we report the results of a set of experimental evaluations whose research goal is threefold:

1. We evaluate our PMem-based HTAP engine and show the effectiveness of our design decisions to exploit PMem characteristics for graph processing. In this context, we aim to investigate, on the one hand, the benefits of using persistent memory for graph processing. On the other hand, we compare our system to disk-based and DRAM-based solutions (§ 7.3).
2. We compare the speed of volatile, persistent, and DRAM/PMem hybrid B^+-Tree index lookups. We quantify the recovery overhead of our hybrid index (which we expect to be insignificant) as a trade-off for increased query performance (§ 7.4).
3. We evaluate our JIT query compilation approach. We demonstrate when and how much it enhances the performance of transactional queries. We expect the JIT compilation to yield benefits especially for long-running and more complex queries (§ 7.5).

7.1 Environment

For the experiments, we used a dual-socket Intel Xeon Gold 5215 server with 10 cores each at max. 3.4 GHz. The server is equipped with 384 GB DDR4 RAM, 1.5 TB Intel Optane DCPMM, and 4 × 1.0 TB Intel SSD DC P4501 Series connected via PCIe 3.1 x4. The server runs CentOS 7.8 (Linux 5.7.7 kernel). The operating mode of the PMem modules is set to AppDirect which allows us direct access to the devices. On the PMem DIMMs, we have created an ext4 file system and mounted it with the DAX option to enable direct loads and stores bypassing the OS cache. For accessing PMem, we used the Intel PMDK version 1.9.1 and libpmemobj-cpp[3] version 1.11. The JIT compilation was done with LLVM version 11.

7.2 Workload & Setup

The Linked Data Benchmark Council (LDBC) specifies benchmarks and benchmarking procedures and also verifies and publishes benchmark results [10]. The LDBC-Social Network Benchmark (SNB) models a social network comprising of different entity types interconnected by relationships – both with property types and property values. Activities of persons are represented as messages about topics or tags that are posted in forums moderated by unique persons. Persons like messages, have interests in tags, are members of forums, and make comments in response to posts or other comments. Message activities are the bulk of the data on the social network. There also are places and organizations to which a person is connected via residence, study, and work relationships. The LDBC-SNB defines an Interactive Workload and a Business Intelligence Workload. The Interactive Workload comprises of three classes of queries: (1) Interactive Complex Read Queries that are relatively complex and traverse a fair portion of the graph data, (2) Interactive Short Read Queries that perform lookups and short traversals within the neighborhood of a node, and (3) Transactional Interactive Update Queries that perform transactional insertions and updates of node and relationship objects [10].

We generated and used the LDBC-SNB data [2] at scale factor (SF) 10 as our benchmark data. As the focus of this paper is on transactional graph processing, not graph analytics, we selected the LDBC-SNB Interactive Short Read (SR) and the Interactive Update (IU) query sets as query workload for our experiments.

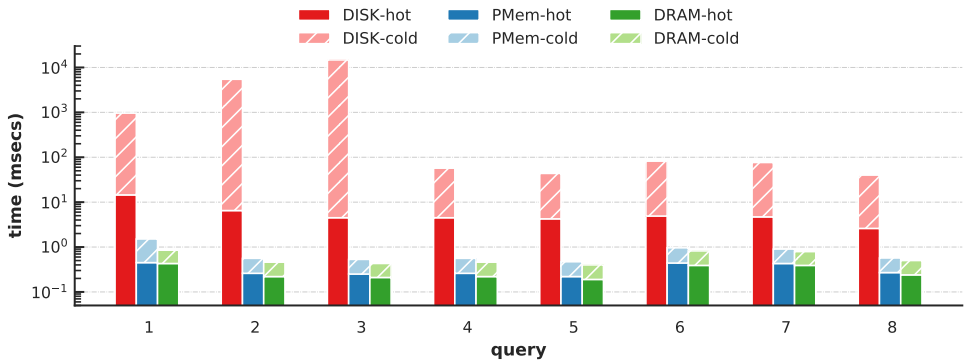

Figure 6: Results for SNB Interactive Updates

7.3 Benefit of PMem

We first want to evaluate how much the design decisions in our PMem-optimized graph engine and our implementation of transaction processing reduce the overhead of PMem in our system (denoted as PMem in the figures) compared to a pure DRAM-based in-memory implementation of it. Moreover, we want to compare the performance gains brought about by the lower access latency of PMem compared to a DISK-based system, in addition to providing persistence. To this end, we employ two baselines: A disk baseline (represented as DISK), which is an open-source native graph database where we stored all the primary data on SSD and created an additional DRAM index. For the DRAM baseline (depicted as DRAM), we adapted our system to additionally run in a pure volatile mode where we keep data entirely in DRAM. We expect our system to outperform the disk-based system. With regards to the DRAM baseline, we anticipate to bridge the performance gap with our PMem-conscious design and achieve a near-DRAM performance while providing persistence, especially for hot runs.

Interactive Short Reads. Fig. 5 shows the query execution times for the SR query set. The execution times are average times of 50 runs on hot data, each with a different input ID parameter. post and cmt (short for *post* and *comment* respectively) represent the two subclasses of a message entity. For PMem, we show the execution times without indexes for single-threaded execution (PMem-s), multi-threaded execution (PMem-p) as well as with indexing support (PMem-i). We employ similar denotations for our DRAM baseline: DRAM-s, DRAM-p, and DRAM-i. For the disk baseline, we also conducted executions with index support and report the performance numbers for hot runs (i.e., when the data is in DRAM), denoted by DISK-i. We used our hybrid DRAM/PMem implementation of the B$^+$-Tree (Section 4) for PMem, while for DRAM, we used a volatile B$^+$-Tree. We maintain the same set of indexes throughout our experiments.

The results in Fig. 5 show that exploiting PMem-specific characteristics in storage architecture and transaction processing can significantly bridge the performance gap between DRAM and PMem. It can be noted that for multi-threaded execution of some of the queries, the execution times are very close since the SR queries are short-running and the PMem latency is already hidden by the CPU caches for hot runs. An interesting research direction is thus to investigate this in the context of graph analytics, where queries are compute-intensive, long-running, and navigate across a significant portion of the graph. While the results show performance improvements of multi-threading both for DRAM and PMem, however, indexes have a stronger influence. Unlike graph analytics that significantly benefit from parallel execution, interactive queries like SR and IU benefit more from indexes, as they are essentially lookup queries whose execution time overhead comes mainly from scanning the tables of record chunks to retrieve the start node object. As a result, we compare the performance of indexed query execution both on our system and on the DISK baseline. We can see from the figure that our PMem-based system outperforms the disk-based system for indexed execution in all the queries, as we had expected.

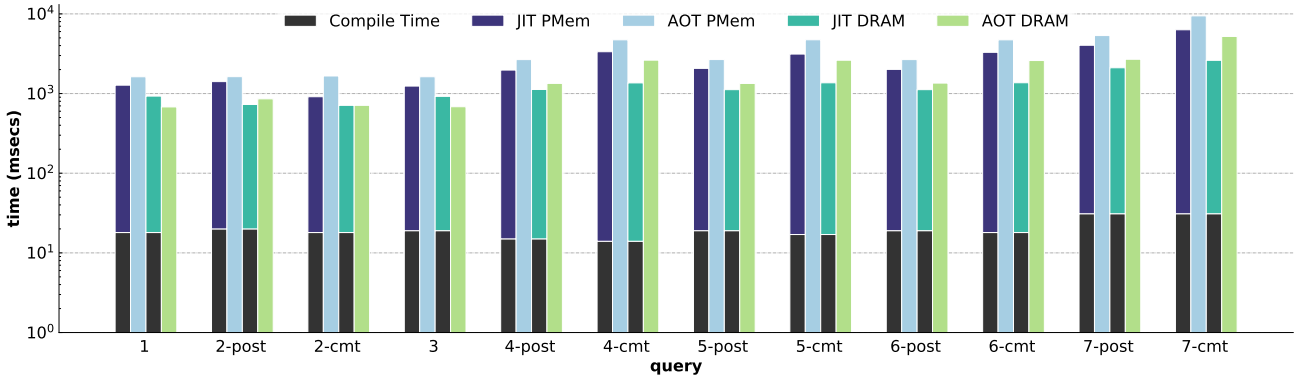

Figure 7: Results for SNB Short Reads with Single Threaded Execution

Interactive Updates. We maintain the indexed query execution and present the execution times for the IU query set with indexed support in Fig. 6. Here, we measured both the times to execute the update queries as well as times for the transactions to commit (i.e., notably, persisting the updates in PMem). Similar to the SR queries, we took the average execution time of 50 runs on hot data with varying object property values as input parameters. In addition to results on hot data, we also present the execution times for cold runs, i.e., for the first query runs. The results show our PMem-based system not only outperforms the disk-based system by an order of magnitude even for hot runs but also performs insert and update operations at near-DRAM latency. For hot data, it is even closer.

Overall, the results of Fig. 5 and Fig. 6 show that in direct comparison with the DRAM variant, our hybrid approach of MVTO implementation to address the specifics of PMem adds only a marginal overhead. This validates our MVCC design decisions of Section 5 and also obviates the need for showing the results of a pure PMem implementation which has an overhead of maintaining dirty versions on PMem.

7.4 Indexes and Recovery

We evaluated index performance and recovery by way of comparing our hybrid index that keeps inner nodes in DRAM, trading-off recovery for improved performance, against two baselines. One a volatile index that keeps all nodes in DRAM and the other a persistent index that stores all nodes on PMem. We evaluated them based on the average time for indexed scans in the SNB SR queries. To study the performance differences, we measured the time to lookup and retrieve a node ID from the appropriate index. Fig. 8 shows the average lookup time for the persistent, volatile, and hybrid indexes - denoted respectively as PMem, DRAM, and Hybrid. The lookup times are averages of all ID value lookups of nodes with the same label type (Person) in all the respective SR queries. The hybrid approach enhances the lookup performance by 2x while keeping the recovery time as low as 8 ms, in comparison to the complete volatile index build time of 671 ms. This recovery overhead would also be necessary for each index created on specific properties. Added up, the overhead of completely rebuilding the indexes in the volatile case is comparatively drastic. Therefore, we see the hybrid variant as a good compromise between runtime performance and recovery.

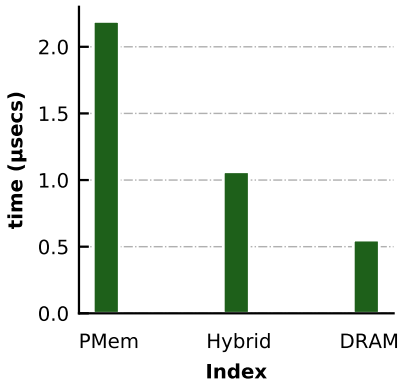

Figure 8: Average Time per Lookup of Persistent, Hybrid, and Volatile Indexes

7.5 JIT

The final part of our evaluation focuses on the JIT query compilation approach. The first two benchmarks show the capability of JIT-compiled code itself, without any mechanism to hide the compilation time. For this purpose, we execute the interactive read and update queries from the SNB. Thereafter, we examine the gain from adaptive execution. Although we expect it to be much more efficient for analytical and long-running queries, it is insightful to see the benefits on short and transactional queries in comparison to AOT-compiled code. In particular, the combination with PMem could make this approach profitable even for short-running queries.

Interactive Short Reads. Fig. 7 shows the results for the SR executed with the JIT query engine. We calculated the average execution time of 50 runs on hot data with different parameters. The queries are executed single-threaded without indexes. The compilation time of the queries is only a few milliseconds. As the number of operators increases, the compilation time increases by only a few milliseconds. However, the results show clearly that the JIT-compiled is always faster than the AOT-compiled code. The JIT-compiled code is mostly even faster when the actual compilation-time of the query is included. Especially more complex queries, like 7-POST and 7-CMT, can benefit from the JIT compilation approach.

Interactive Updates. The results for the IU executed with the JIT query engine are shown in Fig. 9. There are not many optimization possibilities for the generated IR code, as the queries are

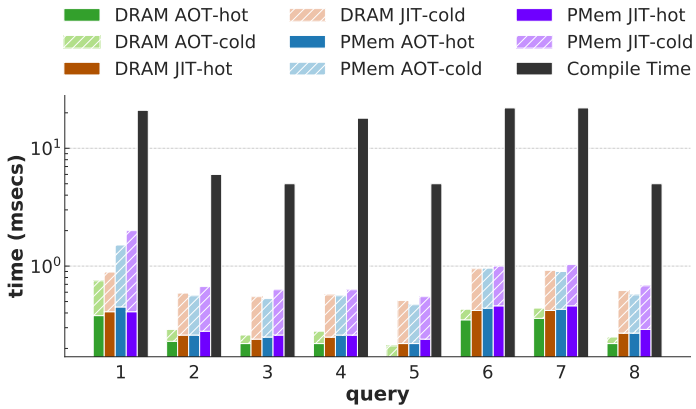

Figure 9: Results for SNB Interactive Updates executed with JIT compiled code

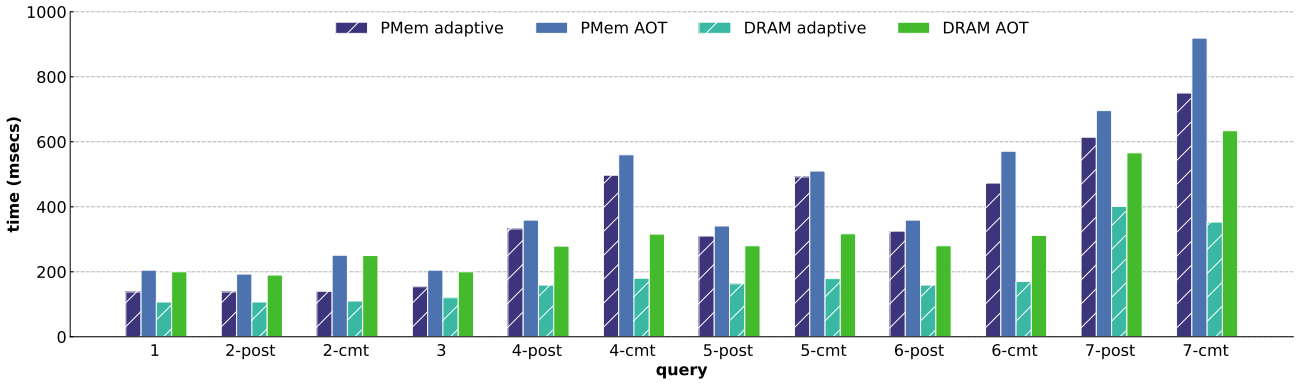

Figure 10: Results for SNB Short Reads with Adaptive Execution

short when index support is enabled. Executing these queries using scans and selections shows similar behavior to the benchmark before. However, here we focus on code for short queries, where the execution time is less than the compilation time. JIT code executed on cold data is noticeably slower, while the resulting performance on hot data is similar to the AOT code. However, executing these queries with the JIT compilation approach shows that it is not always the best option to generate code during runtime for executing a query. The compilation time for these short queries is much higher than the actual execution time. Furthermore, executing these short queries with the adaptive approach leads to the execution of the query pipeline using the AOT-compiled code entirely, which corresponds to the results of the AOT code in Fig. 9.

Adaptive Query Executions. The previous benchmarks show the capability of executing JIT-compiled queries. It is clearly visible that the JIT-compiled code itself outperforms the AOT code on DRAM and PMem. However, waiting for the compilation of the query limits the performance improvement of this approach. The adaptive query execution approach eliminates this problem by executing the AOT code while query compilation is done in the background. Additionally, this is useful to hide the memory access latency of PMem. The next benchmark compares the adaptive query execution approach using morsel-driven parallelism with multi-threaded AOT-compiled query execution. Similar to the previous benchmarks, we execute each query on DRAM and PMem. The results in Fig. 10 show that the adaptive execution is always faster than the multi-threaded AOT execution. The execution on PMem can particularly benefit from the adaptive approach. The additional latency introduced by PMem leads to an earlier execution of the fast JIT-compiled code in the query pipeline stage, which enhances the query processing. For the queries 1, 2-POST, 2-CMT, and 3, it leads to similar execution times for DRAM and PMem. The adaptive approach provides faster query execution times for most queries and in worst-case similar performance than multi-threaded AOT code. More complex queries can benefit even more from the adaptive approach as there is more space for code optimization, like for the queries 7-POST and 7-CMT.

8 CONCLUSION

Persistent memory represents a promising technology for data management solutions whose efficient use requires rethinking data structures and architectures. In this work, we have presented the first results of our PMem-based graph engine for hybrid transactional/analytical workloads. Based on the characteristics of PMem technology, we have discussed, implemented, and evaluated design choices regarding storage structure, transaction, and query processing. The promising results using the LDBC-SNB interactive short read and update query sets show that a PMem-based storage engine that is well-optimized for PMem characteristics incurs only a marginal performance overhead compared to a pure in-memory solution. The main benefits are, among others, the competitive performance without the need to

keep large parts of the data in (volatile) main memory (resulting in constant answer times both for cold and hot data) as well as near-instant recovery guarantees. Additionally, the results have shown that in comparison to AOT-compiled query execution, JIT compilation speeds up query processing when the compilation time is less than the execution time. Particularly, adaptive compilation further enhances query execution performance by hiding PMem access latency. In our ongoing work, we plan to investigate the behavior of complex graph analytics and highly concurrent updates. Moreover, there are several opportunities for further performance improvements, e.g., by employing more hybrid DRAM/PMem approaches such as for dictionaries.

ABSTRACT

Wikipedia, the web-based free content encyclopedia project, is one of the most popular websites on the Web. Its “open-door" policy, allowing anyone to edit, has made Wikipedia the largest and possibly the best encyclopedia in the world. At the same time, the continuously evolving content, constantly updated by a large number of uncoordinated users, renders the maintenance of a clean, consistent encyclopedia an extremely challenging task.

The goal of the WiClean (WC) system presented in this paper is to assist Wikipedia editors in this difficult task. Specifically, we focus on the correctness of Wikipedia *inter-links* that point from one article (entity) to another. Such inter-links form a key component of the structured part of Wikipedia and their correctness is critical for coherent browsing. Given an entity type of interest, our highly parallelizable algorithm identifies relevant edit patterns across revision histories of Wikipedia entities of related types, along with time windows in which partial edits are tolerable. The discovered patterns/windows are then used by WC to alert Wikipedia editors on past edits that appear to be incomplete, as well as to provide users with on-line assistance as they update the encyclopedia. Our experiments with real-life Wikipedia data demonstrate the efficiency and effectiveness of WC in identifying actual errors in a variety of Wikipedia entity types.

1 INTRODUCTION

Wikipedia, the free-content web encyclopedia, is one of the most popular websites on the Web. Per Time magazine, Wikipedia’s "open-door" policy of allowing anyone to edit the data, has made it the largest, and possibly best, encyclopedia in the world [2]. Nonetheless, the continuously evolving content, constantly updated by a large number of uncoordinated users, renders the maintenance of a clean, consistent encyclopedia an extremely challenging task. To understand the volume of the updates, the English Wikipedia in 2018 consisted of 6 million articles, with an average of 3.4 million edits per month, by roughly 30K active editors [4].

The goal of our work is to assist Wikipedia editors in this difficult task. Specifically, we focus here on the correctness of *inter-links* that point from one article to another in the *structured* sections of Wikipedia (such as infoboxes and tables), which is critical for coherent browsing. Maintaining the integrity of these links is challenging, as illustrated by the following example.

Example 1.1. Consider the Wikipedia page of the soccer player Neymar. The links in its infobox point to the page of his current club, Paris Saint Germain F.C. (PSG), his place of birth, and so on. When Neymar moved to PSG in 2017, leaving his previous team, Barcelona F.C., the three related pages, *Neymar*, *PSG*, and *Barcelona F.C.* had to be updated.

There are three typical causes for inconsistently updating these links. First, Wikipedia editors are not provided with a comprehensive list of links that need to be updated as a result of such an event. A typical error related to player transfers is updating only the page of the new club and neglecting to update the page of the old club, which still incorrectly links to the player.

Second, different pages are often edited by different people, typically, in an uncoordinated manner. It could be that, e.g., the page of the club is updated by one dedicated editor, whereas no editor has taken up the responsibility of updating Neymar’s page or even noticed the absence of a corrected link. Moreover, no mechanism alerts the active editors of Neymar’s page of a related update, that may require action on their part.

Third, it is often impractical to correct all links simultaneously. For example, player transfers occur during predetermined periods, referred to as transfer windows, and tend to take a long time to be officially confirmed. In the meantime, many rumors regarding conflicting transfer destinations are posted in various media outlets. Consequently, in that span, there may be hundreds of edits of player pages, adding/removing new/old links, and reverting previous edits, whereas the club pages are commonly updated only once the transfer is officially approved.

More generally, Wikipedia contains very noisy data, as it could be edited by anyone, including bots[1], inexperienced editors, and opposite-agenda editors[2], resulting in editing conflicts[3] and dispute resolution[4]. This process of frequent conflicting edits, culminating in a consistent state, is a naturally evolving mechanism to mitigate noise, due to the distributed and asynchronous nature of Wikipedia edits. Thus, enforcing immediate corresponding updates to all relevant links during the dispute period is impractical and counterproductive. Moreover, the existence of a time window, that may range from hours to months (depending on the context of the update and the involved entities), during which partial inconsistent edits are tolerable, beyond serving as a necessary trigger for the dispute resolution process, also has the advantage of providing users with the most up-to-date, albeit tentative, information.

Previous work. Much research has been devoted to aspects of this problem in the more general context of detecting errors in *knowledge bases* (KBs) [22]. Some of these works [27, 30] also evaluated their solutions over Wikipedia, representing a snapshot of it as a KB, with pages as entities, and entity relations derived from inter-links. Over this representation and an input set of *integrity constraints*, pertaining to entity relations, the objective is to detect all their violations. While these works provide satisfactory solutions for the intended problem over KBs, casting the special case of inconsistencies in the constantly-evolving Wikipedia’s links into this generic framework, omits important practical considerations specific to the operation of Wikipedia.

To illustrate, continuing with our example of player transfers, a possible constraint over the corresponding KB may state that if player A links to club B, then club B also links to player A and vice versa. If there exists only one link or two contradictory links, then a violation of this constraint is detected. There are several drawbacks to applying this approach as a comprehensive solution.

[1] https://www.bbc.com/news/magazine-18892510
[2] https://en.wikipedia.org/wiki/Wikipedia:Lamest_edit_wars
[3] https://en.wikipedia.org/wiki/Edit_conflict
[4] https://en.wikipedia.org/wiki/Wikipedia:Dispute_resolution

First, the most crucial drawback relates to the fact that the constraints are static and lack any temporal dimension. Concretely, the constraint does not account for the time window, discussed in Example 1.1, during which partial edits are acceptable (and, in some cases, practically unavoidable). An inconsistency should be resolved at the earliest appropriate moment but not earlier. In this case, this earliest moment is arguably the end of the transfer window. However, detecting the constraint violation right after Neymar's page is linked to PSG, without a link in the other direction, is treated the same as detecting it long after the end of the transfer window. Consequently, one is uncertain whether to take immediate action or allow the unsupervised process of sequential refining edits to run its course and converge into a consistent state. We note that solutions suggested in previous works (e.g., [27]), discussed above, can successfully identify 'window-less' edits' combinations. That is edits that should all be applied simultaneously and are distributed uniformly across the timeline of Wikipedia's revision history. However, our empirical analysis identified many edit patterns associated with specific time windows, such as in Example 1.1. Our work is, thus, complementary to the above works, as it aims to address specifically these patterns.

Second, most works assume the existence of a set of constraints as input for the solution framework. This is not realistic in the case of Wikipedia. Wikipedia entries encompass a wide array of domains and sub-domains, each with its own set of constraints. While there are broad similarities across related domains, each domain may be infinitely nuanced. Given the volume of domains, entity types, and case-specific subtleties, the task of comprising a nearly exhaustive list of important constraints is impractical, particularly if one is also interested in complex relations (where, e.g., a combination of 10 pages must be consistently updated).

In this line of research, closest to us, is the recent work of [36], where the focus is on Wikipedia, and on top of detecting violations of the given constraints, the solution produces corresponding *correction rules*, that dictate how one can resolve partial edits. This is inferred by examining the revision history, identifying the most common patterns of revision actions for completing each type of partial editing. Nevertheless, this work also does not aim to identify tolerable time windows and targets the scenario where the list of constraints is provided as input (a more detailed comparison to this and previous works is presented in Section 2).

Our approach. To address the above limitations, we present in this paper WiClean (WC), a system that automatically infers common edit patterns (combinations of edits), along with a time window for allowing partial edits of each pattern, alerts editors of inconsistencies, and suggests concrete corrections.

The thesis underlying WC is that the majority of Wikipedia updates follow desirable patterns and lead to consistent states. WC, thus, mines revision logs to identify common update patterns and the time windows in which they occur. Potential errors are then detected by updates that deviate from the patterns and are not completed within the corresponding window. For such partial patterns, WC suggests all completions to known patterns, providing statistical metadata to facilitate an informed course of action.

Before describing our solution techniques, we illustrate the format of the revision history. Figure 1 depicts excerpts from the revision histories of players and clubs merged into a single timeline. The Subject column identifies the article where the addition/removal of a link occurred, the Object column identifies the article to which the added/deleted links point, and the Relation column describes the link type (the column R will be explained later). One can see that, after several edits and reverts, the transfer of Neymar is reflected in his and the teams' pages.

#	+/-	Subject	Relation	Object	Time	R
1	-	Neymar	current_club	Barcelona F.C	...1531	0
2	-	Gianluigi Buffon	current_club	Juventus F.C.	...1534	1
3	-	Neymar	in_league	La Liga	...8711	1
4	-	Barcelona F.C	squad	Neymar	...2804	0
5	+	Neymar	current_club	PSG F.C.	...3321	0
6	+	PSG F.C.	squad	Neymar	...8263	1
7	+	Barcelona F.C.	squad	Neymar	...4040	0
8	+	PSG F.C.	squad	Gianluigi Buffon	...4051	1
9	+	Gianluigi Buffon	in_league	Ligue 1	...3330	1
10	+	Neymar	in_league	Ligue 1	...8711	1
11	-	Juventus F.C.	squad	Gianluigi Buffon	...4058	1
12	+	Neymar	current_club	Barcelona F.C	...5861	0
13	-	Kylian Mbappe	current_club	Monaco F.C.	...9459	1
14	-	Neymar	current_club	PSG F.C.	...3732	0
15	-	Gianluigi Buffon	in_league	Serie A	...3380	1
16	-	Neymar	current_club	Barcelona F.C	...6109	1
17	+	Neymar	current_club	PSG F.C	...7694	1
18	-	Barcelona F.C.	squad	Neymar	...8001	1
19	+	Kylian Mbappe	current_club	PSG F.C.	...9589	1
20	-	Monaco F.C.	squad	Kylian Mbappe	...9451	1
21	+	PSG F.C.	squad	Kylian Mbappe	...9885	1

Figure 1: Actions from revision history of several articles

Methods. Formally, we model Wikipedia entities (articles) and the links between them as a graph. Nodes and edges are labeled by type names. Intuitively, the revision history of each article records the edits made to the outgoing links of the corresponding graph node. Given an entity type of interest, our algorithm identifies meaningful relevant edit patterns across revision histories, along with time windows in which partial edits are acceptable. By making an analogy between link edits (resp. edit patterns) and graphs (graph patterns), we can harness conventional graph mining algorithms to our context. However, some important adaptations must be made to account for (1) the Wikipedia type hierarchy[5] that requires the examination of a larger number of potential patterns, and (2) the distributed nature of the edits across revision histories of multiple entities, that makes the construction of the full edits graph prohibitively expensive. For the former we introduce a join-based computation (optimized by the underlying SQL engine) to quickly prune infrequent patterns; for the latter we use incremental graph construction that considers only relevant entity types.

The discovered windows and patterns are then used by WC to assist Wikipedia editors in correcting/updating Wikipedia links. Here again, we employ an optimized join-based computation to quickly identify potential errors. WC both alerts Wikipedia editors on past edits that appear to be incomplete as well as provides users with on-line assistance as they update Wikipedia.

Our contributions can be summarized as follows:

- **Model.** We formulate and present a simple, natural model for capturing time windows and update patterns of interest. Given an entity type t, our goal is to find related and common update patterns across the Wikipedia graph. Such updates may involve entities of the same or other types. We first introduce the notion of *abstract* update actions that generalize a set of actions involving specific entities to general patterns over the corresponding entity types. We then define the notion of *connected patterns* which include abstract actions that are related (possibly transitively) to entities of the input type of interest. The *frequency* of a pattern, within a time frame w, is then naturally defined as the fraction of entities of type t that participate in a pattern that occurs within the time frame w (Section 3).
- **Identifying windows and patterns.** Building on algorithms for graph mining, we devise a scalable, highly parallelizable algorithm, based on the following three points. (1) We represent

[5]Typically around eight hierarchy levels.

the identified patterns by relational tables, incrementally computed by dedicated relational queries. This allows harnessing the effective optimizations of the SQL engine underlying WC. (2) Unlike conventional graph mining algorithms that assume that the entire graph is given as input, our focus on connected patterns allows WC to incrementally consider only the entity types (and their corresponding revision histories) that may potentially be related to the input type via frequent edit patterns, thereby significantly saving on graph construction. (3) We focus on non-overlapping time windows and split the revision histories accordingly. This reduces the number of actions (edits) to be considered for each window (and resp. the size of the edits graph) and allows parallelizing the processing of the action sets in the different windows (Section 4).

- **Using Windows and patterns.** An immediate application of the discovered patterns is to alert Wikipedia editors on partial edits performed in past windows, as well as to assist users in current edits. For that, we examine the discovered windows and then signal, for each window and pattern, partial edits that may be extended to a full pattern occurrence. Our algorithm builds on the previously mentioned relational representation of patterns and employs dedicated outer-join queries to identify partial pattern occurrences (Section 5).
- **Implementation and experiments.** We have implemented our solution and employed it over real Wikipedia data. We considered a variety of Wikipedia entities, identifying a multitude of interesting time frames and corresponding relevant frequent edit patterns, and signals of updates that deviate from the mined patterns. Our experiments demonstrate the effectiveness of our approach for identifying real-life errors. The experiments further demonstrate the efficiency and scalability of our algorithms, compared to competing baselines (Section 6).

To complete the outline of the paper, we overview related work in Section 2 and discuss future work in Section 7.

Finally, we note that the prototype of WC was demonstrated in [20]. The short paper accompanying the demonstration provided only a high-level overview of its capabilities and user interface whereas the present paper details the model and algorithms underlying our solution as well as their experimental evaluation.

2 RELATED WORK

We overview related work from several related fields.

Wikipedia Cleaning. Much effort has been devoted over the past years to the cleaning and correction of errors in Wikipedia. Our work, which focuses on link correction, is complementary to works on entity resolution, completeness prediction, and vandalism detection [9, 33]. Similarly to our work, [13] also aims to improve inconsistencies in Wikipedia's infoboxes, representing it as an RDF database. However, [13] does not take the revision history into account and instead uses user interaction as the main tool. In contrast, our algorithm requires no user assistance, other than setting the initial parameters.

Revision history as a tool. Revision histories have been used in multiple areas, e.g., in program repairing, in recording provenance in knowledge bases and assisting query answering [10]. In Wikipedia, revision histories have been leveraged for various purposes, such as the discovery of controversial topics, the estimation of an article's translation quality and the detection of vandalism [23]. Other lines of work attempt to learn how to use the edits to enrich Wikipedia, e.g. to edit infoboxes with news extracted from tweets, or to connect Wikipedia edits to recent news articles [17]. Our work is complementary to these efforts, considering the consistency/completeness of edits to multiple related entities.

As mentioned in the introduction, particularly close to our work is [36], which, similarly to WC, infers from edit histories in Wikidata knowledge bases how to correct inconsistencies/violations. Nevertheless, this problem is formalized over a different model with similar but different objectives. One important difference is that in the setting of [36], *the constraints are provided in advance*, and the focus is on correction rules (for violations of these constraints) mining from relevant past edits. Whereas, one of the key contributions of our work is the derivation of such constraints (edit patterns, in our context). Moreover, the setting of [36] does not take into account the time frames in which a given constraint should or should not be enforced. Another key difference is that [36] do not harness the Wikipedia type hierarchy as a means to enrich their constraints of correction rules.

Other works that use the Infobox revision history focus on cleaning tasks. These include refining infobox titles by locating duplicate attributes within each entity type, predicting when a given infobox is likely to be updated and by whom, and identification of vandalizing editors [8].

Constraints inference and enforcement. The patterns we identify can be viewed as a form of *integrity constraints*. There is a large body of work devoted to inferring and enforcing such constraints. Two recent examples are [27, 30]. In [30], both positive and negative examples are used to infer the constraints. Their approach consists of greedily identifying, at each step, the most promising rule, in terms of the coverage of the positive examples. As [30] focus on identifying rules that make good predictions, some of the rules that exceed the confidence threshold will not be found. An alternative approach is taken by [27], where rules are mined via an exhaustive, breadth-first search method. They devise sophisticated pruning strategies and optimizations that enable their solution to efficiently run on large KBs, such as Wikidata.

Many other approaches to KB correction have been explored in the literature, e.g., discovering *denial constraints* [14] and error detection via the few-shot learning framework (e.g., [22]).

A key difference, in our setting, is that the constraints need to be enforced only outside the time frames in which inconsistencies are acceptable. Thus, we focus on a different objective, where in addition to the update patterns, we also identify the corresponding time window for each pattern. Another difference is that we identify patterns from the sequence of actions in the revision log, and not from a static snapshot of the knowledge base. Moreover, the above works (barring [36], which we discussed separately above), are concerned with detecting the rules/constraints, while one additional objective, in our setting, is to also compute correction suggestions for violations (partial patterns) of these rules. Lastly, to our knowledge, we are the first to leverage the type hierarchy to consider more nuanced rules, at varying levels of abstraction.

The importance of considering consistency, w.r.t. a sequence of actions, has recently been emphasized in the vision paper of [12]. Our work matches their motivating use-case, which advocates the usage of Wikipedia revision logs for data cleaning. Another related, complementary line of work deals with optimizing the corrections procedure over the detected constraint violations [11, 19]. It would be interesting to examine whether their techniques may be employed in our setting, to further optimize WC.

(Sequential) itemset/association rule mining. Algorithms for frequent itemset/association rules mining have been the focus of many works, including contexts where the mined items belong to a type hierarchy [32].As we seek connected patterns, conventional

a-priori style algorithms for frequent itemsets mining [7] inapplicable to our setting. Such algorithms recursively assemble larger frequent itemsets from smaller ones, but arbitrary sub-patterns of a connected pattern may not be connected, w.r.t. the input type. Consequently, our solution exploits principles from graph mining algorithms rather than general frequent itemsets.

Another closely related line of work deals with *sequential* itemset/association rules mining, where the pattern is mined from a sequence of items [34, 41] and [5] which discovers temporal rules for web data cleaning. In these works, the focus is also typically on arbitrary items set, rather than connected patterns. More importantly, the order of the items in the sequence is important in these works. In contrast, as explained in Section 3, in our case, only the co-occurrence of items within the given window matters, whereas their relative positioning within the window does not.

An interesting set of works that deal with sequential patterns mining studies probabilistic or uncertain databases [18, 29]. In our setting, there is inherent uncertainly, w.r.t. the (in)correctness of the identified partial updates, and thus examining the connection to such works is an interesting direction for future research.

Graph mining. Graph mining algorithms (see survey in [24]) can be roughly divided into two categories: algorithms that mine patterns in a set of graphs (e.g. [39]) and algorithms that are provided with a single large graph (e.g. [26, 28]). Our context is the latter. Multiple notions of graph pattern frequency have been proposed in the literature, many of which consider the number of distinct isomorphisms from the given pattern graph to the input graph [15, 24]. However, as our goal is to characterize how frequent a pattern is *relative to a particular entity type of interest*, we employ here the notion of frequency, inspired by [16], that counts the number of nodes, out of all nodes of the given type, that are involved in some pattern occurrence. Our notion can also be viewed as a special case of the MNI support in [15], where the isomorphism count focuses only on the given entity type.

As discussed above for association rules mining, since our focus is on connected patterns (and the corresponding frequency notion), algorithms that consider arbitrary sub-graphs (e.g. [21]) are unsuitable for our setting. We follow instead the "grow and store" approach of [26], that iteratively expands previously identified (connected) patterns. However, two issues must be addressed when adapting such a scheme to our context. First, the need to support the Wikipedia type hierarchy entails a richer order relation among patterns (see Section 3), which, to our knowledge, is not supported by any of the existing algorithms for mining connected patterns in graphs. Second, [26] (and all other comparable works), assume that the algorithm receives as input the entire graph. This is impractical in our context. Specifically, as our experiments demonstrate, materializing the complete edits graph from a massive number of entity revision histories is infeasible. Our dedicated algorithm addresses both these issues. In general, modifying solutions that expect the entire graph as input, is, arguably, not trivial. For instance, the work of [40], which leverages the embedding of the nodes to mine patterns, cannot be straightforwardly integrated into our approach of gradually examining larger subgraphs, as the embedding loses its utility if the underlying graph changes.

Another related line of work is Link Prediction [35, 38] that discover missing links within Wikipedia. However, these works do not detect incorrect links that should be removed.

Wikipedia information extraction. To conclude, we note that one may think of the patterns/time windows that we derive as a particular type of information, extracted from Wikipedia revision logs. Much previous work has been devoted to information extraction from Wikipedia *articles* (e.g. [31]) rather than their edit history. As mentioned, some works consider the revision logs, but for other purposes, and could be useful information or tool for us. In particular, [37] devise optimization methods for processing Wikipedia's revision history, as it is a massive and complicated dataset, and [25] infers the level of expertise of a specific editor from statistics of conflicts with other editors.

3 PRELIMINARIES

We start by presenting the data model underlying the system.

Wikipedia Graph. We model the relations between entities at a given point in time using a graph $G(V, E)$. Each node represents an entity and is labeled by a unique name (e.g. Neymar) and a type (e.g. *soccer player*). Each edge represents a relationship between two entities and is labeled accordingly (e.g. *current_club*).

We use an alignment from Wikipedia entities to DBPedia [1] to derive the entity types. The link labels (relationship names) are derived directly from Wikipedia. In general, the types belong to type taxonomy - the higher the type is in the taxonomy the more general it is - and an entity may have multiple types. For two types t, t' we use $t' \leq t$ to denote the fact that t either equals to t' or generalizes it. For example, $Soccer\_Player \leq Athlete \leq Person$. We assume that each entity e has one most specific type to which it belongs and use it as its label, denoted $type(e)$. For a type t we use $entities(t)$ to refer to all entities labeled by a type $t' \leq t$.

Actions and inverse actions. The revision history of Wikipedia entities contains edits to the graph edges. We particularly consider two types of actions: adding *new* edges and deleting *existing* ones. Our model associates each action with a time stamp. We use a triplet of the form $a = (+, (u, l, v), t)$ (resp. $a = (-, (u, l, v), t)$) to denote the addition (rep. deletion) of edge from u to v with label l at time t. We use $source(a) = u$ and $target(a) = v$ to denote the source and target entities, resp., of the added/deleted edge. We say that an action a' is the *inverse* of a preceding action a, denoted $a' = Inv(a)$ if applying a' after a leaves the graph unchanged.

For example, in row #1 in Figure 1 we see an update to Neymar's Wikipedia entry, when a user removed ($-$) the Barcelona ($= v$) team that Neymar ($= u$) was playing at ($= l$), at a certain time (=t), and, action #12 is an inverse action of action #1.

Note that, in Wikipedia, each action appears at the revision history of the *source* node of the edge. Intuitively, this is because the revision history of each article records the edits made to the outgoing links of the corresponding graph node. Updates of other incoming links are recorded in the revision logs of these other pointing entities. Continuing the above example, the two actions #1 and #3 will appear in the revision history of Neymar's page, and the gray action set in Figure 1 is the set of actions taken from entities of the same type (soccer_player).

(Reduced) set of actions. Given a Wikipedia graph $G(V, E)$, a set of entities $S \subseteq V$, and a time frame (referred to as *window*), we consider the set of all actions (denoted as A) that were recorded in the revision history of the entities in S, within the given window.

For instance, Figure 1 shows the set of actions recorded in the revision histories of the entities S = *{Neymar, Kyian_Mbappe, Barcelona_F.C., Gianluigi_Buffon, PSG_F.C., Monaco_F.C., Juvetus_F.C.}* at a given time frame. Observe that all the updated links are *outgoing* links from the entities in S.

In the update processes, some edits may naturally be reversed. To consider only the final effect we focus on *reduced actions sets* that do not include action and its inverse. More formally, given a graph G, we say that two action sets are *equivalent* if, when the

actions are applied on G in the order of their timestamps, they yield the same graph. The reduced set of actions, that remain by removing the rows that their value in column R equals to 0 in the table of Figure 1. We denote it as reduced actions from Figure 1.

Note that up to possibly different timestamps, the reduced version obtained through this iterative removal process is unique, as it contains the same set of graph update operations. Furthermore, the timestamps are no longer important as any permutation of the actions yields the same output graph. We thus consider from now on only reduced sets of actions and ignore the timestamps, referring to actions as pairs $a = (op, (u, l, v))$ where $op \in \{+, -\}$.

Abstract actions. Since we are trying to find general update patterns across the Wikipedia graph, we want to generalize a set of actions involving specific entities to general patterns over the corresponding entity types. For that we define the notion of *abstract actions*. We associate with each entity type t an infinite set of variables $t_1, t_2, \ldots$. Then, an *abstract action* is the pair of the form $a = (op, (t', l, t''))$ where $op \in \{+, -\}$, t' and t'' are type variables, l is an edge label.

Patterns. We define a *pattern* as a set of abstract actions. We consider two patterns identical if they are the same up to isomorphism on the variable names of the same type. We refer to a pattern that contains only a single action as a *singleton* pattern. Given a pattern p we say that a set A' of concrete actions is a *realization* of p (resp. that p is an abstraction of A') if A' may be obtained from p by replacing each variable of type t by a some Wikipedia graph node in $entities(t)$, s.t. distinct variables are assigned different Wikipedia graph nodes.

An observation that will be useful in the sequel is that for a given action a, the set of its possible abstractions can be easily computed by traversing the type hierarchy and replacing $source(a)$ (resp. $target(a)$) by some variable of type $\geq type(source(a))$ ($\geq type(target(a))$).

To illustrate the above notions, in the reduced actions in Figure 1 lines #2 and #13 are both realization of the singleton pattern {-, (player1, current_club, team1)} (which we consider identical, e.g., to the isomorphic pattern {-, (player2, current_club, team2)}). On the other hand, the reduced actions in Figure 1 contain no realization of the pattern
$[\{-, (player1, current\_club, team1)\},$
$\{-, (player1, current\_club, team2)\}]$
as the assigned team nodes have to be distinct in the realization, but all players in the table were removed from a single team.

(Abstract) actions graph. It is useful to make an analogy between action sets and graphs. Given a set of concrete (resp. abstract) actions A (p), consider the directed labeled graph g_A (g_p) with a node per each entity in A (variable in p), labeled by the entity (variable) type name, and where there exists an edge from node v_1 to v_2, labeled $[op, l]$, iff A (p) includes an (abstract) action of the form $(op, (v_1, l, v_2))$. We refer to these graphs as abstract graphs as the actual entity identities (resp. the variable names) that the nodes represent are insignificant.

With this graph view, a realization of a pattern p in a set of actions A corresponds to an isomorphism from g_p to a subgraph of g_A, where the type of each node in p either equals or is more general than the type of its corresponding node in g_A. Given a type t, we say that the pattern p is **connected** (w.r.t. t) iff g_p contains a node variable of type t from which all other nodes are reachable.

Connected patterns. Given an entity type t, we are interested in entities' updates that are related (possibly transitively) to entities of type t. We thus focus on *connected* patterns, where the updated edges are related.

Definition 3.1. For an update pattern p, let g_p be its corresponding abstract graph. Given a type t, we say that the pattern p is **connected** (w.r.t. t) iff g_p contains a node of type t from which all other nodes are reachable.

In the discussion below we refer to such a node (variable) as the pattern's **source** (w.r.t. t). If multiple such nodes exist in the graph, we arbitrarily pick one to serve as the pattern's distinguished source and we use below the term source to refer to this single distinguished node, and denote is as $source_t$.

For example, the pattern shown in Figure 3 is connected w.r.t. to the type $player$. Its corresponding graph g_p appears in Figure 2(a) where all nodes are reachable from the source node $player\_1$. But if we replace the variable $player_1$ in lines 11 and 13 of Figure 3 by a new variable $player_2$, then the pattern becomes disconnected, see Figure 2(b), and composed of two smaller, connected patterns - the abstract actions in lines 10, 5, 2, 7 (with source $player\_1$) and the abstract actions in lines 11, 13 (with source $player\_2$).

For a type t we only consider patterns that are connected w.r.t. t. Thus, for brevity, we use below the term *pattern* to refer to a connected pattern, and omit the type t when clear from the context.

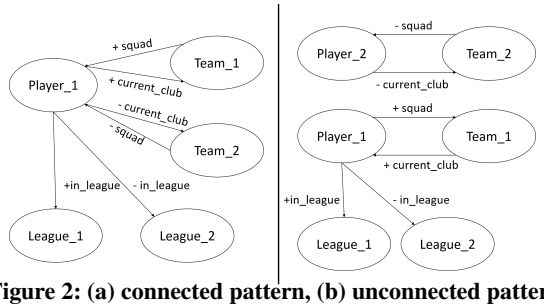

Figure 2: (a) connected pattern, (b) unconnected pattern

Frequent patterns. To define that a pattern is frequent we would like to measure the amount of support that a pattern has, regarding the seed type entities.

Many notions of patterns frequency have been considered in the graph mining literature. Common notions consider the number of distinct isomorphisms from the given pattern graph to the input graph (e.g. occurrence-based support [24] and MNI support [15]. However, as our goal is to characterize how frequent a pattern is *in the context a particular seed type of interest*, we employ here a notion of frequency inspired by the [16] that counts the number of nodes (out of all nodes of the given seed type) that are involved in some pattern. For readers familiar with the *MNI*-based support in [15], we note that our notion of frequency can also be viewed as a special case where the isomorphism count focuses only on the seed entity type node.

Given a type t, a pattern p and a set A of actions, we define the *frequency* of p (w.r.t. to t and A) as the fraction of entities of t that participate as source nodes in a realization of p is A.

Definition 3.2. The *frequency* of a pattern p in a set of actions A, w.r.t. to a type t in p, is defined as $frequency(p, A, t) =$

$$\frac{|\{e \in entities(t) \mid e \text{ appears in realization } entities(t)|}{|entities(t)|}$$

To continue with our running example, consider the actions in Figure 1 and the pattern in Figure 3, and assume there are overall five players in Wikipedia. The frequency of this pattern in the given actions set, w.r.t. to the type $player$, is 0.2 because there is only one player (Neymar) that the patterns hold for (with Neymar mapped to $player\_1$), out of the five existing players. However, the frequency of the partial pattern displayed in figure 3 in lines 1

#	Edit type	Subject	Relation	Object
10	+	$player_1$	current_club	$team_1$
11	-	$player_1$	current_club	$team_2$
5	+	$team_1$	squad	$player_1$
13	-	$team_2$	squad	$player_1$
2	+	$player_1$	in_league	$league_1$
7	-	$player_1$	in_league	$league_2$

Figure 3: Pattern found from set of action in Figure 1

and 2 (gray lines) in this actions set (again w.r.t. the type *player*), is 0.4 because there are 2 players for which that pattern holds.

Partial Order of Patterns. Given a type t, a set A of actions and frequency threshold τ we will be interested in finding patterns whose frequency in A (w.r.t. the given type) is above the threshold. To avoid redundancy, we would like to consider only the most *specific* such patterns. Formally, we say that a pattern p is more specific than a pattern p' (alternatively, p' is more general than p), denoted $p \prec p'$, if p' may be obtained from p by removing some abstract actions, replacing some type variables in p by corresponding variables of a more general type, or both. An alternative definition is close frequent sub-graph, as defined in [39]. To illustrate, for the patterns:

$p_1 = \{(+, (player_1, current\_club, team_1)),$
$(-, (player_1, current\_club, team_2))\}$
$p_2 = \{(+, (athlete_1, current\_club, team_1)),$
$(-, (athlete_1, current\_club, team_2))\}$
$p_3 = \{(+, (athlete_1, current\_club, team_1))\}$

we have that $p_1 \prec p_2 \prec p_3$.

Thus, given a type t and a set A of actions our goal will be to find the most specific patterns with a frequency above a given threshold. Our formal definition refines the closed frequent graph pattern notion of [39], taking the type hierarchy also into consideration when ordering patterns.

Definition 3.3. Given a set of actions A, a type t, and a frequency threshold τ, we say that a pattern p is a *most specific frequent pattern* in A (w.r.t. t and τ), if $frequency(p, A, t) \geq \tau$ and there is no pattern $\hat{p} \prec p$ where $frequency(\hat{p}, A, t_i) \geq \tau$.

Relatively frequent patterns. Finally, note that in the discussion so far, the frequency of patterns p was measured w.r.t. a given type, as the percentage of entities of the given type that serve as a pattern source. In some cases, it is interesting to further explore what percentage of these entities adhere to a more specific pattern p'. For example, what percentage of players among the ones that move to a new team also, change the league. For that we define the notions of *relative* frequency and *relative* frequent patterns.

Definition 3.4. For two patterns p, p' s.t. $p' \prec p$, the *relative frequency* of p' w.r.t. p in a set of actions A (for a given type variable t), is defined as

$rel\_frequency(p', p, A, t) = \frac{frequency(p', A, t)}{frequency(p, A, t)}$.

Definition 3.5. Given a set of actions A, a type t, a pattern p and a relative frequency threshold τ_{rel}, we say that a pattern p' is a *most specific relative frequent pattern* in A, w.r.t. t and p, if $rel\_frequency(p', p, A, t) \geq \tau_{rel}$ and there is no more specific pattern $\hat{p} \prec p'$ where $frequency(\hat{p}, p, A, t) \geq \tau$.

4 FINDING WINDOWS AND PATTERNS

Intuitively, given an entity type t of interest, we wish to signal out significant time frames and identify the most specific frequent patterns in them.

We will first explain how, given a specific window w and frequency threshold τ, the most specific frequent patterns in w (w.r.t. type t), are efficiently identified. The extraction of relative frequent patterns is similar. Finally, we will explain how the windows and thresholds to examine are selected.

As noted in Section 3, the (reduced) set of edit actions performed over Wikipedia entities in the time window w may be viewed as a graph. Thus one may harness graph mining algorithms, such as the ones presented in [24] to identify frequent connected patterns. Such algorithms work roughly as follows. Starting from patterns consisting of a single edge, they incrementally expend the patterns with new edges. At each iteration, they check which of the extended obtained patterns are frequent, prune all the others, and iteratively continue expending the frequent ones.

There are, however, two important issues that one has to address when adapting such a scheme to our context.

1. Supporting the Wikipedia type hierarchy entails a richer order relation among patterns (as defined in Section 3), which to our knowledge is not supported by any of the existing algorithms for mining connected patterns in graphs. While the modifications to the algorithms, to support this, are rather immediate, the number of patterns that now need to be examined becomes larger, and thus the patterns' frequency test must be performed efficiently. For that, we represent each graph's type of relation as a relational table, containing its pattern realizations. That allows us to utilize a join-based computation (optimized by the underlying SQL engine) to quickly prune infrequent patterns.

2. Observe that common graph mining algorithms assume that a full graph is given as input to the algorithm. In our setting, the revision histories are distributed across all Wikipedia entities, and (even when restricted to the time window w) their overall size can be very large. Thus, as our experiments show, materializing the full graph that represents them may be prohibitively expensive. To avoid this, we embed into the discovery of the incremental patterns an analogous incremental graph construction, that materializes only revision histories of entity types that may potentially be related to the input type t via frequent edit patterns. Our pattern mining algorithms is detailed in Algorithm 1. For better understanding the pseudo-code, we first outline the data structures and notations that we make use of. For space constraints, an illustrative example appears in our technical report [3].

4.1 Data Structures and Notation

For each considered time window w, the algorithm incrementally extracts, from the revision histories determined to be relevant, the set of actions performed within the time frame. The actions are abstracted and stored in a dictionary called $abstract\_actions$ whose keys are the time windows. Thus, $abstract\_actions[w]$ denotes a set of abstract actions with realizations in the window w. The corresponding realizations of each such abstract action are stored in a dictionary called $realizations$ whose keys are the time frame and abstract action. Thus, $realizations[w][a]$ denotes the set of realizations of abstract action a within window w.

The identified (relative) patterns, for each time window w (and pattern p in w), are stored in a dictionary named $patterns$ (resp. $rel\_patterns$) whose keys, again, are the time frames (and related patterns). Thus $patterns[w]$ (resp. $rel\_patterns[w][p]$) denotes the set of (relative) patterns computed for time window w (and pattern p in w). We overload notation and also use below $realizations[w][p]$ (resp. $realizations[w][p][p']$ to denote the realizations of the (relative) pattern p (p') within time window w. As mentioned above, the pattern realizations are implemented as relational tables. We will explain this point in details below. Finally, we use an auxiliary data structure $tested[w]$, whose keys are the time frames, to record partial patterns that have already been examined in the computation for the window w.

4.2 Pattern mining

We are now ready to present the Algorithm 1. As mentioned above, the algorithm follows the line of graph mining algorithms such as [15], starting from singleton patterns and incrementally expending them. While doing so it incorporates into the processing the two optimizations mentioned above, to ensure efficient processing in our particular setting. We note that several additional optimization techniques have been introduced in [24, 39], e.g. to minimize the used storage and search space. These are orthogonal to ours and thus, for simplicity of presentation, we follow below the basic scheme of the incremental pattern construction (to which these orthogonal optimizations can later be applied if desired).

Initialization. Our initial entity set S contains the entities of input type t. First, we extract for the given window w edit actions performed on entities in S in time window w. We reduce the set of actions, eliminating redundant edits and computing the possible action abstractions (as explained in Section 3) and store them in $abstract\_actions[w]$ and their corresponding realizations in $realization\_table[w]$. This is performed using the function $reduced\_and\_abstract\_actions(S, w)$ (line 1). $patterns[w]$ stores only abstract actions (singleton patterns) whose source is the seed type t and their frequency in w exceeds the threshold (line 2). We explain below how the frequency is efficiently computed.

Interleaving graph and patterns expansion. We next interleave the extension of considered entity set (and, correspondingly, the considered subgraph representing their respective revision histories), with the extension of the patterns.

To determine which other related entities (and, respectively, entity revision histories) should be considered, we examine the frequent patterns identified so far, to see which additional entity types appear in them, if any (line 4). Correspondingly, we add their (reduced) revision histories within w to the set of considered actions. For that, we employ again the function $reduced\_and\_abstract\_actions(S, w)$ (line 8) that reduces the revision histories and adds the actions abstraction (and their corresponding realizations) to $abstract\_actions[w]$ (resp. $realization\_table[w]$).

Next, we iteratively consider for each previously discovered frequent pattern $p \in patterns[w]$, its graph g_p and attempt to extend it with additional edges (abstract action) $a \in abstract\_actions[w]$, that has not been considered for it yet (lines 9-14). The procedure uses the auxiliary global variable $tested[w]$, (initially the empty set) to record pairs of patterns and actions that have already been examined. It is important to note that by considering all action abstractions (rather than just their base type) we can construct patterns at all abstraction levels.

Extended patterns whose frequency exceeds the threshold are added to $patterns[w]$ (line 14). We will explain later how the pattern realizations and frequency are efficiently computed. When the frequent patterns can no longer be extended *w.r.t. the current set of abstract actions/action realizations*, we check again whether the discovered patterns contain new types whose actions have not yet been considered (line 4). If so, we repeat the graph and patterns extension (lines 5 - 15). Observe that the incremental nature of the patterns' construction allows refining the previously derived patterns with the newly added abstract actions, rather than computing frequent patterns from scratch. In other words, the extension of the actions graph, and the extension of the patterns (w.r.t. the extended graph), interleave well.

Note that, in the presentation so far we keep in $patterns[w]$ *all* the discovered frequent patterns and not just the most-specific ones. This is because such general patterns may still be useful, in later iterations, being expended to other, different most-specific patterns. However, an optimization that we can still employ here is the removal of these (not most-specific) patterns whose expansions have been fully examined, e.g. where all the entities types occurring in them have been thoroughly processed (line 15). Another optimization that we employ (omitted from the pseudo-code) is the cashing of the computed frequencies/realization tables, to be reused if the same patterns are later re-examined with different thresholds. When all patterns have been discovered, we select the most specific ones and return them (line 16).

Computing patterns realization and frequency. To complete the picture we need to explain how the patterns realizations and frequency are computed in lines 12-13 of the algorithm. To efficiently compute (and extend) pattern realizations, we represent each pattern realization in $realizations[w][p]$ by a *relational table* whose attribute names correspond to the pattern variables names, and whose tuples capture the different realizations of the pattern in the given time window (namely the qualifying assignments of concrete Wikipedia graph nodes to the pattern variables).

Now, note that given a pattern p and an abstract action a, there may be several ways to extend the graph g_p with a. First, a's source may be "glued" to any of the nodes (variables) in p of the same type as a (if such exist). Second, for each such possible gluing, a's target may either be added to the pattern as new pattern node (in which case g_p is extended by both a new edge and a new node) or the target may also be glued to an existing same type node (in which case g_p is extended by only a new edge).

We process each such possible extension as follows. Let p' be such an extended pattern. An important observation is that, using the relational representation discussed above, the realization table of the extended pattern p' can be easily computed, from $realizations[w][p]$ and $realizations[w][a]$, via a join-based query. For the glued pattern/action nodes we use equijoin on the corresponding attributes, whereas for the new node (if such exists), we require inequality to all same type attributes. Finally, we only need to project a single column for each pattern attribute. Then, the frequency of a pattern p w.r.t. a type t can be easily computed from the relation, by an SQL count operator that counts the number of distinct nodes appearing in the column corresponding to the pattern's source variable, (then dividing the count by the cardinality of $entities(t)$).

Mining Relative Patterns. To conclude, we note that the computation of *relative* frequent patterns proceeds in a similar manner. The only difference is that each pattern p we begin the expansion process starting from p itself, and relative frequency (rather than just frequency) is computed similarly, but using the formula in Definition 3.4. We omit the details for space constraints.

4.3 Finding Windows and Thresholds

So far we assumed that we are given a window w and a threshold τ, and our goal was to identify the (relative) frequent patterns in w, w.r.t. the seed type t. To identify windows and thresholds of potential interest, we use a simple heuristic, which our experiments show to be extremely effective.

We restrict our attention to non-overlapping time windows and split the revision histories accordingly. This allows parallelizing the processing of the action sets in the different windows. Our analysis of real Wikipedia data indicates this to be a reasonable design choice. For an input type t there are very few meaningful (update-wise) time frames that overlap and those can be merged into a somewhat longer window that includes both update patterns.

Algorithm 1: Mine connected patterns

Input: entity set S,Wikipedia type t, window w, frequency threshold τ, relative threshold τ_{rel}
Output: (relative) patterns and their time frames: $patterns[w]$, rel_patterns[w][p]

1 call reduced_and_abstract_actions(S, w) to create abstract_actions[w] and realizations[w];
2 patterns[w] = $\{\{a\} \mid a \in$ abstract_actions[w] $\wedge type(source(a)) = t \wedge$ frequency($\{a\}$) $\geq \tau$ $\}$;
3 tested[w]={};
4 **while** *new type names found in patterns[w]* **do**
5 **foreach** $p \in$ *patterns[w]* **do**
6 **foreach** *new type name* $t \in p$ **do**
7 S = get_entities(t);
8 call reduced_and_abstract_actions[S, w] to expand abstract_actions[w] and realizations[w];
9 **while** *there exists* $p \in$ *patterns[w],* $a \in abstract\_actions[w]$, *s.t.* $(p, a) \notin$ *tested[w]* **do**
10 tested[w]=tested[w] $\cup \{(p, a_i)\}$;
11 **foreach** *pattern* p' *obtained by expending* p *with* a_i **do**
12 compute realizations[w][p'] from realizations[w][p] and realizations[w][a_i];
13 frequency(p') = $\frac{|distinct\ entities\ of\ type\ t\ in\ realizations[w][p']|}{|entities(t)|}$; **if** *frequency*($p'$) $\geq \tau$ **then**
14 patterns[w]=patterns[w] $\cup \{p'\}$;
15 $prune(patterns[w]), realizations[w]$
16 patterns[w]=most_specific_patterns(patterns[w]);
17 **Return**($patterns$)

Our algorithm is initialized with minimal window size (the system default is two weeks) and frequency thresholds (default 0.7), which are iteratively refined: The window size is extended (resp. the threshold it lowered) if no qualified patterns were found, or if the refinement leads to the discovery of additional patterns. The extension granularity (resp. frequency bound reduction) may be determined by the user. Otherwise, the default refinement policy is to alternate between multiplying the window size by two (retaining the threshold as it) and reducing the frequency thresholds by 20% (retaining the window size). This is repeated as long as the refinement leads to new patterns, up to a maximal window size of one year, and a minimum threshold value of 0.2 (All experiments were run with this setting). We chose the above heuristic by examining several alternatives, as elaborated in Section 6, and chose the one with the lowest running time among all heuristics that performed best in terms of $F1$ score evaluations.

We now present the full algorithm, depicted in Algorithm 2. As mentioned above, given an entity type t, our initial entity set S contains all entities of the input type. Users not familiar with the type hierarchy may provide a seed entity e and the system will use $type(e)$ as an input (lines 1-3). To derive $type(e)$ we use an alignment from Wikipedia entities to DBPedia [1]. Then to find all entities of type t we employ a corresponding inverse index.

We first split the timeline into consecutive time frames of size W_{min} (line 7). Next we call (possibly in parallel) the procedure $Mine\_connected\_patterns$, described in Algorithm 1 in Section 4, for all windows (line 9). We iteratively refine the considered windows width (W_{min}) and frequency threshold (τ) (following the heuristics described above), and until a stable result is obtained (lines 10-11). Finally, for each discovered pattern p in window w, its relative frequent patterns are mined as well (lines 14).

Algorithm 2: Find windows and patterns

Input: Wikipedia type t or seed entity e, min. window width W_{min}, frequency threshold τ, relative threshold τ_{rel}
Output: (relative) patterns and their time frames

1 **if** *t is not given* **then**
2 t = type(e);
3 S = get_entities(t);
4 patterns = [];
5 rel_patterns = [];
6 **Frequent patterns Stage;**
7 split the timeline into a set W of consecutive time frames of size W_{min};
8 **foreach** w *in* W **do**
9 patterns[w]= Mine_connected_patterns($S, t, w, \tau, \tau_{rel}$)
10 **if** *patterns==[] or refine?*(W_{min}, τ,*patterns*)==*True* **then**
11 go to line 7 with the updated W_{min}, τ;
12 **Relative frequent patterns Stage;**
13 **foreach** $w \in W$ **do**
14 rel_patterns[w] = Mine_rel_connected_patterns (patterns[w], rel_patterns[w], abstract_actions[w], realizations[w],τ_{rel});
15 **Return**($patterns, rel\_patterns$)

5 USING WINDOWS AND PATTERNS

We employ the discovered windows and patterns to clean and correct Wikipedia entries, as well as to assist users in editing.

Cleaning. An immediate application of the discovered patterns is to alert Wikipedia editors on partial edits from past windows. For that, we examine the discovered windows and identify for each window and pattern (using an efficient outer-join based algorithm, described below, parallelly processed) partial sets of actions that may be extended to a full pattern occurrence. To assist the editor in determining how (if) the partial edit should be completed (or reversed), we present examples of other full patterns.

To explain how the algorithm works, recall from Section 4.2 that, to discover patterns, we iteratively expand the pattern's graph, joining corresponding action relations to form a relation table that captures the pattern realizations. In each such join, the left-hand side (LHS) relation represents the realizations of a (partially growing) portion of the pattern, and the right-hand side (RHS) relation contains the realizations of the added edge. The join conditions assert the (in)equalities of the corresponding graph nodes. To identify *partial updates*, that haven't been properly completed, we similarly traverse the graph. But instead of the abovementioned *join* operator, we employ a *full outer-join* [6], with analogous (in)equality conditions. Note that, unlike the join, the full outer-join also records in the output relation those LHS (resp. RHS) tuples not matching any RHS (LHS) tuple, *padding the missing attribute values with nulls*. In terms of our patterns, partial pattern realizations (resp. action realizations) that are missing a corresponding action (partial pattern) are also recorded in the relation, padded by null values. The incomplete edits can then be easily identified via a selection query retrieving tuples with null values. A result table keeping the attributes of original action relations is kept to record which missing updates cause null values.

Our algorithm for identifying partial updates is depicted in Algorithm 3. For a time window w and a pattern p, it focuses on the entity types in p. It invokes $reduced\_and\_abstract\_actions$ (described earlier), to examine their revision histories and construct the realization relations of their corresponding abstract actions (lines 1–2.) Next we traverse the pattern's graph g_p, and iteratively outer-join the corresponding relations (lines 8-9). We use $p_1 \ldots p_n$ to denote the incrementally growing sub-patterns (from the first singleton edge a_1, to the full pattern p). The array

Algorithm 3: Identifying partial updates

Input: window w, pattern p
Output: partial realizations of p in w

1 let S be the set of entity types in p;
2 call reduced_and_abstract_actions(S, w) to create abstract_actions[w] and realizations[w];
3 let $e_1, \ldots, e_n$ be the edges in the pattern's graph g_p, in some traversal order;
4 let $a_1 \ldots, a_n$ be the corresponding actions in p;
5 $p_1 = \{a_1\}$;
6 $all\_realizations[p_1] = realizations[w][a_1]$;
7 **for** $i = 2 \ldots n$ **do**
8 $\quad p_i = p_{i-1} \cup \{a_i\}$;
9 $\quad$ compute $all\_realizations[p_i]$ from $all\_realizations[p_{i-1}]$ and $realizations[w][a_i]$ using full outer-join;
10 $partial\_r = \{r \in all\_realizations[p] \mid r$ includes a null value $\}$;
11 **Return**$(partial\_r)$

$all\_realizations[p_i]$ is used record the intermediate (possibly incomplete) pattern instantiations. Finally we return all tuples that include null values (lines 10-11). An example of the algorithm execution appears in our technical report [3].

Edit assistance. Update patterns often appear periodically in multiple windows. For example, transfer windows occur each summer with a similar edit pattern. Our system automatically identifies such periodic patterns/windows and provides online edit assistance (via a plug-in) to users that update pattern entities within a given window, suggesting potential update completions, as explained above. The algorithm for identifying patterns that need completion follows similar lines, with the user alerted on partial edits that involve entities that she is updating.

6 EXPERIMENTS

We open this section by describing the experimental setup, the examined datasets, baselines, and evaluation methods. We then present the results, both in terms of running time and quality. Finally, we present a comparative analysis of heuristics, demonstrating the superior performance of the heuristic used by WC.

6.1 Experimental Setup

We have implemented WC as a web browser extension, with backend in Python, frontend in JavaScript, and SQL over pandas as the underlying query engine. All experiments were executed on an Intel i7 2.4Ghz with 96GB RAM and 16 cores server. We ran experiments over Wikipedia datasets and examined the system performance in terms of running times, the quality of the discovered patterns, and the number of detected errors, w.r.t. these patterns.

For the quality experiments (and measuring the running time) we use the default settings of WC. Recall that our algorithm is initialized with minimal window size (default is two weeks) and frequency thresholds (default 0.8), which are refined throughout the computation. As mentioned, the default refinement policy alternates between multiplying the window size by two and reducing the frequency thresholds by 20%, up to at most one year window and a minimal 0.2 frequency. For other experiments, that test the effect of each parameter, we vary the given parameter while setting all others to default values, as explained below.

Settings. To demonstrate the operation of WC in different entity domains, we examine here three Wikipedia domains: soccer (including players, teams, leagues, etc), cinematography (actors, movies, awards, etc) and US politicians (specifically US senators). To derive patterns (and correspondingly identify potential edit errors) we used the revision history for the year 2018. We then validated the signaled potential errors w.r.t. edits recorded in the revision history of 2019. To further assess (resp. validate) the identified patterns (signaled errors), we have also consulted three domain experts - one expert per each of the three domains.

For the soccer domain, we used major European leagues' soccer players for our seed set of entities. For the cinematography domain, we used actors from Hollywood-produced movies for the seed set. Lastly, in the politicians' domain, we used US senators for the seed entity set. In each domain, we considered different sizes of seed sets by randomly choosing between 100-1K entities from the respective seed type. We run each experiment 5 times and show the average running time (the variance was below 5%). For the entities selection, we used the "recently edited" criterion (edited in the last year of 2018) to focus on active pages with edits that may contribute to the mining process, and may also contain errors. Following Algorithm 2, we also considered related entity types and extracted their revision history in the corresponding period.

Due to the lack of an appropriate API, obtaining the Wikipedia data required crawling and parsing entities and it's revision logs. Nevertheless, we gathered data for 100K entities - about 10^{th} of the million frequently edited Wikipedia's entities [4].

Algorithms. The core of WC is Algorithm 2 (referred in the sequel as WC) which identifies time windows of interest and corresponding edit patterns. A main ingredient of WC is the pattern mining procedure depicted in Algorithm 1 (referred in the sequel as PM) that given a specific window w and frequency threshold τ, identifies the most specific frequent patterns in w (w.r.t. the seed type of interest). As explained in Section 4, PM refines conventional graph mining algorithms [15] by introducing two dedicated optimizations: (1) an efficient join-based SQL computation of patterns realization and frequencies, and (2) an incremental computation that avoids a full materialization of the edits graph. To demonstrate the importance of these two optimizations, we examine the running times of the following four algorithm variants.

- PM, our mining algorithm.
- PM^{-join}, a restricted variant of PM without our dedicated join-based queries. Instead, pattern realizations and frequencies are computed via conventional main memory nested loop.
- PM^{-inc}, a restricted variant of PM that does not utilize our incremental, on-demand graph construction. Instead, the full edits graph for the given window is materialized then given as input to the mining process (but patterns realization/frequency is still computed via our join-based queries).
- $\text{PM}^{-inc,-join}$, conventional graph mining without our two optimizations. The edits graph for the window is materialized as input to the mining process, with the pattern realizations/frequencies computed via the main memory nested loop.

Note that direct comparison to leading graph mining baselines is not possible due to their use of different frequency metric (not capturing connectivity property and relativity to a specific type) and lack of support for type hierarchy. We have thus adapted the most relevant variant to our context, denoted by $PM^{-inc-join}$, and benchmark w.r.t. it. See discussion in Section 2.

6.2 Running Time Analysis

Next, we examine how the running time is affected by (1) the size (number of entities) of the seed type of interest, (2) the frequency threshold, and (3) the window size. In each experiment, we vary one parameter while setting the others to a default value (500 seed entities, 0.7 frequency, and two weeks, resp.). As the results for the different domains show similar trends, we present here a representative set of experiments for the soccer domain.

Note that, as is common in graph mining algorithms, PM^{-inc} and PM$^{-inc,-join}$ require the full edits graph for the given window to be materialized. However, materializing this graph, even for relatively small time windows, can be infeasible. Indeed, our experiments show that even when considering a two-week time window, only 100 seed entities, and revision histories only of entities reachable from the seed set, the graph construction exceeded 24 hours (the time limit for the graph materialization). This is due to the dense connectivity of the Wikipedia graph[6] [4], the previously mentioned high volume of edits, and the lack of adequate API, as noted above. Thus, as the graph must be constructed for each considered window, we initially focus only on the two feasible algorithms: PM and PM^{-join}, with the infeasible algorithms evaluated over reduced inputs. We report below the sizes of the partial graphs built by PM and PM^{-join}. For intuition on the relative savings, we note that the graph for the 100 seed entities during these 2-weeks contains over 100K entities.

Seed set cardinality. We start by examining the running time as a function of the size of the seed set. Naturally, the more entities in the seed set, the more related updates need to be examined and the more revision histories are processed. Consequently the running time of both PM and PM^{-join} increases, as illustrated in Figure 4(a). The threshold is set here to the default value of 0.8 and the window is the month of August. Similar results are obtained for other thresholds/months. Next to the size of each seed set, we give (in parenthesis) the overall number of related entities (graph nodes) processed by the algorithm. In each column, the upper part shows how much time (in hours) it took to parse the revision history of the relevant entities and extract the reduced updates set. This is naturally identical for both algorithms (as they only differ in the computation of pattern realizations/frequencies). It should be noted that this time would be much shorter if Wikipedia had provided a more convincing API for its revision logs or, publicly-available structured revisions database. The lower part of each column shows the running time dedicated to the pattern mining itself. We can see that is significantly shorter for PM that employs our efficient join-based queries. For PM the pattern mining time only marginally grows when the seed set size increases and stays below 15 min, which is very reasonable for offline computation.

Frequency threshold. Next, we examine the running time as a function of the frequency threshold. The seed set size is set to a default size of 500 and the window is the month of August. (Similar results are obtained for other sizes/months). The lower the threshold, the more potential patterns (and revision histories of involved entity types) need to be examined, and, consequently, the processing time of both algorithm increases, as illustrated in Figure 4(b). The processing time for the revision logs is the same in both algorithms, but PM mines the patterns much faster. Again, for PM the pattern mining time increases only moderately when the threshold decreases and stays below 15 min.

Window size. In this experiment, we measure the preprocessing time for varying window sizes. Figure 4(c) illustrates the processing time for 2, 4 and 8 weeks window. Specifically, we see here the running times for the first two weeks of August, the whole month of August, and the two months July and August, but similar results are obtained for other similar-length windows. (The seed set size here is again set to default size of 500 and the frequency default 0.8. Similar results are obtained for other sizes/frequencies). Naturally, the larger the window, the more updates need to be processed and as a result, more patterns may occur. Consequently, the running time increases. Again, the processing time for the revision logs in both algorithms is the same, but PM mines the patterns much faster.

Parallelism. So far we examined the performance of the PM component of WC. To complete the discussion we now examine the full operation of WC, highlighting, in particular, its embarrassingly parallelized nature. Recall that WC splits the timeline into non-overlapping windows that may be processed in parallel. Similarly, independent entity types can be processed in parallel. This is easily exploitable in a multi-core setting as shown in 4(d). We focus here on the pattern mining process (the revision logs processing shows similar trends). The figure shows the time in minutes (in log scale) of the pattern mining computation for a single core vs 16 cores, for varying sizes of seed entity sets. As before, next to the size of each seed set we give in parenthesis the overall number of related entities (nodes) processed by the algorithm. Note that the numbers here are the *total number of nodes* processed through all iterations, for all examined windows and threshold values. Running on 1000 entities takes less than one minute on a single core. 5K entities need 6 minutes to process on one core and about 1 minute on 16 cores. For 100K entities - the largest entities set generated in the algorithm execution on the three domains mentioned above - it took 58 minutes on one core and about 15 minutes on 16 cores. Overall, the parallelization speedup is about 4x.

Based on known statistics of approximately 5.9 million Wikipedia entities (one million of them are of mid-to-high importance) [4], given a preprocessed Wikipedia revisions database/graph (which unfortunately is currently not publicly available), running on all Wikipedia entities will take about six hours (one hour on mid-to-high importance entities) on a 16 core server.

Experiments with small data. As mentioned above, the materialization of the entire edits graph of Wikipedia, which is a necessary input for PM^{-inc} and $PM^{-inc-join}$, takes impractical time. To, nevertheless, evaluate the efficiency of these two algorithms, we also conducted experiments over considerably smaller subsets of the Wikipedia graph. Over such small instances, the running time is less meaningful, however, we can focus instead on the number of considered pattern candidates as an indication of the efficiency of these algorithms. Note that, since this experiment is only possible over small data, typically negligible amounts of noise become significant, and since the number of seed entities is small, many of the identified candidates will exceed the threshold. Therefore, we do not examine any quality indicators.

Concretely, we examined a small subset of Wikipedia, consisting of 10 seed entities from the soccer domain, and all the revisions of these entities that occurred within an arbitrarily chosen two-week period. We constructed the corresponding edits graph, containing the seed entities and a close (2-reachable) neighborhood of these seeds in two phases, as follows. We first added to this graph all the entities that are connected within one link from the seeds and were also edited in the chosen time window, and then we also added, analogously, another layer of neighboring entities - all the entities that are connected within one link to the previously added entities, and were also edited in the chosen time window. We did not extend the graph further, as it could not be materialized within the time frame we defined. The above construction resulted in a graph with roughly 10K entities.

We compared the performance of PM^{-inc} and $PM^{-inc-join}$ over this graph, to that ofPM (our pattern mining algorithm) and PM^{-join} (which does not include our dedicated join-based

[6]Wikipedia contains about 6 million entities (of which 4 million are considered of marginal importance) and over 80 million internal links as to 2010.

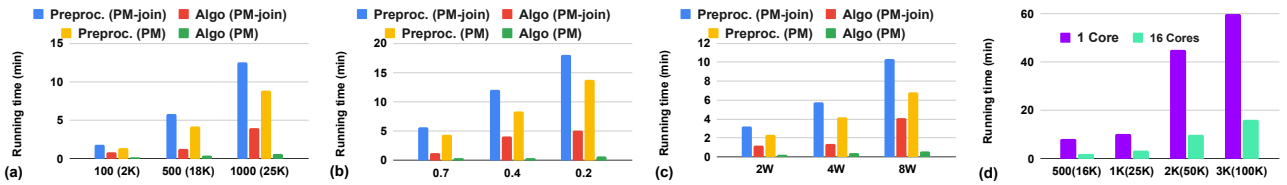

Figure 4: Running time when varying the (a) DB size (b) threshold (c) window size (d) WC execution time on 1 vs 16 cores

queries) over a Wikipedia subgraph of the same size. Recall thatPM and PM^{-join}, in contrast to PM^{-inc} and $PM^{-inc-join}$, do not receive the complete graph as input, rather create the relevant edits subgraph (of the Wikipedia graph) incrementally on-the-fly. Therefore, to ensure a meaningful comparison, we used as input a set of 200 seeds, as this results in subgraphs of roughly 10K entities (which is also the size of the input graphs for PM^{-inc} and $PM^{-inc-join}$). Moreover, as we focus solely on the number of considered candidates, this value will be the same for all variants ofPM, when employed over the same graph, as the frequency definition is identical for all baselines. Therefore, the result will be the same forPM and PM^{-join}, and also the same for PM^{-inc} and $PM^{-inc-join}$. Hence, we essentially compare only two approaches in this experiment (receiving the complete graph in advance versus computing a more relevant subgraph on-the-fly).

The results show that PM^{-inc} and $PM^{-inc-join}$ consider more candidates (524), compared toPM and PM^{-join} (125). This demonstrates the superiority of our incremental graph construction approach, which prunes many of the irrelevant candidates.

6.3 Quality Analysis

To assess the usefulness of WC for error detection we evaluated the quality of the discovered patterns and the validity of the potential errors signaled using these patterns. We employed WC, over the subsets of the Wikipedia 2018 revision log relating to the domains of *soccer*, *cinematography*, and *US politicians*, with the corresponding seed sets consisting of 1000 entities.

Ground truth patterns. To evaluate the correctness and coverage of the detected patterns, we asked each of the three experts to provide a comprehensive list of common periodic update patterns, in structured data. The soccer expert provided 11 such patterns (e.g., the page of a player that won the "Goal of the Month" award should link to the page of the award and vice versa). The cinematography expert provided 8 patterns (e.g., a TV series page should point to all the pages of its specific seasons). Lastly, the politics expert provided 5 patterns (e.g., the page of a newly-elected senator points to her predecessor's page and vice versa).

Discovered patterns and detected errors. Interestingly, the patterns derived by WC are a proper subset of the set of patterns provided by the experts, implying 100% precision. In terms of recall, our algorithm detected 9 (out of the 11) soccer-related patterns, 7 (out of the 8) cinematography related patterns and 4 (out of the 5) US politicians related patterns, yielding an average recall of 83.3% across all the domains. The discovered patterns were then used by WC to detect erroneous updates.

Running Algorithm 3 on the 2018 revision log we have identified 3743 potential errors for the soccer domain, 2554 potential errors for the cinema domain and 1125 potential errors for US politicians. To determine which of these are actual errors, we ran a two-step verification process. First, for each signaled potential error (partial pattern occurrence) we examined whether it still existed after the 2019 updates had been applied. Errors that were eliminated (corrected) are considered true errors. Note, however, that the remaining set may still include actual errors that went unnoticed. To determine how many such signaled, unnoticed errors Wikipedia still contains, we sampled 50 such errors per pattern and asked the relevant domain expert to determine their validity. Next, examples and results of discovered patterns are provided.

Soccer. Out of the 3743 signaled potential errors, 2680 were corrected in 2019 (71.6%). From the remaining examined cases, 82.1% were indeed verified as actual previously unnoticed errors.

To illustrate, the simplest pattern detected in the soccer domain indicates that, after joining a new club, the page of the player should link from the *career* table to the page of the club, which, in turn, should add a link to the player's page in the *current squad* table. This pattern has a frequency of 0.8 in the window consisting of the first week of August. Out of the 50 sampled errors for this pattern (partial pattern occurrences), 48 indeed turned out to be previously unnoticed errors (96%). A more complex pattern includes also the deletion in the player's page of the link to the old club, and vice versa. This pattern has a lower frequency (0.4) and a wider window size (the first two weeks of August). Here, out of 50 sampled potential errors, 44 were verified as actual errors (88%). An example of such an error, detected by the algorithm, relates to the page of Nikola Mitrovic, a player that switched leagues. His new club, ZTE, added him to its current squad table, while the previous club, Kesla, did not remove him. Similarly, Aleksandrs Cauna's page was updated when he joined his new club Jelgava, whereas the page of RFS, his old club, still pointed to his page past the transfer window. A relative frequent pattern, that the algorithm detected, includes an update of the *current league* link in the player's page. While this pattern is much less frequent (since a player may move to a club in the same league, in contrast to the previously mentioned patterns, where a violation almost certainly results in "incomplete" data), its relative frequency, nevertheless, exceeds the threshold. Out of the 50 detected potential errors, 14 were indeed actual previously unnoticed errors.

Cinematography. One example of a detected pattern relates to an actor/actress winning the Oscar award: the page of the winner should link to the page of the award and vice versa. In terms of quality evaluation, out of the 2554 signaled potential errors, 1731 were corrected in 2019 (67.8%). Of the remaining cases, 81.2% were determined to be true unnoticed errors.

US Politicians. An illustrative example of a discovered pattern in the US politics domain pertains to the election of a new senator. Given such an event, the pages of the new senator and the relevant state must point to each other, and also a link to the page of the previous senator is removed from the page of the state. The page of the previous senator should still point to the state, since the only modification relates to the adjacent text, detailing the period during which she held office. Out of the 1125 signaled potential errors, 728 were corrected in 2019 (67.8%). Of the remaining cases, 78.1% were determined to be previously unnoticed errors.

Insights. To conclude, we discuss insights derived from the above evaluation, that reaffirm the distinction between our intended use-cases and those addressed by previous works. As mentioned in the Introduction, our solution focuses on patterns that are associated with a well-defined time window, complementing existing solutions that target 'window-less' constraints. Indeed, for all the discovered patterns, a statistically significant time window was identified. In contrast, of the few overlooked patterns,

Table 1: Sample of heuristics test

(w, τ)	Running time (min)	Precision	Recall	F1 Score
2.0x, 20%	**2**	**1**	**0.84**	**0.91**
1.0x, 20%	1.2	0.88	0.68	0.77
2.0x, 0%	1.2	1	0.75	0.86
1.5x, 10%	3.2	1	0.68	0.81
3.0x, 40%	1.5	0.75	0.88	0.81

two are not clearly associated with any time window. This further reinforces the contrast between our solution and other works.

6.4 Parameter Tuning

When refining the two parameters across different iterations, *PM* alternates between multiplying the window size by two and reducing the frequency threshold by 20%. To arrive at these values, we performed a grid search, selecting the parameters that led to the fastest running time among the options that yield the best $F1$ score (w.r.t. patterns provided by experts). We checked combinations of reducing the threshold by X and multiplying the window size by Y, where X ranges from 1% to 100%, in steps of 5%, and Y ranges from 1.5 to 5, in steps of 0.5. In terms of the bounds for the above parameters, the window size is restricted to the range of two weeks to one year, while the threshold is restricted to $[0.2, 0.7]$. These intervals were also derived via an analogous grid search over various ranges. A sample of the results is depicted in Table 1, where the left column provides the combination of the changes in the values of the window size and the threshold. Note that the first row pertains to the combination used by `WC`.

These results demonstrate the advantages of our balanced approach, compared to more extreme approaches. Namely, opting for very small changes to the parameters increases the running time and lowers the recall. The recall drops because WC would terminate at an early stage, as new patterns are not likely to be discovered compared to the previous iteration. At the other extreme, drastically changing the parameter values, while improving the running time, lowers the precision score. The latter effect is due to quickly reaching iterations where the time window is large and the threshold is low, causing WC to discover erroneous patterns, whereas WC with our heuristic would terminate prior to this point.

7 CONCLUSION

This paper presents WC, a Wikipedia plug-in assisting editors in maintaining the correctness of inter-links. Given an entity type of interest, our efficient, highly parallelizable algorithm identifies relevant edit patterns across revision histories of entities of related types, along with time windows in which partial edits are acceptable. The discovered patterns/windows are then used by WC to alert editors on past edits that appear incomplete, and provide users with on-line assistance as they update Wikipedia. Our experiments with Wikipedia data demonstrate the efficiency and effectiveness of our approach in identifying and correcting errors.

There are several directions for future research. As our work considers inconsistencies in structured parts of Wikipedia, expanding our approach to consider free text, in particular parts related to the inter-links, is a challenge. Another intriguing future direction is enriching the expressiveness of the patterns to support value-specific instantiations (e.g., a pattern specific to PSG, but not to football clubs in general). Finally, applying our ideas to other domains where revision histories are available and link consistency is important (e.g., software repositories) is another challenge.

ABSTRACT

Data quality validation is a crucial step in modern data-driven applications. Errors in the data lead to unexpected behavior of production pipelines and downstream services, such as deployed ML models or search engines. Typically, unforeseen data quality issues are handled via manual and tedious debugging processes in a reactive manner. The problem becomes more challenging in scenarios where large growing datasets have to be periodically ingested into non-relational stores such as data lakes. This is even worse when the characteristics of the data change over time, and domain expertise to define data quality constraints is lacking.

We propose a data-centric approach to automate data quality validation in such scenarios. In contrast to existing solutions, our approach does not require domain experts to define rules and constraints or provide labeled examples, and self-adapts to temporal changes in the data characteristics. We compute a set of descriptive statistics of new data batches to ingest, and use a machine learning-based novelty detection method to monitor data quality and identify deviations from commonly observed data characteristics. We evaluate our approach against several baselines on five real-world datasets, on both real and synthetically generated errors. We show that our approach detects unspecified errors in many cases, outperforms other automated solutions in terms of predictive performance, and reaches the quality of baselines that are hand-tuned using domain expertise.

1 INTRODUCTION

Data-driven decision making is becoming the norm in modern enterprises and organizations, and requires maintaining and regularly updating large datasets, often collected in non-relational stores such as data lakes. A critical step in these scenarios is data quality validation, as the quality of the derived insights and decisions crucially depends on the quality of the collected data [42]. Incorrect or missing data can lead to wrong business decisions and problems in downstream data consumers, such as machine learning (ML) models or search engines [1, 17, 43], and even crash systems, e.g., due to null-pointers originating from missing data. Common sources of errors are bugs in external data sources and data preprocessing code (e.g., when a data engineer accidentally changes a time measurement from seconds to milliseconds in a data-producing pipeline). Such errors often corrupt large parts of the data to ingest and can immediately lead to devastating consequences, e.g., wrong predictions of ML models that consume the data [37]. In this work, we focus on automating the detection of such data quality issues.

We address the following real-world example scenario. Consider a data engineering team at a retail company maintains a search engine for products. To keep the search engine up-to-date, it deploys a pipeline that regularly ingests and indexes external product data from various heterogeneous sources, such as web crawls, log files, key-value stores, or upstream data pipelines. If a data source introduces errors in the data to ingest, such as missing values or wrong encoding of strings, then the products will not be indexed correctly or, even worse, cause the ingestion process to crash. Such data issues are typically handled reactively: the engineering team discovers data issues via alerts from devops engineers, bug reports, and customer reviews. The data is then manually fixed and back-filled. Handwritten code is added to the data pipeline in retrospect to catch the observed type of errors in the future [43].

In this paper, we propose an approach to automate data quality validation in scenarios where large partitions of a growing dataset have to be regularly ingested into a common data store such as a data lake. While relational databases enforce a schema and integrity constraints for their data [13], many modern applications rely on non-relational data stores. Pipelines that do not specify a particular schema or constraints on the data are often much cheaper to operate in cloud environments (e.g., using S3 as a distributed filesystem for storing the data partitions and Apache Spark for processing them).

In contrast to existing work on fine-grained error detection [1, 17, 27, 29, 36, 47], we focus on scenarios where systems regularly ingest batches of external data, and data errors corrupt a large fraction of the batch [42] (Section 3). In the aforementioned retail example, a few missing product reviews in a partition might not cause issues in the downstream systems, as they are programmed to handle that (e.g., by using missing value imputation strategies). However, an unusually high fraction of missing values in the review description is an indicator of a severe problem in one of the external data sources.

We automate the detection of six types of errors (explicit and implicit missing values, numeric anomalies, typos, swapped fields for numeric and textual attributes) as follows: we leverage previously ingested data batches as "positive" examples of "acceptable" data and use a machine learning approach to identify new batches that significantly deviate from the previously observed data. Specifically, we compute a set of descriptive statistics over the ingested data and train a novelty detection ML model [30, 31] to learn the characteristics of the "acceptable" data. We apply the ML model on new data batches to ingest, in order to identify potentially erroneous data batches that significantly differ from previously observed data (Section 4).

Our approach provides several advantages over existing work. First, it does not require domain experts to design and maintain large numbers of rules [3, 20, 43]. Devising such rules and constraints is a very tedious and expensive process as the datasets found in enterprises are typically large and messy [45], especially if they originate from the integration of different external data sources. Secondly, our approach is computationally efficient as the descriptive statistics we apply can be computed in a single

pass over the data. Our novelty detection model has a low number of parameters to optimize. Finally, our automated approach performs well in cases where the data characteristics change over time, in contrast to rule- and constraint-based approaches [20, 43] that require a manual redefinition of rules and constraints.

We evaluate our approach by comparing its predictive performance to automated and hand-tuned variants of the following state-of-the-art solutions: Tensorflow Data Validation [6], Deequ [43], and statistical testing [32, 41]. Then, we evaluate the sensitivity of our approach towards six types of errors (explicit and implicit missing values, numeric anomalies, typos, swapped fields on numeric and textual attributes) and the predictive performance under various error magnitudes (1, 5, 10, 20, . . . , 80%) in a controlled environment for datasets with synthetically generated errors. Finally, we evaluate the detection quality of our approach over time, as (a) the size of the training set for the novelty detection algorithm grows continuously, and (b) its data characteristics change over time. In summary, we make the following contributions:

- We propose an approach to automate data quality validation for data that is periodically ingested into non-relational stores. In contrast to existing solutions, our approach does not require domain experts to define rules or labeled examples, and self-adapts to temporal changes in the data characteristics (Sections 3 & 4);
- We discuss how to apply our approach efficiently via a novelty-detection ML model trained on data quality metrics of the data (Section 4);
- We evaluate our approach against existing baselines on five real-world datasets with real and synthetically generated errors. We find that our approach detects the unspecified errors in many cases under varying error magnitudes, outperforms other automated solutions in terms of predictive performance, and reaches the ROC AUC score of baselines hand-tuned with domain expertise (Section 5).

2 BACKGROUND

In the context of this work, we understand data quality validation as the process of checking that the input data meet the needs of a data-driven application or its underlying business process, where these specific needs are either formulated explicitly with the data standards and policies or assumed implicitly by the application logic. The concept of data quality is broadly defined as a measure of the fitness of the data to their intended uses and purposes [11]. To identify how well the data fit for the intended purpose, the wast body of knowledge [5] suggests several data quality dimensions, such as data *accuracy* (the degree to which the data correctly represent the real-world entity it models), *completeness* (the degree to which the data contain the necessary attributes to model the entity), *validity* (the degree to which the data are stored or represented in a format that is consistent with the domain of values), and others. In practice, data quality is assessed with a set of quantitative metrics that are associated with the aforementioned data quality dimensions. In this section, we briefly introduce the data quality metrics that we leverage in our approach and the machine learning-related background for novelty detection.

Data quality metrics. We consider several quantitative statistics that can be used to identify data quality issues [18]: (*i*) *completeness* - the ratio of non-missing values to the number of records in the data; (*ii*) *the number of distinct values*; (*iii*) statistics for numeric data types, such as *maximum, mean, minimum, and standard deviation*, (*iv*) the ratio of *occurrence for the most frequent value*, etc. These statistics are commonly used in database engines, for data profiling and data quality validation [18] to summarize data of interest and often act as a proxy for the state of data quality. Furthermore, most of the statistics can be cheaply computed in a single scan over the data, except for the number of distinct values and the ratio of the most frequent value, which are typically approximated with the hyperloglog and the count-min sketches respectively [8, 12].

Novelty Detection. Novelty detection is a machine learning technique that aims to identify new patterns and signals that were not present in the training data [30]. It is closely related to anomaly detection as both techniques look for patterns in data that do not conform to the expected behavior [7]. The difference is that anomaly detection assumes that outliers are already present in the training data. In contrast, novelty detection is designed for cases where we only have access to "positive" examples.

Novelty detection is a form of one-class classification [46] (due to the absence of negative examples). Novelty detection algorithms model the data and check whether previously unseen data points resemble the characteristics of the modeled data (i.e., inliers) or deviate from the expected behavior (i.e., outliers). The decision whether or not a new object (i.e., data point) is an outlier against a set of known objects follows the continuity assumption (i.e., two data points that are close in the feature space represent two objects with the resemblance in real life) and usually focuses on distance measures. Common example algorithms in this area are one-class SVMs [44] and isolation forests [26]. For an in-depth overview of the one-class classification problem and novelty detection algorithms, we recommend the reader to refer to Tax [46] and Chandola et al. [7].

3 PROBLEM STATEMENT

In this section, we introduce the problem and its formal definition.

Overview. We address the problem of automating the validation of data quality on dynamic data without relying on domain expertise (e.g., manually specified rules and labeled erroneous data records). As outlined in the running example, we focus on scenarios where data pipelines regularly ingest large batches of potentially erroneous external data and face errors that corrupt a large fraction of the batch.

State-of-the-art solutions in data quality validation typically require domain knowledge to specify explicit rules, constraints, patterns, or labeled examples to verify data quality [6, 18, 20, 43]. They, however, fall short in several cases: (*i*) incomplete domain knowledge (i.e., when data depict complex processes that even domain experts cannot fully comprehend or when the domain expert is unavailable at the given time), the solutions mentioned above might perform poorly both due to false alarms and missed errors as the specified set of rules or labeled examples are insufficient to capture potential errors; (*ii*) manual monitoring of data pipelines to detect data quality issues or deployment of staging environments for software testing are often too costly or time-consuming, and are only conducted reactively; (*iii*) the characteristics of the data might slowly change over time, which implies that manually specified rules have to be constantly adapted and maintained.

These challenges motivate an automatic approach to data quality validation that does not rely on manually specified rules or labeled examples and self-adapts to changes in data characteristics.

Assumptions. For the given use case of the regular ingestion of large batches of a growing dataset, we consider previously observed and successfully ingested data partitions to be of "acceptable" data quality. This assumption is based on our experience with real-world use cases: It is common in production to define principal business and operational performance indicators and monitor them carefully to evaluate business outcomes. For our retail company running example, products that are placed in the wrong category due to various errors lead to negative customer reports or low service ratings, or via incident reporting and tracking systems. This negative feedback serves as a proxy that affects key performance indicators and catches the attention of the responsible staff at some point in time. This, in turn, triggers retrospective analysis. If devastating errors would have occurred in the previously observed data partitions, they would have been detected and fixed after a given time. If errors do not trigger a negative response from the devops engineers or the business after some period of time, we assume that the downstream task is robust to them. Furthermore, existing error detection or data quality validation methods require domain expertise. We focus on real-world scenarios where domain expertise is not available that, in turn, render the majority of data quality monitoring tools inapplicable.

Formal problem statement. Given a structured dataset D of chronologically ordered partitions $d_1, \ldots, d_{t-1}$, each having domain $A = A_1, \ldots, A_M$, we have to predict upon the arrival of a new partition d_t whether this partition is of acceptable quality or it is potentially corrupted w.r.t. a set of data quality metrics $Q = Q_1, \ldots, Q_G$. We map this problem to a "one-class classification" problem [46] where every partition d_i is represented by a feature vector $\mathbf{x}_{d_i} = (x_1, \ldots, x_G) \in \mathbb{R}^G$ of the data quality metrics Q that are computed on every attribute A_i of that partition and a boolean label y_{d_i}, which denotes whether the quality of the batch is acceptable or not. However, we only have access to positive examples during training (hence the term "one class" classification). The classification task is to decide whether a future batch d_t can be considered of acceptable quality (i.e., represents an inlier) or deviates from the state of data quality of the previously observed data batches (i.e., represents an outlier). The main challenge is to model the "acceptable" data in an automated manner, without external specification of the domain or examples of "erroneous" data that have insufficient data quality.

4 APPROACH

Next, we discuss our approach for automating data quality validation of newly observed data batches based on the problem definition we presented in the previous section.

Overview. Figure 1 illustrates our approach: for every observed partition $d_1, \ldots, d_{t-1}$, we model the features $\boldsymbol{x}_{d_i}$ via a set of descriptive statistics computed from the partition ❶. We train a novelty detection model [38] on the resulting feature vectors that learns the characteristics of "acceptable" data ❷. In order to check a new data batch d_t, we compute its feature vector $\boldsymbol{x}_t$ via the chosen descriptive statistics ❸. Next, we apply the novelty detection model to label the new batch as acceptable or erroneous based on the learned decision boundaries of the model ❹. With every new data partition d_t, we re-train the novelty detection model as the training set grows with t. Our method can be integrated into data pipelines to raise alerts about potential degradation of data quality automatically. Note that our approach does not rely on domain expertise expressed in the form of rules, constraints, or labeled data. Still, it remains valid in cases where the task definition is relaxed (e.g., domain knowledge is partially available or some error types are expected).

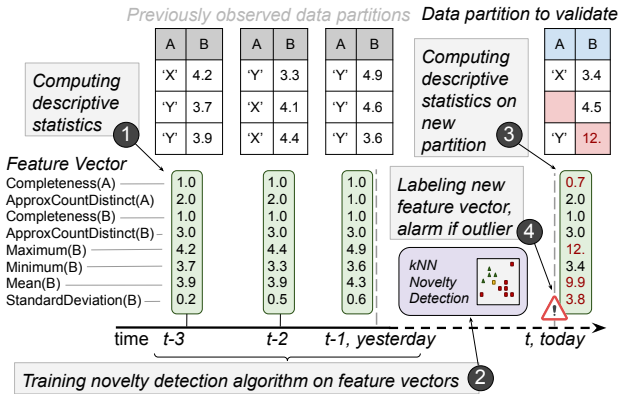

Figure 1: Overview of the approach: for every observed partition (gray tables), we compute a set of descriptive statistics as a feature vector (green, Step 1). We train a novelty detection model that learns the characteristics of acceptable data (Step 2). For the upcoming data partition (blue table), we compute its feature vector (Step 3) and let the model decide whether it is similar to the previously observed data partitions or not (Step 4). In this example, a missing value in column "A" and a numerical outlier in column "B" (red) affect the completeness metric and numeric statistics of the feature vector x_t. That, in turn, raises an alert.

Descriptive statistics as features. For every attribute A_j of the partition d_i, we compute several quantitative measures that correspond to the underlying data quality metrics (see Section 2):

- *Completeness* - the ratio of not-NULL values;
- *Approximate count of distinctive values* - the hyperloglog [12] approximation of the number of distinctive values;
- *Ratio of the most frequent value* - the count sketch [8] approximation of the number of occurrences for the most frequently repeated value, normalized by the batch size;
- *Maximum, mean, minimum, and standard deviation* for numeric data types;
- *Index of peculiarity* [33] for textual data. Index of peculiarity is based on the bi- and trigram tables of a textual attribute and reflects the likelihood of the hypothesis that trigrams in a given word are produced from the same data source that produced the trigram table. This index is originally applied for detection of typographical errors and facilitates detection of typos in text or a "peculiar" occurrence of symbols in words.

$$I(\mathbf{T}) = \frac{1}{2}(\log n(xy) + \log n(yz)) - \log n(xyz) \qquad (1)$$

Equation 1 represents the index of peculiarity for a trigram $\mathbf{T} = (xyz)$, where $n(\ )$ denotes the number of occurrences for a selected bi- or trigram in a textual attribute. Index of peculiarity for a sentence is the root-mean-square aggregation of indices for each trigram that this sentence contains.

Algorithm 1: Pseudocode of our approach.

Input: **t**, query raw data partition; **k**, the number of neighbors;
X, descriptive statistics for previously ingested data partitions;
contamination, the proportion of outliers in X;
dist, distance measure (e.g., Euclidean, Manhattan);
agg, distance aggregation strategy for k nearest data points.
Output: **label**, query data point **t** is inlier/outlier

```
Initialize array statistics; array distances;
        list num_met of metrics for numeric data types;
        list gen_met of metrics for other data types.
foreach attribute A ∈ t do
  metrics = num_met if type(A) is numeric else gen_met
  foreach metric ∈ metrics do statistics.append(metric(A))
end
foreach x ∈ X, tree = BallTree(X, dist) do
  /* .getDist(x, k) returns distances to k nearest
     neighbors of x; agg(array) is an aggregation
     function such as mean, median, or max          */
  distances.append(agg(tree.getDist(x, k))
end
/* percentile(x, q) computes q-th percentile of x   */
threshold = percentile(distances, (1 − contamination))
/* outlier if aggregated distance from t to k nearest
   neighbors exceeds threshold, else inlier         */
return agg(tree.getDist(statistics, k)) < threshold
```

We concatenate attribute-level statistics into a univariate numeric vector. Depending on the number of attributes and their data types, the feature vector varies in length from one dataset to another, where the length remains constant for partitions of the same dataset. We normalize the resulting feature vectors to a scale of 0 to 1. We chose these statistics based on two criteria: (a) low computational complexity and (b) mapping to the error types that often occur in real-world scenarios [47]. For a particular error type that we investigate, we consider statistics that act as proxies for this error type more descriptive than others in detecting data quality degradation. By a proxy we mean a quantitative measure that is expected to change when a particular error occurs (e.g., numeric outliers are likely to affect the statistical distribution of the attribute [18]). There is no single metric that is more descriptive than others for all the given error types. Preliminary results show that specifying only the descriptive statistics that we expect to be changed when an error occurs increases performance of our approach. This happens because, in low-dimensional feature spaces, data points are more distinct and distance-based methods perform better. However, assuming "zero domain knowledge" and unknown error types, we cannot control the choice of descriptive statistics in practice and, thus, train our approach on all statistics. As discussed in Section 2, most of these statistics can be computed in a single scan over the data. Furthermore, we treat the sequence of feature vectors that we collect over time (i.e., $t_{start}, \ldots, t-1$) as separate data points in the training set. Note that this modeling decision does not preserve the order of these feature vectors.

Choice of the novelty detection algorithm. Given the nature of the challenge at hand, i.e., "zero domain knowledge" or unknown error types, only positive examples are available for training. We thus choose one-class classification algorithms (i.e., novelty detection, see Section 2) as the main candidates for our approach. In this work, we considered several candidates for the novelty detection (ND) algorithm: Angle-based Outlier Detector (ABOD), Feature Bagging ensemble for the Local Outlier Factor (FBLOF), Histogram-base Outlier Detection (HBOS), Isolation Forest, and the K Nearest Neighbors algorithm with both the maximum and the mean distance aggregation scheme (KNN and Average KNN, respectively) [30, 31]. To choose one particular ND algorithm for our approach, we conduct preliminary experiments on one dataset (`Amazon Review`, monthly data partition) and three types of errors (explicit and implicit missing values on all attributes, numeric anomalies on the attribute "overall") with 30% of synthetically introduced errors per data batch, in order to determine which algorithm yields better predictive performance on the one-class classification task (for more details, see Section 5). We deliberately chose one dataset and a subset of error types under investigation to avoid overfitting and the selection bias for the evaluation procedure. Table 1 depicts the predictive performance metrics (ROC AUC score [22]) for all the ND candidates, as well as the break-down of the false positive and false negative results. We report the ROC AUC measure as it takes into account both the type-I and type-II errors. Furthermore, it is insensitive to imbalanced datasets and preferred in practice to other performance metrics such as accuracy or F1 score. In our preliminary experiments, we computed other performance metrics alongside the ROC AUC score. We noticed that, since our evaluation scenario introduces a balanced case where a negative counterpart exists for every positive example, accuracy, F1 and ROC AUC scores report similar values. Based on the preliminary results, we chose the k-Nearest Neighbor algorithm with the mean aggregation scheme [38]. This algorithm consistently outperformed other ND candidates on all three error types and produced no false positive results, meaning that no erroneous data batches were labeled as "acceptable". The second best-performing candidate is the Angle-Based Outlier Detection method [23] that yielded comparable predictive performance yet took an order of magnitude longer to train the model and infer the labels.

Nearest-neighbor-based novelty detection. For every data point in the feature space, the k-Nearest Neighbor (kNN) algorithm calculates the average distance to its k nearest neighbors and learns a threshold to decide what data points to consider inliers or outliers [2]. The kNN algorithm has a *contamination* hyperparameter that defines a ratio of data points that are assumed to be incorrectly labeled as inliers. Hence they are labeled as outliers in the training data. This scheme internally translates the one-class classification problem into a standard binary classification problem where the examples of both classes are present. The algorithm utilizes the Ball tree[35] space partitioning data structure - a binary tree where each node represents a multi-dimensional hypersphere (i.e., ball) of partitioned data points. This data structure provides properties that are useful for efficient k-nearest neighbor search. All data points in the training set are represented with distances to their k nearest neighbors. Depending on the design decision, these distances are aggregated into a single numeric value with one of the available aggregation strategies (e.g., mean, median, max). These numeric values are used to learn a decision boundary to differentiate inliers and outliers - a data point is considered an outlier if its aggregated distance to k nearest neighbors exceeds the learned threshold. The threshold is defined with the contamination hyperparameter c that is translated into the $(1-c)$th percentile of the array of aggregated distance for the whole training set. Figure 1 provides a pseudocode representation of the KNN algorithm.

Table 1: Results of the preliminary experiment on performance evaluation for 7 novelty detection algorithms. Three error types under investigation are explicit and implicit missing values, and numeric anomalies, depicted as "Explicit MV", "Implicit MV", and "Anomaly" respectively. We measure predictive performance with the ROC AUC score (AUC), as well as the number of true positive (TP), false positive (FP), false negative (FN), and true negative (TN) results, where FPs are associated with the misclassification rate and FNs - with the false alarm rate.

ND Algorithm	Error type	AUC	TP	FP	FN	TN
One-class SVM	Explicit MV	.9213	178	0	28	150
	Implicit MV	.9213	178	0	28	150
	Anomaly	.9691	178	0	11	167
ABOD	Explicit MV	**.9382**	178	0	22	156
	Implicit MV	**.9382**	178	0	22	156
	Anomaly	.9691	178	0	11	167
FBLOF	Explicit MV	.9353	178	0	23	155
	Implicit MV	**.9382**	178	0	22	156
	Anomaly	.9662	178	0	12	166
HBOS	Explicit MV	.5814	60	118	42	136
	Implicit MV	.5505	60	118	42	136
	Anomaly	.9297	176	2	23	155
Isolation Forest	Explicit MV	.7331	27	151	18	160
	Implicit MV	.5280	27	151	17	161
	Anomaly	.8764	146	32	12	166
KNN	Explicit MV	.9325	178	0	24	154
	Implicit MV	.9325	178	0	24	154
	Anomaly	.9662	178	0	12	166
Average KNN	Explicit MV	**.9382**	178	0	22	156
	Implicit MV	**.9382**	178	0	22	156
	Anomaly	**.9719**	178	0	10	168

Gu et al. [15] present an extensive statistical analysis of nearest neighbor algorithms and report that recent work on this family of methods reaches state-of-the-art performance on novelty detection tasks. Based on the preliminary experiment, we confirm that the kNN novelty detection method performs on par with other approaches or outperformed them, both in terms of the predictive performance and execution time.

Modeling decisions. Next, we discuss several modeling decisions for our kNN-based approach. We choose the Euclidean distance metric as the most commonly used distance measure for the $\mathbb{R}^G$ feature space, and leverage the average distance to k neighbors as an aggregation strategy. Based on preliminary experiments, this decision led to consistently higher predictive performance compared to other settings. Alternative strategies are choosing the largest distance among k neighbors or computing the median. A systematic comparison of kNN algorithms with different distance measures revealed that both the "largest" and the "median" aggregation schemes happen to be less robust than averaging in our setting.

We set the number of neighbors k to aggregate the distance measure to a low factor of five. The variation of this parameter did not lead to significant changes in the predictive performance during the preliminary experiments. The kNN novelty detection algorithm is also parameterized with the contamination parameter [19]. This parameter defines a fraction of data points in the training set to be misclassified as "positive" examples and assumed to be outliers (i.e., false positives). We set the contamination parameter to 1% to keep the ratio of false positives minimal.

Table 2: Characteristics of the datasets. The abbreviations depict, in a direct order, the number of records in the dataset, the number of partitions, the total number of attributes, the average number of records in a data partition, the number of numeric, categorical, and textual attributes. We also report the real-world error types that two datasets with the ground truth, `Flights` and `FBPosts`, contain.

Dataset	Flights	FBPosts	Amazon	Retail	Drug
# records	147640	11157	1494070	541909	161297
# part./attr.	31/9	53/14	1665/9	305/8	3579/6
part. size	~2350	~105	~897	~1776	~45
N/C/T	1/4/0	4/3/2	2/1/4	2/5/1	2/2/1

Dataset	Flights	FBPosts
Errors, %	explicit/implicit missing values, 8-38%	wrong encoding, 16%
	incomplete datetime format, 95%	syntactic errors and translation, 18%
	other syntactic/semantic errors, 60%	

We aim to minimize the number of data points in the training set that are considered to be falsely classified as "inliers". We base this decision on our assumption that all the data partitions are of "acceptable" quality, and no misclassification occurs. Preliminary experiments showed that setting the contamination parameter to 1% leads, on average, to relatively higher predictive performance compared to other values (including 0). Note that automated hyperparameter tuning schemes are challenging in the case of one-class classification problems, as we do not have labels for both of the classes - acceptable and erroneous data.

Application to our example scenario. Based on the running example, imagine the engineering team to apply the proposed approach as a data quality monitoring tool to validate incoming data batches before running data preprocessing and indexing jobs. When a new data batch is examined and no alerts are raised, data pipelines work without any difference and run the downstream preprocessing and indexing job. In case an alert is raised, the team starts a debugging process and applies further error detection and correction strategies. If the method caught the erroneous data batch correctly, the team fixes it and released the quarantined batch back to the pipeline. In the case of false alarms, the data is returned without alterations. The critical point is when the erroneous data batch passes data quality checks and goes further to the downstream pipeline without the errors being fixed (i.e., false positives). In this case, system crashes and degradation in the predictive performance of the underlying ML model might occur.

5 EVALUATION

In this section, we introduce our experimental setup and discuss datasets and metrics for our evaluation. We conduct several experiments. First, we compare the predictive performance of our approach to automated and hand-tuned variants of the following state-of-the-art solutions: Tensorflow Data Validation [6], Deequ [43], and statistical testing [32, 41]. Then, we evaluate the sensitivity of our approach towards six types of errors (explicit and implicit missing values, numeric anomalies, typos, swapped fields on numeric and textual attributes) and the predictive performance under various error magnitudes (1, 5, 10, 20, . . . , 80%)

in a controlled environment for datasets with synthetically generated errors. Finally, we evaluate the detection quality of our approach over time, as (a) the size of the training set for the novelty detection algorithm grows continuously, and (b) its data characteristics change over time.

5.1 Experimental Setup

We evaluate our proposed approach as follows. We experiment with a relational dataset that is partitioned by a chosen temporal attribute (e.g., a creation timestamp for every record). This allows us to simulate our target scenario of the daily ingestion of new data batches in a data pipeline. For every data point that corresponds to a particular day t, we use the previously observed partitions from timestamp 0 to $t-1$ as training data for our approach. Then, we take both the partition d_t and a corrupted version $\hat{d}_t$ as a counterpart, pass it to our model, and have it predict whether the partition is of acceptable data quality or not. Data partitions of acceptable quality are those that do not affect KPIs and usually depend on the downstream ML task. However, to decouple our experimental evaluation from the underlying ML task, we consider partitions of acceptable data quality the ones that do not contain any errors. We apply standard binary classification metrics such as the area under the ROC curve (ROC AUC score [22]) to evaluate how well the approach performs. We also report confusion matrices to analyze misclassification and false alarm rates.

Datasets. We experiment on five publicly available real-world datasets from different application domains. For two of them, we have access to both the erroneous and the cleaned versions of the data [25]. The other three do not contain any errors, we thus generate the errors synthetically [9, 14, 16]. For details, see Table 2.

Datasets with ground-truth errors. The `Flights`[1] dataset [25] contains flight status data that is aggregated from 38 different data sources (the airline and the airport websites, third-party web resources). Each record represents a particular flight on a particular day and includes attributes such as the scheduled departure/arrival, the actual departure/arrival, and the departure/arrival gates. `FBPosts`[2] is a dataset of crawled Facebook posts for which we have chronological information, as well as the erroneous and the manually cleaned versions of the data (using OpenRefine [24]). The dataset contains information about a sample of posts - their title, content type, text, the week it was written, the domain and the image URL, the number of likes, and the web page it was crawled from. Missing values are the most common error type for this dataset. Both datasets have an attribute that defines the chronological order and enables splitting them into partitions. Two variants of each dataset, the one with errors occurred and the one where the errors are fixed, are provided. We utilize these variants as partitions of acceptable data quality and their corrupted counterparts for our evaluation scenario.

Datasets without ground-truth errors. `Amazon Review` [16] and the `Online Retail`[3] [9] are two retail datasets. The `Amazon Review`[4] dataset contains information about product reviews: their ID, title, category, brand, sales ranking, and related products. The `Online Retail` dataset contains historical transactional data from a UK-based retailer. It includes the invoice number, customer ID, country, quantity, description, and the unit price of a product being purchased. The third dataset contains information about `Drug Reviews`[5] [14]. It includes the name of a drug, medical conditions this drug has been designed for, ratings and reviews, the review date, and the number of users who considered this review useful. All three datasets have a mix of numeric and categorical attributes. They also contain an attribute that defines chronological order and enables partitioning, but we do not have ground-truth errors available for them.

Synthetic error types. In order to experiment with the datasets that do not provide ground truth, we inject six types of synthetic errors. We choose these types of errors because (a) they are commonly encountered in real-world use cases in industry and mentioned by many practitioners [6, 18] and (b) the majority of them is used as example error types in the research field of error detection [1, 27, 28, 34, 47]. We briefly describe these error types below.

- *Explicit missing values* - empty cells in the data as a result of wrong data collection or integration (e.g., left outer join of two tables) or, simply, an optional field in a web form that was never filled by the end-user and, thus, assigned as NULL while crawling. We remove a fraction of the values of an attribute, replacing them with NULLs;
- *Implicit missing values* - empty cells in the data that are encoded with values of an attribute's data type that semantically represent a missing value, e.g., a string 'NONE' or a numeric value out of the attribute's domain. In practice, implicit missing values are the result of missing value imputations mechanisms that are implemented in a data pipeline. We replace a fraction of the values of an attribute with 'NONE' values for textual fields or encode it as 99999 for numeric fields.
- *Numeric anomalies* - unexpected numeric values as a result of malfunctioning sensors, errors in scaling or type casting (e.g., change of measurement units from centimeters to meters, wrong parsing of *csv* files due to commas as decimal separators, etc.). For continuous numeric attributes, we corrupt a fraction of the values by replacing them with Gaussian noise that is centered at the mean value of the attribute and has a standard deviation that is scaled randomly from the interval of 2 to 5;
- *Swapped numeric fields* - misplacement of numeric values as a result of user mistake or wrong parsing, such as swapping the length and the width values of a retail product. We choose two numeric fields in the dataset and swap a fraction of the values from one attribute to another and vice versa;
- *Swapped textual fields* - analogous to swapped numeric fields on textual attributes, misplacement of textual values as a result of user mistake or wrong parsing, such as swapping the first name and the surname values of in a user registration form. We choose two textual fields in the dataset and swap a fraction of the values from one attribute to another and vice versa;
- *Typos* - unexpected spelling in textual attributes either due to user mistakes or errors in parsing (e.g., wrong encoding). We apply the "butterfinger" strategy that randomly replaces a fraction of letters in textual attributes with other letters that are neighbors on a "qwerty" keyboard layout.

Given the error types and descriptive statistics under investigation, sampling strategy does not have major effects on predictive performance of our approach in most cases. For instance, explicit

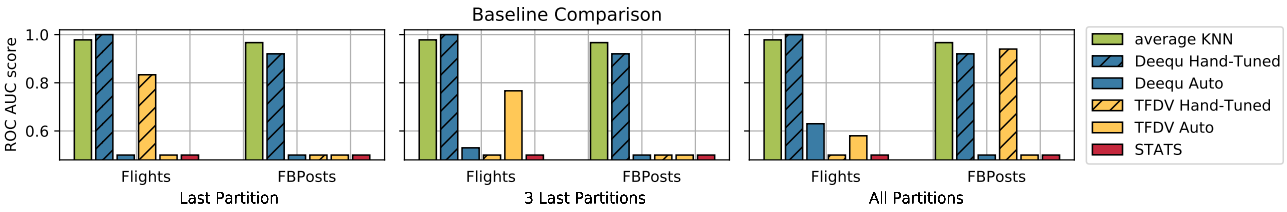

Figure 2: Comparison of the predictive performance of the proposed approach against three baseline solutions: Tensorflow Data Validation, Deequ, and statistical testing. The subplots represent three different training settings where the baselines learn from (a) only one recently observed data partition, (b) a combination of the last three data partitions, and (c) all the observed partitions. The TFDV and Deequ baselines are evaluated in their fully automated variant and a hand-tuned variant applying domain expertise. The bar chart shows that our approach outperforms the other automated baseline solutions and reaches the predictive performance of the hand-tuned baselines. The automated variants of the baselines tend to be conservative and produce false alarms in the majority of cases.

missing values would change the completeness measure, no matter wherein the data partition this error occurs. We use uniform distribution for error generation in the evaluation setup.

Hardware specification. We use an Ubuntu workstation with 8 Intel i7-8550U CPU cores (1.80GHz) and 24Gb RAM. We run all the algorithms with a single process and thread, with an exception of one baseline solution - `Deequ` library - that is built on top of Spark and runs at scale.

5.2 Comparison to Baselines

In our first experiment, we compare the predictive performance of our proposed approach ("avg. kNN" in Figure 2) to the existing baseline solutions: Tensorflow Data Validation [6], Deequ [43], and statistical testing [32, 41]. The purpose of this experiment is to evaluate whether our automated approach can reach the performance of hand-tuned state-of-the-art solutions.

Baselines. We compare the proposed approach against several existing solutions. As the first baseline, we use univariate *statistical tests* to detect shifts in data distribution between the previously observed data partitions and the current batch as an indicator of errors. We use two tests - the Kolmogorov-Smirnov test to detect shifts in continuous numeric attributes [32], and the Pearson's Chi-squared test to detect shifts in frequency distribution for categorical values [41]. For every attribute of a data partition, we run one statistical test that gives a p-value as a measure of whether the data values in the current batch come from different data distribution than the values in previously observed data partitions. We choose a test based on the attribute's data type (numerical or textual data) and compare the outcome to a common threshold of 0.05. Note that we apply Bonferroni correction to account for multiple tests.

We also use the *Tensorflow Data Validation* library [6] (TFDV) to detect data schema violations as an indicator of erroneous partitions. TFDV uses data profiling techniques to model the state of acceptable data quality by inferring their schema - attribute names, data domains, various constraints (e.g., on data distribution, uniqueness, sparsity, etc.). Then, it tests new data against inferred constraints and raises alerts upon schema violation as a signal for potential degradation of data quality. Domain experts use automated schema inference to facilitate data profiling and analysis but they have to hand-tune the schema to keep it up-to-date. In addition to the automated version of TFDV, we apply a hand-tuned version where we define its data schema based on data profiling and manual monitoring of data batches. This setting aims to compare our approach to a baseline solution that exploits domain expertise.

Lastly, we include the *Amazon Deequ* library [42] and utilize its declarative data quality constraints to validate the data. Similar to the TFDV baseline, we evaluate Deequ in both an automated variant and a hand-tuned variant. In the former, Deequ runs data profiling and constraint suggestion algorithms to generate data unit tests to validate the quality of data partitions. In the latter, we utilize a hand-tuned variant where we manually define the checks to apply based on data profiling and inspection.

Evaluation scenario. For a relational dataset d comprised of chronologically ordered partitions $d_{t_1}, \ldots, d_{t_n}$ and timestamps $t_1, \ldots, t_n$, we sequentially pick a timestamp t_k within the interval $start < k < n$, where $start$ is a predefined timestamp number to start with and n is the number of available partitions. We select $start$ as 8 in order to limit the minimum size of the training set to 8 data points. We show the partitions $d_{start}, \ldots, d_{t_{k-1}}$ as training data to each approach.

For the datasets with the ground truth, we leverage the hand-labeled "dirty" versions $\hat{d}_{t_1}, \ldots, \hat{d}_{t_n}$ of these partitions for the evaluation. We give both the clean data partition d_t and its corrupted counterpart $d_{\hat{t}}$ to each approach, and let it decide whether the data batch is of acceptable quality or contains errors. In this experiment, we use only the datasets with available ground truth to compare the predictive performance in real-world cases with unspecified error types, error magnitudes, and real-world temporal changes in data characteristics.

For each approach, we record two predictions at each timestamp t_k in the interval $start < t < n$ - one label for the partition d_t and for the erroneous counterpart $\hat{d}_t$ respectively. We compute the ROC AUC score based on the recorded prediction labels and the ground truth, where d_t has the "inlier" label, and $\hat{d}_t$ has the "outlier" label. We evaluate the automated baseline solutions in three different settings, where the automated inference is based on (a) the last, (b) three last, and (c) all previously observed partitions with no further alteration of the derived rules, constraints, or patterns, to ensure systematic comparison of our approach in a fully automated mode. With the first two settings (one and three data partitions), we evaluate whether using only the most recent data is sufficient for the automated baseline solutions to learn the state of "acceptable" data quality accurately and fast. In contrast, the third setting is applied in order to evaluate the predictive performance of baselines that take the whole training set into account and include "far-in-the-past" data partitions.

For the given experimental scenario and datasets, we spent approximately two hours per dataset for data profiling, manual inspection, and configuration of Deequ and TFDV via programming interfaces. For Deequ, we implemented declarative unit tests for data. For TFDV, we adjusted thresholds to allow for particular fractions of previously unseen data and specified data ranges. We must point out, however, that hand-tuning involved analysis of the ground-truth clean data. In this way, we simulated a "domain expert" who knows what errors are expected in the data. In real-world use cases that assume "zero domain knowledge", the analysis we conducted might be infeasible.

Results. Figure 2 depicts the comparison of the predictive performance of our approach ("Average KNN", green) against the three baseline solutions: Tensorflow Data Validation (yellow), Deequ (blue), and statistical testing (red). The bar charts report predictive performance on the `Flights` and the `FBPosts` datasets under three different training settings. The baselines learn from (a) only one recently observed data partition ("Last Partition", left), (b) a combination of the last three data partitions ("3 Last Partitions", center), and (c) all the observed partitions ("All Partitions", right). Tensorflow Data Validation and Deequ baselines are evaluated in both the fully automated mode and in their hand-tuned variant.

The results indicate that our approach outperforms other automated baseline solutions and reaches the predictive performance of hand-tuned baselines (ROC AUC score of 95%, whereas the hand-tuned Deequ solution reaches 100% and 92% on the Flights and FBPosts datasets, respectively). Other automated solutions tend to produce false alarms in the majority of cases. We attribute this to the fact that the automated baseline solutions are "conservative" and strict in terms of their chosen constraints, and thereby produce false alarms in the majority of cases.

Table 3 depicts average execution times for both our approach and the baselines. It shows that, on average, our approach is at least one order of magnitude faster than the baseline solutions. High computational efficiency is associated with the fact that both the descriptive statistics and the KNN algorithm are easy to compute and train. Since the *Deequ* library is built on top of Spark, this baseline takes more time to check data quality metrics for small datasets due to the large overhead for parallel computation. However, we assume that *Deequ* might be more efficient on large-scale data, where other baseline solutions would perform reasonably slower.

Discussion. The errors in the dataset are mostly missing values or inconsistencies due to data integration (e.g., different datetime formats for different records). To be precise, 95% of the arrival and departure time information have an inconsistent date-time format, with a large fraction of the data missing. Inconsistencies in the datetime format lead to two problems - either the year is omitted, in which case several data preprocessing techniques replace the missing value with the default year 1970, or the day and month values are swapped as the solution has no means of distinguishing these values. 63% of the arrival and departure gates information is inconsistent in the following ways: (1) presence of explicit and implicit missing values; (2) the missing value encoding differs (e.g., '-', '–', 'Not provided by airline'); or (3) the information is semantically incomplete (e.g., the 'Gate 2' value is replaced with the value 'Terminal 8, Gate 2', etc.). Since the cleaned version of the dataset was provided semi-automatically, most of the records which contained missing values were imputed where possible (e.g., by aggregation) or omitted as there were no means to guarantee the correct missing value imputation scheme. 18% of the categorical attribute 'contenttype' have implicit missing value 'nan' or syntactic mismatch in categories (e.g., a combination of German and English words for 'article'). 16% of the attribute 'text' have the wrong encoding.

Our approach performs well on the given datasets and reaches a ROC AUC score of 95%. Many of the baseline solutions, however, perform on the level of random guessing. Further analysis reveals that these baselines label the majority of the data partitions as erroneous (See Table 4). The reason why the data partitions are labeled as erroneous is due to the conservative default settings of the baseline solutions, as they are primarily designed to strictly detect data quality degradation and have false alarm rates as a secondary concern. Further analysis indicates that TFDV presumably detects errors in attributes where we know for certain

Table 3: Average execution time (in seconds) for baseline comparison. We compare our approach (Avg. KNN) against three baselines (Deequ, Tensorflow Data Validation, and statistical testing), each of them computed in three modes, where (a) one last, (b) three last, and (c) all previously observed partitions are used for training. The table shows that the average execution time of our approach is one order of magnitude faster than the baselines.

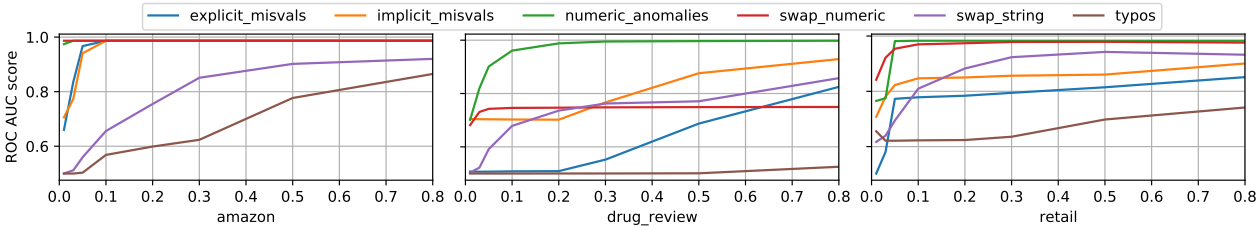

Figure 3: Overview of the predictive performance of our approach on three real-world datasets with synthetically generated errors under varying error magnitude (X-axis, 1 to 80%). We consider six error types: explicit and implicit missing values, numeric anomalies, typos in textual attributes, swapped fields for numeric and textual attributes. We observe two patterns: (a) similar predictive performance regardless of the fraction of errors (flat lines), or (b) gradual growth of the predictive performance towards bigger error magnitude, with the distinctive, more rapid growth for fractions up to 20%.

that there are no errors present. The 'Source' and the 'Flight' attributes of the *Flights* dataset do not contain errors. However, TFDV detects a violation of data schema as there are previously unseen values in the new batch, so the attribute domain has changed. A similar situation holds for the *FBPosts* dataset, with one additional type of alert - "non-boolean values" (as *FBPosts* contains one boolean attribute).

As for the hand-tuned baselines, Deequ reaches a perfect ROC AUC score on the Flights dataset and 92% on the FBPosts with hand-tuned thresholds for the completeness metric. For TFDV, the ROC AUC score ranges from 50 to 82%. The "min domain mass" parameter (i.e., a minimal fraction of data records that have to be included from the inferred data domain) was set to 0 in order to allow for any fraction of previously unseen values in the data partition. Thresholds for the completeness metric were set similarly to the Deequ baseline. This finding highlights that manual data quality monitoring and hand-tuning of existing solutions with the domain expertise is highly dataset-specific and tedious.

Note that, for Tensorflow Data Validation in several settings, the automated variants perform better than the hand-tuned variant. The reason is that the automated variants are retrained after a new data partition becomes available, whereas the hand-tuned variant is specified once on the initial training set (i.e., t_1 to t_{start}).

5.3 Sensitivity to Different Error Types and Magnitudes

In this experiment, we evaluate whether our approach detects all error types under varying error magnitudes with the similar predictive performance or whether there are error types that are harder to detect than others.

Evaluation scenario. For every dataset d with synthetically generated ground truth, we fix the error type and the error magnitude for generating corrupted data partitions $\hat{d}_t$. Other than that, the evaluation scenario is identical to the one in Section 5.2.

Results. Figure 3 shows line charts that represent predictive performance of our proposed approach per dataset and error type, where the x-axes of the plot depict the error magnitude. We are interested in the relationship between the predictive performance of our approach and the fraction of errors that are introduced in data partitions. Two distinctive patterns arise in terms of the curve shapes: (a) flat lines represent similar predictive performance regardless of the fraction of errors, whereas (b) the curves with gradual growth towards more significant error magnitudes mean that it is easier to detect degradation in data quality with greater fractions of the data partition being affected. The latter curves capture rapid increase for smaller fractions of 1 to 20%. The relative difference in predictive performance between the error types varies among the datasets and error magnitudes. Even though the `Drug Review` and the `Online Retail` datasets show resemblance in terms of the ROC AUC score, the `Amazon` dataset exhibits different patterns. For instance, the kNN novelty detection approach shows constant predictive performance rate on `Amazon`'s numeric anomalies but has a "learning curve" for `Drug Review` or `Online Retail`.

Discussion. The figure shows that, in general, the predictive performance differs from one error type to another. We attribute this behavior to two findings from the experiment's analysis. First, some types of errors are, in fact, easier to recognize than others. That statement holds for the use cases of manual data quality monitoring that are conducted by domain experts. For instance, an explicit missing value (e.g., a NULL value) is reasonably straightforward to detect even when few data records are corrupted. Other error types, such as numeric anomalies, can be detected only in cases where the ranges of acceptable values are available, or the assumption on data distribution exist [18]. Comparing ROC AUC scores between the error types, error magnitudes, and datasets indicates that predictive performance is dataset-specific and likely depends on scales and domains of every data attribute. In the majority of cases, however, missing values and numeric anomalies can be detected relatively reliably and result in high ROC AUC scores.

For every error type that we investigate, there are descriptive statistics that provide better features for classification. For instance, the completeness measure is more descriptive to detect explicit missing values. Data distribution measures(e.g., mean, standard deviation, minimum, maximum) are more descriptive to detect numeric anomalies. However, there is no single metric that is more descriptive than others for all given error types.

Note that our approach often performs reasonably well in cases of small error magnitudes (already at 10%), when introduced errors drastically affect the descriptive statistics of a data partition. Should our approach be insensitive to a specific error distribution (or particular error types), our approach can be extended by adding another descriptive statistic that is sensitive to this error distribution or error type.

Based on Figure 3, typos (brown) appear to be the hardest error type that we consider in this study. We assume that the index of peculiarity for textual attributes is a direct proxy for this error. However, predictive performance on the `Drug Review` dataset nearly reaches the level of random guessing, whereas on other datasets it exhibits a slow learning curve. Further experimental analysis reveals several differences between textual attributes on

the datasets under investigation. Our approach performs well in cases where attributes have categorical values with rather low cardinality and high repetition of values (e.g., country code). It also performs well on long texts such as reviews and descriptions with high a likelihood of word repetition within the data batch. In this case, a typo that is introduced in one word that repeats itself in the data batch yields high chances for this error to be detected by our approach, as this word becomes "peculiar" in the context of the data batch. On the other hand, typos that are introduced in almost-unique words that belong to a dictionary of a textual attribute would not be detected as this error replaces one unique word to another. For several curves that involved textual attributes, there exists a downward trend at the beginning when the training set is small. It happens due to our design decision to keep a constant contamination parameter (see Section 4, "Modeling Decisions"). In cases of small training sets, the kNN algorithm learns a broad decision boundary that leads to false positive results (i.e., where the majority of data points are considered inliers). Only with the growing training set, the decision boundary becomes smaller and yields more accurate results. One preventative measure is to ensure large initial training sets. When this is not possible, another option is to adaptively select larger contamination parameters for smaller training sets.

We obtain several findings regarding the relationship between the predictive performance of our approach and error magnitude. In general, we note two patterns in the curve. The first case is where the ROC AUC score remains approximately constant across all error magnitudes and does not depend on the fraction of corrupted records in a data partition. This happens in cases where a few erroneous records in a data partition are sufficient to affect descriptive statistics and reliably identify the data partition as erroneous. The second case is where the ROC AUC score increases gradually with the growth of the error fraction. In this case, the reason is that detecting data quality degradation becomes easier when more data in the partition are corrupted. One example is the explicit missing values error type. Note that, for this example, a clean partition d_t might allow for missing values, so that a simple rule of "100% completeness" is not applicable. Thus, the higher the difference between the fraction of missing values in between clean and erroneous data partitions, the higher is the overall ROC AUC score. Note that the shape of the curve and the rate of growth are dataset-specific.

5.4 Sensitivity to a Combination of Errors

We also extend the experiment from Section 5.3 to evaluate the sensitivity of our approach to scenarios where a combination of two different error types occurs in the same data partition.

Evaluation scenario. For every dataset d with synthetically generated ground truth, we fix the error magnitude to 50% for generating corrupted data partitions $\hat{d}_t$. We choose an attribute A_m of every data partition d_t and apply a pair of error types (if suitable for the attribute's data type). We use all pairwise combinations of error types under investigation. Other than that, the evaluation scenario is identical to the one in Section 5.2. Note that, as we sample the values-to-corrupt uniformly, there is an overlap in selected cells of a data partition d_t for the first and the second error type of the pair ($\sim$ 40%). For the overlapping values, the second error type overrides the changes made by the first type, resulting in approximate distribution of corrupted values to be 20% of the data partition and 30% respectively. In the case when the union of changes provided by each error type exceeds 50% of the data partition, we uniformly sample changes from the union to ensure total error magnitude of 50%. We compare the predictive performance of our approach to the respective performance when only one of the error types is applied.

Results. For every attribute of every dataset and every applied pair of error types under investigation, we computed three ROC AUC scores: the one where only the first error type is applied to corrupt the data, the one where only the second error type is applied, and one for a combination of applied error types. For all computed scores, we report the mean squared error of 0.028 between the ROC AUC score on a combination of error types and the maximum of ROC AUC scores where only one of the two error types is applied.

Discussion. The results indicate that the predictive performance of our approach in the case when two error types are combined is, on average, close to the performance on a single error type, the "easiest to detect" of the two, taking into account reduced error magnitudes (i.e., when errors corrupt 20-30% of the data partition separately, adding up to a total error magnitude of 50%). We generalize this observation to a combination of more than two error types that corrupt a data partition together.

5.5 Detection Quality over Time

In this experiment, we evaluate the detection quality of our approach over time. The motivation behind this experiment is twofold: (a) the size of the training set for the novelty detection algorithm grows continuously, which might gradually improve predictive performance, and (b) data characteristics are volatile and can change over time, which might lead to the occasional degradation of predictive performance.

Evaluation scenario. For every dataset d with synthetic errors, we fix the error type for generating corrupted data partitions $\hat{d}_t$. We compute two labels for every daily-ingested data partition, one for the clean variant and one for the corrupted counterpart. When we visualize ROC AUC scores over time, we aggregate these labels on a monthly basis and plot line charts with months as X-axes. Other than that, we leverage a setup that is identical to previous experiments.

Results. Figure 4 depicts the line charts that represent changes in the predictive performance of our approach over time, where the x-axis is the monthly time window (for clarity reasons, it is shown by year in the "Drug Review" graph). Two distinctive patterns arise in terms of the curve shape: (a) flat lines represent approximately constant predictive performance, whereas (b) curves with the gradual increase indicate improvements over time and, respectively, with the growing size of the training set (see `Drug Review`). The latter examples converge to a stable rate and further resemble the behavior of approximately constant predictive performance.

Discussion. The results indicate how the predictive performance of our approach changes over time, with the corresponding growth of the training set for the novelty detection algorithm to learn from. Similar to the previous section, we see two patterns. First, in most of the cases, the average prediction performance does not change significantly over time. This finding might be counter-intuitive at first, as we usually assume that an ML-based algorithm tends to perform better with more data points to train from. The reason for the approximately constant ROC AUC score is that data points that represent erroneous data partitions are likely to be far from the decision boundaries learned by the kNN

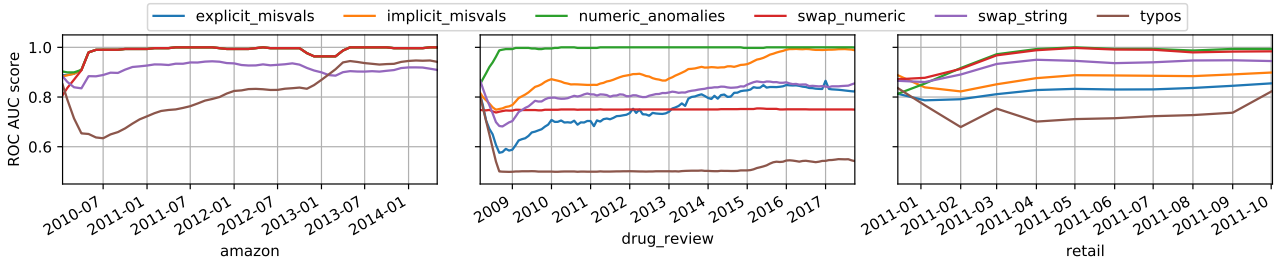

Figure 4: Predictive performance of our approach over time (X-axis). The figure depicts line charts that represent the ROC AUC score for every dataset with the ground truth, per error type over time. Various magnitudes of errors and data attributes are aggregated. The results show that, in the majority of cases, the predictive performance does not improve significantly over time with the growth of the size of the training set. Several cases (Retail, swapped fields and numerical outliers) demonstrate an initial increase of the ROC AUC score, followed by convergence to a stable rate over time. Note that, for the Amazon dataset, line charts that depict missing values, numeric anomalies, and swapped fields error types overlap and are represented by one line (red).

algorithm. These far-off data points (i.e., outliers) are likely to be detected reliably even under the limited size of the training set and, therefore, lead to the stable predictive performance of the kNN novelty detection approach. The second pattern is a gradual increase in the predictive performance in the beginning until we converge to a stable performance rate. Examples are explicit missing values and swapped textual fields for the *Drug Review* dataset. We attribute this pattern to the insufficient size of the training set to learn the decision boundaries that lead to reliable predictions. We assume that the stage of gradual increase in predictive performance corresponds to the "learning process" of the approach to derive accurate decision boundaries with clear benefits of accumulating more data points to the training set. After convergence, re-training of the approach is necessary to self-adapt to temporal changes in data.

The importance of batch frequency. Preliminary experiments show that, when choosing between daily, weekly, and monthly ingestion frequencies, daily ingestion of data led to relatively higher predictive performance. We associate this phenomenon with larger sizes of the training set.

6 RELATED WORK

We distinguish two lines of research that address related data management issues at different angles - *error detection for data cleaning* [1, 27, 36, 40, 47] and *data quality validation* [3, 20, 43].

Error detection for data cleaning. The goal of error detection mechanisms is to find the exact data records and attributes that contain errors. Abedjan et al. [1] consider four different categories of error detection solutions: (a) rule violation, (b) pattern violation, (c) outlier detection, or (d) duplicate conflict resolution based systems. Some of the algorithms require rules or patterns to be specified by the end-user. Outlier detection based methods require clean data to be present in order to "learn" what the inliers are and then decide whether particular records deviate from the expected behavior. Our approach follows similar ideas but constructs feature vectors based on the corresponding data quality metrics that are computed over the data partition instead of relying on the raw data itself. This leads to feature vectors of low dimensionality, fast model training, and guarantees numeric representation of feature vectors. The last category, duplicate conflict resolution systems, handles the specific case of duplicate entities in the data, and does not cover other types of errors. Compared to the existing error detection algorithms, our approach can detect unspecified error types and does not require domain expertise in terms of rules, patterns, or labeled examples.

Data validation. These methods aim to make a decision whether the data is valid w.r.t. particular assumptions. Tensorflow Data Validation [6] models the state of acceptable data quality with the user-defined data schema - attribute names, data domains, various constraints (e.g., on data distribution, uniqueness, sparsity, etc.). It, then, tests new data against the specified constraints and raises alerts upon schema violation. To assist the end-user, initial data schema can be inferred automatically by analyzing reference data (i.e., an "acceptable" data sample). As stated by the authors, schema refinement by domain experts is required to guarantee the performance of the library, and the schema inference functionality is provided as an aid, not a replacement of the domain expert. Data linter [20], on the contrary, validates data against data lints - deviations from accepted practices of data analysis (analogous to code lints - snippets of code that depict deviation from best practices in software engineering). The lints are predefined by the developers of the tool yet are extensible in case customized practices are in place. Another example is the Deequ library for automating the verification of data quality at scale [42], which proposes unit tests for data - a declarative specification of integrity constraints, such as completeness, consistency, syntactic and semantic accuracy, which the end-user needs to specify. Schelter et al. [42] also introduce functionality for automated constraint suggestion based on data profiles (collected descriptive statistics on data attributes). However, this method requires the presence of reference data - a sample of the data population that is considered to be of acceptable quality and is designed to generate suggestions that are validated by a domain expert. The Metanome platform [36] is a tool for data profiling that incorporates numerous algorithms for the detection of functional, order, or inclusion dependencies, as well as cardinality estimation. This method is not a data validation solution as such, but allows to automatically discover patterns from data that later could be used as rules for data quality. Metanome requires "acceptable" data samples to be present for reliable mining of the data quality patterns. As the main purpose of Metanome is data profiling and not directly data quality validation, this framework requires additional rules for detection of data quality issues and cannot be used directly as a data quality validation tool [10].

To summarize, existing approaches require domain knowledge to define rules, denial constraints, patterns, configuration of error detection solutions [1, 27], integrity constraints, data unit tests [42], error generators [39], data schema [6], or data lints [20]. Automation tools exist for data profiling, constraint suggestion, schema inference, or error detection. These solutions assume a domain expert in the loop. Our approach, in contrast, does not require any domain knowledge specified explicitly for common error types. In contrast to existing solutions, it is inspired by the work of Bleifuß et al. [4] on exploring changes in dynamic data, Ehrlinger et al. [10] on automating data quality validation, and Ioannou et al. [21] on generating benchmark data. Finally, as our experimental analysis indicates, few automated solutions for data quality validation appear to be particularly "conservative" and produce false alarms in the majority of cases.

7 CONCLUSION & FUTURE WORK

Data quality validation is crucial for large-scale production pipelines. Challenging cases are the ones where domain expertise is incomplete and data changes over time. We showed that collecting simple descriptive statistics over the data and analyzing them with novelty detection methods makes it possible to distinguish critical errors in data. In contrast to existing solutions, our approach does not require domain experts to define rules or labeled examples, and self-adapts to temporal changes in the data characteristics. We evaluated our approach against existing baselines on five real-world datasets with real and synthetically generated errors. We found that our approach detects the unspecified errors in many cases under varying error magnitudes, outperforms other automated solutions in terms of predictive performance, and reaches the ROC AUC score of baselines that are hand-tuned with domain expertise.

In future work, we plan to investigate more exotic types of errors and intend to look deeper into specific types of errors that are hard to capture by common data quality metrics, e.g., errors that are a deterministic function of the inputs (like accidentally changing the encoding). As there exist few real-world datasets that are available for evaluation purposes in data quality validation on dynamic data, we also intend to provide a set of benchmarking datasets. These datasets should contain a wide range of error types and patterns of temporal changes in data characteristics. This will enable research on controlling the false alarm rates for novelty detection algorithms in data quality validation settings.

ABSTRACT

In this paper, we investigate the efficient computation of the provenance of rich queries over graph databases. We show that semiring-based provenance annotations enrich the expressiveness of routing queries over graphs. Several algorithms have previously been proposed for provenance computation over graphs, each yielding a trade-off between time complexity and generality. Here, we address the limitations of these algorithms and propose a new one, partially bridging a complexity and expressiveness gap and adding to the algorithmic toolkit for solving this problem. Importantly, we provide a comprehensive taxonomy of semirings and corresponding algorithms, establishing which practical approaches are needed in different cases. We implement and comprehensively evaluate several practical applications of the problem (e.g., shortest distances, top-k shortest distances, Boolean or integer path features), each corresponding to a specific semiring and algorithm, that depends on the properties of the semiring. On several real-world and synthetic graph datasets, we show that the algorithms we propose exhibit large practical benefits for processing rich graph queries.

1 INTRODUCTION

Graph databases [32] are part of the so-called NoSQL DBMS ecosystem, in which the information is not organized by strictly following the relational model. The structure of graph databases is well-suited to representing some types of relationships within the data, and their potential for distribution makes them appealing for applications requiring large-scale data storage and massively parallel data processing. Natural example applications of such database systems are social network analysis [13] or the storage and querying of the Semantic Web [5].

Graph databases can be queried using several general-purpose navigational query languages, an abstraction of which is *regular path queries* (RPQs) [6] (or generalizations thereof, such as C2RPQs) on paths in the graph. Recently, based on existing solutions to querying property graphs – such as Neo4j's Cypher [17] query language or Oracle's PGQL [38] – an upcoming international standard language for property graph querying, GQL [22], is being designed as a standalone language complementing SQL. GQL will notably incorporate support for RPQs.

In parallel with these recent developments, the notion of *provenance* of a query result [34], a familiar notion in relational databases, has recently been adapted to the context of graph databases [31], using the framework of provenance semirings [18]. In this framework, edges of a graph are annotated, in addition to usual properties, with elements of a semiring; when evaluating a query, traversing the paths on the graph can generate new annotations depending on the semiring operators, resulting in a semiring value associated with every query result, called the provenance of the query result. By choosing different semirings, different information on the query result can be computed. For example, when edges are annotated with elements of the *tropical* semiring (nonnegative real numbers) expressing the distance between vertices, the provenance of the query result computes the shortest distance of paths that produce this result; when edges are annotated with elements of the *counting* semiring (natural integers) interpreted as multiplicity, the provenance of the query result computes the (possibly infinite in case of cycles) number of ways each query result can be obtained. Underlying properties of the semiring directly control how the information on graph edges is encoded, and also how efficient algorithms for query processing are.

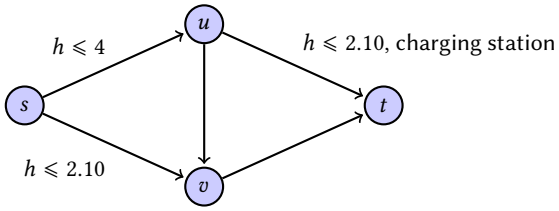

Figure 1: Example road network represented by a graph with provenance annotations along two dimensions: maximum height h (as a positive number) a vehicle must have to use the road segment, and a Boolean indicating the presence of an electrical charging station. When a dimension is not mentioned, the annotations are assumed to be, respectively, $h \leqslant \infty$ and $\neg$(charging station).

Beyond these simple examples of semirings, the framework of semiring provenance also allows modeling of intricate issues, e.g., when the problem of interest can be decomposed into several subproblems and when the resulting provenance does not necessarily correspond to a particular path in the graph.

Example 1.1. Consider the example of a road transportation network modeled as a directed graph with provenance annotations on edges. We can for example encode the presence of points of interests (such as gas stations, restaurants, or electrical charging stations) as Boolean features on edges, and road properties (e.g., maximal height or weight for a bridge or tunnel) as real-valued features.

We will show that, using semiring provenance, we can deal with graph queries that take into account multiple such features: a pair of vertices is valid for the queries if there exists at least one valid path for each restriction between the two locations. An application of this would be to ensure that different vehicle categories (say, a high-clearance truck and an electric car that requires charging on the way) can properly reach a common destination from the same origin.

Another possible semantics for semiring provenance is to check that all paths between two vertices verify (or exclude) some properties (e.g., absence of tolls, or presence of gas stations on the route) thus providing road administrators crucial information on the global state of the roads between two points.

This is illustrated in Figure 1, a road network where some road segments have restrictions on the height on vehicles; this is a first dimension of provenance. The second dimension records whether there exists an electrical charging station on the road segment – in our example, this is the case for only one edge.

In our previous preliminary research [31], we generalized three existing algorithms from a broad range of the computer science literature to compute the provenance of regular path queries over graph databases, in the framework of provenance semirings. Together, these three generalizations cover a large class of semirings used for provenance, each yielding a trade-off between time complexity and generality. We also performed experiments suggesting these approaches are complementary and practical for various kinds of provenance indications, even on a relatively large transport network.

In this paper, we extend this work by:

- Introducing a novel algorithm, MultiDijkstra, for commutative *0-closed* (or *absorptive*) semirings. This algorithm, generalizing Dijkstra's algorithm and leveraging properties of distributive lattices, partially bridges a strong computational gap between two classes of semirings left untreated in our previous research. The complexity of the queries exemplified here belongs in this gap, and strongly motivated our interest to develop the algorithms in this paper. The experiments we performed demonstrate that our new algorithm can scale up to very large networks with dozens of millions of nodes, bringing a notable improvement with respect to the state of the art of provenance computation in graph databases.
- Establishing a precise summary, in the form of a taxonomy, of the algorithms used in our context, along with their complexities and expected properties of the underlying semirings used for the provenance annotations. We also analyze similarities with classes of semirings which are used either for computing provenance of relational algebra queries [19] or of Datalog programs [11].
- Performing a comprehensive set of experiments on real-world data demonstrating the running time of provenance computation over graphs, over a wide variety of semirings and covering different use cases. We also observe that parameters depending on the topology of the graph, such as *treewidth* [27] seem to have a higher impact on the efficiency of the algorithm than distance-based parameters such as the *highway dimension* [4]. The implementation of all algorithms we use for these experiments is freely available at https://bitbucket.org/smaniu/graph-provenance/src/master/.

The paper is organized as follows. We start by introducing in Section 2 some preliminaries: graph databases enhanced by provenance annotations, a short overview of the algebraic theory of semirings, and an explanation on which semiring can be used for provenance annotations in a few selected practical applications. We revisit in Section 3 the algorithms we proposed in [31] and discuss their limitations. Section 4 is a taxonomy summarizing classes of semirings and associated algorithms for graph provenance. In Section 5, we introduce MultiDijkstra and the mathematical theory behind distributive lattices, which MultiDijkstra relies on. We present experimental results comparing all algorithms in practice in Section 6 before discussing related work in Section 7.

2 PRELIMINARIES

The framework we are considering is that of graph databases enriched with semiring-based provenance annotations. We detail here the notation and definitions we previously introduced in [31] and extend it with some additional concepts. We also introduce a large number of example semirings, to illustrate the generality of the problem considered.

2.1 Semirings

The framework for provenance in relational databases introduced by [18] uses the algebraic structure of *semirings* to encode meta-information about tuples and query results. In what follows, we present the basic notions needed for this paper; for further details about the theory and applications of semirings, see [20] and [18, 34] for their applications to provenance.

Definition 2.1 (Semiring). A *semiring* is an algebraic structure $(\mathbb{K}, \oplus, \otimes, \mathbb{0}, \mathbb{1})$ where $\mathbb{K}$ is some set, $\oplus$ and $\otimes$ are binary operators over $\mathbb{K}$, and $\mathbb{0}$ and $\mathbb{1}$ are elements of $\mathbb{K}$, satisfying the following axioms:

- $(\mathbb{K}, \oplus, \mathbb{0})$ is a *commutative monoid*: $(a \oplus b) \oplus c = a \oplus (b \oplus c)$, $a \oplus b = b \oplus a$, $a \oplus \mathbb{0} = \mathbb{0} \oplus a = a$;
- $(\mathbb{K}, \otimes, \mathbb{1})$ is a *monoid*: $(a \otimes b) \otimes c = a \otimes (b \otimes c)$, $\mathbb{1} \otimes a = a \otimes \mathbb{1} = a$;
- $\otimes$ distributes over $\oplus$: $a \otimes (b \oplus c) = (a \otimes b) \oplus (a \otimes c)$;
- $\mathbb{0}$ is annihilator for $\otimes$: $\mathbb{0} \otimes a = a \otimes \mathbb{0} = \mathbb{0}$.

Example 2.2. It is easy to check that the following structures are all semirings:

Tropical semiring. $(\mathbb{R}^+ \cup \{\infty\}, \min, +, \infty, 0)$.

Top-k semiring. For $k \geqslant 1$ some integer,

$$((\mathbb{R}^+ \cup \{\infty\})^k, \min^k, +^k, (\infty, \ldots, \infty), (0, \infty, \ldots, \infty)),$$

where

$$\min^k((a_1, \ldots, a_k), (b_1, \ldots, b_k)) = \min^k\{a_1, \ldots, a_k, b_1, \ldots, b_k\}$$

returns the k smallest entries (with duplicates) among those in a and b, in increasing order, and

$$(a_1, \ldots, a_k) +^k (b_1, \ldots, b_k) = \min^k\{a_i + b_j \mid 1 \leqslant i, j \leqslant k\}.$$

We further impose that only tuples that are in increasing order are valid elements of the semiring. Note that the top-1 semiring is the same as the tropical semiring.

Example: For $k = 2$, $(1,2) \oplus (1,3) = \min^2\{1,1,2,3\} = (1,1)$ and $(1,2) \otimes (1,3) = \min^2\{1+1, 1+3, 2+1, 2+3\} = (2,3)$.

Counting semiring. $(\mathbb{N} \cup \{\infty\}, +, \times, 0, 1)$, where

$$\forall a \in \mathbb{N}^* \quad a + \infty = a \times \infty = \infty \times a = \infty$$

and $0 + \infty = \infty$, but $0 \times \infty = \infty \times 0 = 0$.

Boolean semiring. $(\{\bot, \top\}, \vee, \wedge, \bot, \top)$, where $\bot$ (resp, $\top$) is interpreted as the Boolean false (resp., true) value.

k-feature semiring. For $k \geqslant 1$ some integer,

$$((\mathbb{R}^+)^k, \min, \max, (\infty, \infty, \infty), (0, 0, 0))$$

where min and max are applied pointwise; it also exists in dual form, with min and max exchanged.

Integer polynomial semiring. $(\mathbb{N}[X], +, \times, 0, 1)$ where X is a finite set of variables, and $+, \times, 0, 1$ have their standard interpretations as polynomial operators and polynomial values.

Shortest-path semiring.

$$((\mathbb{R}^+ \cup \{\infty\}) \times \Sigma^*, \oplus, \otimes, (\infty, \varepsilon), (0, \varepsilon))$$

with the following operators $\oplus$ and $\otimes$:

- $(d, \pi) \oplus (d', \pi') = (\min(d, d'), \pi'')$ where π'' is π if $d < d'$, π' if $d > d'$, and $\min(\pi, \pi')$ (in lexicographic order, assuming some order on Σ) if $d = d'$;
- $(d, \pi) \otimes (d', \pi') = (d + d', \pi \cdot \pi')$ if neither d nor d' is ∞; and $(d, \pi) \otimes (d', \pi') = (\infty, \varepsilon)$ if either d or d' is ∞.

As we shall see further, these examples all yield useful applications for provenance over graphs.

We now consider properties of semirings that will be of interest to develop specific algorithms – we will illustrate these properties on the example semirings of Example 2.2. Some of the properties are summarized in Figure 2; ignore annotations for algorithms in blue for now.

A semiring is *commutative* if for all $a, b \in \mathbb{K}$, $a \otimes b = b \otimes a$. A semiring is *idempotent* if for all $a \in \mathbb{K}$, $a \oplus a = a$. In an idempotent semiring we can introduce a *natural order* defined by $a \sqsubseteq b$ iff it exists $c \in \mathbb{K}$ such that $a \oplus c = b$.[1] Note that this order is compatible with the two binary operations of the semiring: for all $a, b, c \in \mathbb{K}$, $a \sqsubseteq b$ implies $a \oplus c \sqsubseteq b \oplus c$ and $a \otimes c \sqsubseteq b \otimes c$. An important property that we wish to use in our setting is that of *k-closedness* [29], i.e., a semiring is k-closed if:

$$\forall a \in \mathbb{K}, \bigoplus_{i=0}^{k+1} a^i = \bigoplus_{i=0}^{k} a^i.$$

Here, by a^i we denote the repeated application of the $\otimes$ operation i times, i.e., $a^i = \underbrace{a \otimes a \otimes \cdots \otimes a}_{i}$. 0-closed semirings (i.e., those in which $\forall a \in \mathbb{K}, \mathbb{1} \oplus a = \mathbb{1}$) have also been called *absorptive*, *bounded*, or *simple* depending on the literature. Note that any 0-closed semiring is idempotent (indeed, $a \oplus a = a \otimes (\mathbb{1} \oplus \mathbb{1}) = a \otimes \mathbb{1} = a$) and therefore admits a natural order.

Example 2.3. All semirings in Example 2.2 are commutative except for the shortest-path semiring (indeed, concatenation is not a commutative operation).

All of them are idempotent, except for the top-k, counting, and integer polynomial semirings.

The natural order of the tropical semiring is the total order $\geqslant$ (note that this is the *reverse* of the standard order on $\mathbb{R}^+ \cup \{\infty\}$).

The tropical, Boolean, k-feature, and shortest-path semirings are 0-closed. The top-k semiring is $(k-1)$-closed. The counting and integer polynomial semirings are not k-closed for any k.

Star semirings [14], also known as *closed semirings*, extend semirings with a unary * operator, having the following property: $a^* = \mathbb{1} \oplus (a \otimes a^*) = \mathbb{1} \oplus (a^* \otimes a)$. Note that, in 0-closed semirings, we necessarily have $a^* = \mathbb{1}$. Similarly, in k-closed semirings, we can define $a^* = \bigoplus_{i=0}^{k} a^i$.

Example 2.4. As just mentioned, since the tropical, Boolean, k-feature, and shortest-path semirings are all 0-closed, we can simply define in all of them $a^* = \mathbb{1}$. Since the top-k semiring is $(k-1)$-closed, we can define a^* with the formula $a^* = \bigoplus_{i=0}^{k} a^i$.

[1] In general semirings, this defines a preorder; antisymmetry of this relation can be shown when the semiring is idempotent.

In the counting semiring we can introduce a star operator with: $0^* = 1$ and $a^* = \infty$ for $a \neq 0$.

It is not possible to simply add a star operator to the integer polynomial semiring (indeed, if the equation $x^* = 1 + (x \times x^*)$ had a solution x^* as a polynomial in x, its degree would be different on the left- and right-hand sides of the equation). However, one can define a more general semiring, that of *formal power series*, in which a star operator can be defined. See [18] for details on the semiring of formal power series, which are not important here.

We will later use the fact that a 0-closed semiring which is also *multiplicatively idempotent* (i.e., in which $a \otimes a = a$ for every a) turns out to satisfy the axioms of *bounded distributive lattices* [8, Theorem 10].

Example 2.5. The only 0-closed semirings that are multiplicatively idempotent from Example 2.2 are the Boolean and k-feature semirings.

2.2 Graph databases with provenance

We now introduce the notion of provenance in graph databases.

Definition 2.6 (Graph Database). A *graph database with provenance indication* (V, E, λ, w) over some semiring $(\mathbb{K}, \oplus, \otimes, \mathbb{0}, \mathbb{1})$ is an edge-labeled directed graph (V, E, λ) together with a *weight function* $w : E \to \mathbb{K}$.

Given an edge $e = (u, v) \in E$, we denote $n[e] = u$ its *destination* (or next) vertex, and $p[e] = v$ its *origin* (or previous vertex). By analogy we write its weight $w[e]$ instead of $w(e)$. Given a vertex $v \in V$, we denote by $E[v]$ the set of edges having v as origin.

A path $\pi = e_1 e_2 \cdots e_k$ in G is an element of E^* with consecutive edges: $n[e_i] = p[e_{i+1}]$ for $i = 1, \ldots, k-1$. We extend n and p to paths by setting $p[\pi] := p[e_1]$, and $n[\pi] := n[e_k]$. A cycle is a path starting and ending at the same vertex: $n[c] = p[c]$. The weight function w can also be extended to paths by defining the weight of a path as the result of the $\otimes$-multiplication of the weights of its constituent edges: $w[\pi] := \bigotimes_{i=1}^{k} w[e_i]$; this can in fact be extended to any finite set of paths by $w[\{\pi_1, \ldots, \pi_n\}] := \bigoplus_{i=1}^{n} w[\pi_i]$. For any two vertices x and y of a graph G, we denote by $P_{xy}(G)$ the set of paths from x to y.

Definition 2.7 (Path Provenance). Let G be a graph database with provenance indication over some semiring $\mathbb{K}$. The *provenance between x and y*, for x and y two vertices of G is defined as the (possibly infinite) sum:

$$\text{prov}_{\mathbb{K}}(G)(x, y) := w\left[P_{xy}(G)\right] = \bigoplus_{\pi \in P_{xy}(G)} w[\pi].$$

Several problems can be defined based on this. Given two vertices s and t, the *single-pair provenance* problem computes the provenance between s and t. Given a vertex s, the *single-source provenance* problem computes the provenance between s and each vertex of the graph. Finally, the *all-pairs provenance* problem computes the provenance for all pairs of vertices.

A *regular path query* (RPQ) [6] defines a set of admissible paths from some vertex s through a regular language over edge labels. The notion of single-source provenance can be generalized to that of RPQ provenance in a straightforward manner, as we did in [31]. We also showed in [31] that computing such a provenance could be reduced in polynomial time to the single-source provenance problem; this works by constructing a product of the graph with

the automaton describing the language of the query. Note that this construction can be done on-the-fly (avoiding generation of inaccessible vertices) and that the size of the automaton is usually quite small; thus, the overhead is usually affordable oven for large graphs as showed experimentally in [31]. We will implicitly use this reduction throughout the paper, meaning that we only need to consider the single-source provenance problem in the rest of the paper. Consequently, we will also ignore edge labels and see a graph database as defined by its vertices, edges, and semiring weights.

2.3 Semantics of path provenance

As defined, the provenance between two vertices in a graph database is in fact a (possibly infinite) sum over the provenances of all paths from the source vertex leading to the target vertex. As we observed in [30], the only possible source of non-finiteness in the sum is due to cycles in the graph, so that we only need to be able to sum all the powers of a given semiring value. For this to be semantically meaningful we need the semiring to be a star semiring, and we additionally need the star operator to verify for all semiring element a: $a^* = \bigoplus_{n=0}^{\infty} a^n$ for some well-behaved infinitary sum operation $\bigoplus$ (namely, associativity, and distributivity of $\otimes$ over this infinitary sum operator). This class of semirings is commonly known as *countably complete star semirings*, *c-complete star semirings* [24], or *ω-complete star semirings*.

Example 2.8. All star semirings identified in Example 2.4 are, indeed, c-complete star semirings. Note that, for k-closed semirings, the infinitary sum $\bigoplus_{n=0}^{\infty} a^n$ is simply $\bigoplus_{n=0}^{k} a^n$, and the condition of being a c-complete star semiring is trivially satisfied by our choice of star operator. In the remaining cases (counting semiring, formal power series, formal language semiring) one can verify that a well-behaved infinitary sum operation can be introduced, and that it verifies $a^* = \bigoplus_{n=0}^{\infty} a^n$.

We also pointed out in [30] that all-pairs graph provenance is equivalent to the computation of the *asteration* of the matrix corresponding to the graph representation with provenance tags as cell-values. With all these definitions in place, we observe that the semantics of provenance over specific semirings actually corresponds to a various number of problems of interest. Remember that using the construction of [31] we can extend this to the provenance of arbitrary RPQs.

Example 2.9. Let G be a graph database over some c-complete star semiring $\mathbb{K}$, and s and t fixed source and target vertices in G. The provenance between s and t corresponds to the following notions, depending on the semiring $\mathbb{K}$:

- **Tropical semiring:** length of shortest path between s and t.
- **Top-k semiring:** lengths of k shortest paths between s and t.
- **Counting semiring:** total number of paths between s and t, edge weights being interpreted as number of edges between two vertices.
- **Boolean semiring:** existence of a path between s and t, depending on the existence of edges denoted by their Boolean weights.
- **k-feature semiring:** minimum feature value along each dimension of all paths between s and t; if min and max are exchanged, maximum feature value along some path from s to t.
- **Formal power series:** how-provenance, see [18].
- **Shortest-path semiring:** pair formed of a length l and path label π such that π is the shortest path from s to t, of length l (if there are multiple shortest paths, π is the first in lexicographic order).

Example 2.10. Let us return to the example in Figure 1. We model the charging station Boolean feature as an integer feature by simply setting $\top = 1$ and $\bot = 0$. We take the (max, min) definition of the k-feature semiring where we compute the maximum value of each feature among some path from origin to destination, and we order heights in decreasing order (e.g., by taking their inverse) so that a higher feature value means a (more restrictive) lower height.

Consider two types of vehicles of interest that want to reach the vertex t from the vertex s: one has height between 3 and 4 meters, the second is a small ($h \leqslant 1.5$) electric car that needs at least one charging station on the road to t. In the presence of the edge from u to v, both of them can reach t from s; without that edge, only the electric car is able to. This is reflected in the provenance: $\mathsf{prov}(G)(s,t) = (4, \text{charging station})$ while $\mathsf{prov}(G \backslash \{(u,v)\})(s,t) = (2.10, \text{charging station})$.

3 EXISTING ALGORITHMS

We now provide a review of three algorithms to solve the single-source provenance problem, also previously described in [31]. Each of these algorithms yields a different trade-off between time complexity and applicability to various types of semirings, as summarized in Table 1.

Algorithm 1 DIJKSTRA – single-source

Input: $(G = (V, E, w), s)$ a graph database with provenance indication over $\mathbb{K}$ and the source s.
Output: Array $\mathbf{w}$ representing the single-source provenance from s of the reachability query.

```
1:  S ← ∅
2:  w[a] ← 𝕆, ∀a ∈ V
3:  w[s] ← 𝟙
4:  while S ≠ V do
5:      Select a ∉ S with minimal w[a]
6:      S ← S ∪ {a}
7:      for each neighbor b of a not in S do
8:          w[b] = w[b] ⊕ (w[a] ⊗ w[ab])
9:      end for
10: end while
11: return w
```

DIJKSTRA. Dijskstra's algorithm is generally used to solve shortest-distance problems in directed graphs. However, as shown also in [31], the algorithm readily generalizes to our semiring context, by placing some restrictions on the semirings used. For instance, the tropical semiring is exactly the semiring that allows to compute the shortest distance, as in the original algorithm. The general flow of the algorithm – using general semiring operations – is outlined in Algorithm 1, and Table 1 indicates its running time (in terms of the graph size and the costs of the semiring operations $\oplus$ and $\otimes$). Dijkstra's algorithm is known to be a very efficient algorithm. However, this efficiency comes from the fact that it uses a priority queue: once a value is extracted from it, we know that it is the correct one – this allows us to only visit each vertex in the graph once. This only works if we apply DIJKSTRA to semirings which are 0-*closed* (or absorptive) and in which an additional condition is satisfied: the natural order is a *total order* [31].

As we shall discuss later, there is a large complexity gap between DIJKSTRA on the one hand and the other two algorithms

Table 1: Required semiring properties and asymptotic complexity for each studied algorithm, where $\mathrm{T}_\bullet$ is the complexity of the elementary semiring operation $\bullet$. The last column assumes constant cost for all semiring operations.

Name	Semiring property	Time complexity (with semiring op.)	Time complexity
MatrixAsteration	star	$O(\lvert V\rvert \mathrm{T}_* + \lvert V\rvert^3(\mathrm{T}_\oplus + \mathrm{T}_\otimes))$	$O(\lvert V\rvert^3)$
NodeElimination	c-complete star	$O(\lvert V\rvert \mathrm{T}_* + \lvert V\rvert^3(\mathrm{T}_\oplus + \mathrm{T}_\otimes))$	$O(\lvert V\rvert^3)$
Mohri	k-closed	Exponential	Exponential
MultiDijkstra	0-closed $\otimes$-idempotent	$O\left(\ell \times (\mathrm{T}_\oplus \lvert V\rvert \log \lvert V\rvert + \lvert E\rvert\,(\mathrm{T}_\oplus + \mathrm{T}_\otimes))\right)$	$O(\ell \times (\lvert V\rvert \log \lvert V\rvert + \lvert E\rvert))$
Dijkstra	0-closed total ordered	$O(\mathrm{T}_\oplus \lvert V\rvert \log \lvert V\rvert + \lvert E\rvert(\mathrm{T}_\oplus + \mathrm{T}_\otimes))$	$O(\lvert V\rvert \log \lvert V\rvert + \lvert E\rvert)$

we discuss in this section – NodeElimination and Mohri – on the other. This is the main motivation to introduce the new algorithm we present in Section 5.

Algorithm 2 Mohri – single-source [29]

Input: $(G = (V, E, w), s)$ a graph database with provenance indication over $\mathbb{K}$ and the source s.
Output: Array $\mathbf{w}$ representing the single-source provenance from s of the reachability query.

```
1:  for i ∈ {1, ..., |Q|} do
2:      w[i] ← r[i] ← 𝕆
3:  end for
4:  w[s] ← r[s] ← 𝟙
5:  S ← {s}
6:  while S ≠ ∅ do
7:      q ← head(S)
8:      dequeue(S)
9:      r' ← r[q]
10:     r[q] ← 𝕆
11:     for each e ∈ E[q] do
12:         if w[n[e]] ≠ w[n[e]] ⊕ (r' ⊗ w[e]) then
13:             w[n[e]] ← w[n[e]] ⊕ (r' ⊗ w[e])
14:             r[n[e]] ← r[n[e]] ⊕ (r' ⊗ w[e])
15:             if n[e] ∉ S then
16:                 enqueue(S, n[e])
17:             end if
18:         end if
19:     end for
20: end while
21: w[s] ← 𝟙
22: return w
```

Mohri. Mohri [29] introduced an algorithm for computing single-source provenance for reachability queries over k-closed semirings. Outlined in Algorithm 2, it performs, in a manner similar to the Bellman–Ford algorithm, step-by-step relaxations over the edges of the graph (lines 13–14), maintaining a queue to decide in which order the elements are inspected. The queue can be chosen in different ways: based on the topology of the graph, e.g., if the graph is acyclic; or a queue prioritized by weight when, e.g., one wishes to compute top-k shortest paths using the top-k semiring.

In the worst case, the theoretical complexity of this approach is exponential in the size of the graph [29], mainly due to the fact that the algorithm may have to visit the same cycle in the graph multiple times. However, the complexity heavily depends on the implementation of the queue. For instance, for top-k shortest paths, implementing a priority queue allows for an efficient algorithm, having polynomial complexity. Indeed, as we shall detail later, for road transportation networks and top-k shortest paths, experiments show an almost linear-time behavior in k and the size of the graph.

In contrast, the algorithm may be much more inefficient in practice for other types of networks (such as social networks). As we conjecture in Section 6, this may be due to the fact that transport networks have relatively low *treewidth* [27]. The treewidth is a parameter measuring how much a graph (or more generally any relational instance) resembles a tree. Many intractable problems over graphs have tractable solutions on instances of fixed treewidth. We confirm in Section 6 that many of the algorithms for provenance computation strongly benefit – in terms of running time – from low treewidth.

Another important graph parameter – stemming from the active research community around computing routing for, e.g, driving directions – the *highway dimension* [4] has been introduced to provide a theoretical basis for the efficiency observed in practice in state-of-the-art heuristics for computing optimal transport paths. This parameter relies heavily on weights on the edges of the graphs and the distribution of shortest distances in the graph. In our experiments in Section 6, we evaluate whether this parameter also explains the practical efficiency of our algorithms for computing the provenance of routing queries.

Algorithm 3 NodeElimination – single-pair

Input: $(G = (V, E, w), s, t)$ a graph database with provenance indication over $\mathbb{K}$, the source s, and the target t.
Output: Single value $\mathbf{w}_{s't'}$ representing the single-pair provenance between s and t of the reachability query.

```
1:  V' ← V ∪ {s', t'}
2:  E' ← E ∪ {(s', s), (t, t')}
3:  for i ∈ V' do
4:      for j ∈ V' do
5:          w^(0)_ij ← { w[ij]          if i ≠ j,
                       { 𝟙 ⊕ w[ij]     if i = j
6:      end for
7:  end for
8:  for k in V do
9:      for each (p, q) s.t. (p, k), (k, q) ∈ E' do
10:         w_pq ← w_pq ⊕ (w_pk ⊗ w*_kk ⊗ w_kq)
11:     end for
12: end for
13: return w_s't'
```

NodeElimination. The most general algorithm available is based on the idea of Brzozowski and McCluskey for obtaining a formal language expression (i.e., a regular expression) equivalent to the language of an automaton [9]. The algorithm is outlined in Algorithm 3. The algorithm works by eliminating vertices one by one and computing the "shortcut" values for each vertex pair, until only the source and target vertices remain. This algorithm works for any *c-complete semiring over which a star operation is defined* – this is necessary for the shortcuts computed in the algorithm to be correct.

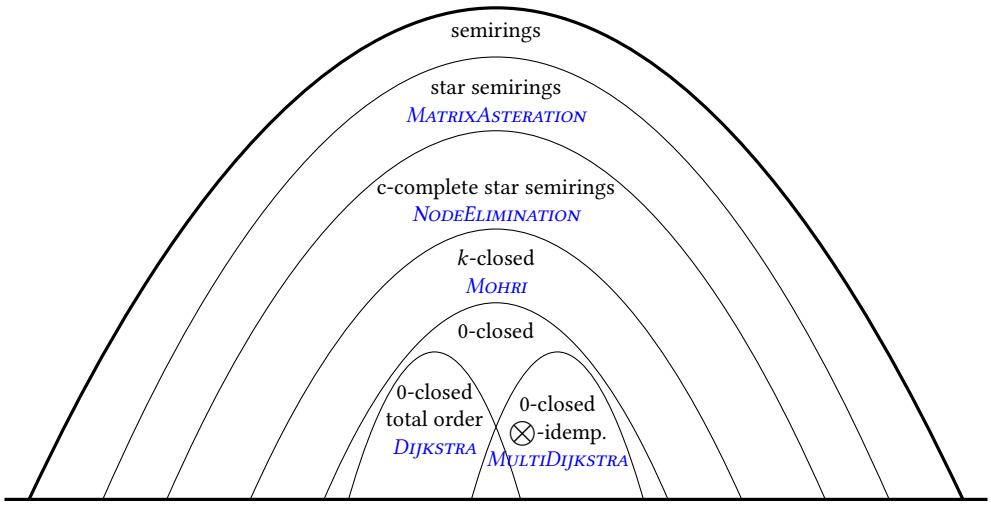

Figure 2: Taxonomy of the semirings used for graph provenance along with algorithms that work on them

In general, the complexity of the algorithm is at least cubic in the number of vertices in the graph, which makes it practically unusable on large graphs. Importantly, however, it also can be shown that its complexity is closely related to the treewidth parameter of the graph. Following a simplicial elimination order (unfortunately not tractable to compute) one can rephrase the complexity shown in Table 1 in terms of the treewidth parameter w by $O(|V|\mathrm{T}_* + |V|w^2(\mathrm{T}_\oplus + \mathrm{T}_\otimes))$. Thus, if the treewidth is small over, e.g., transportation networks, one can benefit from heuristics for finding a suitable elimination order to optimize this algorithm. We dedicate a part of our experiments demonstrating the impact of some heuristics (for instance, focusing on vertices of higher degrees) on the running time of this algorithm.

Related algorithms. Star semirings are also known as closed semirings [2] and the star operation is known as the closure operation. In this sense, all-pair computations correspond to *matrix asteration*. For instance, the NodeElimination algorithm can be used to compute the asteration [2] of a matrix – but, if the semiring is not c-complete, there is no guarantee of a semantics compatible with the intuitive semantics of provenance over graph databases. Matrix asteration allows for a high degree of parallel computation [1].

4 TAXONOMY

We present in Figure 2 a high-level view linking the properties and classes of semiring we presented in Section 2 and their associated algorithms, presented in Sections 3 and 5. The figure shows a clear hierarchy of classes of semirings, both in terms of the complexity of the algorithm and the expressive power of the semirings.

An important practical application that is similar to our setting is the provenance for Datalog queries introduced in [18] and further optimized using circuits [11]. Datalog [3] is a language derived from Prolog, useful for infering new knowledge given existing facts and a set of inference rules. In the papers above, the semiring classes for which optimization of queries is possible are strikingly similar: PosBool(X) and Sorp(X) discussed in [11, 18] correspond respectively to the positive fragment of the Boolean function semiring, and to the free (i.e., most general) 0-closed semiring. In that sense, algorithm optimizations discussed here apply directly to applications such as Datalog query optimization.

5 ALGORITHM FOR 0-CLOSED SEMIRINGS

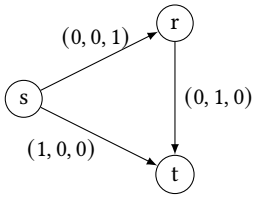
As explained in Section 3, Dijkstra requires a total natural order on the elements of a 0-closed semiring. This is quite a restrictive setting (among the examples from Example 2.2, only the *tropical semiring* fits), while using a more generally available algorithm such as Mohri can lead to practical inefficiency. The question we are addressing in this section is whether we can bridge this complexity gap and still obtain practical algorithms for 0-closed semiring without total orders.

First, we present an example semiring setting, with non-total natural order, where Dijkstra cannot be readily applied.

Example 5.1. Let us consider the 3-feature semiring

$$(\{0,1\}^3, \min, \max, (1,1,1), (0,0,0)).$$

In the example graph below, the provenance between s and t is: $\min(\max((0,0,1),(0,1,0)),(1,0,0)) = (0,0,0)$ and that between s and r is: $\min(\max((1,0,0),(0,1,0)),(0,0,1)) = (0,0,0)$



Assume there would be an order for which Dijkstra computes this provenance. Then, starting from s, Dijkstra would select either r and assign it provenance $(0,0,1)$, which is wrong, or t and assign it provenance $(1,0,0)$, which is also wrong.

In the following, we address this problem and design a new algorithm, MultiDijkstra (for *Multidimensional Dijkstra*) that applies to the more general case of 0-closed semirings for which multiplication is idempotent (such as the k-feature semiring, but also the Boolean function semiring used in probabilistic databases, see [34]). As it turns out, such semirings satisfy the axioms of *bounded distributive lattices* [8, Theorem 10]; this allows us to design an efficient algorithm for answering queries using these types of semirings.

5.1 Mathematical Background

In the following we introduce basic notions about finite distributive lattices. We assume the lattices we use are finite because

we are only ever using the subsemiring generated by edge annotations. As we shall see, this subsemiring is finite when both operations of the semiring are idempotent.

We refer the reader to [36] for more details regarding the theory behind distributive lattices.

5.1.1 Definitions and Notation. A *lattice* $(L, <)$ is a partially ordered set (*poset*) where every two elements have a unique infimum (their *meet*, $\wedge$) and supremum (their *join*, $\vee$). A *lattice embedding* of a lattice L into a lattice K is a one-to-one join and meet homomorphism from L to K. In a poset, an element y covers x (denoted $x \lessdot y$) if $x < y$ and there are no such z such that $x < z < y$. A lattice embedding ℓ is *tight* if $x \lessdot y$ implies $\ell(x) \lessdot \ell(y)$.[2]

An element x of a lattice L is *join-irreducible* if $x = a \vee b$ implies that $x = a$ or $x = b$. The set of non-zero join-irreducible elements of L is denoted $J(L)$. It induces a subposet of L which is also denoted by $J(L)$.

For a subset S of a lattice L, we let $\bigvee S = \bigvee_{x \in S} x$ be the join of the elements of S. We often write $\bigvee_L S$ to specify that the join takes place in L. A subset S of a poset is a *downset* or *ideal* if $x \in S$ and $y \leqslant x$ implies $y \in S$. The minimum downset containing an element x is denoted $\mathtt{id}\, x$. We note $\mathcal{D}(P)$, for a poset P, the family of downsets of P ordered by inclusion.

A *chain* C of length n in a poset P is a subposet isomorphic to the linear order $\mathbb{Z}_n$ on the n elements $\{0, 1, \ldots, n-1\}$. A *chain decomposition* of a poset P is a partition of its elements into a family $\mathcal{C}$ of chains $C_1, \ldots, C_d$. For a family $\mathcal{C} = \{C_1, \ldots, C_d\}$ of disjoint chains, the product $\prod \mathcal{C} := \prod_{i=1}^{d} C_i$ consists of all d-tuples $x = (x_1, \ldots, x_d)$ where $x_i \in C_i$ for each $i \in \{1, \ldots, d\}$. It is ordered by $x \leqslant y$ if $x_i \leqslant y_i$ for each i.

5.1.2 Results. A classical result from Birkhoff [7] establishes an isomorphism between L and $\mathcal{D}(J(L))$:

Theorem 5.2 ([7]). *The map* $\mathbf{S} : x \mapsto \mathtt{id}\, x \cap J(L)$ *is an isomorphism of* L *to* $\mathcal{D}(J(L))$. *Its inverse is* $S \mapsto \bigvee_L S$.

For a chain decomposition $\mathcal{C}$ of a poset, let $\mathcal{C}_0$ be the family of chains we get from the chains in $\mathcal{C}$ by adding a new minimum element to each. In [12], Dilworth proved the following embedding theorem:

Theorem 5.3 ([12]). *For any chain decomposition* $\mathcal{C}$ *of a poset* P *the map* $S \mapsto \bigvee_P S$ *is an embedding of* $\mathcal{D}(P)$ *into* $P = \prod \mathcal{C}_0$.

Then, we obtain the following corollary we will use later:

Corollary 5.4. *Given a chain decomposition* $\mathcal{C}$ *of a distributive lattice* L, *there is a tight embedding of* L *into* $\prod \mathcal{C}_0$.

5.2 Application to Provenance Computation

Corollary 5.4 provides us with a way to compute provenance over distributive lattices using a multidimensional version of Dijkstra's algorithm. Because an embedding is a homomorphism, we can compute each component of $\prod \mathcal{C}_0$ independently. And because the homomorphism is one-to-one, we can easily recover the provenance at the end of the computation.

Example 5.5. If we take a look at distributive lattice of the divisors of 60 with greatest common divisor (gcd) and least common multiple (lcm) as join and meet operators, we notice that the divisors of 60 are either powers of 2, 3, 5 or an lcm of these integers. Thus, they can be represented using three dimensions representing the factorization of 60 along these prime numbers: $\mathit{decompose}(4) = (2, 0, 0)$, $\mathit{recompose}(0, 1, 0) = 3$, and $\mathit{recompose}(2, 1, 0) = 12$. We can then compute *independently* each dimension of the result using Dijkstra's algorithm since each component is totally ordered; then, partial results are combined.

In other words, we can run separately, ℓ times, Dijkstra's algorithm for each dimension of this product, where ℓ is the number of chains in the chain decomposition. This gives us a parameterized algorithm, where ℓ depends on the semiring. For example, for the semiring used in Example 5.1, $\ell = 3$. We outline the algorithm in pseudo-code in Algorithm 4. We need the following routines that are highly specific to the semiring: $\mathit{decompose}(e)$ takes as parameter an element e of L and returns its image $v(e) \in \mathcal{P}$. For the opposite direction $\mathit{recompose}(d_1, \ldots, d_n) = \bigvee_{0 \leqslant i \leqslant n} d_i$ returns as expected an element of L.

We use as a subroutine a slightly modified version of Dijkstra, parameterized by the semiring dimension and working with semirings having elements in vector form, corresponding to the decomposition. *Dijkstra(s,t,i)* $\in J(L)$ computes the provenance between s and t corresponding to the i^{th} dimension of the decomposition.

Example 5.6. We describe the working of Algorithm 4 in the example presented in Example 5.1: first, each edge value is decomposed; this step is easy to follow as the 3-feature values are already presented in decomposed form. A second step consists in calculating values along each dimensions. Algorithm 1 is launched a first time over the graph with edge values corresponding to the first dimension: 0 for (s, r) and (r, t), 1 for (s, t). The result is 0. Algorithm 1 is launched a second time over the graph with edge values corresponding to the second dimension: 0 for (s, r) and (s, t), 1 for (r, t). The result is, again, 0. Finally, Algorithm 1 is launched a third time over the graph with edge values corresponding to the third dimension: 0 for (s, t), 1 for (s, r) and (r, t). The result is 0. This ends the second step. The third step consists in recomposing partial values obtained by successive applications of Dijkstra's algorithm. This ends up to the final provenance value of $(0, 0, 0)$.

Algorithm 4 MultiDijkstra – single-pair

Input: $(G = (V, E, w), s, t)$ a graph database with provenance indication over $\mathbb{K}$, the source s, and the target t.
Output: Single-pair provenance of the reachability query from s to t.

```
1: for each edge e ∈ E do
2:     decompose(w(e))
3: end for
4: for each dimension i do
5:     d_i ← Dijkstra(s, t, i)
6: end for
7: return recompose(d_1, ..., d_n)
```

For the sake of simplicity, we presented the single-pair version of our algorithm. To extend it to the single-source version one only needs to perform the *recompose* subroutine for each vertex in the graph.

To minimize accesses to the *decompose* subroutine – which can be very costly – we optimize MultiDijkstra by adopting a lazy approach, where the *Dijkstra* subroutine calls *decompose* only when needed, storing the decomposition across calls. This avoids scanning the whole graph when s and t are close.

[2] Implicitly from lattice notation to poset notation: $x \vee y = y$ means $x \leqslant y$.

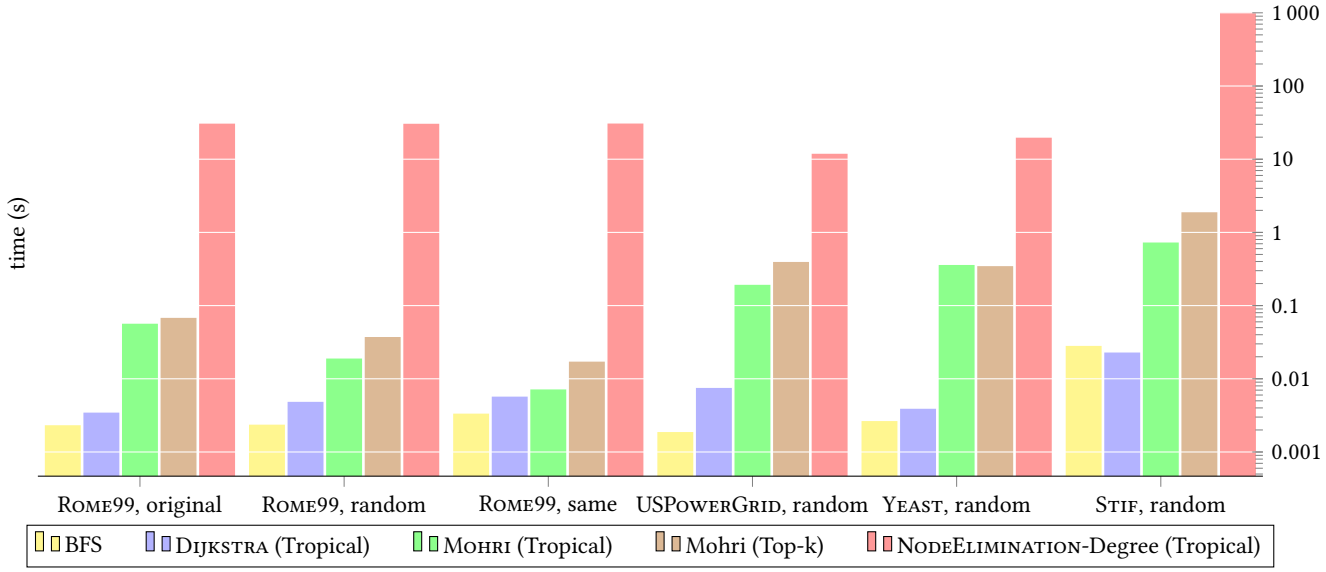


Figure 3: Comparison between algorithms for shortest distances

Table 2: Graph datasets: size and treewidth lower and upper estimates from [27]

type	name	# of vertices	# of edges	tw
infrastructure	Paris	4 325 486	5 395 531	55–521
	Stif	17 720	31 799	28–86
	USPowerGrid	4 941	6 594	10–18
	Rome99	3 353	4 831	5–50
social	Facebook	4 039	88 234	142–237
biology	Yeast	2 284	6 646	54–255

Two other optimizations implemented are a stopping condition that ends the *Dijkstra* subroutine when a visited vertex has value $\mathbb{0}$, and lazy initialization of the priority queue. These two optimizations led to vastly improved computation times over the naive implementation.

5.3 Practical Use Case

As exemplified in the Introduction, k-feature semirings can be used to ensure that all paths from s to t verify a combination of features (they all go through a specific set of points of interests, or verify some road properties) or either ensure the existence of valid paths up to some collection of restrictions. We show in the experimental section that this is tractable for practical use cases (continental-sized areas, around 10^7 vertices). To the best of our knowledge, no solution for this that scales even to graphs of thousands of vertices has been previously proposed.

6 EXPERIMENTS

We performed experiments on real-world graph data, using an Inria computing cluster running the OAR task manager. The individual vertices of the cluster have a minimum of 48 GB of RAM, and run Intel Xeon X5650 or E5-26xx CPUs.

We used datasets[3] from a variety of domains, mostly representing infrastructure networks: the OpenStreetMaps network of Paris (Paris), the Paris public transport network (Stif), and the power grid of the continental US (USPowerGrid). For comparison, we have also evaluated on other types of datasets: a small subset of the Facebook social network (Facebook) and the yeast protein-to-protein interaction network (Yeast). All these datasets come without provenance annotations, that we add in different ways depending on experiments. We also used a real weighted road transportation network dataset Rome99, with tropical semiring annotations, from the 9th DIMACS Implementation Challenge[4]. This dataset consists of a large portion of the directed road network of the city of Rome, Italy, from 1999. Basic information about the resulting graphs are summarized in Table 2.

For datasets without provenance annotations, unless specified differently, we randomly generate weights in the tropical semiring for benchmarks, uniformly between 1 and 3 000. To be able to compare the impact of the weights on the performance of the algorithms, we also use a constant-weight setting, where all weights equal to 1. Each experiment generally represents the average over 10 runs (random choices of origin and destination vertices).

Our experimental study is focused on comparing the four algorithms presented in this paper, over several semirings. We provide a comparison of all of our algorithms for the computation over the tropical semiring (shortest distance), since all algorithms can be used in this setting. We investigate the running time and the number of relaxation steps performed by Mohri and MultiDijkstra algorithm, using initial weights provided by the dataset Rome99, as well as custom weights (all identical and all random); we then study over all datasets the impact of the elimination order heuristic on the overall performance for NodeElimination. We then finish with the comparison between our new algorithm and previous solutions to demonstrate its efficiency.

Evaluating shortest distances. We start by evaluating how the algorithms deal with the shortest distance semiring, i.e., the tropical and top-k semiring (by setting $k = 1$). The properties of this semiring allow their implementation for the first three algorithms:

[3]These datasets were used in [27] for treewidth computation experiments, and are downloadable from https://github.com/smaniu/treewidth/; some of them originate from http://snap.stanford.edu/data/index.html.

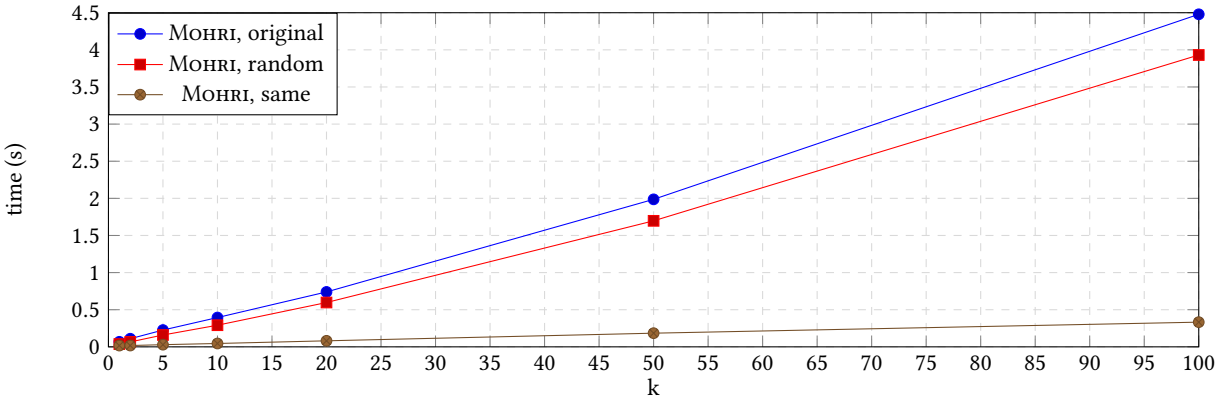

Figure 4: Computation time for Mohri over the top-k distances semiring, for varying values of k and varying weight assignments (Rome99)

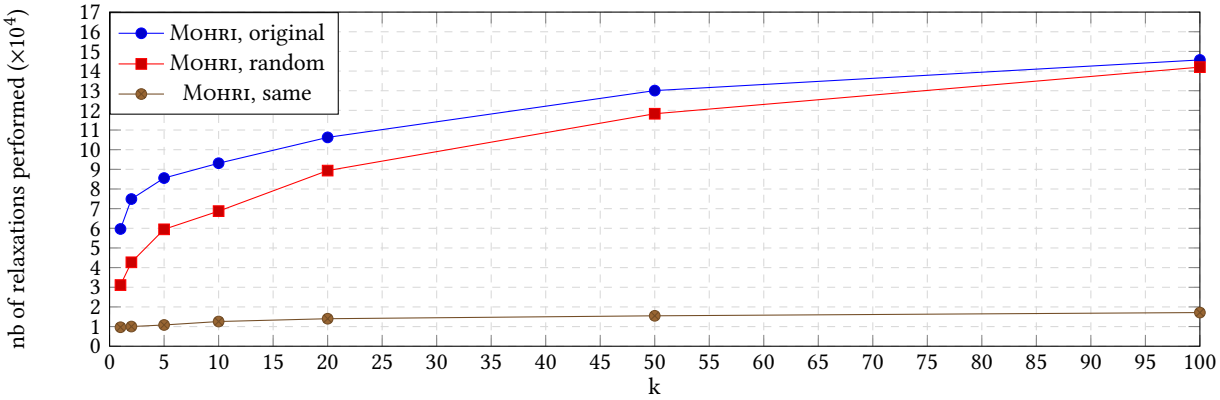

Figure 5: Number of relaxations performed by Mohri over the top-k distances semiring, for varying values of k and varying weight assignments (Rome99)

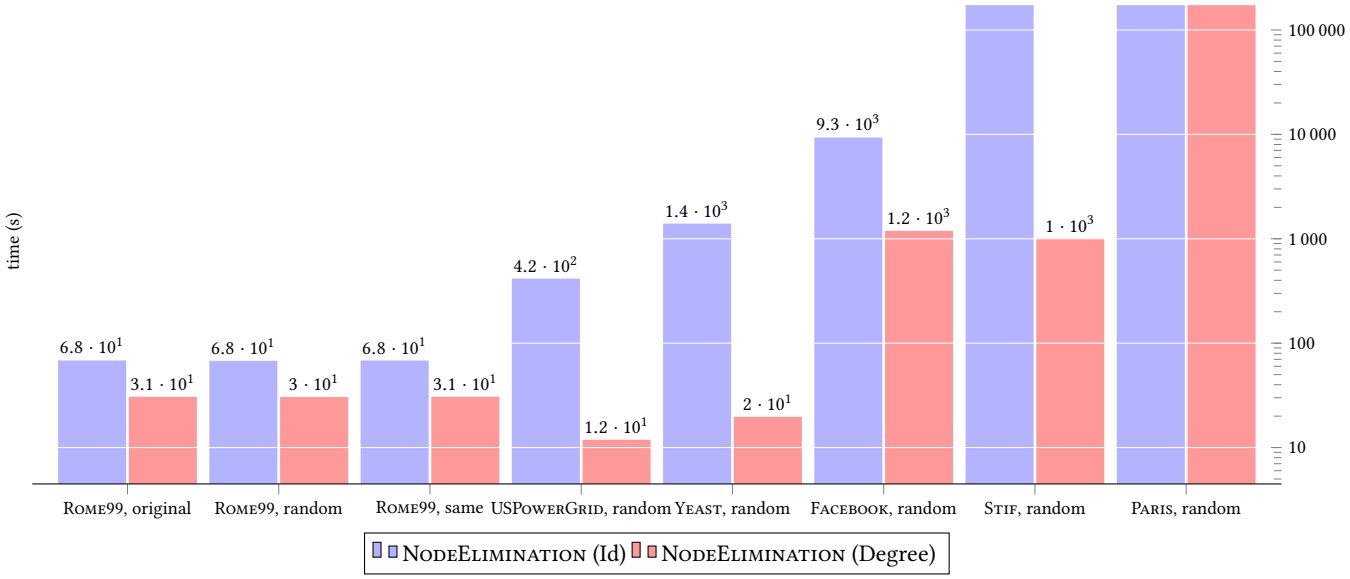

Figure 6: Comparison between elimination orders for NodeElimination algorithm (tropical semiring). Values greater than 100 000 s are timeouts.

Dijkstra, Mohri, and NodeElimination, whereas MultiDijkstra reduces to Dijkstra in that case. We also implemented a breadth-first-search traversal for computing accessibility with no provenance information (BFS). This also allows us to compare the performance of algorithms against non-annotated graph databases.

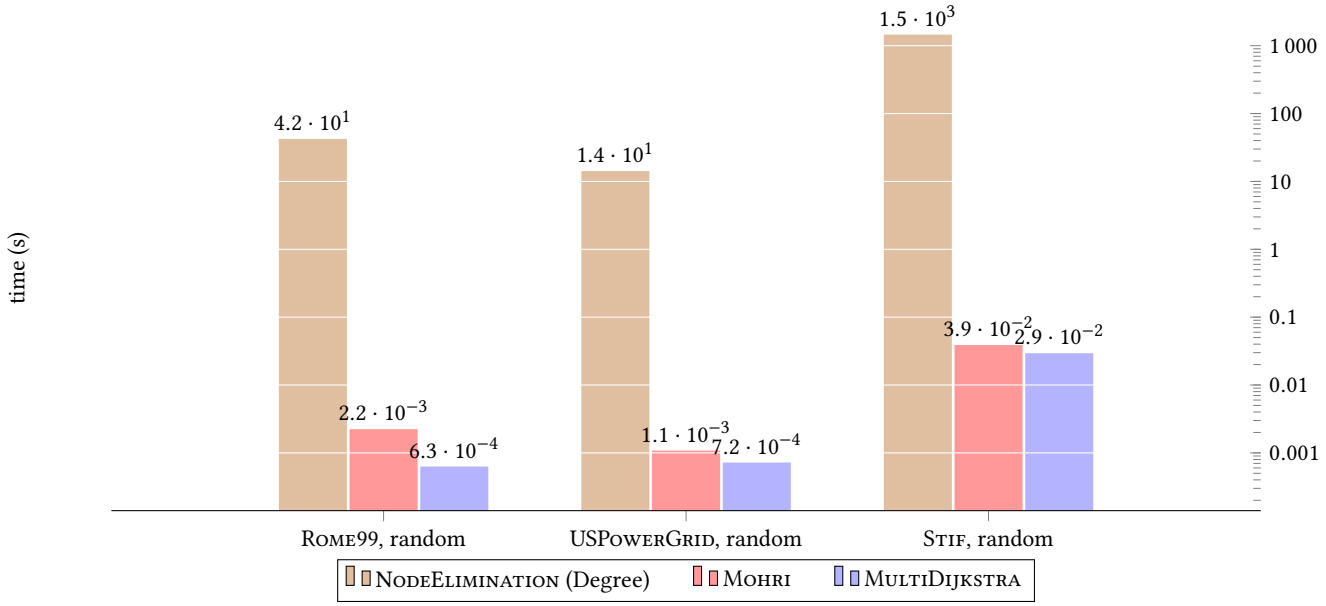

Figure 7: Comparison between NodeElimination, Mohri, and MultiDijkstra (3-feature semiring)

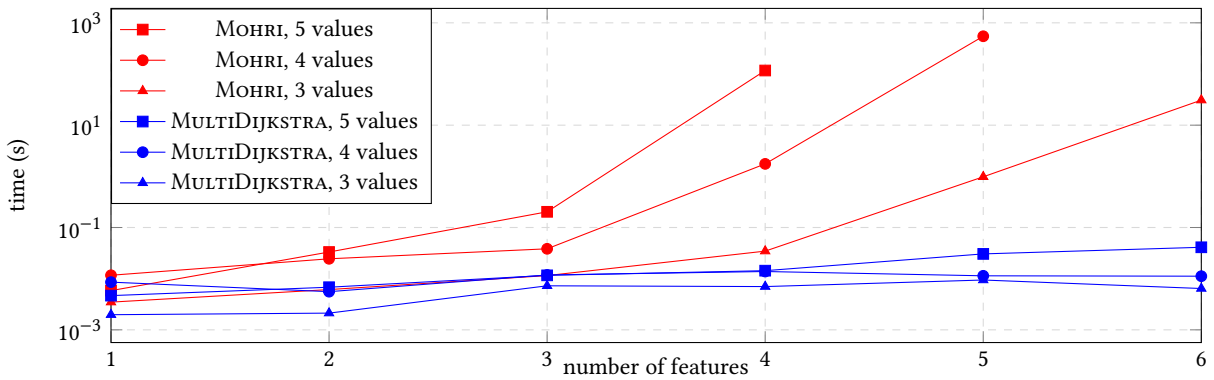

Figure 8: Computation time for Mohri and MultiDijkstra depending on the number of dimensions (Rome99)

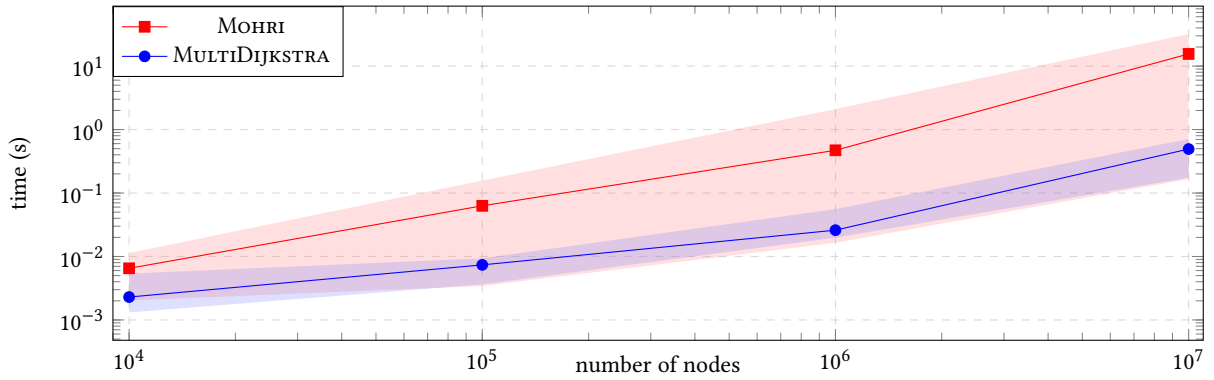

Figure 9: Average computation time for Mohri and MultiDijkstra over random graphs depending on the number of nodes; shaded areas indicate minimum and maximum computation times observed (3-feature semiring)

Figure 3 shows, on a logarithmic scale, the result for our graphs, and for some settings of weights (original, random, or same weights). It is immediately clear from the figure that the choice of algorithm is crucial: we need the most specialized algorithm for the semiring we use: Dijkstra is more efficient than Mohri which is more efficient than NodeElimination. Even for Mohri, we notice that using it configured for the top-k semiring with $k = 1$ does introduce an overhead in execution; when using the tropical semiring directly the overhead is smaller. We also show the overhead introduced when using provenance annotations is quite limited, as the difference between Dijkstra and BFS is less than an order of magnitude for each dataset, and Dijkstra

sometimes even outperforms BFS. Finally, NodeElimination is always several orders of magnitude slower than Dijkstra. Another encouraging result is that Mohri – which allows more classes of semirings than Dijkstra – has a reasonable running time in practice, despite the stated exponential complexity bound in the original paper. We turn to evaluating its performance next.

Mohri in practice. In Figure 4 and in Figure 5 we respectively study the impact of the factor k on the running time and on the number of computations performed by the algorithm. Our results show that the computational time is linear in k, though this is not the case for the number of relaxations, which increases sublinearly in k. This means that for large values of k the algorithm spends most of its time maintaining the queue.

We also compare the performance of the algorithm depending on weight assignment (original, random, same). It seems that considering random values instead of "real" values has almost no significant impact over the efficiency of the algorithm. This is a somewhat disappointing result because it rules out the possibility to parametrize the complexity of the algorithm through network parameters, for instance, in terms of the *highway dimension* [4] – a graph parameter that has been successfully applied for understanding the efficiency of state-of-the-art shortest-distance algorithms in road networks. However, the performance increases significantly when all weights are uniform, which may be expected since computation of shortest distances become far simpler, and far more paths have equal distance.

As pointed out in Section 3 this algorithm performs extremely well over transportation networks. We wanted to provide a comparison of its working time for different kinds of graphs (especially graphs whose treewidth is large relative to their size). For this purpose we used a social network dataset: who-trusts-whom network of people who trade using Bitcoin on a platform called Bitcoin Alpha [25, 26] (3 783 vertices and 24 186 edges). The algorithm times out after 48 hours.

What we can learn from this is that the key property making Mohri so efficient over transportation networks is not due to distance properties (e.g., highway dimension) – impacted by the weights of the connections – but rather by topological properties of the underlying graph (e.g., treewidth).

Ordering for NodeElimination. NodeElimination's perfomance, due to its main loop of creating "shortcuts" in the graph, is heavily dependent on the order in which the vertices are eliminated. This elimination ordering is strongly linked to the *treewidth* parameter of the graph. For instance, following a degree based elimination order gives an upper bound on this parameter.

Hence, we have compared different elimination orders for NodeElimination and found out that the minimum degree based elimination order (*Degree*) greatly improves the efficiency of this algorithm compared to having no such heuristic (*Id*). This improvement can be dramatic, as for the Yeast dataset where the algorithm is two orders of magnitude faster. As expected, weights over the edges doesn't impact the running time, as shown in Figure 6.

This is important in practice: running NodeElimination on low-treewidth graphs (e.g., infrastructure and transport networks) can be the difference between the algorithm being unusable and allowing reasonable running times. Taking into account that NodeElimination allows for a large class of semirings, this can have a significant real-world application impact.

MultiDijkstra. We now evaluate MultiDijkstra, our contribution to bridging the gap between absorptive semirings and more general ones. We compare it to Mohri and NodeElimination in the case of the k-feature semiring, which is kind of the canonical semiring that is 0-closed and multiplicatively idempotent. Figure 7 showcases this on 3 datasets. In all cases, our new algorithm is between 3 and 4 orders of magnitude faster than NodeElimination, depending on the network we use, and significantly faster than Mohri.

We then performed an additional experiment (Figure 8), examining the impact of the number of features and values actually used in each feature on the running time of both algorithms. We found out that when either one of the two criteria reaches 4, Mohri times out while MultiDijkstra keeps scaling.

Finally, Figure 9 presents a comparison between Mohri and MultiDijkstra on large Erdős–Rényi random generated graphs (generated using Python networkx's *fast_gnp_generation* method, using an average of 1.7 edges per vertex) show that our new algorithm is still tractable for continental-sized graphs of millions of vertices. Interestingly, MultiDijkstra also exhibits a much smaller variance than that of Mohri, whose performance varies by more than one order of magnitude between runs.

7 RELATED WORK

The idea of encapsulating operations carried along by graph algorithms in terms of semirings has been really common for decades. In [10, Chapter 25] the authors presented two of the classical graph algorithms, Floyd–Warshall and transitive closure algorithm in terms of *closed semirings*. The APSP (*All-Pairs Shortest-Path* problem) is elegantly expressible using star semirings; hence, research focused on the links to linear algebra through matrix computations [1], allowing to speed up the response time using parallel computations. Recent work on semiring-based graph processing has provided to the community some tools such as GraphBLAS [23], a library of kernel functions dedicated to optimize linear algebra computations over sparse matrices. Unfortunately, this tool focuses essentially on matrix and vector products and is not amenable to express priority queue management such as those needed for Mohri, Dijkstra, MultiDijkstra. Only NodeElimination and the matrix asteration algorithms could benefit of a GraphBLAS implementation: this might increase their performance, even when retaining their higher asymptotic complexity with respect to other algorithms.

Amongst many other fields, semirings have been successfully applied in constraint-solving programming [8], linguistic structure prediction [37] and formal language theory [33]. This algebraic structure is also perfectly suited to the modeling of dynamic programming [21].

The notion of provenance has also been initially developed using semirings [18], either for relational databases and Datalog programs, leading to practical systems such as [35], an extension to PostgreSQL adding the support for provenance. Many representation frameworks have been successfully applied to speed up the computation of the provenance for Datalog programs, most notably a circuit-based provenance approaches [11] and the solving of fixed-point equations using derivation tree analysis [15]. The latter approach led to a proof-of-concept implementation [16] of the resolution of fixed-point equations over *c-continuous semirings* using the Newton method.

Compared to our work, relational databases lack the effective support for navigational queries (recursion is an issue) and Datalog programs are much more expressive than graphs (they are closely related to hypergraphs), so we suspect query answering in Datalog would be highly inefficient for the continental-sized road-network datasets we target, though we leave this investigation for future work.

Numerous notions of provenance co-exist in the literature and each target different usages. The notion we use in this paper considers the provenance to be computational rather than just informational: we can apply operations over our provenance values with different semantics depending on the underlying semiring. Some practical systems, such as [28] rely on property graphs to represent provenance annotations, that are of an informational rather than computational nature. Those systems focus on the further querying of obtained provenance to derive additional information about the process.

8 CONCLUSIONS

We presented in this paper a study on evaluating the provenance of rich graph queries using the semiring provenance framework. We established a taxonomy of semiring classes, based on their properties. This in turn allows us to find, for a set of important semiring classes, the most appropriate algorithm, enabling real-world applicability. We introduce a new algorithm, MultiDijkstra, which bridges the gap between algorithms for absorptive semirings and ones for more general classes.

Experimentally, on graph datasets from various domains, we showed that making sure that the appropriate algorithm is chosen for the semiring specialization is crucial; gains of several orders of magnitude are observed between algorithms on the same graph datasets. Moreover, we notice that algorithms for which their theoretical complexity is high perform well in practice, especially on graphs having relatively low treewidth.

We believe the link with classes of semiring for which an optimization for the computation of the provenance for Datalog queries exists is a key observation for optimizing computations in our framework. Investigating this further will allows us to benefit from the rich literature around Datalog provenance (in particular, [11]) and to compare to our solutions.

ABSTRACT

Sequential pattern analysis has become a mature topic, with a lot of techniques for a variety of sequential pattern mining-related problems. Moreover, tailored solutions for specific domains, such as business process mining, have been developed. However, there is a gap in the literature for advanced techniques for efficient detection of arbitrary sequences in large collections of activity logs. In this work, we make a threefold contribution: (i) we propose a system architecture for incrementally maintaining appropriate indices that enable fast sequence detection; (ii) we investigate several alternatives for index building; and (iii) we compare our solution against existing state-of-the-art proposals and we highlight the benefits of our proposal.

1 INTRODUCTION

Event log entries refer to timestamped event metadata and can grow very large; e.g., even a decade ago, the amount of log entries of a single day was at the order of terabytes for certain organizations, as evidenced in [3]. Due to their timestamp, the log entries can be regarded as event sequences that follow either a total or a partial ordering. The vast amount of modern data analytics research on such sequences is divided into two broad categories.

The first category comprises sequential pattern mining [11], where a large set of sequences is mined to extract subsequences that meet a variety of criteria. Such criteria range from frequent occurrence, e.g., [23, 33] to importance and high-utility [12]. In addition, there are proposals that examine the same problem of finding interesting subsequences in a huge single sequence, e.g., [25]. However, these techniques fail to detect arbitrary patterns, regardless of whether they are frequent or interesting; e.g., they are tailored to a setting where a support threshold is provided and only subsequences meeting this threshold are returned, whereas we target a different problem, that is to return all subsequence occurrences given a pattern.

The second category of existing techniques deals with detecting event sequences on the fly and comprises complex event processing (CEP). CEP is a mature field [14, 34] and supports several flavors of runtime pattern detection. We aim to solve a similar problem to CEP but tailored to a non-streaming case, where pattern queries are submitted over potentially very large log databases. Since logs continuously arrive, we account for periodic index building and we support pattern matching where the elements in the pattern are not strictly in a sequence in the logs, e.g., in the log sequence `ABBACC`, we are interested in detecting the occurrence of the pattern `ABC` despite the fact that in the original sequence other elements appear in between the elements in the searched pattern. Given that we relax the constraint of strict contiguity, techniques based on suffix trees and arrays are not applicable. Contrary to CEP, we aim to detect all pattern occurrences efficiently and not only those happening now.

In summary, our contribution is threefold: (i) we propose a system architecture for incrementally maintaining appropriate indices that enable fast sequence detection and exploration of pattern continuation choices; (ii) we investigate several alternatives for index building; and (iii) we compare our solution against existing suffix array-based proposals, focusing on logs from business processes, showing that not only we can achieve high performance during indexing but we also support a broader range of queries. Compared to other state-of-the-art solutions, like Elasticsearch, we perform more efficient preprocessing, while we provide faster query responses to small queries remaining competitive in large queries in the datasets examined; additionally, we build on top of more scalable technologies, such as Spark and Cassandra, and we inherently support pattern continuation more efficiently. Finally, we provide the source code of our implementation.

The structure of the remainder of this paper is as follows. We present the notation and some background next. In Section 3, we introduce the architecture along with details regarding preprocessing and the queries we support. We discuss the index building alternatives in Section 4. The experimental evaluation is in Section 5. In the last sections, we discuss the related work, open issues and present the conclusions.

2 PRELIMINARIES

In this section, we first present the main notation and then we briefly provide some additional background with regards to the techniques against which we compare our solution.

2.1 Definitions and notation

We aim to detect sequential patterns of user activity in a log, where a log contains timestamped events. The events are of a specific type; for instance, in a log recording the user activity on the web, an event type may correspond to a specific type of click and in business processes, an event corresponds to the execution of a specific task. The events are logically grouped in sets, termed as cases or sessions or traces[1], which may correspond to a specific session or the same process instance or, in the generic case, grouped by other user-defined criteria. More formally:

[1] In this work, we use the terms trace, case and session interchangeably.

	Our Method	Exact rooted subtree matching
Supported policy	SC, STNM	SC, Tree Matching
Database usage	Yes	No
Preprocess rationale	Indexing of all possible pairs	Indexing of all the subtrees
Query processing rationale	Combination/merging of results of pairs in the query sequence	Binary search in the subtrees space

Table 1: Differences between the technique in [19] and our method

Symbol	Short description
L	the log containing events
A	the set of activities (or tasks), i.e., the event types
E	the set of all events
C	the set of cases, where each case corresponds to a single logical unit if execution, i.e., a session, a trace of a specific business process instance execution, and so on
ev	an event ($ev \in E$), which is an instance of an event type
ts	the timestamp of an event (also denoted as $ev.ts$)
l	the size of A, $\|A\|$
n	the maximum size of a case
m	the size of C, $\|C\|$

Table 2: Frequently used symbols and interpretation

Definition 2.1. (Event Log) Let A be a finite set of activities (tasks). A log L is defined as $L = (E, C, \gamma, \delta, ts, \preceq)$ where E is the finite set of events, C is the finite set of Cases, $\gamma : E \rightarrow C$ is a surjective function assigning events to Cases, $\delta : E \rightarrow A$ is a surjective function assigning events to activities, ts records the timestamp denoting the recording of task execution and $\preceq$ is a strict total ordering over events belonging to a specific case, normally based on execution timestamps.

The notion of timestamp requires some further explanation. In sessions like web user activity and similar ones, events are usually instantaneous. However, this is not the case in task executions in business processes. In the latter case, the timestamp refers to either the beginning of the activity or its completion, but in any case, logging needs to be consistent. The duration of activities can only be estimated implicitly and not accurately from the difference between the timestamps of an event and its successor, because there may be delays between the completion of an activity and the beginning of the execution of the next activity downstream. However, systematic analysis involving task duration can be conducted only if the exact task duration is captured, which requires extensions to the definition above. Such extensions is out of the scope of this work and are orthogonal to our contributions.

Table 2 summarizes the main notation; $|A|$ is denoted as l, the maximum size of a case is denoted as n, and the size of the set of cases $|C|$ is denoted as m.

Next, to provide the context of the queries we aim to support, we define the two main types of event sequence detection that we employ in this work:

Strict contiguity (SC) , where all matching events must appear strictly in a sequence one after the other without any other non-matching events in-between. This definition is widely employed in both exact subsequence matching and CEP systems and stream processing engines, such as Flink [6].[2] For example, SC applies when we aim to detect pattern occurrences, where a search for a product on an e-shop website is immediately followed by adding this product to the cart without any other action in between.

Skip-till-next-match (STNM) , where strict contiguity is relaxed so that irrelevant events are skipped until we detect the next matching event of the sequential pattern [34]. STNM is required when, for example, we aim to detect pattern occurrences where after three searches for specific products there is no any purchase eventually in the same session.

Example: let us assume that we look for a pattern `AAB`, where `A,B` are activities. Let us also assume that a log contains the following sequence of events `<AAABAACB>`, where the timestamps are implicit by the order of each event. SC detects a pattern occurrence starting at the 2nd position, whereas STNM detects two occurrences; the first one contains the events at the 1st, 2nd and 4th position, while the second one contains the events at the 5th, 6th and 8th position. Note that other types of event sequence detection allow for additional and overlapping results, e.g., to detect a pattern in the 1st, 3rd and 8th position, as discussed at the end of this work [34].

2.2 Exact rooted subtree matching in sublinear time

Strict contiguity (SC) is directly relevant to subsequence matching and tree-based techniques have been used for a long time for finding sub sequences in large datasets. Suffix trees and suffix arrays are commonly used to this end. The method presented in [19] can find subtrees in sublinear time and it has been used to detect possible continuations of a given event sequence in business processes in [27].

In a nutshell, the technique in [19] solves the problem of finding the occurrences of a subtree with m modes in a tree T with n nodes in $O(m + logn)$, after pre-processing the tree. First, the string W corresponding to T is created; this is achieved through traversing the tree in a preorder manner and adding a 0 every time we recur to a previous level. This yields a W of length equal to $2n$. W is then used to create a suffix array A, in which the starting positions of the $2n$ suffices are specified. After discarding those starting with 0, we end up with n suffices. The main property of A is that suffices are sorted by the nodes' order. The subtree to be searched in T is first mapped to a preorder search string, and then a binary search in A is performed.

In Table 1 we present the high-level differences between this method and our proposal. We rely on simple indexing employing a database backend, while, during query processing, the main

[2] https://ci.apache.org/projects/flink/flink-docs-stable/dev/libs/cep.html

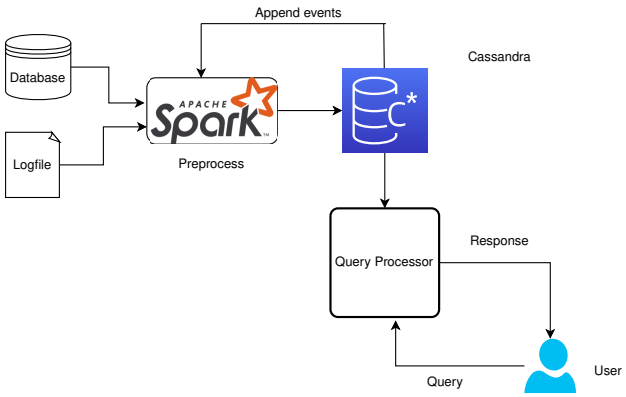

Figure 1: Architecture overview

operation is merging and post-processing of sorted lists, as explained in the next sections. More importantly, we support both STNM and SC pattern types.

3 SYSTEM ARCHITECTURE

There exist several CEP proposals along with fully-fledged prototypes and complete systems that allow users to query for Strict contiguity (SC) or Skip-till-next-match (STNM) patterns, but these are operating in a dynamic environment over a data stream. Therefore, we need to develop a system that can receive adhoc pattern queries over a large collection of logs and process them in an efficient manner. These queries will be defined later in this section and are broadly divided into three main categories (statistics, pattern detection and pattern expansion). We focus on offline pattern detection, but we account for the fact that the logs are constantly growing bigger and bigger. This entails that any practical approach needs to be incremental, i.e., to support the consideration of new logs periodically.

The overview of our proposed architecture is shown in Figure 1. There exists a database infrastructure containing old logs and, periodically, new logs are appended. There are two main components in the architecture. The pre-processing component constructs and/or updates an inverted index that is leveraged during query processing. This index is stored in a key-value database to attain scalability. In our implementation, we have chosen Cassandra[3], because of its proven capability to deal with big data and offer scalability and availability without compromising performance. However, any key-value store can be used in replacement.

The second component is the query processor, which is responsible for receiving user queries, retrieving the relevant index entries and constructing the response.

These two components are described in more detail in the remainder of this section, while indexing is discussed in the next section.

3.1 The pre-processing component

The log database has a typical relational form, where each record corresponds to a specific event. More specifically, each row in the log database contains the trace identifier, the event type, the timestamp and any other application-specific metadata that play no role in our generic solution. The second input of the pre-processing component contains the more recent log entries that have not been indexed yet. For example, if the index is updated on a daily basis, the log file is expected to contain from a few thousand of events up to several millions.

[3]https://cassandra.apache.org/

trace: <(A,1), (A,2), (B,3), (A,4), (B,5), (A,6)>		
Pair	**Strict Contiguity**	**Skip till next match**
(A,A)	(1,2)	(1,2),(4,6)
(B,A)	(3,4),(4,5)	(3,4),(5,6)
(B,B)	-	(3,5)
(A,B)	(2,3),(4,5)	(1,3),(4,5)

Table 3: Pairs created per different policy.

Pattern indexing and querying is applied per trace. In other words, for each distinct trace, a large sequence of all its events is constructed sorted by the event timestamps. To this end, the recent logfile is combined with the log database. In addition, and since the trace may span many indexing periods, new log entries need to combined with already indexed events in the same trace in a principled manner to avoid duplicates. If new logged events belong to a trace already started, we extract stored information from the indexing database (the exact procedure will be described in detail shortly).

Based on these trace sequences, we build an inverted indexing of all event pairs. That is, we extract all event pairs from each trace, and for each pair we keep its trace along with the corresponding pair of timestamps. This information is adequate to answer pattern queries efficiently, where these queries may not only refer to pattern detection, but frequency counts and prediction of next events, as discussed in Section 3.2.1. The index contains entries of the following format: `(A,B):{(trace12, 2,5),(trace12, 7,11), (trace15,1,6),. . . }`. In this example, the pair of event types `(A,B)` has appeared twice in trace12 at timestamps (2,5) and (7,11), respectively, and once in trace15.

The pre-processing component is implemented as a Spark Scala program to attain scalability. Next, we delve into more details regarding pre-processing subparts.

3.1.1 Creation of event pairs. There are more than one ways to create pair of events in a trace, which depends on the different policy applied. We have already given two policies, namely SC and STNM, which impact on how pairs are created.

Let us assume that a specific trace contains the following sequence of pairs of event types and their timestamps: `trace: <(A,1), (A,2), (B,3), (A,4), (B,5), (A,6)>`. Table 3 shows the pairs created per different policy. This example shows a simplified representation of the inverted indexing. SC detects only the pairs of events that are consecutive. There is no pair pair `(B,B)` because there is an event `(A)` between the two Bs in the trace. As expected, the SC policy creates less pairs per trace and is also easier to implement.

STNM skips events until it finds a matching event, but there are no overlapping pairs, the timestamps of which are intertwined. For example, regarding pair `(A,B)`, we consider only the (1,3) pair of timestamps and not (2,3). The complexity of pair creation in STNM is higher and there are several alternatives that are presented in Section 4.

A final note is that our approach can work even in the absence of timestamps. In that case, the position of an event in the sequence can play the role of the timestamp.

Algorithm 1 Update index

```
1: Input : new_events
2: traces ← transform new_events to traces as in the Seq table
3: temp ← LastChecked table joined with traces
4: new_pairs ← [ ]
5: for all trace in traces do
6:     extract events
7:     for all (ev_a, ev_b) do
8:         lt ← temp.get(ev_a, ev_b).last_completion for the same trace
9:         if ev_a.ts > lt then
10:            new_pairs += create_pairs(ev_a, ev_b)
11:        end if
12:    end for
13: end for
14: append new_pairs to the Index table
```

Algorithm 2 Pattern detection

```
1: procedure getCompletions(< ev_1, ev_2, ..., ev_p >)
2:     previous ← Index.get(ev_1, ev_2)
3:     for i =2 to p − 1 do
4:         idx_completions ← Index.get(ev_i, ev_{i+1})
5:         for all c in idx_completions grouped by trace do
6:             new ← [ ]
7:             for all pr in previous for the same trace do
8:                 if pr.last_event.ts == c.first.ts then
9:                     append c to pr and add to new
10:                end if
11:            end for
12:            previous ← new
13:        end for
14:    end for
15:    return previous
16: end procedure
```

3.1.2 Tables in the indexing database. The pre-processing phase creates and updates a set of tables, which can all be stored in a key-value store, such as Cassandra. The first one contains the trace sequence, so that there is no need to be reconstructed from scratch every time is needed, e.g., to append new events. The second one is the index presented earlier. The other tables are auxiliary ones, which are required during index creation and query answering.

- **Seq** with key: $trace_{id}$ and value: $\{(ev_a, ts_a), (ev_b, ts_b), ...\}$. This table contains all traces that are indexed. It is used to create and update the main index; new events belonging to the same trace are appended to the value list.
- **Index** with a complex key: (ev_a, ev_b) and value containing a list of triples: $\{(trace_{id}, ts_a, ts_b), ...\}$. This is the inverted index, which is the main structure used in query answering.
- **Count** with key a single event type: ev_a and value a list of triples: $\{(ev_b, sum\_duration, total\_completions), (ev_c, sum\_duration, total\_completions), ...\}$. For each event ev_a, we keep a list which contains the total duration of completions for a pair (ev_a, ev_x) and the total number of completions. This is used to find the most frequent pairs where an event appears first and also we can leverage the duration information in case further statistics are required.
- **Reverse Count**, which has exactly the same form of key and value with **Count**, but the statistics refer to pairs that have the event in the key as their second component
- **LastChecked** with complex key a pair (ev_a, ev_b) and value a list of pairs: $\{(trace_{id}, last\_completion), ...\}$. The length of the list is the number of traces in which the pair (ev_a, ev_b) appears. The $last\_completion$ field keeps the last timestamp of ev_b in a pair detection. This table is used to prevent creating and indexing pairs more than once.

3.1.3 Index update. In dynamic environments, new logs arrive continuously, but the index is not necessarily updated upon the arrival of each new log record. New log events are batched and the update procedure is called periodically, e.g., once every few hours. To avoid the generation of duplicates, the LastChecked table introduced above plays a crucial role. The index update rationale is illustrated in Algorithm 1.

In line 3 of the algorithm, we extract the LastChecked table and keep only its part that refers to the traces that their id appears in new events. In line 10, the *create_pairs* procedure is not specifically described here but can be any of the algorithms presented in Section 4 depending also on the policy employed.

A subtle point is that the index may grow very large. To mitigate this, a separate index table can be used for different periods, e.g., for different months. In addition, the traces corresponding to completed sessions can be safely pruned from the Seq table, along with the corresponding value entries in LastChecked.

3.2 The query processor component

The architecture described can support a range of pattern queries that are presented in Section 3.2.1. In Section 3.2.2, we give different solutions for predicting subsequent events in a pattern while trading off accuracy for response time.

3.2.1 Different type of queries. The query input is a pattern (i.e., a sequence) of events $< ev_1, ev_2, ev_3, \ldots, ev_p >$ for all supported query types. The query types in ascending order of complexity are as follows:

- **Statistics.** This type of query returns statistics regarding each pair of consecutive events in the pattern. The statistics are those supported by the Count table, namely number of completions and average duration. Also, from the LastChecked table, the timestamp of the last completion can be retrieved. The pairwise statistics can provide useful insights about the behavior of the complete pattern with simple post-processing and without requiring access to any other information. For example, the minimum number of completions of a pair provides an upper bound of the completions of the whole pattern in the query. Also, the sum of the average durations gives an estimate of the average duration of the whole pattern. Finally, the number of completions could be more accurately bounded if all pairs in the pattern are considered instead of the consecutive ones only; clearly, there is a tradeoff between result accuracy and query running time in this case.
- **Pattern Detection.** This query aims to return all traces that contain the given pattern. Query processing starts by searching for all the traces that contain event pair (ev_1, ev_2). At the next step, the technique keeps only the traces where the same instance of ev_2 is followed by e_3 to the pattern; to this end, it finds all the traces that contain (ev_2, ev_3) and keeps those for which ev_2 has the same timestamp in both cases. Up to now, we have found the traces that contain

Algorithm 3 Accurate exploration of events

1: **Input:** pattern $e_1, ev_2, ..., ev_p$
2: candidate_events ← from Count Table get all events that has ev_p as first event
3: propositions← [ ]
4: **for all** *ev* in candidate events **do**
5: tempPattern ← append *ev* to pattern
6: candidate_pairs ← **getCompletions**(TempPattern)
7: proposition ← apply time constraints to candidate pairs (optional)
8: append proposition to propositions
9: **end for**
10: return propositions sorted according to Equation (1)

(ev_1, ev_2, ev_3). The execution continues in the same way up to ev_p, as shown in Algorithm 2. It is trivial to extend the results with further information, such as the starting and ending timestamp.

- **Pattern Continuation.** Another aspect for pattern querying is exploring which events are most likely to extend the pattern in the query. This has several applications, such as predicting an upcoming event given partial pattern in an incomplete trace, or computing the probability of an event to appear in a pattern, based on prior knowledge. In this query, the response contains the most likely events that can be appended to the pattern, based on a scoring function. Equation 1 gives a score for a proposed event. Total completions refer to the frequency of this event to follow the last event in the query pattern, while average duration favors events that appear closer to the pattern in the original traces.

$$Score = \frac{total\_completions}{average\_duration} \quad (1)$$

3.2.2 Pattern Continuation Alternatives. Exploring events for pattern continuation can be computationally intensive, depending on the log size. Some times, we want accurate responses, while in other cases it is adequate to receive coarser insights so that we can trade accuracy for response time. We present three alternative ways of exploring events, namely one accurate, one fast heuristic and one hybrid that is in between the previous two.

- **Accurate.** In Algorithm 3, we present the outline of this method. In line 2 we use the Count table to find all event pairs that begin with the last event of the pattern and collect the second events of the pairs in the candidate_events list. The procedure getCompletions is already provided in Algorithm 2. We also allow for constraints in the average time between the last event in the pattern and the appended event; these constraints are checked in line 7. The strong point of this approach is that all pattern continuations are accurately checked one-by-one; the drawback is that the response time increases rapidly with the size of log files and the number of different events.

- **Fast.** In Algorithm 4 we perform a heuristic search. We start by finding the upper bound of the total times the given pattern has been completed (lines 3-8). Then, for every possible event *ev*, we approximate the upper bound if this event is added at the end of the pattern, by keeping the minimum between the max_completions and the total completions of *ev* (line 11). The strong point of this approach is that it is fast, since it extracts precomputed statistics from the indexing database but the results rely only on approximations.

Algorithm 4 Fast exploration of events

1: **Input:** Pattern $e_1, ev_2, ..., ev_p$
2: max_completions ← ∞
3: **for all** (ev_i, ev_{i+1}) in pattern **do**
4: count ← Count Table get ev_i, ev_{i+1}
5: **if** count.total_completions < max_completions **then**
6: max_completions ← count.total_completions
7: **end if**
8: **end for**
9: propositions ← [ ]
10: **for all** ev in Count.get(ev_p) **do**
11: completions ← min(max_completions,ev.total_completions)
12: append (ev.event,completions,ev.average_duration) to propositions
13: **end for**
14: return propositions sorted according to Equation (1)

Algorithm 5 Hybrid exploration of events

1: **Input:** Pattern $e_1, ev_2, ..., ev_n$
2: **Input:** topK
3: fast_propositions ← run Algorithm 4 for the input pattern
4: propositions ← run Algorithm 3 for topK of fast_propositions
5: return propositions sorted according to Equation (1)

- **Hybrid.** Lastly, in Algorithm 5 we perform a trade off between accuracy and response time. This flavor receives topK as an input parameter. First, the fast alternative runs to provide an initial ranking of possible pattern continuations. Then, for the topK intermediate results, the accurate method runs. In this flavor, the trade-off is configurable. Setting topK to l, the technique degenerates to the accurate, while setting topK to 0 is equal to the fast only alternative.

4 ALTERNATIVES FOR INDEXING EVENT PAIRS

The indexing of event pairs largely depends on the pattern detection policy. For the Strict contiguity (SC) policy, the process is straightforward. For Skip-till-next-match (STNM), there are three flavors. Each trace is processed separately in parallel using Spark. Below, we show the processing per trace; therefore the overall complexity for the complete log needs to be increased by a factor of O(m). The techniques presented in this section refer to the implementation of the *create_pairs* procedure in Alg. 1.

4.1 Strict Contiguity

This method is straightforward: we parse each trace and we add the consecutive trace events in the index. The complexity is $O(n)$, where n is the size of a trace sequence in the log file.

4.2 Skip-till-next-match

The three different ways to calculate the event pairs using the skip-till-next-match (STNM) strategy have different perspectives.

Algorithm 6 Parsing method (per trace)

```
    checkedList ← [ ]
    for i in (0, trace.size-1) do
        inter_events ← [ ]
        if ev_i.type not in checkedList then
5:          for j in (i,trace.size) do
                if ev_i.type==ev_j.type then
                    update inv_index with (ev_i, ev_j)
                    for all inter_e in inter_events do
                        update inv_index with (ev_i, inter_e)
10:                 end for
                    reset inter_events
                else if ev_j.type not in inter_events then
                    update inv_index with ev_i, ev_j
                    append ev_j to inter_events
15:             end if
            end for
            append ev_i to checkedList
        end if
    end for
```

The *Parsing* method computes pairs while parsing through the sequence. The *Indexing* method, first detects the positions of each distinct event and then calculates the pairs. Finally, the *State* method updates and saves a state for the sequence for each new event.

Each method can be used in different scenarios. As we will show in the experimental section, the *Indexing* method dominates in the settings investigated. But this is not necessarily always the case. For example, if we operate in a fully dynamic environment, where new events are appended continuously as a data stream, its easier to keep a state of the sequence than calculating all the pairs from the start. However, in our core scenario where new logs are processed periodically, all three ways apply. In addition, if a domain has a lot of distinct events, i.e., l is very high and much higher than the cardinalities examined, the *Indexing* method becomes inefficient and thus is better to use the *Parsing* one.

Parsing method. The main structure is inv_index, which is a trace-specific part of the Index table. For each trace, the entries of this table are augmented in parallel and since there is no ordering in the values, this is not a problem.

The main rationale is shown in Algorithm 6, which contains two main loops, in line 2 and in line 5, respectively. The idea is to create all the event pars (ev_i, ev_j), in which ev_i is before ev_j. The checkedList prevents the algorithm from dealing with events types that has already been tested. While looping through the trace sequence for an event ev_1, the algorithm appends all new events to inter_events until it finds an event, ev_2 that has the same type as ev_1. When this happens it will create all the pairs of ev_1 with the events in the inter_events list (line 8-10) and will empty it (line 11). After that point, the algorithm proceeds with creating pairs where the timestamp of the first event is now equal to ev_2's timestamp. While updating the index, some extra checks are performed to prevent entering the same pairs twice.

Complexity Analysis. Even though there are two loops iterating the events, the if statement in line 4 can be true only up to l times (where l is the number of distinct elements) and so the complexity is $O(nl^2)$, with n being the length of the trace sequence. The space required is $O(n+l^2)$, for the inv_index and the checkedList.

Algorithm 7 Indexing method (per trace)

```
1:  indexer ← map(event_id):[timestmap1,timestamp2,...]
2:  for all ev_a in indexer do
3:      for all ev_a in indexer do
4:          CreatePairs(indexer[ev_a.tsList],indexer[ev_b.tsList]))
5:      end for
6:  end for
    procedure CreatePairs(times_a,times_b)
        i,j,prev ← 0,0,-1
        pairs ← [ ]
        while i < times_a.size and j < times_b.size do
5:          if times_a[i] < times_b[j] then
                if times_a[i] > prev then
                    append (times_a[i],times_b[j]) to pairs
                    prev ←times_b[j], i←1, j←1
                else
10:                 i←1
                end if
            else
                j←1
            end if
15:     end while
        return pairs
    end procedure
```

Algorithm 8 State method (per trace)

```
1:  index ← HashMap((ev_i, ev_j):[ts_1, ts_2, ts_3...])
2:  for all ev in the trace do
3:      Add_New(index,ev)
4:  end for
5:  return index
6:  procedure Add_New(index, new_event)
7:      for all combinations where new_event is the 1st event
    in index do
8:          update state
9:      end for
10:     for all combinations where new_event is the 2nd event
    in index do
11:         update state
12:     end for
13: end procedure
```

Indexing method. The key idea is to read the whole sequence of events while keeping the timestamps in which every event type occurred (line 1). Then, for every possible combination of events we run the procedure, in which we create the pairs. The procedure is similar to a merging of two lists, while checking for time constrains. More specifically, in line 5, the order of the events is checked and then in line 6, we ensure that there are no overlapping event pairs.

Complexity Analysis. In line 1, we loop once the entire sequence to find the indexes of each distinct event ($O(n)$). Then, the next loops in lines 2-3 retrieve all the possible event pairs ($O(l^2)$) and finally the procedure in line 4, will pass through their indices ($O(n)$). This gives a total complexity of $O(n+l^2n)$, which is simplified to $O(nl^2)$. The total space required is $O(n+l^2)$, for the partial and the pairs. I.e., the complexity is similar to the *Parsing* method.

State method. The algorithm is based on a Hash Map, which contains a list of timestamps for each pair of events. We first initialize the structure by adding all the possible event pairs that can be created (line 1) through parsing the sequence and detecting all distinct event types that appear. Then we loop again through the event sequence. While looping through the sequence we add new event (ev_i) in the structure, by first updating all the the pairs that have ev_i as the first event and then as the second (procedure lines 7-12). During these updates, we ensure that no pair is overlapping. The update operation is as follows. For each (ev_i, ev_j) entry in the HashMap, if the list of the timestamps has even size, we append $ev_i.ts$; otherwise we do nothing. Similarly, for each (ev_j, ev_i) entry in the HashMap, if the list of the timestamps has odd size, we append $ev_i.ts$; otherwise we do nothing. At the end, we trim all timestamp lists of odd size (not shown in the algorithm).

Complexity Analysis. The space complexity is $O(l^2)$ due to the HashMap. In line 2, the loop is passing through all the events in the sequence and for every event executes the procedure Add_new. This procedure has two loops passing through the set of distinct events (l), which gives us a total complexity of $O(nl)$ multiplied by the complexity to access the HashMap, which is $O(1)$ in the average case. Despite this lower complexity, in the evaluation section, we will provide evidence that the overheads due to the HashMap access are relatively high.

Implementation information. We have used Spark and Scala for developing the pre-processing component, which encapsulates the event pair indexing, and Java Spring for the query processor. The source code is publicly available on GitHub.[4],[5]

5 EVALUATION

We used both real-world and synthetic datasets to evaluate the performance of the proposed methods. We start by presenting the datasets, followed by the evaluation of the different flavors of indexing event pairs. Then we compare the preprocess time with the proposal in [19] and Elasticsearch v7.9.1 and finally we show the response time for queries that executed in both methods. In query processing, we also compare against SASE [34].[6] All tests were conducted on a machine with 16GB of RAM and 3.2GHz CPU with 12 cores. Cassandra is deployed on a separate machine with 64GB of RAM and 2GHz CPU. Each experiment is repeated 5 times and the average time is presented.

5.1 Datasets

The real-world datasets are taken from the Business Process Intelligence (BPI) Challenges, and more specifically from the years 2013, 2017 and 2020. BPI13[7] is an event log of Volvo IT incident and problem management. It includes 7,554 traces, which contain 65,533 events in total. The mean, min and max number of events per trace for this dataset are 8.6, 1 and 123, respectively. BPI17[8] is an event log, which corresponds to a loan application of an Dutch financial institute. It includes 31,509 traces, which contain over 1M (1,202,267) events in total. The mean, min and max number of events per trace for this dataset are 38.15, 10 and 180, respectively.

[8]https://data.4tu.nl/articles/BPI_Challenge_2017/12696884

Log file	Number of traces	Activities
max_100	100	150
max_500	500	159
med_5000	5,000	95
max_5000	5,000	160
max_1000	1,000	160
max_10000	10,000	160
min_10000	10,000	15
bpi_2013	7,554	4
bpi_2020	6,886	19
bpi_2017	31,509	26

Table 4: Number of traces and distinct activities for every process-like event log.

From BPI20[9], we use an event log of requesting for payment for a business trip. This is the smaller real-world dataset. It includes 6,886 traces, which contain 36,796 events. The mean, min and max number of events per trace for this dataset are 5.3, 1 and 20, respectively.

We also created synthetic datasets. First with the help of the PLG2[10] tool, we created 3 different processes, with different number of distinct activities (15,95,160). Then by modifying the number of traces per logfile, we created logs that contain from 500 to 400,000 events. The log files are in the XES[11] format. In Figure 2, the distributions of events per trace and unique activities per trace are shown. The purpose of these figures is to provide evidence that our test datasets cover a broad range of real-world trace profiles, thus the experimental results are trustworthy. In general, logs with the terms "med" and "max" in their name have more events per trace and much more unique activities than those with the term "min". Summary metadata are also in the Table 4. The process-oriented logs are not big, but are used in order to compare our approach against the one in [19], which has been employed in pattern continuation in business processes. This method cannot handle much bigger datasets. To test the scalability of our solution, we employ some additional random datasets that will be introduced separately.

5.2 Evaluating the different ways of indexing pairs

In this section, we evaluate the different flavors that index the event pairs according to the skip-till-next-match (STNM) policy. We aim to find the pros and cons for each flavor in Section 4 and also define the different real life scenarios to use them complementing the discussions already made above. We start the evaluation using the datasets in Table 4. The results are shown in Table 5. The main observation is that all three flavors perform similarly while indexing process-like datasets. When the relative differences are larger (e.g., larger than 30% for bpi_2020), the absolute times are small, so the impact of different decisions is not that important.

These datasets are not big. To better test the potential of the three alternatives, we created log files in which the events were not based on a process. We range the number of traces from 100 to 5000, the number of max events per trace from 50 to 4000

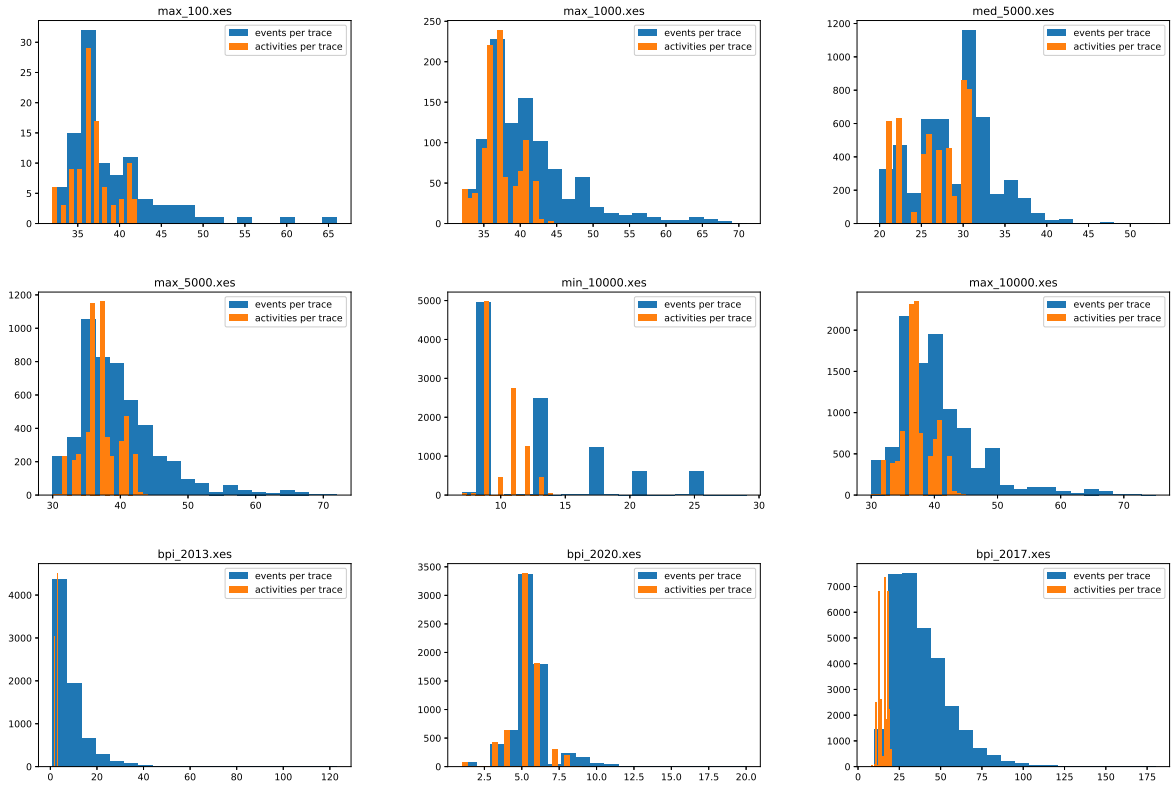

Figure 2: Distributions of the number of events and activities (i.e., unique event types) per trace for every process like log file.

Log file	Indexing	Parsing	State
max_100	4.874	4.49	4.572
max_500	8.454	7.109	7.294
max_1000	10.656	10.407	10.447
med_5000	23.105	22.601	22.417
max_5000	38.152	34.854	38.444
max_10000	79.863	77.964	80.796
min_10000	15.604	13.979	13.625
bpi_2020	6.803	10.384	8.822
bpi_2013	9.528	8.044	8.197
bpi_2017	170.9	171.666	179.352

Table 5: Execution times of different methods (in seconds).

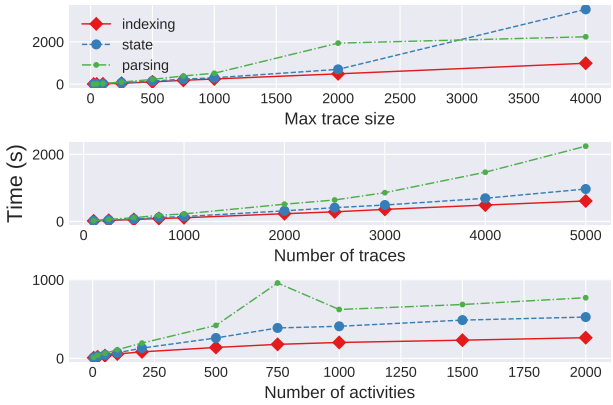

Figure 3: Comparison of execution times of the three different approaches of indexing the event pairs according to the STNM policy for large random logs.

and the number of activities from 4 to 2000. We refer to them as random datasets, due to the lack of correlation between the appearance of two events in a trace, which is not the typical case in practice, and renders the indexing problem more challenging.

The results are presented in Figure 3. In the first plot, we set the number of traces equal to 1000 and the number of different activities equal to 500, while changing the number of max events per trace from 100 to 4000. I.e., we handle up to 4M events. In the second plot, we keep the maximum number of events per trace and distinct activities to 1000 and 100, respectively while increasing the number of traces from 100 to 5000. I.e., we handle up to 5M events. Lastly, we maintain both the number of traces and maximum number of events to 500 and increase the distinct activities from 4 to 2000.

From the Figure 3, we can observe that the Indexing alternative outperforms the other two, in some cases by more than an order of magnitude. The simplicity of this method makes it superior to State, even though the time complexity indicates that the latter is better. The State method performs better than Parsing; especially in the third plot we can see the non-linear correlation between the execution time and the number of distinct activities.

In summary, our results indicate that indexing is the most efficient flavor to use when dealing with log files considered periodically (so that new log entries are a few millions): it has

Log file	[19]	Strict (1 thread)	Strict	Indexing (1 thread)	Indexing	Elasticsearch
max_100	1.054	3.764	3.701	5.398	4.874	0.67

Table 6: Comparison of execution times between [19] and our proposal (time in seconds).

minimum space complexity and it has the best executing time. On the contrary, State is preferable when operating in a dynamic environment, when for example new logs will be appended at the end of every few minutes and some traces will be active for weeks. State allows to save the current state of the log and, when new events are appended, it can calculate the event pairs without checking the previous ones. Even though the space complexity is higher than the other methods, it is expected to dominate in a real dynamic scenario.

5.3 Pre-process comparison

Based on the previous results, we continue the comparison using only the Indexing alternative for the STNM policy. We compare the time for building the index for both SC and STNM against [19], which supports only SC, and against Elasticsearch. The results are presented in Table 6; to provide the full picture we run Spark in two modes, namely using all the available machine cores and using a single Spark executor. The latter allows for direct comparison against non-parallel solutions.

Considering how [19] works, logs that are based on processes are easier to handle. We can split the test datasets of table 4 into three categories, namely small synthetic datasets (100-1000 traces), large synthetic datasets (5000 & 10000 traces) and real datasets (from the BPI challenge). In the first category, Strict performs almost the same as [19], while Indexing has significantly higher execution time, due to the more complex process it runs. In the second category, Strict scales better and achieves better times than [19]. Finally, in real datasets, our method achieves two order of magnitude lower times compared to [19]. When using the bpi_2017 dataset, [19] could not even finish indexing in 5 hours. This is probably based on the large amount of events (≈1.2M) combined with the high number of distinct events per trace. This lead to a very large suffix array, which probably could not fit in main memory and ended up doing an extensive amount of I/Os. For the same dataset, both Indexing and Strict managed to create inverted indexing in less than 3 minutes when using all machine cores.

Compared to Elasticsearch, we can observe that our best performing technique is on average faster for the last two categories (large synthetic and real datasets). In the larger real dataset, building an index to support STNM queries according to our proposal is more than 2.1X faster than Elasticsearch.

Parallelization-by-design is a big advantage of our method; we do not simply employ Spark but we can treat each trace in parallel. Further, parallelization applies to both the event-pair creation and the storage (Cassandra is a distributed database). As shown in Table 6, indexing can run even 10 times faster when using all 12 cores available. This is not the case for the [19] and other solutions, like Elasticsearch. However, there exist some structures that build suffix trees in parallel [2, 13, 20]. But still, the most computational intense process is to find all the subtrees and store them. The number of subtrees is increased with the number of leaves, which depends on the different traces that can be found in a logfile.

Log file	[19]	Our method (2)	Our method (10)
max_100	0.0023	0.007	0.022
max_500	0.0026	0.020	0.029
max_1000	0.0022	0.010	0.050

Table 7: Comparison response times in seconds

5.4 Query response time

We start by comparing the response time for a single query, between our method and the one in [19]. Since [19] supports the strict contiguity (SC) policy solely, we use this policy to create the inverted index and then execute a pattern detection query, as described in Section 3.2.1. Then, we compare the STNM solutions against Elasticsearch and SASE, which does not perform any preprocessing. We do not employ Elasticsearch in the SC experiments, because it is more suitable for STNM queries; more specifically, supporting SC can be achieved with additional expensive post-processing. Finally, we compare the pattern continuation methods and show the effectiveness of the trade-off between accuracy and response time.

5.4.1 Comparison against [19] for SC. The results of the comparison are shown in Table 7. In the first column, we can see the response time of [19] for the different log files. In the next 2 columns, we have different response times for detection queries, for pattern length equal to 2 and 10, respectively. As discussed in Section 2.2, all subtrees are precalculated and stored, which means that the detection query time is $O(logn + k)$ where n here is the number of different subtrees and k is the number of subtrees that will return. As such, for [19], the response time does not depend on the querying pattern length. On the other hand,

Log file	Elasticsearch	SASE	Our method

Table 8: Response times for STNM queries in seconds

our proposal incrementally calculates the completion for every event in the pattern as described in Section 3.2.1; as such, the response time depends on the pattern length. In Figure 4, we show how response time increases with respect to the querying pattern length.

The experiments in Table 7 were executed 5 times and we presented the mean response time. However, we have noticed a fluctuation in response times, which is affected by the events in the pattern. Each event has a different frequency in the log files; e.g., starting and ending events are more frequent than some events that correspond to an error. When events in the querying pattern have low frequency, the response time will be shorter because there are fewer traces that need to be tested.

For small patterns, with length equal to 2-5, we get similar response times between the two methods, while [19] is always faster. As pattern length increases, our method's response time increases as well, but we also return as a by-product detection for all the sub-patterns.

In summary, the table shows the penalty we pay against a state-of-the-art technique during subsequence matching; however, the benefits of our approach are more significant: we allow efficient indexing in large datasets and we support, with similar times, pattern queries using the STNM policy.

5.4.2 Comparison against Elasticsearch and SASE for STNM. In Table 8, we present comparison against SASE and Elasticsearch

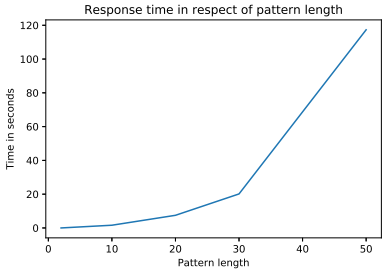

Figure 4: Response time with respect to the querying pattern length

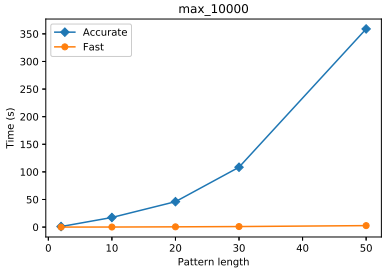

Figure 5: Response time for different pattern continuation methods for different query pattern lengths

query response times, when, in each experiment, we search for 100 random patterns. There are two main observations. Firstly, running techniques that perform all the processing on the fly without any preprocessing, such as SASE, yields acceptable performance in small datasets but significantly degrades in larger datasets, such as bpi_2017 and max_10000. In the former dataset, techniques that perform preprocessing are faster by 2 orders of magnitude. Secondly, there is no clear winner between Elasticsearch and our solution. But, in general, we are faster for small queries of pattern size equal to 2 and in all but one dataset for pattern size equal to 5, while Elasticsearch runs faster for pattern length equal to 10. However, for the longest running long queries, our solution is only 15.8% slower. Therefore, we can claim that our solution is competitive for large query patterns. Moreover, we can relax our query method to achieve faster times, as explained in the next part of the evaluation, while we support pattern continuation more efficiently due to the incremental approach of pattern processing that we adopt; i.e., we do not have to repeat the complete query from scratch.

5.4.3 Comparison of pattern continuation alternatives. In Figure 5, we show the response times between Accurate and Fast method for the dataset max_10000. We can see that the Accurate method follows the same pattern as the graph in Figure 4, which is what we expected as it performs pattern detection for every possible subsequent event in the pattern. On the other hand, there is no significant increase of response time for the Fast heuristic with regards of the pattern length.

We are trying to fill this performance gap with the Hybrid alternative. In Figure 6, we use again the max_10000 dataset and a pattern with 4 events and we show the response time with respect to the *topK* parameter given to Hybrid. The response time for both Accurate and Fast is constant, because they do not use this parameter. As expected, the time increases linearly as k increases.

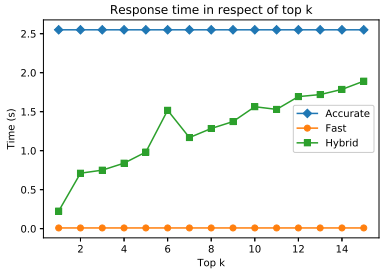

Figure 6: Response time of pattern continuation methods for different *topK* values

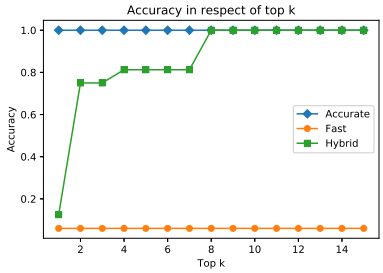

Figure 7: Accuracy of pattern continuation methods for different *topK* values

Fast's execution time is the lower bound and Accurate's is the upper one.

For the same setup, we perform an accuracy test presented in Figure 7. We use as ground truth the events returned from the Accurate method and compute the accuracy as the fraction of the events in the top k propositions from Hybrid that exist in the propositions reported by Accurate, where k is the number of propositions returned from Accurate. The accuracy is increasing as the number of k increases until it reaches 100% for k=8. For the same value, response time is half of the Accurate, as shown in the previous graph. Also in this example we could achieve a 80% accuracy with k=2 and 1/3 of the response time that Accurate would have taken.

6 RELATED WORK

Our work relates to several areas that are briefly described here in turn.

Complex event processing. There are number of surveys presenting scalable solutions for the detection of complex events in data stream. A variety of general purpose CEP languages have been developed. Initially, SASE [30] was proposed for executing complex event queries over event streams supporting SC only. The SQL-TS [24] is an extension to the traditional SQL that supports search for complex and recurring patterns (with the use of Kleene closure), along with optimizations, to deal with time series. In [9], the SASE language was extended to support Kleene closures, which allow irrelevant events in between thus covering the skip-till-next-match (STNM) and skip-till-any-match strategies. An extensive evaluation of the different languages was presented in [34] along with the main bottlenecks for CEP. In addition, the K*SQL [21] language, is a strict super-set of SASE+, as it can work with nested words (XML data). Besides the languages, most of these techniques use automata in order to detect specific patterns in a stream, like [18]. Our technique differs from them as we do not aim to detect patterns on the fly, but instead, to construct the infrastructure that allows for fast pattern queries in potentially large databases. To this end, the work in [22] also uses pair of events to create signatures, but for scalability purposes, this work considers only the top-k most frequent pairs, which yields an approximate solution, whereas we focus on exact answers. In addition, [22] focuses on the proposal of specific index types, whereas we follow a more practical approach, where are indices are stored as Cassandra tables to attain scalability.

Pattern mining. For non-streaming data, a series of methods have been developed in order to mine patterns. The majority of these proposals are looking for frequent patterns; e.g., Sahli et al in [26] proposed a scalable method for detecting frequent patterns in long sequences. As another example, in several other fields such as biology, several methods have developed, which are typically based in statistics (e.g., [1, 15]) and suffix trees (e.g., [10]). Parallel flavors have also been proposed, e.g., in [7]. Other forms of mined patterns include outlying patterns [5] or general patterns with high utility as shown in [32]. It is not trivial to build on top of these techniques to detect arbitrary patterns, because these techniques typically prune non-interesting patterns very aggressively.

Business processes. There are applications in business process management that employ pattern mining techniques to find outlier patterns and clear log files from infrequent behavior, e.g., [16, 28], in order to facilitate better process discovery. Another application is to predict if a trace will fail to execute properly; for example, in [4, 17], different approaches to predicting the next tasks of an active trace are presented. None of these techniques addresses the problem of efficiently detecting arbitrary sequences of elements in a large process database as we do, but the technique in [27] encapsulates our main competitor, namely [19]. Finally, in [8], a query language over business processes was presented to support sub-process detection. The proposed framework can be leveraged to support SC and STNM queries over log entries rather than subprocesses, but this entails using a technique like SASE, without any pre-processing. Our evaluation shows that such techniques are inferior to our solution.

Other data management proposals. The closest work to ours from the field of data management is set containment join queries, e.g., [31]. However, this type of joins does not consider time ordering. An interesting direction for future work is to extend these proposals to work for ordered sequences rather than sets; to date, this remains an open issue.

7 DISCUSSION

We have proposed a methodology to detect pattern according to the Strict contiguity (SC) and Skip-till-next-match (STNM) policy in large log databases, assuming that new events arrive and processed in big batches. However, there are several issues that need to be addressed with a view to yielding a more complete solution. First, sequential patterns, in their more relaxed form, allow for overlappings, which is commonly referred to as the skip-till-any-match policy. Supporting such patterns places additional burden to both the indexing process and query execution. Second, in many cases, assuming a total ordering is restrictive and also, the way some events may be logged, even in the same trace, cannot be regarded as following a total order. For example, in predictive maintenance in Industry 4.0, it is common to group events in large sets ignoring their relative order, e.g., [29]. Extending

our approach to operate under partial ordering is an interesting extension. Additionally, judiciously choosing the optimal update period is an open issue and gives rise to a multi-objective problem where low indexing time and result timeliness are contradicting objectives. Finally, the pattern continuation techniques can account for other operation modes, where an event is not appended only at the end, but also at arbitrary places in the query pattern. Our proposal can be easily extended to cover these cases, but we omit details here.

8 CONCLUSION

Despite the big advances in complex event processing and sequential pattern mining, efficient detection of arbitrary subsequences in log databases is an overlooked issue. Our proposal fills this gap and proposes indexing techniques along with query evaluation algorithms that allow the user to detect any patterns according to either the strict contiguity and the skip-till-next-match policy. Compared to subsequence matching techniques that support only strict contiguity, we show that our indexing can scale and also, query processing times are competitive when both approaches are applicable. Compared to Elasticsearch, a state-of-the-art solution, we build the indices faster and we run small queries faster, while we are competitive in large queries. Further, our solution can support exploration of pattern extension alternatives with different trade-offs between running time and accuracy and builds on top of scalable technologies, like Spark and Cassandra.

ABSTRACT

Detection of anomalies (i.e., *outliers*) in multi-dimensional data is a well-studied subject in machine learning. Unfortunately, unsupervised detectors provide no explanation about why a data point was considered as abnormal or which of its features (i.e. subspaces) exhibit at best its outlyingness. Such *outlier explanations* are crucial to diagnose the root cause of data anomalies and enable corrective actions to prevent or remedy their effect in downstream data processing. In this work, we present a comprehensive framework for comparing different unsupervised outlier explanation algorithms that are domain and detector-agnostic.

Using real and synthetic datasets, we assess the effectiveness and efficiency of two *point explanation* algorithms (Beam [28] and RefOut [18]) ranking subspaces that best explain the outlyingness of *individual* data points and two *explanation summarization* algorithms (LookOut [15] and HiCS [17]) ranking subspaces that best exhibit as *many outlier points* from inliers as possible. To the best of our knowledge, this is the first detailed evaluation of existing explanation algorithms aiming to uncover several missing insights from the literature such as: (a) Is it effective to combine any explanation algorithm with any off-the-shelf outlier detector? (b) How is the behavior of an outlier detection and explanation pipeline affected by the number or the correlation of features in a dataset? and (c) What is the quality of summaries in the presence of outliers explained by subspaces of different dimensionality?

1 INTRODUCTION

Detecting and diagnosing data anomalies are important tasks in data processing pipelines used to build industrial-strength Machine Learning (ML) systems [32]. Clearly, data points that significantly deviate from other points in a dataset may be systematic errors, i.e., *outliers*, or may manifest changes in the data generation process per se, i.e., *novelties*, that decrease the accuracy of the predictive models constructed downstream [29, 48]. In scientific and industrial monitoring applications, anomaly detection is often the ultimate goal of the data analysis as it enables the identification of unusual measurements (e.g., related to faults, bio-indices, etc.) and/or of suspicious activities (e.g. intrusions, fraud, etc.). Several unsupervised algorithms for anomaly detection have been proposed [2, 51] using different methods (e.g., proximity or isolation based) to distinguish outliers from inliers when labels of data points are impossible or difficult to obtain. Unfortunately, these algorithms do not explain why a data point was considered as abnormal, leaving analysts with no guidance about where to begin their investigation.

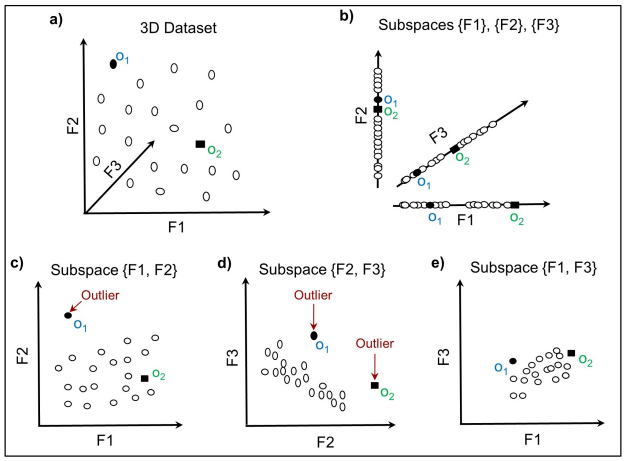

Figure 1: A 3*d* dataset with three 1*d* and 2*d* feature subspaces

In this paper, we focus on algorithms explaining the *outlyingness* aspects of multi-dimensional data points in the form of subspaces of data features that best explain why a given outlier deviates the most from the inliers. Such *explanations* are crucial to diagnose the root cause of data anomalies [3] and enable corrective actions to prevent or remedy their effect in downstream data processing (e.g. by repairing data errors or retraining the predictive models for concept drifts).

To illustrate, assume that we have a three dimensional dataset with features F_1, F_2 and F_3 and that we would like to explain the outlyingness of points $o1$ and $o2$ depicted by a black circle and a black square in Figure 1-a). In the full dimensional space of the dataset, $o1$ exhibits a small deviation from most of the other points in the dataset while $o2$ looks like an inlier although it exhibits a significant outlyingness when considering the subset of features $\{F_2, F_3\}$ (see Figure 1-d). We refer to the former case as *full space* outliers and to the latter as *subspace* outliers. In both cases, we are interested in explaining under which feature sets (aka subspaces) points exhibit a high outlyingness. None of the 1*d* subspaces $\{F_1\}$, $\{F_2\}$ and $\{F_3\}$ explain the outlyingness of the two points (see Figure 1-b). The same is true for the 2*d* subspace $\{F_1, F_3\}$ (see Figure 1-e). Subspace $\{F_1, F_2\}$ explains the outlyingness of $o1$ only (see Figure 1-c), while $\{F_2, F_3\}$ explains the outlyingness of both points (see Figure 1-d). We can observe that outlyingness of $o1$ is higher in $\{F_1, F_2\}$ than in $\{F_2, F_3\}$. Features contained into the explanation of an outlier are called *relevant*. For instance, F_1 and F_2 are relevant to the explanation of $o2$.

†This work received funding by the CY Initiative of Excellence (grant "Investissements d'Avenir" ANR-16-IDEX-0008) and developed during the author stay at the CY Advanced Studies, whose support is gratefully acknowledged.

We are primarily interested in *unsupervised* algorithms that are both *domain-agnostic* (i.e., suitable for datasets from various domains) and *detector-agnostic* (i.e., they can be employed to explain outliers produced by any off-the-self detector). Our choice of explanation algorithms is motivated by the fact that no detector is good in all possible settings w.r.t data characteristics (see the conclusions of several experimental studies [6, 8, 14]). Hence we are interested in decoupling the outlier explanation from detection, in contrast to several techniques proposed in Explainable Artificial Intelligence (XAI) such as output contribution of attribute values [24, 33] or partial dependence plots [11].

We evaluate two *point explanation algorithms*, *RefOut* [18] and *Beam* [28], that rank subspaces best explaining the outlyingness of *individual* data points, and two *explanation summarization algorithms*, *LookOut* [15] and *HICS* [17], that rank subspaces best explaining the outlyingness of as *many* outlier points as possible. These algorithms rely on outlyingness criteria of existing detectors such as Local Outlier Factor (LOF) [5], Angle Based Outlier Detection (ABOD) [21] or Isolation Forest (iForest) [23].

Although there exist several efforts for benchmarking outlier detectors in batch [6, 8, 12, 42] and stream [22, 43] processing settings, outlier explanation and summarization algorithms have not yet been thoroughly evaluated under realistic assumptions. To the best of our knowledge, this is the first comprehensive and detailed evaluation of existing algorithms aiming to uncover several insights missing from the existing literature. More precisely, our evaluation aims to answer the following questions: ***1.*** *Is it effective to combine any explanation algorithm with any off-the-shelf outlier detector?* ***2.*** *How is the behavior of an outlier detection and explanation pipeline affected by the number of features or their correlation in a dataset?* ***3.*** *What is the quality of summaries in the presence of outliers explained by subspaces of different dimensionality?*

The remaining of the paper is organized as follows. Section 2 introduces the outlier detectors and the point explanation and summarization algorithms we integrated in our experimental testbed. Section 3 details the pipelines of algorithms, the datasets as well as the evaluation metric used in our testbed. Section 4 presents the conducted experiments and the conclusions drawn regarding the missing insights. Section 5 surveys additional explanation algorithms for data in rest or in motion and justify why they have not been included in our study. Section 6 concludes our work and presents plans for future research.

2 OUTLIER DETECTION AND EXPLANATION ALGORITHMS

2.1 Unsupervised Outlier Detectors

Several methods have been proposed in the literature to measure the abnormality of a data point in a dataset. In the following, we survey three unsupervised methods that are widely used for detecting outliers in datasets with multiple numerical[1] features [6, 8, 12, 13, 42]. As the objective of outlier explanation is to retrieve subspaces where the outliers are clearly separable from inliers, we did not include any subspace-based outlier detector [20, 36] to assess the quality of a particular subspace examined by the explainer. The outlyingness criteria underlying each method have respective strengths and weaknesses w.r.t. the characteristics of the datasets (e.g., dimensionality) and outliers (e.g., highly clustered or not).

[1]Anomaly detection methods for categorical data [41] are outside the scope of this work.

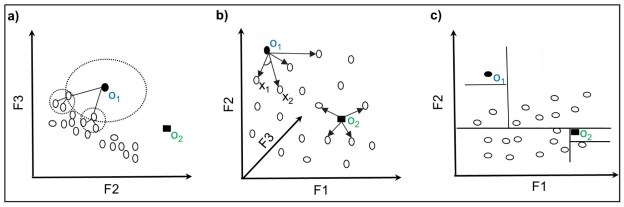

Figure 2: Examples of outliers in different subspaces detected by (a) LOF, (b) Fast ABOD and (c) iForest

Density-Based methods, such as Local Outlier Factor (LOF) [5] take into account the local density of points when searching for outliers. An example of outliers detected by LOF is illustrated in Figure 2-a). The point $o1$ is considered to be an outlier as it lies on a sparse area while its nearest neighbors lie on dense areas. The distance of a point p from o is computed using the following *reachability distance* (reach-dist):

$$\text{reach-dist}_k(p \leftarrow o) = max\{k\text{-dist}(o), d(p,o)\}$$

where k-dist(o) is the distance of o to its kth nearest neighbor and $d(p,o)$ is the direct distance (e.g., Euclidean) between the two points. LOF computes the local reachability density of a point p as the inverse of the average reachability distance of p from its k-nearest neighbors (kNN):

$$\text{lrd}_k(p) = 1/(\text{mean}_{o \in kNN(p)} \text{reach-dist}_k(p \leftarrow o))$$

Finally, the density of a point is compared to the average local reachability density of its neighbors to obtain a *score*:

$$\text{LOF}_k(p) = \text{mean}_{o \in kNN(p)} \frac{\text{lrd}_k(o)}{\text{lrd}_k(p)}$$

LOF's time complexity is $O(N^2)$, where N is the number of points in a dataset. Inliers obtain scores around 1 while outliers obtain scores significantly larger than 1. LOF distinguishes effectively outliers from inliers in regions of *varying density* where outliers lie on highly sparse areas far from dense clusters.

Angle-Based methods compute for each given point, the angles to other data points N. The Angle Based Outlier Detector (ABOD) [21] uses the variance of these angles as an outlyingness score. For example, as we can see in Figure 2-b), $o1$ is an outlier as its neighbors are located in similar directions (small angle variance), but o_2 is an inlier as it is surrounded by its neighbors in various directions (high angle variance). The ABOD score for a given point $o1$ and any pair of points $x1$, $x2$ is computed as:

$$ABOD(o_1) = \underset{x_1,x_2 \in N}{\text{Var}} \left(\frac{\langle \overrightarrow{x_1 o_1}, \overrightarrow{x_2 o_1} \rangle}{\|\overrightarrow{x_1 o_1}\|^2 \cdot \|\overrightarrow{x_2 o_1}\|^2} \right)$$

As ABOD's time complexity is $O(N^3)$, we are focusing on an efficient ABOD variant ($O(kN^2)$), called *Fast ABOD*, which computes the angles of a particular point only to its k-nearest neighbors. Small angle variance results to high ABOD score indicating high outlyingness. Intuitively, a point is more likely to be an outlier when it lies on the borders of the data distribution. ABOD avoids to compute the distance between points, hence it is a suitable detector for high dimensional datasets.

Isolation-Based methods estimate the probability of a point to be an outlier on the basis of the number of partitions needed to isolate it from the other points in a dataset. The less partitions needed to isolate, the more likely a data point is to be an outlier. For instance, in Figure 2-c) the point o_1 is an outlier as it needs less partitions to be isolated compared to the inlier o_2. Isolation Forest

(iForest) [23] exploits this property using a forest of random trees built on samples of the dataset by uniformly selecting features and their split values. The outlyingness score of a data point is then computed by averaging over all trees the path length from the root to the leaf node with the data point:

$$s(x, n) = 2^{-\frac{E(h(x))}{c(n)}}$$

The score assigned to points is normalized within the range [0,1], with outliers getting a score close to 1. iForest has a small memory-footprint ($O(tn)$), where t is the number of trees and n is the subsample size. It achieves a sublinear time-complexity ($O(tnlogn)$) by exploiting subsampling and by eliminating the heavy cost of distance computation. Being agnostic to the distances (or densities) of points, iForest is able to detect outliers effectively even if they are lying on less dense areas than the majority of the points.

2.2 Point Explanation Algorithms

The objective of a point explanation algorithm is to discover the subspaces that best explain the outlyingness of a multi-dimensional point, i.e. the feature sets where this point deviates most in the dataset. Such subspaces are called *relevant* w.r.t. to the explanation of an outlier. Point explanation algorithms essentially rely on a *search strategy* for exploring feature subspaces in a dataset and an *outlyingness criterion*. The main challenge is that no interesting monotonic property holds for most outlyingness criteria [28], which prevents us to effectively prune the exponential space of feature sets (2^d) w.r.t. data dimensionality (d). Using the detectors presented previously, an outlier discovered in low-dimensional subspaces may become invisible, i.e., masked by inliers in high-dimensional subspaces and vice versa.

RefOut [18] is a sampling based algorithm which employs a stage-wise technique exploiting *random subspace projections* to find relevant subspaces of a *fixed dimensionality*. The main algorithmic steps of RefOut are illustrated in Figure 3. Initially, RefOut builds a random pool of size n with random subspace projections drawn from the full feature space of the dataset. In the example of Figure 3, we depict a pool of size 4 that contains $3d$ random subspaces (i.e, 50% of the $6d$ dataset). Using an off-the-self detector, the to-be-explained outlier $p1$ is scored in each subspace of the pool. To avoid dimensionality bias when scoring subspaces, the score of a point p in a subspace s, denoted as $score(p_s)$ is standardized using Z-score as follows:

$$score(p_s)' = \frac{score(p_s) - \overline{score_s}}{\sqrt{Var(score_s)}}$$

RefOut follows a stage-wise technique. In stage 1, RefOut assesses every single feature in the pool. In other words, in this stage it collects the best univariate subspaces. In our example, for the feature $F1$ RefOut partitions the pool into two populations of random subspaces w.r.t. whether they contain or not the feature $F1$. To assess the importance of a feature for explaining the outlyingness of the point $p1$, RefOut quantifies the discrepancy of score populations between the two partitions under the hypothesis that they have equal means. To test this hypothesis, the two-sample Welch's t-test [46] is employed as the two samples may have unequal variances and/or unequal sample sizes. The partitioning is repeated for every feature in the pool and the top-k ones with the highest discrepancy are kept; in our example we kept only $\{F1\}$ for simplicity. In stage 2, RefOut applies the same partitioning and scoring process for $2d$ subspaces by

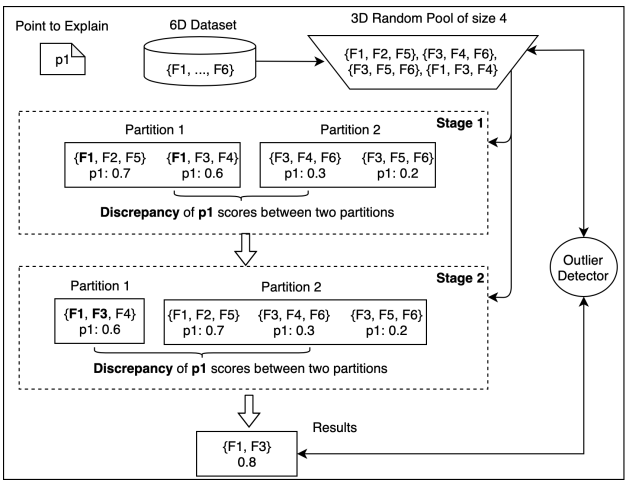

Figure 3: RefOut steps to find $2d$ subspaces from a $6d$ dataset to explain the point p1

taking the Cartesian product of the top-k subspaces from the previous stage with all the univariate subspaces drawn from the pool. In our example, since we are interested in $2d$ explanations the process stops at stage 2 and the best subspace ($\{F1, F3\}$) is returned as explanation of point $p1$. When multiple outliers have to be explained, RefOut searches for relevant subspaces for every point individually.

To sum up, the core idea of RefOut is to make subspace selection adaptive to the outlyingness score of each point and flexible w.r.t. different detectors. It relies on a pool of random subspace projections to assess the important features, that may contribute to the detection of relevant subspaces for a specific point. As feature importance is measured via the discrepancy of outlyingness score distributions, RefOut's effectiveness depends strongly on the ability of an off-the-self outlier detector to assign high scores to outliers. In particular, RefOut makes the assumption that outliers explained in low-dimensional subspaces exhibit a significant outlyingness also in their high-dimensional supersets.

Beam [28] is a *stage-wise* greedy algorithm that takes as input a particular point and returns the subspaces, up to a given dimensionality, that best explain its outlyingness. Although the maximum dimensionality of subspaces returned by Beam is predefined, the algorithm may output subspaces of varying dimensionality. Beam maintains two lists: (i) a *global list* of the best subspaces considered as relevant across stages, (ii) a *stage list* with the best subspaces in each stage. The main algorithmic steps of Beam are illustrated in Figure 4 via an example requesting to explain the outlyingness of a point $p1$ of a $6d$ dataset with up to $3d$ subspaces. Using an outlier detector, Beam scores exhaustively in stage 1 all the 15 $2d$ subspaces drawn from the 6 features space of the dataset for the point $p1$. Then, the top-k scored $2d$ subspaces will be inserted both into the *stage list* and *global list*. In stage 2, the best $2d$ subspaces kept in *stage list* will be combined with other features to form $3d$ subspaces as depicted in Figure 4. The top-k $3d$ subspaces are then kept in the *stage list*, while the *global list* is updated with the $3d$ subspaces with higher scores for $p1$ than the $2d$ subspaces previously computed. As we required $3d$ explanations in our example, the process will stop at stage 2. The *global list* is then returned as the result of the algorithm.

In a nutshell, Beam is a *stage-wise* greedy algorithm that exploits the top-k best relevant subspaces returned by early stages

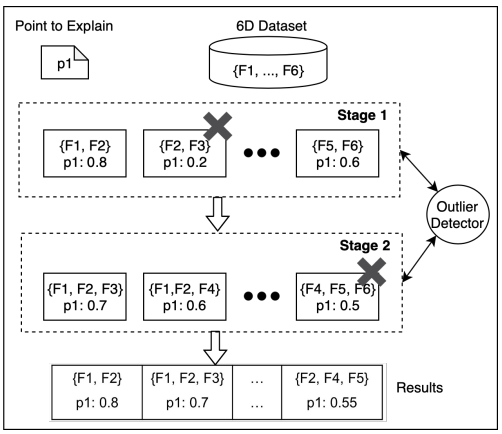

Figure 4: Beam steps to find subspaces up to 3 dimensions from a 6d dataset to explain the point p1

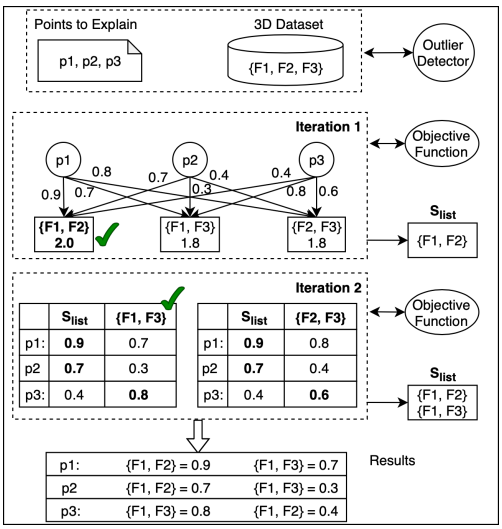

Figure 5: LookOut steps to find 2d subspaces from a 3d dataset with budget b = 2 (bold values indicate the highest scores per table row)

to search for relevant subspaces in latter stages. Hence, its effectiveness depends strongly on whether a given point obtains a high outlyingness score in *lower projections* of the relevant subspace(s) that should be finally returned. In order to make a fair comparison with RefOut, we report only the best subspaces from the *stage list* in the final stage i.e., subspaces of predefined maximum dimensionality. We call this variation $Beam_{FX}$.

2.3 Explanation Summarization Algorithms

The objective of an explanation summarization algorithm is to discover for a set of outlier points, the subspaces that distinguish as many outliers from inliers as possible. Explanation summarization algorithms also rely on a *search strategy* to explore feature subspaces in a dataset. The main difference is that the *outlyingness criterion* is applied *collectively* for all outliers rather than individually. The additional challenge stems from the fact that some outliers may be explained by subspaces of different dimensionality or in an extreme case all outliers could be explained by different subspaces. We should stress that explanation summarization is different from group identification and explanation. In the former case, we consider all the to-be-explained points as one group, while on the latter, the objective is to identify these anomalous groups and retrieve explaining subspaces that segregate each group from the normal instances [25].

LookOut [15] searches *exhaustively* subspaces of *fixed* dimensionality and returns those that exhibit a certain *utility*. LookOut was genuinely used to obtain 2d subspaces that can be easily visualized in order to explain a set of outliers. However, we used the algorithm to explore subspaces of high dimensionality as well. LookOut formalizes explanation summarization as maximization problem using an objective function equipped with the following properties: (i) *non-negative* , (ii) *non-decreasing* and iii) *sub-modular*. As submodular optimization is known to be an **NP-hard** problem, greedy approximation techniques are used (e.g., with a 63% approximation guarantee [27]). The main algorithmic steps of LookOut are depicted via an example in Figure 5. Given (i) a set of outlier points $P = \{p1, p2, p3\}$ and (ii) a number of top-k explanation summaries (i.e., the budget of the computation), LookOut constructs a subspace list S_{list} with the top-k subspaces that maximize the scores of the three points i.e., they provide a concise summary. Initially, LookOut employs an off-the-self outlier detector to score all outliers in the three possible 2d subspaces drawn from the 3d feature space of the dataset. LookOut's objective function for concise summarization is defined as follows:

$$f(S_{list}) = \sum_{p_i \in P} \max_{s_j \in S_{list}} score_{i,j}$$

where $score_{i,j}$ represents the outlier score that point p_i received in subspace s_j. Then, to assess utility of a subspace s to the S_{list}, LookOut examines its marginal gain computed as:

$$\Delta_f(s|S_{list}) = f(S_{list} \cup s) - f(S_{list})$$

In our example of Figure 5, S_{list} is initially empty and subspace $\{F1, F2\}$ is inserted during the first iteration as all three points obtain their best outlyingness score in this subspace. During the second iteration, LookOut examines which of the two remaining subspaces $\{F1, F3\}$ and $\{F2, F3\}$ provide the greatest marginal gain for S_{list}. In our example, $\{F1, F3\}$ has a higher marginal gain than $\{F2, F3\}$ as its maximizes $p3$'s score, while $p1$ and $p2$ scores are already maximized by $\{F1, F2\}$. The two subspaces are compared w.r.t. the maximum scores of every point currently in S_{list}. As the budget in our example is 2 i.e., the number of subspaces that will be included in explanation, the process stops and the S_{list} is returned as a summary of the subspaces explaining the points given as input.

In a nutshell, LookOut returns the top-k subspaces of fixed dimensionality that concisely explain multiple outliers. A subspace is considered a good summary candidate at a certain iteration step if it maximizes the overall score for at least one outlier. Hence, LookOut's effectiveness strongly depends on the ability of an off-the-self outlier detector to highly score outliers in their relevant subspaces.

High Contrast Subspaces (HiCS) [17] relies on a subspace search strategy that exploits combinations of correlated features called high contrast subspaces. The underlying intuition is that high contrast subspaces have many empty regions and few very dense regions, thus they are good candidates for separating outliers from inliers. Figures 6-a) to -c) illustrate three subspaces with correlated features ($\{F0, F1\}$, $\{F0, F1, F8\}$ and $\{F11, F12, F13\}$) while Figure 6-d) a subspace with non correlated features ($\{F11, F12\}$).

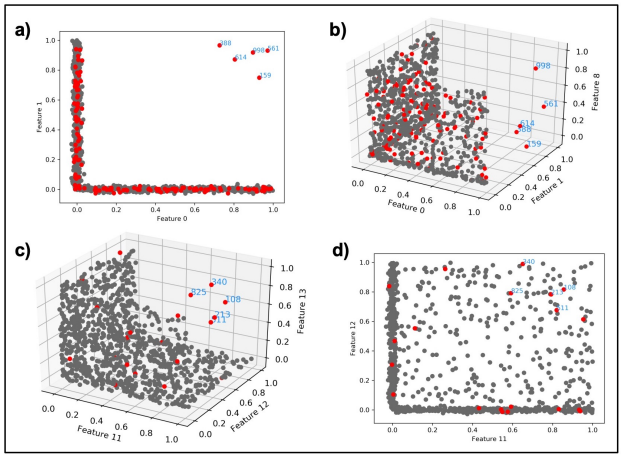

Figure 6: Data distribution in augmented/projected subspaces of HiCS Datasets

Subspace contrast in HiCS is measured using two-sample statistical tests[2] which are applied to the raw feature values under the null hypothesis that *both samples originate from the same underlying probability density function*. To enhance statistical precision, HiCS performs the statistical test for several Monte Carlo iterations and the average score is computed per subspace.

HiCS searches for high contrast subspaces via a stage-wise technique. In the first stage, it scores exhaustively all the 2d subspaces and selects the top-k based on their contrast. In next stage, the best 2d subspaces, are used to construct 3d subspaces scored again based on their contrast. The same procedure is repeated for several stages until reaching the full feature space d of a d-dimensional dataset; hence, the algorithm may retrieve subspaces of varying dimensionality. HiCS has been originally evaluated with LOF, but in principle any other off-the-self detector could be employed. In order to make a fair comparison with LookOut, we force HiCS to return subspaces of fixed dimensionality up to a predefined stage. We call this variation $HiCS_{FX}$.

To conclude, HiCS is a best effort algorithm that exploits subspaces with correlated features to discover summaries of varying dimensionality. Although the assumption that outliers are more likely to appear in correlated features seems effective for highly clustered anomalies, correlated subspaces may not always explain outliers, as depicted in Figure 1-e). The main novelty of HiCS lies in the decoupling of the subspace search strategy from the scores assigned by an off-the-self detector to a set of outliers.

3 BENCHMARKING ENVIRONMENT

The algorithms along with the datasets used in our testbed are available in our GitHub repository[3] to ensure repeatability of our experiments. Regarding outlier detectors, we used the implementation of LOF and iForest from Scikit-learn [30] and Fast ABOD from PyOD [50]. We have implemented LookOut, RefOut and Beam in java and modified HiCS implementation from ELKI [37]. Our primary concern in this work is the correctness of the implemented explanation algorithms. All experiments were performed in a Windows personal computer with a 4 core Intel i7 processor and 16GB of main memory.

[2]The Welch's t-test or the Kolmogorov-Smirnov test.

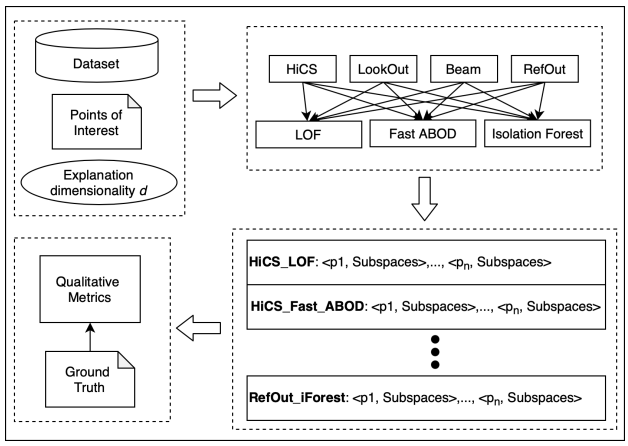

Figure 7: Pipelines of outlier detectors & explainers

3.1 Pipelines of Executed Algorithms

As illustrated in Figure 7, given (i) a dataset, (ii) a set of outliers (points of interest) and (iii) a target dimensionality to explain them, we execute all the possible pairs of explanation and detection algorithms. Each executed pipeline results to a list of *fixed*-dimensionality subspaces considered as relevant to each point of interest. The effectiveness of each pipeline is assessed using the relevant subspace(s) per point available in the ground truth of each dataset and the metric that we define in Section 3.3.

Regarding the choice of outlier detectors, we included in our testbed only LOF, Isolation Forest and Fast ABOD as representative of three widely used families of batch detection algorithms namely density, isolation and angle based outlier detection. As reported by several experimental studies [6, 8, 13] these algorithms frequently outperform distance or cluster-based algorithms in real and synthetic datasets while they do not require a thorough tuning of their hyper-parameters. Note also that experimentation with supervised detectors was outside the scope of our work due to the scarcity of labels regarding outlier/inlier data points.

To be able to retrieve the explaining subspaces for a number of outliers given as input, LookOut, Beam and RefOut heavily depend on the scores assigned by the detector in subspaces of different dimensionality explaining the given outliers. To shed some light regarding whether the explainers retrieve the relevant subspaces per outlier in practical settings, we employed unsupervised detectors that are not very sensitive to their hyper-parameter tuning. For LOF we use k = 15 and for Fast_ABOD k = 10. We run iForest for 10 repetitions to reduce the variance of outlyingness scores and the average score is computed for every point, using t = 100 trees and $sub-sample\ size$ = 256. These hyper-parameter values have been used in related experimental studies as [6], and allow us to detect the outliers in all datasets of our testbed. Hence, we can draw valuable conclusions for the subspace search techniques of explainers rather than the quality of the employed detector.

Regarding the hyper-parameters of the explainers, for HiCS we use $candidateCutOff$ = 400, a = 0.1, $Monte\ Carlo\ Iterations$ = 100 and Welch's t-test is performed. For LookOut we use $budget$ = 100. For Beam we use $beam-width$ = 100. For RefOut we use $poolsize$ = 100, $beam-width$ = 100, the random subspace dimensionality is set to 70% of dataset's dimensionality and Welch's t-test is performed. For HiCS, Beam and RefOut we return the top-100 subspaces as the final result.

Characteristics	Real Datasets (# 3)	Synthetic Datasets (# 5)
Outlier Type	Full Space	Subspace
Explanation Dimensionality	2-4 d	2-5 d
% Contamination with Outliers	10%	2, 3.4, 5.9, 10, 14.3 %
# Relevant Subspaces	60 (A), 151 (B), 249 (C)	4, 7, 12, 22, 31
# Relevant Subspaces per Outlier	3 (1 per dimensionality)	1 (91% outliers), 2 (9% outliers)
# Outliers per Relevant Subspace	1 (A), 1.13 (B), 1.45 (C)	5
% Relevant Feature Ratio	100%	35, 21, 12, 7, 5 %
Outlier Visibility w.r.t. Relevant Subspaces	Projections / Augmentations	Augmentations

Table 1: Characteristics of real and synthetic datasets

3.2 Real and Synthetic Datasets

In this section we describe the real and synthetic datasets used in our testbed. The main challenge in explaining outliers stems from the exponential search space of feature subspaces rather than the size of the dataset. The difference in the execution time of explainers depends more on the pruning strategy they employ to enumerate subspaces rather than on the time spent by detectors to score the explored subspaces. The selected datasets are suitable for assessing the quality of outlier explanation algorithms, as they provide the gold standard regarding the subspace(s) explaining each anomaly. To reduce confounding factors in the experimental evaluation of the algorithms, the selected datasets are mainly contaminated with *density-based* outliers. Outliers of this type can be detected by LOF but under certain conditions also by other detectors like ABOD and iForest (see Section 4). The main characteristics of our datasets are summarized in Table 1.

Breast, Breast Diagnostic and *Electricity Meter* are real-world datasets widely used to benchmark ML methods for anomaly detection [9]. To facilitate comparison with already published results, we used the version of these datasets[4] made available by the authors of RefOut algorithm [18]. Specifically, Breast (A) contains 198 points, 31 features and 20 outliers, Breast Diagnostic (B) contains 569 points, 30 features and 57 outliers and Electricity (C) contains 1205 samples, 23 features and 121 outliers. The ground truth provided per dataset contains the outliers detected by LOF resulting 10% contamination with outliers. Note that the experiments in [18] revealed that the reported outliers are *full space*. To obtain the best subspaces explaining them[5], we followed the method as described in [18] by performing an exhaustive search from 2 up to 4 dimensions for every dataset using LOF and keeping the top scored subspace per outlier at the corresponding dimension. We started from 2 dimensions as the initial step of HiCS and Beam perform an exhaustive search in 2d subspaces. We should stress that outliers are identifiable by LOF in both *lower dimensional projections* and *augmentations* (i.e., supersets) of the relevant subspaces. These datasets challenge summarization algorithms (HiCS and LookOut) as subspaces can best explain one outlier on average, e.g., for Electricity there are 1.43 outliers explained per relevant subspace (see Table 1).

HiCS synthetic datasets[6] were created by the authors of the HiCS [17] algorithm featuring *subspace outliers*. They initially splitted the datasets into 2d up to 5d subspaces, and generated high density clusters in each subspace. Then, they randomly picked 5 points and modified them to deviate from all clusters in each subspace. From these datasets we picked the dataset with the maximum dimensionality (100d) and splitted it into five sub-datasets from 14 up to 100 dimensions. The ratio of relevant features is depicted in Table 1 ordered from low (14d) to high (100d) number of features. Note that every dataset contains 1000 points. As illustrated in Figure 8 and Table 1, this split produced datasets of increasing (i) data dimensionality (i.e., number of features), (ii) number of relevant subspaces of different dimensionality and (iii) contamination with outliers. In HiCS datasets, the relevant subspaces and the outliers were given but there was no association between them. To identify the relevant subspace per outlier, we run LOF and keep the top-5 outliers with the highest scores per relevant subspace. The so obtained ground truth is aligned with the original contamination of the dataset with 5 points deviating in each relevant subspace that can be easily detected by LOF. An example of a 2d and a 3d relevant subspace is illustrated in Figures 6-a) and -c).

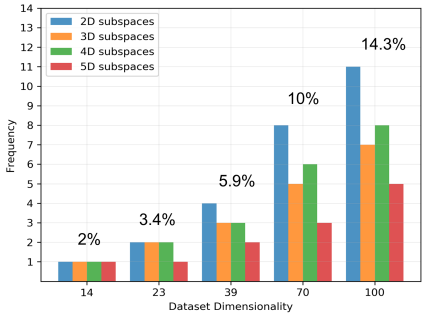

Figure 8: Dimensionality of subspaces relevant to outliers and contamination ratio of HiCS datasets

Note that the vast majority (~ 91%) of outliers in HiCS datasets is explained by one subspace and few outliers (~ 9%) by two different subspaces. These subspaces follow the properties: (i) they are disjoint in terms of features, (ii) each subspace can explain exactly five outlier points, (iii) they have highly correlated features, (iv) outliers are identifiable by the detectors in *augmented subspaces*, i.e., supersets of the relevant features (see example of Figures 6-a) and -b) and (v) outliers are mixed with inliers in *lower dimensional projections* of relevant subspaces (see example of Figures 6-c) and -d). Note that all outliers in HiCS datasets can be discovered by the three detectors used in our testbed.

3.3 Evaluation Metric

In this section we present the metric used to evaluate the effectiveness of the 12 pairs of outlier detection and explanation

[4]https://www.ipd.kit.edu/~muellere/RefOut/
[5]We discovered that the subspaces originally reported by the authors of RefOut were not optimal for most outliers.
[6]https://www.ipd.kit.edu/~muellere/HiCS/

algorithms (see Figure 7). Although outlier explanations target human analysts, we have not conducted user studies as our datasets are equipped with ground truth regarding which subspaces are relevant to the outliers they contain.

We denote the set of points of interest as P, the set of the relevant subspaces per point $p \in P$ as REL_p, and the returned subspaces from an explanation algorithm a to a point p as $EXP_a(p)$. The first metric we used is Mean Recall (see Eq. **??**) of an explainer a for a set of points P, assessing how many relevant subspaces were returned on average by a for every point $p \in P$. Note that a subspace in $EXP_a(p)$ is considered relevant only if it is a member of REL_p. I.e., a subspace in $EXP_a(p)$ is considered relevant for a point p only if it is identical with a subspace in REL_p. We consider only the Recall (see Eq. **??**) of points that are explained at a given dimensionality according to the ground truth. As described in Section 3.2, every point has very few relevant subspaces in our datasets. Thus high Mean Recall means that the explainer was able to exploit the relevant subspaces for the majority of the points explained at a given dimensionality. As each outlier in our datasets has very few relevant subspaces (specifically 1-3), we selected the MAP metric penalizing detectors that do not rank the relevant subspace(s) for an outlier within the top positions [40]. To compute MAP of an explainer a for a set of points P, we initially compute the precision (see Eq. 1) which is used to compute the Average Precision (see Eq. 2). $P@k(p)$ denotes the precision up to a k-th position of the returned subspaces in $EXP_a(p)$. The Boolean function $rel(k)$ indicates whether a subspace at the k-th position of $EXP_a(p)$ is relevant or not. Then, MAP is computed using the Average Precision of all points explained at a given dimensionality (see Eq. 3) according to the ground truth. A high MAP value indicates that for several points, the explainer was able to find and highly score their relevant subspaces using an outlier detector. Compared to other metrics such as accuracy, precision or recall, MAP better captures the scoring nature of outlier explanation algorithms: the discovered relevant subspaces should be ranked at the top positions of the list of candidates an algorithm considers. On the contrary, binary metrics like accuracy, precision and recall do not account for the ordering of the results. Note that [6, 8] use average precision to assess the quality of the outlier detector while [28] uses precision and recall to assess the explanation quality. To the best of our knowledge, it is the first work that relies on MAP to assess effectiveness of the subspace search strategies of different explainers.

$$\text{Precision}_a(p) = \frac{|REL_p \cap EXP_a(p)|}{|EXP_a(p)|} \tag{1}$$

$$\text{AveP}_a(p) = \frac{\sum_{k=1}^{|EXP_a(p)|} \text{P@k}(p) * rel(k)}{|REL_p|} \tag{2}$$

$$\text{MAP}_a(P) = \frac{1}{|P|} \sum_{p \in P} \text{AveP}(p) \tag{3}$$

4 EXPERIMENTS AND INSIGHTS

In this section we present our experiments for comparing point explanation and summarization algorithms. Our testbed includes the real datasets used in the evaluation of RefOut [18] as well as the synthetic datasets used in the evaluation of HiCS [17]. Both types of datasets were originally used to assess the effectiveness of detecting outliers hidden in subspaces rather than the suitability of the subspaces that led to the detection of those outliers. To the best of our knowledge, the only study investigating recall and precision of the subspaces of varying dimensionality retrieved by Beam was presented in [28] running on HiCS [17] datasets. In our study, we incorporate three more explainers, namely RefOut [18], HiCS [17] and LookOut [15], using also real world datasets. Moreover, in contrast to [28] we formulate different trade-offs by evaluating the pruning strategies under different explanation sizes as well as full and sub-space outliers.

4.1 Evaluation of Point Explanation Algorithms

The experiments of this section aim to answer two questions: (a) Is it effective to combine any explanation algorithm with any off-the-shelf outlier detector? (b) How is the behavior of outlier detection and explanation pipelines affected by the number of features in a dataset? To answer these questions, we run Beam and RefOut with LOF, Fast ABOD and iForest using the settings described in Section 3.1 for the synthetic and real-world datasets presented in Section 3.2. Figure 9 depicts for each dataset, the MAP (y-axis) of different outlier detection and explanation pipelines for explanations of increasing dimensionality (x-axis).

Figures 9-a) to -e) illustrate the MAP obtained in the five synthetic datasets of our testbed. Starting from the 14 dimensions in Figure 9-a), we observe that RefOut with LOF achieves optimal MAP as it retrieves and gives the highest score to the relevant subspaces for all the outliers, regardless of the explanation dimensionality. This is because (i) HiCS datasets contain highly clustered anomalies, thus LOF is the most suitable detector and (ii) the pool of RefOut contains low dimensional subspaces in which outliers can be more easily detected. Note that Beam with LOF has lower MAP for high explanation dimensionality since it does not retrieve all the relevant subspaces. Passing to 23 dimensions in Figure 9-b), the effectiveness of every pipeline drops especially for high dimensional explanations. RefOut with LOF seems to not be affected up to 3d explanations. An interesting behavior observed in this plot is that Beam is more effective with Fast ABOD and iForest than with LOF. This is due to the fact that the stage-wise strategy of Beam requires to collect lower dimensional projections of the relevant subspaces, so they could be formed in the final stage. Recall that in HiCS datasets, outliers are not separated from inliers in lower projections of the relevant subspaces (see Figure 6). According to complementary experiments not presented here due to space restrictions, in the early stages of Beam, the score distributions of outliers and inliers overlap less when Fast ABOD and iForest is used instead of LOF.

While the dimensionality of datasets increases, the same trends are observed in Figures 9-c) to -e). In general, Beam is able to retrieve all relevant 2d subspaces with the three detectors due to the exhaustive scoring of all feature pairs. However, its effectiveness starts dropping when the dimensionality of explanations increases. As the number of Beam stages increase, more subspaces need to be collected stage-wise with smaller differences in their score. RefOut proves to be more sensitive than Beam w.r.t. the number of features in the dataset D. As the dimensionality of random subspace projections in the pool is proportional to D's dimensionality, it becomes more difficult for RefOut to identify important features due to the less distinguishable score populations in subspaces. Observe that none of the algorithms seem to work for 4d explanations from 70 dimensions and higher and for 5d explanations from 23 dimensions and higher. Note that we run 10 times iForest (see Section 3.1) for every subspace considered

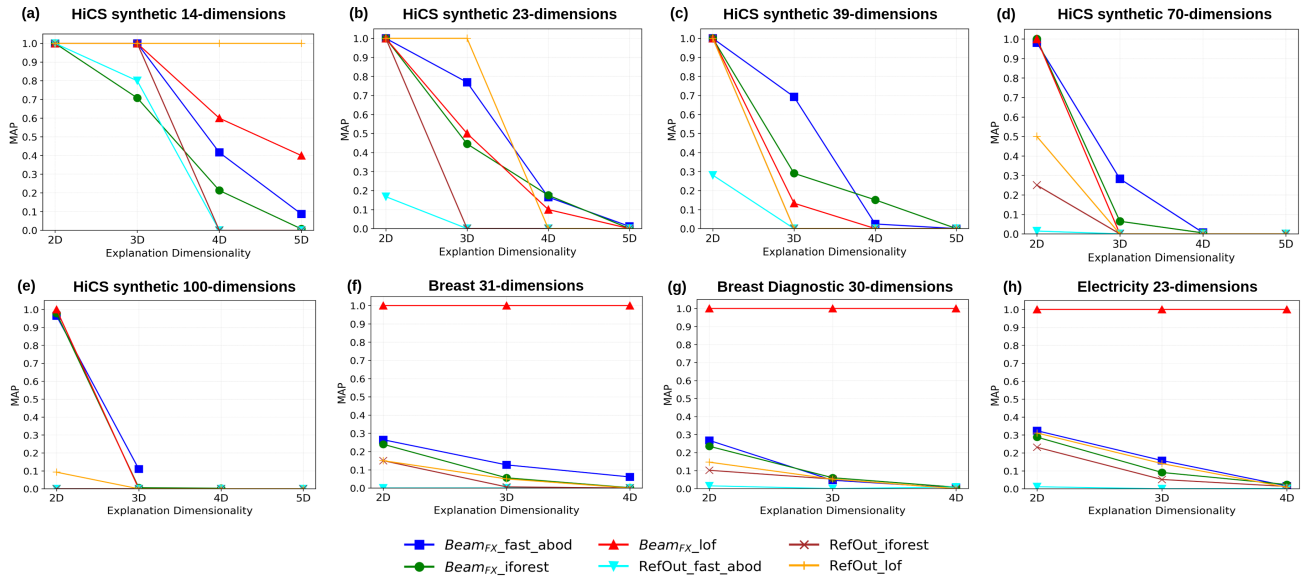

Figure 9: Mean Average Precision (MAP) of Beam and RefOut in HiCS synthetic datasets (a)-(e) and real-world datasets (f)-(h) for explanations of increasing dimensionality (best viewed in color)

by Beam up to 4d explanations for 70d and 100d datasets and Fast ABOD up to 4d explanations in 70d and up to 3d in 100d datasets. Specifically, to explain 100 outliers with 5d explanations in a 70d dataset, Beam needs to assess approximately 2.2M subspaces. In Section 4.3, we demonstrate that Beam requires an efficient detector such as LOF to assess a significant amount of subspaces.

Figures 9-f) to -h) illustrate the MAP obtained in the three real-world datasets of our testbed. Recall that in these datasets, the majority of the outliers are identifiable even in the full feature space. In general, Beam with LOF retrieves the optimal subspace for every outlier point (MAP = 1), despite of the explanation dimensionality. However, the effectiveness of Beam with Fast ABOD and iForest is significantly lower. On the contrary, RefOut seems to have very low MAP regardless of the employed detector. This is because RefOut cannot distinguish which features of full space outliers affect significantly the score populations generated by the corresponding detector.

Lessons Learned. Depending on the dataset characteristics, outlier detectors behave differently, affecting the effectiveness of explanation algorithms. A critical factor is whether outliers are masked by inliers in lower dimensional projections of the relevant subspaces (as in HiCS datasets). In this case, for datasets and explanations of low dimensionality, RefOut's random projection technique along with a detector suitable for the nature of outliers (e.g., LOF for clustered outliers) is preferred. For high dimensional datasets and low explanation dimensionality, Beam's stage-wise technique along with iForest or ABOD can effectively capture the small deviation of outliers in the subspaces considered by early stages. None of the algorithms seems to work for high explanation dimensionality (e.g., 4d and 5d) and high dataset dimensionality (e.g., 70d and 100d). When outliers are also visible in the full feature space (as in real-world datasets) the random projection technique exhibits poor MAP as it fails to find relevant features that significantly affect the score distributions. In this case, a stage-wise technique coupled with a suitable detector should be preferred regardless of the explanation dimensionality.

4.2 Evaluation of Summarization Algorithms

The experiments presented in this section aim to answer three questions: (a) Is it effective to combine any explanation summarization algorithm with any outlier detector?, (b) How is the behavior of outlier detection and explanation pipelines affected by the number of features or their correlation in a dataset?, and (c) What is the quality of summaries in the presence of outliers explained by subspaces of different dimensionality? To answer these questions, we run HiCS and LookOut with LOF, Fast ABOD and iForest using the settings described in Section 3.1 for the synthetic and real-world datasets presented in Section 3.2. Figure 10 depicts per dataset the MAP (y-axis) of different pairs of outlier detection and explanation algorithms for explanations of increasing dimensionality (x-axis). Despite the fact that HiCS does not use any detector to search candidate subspaces, it employs a detector to rank the retrieved subspaces. Thus, its effectiveness should be also evaluated for different detectors.

Figures 10-a) to -e) show the MAP of different algorithms for the five synthetic datasets of our testbed. Starting from 14 dimensions in Figure 10-a), HiCS and LookOut with LOF achieve optimal MAP regardless of the explanation dimensionality. As dataset's dimensionality and outlier ratio increase in Figures 10-b) to -e), HiCS with LOF and Fast ABOD are the most effective because (i) small groups of outliers are hidden within subspaces with correlated features and (ii) outliers are highly clustered at the borders of data distribution, allowing LOF and Fast ABOD to score their relevant subspaces at the top positions. The lowest MAP value of HiCS is observed in the 39 dimensional dataset where some 4d relevant subspaces do not contain highly correlated features. This drop clearly demonstrates the strong dependency of HiCS on the feature correlation heuristic.

As we can see in Figures 10-b and -e) LookOut's effectiveness significantly drops as the explanation dimensionality increases in higher dimensional datasets. One reason of this drop is related to the lower scores returned by the detectors in high dimensional subspaces. An additional reason stems from the existence of points exhibiting high outlyingness also in their augmented

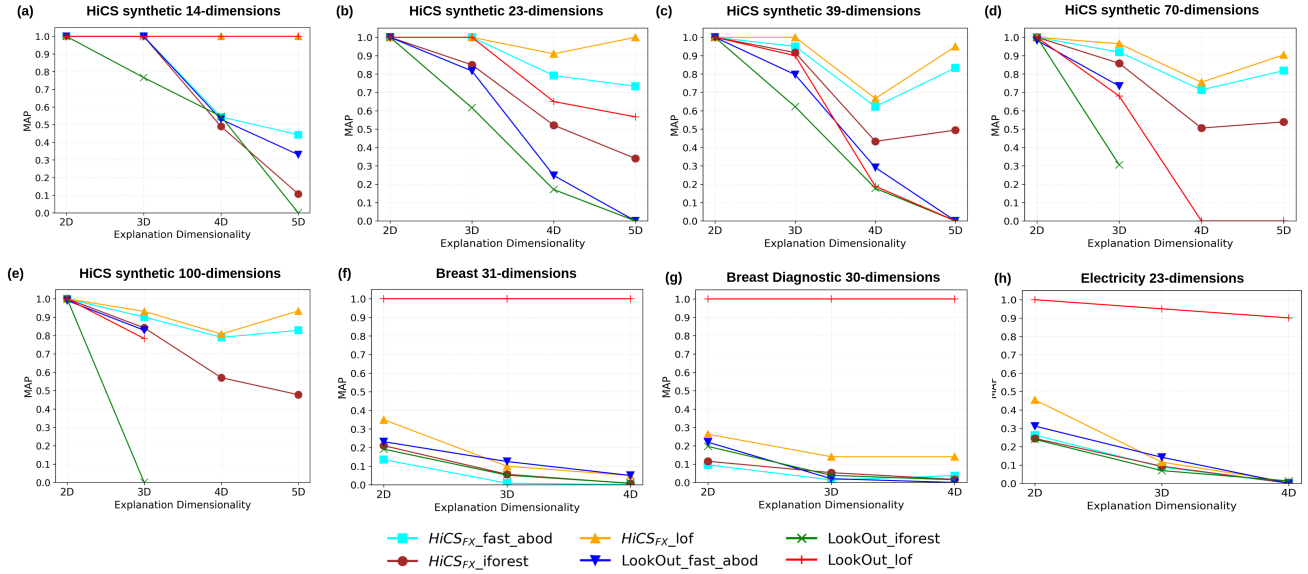

Figure 10: Mean Average Precision (MAP) of HiCS and LookOut in HiCS synthetic datasets (a)-(e) and real-world datasets (f)-(h) for explanations of increasing dimensionality (best viewed in color)

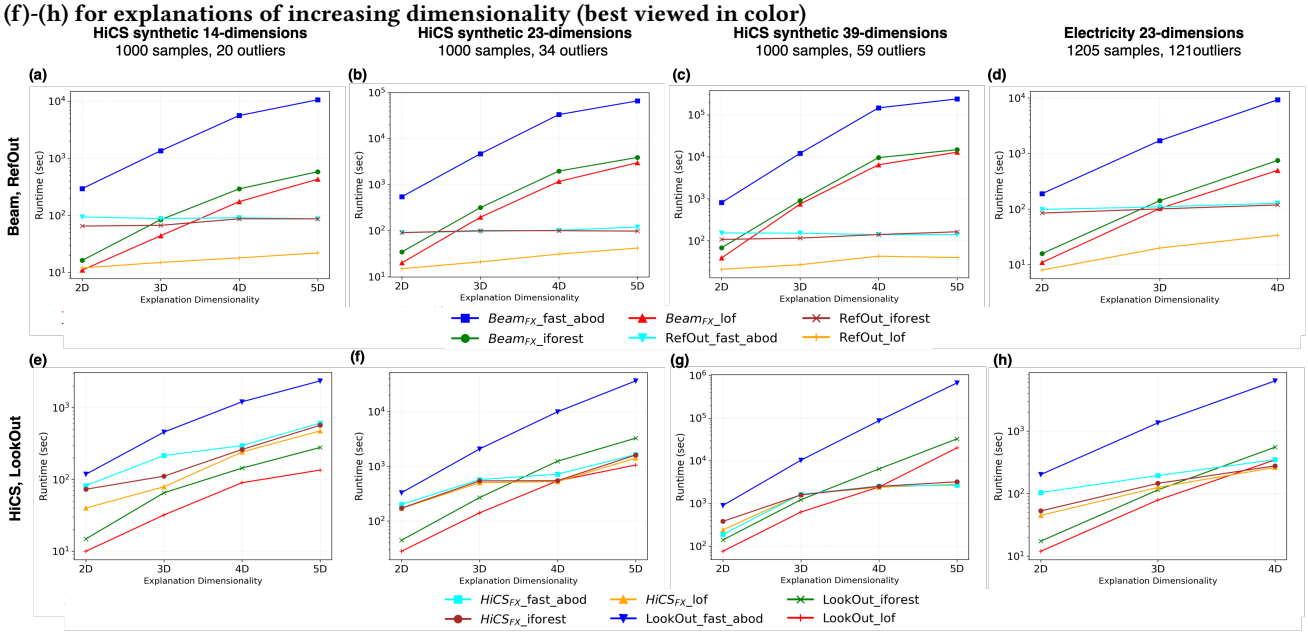

Figure 11: Runtime of detection and explanation pipelines (best viewed in color)

subspaces. According to complementary experiments not presented here due to space restrictions, detectors (especially LOF and iForest) assign higher scores to outliers in their augmented subspaces of dimensionality d than to outliers explained exclusively in d. As the outlier ratio increases along with dataset's dimensionality, more outliers get high scores in their augmented subspaces of a requested dimensionality. As a small fraction of outliers is explained by high dimensional subspaces, LookOut mainly retrieves augmented subspaces of outliers explained in lower dimensions that provide higher marginal gain. Observe that LookOut with Fast ABOD starts performing better than with LOF for high dataset dimensionality. Note that we run LookOut with LOF up to 4d explanations in 100 dimensions and Fast ABOD and iForest only up to 3d explanations for 70 and 100 dimensions. Specifically, to explain the outliers with 4d explanations in a 70d dataset, LookOut needs to assess 900K subspaces. In Section 4.3, we demonstrate that LOF is the most efficient detector when a significant amount of subspaces need to be assessed.

Figures 10-f) to -h) illustrate the MAP obtained in the 3 real-world datasets of our testbed. HiCS has poor MAP regardless of the explanation dimensionality or the detector used. This is because outliers are not contained in subspaces with highly correlated features. LookOut with LOF is the most effective as it is able to retrieve almost all relevant subspaces even when they maximally explain one outlier. On the contrary, LookOut with iForest and Fast ABOD exhibit poor performance as they are not able to highly score the relevant subspaces.

Lessons Learned. The fact that relevant subspaces may be formed by highly correlated features could be exploited to avoid a blind search of subspaces. When datasets exhibit strong feature correlation in relevant subspaces, HiCS exploits this heuristic and provides the best performance regardless of the dataset's

or explanation's dimensionality. It only depends on the ability of LOF or Fast ABOD to highly rank the retrieved subspaces. LookOut is as effective as HiCS in the synthetic datasets for low dataset dimensionality (e.g. 14d). When subspaces are formed by uncorrelated features, LookOut is a better alternative. However, LookOut is heavily impacted by the varying dimensionality of subspaces explaining different outliers. Indeed, the utility of subspaces in LookOut is defined exclusively in terms of their scores, without considering any semantic property of explanations such as the coverage of the points to be explained, or the overlap or the equivalence of subspaces in the explanation summaries.

4.3 Algorithms RunTime & Tradeoffs

In this section we report the execution time of the two point explanation and the two summarization algorithms we evaluated their effectiveness in Sections 4.1 and 4.2. In this respect, we are using the same synthetic (up to HiCS 39d) and real (Electricity 23d) datasets containing a similar amount of samples ($\sim$ 1000). We report execution time only for Electricity as it contains the highest number of samples exhibiting the same behavioral trends as the other two real datasets. Recall that as we are looking for explanations of fixed dimensionality (2-5d) the ratio of relevant features decreases as dataset's dimensionality increases.

Outlier Detection. Unlike HiCS, subspace search in explanation algorithms like Beam, RefOut and LookOut, heavily depends on the efficiency (and effectiveness) of used off-the-self detectors. According to the performance curves of detection and explanation pipelines depicted in Figure 11, LOF is the fastest followed by iForest and Fast ABOD across all datasets and explanation algorithms. This is due to low number of samples ($\sim$ 1000) despite the fact that iForest has the lowest time complexity. A similar result has been reported in [8] for the same hyper-parameter settings as those used in our testbed (see Section 3.1). Note that for iForest we report the average time out of 10 repetitions per subspace. Specifically, to score a single subspace LOF needed 0.05, iForest 0.2 and Fast ABOD 2 seconds approximately.

Point Explanation. The runtime of pipelines involving Beam, RefOut are illustrated in Figures 11-a) to -d). Critical factors affecting Beam's efficiency are: (i) the requested explanation dimensionality (more stages to be built), (ii) the dataset's dimensionality (more subspaces to be assessed per stage), (iii) the efficiency of the employed detector and (iv) the number of outliers to explain (the process is repeated per outlier). However, due to its random sampling technique, RefOut's runtime is relatively stable regardless of the explanation or dataset's dimensionality. Note that up to 39d datasets and 2d explanations, RefOut and Beam with LOF need almost the same time to assess a similar amount of subspaces. RefOut with LOF outperforms Beam with LOF from 1 (in real datasets) up to 3 orders (in synthetic datasets) of magnitude for 39d datasets and 5d explanations.

Explanation Summarization. The runtime of pipelines involving LookOut and HiCS are illustrated in Figures 11-e) to -h). The critical factors affecting LookOut's efficiency are: (i) dataset's and explanation dimensionality (exhaustive subspace search) and (ii) the efficiency of the employed detector. On the other hand, by decoupling subspace search from outlier scoring, the critical factor of HiCS efficiency is only the explanation dimensionality (more subspaces to be assessed per stage). Thus, HiCS exhibits similar running times when executed with LOF, iForest and Fast ABOD (used only to rank the discovered subspaces). Surprisingly, LookOut with LOF[7] outperforms all HiCS pipelines up to 4d explanations (by 1 order of magnitude in 2d). For the size of datasets used in our experiments, HiCS statistical tests to assess feature correlation prove to be more costly than LOF distance calculation of points to assess their outlyingness. Performance gains of LookOut with LOF drop as we increase the number of features along with explanation dimensionality, leading HiCS to outperform LookOut in the 39d dataset for 5d explanations.

Table 2 demonstrates the point explanation and summarization algorithms along with their corresponding detector that exhibit the best tradeoff between effectiveness (according to Figures 9 and 10) and efficiency (according to Figure 11) from 2d up to 5d explanations across decreasing relevant feature ratios. For every cell we take the top pair of algorithms according to their efficiency and effectiveness in pareto order. We prioritize generic algorithms like LookOut over algorithms like HiCS that work under specific conditions. For instance, LookOut with LOF is slightly less effective than HiCS with LOF in Figure 10-c), while they have the same execution time in Figure 11-g). In cells 2d and 3d with a 12% ratio, we consider that LookOut achieves a better tradeoff since it is more generic than HiCS. When point explanation or summarization algorithms exhibit zero effectiveness in all executed pipelines for a particular dataset and explanation dimensionality, no top pair is reported. For instance, for 5d and 21% or 12% ratios only one pair for detection and summarization algorithms is reported (HiCS with LOF) as no point explanation algorithm succeeds to return relevant 5d explanations. The main conclusions drawn from Table 2 are:

1. *State-wise subspace search* employed by Beam achieves the best tradeoff for full space outliers. Both its effectiveness and efficiency significantly decrease for subspace outliers as the ratio of relevant features decreases. However, it is the only option for high explanation dimensionality (3d - 4d) and low relevant feature ratio ($<$ 12%).

2. *Random subspace projection* employed by RefOut provides a good tradeoff for subspace outliers with a medium ratio of relevant features (35% and 21%). Its effectiveness drops to zero as the explanation dimensionality becomes greater than 3d (for 21% ratio).

3. *Exhaustive subspace search* employed by LookOut exhibits top effectiveness and efficiency for full space outliers regardless of the explanation dimensionality, as well as, for subspace outliers up to 3d. Its effectiveness significantly drops for subspace outliers explained by subspaces greater than 3d (for 21% ratio).

4. *Correlation heuristic* exploited by HiCS achieves the best tradeoff for 4d-5d explanations especially when the relevant feature ratio is low. This heuristic however, strongly depends on the data distribution as highly clustered outliers may are not always be visible in correlated features.

5 RELATED WORK

In this section we survey additional explanation algorithms for data in rest (databases) or in motion (streams) and justify why they have not included in our benchmark.

Explaining Black-Box Models. Several methods have been proposed to explain why a supervised model predicted a particular label for a particular example [10, 19, 24, 26, 33]. LIME [33] constructs a linear interpretable model that is locally faithful to the

[7] LookOut has been experimentally evaluated by its authors [15] only with iForest and 2d explanations.

Table 2: Tradeoffs of outlier detection and explanation algorithms

predictor. [10, 19] explain the model by perturbing the features to quantify their influence on predictions. Other works aim to produce explanations in the form of feature relevance scores by comparing the difference between a classifier's prediction score and the score when a feature is assumed to be unobserved [34], or by considering the local gradient of the classifier's prediction score with respect to the features for a particular example [4]. [38, 39] considered how to score features in a way that takes into account the joint influence of feature subsets on the classification score. This body of work requires as input a supervised model rather than an unsupervised anomaly detector. However, in real application settings it is difficult or even impossible to label data as anomalous or normal examples [12].

Explaining Outliers in Query Answers. Scorpion [47] was the first system for explaining outliers in the result of group-by queries. Given a set of outliers spotted by analysts on the results of queries, the system searches for a logical formulae that describes a set of tuples that contribute most to the excessively high or low aggregate value of a specific group. It is hard to extend this work for explaining outliers recognized by off-the-self detectors. Furthermore, empirical explanations for data points that violate specific data quality constraints (i.e., inconsistencies w.r.t. domain-specific rules) have been studied in [7]. A glitch explanation is a collection of values of features that have statistically significant propensity signatures. In our work, we are interested in a quantitative form of data anomalies frequently encountered in transaction or measurement-based datasets, i.e., outliers in numerical features for which quality constraints are difficult or impossible to obtain. Finally, an interactive explanation discovery system has been proposed [35]. It relies on a set of explanation templates given by analysts that need to be precomputed per dataset. Neither of the previous methods satisfy our requirements for explaining data anomalies in a way that is both domain and detector agnostic without making strong assumptions regarding how the input datasets have been processed.

Explaining Outliers in Temporal Data. MacroBase [1] enables efficient, accurate, and modular analyses that highlight and aggregate important and unusual behavior in fast data. It introduces an operator for explaining outliers in a data stream based on the categorical features rather than the numerical features used to actually detect outliers. In contrast to the notion of relevant subspaces, the explanation of continuous outliers consists of conjunctions of categorical features whose values cover most of the outliers detected by a density-based method called MAD. ExplainIT [16] is a recent system for unsupervised root-cause analysis of time series that shares similar motivations with MacroBase. It empowers a declarative interface (SQL based) for specifying a large number of cause hypothesis that need to be tested and ranked to assist analysts with a reduced number of causal dependencies that have to exploit regarding an observed phenomenon. The use of causal models for explaining data outlyingness is an interesting idea that we plan to study in the future by leveraging our previous work on scalable algorithms for causal feature discovery [45]. Finally, EXstream [49] is a system providing high-quality explanations for anomalous behaviors of streaming data that analysts annotate using CEP-based monitoring results. Explanations take the form of logical formulae in CNF involving relational predicates (i.e., $=$, $<$, $\leq$) over feature values computed for time series. Authors formalize the problem of optimally explaining anomalies in CEP as an information reward maximization problem. In this respect, an entropy-based distance function of time series is used to measure the contribution in the reward of each feature. As the reward function is sub-modular, greedy approximation techniques could be used as in the case of LookOut [15]. Computing explanations based on single-feature rewards bears similarity with the univariate feature selection problem while computing subspace based outlier explanations is closer to the more complex problem of multivariate feature selection [45].

6 CONCLUSIONS AND FUTURE WORK

In this experimental study, we addressed missing insights regarding the performance of existing outlier explanation and summarization algorithms under realistic settings. We underlined the main challenge that stems from the lack of inherent pruning properties to effectively search the exponential space. Existing subspace search strategies exploit the distributional characteristics either: (i) of data such as features' correlation in subspaces (HiCS [17]) or (ii) of scores given by an outlier detector in subspaces (LookOut [15], Beam [28] and RefOut [18]). The former strategy is effective when highly clustered outliers over correlated features are contained in datasets regardless of their dimensionality, while the latter is effective in low explanation dimensionality where the outlier detectors can discriminate accurately the outliers from the inliers. It remains open to assess whether the low dimensional subspaces retrieved by an explainer are projections of a high dimensional subspace fully explaining a specific point.

We should additionally note that the detection of outliers in LOF, ABOD and iForest, is actually decoupled from the search of subspaces likely to contain them. HiCS, RefOut and Beam instead are *explaining outlier detectors* that rely on per-subspace measures to quantify the explanation quality of subspaces. We are planning to extend our testbed with recent works [44] taking into account the relationship between subspaces using a dimension-based measure of their explanation quality. Moreover, in case of recurring anomaly patterns, it is also interesting to benchmark group-based explanation summarization techniques [25].

Another interesting aspect would be to investigate outlier explanation in stream processing settings such as LODA [31].

We should finally stress that existing outlier explanation and summarization algorithms actually provide *descriptive explanations*. In essence, subspace explanations are verbose descriptions of the decision boundary discovered by unsupervised detectors to distinguish inliers from outliers. This is the reason why explanation tasks should be re-executed for every new bunch of data made available in ML pipelines even if they stem from the same generative process. As summarization algorithms can only exploit the subspaces which are assessed to be relevant to a given set of points, they may result in summaries of very poor quality when individual outliers are explained by disjoint feature subsets. In this respect, we are planning to build a surrogate model to predict the scores (or labels) of points produced by an unsupervised outlier detector and approximate its decision boundary using minimal predictive signatures. Such *predictive explanations* overcome the high computation cost of subspace search per point and provide formal guarantees regarding minimality in the explanation dimensionality.

ABSTRACT

We study techniques for clustering large collections of sets into DBSCAN clusters. Sets are often used as a representation of complex objects to assess their similarity. The similarity of two objects is then computed based on the overlap of their set representations, for example, using Hamming distance. Clustering large collections of sets is challenging. A baseline that executes the standard DBSCAN algorithm suffers from poor performance due to the unfavorable neighborhood-by-neighborhood order in which the sets are retrieved. The DBSCAN order requires the use of a symmetric index, which is less effective than its asymmetric counterpart. Precomputing and materializing the neighborhoods to gain control over the retrieval order often turns out to be infeasible due to excessive memory requirements.

We propose a new, density-based clustering algorithm that processes data points in any user-defined order and does not need to materialize neighborhoods. Instead, so-called backlinks are introduced that are sufficient to achieve a correct clustering. Backlinks require only linear space while there can be a quadratic number of neighbors. To the best of our knowledge, this is the first DBSCAN-compliant algorithm that can leverage asymmetric indexes in linear space. Our empirical evaluation suggests that our algorithm combines the best of two worlds: it achieves the runtime performance of materialization-based approaches while retaining the memory efficiency of non-materializing techniques.

1 INTRODUCTION

We consider the problem of partitioning large collections of sets into DBSCAN [15] clusters. Our work is motivated by a process mining use case at Celonis SE that models processes as sets. A *process* is a sequence of timestamped activities. Large companies store hundreds of millions of activities in millions of processes. In order to analyze the processes, they should be clustered into groups of similar activity sequences that can be further explored [5, 22, 39]. To this end, a process is represented by the set of all its neighboring activity pairs, e.g., the process with the activity sequence (S, O, P, H, R, F, E) (Start, Order, Pay, sHip, Return good, reFund, End) is represented by the set $\{(S, O), (O, P), (P, H), (H, R), (R, F), (F, E)\}$. The similarity of two processes is then assessed by the Hamming distance[1] of their set representations.

Sets are used in many other applications [29] to represent objects for the purpose of clustering, e.g., sales may be represented by sets of product categories, photos by sets of tags and title words, user interactions on a website by sets of visited links, users of a social network by their group memberships, or users of a music streaming platform by sets of tracks they listen to.

[1]Hamming distance $H(r, s) = |r \cup s| - |r \cap s|$ for two sets r and s.

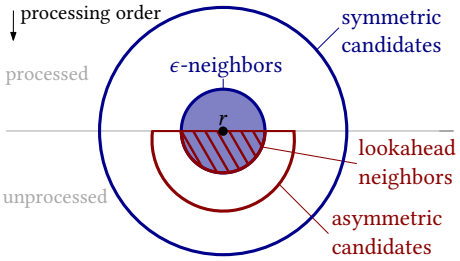

Figure 1: Symmetric candidates with ϵ-neighbors (blue); asymmetric candidates with lookahead neighbors (red).

The popular DBSCAN (Density-Based Spatial Clustering of Applications with Noise) algorithm [15] identifies clusters of arbitrary shape without requiring the number of clusters as input. Intuitively, DBSCAN finds dense regions that are separated by regions of lower density. The density of a region (given a distance function between pairs of data points) is defined by two parameters: the number of neighbors, *minPts*, and the radius, ϵ, of the neighborhood. A data point is called *core point* (i.e., it is at the core of a dense region) if it has at least minPts neighbors (including itself) within radius ϵ; a non-core point in the ϵ-neighborhood of a core point is a *border point* (i.e., it is at the border of a dense region); all other points are *noise* [37].

The runtime of the DBSCAN algorithm heavily depends on the efficiency of the neighborhood computation. In our experiments, the neighborhood computation accounts for up to 99% of the overall runtime for some datasets. Therefore, in order to efficiently cluster large collections of sets, effective indexing techniques for sets are required.

Similarity indexes for sets have been proposed in the context of ϵ-neighborhood joins, which are executed in an index nested loop fashion. A prominent representative is the *prefix index* [1, 8], which is linear in size and has been shown to be highly effective [29]. The *symmetric* prefix index returns the complete ϵ-neighborhood for a given query point r. The *asymmetric* prefix index assumes a processing order on the sets in R and retrieves only the *lookahead neighbors*: the ϵ-neighbors that follow r in processing order. A typical processing order for sets is based on the set sizes (ties broken arbitrarily). The *asymmetric* prefix index further leverages the length information to avoid many of the candidates that the symmetric index must inspect (among the unprocessed sets). Figure 1 illustrates the ϵ-neighborhood, the lookahead neighbors, and the candidate regions of symmetric and asymmetric index, respectively. The region above the gray line represents the sets that have been processed before r, the region below the gray line are unprocessed sets. The circles and semicircles show subset relationships.

Clearly, the asymmetric prefix index is preferable in terms of effectiveness over its symmetric counterpart. Unfortunately, there is an inherent mismatch between the asymmetric index and the DBSCAN algorithm. DBSCAN suffers from the following issues when executed with the asymmetric index: (1) *Core status*

problem: The lookahead neighbors of r are not sufficient to update the core status of r. (2) *Border vs. Noise problem:* To distinguish border points from noise, a border point must be visible from a core point, which is not guaranteed by the asymmetric lookahead neighborhood. (3) *Disconnected clusters:* To guarantee connected clusters, DBSCAN imposes a (partial) processing order on the neighborhood computations: all core points of the current cluster must be expanded (i.e., their neighborhood must be computed) before any point belonging to a different cluster is processed.

A well-known clustering approach [3] is based on a self-join that precomputes and materializes all neighborhoods. The precomputed neighborhoods are then used while executing DBSCAN. This approach can leverage the asymmetric index and is efficient in runtime. Unfortunately, this join-based technique requires quadratic memory in the worst case and suffers from a large memory footprint in practice. For example, for our social media dataset (LIVEJ) that stores the interests of 3.1M users, this approach requires almost 100GB of memory.

Summarizing, applications that must cluster large collections of sets have two options, which we call Sym-Clust and Join-Clust. (1) Sym-Clust: Retrieve the full ϵ-neighborhoods in the processing order imposed by DBSCAN using the symmetric index. (2) Join-Clust: Compute and materialize neighborhoods in a join using the effective asymmetric index. None of the options is satisfying: Sym-Clust runs almost up to an order of magnitude slower than Join-Clust, while Join-Clust is infeasible for many datasets and parameter settings due to its excessive memory usage.

We propose a new clustering algorithm, *Spread*, that computes correct DBSCAN clusters using the asymmetric prefix index. Spread runs in linear space and does not need to materialize the (quadratic-size) neighborhoods. Spread avoids symmetric neighbor computations, therefore reducing the number of neighbors retrieved by Sym-Clust. So-called *backlinks* are introduced to achieve a correct clustering. Backlinks are dynamically added and removed as required and occupy only a small fraction of the memory that is used by materialized neighborhoods. Spread maintains a graph of subclusters in a disjoint-set data structure and guarantees that connected components in the resulting graph represent correct DBSCAN clusters.

In general, Spread can process data points in any *user-defined order* given an index that retrieves the lookahead neighbors, i.e., all data points that follow the query point in the user-defined processing order. In our usage scenario – set clustering – the processing order is defined by the set sizes (ties broken arbitrarily) and the asymmetric prefix index retrieves lookahead neighbors.

Summarizing, our contributions are the following:

- We propose *Spread*, a novel algorithm for partitioning large collections of sets into DBSCAN clusters. To the best of our knowledge, this is the first linear space DBSCAN-compliant algorithm that leverages the *asymmetric* prefix index for sets.
- We introduce the new concept of *backlinks* that keep sufficient information to build correct clusters independently of the processing order that the user imposes on Spread. We prove invariants for backlinks and the correctness of our approach.
- Our extensive empirical evaluation on 13 real-world datasets suggests that Spread is as fast as Join-Clust (that materializes all neighborhoods) while being competitive in memory usage with Sym-Clust (that computes all neighborhoods on the fly).

The remainder of this paper is organized as follows. In Section 2, we cover the background on ϵ-neighborhood and set similarity, indexing techniques for sets, and density-based clustering, and we define the *density-based set clustering problem*. Section 3 presents the two baseline approaches for density-based set clustering, Join-Clust and Sym-Clust. In Section 4, we present Spread, our time- and space-efficient solution for density-based set clustering. We evaluate our solution against the baseline algorithms and discuss the results in Section 5. Related work is summarized in Section 6. Finally, Section 7 concludes this paper.

2 BACKGROUND & PROBLEM DEFINITION

We revisit set similarity indexes and density-based clustering, and define our problem. To simplify the presentation, we focus on prefix indexes for the Hamming distance. Our results, however, extend to other distance and similarity measures (e.g., Jaccard or Cosine) and the respective indexes [12, 29, 40]. The required adaptations of the index that have been studied in the context of set similarity joins [29, 49] (e.g., prefix length, size lower bound, equivalent overlap) also apply to our scenario.

2.1 Set Similarity and ϵ-Neighborhood

R is a collection of n unique sets, each set $r \in R$ consists of unique tokens $t_1, \ldots, t_m$, $|r| = m$. The *processing order*, $\succ$, is a total order defined over R. The similarity between two sets r and s is assessed by the Hamming distance, $H(r, s) = |r \cup s| - |r \cap s|$, which counts the number of tokens that exist only in one of the sets, e.g., $H(r_1, r_2) = 4$ and $H(r_2, r_3) = 3$ for the sets in Figure 2.

The *ϵ-neighborhood* of set r includes r and all sets within distance ϵ from r, $N_\epsilon(r) = \{s \in R \mid H(r, s) \leq \epsilon\}$. A *region query* on r computes $N_\epsilon(r)$. A set r splits its ϵ-neighborhood into two disjoint parts based on the processing order: the *lookahead neighbors* that follow r in processing order, $N_\epsilon^{\succ}(r) = \{s \in N_\epsilon(r) \mid s \succ r\}$ and the *preceding neighbors*, $N_\epsilon^{\prec}(r) = \{s \in N_\epsilon(r) \mid s \prec r\}$.

2.2 Indexing Techniques for Sets

Prefix Filter and Inverted Index. A naive approach computes a region query $N_\epsilon(r)$ by verifying the predicate $H(r, s) \leq \epsilon$ for all sets $s \in R$. An effective indexing technique, which was originally developed for set similarity joins [2, 29], is based on the so-called prefix filter. The prefix, π_r, of a set r consists of the first π tokens of r according to some total token order (which must be the same for all sets). The prefix length depends on the distance function and is $\pi = \epsilon + 1$ for the Hamming distance. Figure 2 shows the prefix of three sets for distance threshold $\epsilon = 3$ and a numerical token order. The prefix filter works best if the tokens in the prefix are infrequent, thus the tokens are typically ordered by ascending global token frequency.

A set $s \in R$ can be in the ϵ-neighborhood $N_\epsilon(r)$ only if the prefixes of r and s share at least one token, i.e., $H(r, s) \leq \epsilon \Rightarrow \pi_r \cap \pi_s \neq \emptyset$ (assuming $|r| + |s| > \epsilon$; otherwise r and s are always similar). Therefore, if two sets do not share a token in the prefix, the pair can be safely pruned. If two sets r and s share a prefix token, (r, s) is a *candidate pair* and must undergo *verification*, i.e., the predicate $H(r, s) \leq \epsilon$ must be evaluated. Candidates that fail verification are *false positives*. Mann et al. [29] discuss efficient prefix-based verification.

Symmetric Prefix Index. An inverted index on the prefix tokens is used to retrieve candidate pairs efficiently. The inverted index maps prefix tokens to sets that contain that token in the prefix. A lookup of set r retrieves all lists of the prefix tokens of r. The

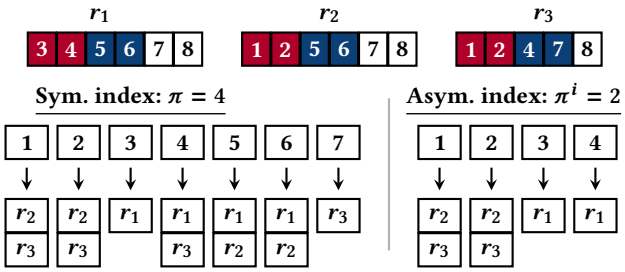

Figure 2: Symmetric and asymmetric prefix index, $\epsilon = 3$.

union of these lists (except r itself) are the candidates of r. The index is *symmetric* and returns the ϵ-neighborhood of r.

For example, the candidates for r_2 returned by the symmetric index, $\pi = \epsilon + 1 = 4$, in Figure 2 are $\{r_1, r_3\}$ (resulting from the union of $[r_2, r_3]$ for token 1, $[r_2, r_3]$ for token 2, $[r_1, r_2]$ for token 5, and $[r_1, r_2]$ for token 6). Candidate r_1 is a false positive since $H(r_1, r_2) > \epsilon$; r_3 is a true positive due to $H(r_2, r_3) \leq \epsilon$.

Asymmetric Prefix Index. We construct an *asymmetric* prefix index that returns only the lookahead neighbors, $N_\epsilon^{\succ}(r)$. To this end, we define a length-based processing order on R (longest to shortest): r precedes s if $|r| > |s|$, i.e., $|r| > |s| \Rightarrow s \succ r$; ties ($|r| = |s|$) are broken by the lexicographic order of the sorted sets.

Since we are interested only in sets $s \in N_\epsilon(r)$ that are no larger than r, $|s| \leq |r|$, we need to index only a subset of the prefix tokens: the tokens in the so-called *indexing prefix* [49]. The so-called *probing prefix* of the lookup set, r, remains of length $\pi = \epsilon + 1$. For the Hamming distance, the indexing prefix is of length $\pi^i = \left\lfloor \frac{\epsilon}{2} + 1 \right\rfloor$. For $\epsilon > 0$, the probing prefix is always longer than the indexing prefix, e.g., $\pi = 4$ and $\pi^i = 2$ for $\epsilon = 3$. A shorter prefix results in fewer candidates and renders the asymmetric index more effective than its symmetric counterpart.

In the case of r_2, the asymmetric index, $\pi^i = 2$, in Figure 2 returns only a true positive candidate, r_3. The false positive candidate, r_1, which is returned by the symmetric index, is avoided.

2.3 Density-Based Clustering

We formally define DBSCAN clusters and the related concepts. A set r represents a point to be clustered. The *density* of r is the number of ϵ-neighbors $|N_\epsilon(r)|$ (cf. Section 2.1).

Core, Border, Noise. A set r is a *core point* iff the ϵ-neighborhood of r contains at least minPts sets: r is core $\Leftrightarrow |N_\epsilon(r)| \geq$ minPts. A set s is a *border point* iff it is in the ϵ-neighborhood of a core point r and s is not core: s is border $\Leftrightarrow s \in N_\epsilon(r) \wedge |N_\epsilon(r)| \geq$ minPts $\wedge$ $|N_\epsilon(s)| <$ minPts. All remaining sets in R are *noise*. We denote the set of core and border points with $\mathcal{C}$ and $\mathcal{B}$, respectively. The set of noise points is $\mathcal{N} = R \setminus (\mathcal{C} \cup \mathcal{B})$.

Density-Reachability. Let $r, s \in R$ and r is core: s is *directly density-reachable* from r iff s is in the ϵ-neighborhood of r: $r \blacktriangleright s \Leftrightarrow s \in N_\epsilon(r)$. If there is a sequence of sets $r_1, r_2, \ldots, r_k$ with $r_1 = r$ and $r_k = s$, $r_i \blacktriangleright r_{i+1}$ for $1 \leq i < k$, s is *density-reachable* from r, denoted $r \blacktriangleright \ldots \blacktriangleright s$. Two sets r, s are *density-connected* if there is a set x s.t. both r and s are density-reachable from x.

A *density-based cluster* is a subset $C_i \subseteq R$ that satisfies two criteria [38]:

(1) *Maximality* $\mathbb{M}$*:* For any two sets $r, s \in R$, $r \in C_i$. If s is density-reachable from r, then $s \in C_i$. Formally,

$$\forall r, s \in R : r \in C_i \wedge r \blacktriangleright \ldots \blacktriangleright s \implies s \in C_i$$

Table 1: Notation overview.

Notation	Description
R	a collection of sets
r, s, x	sets of R
$\|r\|$	cardinality of set r
$r \prec s, r \succ s$	r precedes/succeeds s (in R)
$H(r, s)$	the Hamming distance of two sets r, s
π, π^i	probing/indexing prefix
ϵ	distance threshold
minPts	minimum density s.t. a set r is core
$N_\epsilon(r)$	full ϵ-neighborhood of r
$N_\epsilon^{\prec}(r), N_\epsilon^{\succ}(r)$	preceding/lookahead neighbors of r
$r \blacktriangleright s$	s is directly density-reachable from r
$r \blacktriangleright \ldots \blacktriangleright s$	s is density-reachable from r
$\mathcal{C}, \mathcal{B}, \mathcal{N}$	the set of core, border, and noise sets
C_i	a density-based cluster with id i

(2) *Connectivity* $\mathbb{C}$*:* For any two sets r, s in C_i, there is a set x that density-connects r and s. Formally,

$$\forall r, s \in R : r, s \in C_i \implies \exists x \in C_i : r \blacktriangleleft \ldots \blacktriangleleft x \blacktriangleright \ldots \blacktriangleright s$$

DBSCAN Clustering. A border point may be part of multiple density-based clusters such that the clusters overlap. We define the *DBSCAN clustering* that partitions the data into non-overlapping clusters. The standard DBSCAN algorithm [15] produces a DBSCAN clustering.

Definition 2.1. Let $R^* = R \setminus \mathcal{N}$ and $C_1, C_2, \ldots, C_k$ be density-based clusters such that $\bigcup_{i=1}^{k} C_i = R^*$. A DBSCAN clustering is a partitioning $\Gamma = \{C'_1, C'_2, \ldots, C'_k\}$, $C'_i \subseteq C_i$, such that $\bigcup_{i=1}^{k} C'_i = R^*$, $C'_i \cap C'_j = \emptyset$ for $i \neq j$.

A *subclustering* of a cluster C_i, $\psi_i = \{c_1, c_2, \ldots, c_l\}$, is a partitioning of C_i into $1 \leq l \leq |C_i|$ non-empty, disjoint subclusters, $c_j \subseteq C_i$, such that $\bigcup_{j=1}^{l} c_j = C_i$, $c_j \cap c_k = \emptyset$ for $j \neq k$.

A *subcluster graph* of R^* is an undirected graph in which nodes are subclusters and an edge between two nodes can only exist if the respective nodes are in the same DBSCAN cluster.

2.4 The DBSCAN Algorithm

The standard DBSCAN algorithm [15] forms clusters by repeatedly picking a seed point from the set of unvisited data points (initially all points are unvisited). If the seed is a core point, it forms a new cluster with all points that are density-reachable from the seed and are not yet assigned to a cluster. The set of density-reachable points is computed by recursively adding the ϵ-neighbors of all core points to the current cluster. The algorithm terminates when all points have been visited. Points that cannot be assigned to a cluster are noise.

2.5 Problem Statement

Definition 2.2 (Density-Based Set Clustering). Given a collection of sets R, a distance threshold ϵ, and the neighborhood density minPts, the goal is to find a DBSCAN clustering $\Gamma = \{C_1, C_2, \ldots, C_k\}$ of R.

For sets, asymmetric indexes with a lookahead neighbor function $N_\epsilon^{\succ}(r)$ promise the best performance (cf. Section 2.2). Given an ordering $\succ$ on R, we strive for a time- and space-efficient algorithm that solves the density-based set clustering problem with an asymmetric index.

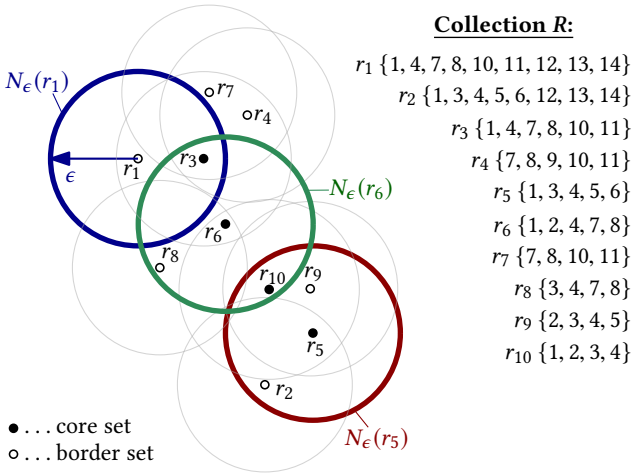

Figure 3: Running example, $\epsilon = 3$, minPts = 4.

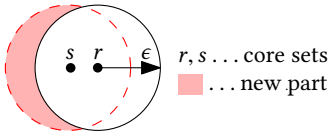

Figure 4: Redundant neighborhood queries.

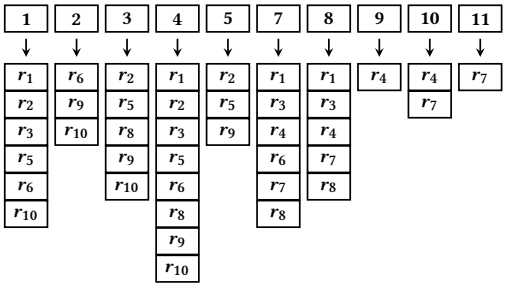

Figure 5: Symmetric prefix index on r_1-r_{10}, $\epsilon = 3$, $\pi = 4$.

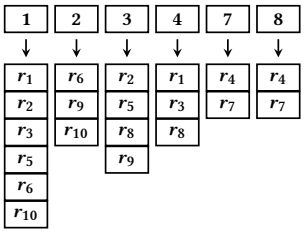

Figure 6: Asymmetric prefix index on r_1-r_{10}, $\epsilon = 3$, $\pi^i = 2$.

Running Example. Figure 3 shows an example collection R of ten sets, r_1–r_{10}, and their neighborhoods for Hamming distance $\epsilon = 3$. Sets r_3, r_5, r_6, and r_{10}, are core sets; all sets r_1–r_{10} form a single cluster.

3 BASELINE APPROACHES

This section presents two baseline solutions for the density-based set clustering problem. (1) *Sym-Clust* is memory-efficient and follows the standard DBSCAN approach with the symmetric prefix index to answer neighborhood queries on the fly. (2) *Join-Clust* is speed-optimized and materializes all ϵ-neighborhoods using a state-of-the-art set similarity join algorithm [2] (which leverages the asymmetric prefix index) before the standard DBSCAN algorithm is executed.

Both baselines leverage state-of-the-art set indexes. We are not aware of other previous solutions that can outperform Sym-Clust or Join-Clust for the density-based set clustering problem. Note that using the standard DBSCAN [15] (rather than some advanced techniques presented in later works, cf. Section 6) is not a limiting factor: Most of the overall execution time is spent computing the neighborhoods, and prefix-based indexes are highly efficient in combination with efficient verification [29].

3.1 Sym-Clust: DBSCAN with Inverted Index

When the standard DBSCAN algorithm (cf. Section 2.4) picks a seed point that is core, it forms a cluster with all points that are density-reachable from the seed. The density-reachable points are computed by pushing all core neighbors of the seed onto a stack. Then, each point on the stack is processed in the same manner (i.e., all its core neighbors are pushed onto the stack) until the stack is empty. All neighbors of core points retrieved in this process belong to the cluster.

The neighborhood queries will overlap to some extent. Assume r is processed before s, $s \in N_\epsilon(r)$, then $|N_\epsilon(s) \cap N_\epsilon(r)| \geq 2$ (at least r and s are in both neighborhoods). Since r assigns all its neighbors to the current cluster, only the non-overlapping neighbors of s, $N_\epsilon(s) \setminus N_\epsilon(r)$, will further increase the cluster.

Figure 4 illustrates this observation for the neighborhoods of two example points r (black circle) and s (red circle): only the new, non-overlapping area of $N_\epsilon(s)$ (shaded in red) is relevant for expanding the cluster.

The standard DBSCAN algorithm requires the use of a symmetric index since it assumes to see all neighbors of a point s when s is processed. The asymmetric index is not compatible with the standard DBSCAN algorithm: We cannot impose an order on the points such that all non-overlapping neighbors of s follow s in the processing order. Further, the size of the neighborhood of s, $|N_\epsilon(s)|$, is required to decide its core status.

Figure 5 shows the symmetric prefix index for our running example, $\epsilon = 3$, $\pi = \epsilon + 1 = 4$. We probe $r_8 = \{3, 4, 7, 8\}$. The prefix of r_8 consists of all tokens in r_8 (due to $|r_8| = \pi$). The union of the respective index lists yields the candidates $\{r_2, r_5, r_9, r_{10}, r_1, r_3, r_6, r_4, r_7\}$. Note that the candidates include both sets that are smaller and sets that are larger than r_8.

The so-called *length filter* [2], an optimization of the symmetric prefix index that also applies to its asymmetric counterpart, prunes candidates r_2 and r_1. Due to their length difference to r_8, they cannot be in the ϵ-neighborhood of r_8. By ordering the lists in processing order (i.e., longer sets precede shorter sets, as illustrated in Figure 5), the length filter can prune the head (sets that are too long) and the tail (sets that are too short) of a list without inspecting all elements in head and tail, respectively.

All candidates that are not pruned by the length filter must undergo verification. Only r_6 passes verification, therefore $N_\epsilon(r_8) = \{r_8, r_6\}$, and r_8 is classified as non-core (minPts = 4).

Complexity Analysis. We probe each set $r \in R$ against the index once. With cost C for an index lookup and $n = |R|$, the runtime is $O(n \cdot C)$; $C = O(n)$ since r may have $O(n)$ neighbors, thus the overall runtime of Sym-Clust is $O(n^2)$. The symmetric index is of linear size leading to space complexity $O(n)$.

Algorithm 1: Materialize-Neighborhoods(R, ϵ)

Input: Collection of sets R, distance threshold ϵ
Result: Materialized neighborhoods of R w.r.t. ϵ

$I \leftarrow$ Create-Index (R, ϵ);
$pairs \leftarrow \emptyset$ // Result set of similar pairs
foreach $r \in R$ *in processing order* **do**
  $M \leftarrow$ Probe (r, I, ϵ) // candidates with prefix overlaps
  foreach $(s, po) \in M$ **do** // po . . . prefix overlap
    if Verify-Pair (r, s, ϵ, po) **then**
      $pairs \leftarrow pairs \cup \{(r, s)\}$
$neighborhoods \leftarrow$ new associative array of size $|R|$;
foreach $(r, s) \in pairs$ **do**
  $neighborhoods[r] \leftarrow neighborhoods[r] \cup \{s\}$;
  $neighborhoods[s] \leftarrow neighborhoods[s] \cup \{r\}$;
return *neighborhoods*

Algorithm 2: Create-Index (R, ϵ)

Input: Collection of sets R, distance threshold ϵ
Result: Inverted index of R w.r.t. ϵ

$I \leftarrow \emptyset$ // inv. index of set prefixes, $I_{r[p]}$ . . . list of token $r[p]$
foreach $r \in R$ **do**
  $\pi \leftarrow \left\lfloor \frac{\epsilon+2}{2} \right\rfloor$ // indexing prefix length of r
  for $p \leftarrow 1$ **to** π **do** $I_{r[p]} \leftarrow I_{r[p]} \cup \{r\}$;
return I

Algorithm 3: Probe (r, I, ϵ)

Input: Probing set r, inv. index I, distance threshold ϵ
Result: Set of candidates for r w.r.t. ϵ

// M maps a candidate s to its prefix overlap with r
$M \leftarrow$ new associative array // candidates
$\pi \leftarrow \epsilon + 1$ // probing prefix length of r
$lb_r \leftarrow |r| - \epsilon$ // size lower bound wrt. r
for $p \leftarrow 1$ **to** π **do**
  foreach $s \in I_{r[p]}$ *in proc. order* **do** // list of token $r[p]$
    if $|s| < lb_r$ **then break** ;
    else // add candidate
      if $s \notin M$ **then** $M[s] \leftarrow 0$; // init.
      $M[s] \leftarrow M[s] + 1$ // incr. overlap of (r, s)
return M

Algorithm 4: Verify-Pair (r, s, ϵ, po)

Input: Probing set r, candidate set s, distance threshold ϵ, prefix overlap po
Result: True iff r and s are similar w.r.t. ϵ, false otherwise

// cf. Mann et al. [29] for prefixes, equiv. overlaps, and Verify proc.
$\pi_r, \pi_s \leftarrow$ probing resp. indexing prefix length of r resp. s;
$w_r, w_s \leftarrow \pi_r$- resp. π_s-th token in r resp. s;
$t \leftarrow$ equivalent overlap for r, s, and ϵ;
if $w_r < w_s$ **then**
  return Verify $(r, s, t, po, \pi_r + 1, po + 1)$
return Verify $(r, s, t, po, po + 1, \pi_s + 1)$

3.2 Join-Clust: Materialized Neighborhoods

Join-Clust executes a set similarity self-join on R and materializes the ϵ-neighborhoods in main memory. The self-join traverses all sets of $r \in R$ in processing order and computes their lookahead neighbors, $N_\epsilon^\succ(r)$. The lookahead neighbors of r are appended to the list of r's neighbors, and r is appended to the neighborhood lists of all $s \in N_\epsilon^\succ(r)$. After processing all sets, the neighborhood list of each set $r \in R$ is complete and stores $N_\epsilon(r)$.

Next, standard DBSCAN (cf. Section 2.4) is executed to form clusters using the materialized neighborhoods. Algorithms 1–4 implement the similarity join with neighborhood materialization, index creation, probing, and efficient verification [29].

Mann et al. [29] found that the prefix-based index in combination with the length filter can be considered state of the art given an efficient verification procedure (which we use).

Figure 6 shows the asymmetric prefix index for our running example, $\epsilon = 3$, $\pi^i = 2$. We probe $r_8 = \{3, 4, 7, 8\}$ and look up the lists of the tokens 3, 4, 7, and 8 (the length of the probing prefix is $\pi = 4$). Since we are only interested in the lookahead neighbors, i.e., all neighbors that follow r_8 in processing order, we need to inspect the lists only starting from the point where r_8 or a set $r_i \succ r_8$ appears. The length filter does not prune any candidate in this example, and the candidate set is $\{r_9\}$. Since $H(r_8, r_9) > \epsilon$, the lookahead neighborhood of r_8 is empty, $N_\epsilon^\succ(r_8) = \emptyset$.

In the context of the self-join, r_8 will be retrieved as a lookahead neighbor of r_6, which is processed before r_8. Therefore, the neighborhood list of r_6 will store r_8 and vice versa.

Join-Clust produces fewer candidates than Sym-Clust and is therefore faster. However, the efficiency of Join-Clust comes at the cost of a larger memory footprint since all neighborhoods must be materialized.

Complexity Analysis. A neighborhood query is a constant-time lookup and a traversal of $O(|N_\epsilon(r)|)$ neighbors. In the worst case, the join reports $O(n^2)$ pairs. Consequently, materializing the neighborhoods takes $O(n^2)$ time and space for $n = |R|$. The asymmetric prefix index requires only $O(n)$ space and does not dominate memory usage.

4 THE SPREAD ALGORITHM

We present *Spread*, a novel time- and space-efficient solution for the density-based clustering problem. Spread leverages the effective asymmetric index and clusters all sets by traversing the sets in processing order. We identify key challenges that must be solved, discuss the algorithm, prove its correctness, analyze time and space complexity, and sketch a multi-core extension.

4.1 Key Challenges

Since Spread uses an asymmetric neighborhood index, a processing order, $\succ$, must be imposed on the data points, and an index lookup of query point r retrieves only the lookahead neighbors, $N_\epsilon^\succ(r)$. To achieve a correct clustering without materializing the neighborhoods, three key challenges must be solved.

In the following discussion, we assume that all sets of R are processed in processing order. When the *current set* r_i is to be processed, we know the core status of all preceding sets, $r_j \prec r_i$, but we do not know the core status of any unprocessed sets, $r_k \succ r_i$. We further assume that all sets $r \in R$ that are directly density-reachable from any r_j that precedes r_i (i.e., are neighbors of a core point $r_j \prec r_i$) are assigned to the same cluster as the core point r_j; this may also include sets $r_k \succ r_i$ that have not been processed yet.

Core Status. A set r_i is core if $|N_\epsilon(r_i)| \geq$ minPts. Sym-Clust and Join-Clust have access to the full neighborhood, $N_\epsilon(r_i)$, thus deciding the core status of r_i is trivial. In contrast, Spread sees only the lookahead neighbors, $N_\epsilon^\succ(r_i)$. To identify the core status of r_i, however, additional knowledge about the size of the preceding neighborhood, $N_\epsilon^\prec(r_i)$, is required.

Consider probing $r_i = r_5$ in our running example. According to our assumptions, the core status of sets r_1–r_4 is known (only r_3 is core), and all neighbors of r_3 are in cluster $C_3 = \{r_1, r_3, r_4, r_6, r_7\}$. An index lookup of r_5 returns $N_\epsilon^\succ(r_5) = \{r_9, r_{10}\}$. Since $\left|N_\epsilon^\succ(r_5)\right| + 1 = 3 < 4 =$ minPts we cannot decide if r_5 is core. In fact, r_5 should be classified core since the full neighborhood is $N_\epsilon(r_5) = \{r_2, r_5, r_9, r_{10}\}$ (cf. red circle in Figure 3).

Border vs. Noise. Assume that the current set r_i is a non-core point that is not assigned to any cluster. We need to decide if r_i is border or noise. A border point has at least one core point in its neighborhood. None of the preceding neighbors, $r_j \in N_\epsilon^\prec(r_i)$, is core, otherwise r_i would be assigned to the cluster of r_j. Thus, r_i is core iff one of the lookahead neighbors is core. Unfortunately, we do not know the core status of the lookahead neighbors and can therefore not label r_i as border or noise.

Assume a core point, $r_k \in N_\epsilon^\succ(r_i)$, among the lookahead neighbors of r_i. When r_k is processed, r_k will not see r_i in its lookahead neighborhood since $r_i \prec r_k$. Therefore, r_i will not be included into the cluster of r_k and will wrongly be classified noise. The challenge is to correctly decide the border status of r_i despite seeing only the lookahead neighbors of r_i and r_k.

In our running example, r_1 is processed first. Thus, no core points are known and no clusters exist. $N_\epsilon^\succ(r_1) = \{r_3\}$ and r_1 remains noise (cf. blue circle in Figure 3). When the neighbor r_3 of r_1 is processed, r_3 will be detected as a core point and start a new cluster. However, since r_3 only sees its lookahead neighbors, $N_\epsilon^\succ(r_3) = \{r_4, r_6, r_7\}$, r_1 is not included into the cluster and is not detected as a border point.

Disconnected Clusters. Assume that the current set r_i is core and there is a core point $r_j \prec r_i$ in a cluster C_j, $r_i \notin C_j$. The current set r_i will assign all its lookahead neighbors to its cluster, $C_i = C_i \cup N_\epsilon^\succ(r_i)$ (C_i can be a new cluster started by r_i or an existing cluster to which r_i belongs). Unfortunately, we cannot assume that C_i and C_j are indeed distinct clusters: there can be a core point $r_k \succ r_i$ that density-reaches both r_i and r_j, i.e., C_i and C_j should form a single cluster. In general, multiple subclusters of the same DBSCAN cluster may grow independently. The challenge is to identify subclusters that should be merged and to merge them efficiently.

We process the current set $r_i = r_6$ in our running example. According to our assumptions, we know that r_3 and r_5 are core and we are aware of two clusters, $C_3 = \{r_1, r_3, r_4, r_6, r_7\}$, $C_5 = \{r_2, r_5, r_9, r_{10}\}$. In addition, assume that we know that r_6 is core. Then, r_6 extends its current cluster, C_3, with its lookahead neighbors $N_\epsilon^\succ(r_6) = \{r_8, r_{10}\}$. Note that r_{10} is already part of cluster C_5. Since we do not know the core status of r_{10}, we cannot decide if C_5 and C_3 should be merged into a single cluster. If r_{10} is core, r_5 and r_3 are density-reachable from r_{10} and should be in the same cluster. If r_{10} is a border point, however, the clusters must not be merged, and r_{10} can be assigned to either C_5 or C_3.

4.2 Data Structures

Disjoint-Set. The disjoint-set (or union-find) data structure maintains a dynamic collection of non-overlapping sets for n objects in $O(n)$ space [10, 41]. A typical use case is the efficient computation of (minimum) spanning trees. It supports three operations: (1) For a given element u, make_set(u) creates a new (singleton) set that contains u. (2) The union(u, v) operation merges the two sets that contain u resp. v into a new set. (3) find_set(u) returns the representative for the set that contains u or ∞ if u is not found. The amortized worst-case time complexity is $\Theta(\alpha(n))$ for all operations, $\alpha(.)$ being the inverse Ackermann function. In practice, $\alpha(n)$ is considered a constant. In our setting, set elements are subclusters, and the disjoint-set data structure links subclusters that belong to the same DBSCAN cluster.

Backlinks. The backlinks data structure of a set $r \in R$ is a collection of unique references to other sets s that precede r, $s \prec r$. The backlinks bl support the add operation, $bl \cup \{s\}$, which adds a reference to a new set s in time $O(1)$ (on average). Depending on the type of sets that are referenced in the backlinks, we distinguish core and non-core backlinks, denoted *c_bl* and *nc_bl*, respectively. We implement backlinks as unordered sets of integer identifiers.

4.3 The Algorithm

Algorithm 5 shows the pseudocode of Spread. We use the following notation: r is the current probing set, $s \succ r$ is a lookahead neighbor, and $x \prec r$ is a preceding neighbor. Initially, all sets are noise, i.e., their cluster identifier is $-\infty$, $\forall r \in R : r.cid = -\infty$. Although we initialize all sets in Algorithm 5 explicitly (lines 3–4), this can also be done during indexing (cf. Algorithm 2).

Algorithm Outline. Spread proceeds in three main steps: (1) A counter and the processing order guarantee that the cardinality of the ϵ-neighborhood is known when a set is processed despite using the asymmetric prefix index. (2) Each set is assigned to a subcluster solely based on its lookahead neighboorhood. Subclusters of the same DBSCAN cluster are linked in a subcluster graph. Backlinks ensure that we do not miss border sets or links between subclusters. (3) Each connected component in the subcluster graph represents a DBSCAN cluster.

Core Status. A set r is core if $|N_\epsilon(r)| \geq$ minPts. In Spread, however, only $N_\epsilon^\succ(r)$ is computed. To capture the cardinality of $N_\epsilon^\prec(r)$, we store a density counter with each set r, denoted $r.dens$. Initially, $\forall r \in R : r.dens = 1$. For every lookahead neighbor $s \in N_\epsilon^\succ(r)$, $r.dens$ and $s.dens$ are incremented (due to the symmetry of the distance). Core set identification is highlighted in green.

Border vs. Noise. A probing set r that is not core is a border set iff $\exists y \in N_\epsilon(r) : y$ is core. Due to our processing order and the fact that only $N_\epsilon^\succ(r)$ is computed, the existence of a core neighbor y may be unknown when r is probed. However, for each $s \in N_\epsilon^\succ(r)$, we know that r is part of $N_\epsilon^\prec(s)$. We store this information by adding r to the non-core backlinks $nc\_bl[s]$ of each $s \in N_\epsilon^\succ(r)$ (lines 31–33). Then, the first $s \in N_\epsilon^\succ(r)$ that becomes core claims r (and all other unassigned sets in $nc\_bl[s]$) as border point for its subcluster. If none of the neighbors $s \in N_\epsilon^\succ(r)$ becomes core, then r remains noise. Lines 26–30 deal with a special case: If any $s \in N_\epsilon^\succ(r)$ is already core when r is probed, then s claims r immediately without adding r to its non-core backlinks. The relevant code lines are marked in red.

Subcluster Linkage. If the probing set r is core and a core neighbor y is part of another subcluster, the subclusters of r and y must be linked in our subcluster graph. The subcluster graph represents all connected components of subclusters, each of which is

a DBSCAN cluster. We use the disjoint-set data structure ds to track the connected components. Two subclusters u, v are linked by $ds.\text{union}(u, v)$. We may not be able to determine if there is a set $s \in N_\epsilon^\succ(r)$ that is core before s is probed. We use the core backlinks, c_bl, to book-keep potential subclusters for linkage: r adds its subcluster identifier to $c\_bl[s]$ of each $s \in N_\epsilon^\succ(r)$ (lines 22-23). After $N_\epsilon^\succ(r)$ has been processed, a link between the subcluster of r and every entry in $c\_bl[r]$ is created (line 24). The special case when s is already core allows us to create the link immediately without using core backlinks (lines 20–21). Linkage is only required if two subclusters coalesce (condition in line 19). Otherwise, r simply claims $s \in N_\epsilon^\succ(r)$ for its subcluster (lines 17–18). Linkage of subclusters is highlighted in blue ▢.

All backlinks of r are released after r has been processed to save memory (line 34). The subcluster graph in ds is used to assign consistent cluster IDs in a final scan over R (lines 35–36).

4.4 Correctness

We show that Algorithm 5 partitions R into DBSCAN clusters (cf. Definition 2.1). Set $r_i \in R$ is the i-th set of R in processing order. We prove the correctness by induction over i and increasing subsets $R^i \subseteq R$. $R^0 = \emptyset$, $R^i = R^{i-1} \cup \{r_i\} \cup N_\epsilon^\succ(r_i)$ for $1 \leq i \leq n = |R|$, thus $R^n = R$. Due to space constraints, we omit the full proofs and only provide the invariants that must be shown.

Core Status. The core status of set r_i is determined in the i-th iteration of the main loop. r_i is core if $\text{minPts} \leq |N_\epsilon(r_i)| = 1 + \left|N_\epsilon^\prec(r_i)\right| + \left|N_\epsilon^\succ(r_i)\right|$. In line 5, $r_i.dens = 1 + \left|N_\epsilon^\prec(r_i)\right|$. Lines 6–11 compute $N_\epsilon^\succ(r_i)$. The index lookup in line 6 returns candidate set M, $N_\epsilon^\succ(r_i) \subseteq M \subseteq \{s \mid s \succ r_i\}$. Every set $s \in M$ is verified in line 9 such that $N_\epsilon^\succ(r_i)$ is available starting from line 12.

Lemma 4.1. *Algorithm 5 correctly identifies* all *core sets in R.*

Proof Sketch. We show that at the start of the i-th iteration in line 5, for all r_k and r_j, $1 \leq k < i \leq j$ the following invariants hold: (I1) $r_k.dens = |N_\epsilon(r_k)|$; (I2) $r_j.dens = 1 + \left|\{r_k \mid r_j \in N_\epsilon^\succ(r_k)\}\right|$, i.e., $r_i.dens = 1 + \left|N_\epsilon^\prec(r_i)\right|$. Further, (I3) in line 12 of the i-th iteration, $r_i.dens = |N_\epsilon(r_i)|$, i.e., Algorithm 5 correctly identifies the core status of r_i. □

Border vs. Noise. Lines 25–33 cover the case that r_i is not core. If any $s \in N_\epsilon^\succ(r_i)$ qualifies as core, s claims r_i. Otherwise, r_i is stored in the non-core backlinks $nc\_bl[s]$ of every $s \in N_\epsilon^\succ(r_i)$ (lines 31–33). The next core neighbor in processing order claims r_i (lines 14–15) such that all border sets are assigned to a cluster.

Lemma 4.2. *Algorithm 5 correctly clusters* all *border sets in R.*

Proof Sketch. At the start of the i-th iteration, the following invariant holds for all border sets $r_k \in \mathcal{B}$, $1 \leq k < i$: if r_k is not stored in $nc\_bl[s]$ for any $s \in N_\epsilon^\succ(r_k)$, $s = r_i$ or $s \succ r_i$, then r_k is assigned to the cluster of a core point in its neighborhood. □

Subcluster Linkage. Lines 12–24 cover the case that r_i is core. Each core point may form a subcluster on its own or together with other core points. We must ensure that all subclusters of the same DBSCAN cluster are linked in the disjoint-set, ds.

Lemma 4.3. *Algorithm 5 correctly links* all *subclusters in R.*

Proof Sketch. At the start of the i-th iteration, the following invariant holds for all core neighors $c \in CN(r_k) = N_\epsilon(r_k) \cap C$ of a core set $r_k \in C$, $1 \leq k < i$: (a) c and r_k have the same cluster representative (in ds), or (b) c is stored in some $c\_bl[s]$, $s \in N_\epsilon^\succ(r_k)$, $s = r_i$ or $s \succ r_i$. □

Algorithm 5: Spread(R, ϵ, minPts)

Input: Collection of sets R, distance threshold ϵ, min. density minPts
Result: A correct DBSCAN clustering of R w.r.t. ϵ, minPts

```
1  ds ← new disjoint-set; nc_bl, c_bl ← new backlinks;
2  I ← Create-Index(R, ε);
3  foreach r ∈ R do
4      r.dens ← 1; r.cid ← −∞; ds.make_set(r.id);
5  foreach r ∈ R in processing order do
6      M ← Probe(r, I, ε);
7      N_ε^≻(r) ← ∅;
8      foreach (s, po) ∈ M do // po ... prefix overlap
9          if Verify-Pair(r, s, ε, po) then
10             r.dens ← r.dens + 1; s.dens ← s.dens + 1;
11             N_ε^≻(r) ← N_ε^≻(r) ∪ {s};
12     if r.dens ≥ minPts then // r is core
13         if r.cid = −∞ then r.cid ← r.id;
14         foreach x ∈ nc_bl[r] do // claim border sets x ≺ r
15             if x.cid = −∞ then x.cid ← r.cid;
16         foreach s ∈ N_ε^≻(r) do // s ≻ r
17             if s.cid = −∞ then // claim unclaimed s ≻ r
18                 s.cid ← r.cid
19             else if r.cid ≠ s.cid then // s already claimed
20                 if s.dens ≥ minPts then // s is core
21                     ds.union(r.cid, s.cid) // link subclusters
22                 else // remember core neighbor r
23                     c_bl[s] ← c_bl[s] ∪ {r.cid}
24         foreach x ∈ c_bl[r] do ds.union(r.cid, x);
25     else // r is not core, i.e., r.dens < minPts
26         if r.cid = −∞ then // claim potential border set r
27             foreach s ∈ N_ε^≻(r) do
28                 if s.dens ≥ minPts then // s is core
29                     if s.cid = −∞ then s.cid ← s.id;
30                     r.cid ← s.cid; break;
31         if r.cid = −∞ then // remember potential border set r
32             foreach s ∈ N_ε^≻(r) do
33                 nc_bl[s] ← nc_bl[s] ∪ {r}
34     release c_bl[r] and nc_bl[r] // not needed anymore
35 foreach r ∈ R do // final assignment of cluster IDs
36     if r.cid ≠ −∞ then r.cid ← ds.find_set(r.cid);
```

Theorem 4.4. *Algorithm 5 returns a correct set clustering* $\Gamma = \{C_1, C_2, \ldots, C_k\}$ *of R according to Definition 2.1.*

Proof Sketch. By Lemmata 4.1–4.3 and due to our final scan over R (lines 35–36), $x.cid = ds.\text{find\_set}(x.cid)$ holds for all $x \in R$. Initially, $x.cid = -\infty$ for all $x \in R$. The cluster IDs are updated only for border and core sets. Consequently, $x.cid = -\infty$ holds for all $x \in R \setminus (C \cup \mathcal{B}) \equiv \mathcal{N}$, i.e., also noise is correctly identified. □

4.5 Complexity Analysis

Memory. The asymmetric prefix index requires $O(n)$ space. In addition, Spread maintains the following data structures. (i) A density counter for each set $r \in R$ requires $O(n)$ space. (ii) A disjoint-set data structure with at most $O(n)$ entries, i.e., the disjoint-set structure requires $O(n)$ space [41]. (iii) In the worst case, we allocate two backlink structures for each $r \in R$, i.e., $O(n)$ backlinks. We release $c\_bl[r]$ and $nc\_bl[r]$ after probing r. Backlinks are only extended in lines 23 and 33. However, both lines are executed iff $\nexists s \in N_\epsilon^>(r) : s$ is core. Set s is core iff $s.dens \geq$ minPts, and the density is updated for every neighbor, therefore any backlink holds at most minPts entries. As a result, no more than $O(n \cdot \text{minPts})$ entries are allocated, thus requiring $O(n)$ space since minPts and ϵ are constants. *Runtime.* For each $r \in R$, we process $O\left(\left|N_\epsilon^>(r)\right|\right)$ neighbors and the backlinks of r if it is core. Recall that the disjoint-set operations take constant time. Therefore, the final for-loop (lines 35–36) runs in $O(n)$ time. Overall, Spread runs in $O\left(n^2\right)$ time and $O(n)$ space.

4.6 Multi-core Extension

Spread is designed as a single-core algorithm. We sketch an extension to multi-core processors that requires little synchronization between threads. Our extension is based on the observation that Spread spends most of the runtime in neighborhood computations (lines 6-11). While for some datasets the neighborhood computation accounts for only about half of the overall runtime (e.g., 55% for ORKUT, $\epsilon = 3$), for the configuration with the highest runtime in our experiments (CELONIS1, $\epsilon = 5$), Spread spends over 99% of the runtime in computing the neighborhoods.

We distribute the workload to $k + 1$ threads, $T_1, T_2, \ldots, T_{k+1}$. Threads $T_1 - T_k$ are responsible for the neighborhood computations (lines 6-11), T_{k+1} performs the actual clustering (lines 12-34). The runtime of the other steps in the algorithm is negligible.

Neighborhood Computation. Let $r_i \in R$, $1 \leq i \leq |R|$ be the i-th set of R in processing order. Thread T_j, $1 \leq j \leq k$, computes the neighborhoods $N_\epsilon^>(r_i)$ of all r_i with $j = i \mod k$ (i.e., round robin). Each thread processes the assigned sets r_i in processing order (i.e., increasing values of i). The neighborhood computation in Algorithm 5 is interleaved with updating the density counters of r_i and its neighbors. Only this step requires synchronization (e.g., using atomic writes) since multiple threads may access the same counter concurrently. We do not expect congestions since the density updates are distributed over all neighbors.

Cluster Scan. Thread T_{k+1} scans the sets in processing order and performs the steps in lines 12-34 (maintain backlinks and disjoint-set, assign preliminary cluster IDs). After processing a set r_i, the memory for the neighbors of r_i is released.

Synchronization. We need to make sure that T_{k+1} processes set r_i only after r_i's neighbors have been computed. This can be achieved with a lock (implemented as condition variable[2]) on r_i that is held by T_j, $j \leq k$, until the neighborhood of r_i is computed. T_{k+1} needs to get the lock on r_i before processing it.

Memory. T_{k+1} releases the neighbors after processing them. If the parallel neighborhood computation is faster than T_{k+1}, the precomputed neighborhoods will fill up the memory. This is avoided with a shared counter that is incremented by $T_1 - T_k$ (when they process a new set r_i) and is decremented by T_{k+1} (after processing r_i). The neighborhood computation of r_i is postponed until the counter is below some threshold that bounds the number of concurrently materialized lookahead neighborhoods.

[2] A queue of threads waiting for a condition to become true.

Table 2: Characteristics of datasets.

Dataset	Coll. Size	Set Size		Univ. Size
		avg.	max.	
BMS-POS[4]	$3.2 \cdot 10^5$	9.3	164	$1.7 \cdot 10^3$
FLICKR[5]	$1.2 \cdot 10^6$	10.1	102	$8.1 \cdot 10^5$
KOSARAK[6]	$6.1 \cdot 10^5$	11.9	$2.5 \cdot 10^3$	$4.1 \cdot 10^4$
LIVEJ[7]	$3.1 \cdot 10^6$	36.4	300	$7.5 \cdot 10^6$
ORKUT[7]	$2.7 \cdot 10^6$	119.7	$4.0 \cdot 10^4$	$8.7 \cdot 10^6$
SPOT[8]	$4.4 \cdot 10^5$	12.8	$1.2 \cdot 10^4$	$7.6 \cdot 10^5$
CELONIS1	$8.2 \cdot 10^6$	20.3	91	$1.2 \cdot 10^4$
CELONIS2	$2.6 \cdot 10^6$	22.1	130	$3.5 \cdot 10^3$

5 EXPERIMENTAL EVALUATION

Algorithms. We compare our solution, Spread, against the two baseline approaches Sym-Clust and Join-Clust (cf. Section 3). All algorithms are single-threaded C++ implementations (2017 standard). Our implementations of Spread, Join-Clust, and the index of Sym-Clust follow the guidelines by Mann et al. [29], e.g., regarding symmetric and asymmetric prefix index, candidate generation, and optimized prefix-based verification.

Datasets. We execute all experiments on 13 real-world datasets: (a) Nine of the datasets where previously used for benchmarking set similarity joins [16, 29]: BMS-POS, DBLP, ENRON, FLICKR, KOSARAK, LIVEJ, NETFLIX, ORKUT, and SPOT. For a description of the datasets and preprocessing instructions[3] we refer to Mann et al. [29]. (b) Four large real-world datasets from the process mining domain, CELONIS1–4, that store one set per process. Compared to most datasets of the join benchmark, the universe size of these datasets is rather small. Table 2 summarizes important characteristics of our benchmark data.

Due to space constraints we omit detailed results for the following datasets: (a) DBLP, ENRON, and NETFLIX show very low runtimes (< 4s) and a small and stable memory footprint (< 1GiB) for all algorithms and configurations. (b) CELONIS3–4 show results similar to the other process mining datasets.

Parameters. The algorithms take two parameters: the neighborhood radius, ϵ, and the density, minPts. Typically, density-based clustering is sensitive to ϵ and quite robust to minPts. In our experiments, we vary both parameters: $\epsilon \in \{2, \mathbf{3}, 4, 5\}$ and minPts $\in \{2, 4, 8, \mathbf{16}, 32, 64, 128\}$ (defaults in bold font).

Environment. All experiments have been conducted on a 64-bit machine with 2 physical Intel Xeon E5-2630 v3 CPUs, 2.40GHz, 8 cores each (i.e., 16 logical processors, hyper-threading disabled). The cores share a 20MiB L3 cache and have another 256KiB of independent L2 cache. The system has 96GiB of RAM and runs Debian 10 Buster (Linux 4.19.0-12-amd64 #1 SMP Debian 4.19.152-1 (2020-10-18)). Our code is compiled with `clang`[9] version 7, highest optimization level (`-O3`). The runtime is measured with `clock_gettime`[10] at process level, memory usage is the `heap`

Table 3: Index & cluster statistics for $\epsilon = 3$, minPts = 16.

(a) BMS-POS.

	Candidates	True Positives	Clusters
Sym-Clust	$3.9 \cdot 10^9$	$38.0 \cdot 10^6$	1
Join-Clust	$640.0 \cdot 10^6$	$38.0 \cdot 10^6$	1
Spread	$640.0 \cdot 10^6$	$38.0 \cdot 10^6$	1

(b) KOSARAK.

	Candidates	True Positives	Clusters
Sym-Clust	$40.7 \cdot 10^9$	$2.8 \cdot 10^9$	5
Join-Clust	$7.0 \cdot 10^9$	$2.8 \cdot 10^9$	5
Spread	$7.0 \cdot 10^9$	$2.8 \cdot 10^9$	5

(c) CELONIS1.

	Candidates	True Positives	Clusters
Sym-Clust	$644.6 \cdot 10^9$	$7.4 \cdot 10^6$	5,075
Join-Clust	$131.5 \cdot 10^9$	$7.4 \cdot 10^6$	5,075
Spread	$131.5 \cdot 10^9$	$7.4 \cdot 10^6$	5,075

peak of Linux `memusage`[11] (using `LD_PRELOAD`). A single instance is executed at a time with no other load on the machine.

5.1 Index & Cluster Statistics

We compare the number of candidates, true positives, and the number of clusters. The numbers are sums over all region queries. Table 3 shows the results obtained for BMS-POS, KOSARAK, and CELONIS1. We observe that Spread produces exactly the same number of candidates as Join-Clust since both solutions use the asymmetric index. Sym-Clust generates significantly more candidates due to the symmetric prefix index and the symmetric distance computations. For CELONIS1, Spread and Join-Clust verify about 5 times fewer candidates compared to Sym-Clust.

5.2 Runtime Efficiency

We measure the overall runtime, i.e., the CPU time that is required to cluster all sets into DBSCAN clusters (excluding the time to load the data from disk). Figure 7 shows the results for varying ϵ (minPts = 16). We observe that Sym-Clust is not competitive in terms of overall runtime in most cases. For all datasets, except KOSARAK and SPOT, the runtime of Sym-Clust increases much faster with ϵ than observed for Join-Clust and Spread. This is mainly due to the use of the symmetric prefix index (more candidates) and redundant computations (symmetric pairs).

Our experiments reveal that Join-Clust suffers from the following issues: (i) High runtimes for LIVEJ, ORKUT, and SPOT due to the expensive neighborhood materialization. (ii) Join-Clust runs out of memory for many instances (missing points in plots), in particular for FLICKR (any ϵ), KOSARAK ($\epsilon \geq 4$), LIVEJ, ORKUT, and SPOT ($\epsilon \geq 3$).

Spread outperforms its competitors in most settings and is competitive with Join-Clust otherwise (cf. Figures 7a, 7g, and 7h). For CELONIS1 and CELONIS2, Spread outperforms Sym-Clust by almost an order of magnitude and is competitive with Join-Clust.

Figure 8 shows the runtime results for varying minPts values ($\epsilon = 3$). We observe that the runtime of all three solutions is quite robust to minPts. The insights are similar for all datasets and values of ϵ. We include the plots for BMS-POS and KOSARAK.

[11] https://man7.org/linux/man-pages/man1/memusage.1.html

5.3 Memory Efficiency

We study the memory usage of Join-Clust, Sym-Clust, and Spread. All three solutions store (i) the collection, (ii) the inverted index, (iii) the candidates, and (iv) the result of a region query on the heap. The symmetric prefix index of Sym-Clust is larger than the asymmetric index, but still linear in the collection size. Sym-Clust generates more candidates than Join-Clust and Spread (cf. Section 5.1), which both use the asymmetric prefix index . Join-Clust materializes all neighborhoods in main memory. Sym-Clust and Spread materialize only a single neighborhood at a time. Spread stores also backlinks and the disjoint-set in main memory.

Figure 11 shows our results for varying ϵ (minPts = 16, y-axis log scale). Join-Clust runs out of memory for many instances (cf. Section 5.2). The neighborhood materialization in Join-Clust can be memory intensive even for small values of ϵ. We observe different growth rates with increasing radius ϵ, which we attribute to the different neighborhood sizes. The memory consumption of Sym-Clust is significantly lower and robust to varying ϵ. Spread shows a similar behavior. In some cases (e.g., LIVEJ, ORKUT), Spread occupies even less memory than Sym-Clust. When few backlinks are materialized, the smaller asymmetric prefix index of Spread outweighs the storage overhead for the backlinks.

Figure 12 shows the memory usage over minPts ($\epsilon = 3$, log-log scale). The memory consumption of Sym-Clust and Join-Clust is stable w.r.t. increasing values of minPts, while the memory usage of Spread slightly increases. This is due to the number of concurrently stored backlinks: the larger minPts, the higher the chance that a succeeding core neighbor is not yet classified, which triggers the creation of a backlink entry. The memory grows slowly with increasing minPts and does not limit the scalability of Spread. We include the results for BMS-POS and KOSARAK, $\epsilon = 3$; other datasets and ϵ values show similar results.

Backlinks Peak. We evaluate the effect of releasing the backlinks of a set in Spread after the set has been processed (cf. line 34, Algorithm 5). Figures 10 and 14 show the peak number of allocated backlinks relative to the maximum number of backlinks for varying ϵ (minPts = 16) and minPts ($\epsilon = 3$), respectively. Since two backlink structures, core (green) and non-core (orange), are maintained for each set in R, at most $2|R|$ backlinks can be allocated (light blue). Deallocating the backlinks of probed sets is highly effective: Only a small fraction of the maximum number of backlinks is allocated at any point in time. For increasing values of ϵ and minPts also the number of allocated backlinks grows.

5.4 Scalability

We evaluate the scalability of Spread and its competitors to increasing data sizes. To this end, we increase the size of BMS-POS and KOSARAK using the procedure of Vernica et al. [42]. This approach does not affect the token universe, and the number of similar pairs in the dataset increases linearly with the data size.

Figure 9 (runtime) and Figure 13 (main memory) report the results for our default parameter setting. Spread shows runtimes similar to Join-Clust and outperforms Sym-Clust by a factor of about 12 (BMS-POS) resp. 5.7 (KOSARAK) on the largest dataset (×16). As we increase BMS-POS by a factor of 16, the runtime increases by a factor of 195 for Spread, 204 for Join-Clust, and 460 for SymClust. The memory grows linearly for all measured data points and increases by a factor of about 2 when we double the data size. Join-Clust requires 18-25 (BMS-POS) resp. 499-569 (KOSARAK) times more memory than its competitors and runs out of memory on KOSARAK except for the ×1 dataset.

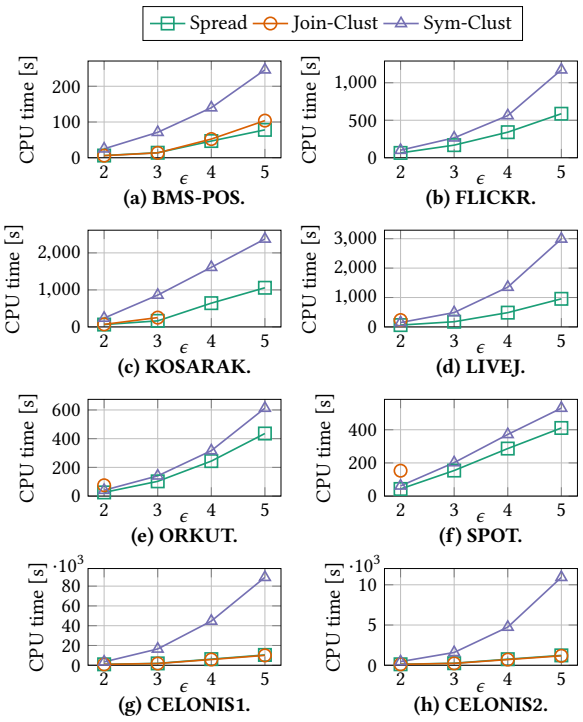

Figure 7: Runtime over ϵ, minPts = 16.

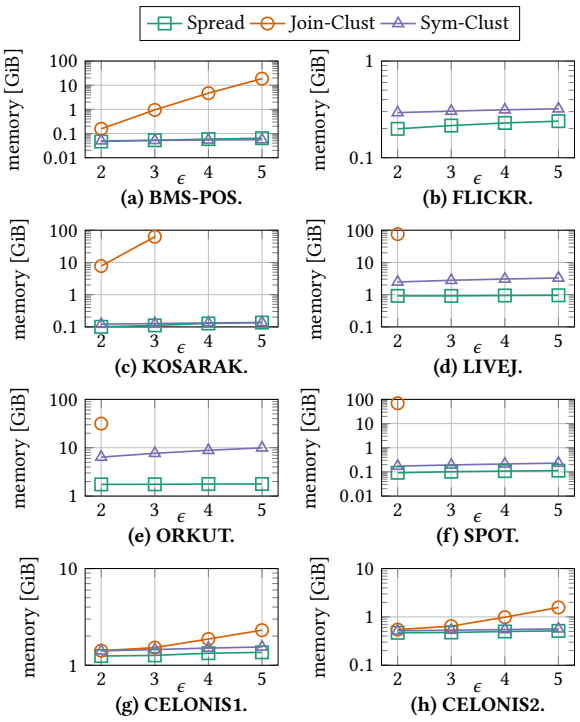

Figure 11: Main memory over ϵ, minPts = 16.

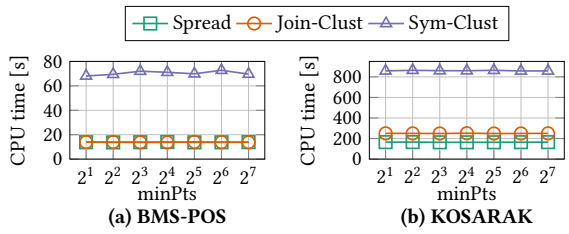

Figure 8: Runtime over minPts, ϵ = 3.

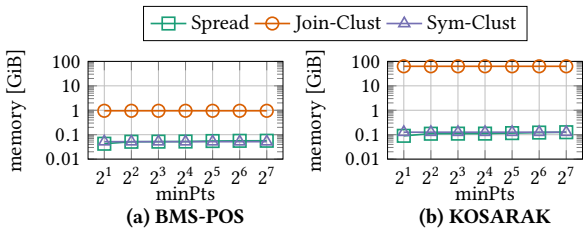

Figure 12: Main memory over minPts, ϵ = 3.

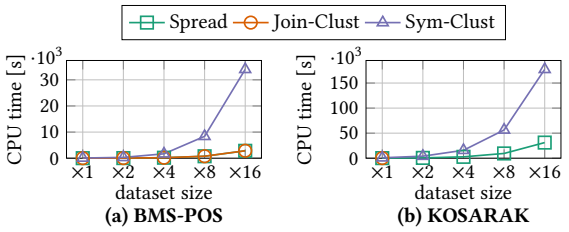

Figure 9: Runtime over data size, ϵ = 3, minPts = 16.

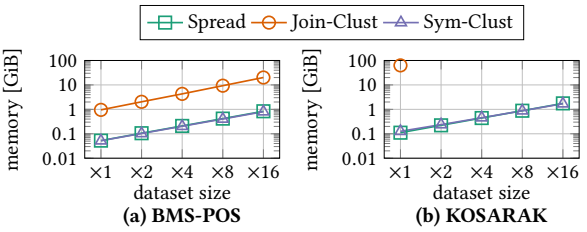

Figure 13: Main memory over data size, ϵ = 3, minPts = 16.

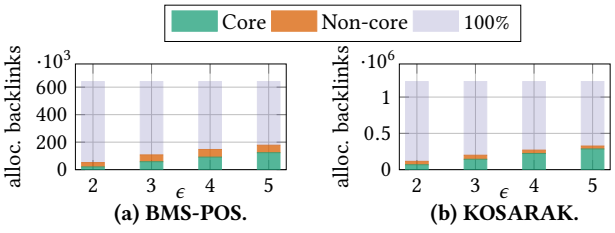

Figure 10: Backlinks peak over ϵ, minPts = 16.

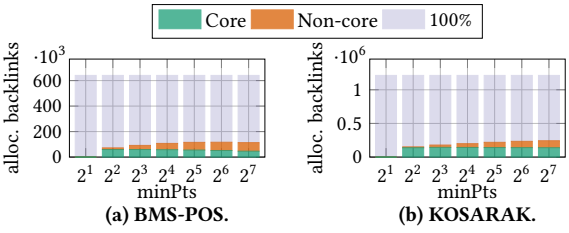

Figure 14: Backlinks peak over minPts, ϵ = 3.

Summarizing, Spread clearly outperforms Sym-Clust in runtime (by a factor of 5-12) and Join-Clust in memory usage (by more than an order of magnitude) as we increase the data size.

6 RELATED WORK

Indexes for Sets. Most set similarity joins operate on an inverted list index that maps signatures to candidate sets. Various signatures have been proposed [2, 8, 40, 45]. Prefixes [8] in conjunction with the length filter [1] have been shown to prune sets effectively. More sophisticated filters include positional and suffix filter [49], the removal filter [35], the position-enhanced length filter [28], and the adaptive prefix filter [44]. Wang et al. [46] leverage the similarity of the sets in an ϵ-neighborhood to reduce the overall number of false positives. Dong et al. [13] propose a size-aware algorithm that runs in $o(n^2) + O(k)$ time for k result pairs. Qin and Xiao [34] propose the pigeonring, a generalization of the pigeonhole principle that yields stronger constraints. Indexing and join techniques for sets have been studied extensively in the single-machine [29] and the distributed context [16].

Most of these approaches focus on self-joins, which order the sets and compute the lookahead neighborhood to avoid symmetric distance computations. In our work, we use the prefix filter, but any of the other asymmetric indexes is applicable.

Efficient Region Queries. Ester et al. [15] propose the first exact DBSCAN algorithm with $O(n \log n)$ runtime for vectors of arbitrary dimension. $O(n \log n)$ runtime holds for a small number of neighbors (compared to n) and an index with $O(\log n)$ lookup time. Henceforth, efficient region query computation has been of great interest and many improvements have been proposed. Brecheisen et al. [7] use minPts-nearest neighbor queries to identify core points and postpone the other distance computations until the distances are required to get a correct DBSCAN clustering. The proposed *Xseedlist* data structure is designed for expensive distance functions and assumes a cheap but selective filter. These assumptions do not hold for sets: The verification (i.e., distance computation) of candidate pairs has shown to be highly efficient [29] (a small number of integer comparisons). Brecheisen et al. must insert the candidates into the Xseedlist data structure, which maintains sorted lists of candidates. Due to the expensive sorting procedure, we do not expect Xseedlist to improve the DBSCAN algorithm for sets. TI-DBSCAN [25] exploits the triangle inequality to reduce the search space of region queries. The solution is not index-based, sorts the points w.r.t. a reference point, and shifts a window of size 2ϵ over the sorted points. The reference point is the point with minimal values in all dimensions. This is equivalent to the empty set, and our processing order in combination with the prefix index for sets subsumes this technique. Patwary et al. [32] introduce PARDICLE, a parallel approximate density-based clustering algorithm for Euclidean space. Its aim is to reduce the neighborhood computation time by sampling high-density regions. Kumar and Reddy [26] propose a new graph-based index structure called Groups. It discovers groups of patterns in two scans over the dataset and applies a standard DBSCAN afterwards. Groups accelerates region queries by pruning noise points effectively. This technique assumes Euclidean distance and does not consider Hamming distance or other set similarity measures. Recently, Jiang et al. [24] proposed SNG-DBSCAN, which prevents the computation of the full ϵ-neighborhood graph via subsampling its edges. This results in $O(sn^2)$-time complexity with s being the sampling rate. Under certain distribution assumptions, SNG-DBSCAN has been shown to preserve the exact ϵ-neighborhood graph for $s \approx (\log n)/n$ with $O(n \log n)$ runtime.

DBSCAN Techniques. Yang et al. [51] propose the distributed DBSCAN-MS clustering algorithm for metric spaces. DBSCAN-MS uses pivots to map the data from metric space to vector space, where it is partitioned in order to be distributed. A local DBSCAN is then executed on each partition. Our solution does not rely on the metric properties of set distances, but uses specialized set indexes. However, our techniques may be leveraged in the context of DBSCAN-MS, where the data points are ordered by one of the dimensions for efficient neighborhood queries.

Patwary et al. [31] propose PDSDBSCAN, a parallel DBSCAN algorithm that uses the disjoint-set data structure to connect data points into clusters. We only insert links between subclusters into the disjoint-sets structure, while PDSDBSCAN inserts a link for each neighbor, rendering the number of required union operations a bottleneck for this approach.

Böhm et al. [3] use a block-nested loop join and buffer the join result to reduce the number of block accesses required to compute ϵ-neighborhoods. CUDA-DClust [4] is a GPU-based solution that splits clusters into chains that are expanded from different starting points in parallel. In order to merge chains into clusters, a quadratic-size bit matrix is used. We maintain only a linear number of links and leverage disjoint-sets to merge clusters. Incremental DBSCAN algorithms [14] deal with updates on an existing clustering. Similar to our approach, these techniques may need to merge clusters when new points are inserted. None of the above solutions supports asymmetric neighborhood indexes.

Numerous parallel and distributed algorithms [9, 11, 18–21, 23, 36, 38, 47, 50] as well as approximations [17, 27, 43, 48] have been proposed. We present an exact, single-core solution for sets.

7 CONCLUSION

In this paper, we have investigated clustering techniques for large collections of sets. Our work was motivated by an application in process mining that models processes as sets to assess their similarity. We have shown that the solutions that are currently available, Sym-Clust and Join-Clust, are not satisfying: Sym-Clust is slow since it cannot use effective asymmetric set indexes, while Join-Clust is infeasible for many settings due to its excessive memory usage. We introduced a novel, density-based clustering algorithm, Spread, that can process data points in any user-defined order and is therefore fit for the use with asymmetric indexes. Spread combines the best of both worlds: It uses the effective asymmetric index of Join-Clust, but like Sym-Clust does not need to materialize the neighborhoods. We introduced so-called backlinks to guarantee a correct DBSCAN clustering and showed the correctness of our approach. To the best of our knowledge, Spread is the first DBSCAN-compliant algorithm that uses an asymmetric index and runs in linear space.

Spread uses the index as a black box and works with any data type. Interesting future work includes evaluating the performance of Spread for vector data, where candidates are generated using a sliding window that is shifted along one dimension. The data points in the window are candidates, i.e., the window simulates an asymmetric index for Spread.

ABSTRACT

Assessment is the process of comparing the actual to the expected behavior of a business phenomenon and judging the outcome of the comparison. In this paper we propose assess, a novel querying operator that supports assessment based on the results of a query on a data cube. This operator requires (1) the specification of an OLAP query over a measure of a data cube, to define the target cube to be assessed; (2) the specification of a reference cube of comparison (benchmark), which represents the expected performance of the measure; (3) the specification of how to perform the comparison between the target cube and the benchmark, and (4) a labeling function that classifies the result of this comparison using a set of labels. After introducing an SQL-like syntax for our operator, we formally define its semantics in terms of a set of logical operators. To support the computation of assess we propose a basic plan as well as some optimization strategies, then we experimentally evaluate their performance using a prototype.

1 INTRODUCTION

Assume an analyst wants to *assess* the state of milk sales in France for 2019. She will have to issue a query against an OLAP server to obtain a cube, and then ask: "how good, normal, surprising, etc. is the situation I observe for this particular cube as compared to some reference data?". Assessment, as a process, is about comparing the actual to the expected behavior and judging, for instance through a *labeling*, the outcome of the comparison. Examples of how to assess the status of a cube (or of each single cell of a cube) include its comparison to:

(1) ...a predefined target goal for the sales, e.g., because of the existence of a predefined KPI (Key Performance Indicator);
(2) ...a predefined golden standard, acting as a reference benchmark (e.g., comparing French milk sales against the EU average) or, as an example in another domain, comparing a stock value to the S&P 500 index);
(3) ...sibling cells, i.e., cells describing a similar context and sharing some dimension values (i.e., compare sales for yogurt and ice-cream in Greece in 2019, or milk sales in Spain and Italy for 2019);
(4) ...the expected status of the cube as can be predicted from the past (e.g., compare actual milk sales in December 2018 with those that can be predicted from the sales of the previous six months).
(5) ...a new, derived measure produced via a function whose formula involves other measures (e.g., profit=storeSales-storeCost).

This kind of tabular data assessment is consistently reported as a frequent activity of data explorers [3, 12, 23] who often use SQL in combination with languages like Python and R. Noticeably, assessment is one of the user's intentions considered in the *Intentional Analytics Model* (IAM), which has been envisioned as a way to tightly couple OLAP and analytics [4, 21]. The IAM approach relies on two major cornerstones: (i) the user explores the data space by expressing her analysis *intentions* rather than by explicitly stating what data she needs, and (ii) in return she receives both multidimensional data and knowledge insights in the form of annotations of interesting subsets of data. Among the five intention operators proposed, assess is meant to judge a cube measure with reference to some baseline.

In this paper we adopt the OLAP-centered nature of the IAM and operate in the context of a traditional OLAP environment with cubes, dimensions, hierarchies, and measures. This allows us to take advantage of the neat logical-level schema structure of OLAP and focus on the essence of the paper, which is proposing an assess operator to complement the traditional OLAP roll-up's and drill-down's. The idea of how to perform an assessment for the measure values of a cube encompasses (a) the specification of another cube, called *benchmark*, that represents the expected or desirable performance of the measure; (b) the *comparison* of the measure under investigation to the benchmark measure (for instance via a simple mathematical difference); and (c) the characterization, or *labeling*, of the status of the original cell based on the result of the comparison.

Example 1.1. Given a SALES cube, the user's intention described above can be expressed with this statement:

```
with SALES
for year = '2019', product = 'milk'
by year, product
assess quantity against 1000
using ratio(quantity, 1000)
labels {[0, 0.9): bad, [0.9, 1.1]: acceptable, (1.1,inf): good}
```

Intuitively, the total quantity of milk sold in France in 2019 is labeled as bad/acceptable/good depending on the ratio with the target value 1000. □

Summary of contributions. Our contributions can be listed as follows:

- We introduce a novel operator, assess, that allows to automatically evaluate and characterize the result of a cube query.

- We introduce alternatives for specifying benchmarks, comparison, and labeling schemes against which the results of a cube query can be compared and evaluated. For each alternative we provide rigorous definitions and semantics, based on a set of logical operators, as well an SQL-like syntax for the specification of an assess statement.
- We discuss alternative plans for the execution of assess statements and experimentally evaluate them for their efficiency and scalability.

Roadmap. In Section 2 we formalize the involved concepts and give definitions. In Section 3 we explain how assessments are computed and introduce the alternatives of the assess operator, while in Section 4 we provide its syntax and semantics. In Section 5 we present alternative strategies for query execution and in Section 6 we experimentally evaluate them. In Section 7 we discuss the related work. Finally, in Section 8 we summarize our findings and discuss our future work.

2 FORMALITIES

To simplify the formalization, we will restrict to consider linear hierarchies.

Definition 2.1 (Hierarchy and Cube Schema). A *hierarchy* is a triple $h = (L, \geq, \geq)$ where:

(i) L is a set of categorical *levels*, each coupled with a *domain* of values (a.k.a. as *members*), $Dom(l)$;
(ii) $\geq$ is a *roll-up* total order of L; and
(iii) $\geq$ is a *part-of* partial order of $\bigcup_{l \in L} Dom(l)$.

The part-of partial order is such that, for each couple of levels l and l' such that $l \geq l'$, for each member $u \in Dom(l)$ there is exactly one member $u' \in Dom(l')$ such that $u \geq u'$.

A *cube schema* is a couple $C = (H, M)$ where:

(i) H is a set of hierarchies;
(ii) M is a tuple[1] of numerical measures, each coupled with one aggregation operator $op(m) \in \{\mathsf{sum}, \mathsf{avg}, \ldots\}$.

Example 2.2. As a working example we will use cube schema SALES $= (H, M)$, where

$$H = \{h_{\mathsf{Date}}, h_{\mathsf{Customer}}, h_{\mathsf{Product}}, h_{\mathsf{Store}}\},$$
$$M = \langle \mathsf{quantity}, \mathsf{storeSales}, \mathsf{storeCost} \rangle,$$
$$\mathsf{date} \geq \mathsf{month} \geq \mathsf{year},$$
$$\mathsf{customer} \geq \mathsf{gender},$$
$$\mathsf{product} \geq \mathsf{type} \geq \mathsf{category},$$
$$\mathsf{store} \geq \mathsf{city} \geq \mathsf{country}$$

and $op(\mathsf{quantity}) = op(\mathsf{storeSales}) = op(\mathsf{storeCost}) = \mathsf{sum}$. As to the part-of partial order we have, for instance, Fresh Fruit $\geq$ Fruit and 1997-04-15 $\geq$ 1997. □

Aggregation is the basic mechanism to query cubes, and it is captured by the following definition of group-by set. As normally done when working with the multidimensional model, if a hierarchy h does not appear in a group-by set it is implicitly assumed that a complete aggregation is done along h.

Definition 2.3 (Group-by Set and Coordinate). Given cube schema $C = (H, M)$, a *group-by set* of C is a tuple of levels, at most one from each hierarchy of H. The partial order induced on the set of all group-by sets of C by the roll-up orders of the hierarchies in H, is denoted with $\geq_H$. A *coordinate* of group-by set G is a tuple of members, one for each level of G. Given coordinate γ of group-by set G and another group-by set G' such that $G \geq_H G'$, we will denote with $rup_{G'}(\gamma)$ the coordinate of G' whose members are related to the corresponding members of γ in the part-of orders, and we will say that γ *roll-up*s to $rup_{G'}(\gamma)$. By definition, $rup_G(\gamma) = \gamma$.

Definition 2.4 (Detailed Cube). Let G_0 be the top group-by set in the $\geq_H$ partial order (i.e., the finest one). A *detailed cube* over C is a partial function C_0 that maps the coordinates of G_0 to a numerical value for each measure m in M.

The function is partial since cubes are normally *sparse*: not all possible business events actually occur, and a coordinate participates in the function only if the event it describes took place. Each coordinate γ that participates in C_0, with its associated tuple t of measure values, is called a *cell* of C_0 and denoted $c = \langle \gamma, t \rangle$. With a slight abuse of notation, we will also consider a cube as the set of the coordinates corresponding to its cells, so we will write $\gamma \in C_0$ to state that $\langle \gamma, t \rangle$ is a cell of C_0.

Example 2.5. Three group-by sets of SALES are

$$G_0 = \langle \mathsf{date}, \mathsf{customer}, \mathsf{product}, \mathsf{store}\} \rangle$$
$$G_1 = \langle \mathsf{date}, \mathsf{type}, \mathsf{country} \rangle$$
$$G_2 = \langle \mathsf{month}, \mathsf{category} \rangle$$

where $G_0 \geq_H G_1 \geq_H G_2$. G_0 is the top group-by set. G_1 aggregates sales by date, product type, and store country (for all customers), G_2 by month and category (for all customers and stores). Examples of coordinates of the three group-by sets are, respectively,

$$\gamma_0 = \langle \text{1997-04-15}, \text{Eric Long}, \text{Lemon}, \text{SmartMart} \rangle$$
$$\gamma_1 = \langle \text{1997-04-15}, \text{Fresh Fruit}, \text{Italy} \rangle$$
$$\gamma_2 = \langle \text{1997-04}, \text{Fruit} \rangle$$

where $rup_{G_1}(\gamma_0) = \gamma_1$ and $rup_{G_2}(\gamma_1) = \gamma_2$. An example of cell of a detailed cube over SALES is $\langle \gamma_0, \langle \mathsf{quantity} = 5, \mathsf{storeSales} = 20, \mathsf{storeCost} = 12 \rangle \rangle$. □

Definition 2.6 (Cube Query and Derived Cube). Given a detailed cube C_0 over schema C, a *query* over C_0 is a quadruple $q = (C_0, G_q, P_q, M_q)$ where:

(i) G_q is a group-by set of C;
(ii) P_q is a (possibly empty) set of selection predicates each expressed over one level of H;
(iii) $M_q \subseteq M$.

The result of q is called a *derived cube*, i.e., a partial function that assigns to each coordinate γ of G_q satisfying the conjunction of the predicates in P_q and to each measure m in M_q the value computed by applying $op(m)$ to the values of m for all the coordinates of C_0 that roll-up to γ, provided that such coordinates of C_0 exist.

Like detailed cubes, even derived cubes can be sparse; a coordinate γ does not participate in the function if there is no coordinate in C_0 that rolls-up to γ. Like for detailed cubes, we will write $\gamma \in C$ to state that γ is a coordinate of the derived cube C. Consistently with this, we will denote with $|C|$ the number of coordinates in C.

Example 2.7. A cube query over SALES is $q = (C_0, G_q, P_q, M_q)$ where $G_q = \langle \mathsf{product}, \mathsf{country} \rangle$, $P_q = \{\mathsf{type} = \text{'Fresh Fruit'}, \mathsf{country} = \text{'Italy'}\}$, and $M_q = \langle \mathsf{quantity} \rangle$. A cell of the resulting

[1] When dealing with tuples we will write $t_1 = t_{2|_{sort(t_1)}}$ to denote that tuple t_1 is contained in tuple t_2; (t_1, t_2) to denote the tuple that concatenates t_1 and t_2; $t_{|_X}$ to denote the projection of tuple t on its component(s) X [1].

```
select country, product, sum(quantity) as quantity
from sales s
  join customer c on c.ckey = s.ckey
  join product p on p.pkey = s.pkey
where type = 'Fresh Fruit' and country = 'Italy'
group by country, product
```

Listing 1: Getting the sales of fresh fruit products in Italy (Example 2.7)

cube is $\langle\langle \text{Apple}, \text{Italy}\rangle, \langle \text{quantity} = 100\rangle\rangle$. The SQL formulation of q on a star schema is given in Listing 1. □

3 COMPUTING AN ASSESSMENT

Basically, the assessment of the values of a measure m in a cube C (called *target cube*) is done in three steps:

(1) the specification of a *benchmark*, i.e., a cube B such that (i) its cells can be mapped one-to-one with the cells of C, and (ii) it has a measure m' representing the expected/acceptable/normal performance of m;
(2) the cell-wise *comparison* of m to m', which can be done in a basic way (e.g., algebraic/absolute/normalized difference, percentage) or using more elaborate schemes (e.g., z-scoring), possibly after applying some *transformations* to m and m' (e.g., to compute derived measures);
(3) the characterization, or *labeling*, of the status of each cell of C based on the result of the comparison; in the simplest case, this is done using a set of rules that map the result of the comparison to a set of predefined labels (e.g., "insufficient", "excellent", etc.).

3.1 Benchmarks

The specification of the benchmark is given by the analyst at the posing of the query. Thus, the question is *"tell me how we are doing with respect to this benchmark"*.

A thorough comparison of a target cube C against a benchmark B would require that the latter comes with the same level members so that, for each cell of C, we can map onto a cell of B. However, in practical cases, due to cube sparsity, there is no guarantee that all cells can be mapped —especially if the benchmark is retrieved from the web or other external data sources. Thus, in the following we provide a broad definition of the conditions under which two cubes are joinable, i.e., one of them can be used as a benchmark to assess the other; in this definition, we will just require that the two cubes have the same group-by set.

Definition 3.1 (Cube Joinability). Let a target cube C over cube schema $\mathcal{C}$ and a benchmark B over $\mathcal{B}$ (where possibly, but not necessarily, $\mathcal{B} = \mathcal{C}$) be given. Let $q = (C_0, G_C, P_C, M_C)$ and $q' = (B_0, G_B, P_B, M_B)$ be the queries that resulted in C and B, respectively. We say that C and B are *joinable* if

$$G_C = G_B$$

In OLAP terms, two cubes are joinable if a drill-across is possible between C and B.

Let $\mathcal{C} = (H, M)$ be the schema of the target cube C, and C_0 be the detailed cube from which C is derived. There are four types of benchmarks we consider in our approach:

- *Constant benchmarks.* Here the user simply wants to assess the cells of the target cube C against some fixed value, as typically done with key performance indicators. In this case, the benchmark B has schema $\mathcal{B} = (H, \langle m_{const}\rangle)$; its cells have exactly the same coordinates as C, and all of them store a constant value in m_{const}. The cell-to-cell mapping is trivially based on equality of coordinates.
- *External benchmarks.* Here the user's goal is to assess the target cube against the data stored in a cube with schema $\mathcal{B} = (H', M')$. In principle, as long as $\mathcal{B}$ includes the group-by of the target cube (which ensures joinability), it is not necessary to impose further constraints on $\mathcal{B}$. However, for simplicity, in the following we will assume that the external benchmark has been reconciled with the target cube so that $H = H'$ and that all necessary transcodings to level members have been applied (see e.g. [10] for an approach that can be pursued to this end). Thus, also in this case, mapping is based on equality of coordinates.
- *Sibling benchmarks.* The idea here is to compare the values of a measure in a slice on member $u \in Dom(l)$ with the values of the same measure in another slice of C related to a sibling member $u_{sib} \in Dom(l)$ (e.g., assess the sales of fruit in Italy with reference to those in France). In this case, the benchmark has the same schema $\mathcal{C}$ of the target cube. Both cubes have the same group-by set, but while the cells in C are those obtained from C_0 using predicate $l = u$, those in B are obtained from C_0 using predicate $l = u_{sib}$. Then the cell-to-cell mapping is established by replacing u with u_{sib} in each coordinate of C.
- *Past benchmarks.* In this case the user wants to assess the values taken by a measure m in some time slice with the values that can be predicted for m based on a number of past time slices. Like in the previous case, it is $\mathcal{B} = \mathcal{C}$. The cells of B have exactly the same coordinates as C, but the (actual) values of m are replaced with the predicted ones.

Example 3.2. Let C be the derived cube obtained by query q in Example 2.7 (total quantity sold by product and country for fresh fruit products and Italy). An example of (joinable) sibling benchmark is B returned by q', being q' obtained from q by replacing Italy with France. B can be used to assess the sales of fresh fruit in Italy against those in France. The cell-to-cell mapping is established by replacing Italy with France; so, for instance, coordinate $\langle \text{Apple}, \text{Italy}\rangle$ is mapped onto $\langle \text{Apple}, \text{France}\rangle$. □

3.2 Comparison & Transformation

The essence of assessment is to contrast the actual performance against its expected value. Thus, the goal of this step is to provide the means to express and perform the evaluation of how far apart the query result and the benchmark are. We refer to this action as *comparison* to express the idea that this is not necessarily a simple measure difference. Modeling-wise, we assume that a library of comparison functions, all with signature $\delta : \mathbb{R} \times \mathbb{R} \to \mathbb{R}$, is available to the users. Practically, a cell-wise comparison between measures of the target and benchmark can be easily implemented via different functions obeying the above signature, the simplest choice being a *difference* (either *algebraic*, or *absolute*, or *normalized*, etc.). In our examples, we will use two library functions of our system, named difference and ratio.

One could possibly expect that, once the target cube and the benchmark have been obtained, their comparison is immediately applicable. Interestingly, this is not always the case, since the comparison may require the computation of derived measures. For instance, with reference to the SALES cube, comparing the actual profit for some given sales requires to compute a derived measure as profit = storeSales – storeCost. Clearly, this requires

```
def difference(a, b):
    return a - b

def minmaxnorm(a):
    minv = a.min()
    maxv = a.max()
    return (a - minv) / (maxv - minv)
```

Listing 2: Implementation of the difference and minmaxnorm functions

that either of, or both, the target and the benchmark measures pass through a set of *transformations* to be actually comparable. The transformations that are applicable to target cubes and benchmarks can be simple (like the above mentioned one, where the measures are computed via simple per-cell arithmetic operations), or more complex ones (like ranking or z-scoring) which require a holistic scan of the entire cube and cannot produce the new value on a per-cell basis.

We forego the formalities of the computation of the derived measures (to be discussed in Section 4.2) and simply mention that we assume a functional-style composition of the invocation of functions from our library of functions in a nestable way. For example, the min-max normalization of the difference between storeSales and target value 1000 is computed as

minMaxNorm(difference(storeSales,1000))

Listing 2 shows the implementation of these two functions in Python using Pandas DataFrames.

3.3 Labeling

The goal of this step is to associate each cell of the target cube with a label, taken from a predefined set, to express an evaluation of that cell with reference to the benchmark. Clearly, ordinal labeling will frequently be the case, however, for the sake of generality *we assume labels to be nominal*, i.e., categorical. Given a finite set of distinct values L, a labeling function has the form $\lambda : \mathbb{R} \rightarrow L$. Each value resulting from the comparison of a target cube cell with the corresponding benchmark cell is fed to the labeling function, and assigned the appropriate label.

There are some properties of interest for a labeling function:

- The labeling of comparison values is generic enough to also incorporate the labeling based on the actual value of the cell, without the usage of any benchmark and comparison. One simply needs to assign a fixed benchmark of zeros for all cells and a simple arithmetic difference as the comparison function.
- A labeling function should partition the values of the comparison into equivalence classes, i.e., there must be a *complete* mapping of the values of the domain of the comparison to a set of *non-overlapping*, disjoint labels. Thus, every cell of the result is assigned to exactly one label.
- The labeling function does not necessarily have to be predefined before the query. Assuming, for example, that a Likert-like scale based on the absolute difference value is to be adopted, the labeling function is produced after the results are obtained and split into a fixed number of groups (say 5).

With reference to the last point, in the sequel we introduce and explain two cases of labeling functions.

3.3.1 Labeling based on explicit ranges. In this case, we label each cell based on the result of the comparison between the

```
def 5stars(a):
    return pd.cut(a, [-1, -0.6, -0.2, 0.2, 0.6, 1.0],
    include_lowest = True,
    labels=["*", "**", "***", "****", "*****"])
```

Listing 3: Implementation of the 5stars function

measure values of (a) the target and (b) the benchmark cube, using a set of explicitly-specified rules. This is the case, e.g., where the organization has predetermined goals to achieve (expressed via the benchmark), and the (positive or negative) deviation from these goals characterizes the extent of success or failure.

Example 3.3. Let a query be given that computes the total store sales by customer gender, returning a target cube C with two cells, say $C = \{\langle \text{male}, 4400\rangle, \langle \text{female}, 6900\rangle\}$. Assume that we have specified an external benchmark with two cells also, $B = \{\langle \text{male}, 5400\rangle, \langle \text{female}, 6400\rangle\}$. Finally, assume that we specify a range-based labeling function called 5stars to be applied over the min-max normalized difference x of the target cube and the benchmark:

$$\lambda_{\text{5stars}}(x) = \begin{cases} *, \text{ if } -1 \leq x \leq -0.6 \\ **, \text{ if } -0.6 < x \leq -0.2 \\ ***, \text{ if } -0.2 < x \leq 0.2 \\ ****, \text{ if } 0.2 < x \leq 0.6 \\ *****, \text{ if } 0.6 < x \leq 1 \end{cases}$$

Then, the two cells are labeled as '*' and '*****', respectively. Listing 3 shows the implementation of the 5stars function in Python using Pandas DataFrames; the cut function of Pandas bins values into discrete intervals. □

3.3.2 Labeling based on the overall value distribution. Explicitly providing rules and ranges for the labels has the benefit that the decision on which label to give to a cell of the target cube is *local*, i.e., it depends only on the value of the cell's measure, the benchmark's measure, and the result of their comparison. However, the labeling function can also be based on a *holistic* assessment of the overall distribution of the values of the comparison function. In this case, the labeling function first groups the cells of the target cube based on the result of their comparison with their respective benchmark cell, and then gives a label to each group. The simplest possibility would be to split the comparison value into quartiles or, more generally, into k groups, and label each group as 'top-1', 'top-2', ..., 'top-k'. This involves simply the ranking of the values and the splitting of the ordered set of cells into k groups. Assuming a fixed set of k labels, the label is then determined by the position of a cell in the ranking.

Overall, labels can be assigned either by fixing the number of labels to a constant number and constructing equi-depth or equi-width histograms, or by allowing the system to come up with the optimal number of clusters and assign cells accordingly. More simplistic schemes (e.g., rounding the z-score of the comparison values) can also be devised. Overall, the idea of these labeling schemes is to avoid predefining ranges, and allowing labels to adapt to the distribution of the comparison values.

4 SYNTAX & SEMANTICS OF THE ASSESS OPERATOR

In this section, we formally define the syntax and semantics of the assess operator. We begin by introducing in Section 4.1 a user-friendly SQL-like syntax, to facilitate end users in posing

assessment queries with both expressive power and ease. Then, we move on to define the semantics of the assess operator in Section 4.3. To support this task, in Section 4.2 we preliminarily define a set of logical operators.

4.1 Syntax

The general syntax for writing a statement based on the assess operator includes three parts: one (consisting of the with, assess, by, and for clauses) that specifies the target cube; one (consisting of the against clause) that specifies the benchmark; one (consisting of the using and labels clauses) that specifies the assessment method. Importantly, as we will explain in Section 4.3, the benchmark specification drives the mapping of the assess syntax to the logical operators defined in Section 4.2.

with C_0 [for P] by G
assess|assess* m [against $< benchmark >$]
[using $< function >$] labels λ

where C_0 is a detailed cube (with schema $C = (H, M)$), m is a measure of C_0, P is a set of conjunctive selection predicates each over one level of H, G is a group-by set of C, $< benchmark >$ is the benchmark specification, $< function >$ specifies what will be compared and how, and λ is a labeling function (optional parts of the syntax are in brackets). While in assess only the cells of the target cube that have a match in the benchmark are returned, in the assess* variant all the cells of the target cube are returned, possibly completed with null labels.

The target cube, C, is defined by aggregating C_0 on G and selecting the cells that meet the conjunctive predicates in P.

As to the benchmark, its specification can take different forms:

- For constant benchmarks, the against clause has the form

  against v

  where v is a value compatible with m. The benchmark B is characterized by $G_B = G_C$, $P_B = P_C$. B has a measure m_{const} which takes value v in all cells. A particular case is when the user wants to *directly* assess the measure value without using any specific value. In this case the against clause is omitted; as mentioned in Section 3.3, this practically corresponds to adopting a dummy benchmark where all cells are zeros.
- For external benchmarks, the against clause takes the form

  against $B.m_b$

  where B is a cube and m_b is one of its measures. Note that C and B are joinable only if they have the same group-by set.
- In a sibling benchmark, the for clause must include a predicate which slices the target cube on member u of level $l_s \in G_C$. In this case, m is assessed against a benchmark related to a different member of l_s, say u_{sib}:

  with $< cube >$ for $p_1, \ldots, p_k, l_s = u$ by G
  assess m against $l_s = u_{sib}$
  using $< function >$ labels λ

  Here the benchmark is characterized by $G_B = G_C$ and $P_B = P_C \setminus \{p_s\} \cup \{(l_s = u_{sib})\}$. In practice, the slicing on u is replaced by one on u_{sib}.
- In a past benchmark the syntax takes the form

  with $< cube >$ for $p_1, \ldots, p_k, l_t = u$ by G
  assess m against past k
  using $< function >$ labels λ

  where l_t is a temporal level, $l_t \in G$, and k is an integer. Here the benchmark is isomorphic to C, except that the values of m are those predicted based on a time series of length v.

Finally, as to the assessment method, its specification is based on the using and labels clauses.

- The using clause specifies a (nested) function that describes how the comparison is made, including possible transformations to be made on measures (e.g., the computation of a derived measure). Here, a keyword benchmark is used to distinguish, when necessary, the cells of the target cube from the corresponding ones in the benchmark.
- The labels clause specifies a labeling function, either based on explicit ranges or on the overall value distribution, to be applied to the result of the computation specified by the using clause. A range-based labeling function can be either predeclared by the user and given a name (e.g., 5star in Example 3.3) or declared inline within the statement by listing its set of ranges with the corresponding label; the user is in charge of ensuring that the set of ranges is complete and non-overlapping. A set of library labeling function based on the value distribution (e.g., quartiles) is also made available to users.

In all cases above, the result returned to the user includes, for each cell, (i) its coordinate, (ii) the value of m for that coordinate, (iii) the value of the benchmark measure, (iv) the value resulting from the comparison, and (v) the corresponding label. The benchmark measure is m_{const} for constant benchmarks, m for sibling and past benchmarks, and m_b for external benchmarks.

Example 4.1. The first example gives an absolute assessment of the total monthly sales in terms of quartiles:

```
with SALES by month
assess storeSales labels quartiles
```

Similarly, sales can be assessed against a goal value, say 1000, via a 5 star scale in the [0..1] range by first normalizing the difference and then using the range-based labeling function specified in Example 3.3:

```
with SALES by month
assess storeSales against 1000
using minMaxNorm(difference(storeSales,1000))
labels 5star
```

The following statement uses a sibling benchmark; for each product of type fresh fruit, the total quantity sold in Italy is assessed against the one in France. For each product, assessment is based on the ratio between (i) the difference in quantities sold in Italy and France, and (ii) the total sales of fresh fruit in Italy; this ratio

is computed using library function *percOfTotal*.

```
with SALES
for type = 'Fresh Fruit', country ='Italy'
by product, country
assess quantity against country = 'France'
using percOfTotal(difference(quantity, benchmark.quantity))
labels {[-inf, -0.2): bad, [-0.2,0.2]: ok, (0.2, inf]: good},
```

Finally, in the next statement we use a past benchmark; specifically, we assess the sales of a specific store in July 1997 against the past four months:

```
with SALES
for month = '1997-07', store = 'SmartMart'
by month, store
assess storeSales against past 4
using ratio(storeSales, benchmark.storeSales)
labels {[0, 0.9): worse, [0.9, 1.1]: fine, (1.1,inf): better}
```

□

4.2 Logical operators

This section introduces the logical aspects behind the different steps of the evaluation of an assess statement, formulated as logical operators. Note that our aim is not to propose a logical language for manipulating cubes (such languages exist, see e.g. [2]) but to describe specific cube manipulations required to logically optimize assess statements. In particular, we do not detail the classical (roll-up, etc.) cube manipulations.

We recall from Section 2 that a cube is defined as a partial function that maps coordinates into tuples of measures. For a cube C and a coordinate γ such that $C(\gamma) = t$, we denote with $c = \langle \gamma, t \rangle$ the cell defined by $C(\gamma)$ and we abusively note $c \in C$. We define operators that respect the closure property, in the sense that they operate on cubes and specify cubes.

Get. The first basic operator consists of obtaining the result of a cube query. Given a cube C over a schema $\mathcal{C} = (H, M)$, a set of selection predicates P and a group-by set G of $\mathcal{C}$, the get operator corresponds to the cube query $q = (C, G, P, M)$, is denoted by $[q]$, and defines the derived cube being the result of q. Note that $[(C, G_0, \emptyset, M)]$ is simply noted $[C]$ in what follows. Besides, the derived cube returned by get can be renamed using the notation $[(C, G, P, M)] \rightarrow name$.

Join $\boxtimes$. The join operation is essential for putting together the target cube (C_1) and the benchmark (C_2). In OLAP terms this is a drill-across operation, or join applied to cubes.

Let C_1 and C_2 be two joinable cubes over schemas $\mathcal{C}_1$ and $\mathcal{C}_2$. As already stated, we assume for simplicity that the two cubes share the same hierarchies, so that $\mathcal{C}_1 = (H, M_1)$ and $\mathcal{C}_2 = (H, M_2)$.

$$C_1 \boxtimes C_2 = \{\langle \gamma, (t, t') \rangle | \langle \gamma, t \rangle \in C_1, \langle \gamma, t' \rangle \in C_2\}$$

The schema of the resulting cube is $(H, (M_1, M_2))$.

We also define a version of join where we allow partial joining in the sense that join is made on a subset of the levels of H. Formally:

$$C_1 \boxtimes_{l_1,\ldots,l_m} C_2 = \{\langle \gamma, (t, t^1, \ldots, t^p) \rangle | \\ \langle \gamma, t \rangle \in C_1, \langle \gamma^j, t^j \rangle \in C_2, \gamma_{|_{l_1,\ldots,l_m}} = \gamma^j_{|_{l_1,\ldots,l_m}}, j \in [1, \ldots, p]\}$$

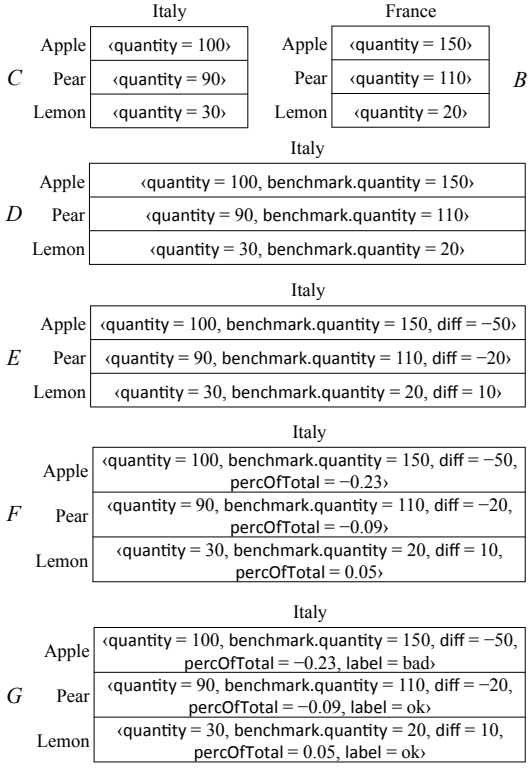

Figure 1: Derived cubes resulting from the application of logical operators for the sibling intention in Example 4.5

Note that, differently from the (natural) join defined above, this partial join is not commutative.

Finally, the assess* syntactical variant (that also returns the non-matching cells of the target cube) uses a left-outer join $C_1 \ ^* \boxtimes \ C_2$ where non-matching cells are completed with null values.

Example 4.2. Figure 1 shows the results, C and B, of the following get operations:

```
C =[(SALES, ⟨product, country⟩,
    {type = 'Fresh Fruit', country = 'Italy'},
    ⟨quantity⟩)]
B =[(SALES, ⟨product, country⟩,
    {type = 'Fresh Fruit', country = 'France'},
    ⟨quantity⟩)] → benchmark
```

(cube B is given alias benchmark) and the result of their partial join, $D = C \boxtimes_{\text{product}} B$. □

Cell-Transform $\boxminus$. This operator specifies a cell-at-a-time operation that takes a cube and a function, and outputs a cube where a new measure is added, containing the value of the function applied over the measure(s). Let $\mathcal{C} = (H, M)$ be the schema of cube C with group-by set G, and $\overline{M}$ be a subtuple of M. Let f be a function defined on a tuple of parameters compatible with $\overline{M}$; then the cell-transformation operation operated by f returns a cube defined by:

$$\boxminus_{f \rightarrow name, \overline{M}}(C) = \{\langle \gamma, (t, \langle f(\overline{M}) \rangle) \rangle \mid \langle \gamma, t \rangle \in C\}$$

The schema of the resulting cube is $(H, (M, \langle name \rangle))$, where *name* is the derived measure returned by f.

C'

	Italy	France
Apple	‹quantity = 100›	‹quantity = 150›
Pear	‹quantity = 90›	‹quantity = 110›
Lemon	‹quantity = 30›	‹quantity = 20›

D'

	Italy
Apple	‹quantity = 100, qtyFrance = 150›
Pear	‹quantity = 90, qtyFrance = 110›
Lemon	‹quantity = 30, qtyFrance = 20›

Figure 2: Example of application of the pivot operator

H-Transform $\boxdot$. This operator considers holistic (H) transformations, in the sense that computing a new measure value for each cell of cube C requires to know *all* the cells of C.

Let again $\overline{M}$ be a subtuple of M as above. In this case, function f operates on a tuple of parameters compatible with $\overline{M}$ *and* on a set of tuples. The H-transformation of C operated by f returns a cube defined by:

$$\boxdot_{f \to name,\overline{M}}(C) = \{\langle \gamma, (t, \langle f(\overline{M}, C)\rangle)\rangle \mid \langle \gamma, t\rangle \in C\}$$

The schema of the resulting cube is $(H, (M, \langle name\rangle))$, where *name* is the extra measure returned by f.

Example 4.3. The following cell-transformation extends cube D with a derived measure storing their difference:

$$E = \boxminus_{difference \to \text{diff},\langle \text{quantity,benchmark.quantity}\rangle}(D)$$

Then, cube F is obtained from E by applying an H-transformation as follows:

$$F = \boxdot_{percOfTotal \to \text{percOfTotal},\langle \text{diff,quantity}\rangle}(E)$$

where holistic function $percOfTotal$ operates on a tuple of two parameters a and b and computes, for each cell, the ratio between a and the sum of b over all cells. □

Pivot $\boxplus$. This operator takes a cube including a set of k slices of some level l (a cube *slice* is the set of cells corresponding to one single member of a level), among which only one slice for a given member $u_k \in Dom(l)$ is returned. Each coordinate γ of this slice in the returned cube is associated with its initial tuple of measures t, concatenated with all the p measures $\overline{M} = \langle m^1, \ldots, m^p\rangle$ of all its $k-1$ neighbor coordinates γ' in the initial set of k slices. The new measures are renamed $name^1, \ldots, name^p$. Formally, given cube C with schema $C = (H, M)$, let $u_1, \ldots, u_k \in Dom(l)$ be the members of l on which the slices are defined. Let u_k be the reference slice for pivoting. Then

$$\boxplus_{\langle m^1 \to name^1, \ldots, m^p \to name^p\rangle, l, u_k}(C) = \{\langle \gamma, (t, \langle v_1^1, \ldots, v_{k-1}^1, \ldots, v_1^p, \ldots, v_{k-1}^p\rangle)\rangle \mid \langle \gamma, t\rangle \in C, \gamma_{|_l} = u_k, \langle \gamma', t'\rangle \in C, \gamma'_{|_l} = u_i, \gamma_{|_{G\setminus l}} = \gamma'_{|_{G\setminus l}}, t'_{|_{m^j}} = v_i^j, i \in [1, k-1], j \in [1, p]\}$$

where the t's are tuples of measure values. The schema of the resulting cube is $(H, (M, name^1, \ldots, name^p))$ where in turn $name = \langle m_1, \ldots, m_{k-1}\rangle$.

Example 4.4. Figure 2 shows the result C' of the following get operator:

$C' =$[(SALES, ⟨product, country⟩,
{type = 'Fresh Fruit', country ∈ {'Italy', 'France'}},
⟨quantity⟩)]

Cube C' includes two slices for country. By applying the following pivot operator:

$$D' = \boxplus_{\langle \text{quantity}\rangle \to \text{qtyFrance,country,'Italy'}}(C')$$

a cube D' is obtained that includes only the reference slice ('Italy'), with an extra measure qtyFrance. □

4.3 Semantics

Assume the expression of the assess operator as defined in Section 4.1:

with C_0 [for P] by G
assess m [against < *benchmark* >]
[using < $function$ >] labels λ

In terms of the logical operators introduced in Section 4.2, let

(1) $\boxdot_{\Delta,}(\cdot)$ be the composition of the comparison/transformation functions denoted by the using clause.
(2) $\boxdot_{\lambda,}(\cdot)$ be the transformation that applies the labeling function denoted by the labels clause.

Without loss of generalization, we assume that the functions that are used for the comparison and the labeling are holistic. Clearly, the application of cell-based functions is also possible (and most welcome for efficiency and optimization purposes).

The semantics of an assess statement is defined as

$$\boxdot_{\lambda \to m^\lambda, m^\Delta}(\boxdot_{\Delta \to m^\Delta, \overline{M}}(C))$$

where the definition of cube C depends on the type of benchmark used, which in turn is determined by the form taken by the against clause as explained in Section 4.1:

- Constant benchmark: $C = [(C_0, G, P, M)]$.
- External benchmark B: $C = [(C_0, G, P, M)] \boxtimes [B]$
- Sibling benchmark:

$$C = [(C_0, G, P, M)] \boxtimes_{G\setminus l_s} [(C_0, G, P_B, M)] \to \text{benchmark}$$

where $P_B = P \setminus \{(l_s = u)\} \cup \{(l_s = u_{sib})\}$.

- Past benchmark:

$$C = [(C_0, G, P, M)] \boxtimes_{G\setminus l_t} (\boxminus_{regression \to M', M}(\boxplus_{M \to M', l_t, u}([(C_0, G, P_B, M)] \to \text{benchmark})))$$

where $P_B = P \setminus \{(l_t = u)\} \cup \{(l_t \in \{u_1, \ldots, u_k\})$, members $u_1, \ldots, u_k$ are predecessors of u for level l_t, and $regression$ is a time series prediction function.

Note that, in the assess* variant, the inner join is replaced by a left-outer join. In all cases, the resulting cube has schema $(H, \langle m, m^B, m^\Delta, m^\lambda\rangle)$ The benchmark measure m^B is m_{const} for constant benchmarks, m for sibling and past benchmarks, and m_b for external benchmarks.

Example 4.5. Consider again some of the statements of Example 4.1. The first one relies on a constant benchmark:

with SALES by month
assess storeSales labels quartiles,

and corresponds to the logical expression:

$$\boxdot_{quartiles,\langle \text{storeSales}\rangle}([(\text{SALES}, \langle \text{month}\rangle, \emptyset, \langle \text{storeSales}\rangle)])$$

The one based on a sibling benchmark,

```
with SALES
for type = 'Fresh Fruit', country ='Italy'
by product, country
assess quantity against country = 'France'
using percOfTotal(difference(quantity, benchmark.quantity))
labels {[-inf, -0.2): bad, [-0.2,0.2]: ok, (0.2, inf]: good},
```

corresponds to the following plan (see Figure 1):

(1) get the target cube:

$$C = [(\text{SALES}, \langle \text{product}, \text{country} \rangle, \{\text{type} = \text{'Fresh Fruit'}, \text{country} = \text{'Italy'}\}, \langle \text{quantity} \rangle)]$$

(2) get the benchmark:

$$B = [(\text{SALES}, \langle \text{product}, \text{country} \rangle, \{\text{type} = \text{'Fresh Fruit'}, \text{country} = \text{'France'}\}, \langle \text{quantity} \rangle)] \rightarrow \text{benchmark}$$

(3) (partially) join C and B:

$$D = C \boxtimes_{\text{product}} B$$

(4) transform D:

$$E = \boxminus_{difference \rightarrow \text{diff}, \langle \text{quantity,benchmark.quantity} \rangle}(D)$$

(5) transform E:

$$F = \boxdot_{percOfTotal \rightarrow \text{percOfTotal}, \langle \text{diff,quantity} \rangle}(E)$$

(6) transform F:

$$G = \boxminus_{range(\{[-\text{inf},-0.2):\text{bad}, [-0.2,0.2]:\text{ok}, (0.2,\text{inf}]:\text{good}\}), \langle \text{percOfTotal} \rangle}(F)$$

The last one uses a past benchmark:

```
with SALES
for month = '1997-07', store = 'SmartMart'
by month, store
assess storeSales against past 4
using ratio(storeSales, benchmark.storeSales)
labels {[0, 0.9): worse, [0.9, 1.1]: fine, (1.1,inf): better}
```

and corresponds to the following plan:

(1) get the target cube:

$$C = [(\text{SALES}, \langle \text{month}, \text{store} \rangle, \{\text{month} = \text{'1997-07'}, \text{store} = \text{'SmartMart'}\}, \langle \text{storeSales} \rangle)]$$

(2) get the data for the benchmark:

$$B = [(\text{SALES}, \langle \text{month}, \text{store} \rangle, \{\text{month} \in [\text{'1997-03'}; \text{'1997-06'}], \text{store} = \text{'SmartMart'}\}, \langle \text{storeSales} \rangle)] \rightarrow \text{benchmark}$$

(3) pivot B:

$$D = \boxplus_{\langle \text{storeSales} \rangle \rightarrow \text{past,month,'1997-06'}} B$$

(4) transform D:

$$E = \boxminus_{regression \rightarrow \langle \text{storeSales} \rangle, \text{past}} D$$

(5) (partially) join C and E:

$$F = C \boxtimes_{\text{store}} E$$

(6) transform F:

$$G = \boxminus_{ratio \rightarrow \text{r}, \langle \text{storeSales,benchmark.storeSales} \rangle} F$$

(7) transform G:

$$\boxminus_{range(\{[0,0.9):\text{worse}, [0.9,1.1]:\text{fine}, (1.1,\text{inf}):\text{better}\}), \langle \text{r} \rangle} G$$

5 OPTIMIZING ASSESS STATEMENTS

This section illustrates how the logical operators introduced above allow to optimize the evaluation strategies of assess in a rule-based fashion. We start by giving basic algebraic properties of the operators, and then present optimization schemes exploiting these properties.

5.1 Basic properties

Commutativity of transform (P_1). An important feature of the transform operators is that they preserve the set of coordinates of the cube they are applied to, monotonically adding new measures to it. In other words, the operators commute when one does not need the result of the other. Formally,

$$\boxminus_{f \rightarrow n_f, M'}(\boxminus_{g \rightarrow n_g, M}(C)) = \boxminus_{g \rightarrow n_g, M}(\boxminus_{f \rightarrow n_f, M'}(C))$$

if $n_g \notin M'$ and $n_f \notin M$. The same property holds for $\boxdot$, and for combinations of $\boxdot$ and $\boxminus$.

Pushing join through transformation (P_2). A join can be pushed before a cell-transformation, if the transformation is applied to the measures of only one of the joined cubes, by applying the transformation directly over that cube and removing the pivot operation needed to guarantee the two cubes are joinable. Formally,

$$(C, G, P, M) \boxtimes_{G \setminus \{l\}} (\boxminus_{f \rightarrow n_f, M_2} \boxplus_{M_1 \rightarrow M_2, l, u} (C, G, P', M_1)) = \boxminus_{f \rightarrow n_f, M_1}((C, G, P, M) \boxtimes_{G \setminus \{l\}} (C, G, P', M_1))$$

where $P' = P \setminus \{(l_s = u)\} \cup \{(l_s \in \{u_1, \ldots, l_n\})$.

Replacing join with pivot (P_3). Joining different slices of the same cube can be done either by getting each slice individually and partially joining them, or by getting the slices together and pivoting all but one of them. Formally,

$$[(C, G, P, M)] \boxtimes_{G \setminus \{l\}} [(C, G, P', M)] = \boxplus_{M \rightarrow M', l, u} [(C, G, P_{all}, M)]$$

where M' is a tuple of measure names not in M, $P' = P \setminus \{(l = u)\} \cup \{(l \in \{u_1, \ldots, u_n\})$ and $P_{all} = P \setminus \{(l = u)\} \cup \{(l \in \{u, u_1, \ldots, u_n\})\}$.

5.2 Optimization strategies

In a classical interactive cube analysis, a user expresses high-level manipulations through front-end applications over DBMSs. We assume the same context, where cubes are accessed through cube queries (our logical get operation), over an already properly optimized DBMS. In this setting, we work under the following hypotheses: (i) the get, join, and pivot logical operations can be executed via SQL queries; (ii) the results of these SQL queries fit in main memory; (iii) all transformations are seen as black-box functions, thus they are not pushed to SQL. The optimization opportunities of assess statements are then related to which logical operators are pushed to SQL.

Following the above assumptions, for an assess statement we consider three possible plans, based on different execution strategies, as described in the following subsections.

```
select t1.country, t1.product,
       t1.quantity, t2.quantity as bc_quantity
from
  (select country, product, sum(quantity) as quantity
   from sales s
     join customer c on c.ckey = s.ckey
     join product p on p.pkey = s.pkey
   where type = 'Fresh Fruit' and country = 'Italy'
   group by country, product) t1,
  (select country, product, sum(quantity) as quantity
   from sales s
     join customer c on c.ckey = s.ckey
     join product p on p.pkey = s.pkey
   where type = 'Fresh Fruit' and country = 'France'
   group by country, product) t2
where t1.product = t2.product
```

Listing 4: Getting the pivoted cube of the sibling intention following JOP

5.2.1 Naive Plan. A *Naive Plan* (NP) faithfully reproduces the sequences of operations shown in Section 4.3; only the get operations are pushed to SQL and all other operations are executed in memory. NP is feasible for all benchmark types.

Example 5.1. Consider the sibling statement of Example 4.5. Its NP consists in translating individually each get operation into an SQL call, to retrieve the target and benchmark cubes. Specifically, the first get operation is translated in the SQL query of Listing 1; the second get operation consists of the same SQL code where the selection is made on 'France' instead of 'Italy'. All other subsequent operations of that statement, i.e., the partial join and the transformations, are done in memory.

5.2.2 Join-Optimized Plan. In a *Join-Optimized Plan* (JOP), also the join is pushed to SQL to take advantage of the DBMS optimizer. This requires that the plan starts with the subexpression $C \boxtimes B$, where C and B are two get operations, so that all three operations can be pushed to SQL. JOP is not feasible for constant benchmarks, since there is no join to be done; for the other benchmark types, it may require property P_2 to be applied to NP to postpone cell-transformations after the join.

Example 5.2. Consider the sibling statement of Example 4.5, and the subexpression of step (3): $D = C \boxtimes_{\text{product}} B$. This subexpression is translated to the SQL query of Listing 4, with one inner subquery for each get operation C and B, and an outer query for joining them. □

Example 5.3. As mentioned above, property P_2 can be used to put an assess statement in a form that allows pushing the join to SQL. Consider for instance the five first steps of the past statement of Example 4.5. Applying property P_2 turns these steps into the plan:

(1) get the target cube:

$$C = [(\text{SALES}, \langle \text{month}, \text{store} \rangle, \{\text{month} = \text{'1997-07'}, \text{store} = \text{'SmartMart'}\}, \langle \text{storeSales} \rangle)]$$

(2) get the data for the benchmark:

$$B = [(\text{SALES}, \langle \text{month}, \text{store} \rangle, \{\text{month} \in [\text{'1997-03'}; \text{'1997-06'}], \text{store} = \text{'SmartMart'}\}, \langle \text{storeSales} \rangle)] \rightarrow \text{benchmark}$$

(3) (partially) join C and B:

$$D = C \boxtimes_{\text{store}} B$$

(4) transform D:

$$E = \boxminus_{regression \rightarrow \langle \text{storeSales} \rangle, \text{benchmark.storeSales}} D$$

The subexpression $D = C \boxtimes_{\text{store}} B$ can be then pushed to SQL. □

5.2.3 Pivot-Optimized Plan. The goal of a *Pivot-Optimized Plan* (POP) is to let the DBMS compute pivot operations. To this end, whenever the plan starts with the subexpression $C \boxtimes B$, where C and B are get operations on the same cube, the join operation is replaced with the pivot operation using property P_3, resulting in a pivot operation for aligning the target and benchmark slices. Both operations (get and pivot) are then pushed to SQL. POP is feasible only for sibling and past intentions, which get multiple slices from a single cube.

Example 5.4. Consider the sibling statement of Example 4.5. Using property P_3 allows to rewrite the plan to (see also Figures 1 and 2):

(1) get the (target+benchmark) cube:

$$C' = [(\text{SALES}, \langle \text{product}, \text{country} \rangle, \{\text{type} = \text{'Fresh Fruit'}, \text{country} \in \{\text{'Italy'}, \text{'France'}\}, \langle \text{quantity} \rangle)]$$

(2) pivot C':

$$E = \boxplus_{\langle \text{quantity} \rightarrow \text{qtyFrance} \rangle, \text{country}, \text{'Italy'}} (C')$$

(3) transform D':

$$E' = \boxminus_{difference \rightarrow \text{diff}, \langle \text{quantity}, \text{qtyFrance} \rangle} (D')$$

(4) transform E':

$$F' = \boxdot_{percOfTotal \rightarrow \text{percOfTotal}, \langle \text{diff}, \text{quantity} \rangle} (E')$$

(5) transform F':

$$G' = \boxminus_{range(\{[-\text{inf}, -0.2):\text{bad}, [-0.2, 0.2]:\text{ok}, (0.2, \text{inf}]:\text{good}\}), \langle \text{percOfTotal} \rangle} (F')$$

Listing 5 shows the resulting SQL query. Likewise, the past statement, in the form given in Example 5.3, can be rewritten with P_3 as:

(1) get (target+benchmark) cube:

$$D = [(\text{SALES}, \langle \text{month}, \text{store} \rangle, \{\text{month} \in [\text{1997-03}; \text{1997-07}], \text{store} = \text{'SmartMart'}\}, \langle \text{storeSales} \rangle)]$$

(2) pivot D:

$$E = \boxplus_{\langle \text{storeSales} \rangle \rightarrow \text{past}, \text{month}, \text{'1997-07'}} (D)$$

(3) transform E:

$$F = \boxminus_{regression \rightarrow \text{benchmark.storeSales}, \langle \text{past} \rangle} (E)$$

(4) transform F:

$$G = \boxminus_{ratio \rightarrow \text{r}, \langle \text{storeSales}, \text{benchmark.storeSales} \rangle} (F)$$

(5) transform G:

$$\boxminus_{range(\{[0,0.9):\text{worse}, [0.9,1.1]:\text{fine}, (1.1, \text{inf}):\text{better}\}), \langle \text{r} \rangle} (G)$$

Under this form, the first two steps of the plan can be transformed into SQL calls. □

```sql
select 'Italy' as country, product,
  quantity, bc_quantity
from
  (select country, product, sum(quantity) as quantity
   from sales s
     join customer c on c.ckey = s.ckey
     join product p on p.pkey = s.pkey
   where type = 'Fresh Fruit'
         and country in ('Italy', 'France')
   group by country, product)
pivot (
  sum(quantity) for country
    in ('Italy' as quantity, 'France' as bc_quantity)
)
where quantity is not null and bc_quantity is not null
```

Listing 5: Getting the pivoted cube of the sibling intention following POP

Table 1: Formulation effort for different intentions

	Constant	External	Sibling	Past
SQL:	481	989	1169	1954
Python:	7006	6193	6309	7049
Total:	7487	7182	7478	9003
assess:	143	260	270	254

6 EXPERIMENTS

To test our approach, we implemented the assess operator relying on the simple multidimensional engine described in [6], which uses multidimensional metadata to rewrite OLAP queries on a star schema stored in Oracle 11g DBMS. Post-processing of the results (e.g., to apply transformations) is then done via off-the-shelf Python Scikit-learn over Pandas DataFrames. All tests were run on an Intel(R) Core(TM)i7-6700 CPU@3.40GHz CPU with 8GB RAM.

The prototype was tested against the Star Schema Benchmark (SSB) cube, described by four hierarchies; please refer to [14] for the logical schema of the SSB dataset. As commonly done in OLAP settings, primary and foreign keys were indexed using B-Trees, and materialized views were created to improve performances. The experiments are focused on four assess statements of different types, henceforth referred to as Constant, External, Sibling, and Past, respectively.

6.1 Formulation effort

The first goal of our experiments is to evaluate the saving in user's effort when writing an assess statement over the one necessary to obtain the same result using plain SQL and Python. To this end we adopt the simple metric proposed in [11], where the ASCII character length is used as as a proxy for the effort it takes to craft a query. The results are shown in Table 1. For SQL and Python we considered the code generated by our prototype when following the less complex plan. Nevertheless, as expected, the total formulation effort using SQL+Python is, for each intention type, more than one order of magnitude larger than using assess statements.

6.2 Efficiency and scalability

Our second experimental goal is to evaluate the efficiency of our approach in executing (i) different types of intentions, (ii) with different execution plans, and (iii) on cubes with different cardinalities. To achieve (iii) we generated three detailed SSB cubes, namely SSB_1, SSB_{10}, and SSB_{100}, with different scale factors resulting in the following cardinalities:

$$|SSB_1| = 6 \cdot 10^6$$
$$|SSB_{10}| = 6 \cdot 10^7$$
$$|SSB_{100}| = 6 \cdot 10^8$$

Note that the cardinality of each cube is equal to the number of tuples in the corresponding fact table. Since the by and for clauses of each assess statement are not changed, scaling up the cardinality of the detailed cube implies that also the cardinality of the target cube scales up as shown in Table 2. To reduce the impact of caching, each assess statement was executed five times on each detailed cube, and the execution times were averaged.

Table 2: Target cube cardinalities for each intention type applied to each detailed cube

	SSB_1	SSB_{10}	SSB_{100}
Constant	$1.2 \cdot 10^5$	$1.2 \cdot 10^6$	$1.2 \cdot 10^7$
External	$2.4 \cdot 10^4$	$2.5 \cdot 10^5$	$2.5 \cdot 10^6$
Sibling	$2.4 \cdot 10^4$	$2.5 \cdot 10^5$	$2.5 \cdot 10^6$
Past	$1.5 \cdot 10^3$	$1.6 \cdot 10^4$	$1.6 \cdot 10^5$

Table 3: Minimum execution times (in seconds) for different intentions (in parentheses, the corresponding execution times for NP)

	SSB_1	SSB_{10}	SSB_{100}
Constant	0.60 (0.60)	6.77 (6.77)	45.14 (45.14)
External	0.27 (0.31)	2.38 (2.60)	32.86 (35.60)
Sibling	0.32 (0.42)	3.69 (4.97)	49.61 (99.93)
Past	1.20 (3.21)	11.72 (30.93)	118.25 (321.11)

Figure 3 shows, on a logarithmic scale, the times in seconds for executing the Constant, External, Sibling, and Past intentions using the NP, JOP, and POP plans, for increasing cube cardinalities. As to Constant, assessing a target cube of $1.2 \cdot 10^7$ tuples (derived by querying SSB_{100}) takes about 45 seconds, mostly employed to get the data from the DBMS. Note that, since this assessment does not require the retrieval of a benchmark cube, only NP is feasible. As to External, the only possible plans are NP and JOP (POP is not feasible here), with JOP providing the best performance. As to Sibling and Past, POP performs the best, taking 50 seconds and 118 seconds, respectively. Being based on the pivot operator, POP gets in both cases the target cube and the benchmark at once by retrieving the slices required together. In other words, POP avoids the join between the target cube and the benchmark, a time-consuming operation for NP and JOP. Overall, NP has the worst performance, since (i) it requires to separately get both cubes and join them into main memory, and (ii) it may load into main memory unnecessary data (i.e., the tuples that will not match in the join). Overall, we can conclude that (i) JOP, when applicable, outperforms NP, and (ii) POP, when applicable, outperforms JOP and NP. This is summarized in Table 3 which, for each benchmark type, compares the best performance with the one of the naive execution strategy. Remarkably, this table also clearly shows that our approach scales linearly for all the intentions.

Our last experimental goal is to understand which are the most expensive execution steps, i.e., those for which there is room for further optimizations. The overall execution time for

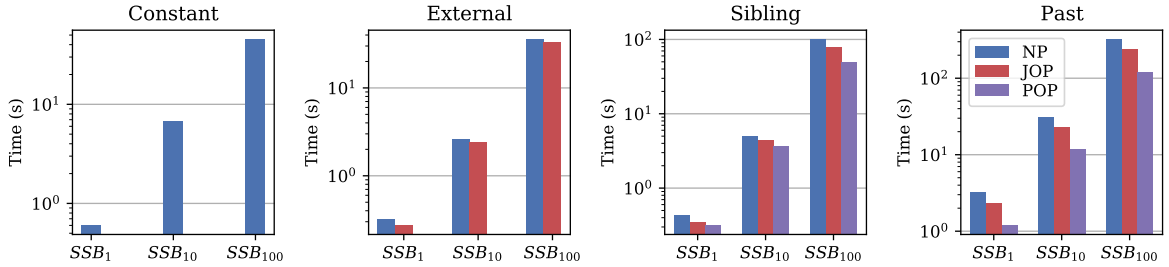

Figure 3: Execution times for increasing cardinalities of the target cube C

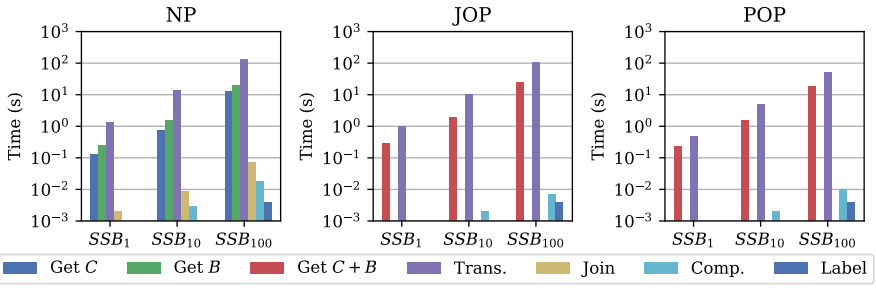

Figure 4: Breakdown of the execution time of the Past intention for increasing cardinalities of the target cube C

an intention can be broken down into the time necessary to (1) get the target cube, (2) get the benchmark, (3) transform the two cubes (e.g., to apply regression in past benchmarks), (4) join them, (5) compute the comparison/transformation, and (6) label the result. This breakdown is shown in Figure 4 for each plan and with increasing cube cardinalities. We focus on the Past intention, that is the most complex one since forecasting measure values requires to compute a regression. First of all, we observe that the execution times for comparison and labeling are in the order of milliseconds. Thus, not surprisingly, they are negligible with respect to the time necessary to get and join the cubes. For all three plans, transformation is the most time-consuming step, since linear regression has to be applied to huge numbers of tuples. As to the time for accessing data, note that:

- NP brings both the target C and benchmark B cubes into main memory to join them; the cost for this main-memory join is lower than the ones for getting the two cubes, but still not negligible. The cost for the pivot operation is counted as transformation.
- JOP pushes the join to SQL; thus, in this case the cost for the join is counted together with the one for getting $C+B$. The cost for the pivot operation is counted as transformation.
- POP replaces the join with a pivot operation and pushes it to SQL, thus, the cost of pivot here is part of the cost for getting $C+B$.

7 RELATED WORK

7.1 OLAP models and operators

OLAP comes with a large number of proposals on its foundations and operators, all of which slowly converged towards the core ideas of cubes, dimensions, dimension hierarchies, and levels as well as operators like roll-up, drill-down, slice, drill-across during the late '90s. To avoid overcrowding the discussion, we refer the interested reader to an excellent survey [16].

Over the years, several operators have been proposed to complement the fundamental ones. The *DIFF* operator [17] returns the set of tuples that most successfully describe the difference of values between two cells of a cube that are given as input. The same author also describes a method that profiles the exploration of a user and uses the Maximum Entropy principle to recommend which unvisited parts of the cube can be the most surprising in a subsequent query [18]. Finally, the *RELAX* operator allows to verify whether a pattern observed at a certain level of detail is present at a coarser level of detail too [19].

In a different line of research, prediction cubes are proposed with the characteristic property that each of the cells comes with a model that is trained to produce a predictive model with data that correspond to that cell [5]. Then, a comparison between model and actual value is also possible, assessing the model's accuracy. Also, the Shrink operator [9, 15] has been proposed to reduce the result size of a query with minimal loss of information value via the calculated fusion of data slices.

Alternative operators have also been proposed in the Cinecubes method [7, 8]. The goal of this effort is to facilitate automated reporting, given an original OLAP query as input. To achieve this purpose two operators (expressed as *acts*) are proposed, namely, (a) *put-in-context*, i.e., compare the result of the original query to query results over similar, sibling values; and (b) *give-details*, where drill-downs of the original query's groupers are performed.

Compared to the previous proposals, our work on the explicit introduction of an assess operator differs in the fundamental problem it addresses. The works of Sarawagi are mostly of explanatory rather than assessment nature. Similarly, prediction cubes are trying to assess the impact of a set of predictor attributes on a class label in the context of a data cube, via an introduced model for their relationship —again, the emphasis is on trying to explain what we see rather than trying to provide assessments and labels on the comparison of the assessment. The Shrink operator is intended to compress without losing too

much information. The Cinecubes approach introduces an automatically invoked model of assessment in its put-in-context act; this is indeed a first form of assessment, although not tunable or explicitly invoked by the user.

7.2 The Intentional Analytics Model

The IAM for OLAP was introduced in [20]. Later this proposal was significantly extended [21]. The main idea behind the intentional model for OLAP is that OLAP models need to be extended with (a) new operators, (b) altering of the definition of a query result, (c) introducing highlights to annotate the answers. To address the first requirement, the traditional roll-ups and drill-downs operators were complemented with operators that pertain to the *intention* of the user towards the data —i.e., what is the reason why the user poses the query. The original, large set of operators (including operators like verify and analyze) was later solidified and formalized into five operators, namely, describe, assess, explain, predict, and suggest [21]. The result of a query is also redefined as a combination of data and KDD *models* that are applied over the data. Also, the resulting data and models are evaluated with respect to their interestingness to produce highlights, i.e., subsets of the data that provide the most of novel information to the user. The foundations of the model can be linked to Bloom's taxonomy and Anderson and Krathwohl's refinement to it [13, 22], which organize cognitive tasks as: (a) remembering, (b) understanding, (c) applying a procedure, (d) analyzing (component interrelationships), (e) evaluating (with respect to criteria and standards), and (f) creating.

Although the IAM acts as an all-encompassing framework for defining new operators, results, and highlights for OLAP, the goal of the previous works was not go down into the details of each operator, but rather to dictate templates on what kind of algebraic operators we can introduce. The particularities of the describe operator (supporting the understanding process in Bloom's framework) were further explored [4]. The current paper extends the originally proposed assess operator (in turn, inspired by the put-in-context operator) in significantly deeper ways, as it comes with several alternatives that were not obviously expressed in the original work [21], as well as with the syntax of an SQL-like language and optimization techniques.

8 CONCLUSIONS

In this paper we have introduced the assess operator to automatically evaluate and characterize the result of a cube query in terms of labels given to the single cells based on their comparison with a benchmark. We have provided several alternatives for specifying benchmarks, comparison, and labeling schemes. Finally, we have discussed alternative plans for the execution of assess statements showing that their performance is perfectly in line with the *right time* requirement of analysis sessions.

Our future work on the assess operator will develop in different directions:

- Consider cube schemas including descriptive properties of levels (e.g., the population of a country). Introducing properties will enable users to express more complex statements, e.g., to compare *per capita* sales of different countries.
- Devise strategies for effectively completing partial assess statements, for instance, ones where the against, using or benchmark clauses are not specified by the user. Interestingly, this could require different possibilities to be tested and ranked based on their expected interest for the user.
- Enhance the expressiveness of the assess operator by considering more complex labeling functions (e.g., functions based on ranges that depend not only on comparison values of cells, but also on their coordinates) and additional types of benchmarks (for instance to let the sales of milk be assessed against those of drinks, i.e., against an ancestor of milk in the roll-up order).
- Investigate the relevant properties of our logical operators and develop a cost-based optimization strategy.

SolveDB$^+$: SQL-Based Prescriptive Analytics

Laurynas Siksnys, Torben Bach Pedersen, Thomas Dyhre Nielsen, Davide Frazzetto
Department of Computer Science, Aalborg University, Denmark
{ siksnys, tbp, tdn }@cs.aau.dk david.frazzetto@gmail.com

ABSTRACT

Today, advanced data analysts make use of both predictive models and optimization problem solving to build data-driven decision making applications, a combination of technologies recently termed *Prescriptive Analytics* (PA). Current PA applications typically have multiple layers of poorly integrated components: a relational DBMS for data storage/management, ML tools for prediction, and specialized software packages for problem modeling and optimization problem solving. This complex stack leads to inefficient, labor-intensive, and error-prone PA workflows, blocking wider adoption of PA. In this paper, we present SolveDB$^+$ – an RDBMS for PA applications which supports all PA steps with *modeling*, *predictive*, and *optimization* functionalities, and integrates these in a common SQL-based framework. Major SolveDB$^+$ novelties are 1) a powerful SQL-based approach for PA problem specification and solving, 2) an extensible in-DBMS infrastructure for prediction and optimization solvers, and 3) in-DBMS modeling and management of PA models. SolveDB$^+$ significantly improves both PA developer productivity and performance.

1 INTRODUCTION

As the next step after Predictive Analytics, *Prescriptive Analytics* (PA) has recently emerged as a new frontier in analytics, combining data management, predictive analytics and ML, and operations research [17]. PA provide a specific course of action for questions such as "How should we maximize our sales in Europe?" PA systems are still in their infancy, typically glued together in an ad-hoc system with separate analytics and optimization tools on top of an RDBMS. There are no integrated PA platforms that combine *data management*, *predictive*, and *optimization* functionalities using a single language, e.g., the frequently used in-DBMS analytics engines only support the first two.

As a running PA example, we consider renewable energy optimization. In a building, PV panels produce intermittent, varying electricity, to run its Heating, Ventilating, and Air Conditioning (HVAC) system. We want to reduce energy costs by using more PV electricity, which requires aligning HVAC operation to PV supply ahead of time, taking forecasted prices and user comfort into account. Table 1 shows a dataset for this case. Input data is a multivariate time series of outdoor (`OutTemp`)/indoor (`inTemp`) temperatures, HVAC consumption (`hLoad`), and PV production (`pvSupply`) per hour. Rows 07:00 - 11:00 are historical data from sensors. Rows 12:00 - 16:00 define future states: `outTemp` contains forecasted outside temperatures; the unknown values of `inTemp`, `hLoad` and `pvSupply` in 12:00 - 16:00 represent decision variables for which PA should compute values by aligning `hLoad` with `pvSupply` at the next 5 hours such that `inTemp` remains within the 20–24°C comfort range and HVAC power limits (0–17kW) are respected. The workflow below exemplifies the 5 overall phases of PA seen in Figure 1.

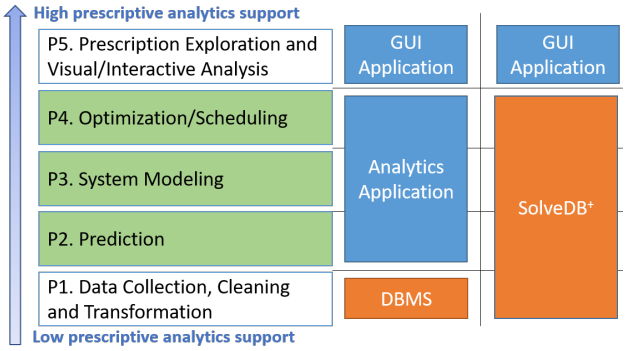

Figure 1: The 5 PA phases and the used software stacks

P1: Collect, clean, validate, and transform the input data.
P2: Predict PV supply given `pvSupply` and `outTemp`.
P3: Model `inTemp` dynamics in relation to `inTemp` and `hLoad`, which requires tuning parameter values specific to this building.
P4: Find optimal `hLoad` values by minimizing electricity cost subject to initial conditions, `pvSupply`, `hLoad`, and comfort constraints, applied over the calibrated model (P3).
P5: Analyze, visualize, and validate the results.

Traditionally, this PA workflow requires a complex software stack with different tools for data management, forecasting, system modeling, and optimization, leading to several *problems*: **Steep Learning Curve:** Different tools have different usage and modeling methodologies, making the learning curve for building PA applications much steeper, which, in turn, leads to more *errors* and *misuse*. **Poor Developer Productivity:** The tools are based on different programming/query languages and have to be glued together in ad-hoc ways to realize PA workflows, leading to *poor developer productivity*, *tool incompatibilities*, and even more *errors* [2]. **Bad performance:** Large amounts of data have to be shipped back and forth between the many tools, leading to high *I/O and memory costs* and *long runtimes* (see Sec. 5). To remedy these problems,these *research challenges* (RCs) must be met:
RC1: Provide a concise yet powerful SQL-based syntax for PA decision problems, supporting efficient query processing.

Table 1: Input dataset for campus energy management.

2017/07/02 16:00	11	?	?	?

RC2: Provide a concise yet powerful way to share optimization models across sub-problems of the overall PA problem.
RC3: Provide a powerful, easy-to-use, and extensible way of transparently integrating external prediction functionality into PA workflows.
RC4: Seamlessly integrate RC1–RC3 in a SQL-based system.

To meet these challenges, we present SolveDB$^+$. The fact that most PA systems use an RDBMS for data storage [16, 17] combined with the huge popularity of in-DBMS analytics (see Sec. 2), motivates us to propose the first SQL-based in-DBMS platform for PA applications, with these features (www.daisy.aau.dk/solvedb):

Supporting all PA phases: SolveDB$^+$ integrates data management, prediction, system modeling, and optimization in a single tool, yielding better PA productivity. **Extensibility:** SolveDB$^+$ allows developers to add new functionalities for custom PA applications. **Unified SQL-Based PA language:** SolveDB$^+$ extends SQL with new declarative constructs for unified PA problem modeling and analytical functionalities. An entire PA workflow, including forecasting, simulation, and optimization models, can be expressed in a single extended SQL query. **High performance:** The built-in PA algorithms (and user extensions) run in-DBMS, yielding more efficient execution and data exchange. Our experiments show that SolveDB$^+$ yields up to three orders of magnitude better performance for individual PA steps, and up to 3.5 times faster execution and 3 times smaller implementations for complete PA workflows, compared to state-of-the-art baselines, thus combining performance with usability/productivity.

The remainder of the paper is structured as follows. Section 2 discusses related work. Section 3 describes SolveDB$^+$'s prediction framework. Section 4 presents its new PA problem modeling features. Section 5 provides the experimental evaluation. Finally, Section 6 concludes and points out future work.

2 RELATED WORK

A recent extensive survey [16] identifies major emerging trends, remaining challenges, and available technology in the field of PA. In the classification used in this survey, SolveDB$^+$ falls in the category of analytical DBMSes, where analytical functionality is integrated directly within the DBMS back-end. Efforts within this category can be classified into *prediction* DBMSes, for forecasting and probabilistic analysis, and *optimization* DBMSes, for optimization problem solving. Table 2 summarizes and compares essential relevant systems in these sub-categories. The systems are compared in terms of: 1. *What primary language is used for data management* (Data QL); 2. *What primary language is used to specify analytics (incl., prediction and optimization) tasks* (Anl. QL); 3. *Does the system offer native support for predictions?* (Pred); 4. *Does the system offer native support for physical system models and estimating their parameters?* (Est), 5. *Does the system support optimization problem solving?* (Opt); 6. *Does the system support optimization (sub-)models that can be stored natively and manipulated as first-class citizens in the database, and re-used to forms more complex models?* (Mod). We now review these systems.

In-DBMS analytics is a major trend. Among prediction DBMSes, forecasting and in-database ML is supported by the major commercial DBMSes, Oracle [27], SQL Server [32], and TeraData [13]. Recently, HyPEr [12] and DB4ML [10] provide in-DBMS ML for main memory DBMSes. These systems provide efficient in-DBMS forecasting/ML functions, but lack automatic forecasting model selection, parameter estimation, optimization problem solving, and model management, unlike SolveDB$^+$. The

open source alternative MADlib [5] extends PostgreSQL with UDFs specialized for ML tasks like clustering, classification, and forecasting. Similar to MADlib, pgFMU [28] offers PostgreSQL UDFs for in-DBMS simulation and parameter estimation of *Functional Mock-up Units* (FMUs). These are interoperable simulation models that can define dynamic behaviour of complex physical systems. While FMUs are often used for predictions (P2, see Figure 1), pgFMU does not support including FMUs into user-defined optimization problems (P4). In comparison, SolveDB$^+$ supports (less detailed) so-called *grey-box* models that can be both simulated and optimized in the same environment. Among stand-alone DBMSes, F^{2}DB [15] focuses on time series forecasting in an SQL-based environment. While F^{2}DB specializes in, and is highly optimized for, time series forecasting tasks and employing specific model reuse and maintenance techniques, it does not support the development and integration of user-defined "do-it-yourself" models and generic library models, unlike SolveDB$^+$. In the Big Data context, systems such as SystemML [1], MLBase [14], and SciDB [11] integrate general-purpose declarative machine learning tools that offer scalable distributed computations. In the context of PA, *all* systems (except pgFMU) in this category *only offer support for the predictive analytics phase (P2).*

The optimization DBMSes have focused on advanced what-if scenarios, in-DBMS optimization problem solving, and search under advanced forms of constraints. Systems such as Searchlight [19] and PaQL [8] exploit powerful constraint solvers when processing advanced data search queries. InezDB [21] proposes a formal logic for the symbolic manipulation of optimization models inside a DBMS. Tiresias [23] and LogicBlox [6] provide users a Datalog-based language for what-if scenario analysis. Being the predecessor of SolveDB$^+$, SolveDB [31] is an extension of PostgreSQL for in-DBMS optimization problem solving and solver integration. SolveDB$^+$ extends SolveDB in the directions covering the highlighted PA phases in Figure 1. These new features in SolveDB$^+$, together with their impact (to be observed in Section 5), are highlighted in Table 3. These correspond 1-1 to the research challenges RC1–RC3 mentioned in Section 1, while the integrated SolveDB$^+$ system corresponds to RC4.

Table 3: New features of SolveDB$^+$ compared to SolveDB.

Feature	Description	Impact
In-DBMS Predictive Framework	Specialized forecasting models that are easy to install, (auto)select, and use.	Forecasting easier to use and up to 6 times faster.
Shared Optimization Models	Allow defining reusable optimization (sub-)models stored in-database with their objective functions, constraints, and data specs.	Up to: 2X less code for P3-P4, 16% less code for P1-P4, similar performance.
New Language Features	Asterisk notation, common decision table expressions, model inlining allow specifying PA problems more concisely/efficiently.	Up to 5X less code for P2-P4, similar performance.

In summary, Table 2 shows that while predictive and optimization DBMSes offer some level of in-DBMS analytics support, they do it only for *some* PA phases and do not offer "SQL for all PA phases" like SolveDB$^+$. In comparison, SolveDB$^+$ is the only system to combine and unify predictions and optimization problem solving within a single SQL-based system.

Explainability, also called interpretability, of ML pipelines has received much attention in recent years. It has been considered both for specific categories of ML pipelines, e.g., user group analytics [25] or data exploration [18], and more generally in a survey of AutoML pipelines [33]. In comparison, SolveDB$^+$ focuses on another category, PA pipelines, and supports explainability in PA phases P1-P4. For P1, we do not claim any new contributions, but simply offer the time-honored explainability of SQL. For (external) Prediction methods (P2), we inherit their existing explainability and add to it by declaratively specifying input and output in the solver specs. For System Modeling (P3) and for overall integration of the phases, our high-level declarative SQL-based syntax and shared models allow a higher level of abstraction which is more compact and explainable than a traditional imperative-style ML pipeline. For Optimization (P4), the declarative specifications of objective functions are immediately explainable. Section 5 provides more details.

Another key aspect of ML pipelines is their connectivity to other components/frameworks [33]. As for the "inbound" connectivity, external components are integrated for use in SolveDB$^+$ in two ways. Like other in-DBMS analytics tools (see Tab. 2), SolveDB$^+$ uses UDFs to wrap external functions for direct use in SQL queries, Specifically to SolveDB$^+$, the solver concept is used to integrate external prediction components in a seamless way (see Sec. 3). As for the "outbound" connectivity, SolveDB$^+$ can be integrated in larger pipelines just like other SQL-based in-DBMS analytics tools.

3 PREDICTION

The first phase in Figure 1 *P1: Data Collection, Cleaning, and Transformation* is well supported by the SQL queries, built-in functions, and UDFs of traditional RDBMSes [16], including SolveDB$^+$. Since PA applications need to look ahead in time, effectively supporting the next phase *P2: Prediction* is a key research challenge (RC3). This section describes how we meet RC3. While SolveDB$^+$ can accommodate different models and algorithms for prediction (using both built-in and external tools), it offers dedicated support

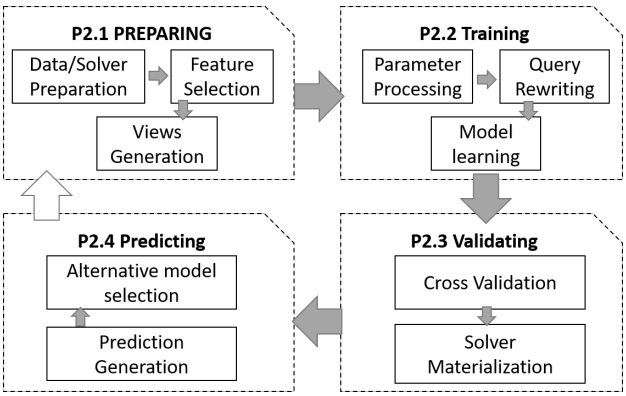

Figure 2: Prediction process + SolveDB$^+$ implementation.

for *time series forecasting* methods. These are widely used for data-driven prediction based on current and historical data.

3.1 Time series forecasting in SolveDB$^+$

Following the energy planning example, the input to the prediction phase is the time series shown in Table 1. The objective is to predict the PV supply for the next 5 hours, by filling in the missing `pvSupply` values in Table 1. This is accomplished by a specific time series forecasting method (e.g., regression) involving a number of steps, as shown in Figure 2: *preparing* – extracting and formatting the data to fit forecasting models, *training* – fitting the forecasting models on the dataset, *validating* – validating the models using cross validation or other evaluation procedures, and *predicting* – forecasting new values.

To support the user in using these methods, SolveDB$^+$ provides its in-DBMS *Predictive Framework*, which (1) exposes various time-series forecasting methods through SQL ("transparently integrating" in RC3), (2) hides the complexity ("easy-to-use" in RC3) of choosing and using these methods (the *preparation*, *training*, *validation*, and *prediction* steps), and (3) offers different extensibility options when a new forecasting method needs to be integrated ("extensible" in RC3). For example, the prediction problem above can be solved in two different ways, using:

Specific forecasting method The following example query invokes the specific forecasting method ARIMA:

```
1 SOLVESELECT t(pvSupply) AS (SELECT * FROM input)
2 USING arima_solver(predictions := 5, time_window := 5,
3                    features := outTemp)
```

To expose the method, SolveDB$^+$ uses the specialized **`SOLVESELECT`** statement (extending the one from SolveDB [31]), to be described in detail in Section 4. It invokes a SolveDB$^+$-native *solver* (*arima_solver*) to derive a so-called *output relation* (a database table) from a so-called *input relation* (**`SELECT * FROM`** `input`) by adding/deleting rows or filling in values in the specified *decision columns*. In this example, the decision column is `pvSupply`, the values of which are requested to be populated by *arima_solver*. The output relation has the same schema as the input relation, but with the `pvSupply` column filled as shown in Table 4. To derive the output relation from the input relation, `arima_solver` additionally takes solver parameters: the number of predictions (*predictions := 5*), the number of time steps to use for training (*time_window:=5*), and the column (*features:=outTemp*) to use as a feature attribute. The solver then performs the steps of *preparation*, *training*, *validation*, and *prediction* (see Figure 2) using the ARIMA model

Table 4: Output of the *Prediction* phase for the example.

time	outTemp	inTemp	hLoad	pvSupply
2017/07/02 07:00	05	21	100	0
2017/07/02 08:00	06	20.5	250	0
2017/07/02 09:00	06	21	150	200
2017/07/02 10:00	07	23	120	254
2017/07/02 11:00	08	23	80	320
2017/07/02 12:00	09	?	?	**200**
2017/07/02 13:00	11	?	?	**220**
2017/07/02 14:00	12	?	?	**260**
2017/07/02 15:00	11	?	?	**140**
2017/07/02 16:00	11	?	?	**0**

trained on data from the input relation with the given parameters. Thus, **SOLVESELECT** allows the user to invoke any specific predictive solver installed in SolveDB$^+$, including solvers for Linear Regression, Logistic Regression, ARIMA, or the powerful *Predictive Advisor* described next. The carefully designed use of the solver ensures the transparency mentioned in RC3.

Predictive Advisor Users can get automated model selection and configuration by using the *Predictive Advisor*, exposed as `predictive_solver`. This solver hides *model selection*, *feature selection*, and *parameter fitting* from the user, and transparently performs *preparation*, *training*, *validation*, and *prediction* and fills in the missing values in the input relation, thus ensuring "easy-of-use" in RC3. Now, the prediction query above can be rewritten as the following simpler query:

```
1 SOLVESELECT t(pvSupply) AS (SELECT * FROM input)
2 USING predictive_solver()
```

The extensibility offered by SolveDB$^+$ also allows for alternative automated predictive frameworks to be integrated as part of the SolveDB$^+$ predictive advisor ("extensible" in RC3).

3.2 Steps of the Predictive Framework

In SolveDB$^+$, the underlying steps of *preparation*, *training*, *validation*, and *prediction* are standardized and their common routines are shared among different forecasting methods, (ensuring "easy-of-use" in RC3.

P2.1 Preparing When the predictive solver (e.g., `arima_solver`) is invoked, the input relation is first analyzed. The framework extracts *decision* (i.e., to be populated with values) and *feature* (to be used as features) columns specified by the user. After recognizing the types of the input columns, it selects candidate solvers from the pool of predictive solvers by comparing the set of decision and features columns to those supported by the solvers. The framework logically partitions the input relation into the training, test, and validation segments by matching the schema for each candidate solver. The selected solver(s) are then used for the training step.

P2.2 Training Next, the model-specific parameters of the candidate solvers are tuned on the training segment of the input relation. The predictive framework automatically generates a **SOLVESELECT** query that specifies an optimization problem with model parameters as decision variables to optimize. This optimization problem is solved by utilizing the solving capabilities of SolveDB$^+$ (Section 4). For example, the ARIMA solver is installed with the standard ARIMA parameters `ar`, `i`, and `ma`, each associated to the domain $[0, 5]$. Therefore, `predictive_solver` described earlier automatically and transparently invokes the following parameter estimation query:

```
1 SOLVESELECT p(ar, i, ma) AS
2   (SELECT NULL::int AS ar,NULL::int AS i,NULL::int AS ma)
3 MINIMIZE(SELECT arima_rmse(
4          ar:=SELECT ar FROM p,
5          i := SELECT i FROM p,
6          ma := SELECT ma FROM p))
7 SUBJECTTO (
8          SELECT 0 <= ar <= 5, 0 <= i <= 5, 0 <= ma <= 5
9          FROM p)
10 USING swarmops.pso()
```

The above **SOLVESELECT** query specifies a global black-box optimization problem, where the values of the parameters `ar`, `i`, and `ma` are found by minimizing the RMSE between the training set and the ARIMA predictions, computed by the function `arima_rmse` in the **MINIMIZE** clause (line 3). The **SUBJECTTO** clause specifies the range in which the parameters can vary. The optimization solver `swarmops` uses a built-in particle swarm optimization method [20] to iteratively attempt to improve a candidate solution with regards to RMSE.

P2.3 Validating Next, the candidate predictive solvers are compared using cross validation. The solver/model leading to the lowest error is selected. As a side effect, the calibrated model instances are stored in a database as user-defined type (UDT) entities for fast reuse of the solver result later.

P2.4 Predicting Finally, predictions are generated by the selected best candidate solver and returned to the user in the form of an output relation of **SOLVESELECT** (Table 4). As **SOLVESELECT** expresses a view over the input relation (Table 1), no user tables are modified in the database.

3.3 Developer Interface

SolveDB$^+$ addresses the "extensible" in RC3 by providing the user with a developer interface to install new in-DBMS predictive solvers. There exists two categories of solvers: *black box* and *white box*. *Black box* solvers are expected to manually handle the steps of data preparation, feature selection, cross-validation, etc., thus *overriding* the predictive framework functionalities. In contrast, *white box* solvers expose the model specifics (e.g., model parameters, their types, etc.) as well as model training and prediction logic to the predictive framework. This way, the solvers may use the functionalities (e.g., **SOLVESELECT**) provided by SolveDB$^+$ for preparing, training, and validating. Such solvers use the solver extensibility capabilities already present in SolveDB [31]. This allows the developers to easily expand the system by taking advantage of existing SolveDB$^+$ solvers/functionality and integrating new prediction models from existing frameworks, e.g., Scikit-Learn [3], Weka [9], MATLAB [22], Statsmodels [29], and TensorFlow[7].

As we will show in Section 5, SolveDB$^+$ is able to offer reduced PA application development efforts and improved overall performance after the integration of desired solvers, yielding up to 5 times more compact problem specifications and up to 6 times reduced forecasting time, compared to SolveDB and commonly used predictive frameworks.

4 OPTIMIZATIONS AND SYSTEM MODELING

Optimization problem solving is essential in 3 of the 5 PA phases (P2, P3, P4), and it therefore plays an essential role in SolveDB$^+$. To deal with optimization problems, SolveDB$^+$ borrows a number of solvers from SolveDB for the different classes of optimization problems, including *linear programming* (LP), *mixed-integer programming* (MIP), and blackbox global optimization (GO), some of

Table 5: LR problem variable layout and a new c_mask column introduced during the CDTE rewrite

id	*pOTemp*	*pMonth*	*pEps*	*error*	**c_mask**
1	*pOTemp*	*pMonth*	*pEps*	e_1	B'11'
2				e_2	B'01'
...				...	B'01'
M				e_M	B'01'

which were already demonstrated in Section 3. To address RC1, SolveDB$^+$ further extends the query syntax used for accessing these solvers. We now elaborate on these new language features.

4.1 Model Specification Syntax

SolveDB$^+$ uses the following syntax to interact with various (e.g., LP/MIP) solvers registered in the active database:

```
1 {SOLVESELECT | SOLVEMODEL}
2         [alias[(col_name[,...])] AS](select_stmt)
3 [INLINE [alias                   AS](select_stmt) [,...]]
4 [WITH   [alias[(col_name[,...])] AS](select_stmt) [,...]]
5 [MINIMIZE (select_stmt) [MAXIMIZE (select_stmt)] |
6  MAXIMIZE (select_stmt) [MINIMIZE (select_stmt)]]
7 [SUBJECTTO [alias AS] (select_stmt) [,...]]
8 [USING solver_name[.method_name][(param[:=expr][,...])]]
```

As shown earlier, the user can use **SOLVESELECT** to define a *model* and pass it to SolveDB$^+$-compliant solver `solver_name` for evaluation using an optionally specified solving method, `method_name`, all defined as follows.

A *problem model* m is defined as a 4-tuple (D, R, s, m). D is the specification of *data and decision variable columns* (lines 2,4). R is the specification of rules that define how the values of the decision variable columns should be instantiated (lines 5-7). s is the name of the solver (`solver_name`) that should evaluate the rules R on the given D using some method m (`method_name`, line 8). Both D and R define two separate sets of specially annotated database relations. Specifically, $D = (D_1^{a_1}, D^{a_2}, \ldots, D_N^{a_N})$ where, $\forall i \in 1 : N, D_i^{a_i} = (c_1, \ldots, c_k, \overline{c_1}, \ldots, \overline{c_l})$ is a SELECT statement (`select_stmt`) defining a database relation with the alias a_i (`alias`) assigned and defined by k *data columns* $c_1, \ldots, c_k$ and l so-called *decision columns* $\overline{c_1}, \ldots, \overline{c_l}$ (`col_name`). Decision columns denote that their rows are decision variables, the values of which should be computed by s. Here, $D_1^{a_1}$ (line 2) is denoted as *input relation*. In a similar way, $R = (R_1^{min}, R_2^{max}, R_3^{a_3}, \ldots, R_M^{a_M})$ is a set of relations that contain s-specific representations of rules defining how decision column values in D should be computed. For convenience, the aliases of R_1^{min} and R_2^{max} are fixed and they are specified in the **MINIMIZE** and **MAXIMIZE** clauses, respectively (line 5-6). The remaining $R_3^{a_3}$ to $R_M^{a_M}$ are specified in the **SUBJECTTO** block along with their respective aliases (line 7). This provides powerful yet concise model specs for RC1.

A *solver* in SolveDB is a user-defined function (UDF) capable of producing (a query for) a so-called *output relation* O in the schema of the *input relation* $D_1^{a_1}$ from a given problem model instance (D, R, s, m) and additionally supplied solver parameters `param` (line 8). SolveDB$^+$ assumes the following standard scoping rules within SOLVESELECT. Each $d_i^{a_i} \in D$ may access a relation $d_j^{a_j} \in D$ using the alias a_j if $j < i$, i.e., $\forall d_i^{a_i} \in D : scope(d_i^{a_i}) = \{(a_j \mapsto d_j^{a_j} | d_j^{a_j} \in D, j < i\}$. Each $r_i^{a_i} \in R$ may access all data and decision variable tables, i.e., $\forall r_i^{a_i} \in R : scope(r_i^{a_i}) = \{(a \mapsto d^a | d^a \in D\}$.

For example, consider a predictive solver (for P2) based on linear regression (LR). In SolveDB$^+$, LR model parameter estimation is specified using the following **SOLVESELECT**:

```
1 SOLVESELECT p(pOTemp, pMonth, pEps) AS (SELECT * FROM pars)
2 WITH e(error) AS (SELECT *, NULL::float8 AS error
3                   FROM input)
4 MINIMIZE (SELECT sum(error) FROM e)
5 SUBJECTTO(SELECT -1*error <=
6   (pOTemp*outTemp + pMonth*month(time) +
7   pEps - pvSupply) <= error FROM e, p)
8 USING solverlp.cbc()
```

Here, lines 1-3 specify model *data and decision columns*. Lines 4-7 specify *rules* that define an objective function and constraints that involve decision variables from the tables p and e. Finally, line 8 specifies *solverlp* and *cbc* as a SolveDB$^+$-compatible solver and a solving method, respectively.

This general **SOLVESELECT** syntax based on standard SQL SELECTs allows exposing different kinds of models and solvers to user queries in a powerful yet concise way (RC1). Compared to SolveDB, SolveDB$^+$ uses a number of novel modeling features unavailable in SolveDB. These are outlined in the remainder of this section.

4.2 Asterisk notation

To support RC1's need for concise and powerful syntax , SolveDB$^+$ proposes the asterisk (*) notation for decision variable column specification (`col_name`). Like SELECT * in the standard SQL, this allows declaring all table columns as decision variables, thus offering more compact problem specifications. Using asterisks, Line 1 in the above optimization problem can be concisely specified as **SOLVESELECT** `p(*)` **AS** (**SELECT** * **FROM** `pars`).

4.3 Common Decision Table Expressions

In SolveDB, the **WITH** clause within **SOLVESELECT** is not supported. Consequently, decision columns (variables) are only allowed in a single (input) relation $D_1^{a_1}$ (i.e., $N = 1$). Therefore, objective and constraint (SELECT) expressions in the **MINIMIZE**/ **MAXIMIZE** and **SUBJECTTO** blocks may become unnecessarily large and complex. Consider the LR model fitting example. This problem uses 2 collections of decision variables: *pOTemp*, *pMonth*, *pEps* as model parameters and e_1, e_2, ..., e_M ($M >> 3$) as prediction errors. One of the most convenient ways to arrange these variables in a single input relation in SolveDB is depicted in Table 5. Here, *pOTemp*, *pMonth*, *pEps* are contained within a single row and e_1, ..., e_M contained within a single column, with many "empty cells" representing *unbound* decision variables. When not referenced within **MINIMIZE**/**MAXIMIZE** and **SUBJECTTO** expressions, such unbound variables are automatically excluded from computations by SolveDB$^+$. Still, referencing *pOTemp*, *pMonth*, *pEps* in the objective and constraint expressions is quite cumbersome - the user is required to supply the predicate **WHERE** `id=1` in all relevant **MINIMIZE**/ **MAXIMIZE**, and **SUBJECTTO** expressions. This makes problem specifications complex and less readable, especially when more than two variable collections are modeled.

Again meeting RC1's need for concise and powerful syntax, SolveDB$^+$ proposes to extend the SOLVESELECT clause with so-called *Common Decision Table Expressions* (CDTEs). As an extension of Common Table Expressions (CTEs, i.e. WITH queries), these allow specifying additional temporary relations, $D_2^{a_2}$, ..., $D_N^{a_N}$, with or without decision columns, where each relation $D_i^{a_i}$ can be accessed from SELECTs of $D_j^{a_j}$, $j > i$, and in the

MINIMIZE/**MAXIMIZE** and **SUBJECTTO** blocks ($R_1^{min}, \ldots, R_M^{ctr_M}$) using the alias a_i. All decision variables of $D_1^{a_1}, \ldots, D_N^{a_N}$ are solved together in a single optimization problem. Note, when the list of the decision columns is empty ($|\{\overline{c} \in D_i^{a_i}\}| = 0$), the CDTE has the semantics of the standard CTE. As demonstrated earlier, CDTEs in SolveDB$^+$ allow conveniently modeling two or more collections of decision variables, unlike SolveDB.

Efficient CDTE query evaluation ("efficient query processing" in RC1): SolveDB$^+$ efficiently evaluates SOLVESELECT queries with CDTEs in two different ways. SolveDB$^+$ either rewrites the CDTEs to a single input relation and standard CTEs, or passes them to a solver for specialized processing. The first approach is preferred, as it is transparent and applicable to all registered SolveDB$^+$ solvers. Here, SolveDB$^+$ first generates a new input relation ($D_1'^{a_1}$) by joining all CDTEs with decision variables and adding a special bit string attribute `c_mask` (see Table 5) to denote CDTEs relevant to specific rows. Then, SolveDB$^+$ generates and processes a new SOLVESELECT *without* decision variables in CDTEs, by using different projections over the new input relation:

```
1 SOLVESELECT l(pOTemp,pMonth,pEps,error) AS
2             (SELECT * FROM input)
3 WITH p AS (SELECT pOTemp, pMonth, pEps FROM l
4            WHERE (c_mask & b'10') <> b'00'),
5      e AS (SELECT error FROM l
6            WHERE (c_mask & b'01') <> b'00')
7 MINIMIZE(SELECT sum(error) FROM e) ...
```

This syntactical extension does not increase the expressive power of SOLVESELECT as the WITH sub-expressions can always be combined into a joint input relation. Instead, CDTEs allow a more intuitive and comcise organization of decision variables in a SOLVESELECT query ("powerful yet concise" in RC1), which is particularly useful when dealing with many auxiliary variables in complex PA cases.

4.4 Shared Models and Model Management

PA applications often build (optimization) models by combining several existing models, e.g. for P3 in our use-case we want to use a generic linear time-invariant *state-space model* (LTI) for capturing temperature dynamics of the HVAC-equipped campus building, and then apply this model in two optimization problems – *LTI model parameter estimation* and *electricity cost optimization* – P3 and P4 in Figure 1. For the first problem, we want to use our input data to estimate the parameters a_1, b_1, and b_2 of the following discrete LTI model for this specific building:

$$x[n+1] = \begin{bmatrix} a_1 \end{bmatrix} \mathbf{x}[n] + \begin{bmatrix} b_1, b_2 \end{bmatrix} \mathbf{u}[n]$$
$$y[n] = \begin{bmatrix} 1 \end{bmatrix} \mathbf{x}[n] + \begin{bmatrix} 0, 0 \end{bmatrix} \mathbf{u}[n]$$

Here, $\mathbf{x}$ is the system 1×1 *state vector* denoting the *inside temperature* of the building; $\mathbf{u}$ is the system 2×1 *input vector* denoting *outside temperature* and applied *HVAC load*, and $\mathbf{y}$ is the 1×1 *output vector* which just "feeds forward" the inside temperature.

In the second problem, we want to use this LTI model with instantiated parameters a_1, b_1, and b_2 inside the cost optimization problem with additionally specified constraints on state variables (inside temperature bounds) and input variables (HVAC power bounds). Obviously, these two problems share the common specification of the generic LTI model (i.e., equations above). However, the LTI model constraints have to be redefined in each of the problems when using SolveDB, as there is no way to reuse them.

Algorithm 1: Problem model instantiation

Input: m - a generic model; Δm - instantiation model
Output: m' - an instantiated model

1 $D \leftarrow \{d^{alias} \in m.D | alias \notin \{alias | d^{alias} \in \Delta m.D\}\} \cup \Delta m.D$
2 $R \leftarrow \{r^{alias} \in m.R | alias \notin \{alias | r^{alias} \in \Delta m.R\}\} \cup \Delta m.R$
3 **return** *(D, R, m.s, m.m)*

To address RC2, SolveDB$^+$ proposes the concept of a *shared problem model*. The shared problem model is a special user-defined data type (UDT), which can be created via the **SOLVEMODEL** clause sharing the same syntax as **SOLVESELECT** (see above). Instead of returning an output relation, this new clause returns the UDT with the complete problem specification inside, i.e., (D, R, s, m). In SolveDB$^+$, such UDTs can be *transformed*, *used in computations*, or *stored* in a database using SolveDB$^+$ queries. The shared LTI model of the building inside temperature can be specified, for example, as:

```
1 SELECT (SOLVEMODEL
2   pars  AS (SELECT 0.0 AS a1,0.0 AS b1,0.0 AS b2)
3 WITH
4   data0 AS (SELECT 21.0 AS inTemp),
5   data  AS (SELECT time,outTemp,inTemp,hLoad FROM input),
6   simul AS (
7     WITH RECURSIVE t(time, x, inTemp) AS (
8       -- Initial data, for step 0
9       SELECT (SELECT min(ts) FROM data) AS time,
10             (SELECT x0 FROM data0) AS x,
11             (SELECT intemp0 FROM data0) AS inTemp
12    UNION ALL
13      -- Computed data, for steps > 0
14      SELECT (SELECT time+interval '1 hour'),
15             (SELECT a1*x+b1*outTemp+b2*hLoad FROM pars),
16              n.inTemp
17      FROM t LEFT JOIN LATERAL
18               (SELECT time, inTemp, outTemp, hLoad
19                FROM data) AS n
20             ON t.time = n.time - interval '1 hour'
21      WHERE (time < (SELECT max(time) FROM data))
22    SELECT time, x, intemp FROM t)))
```

As seen in the example, this model is, essentially, a placeholder with (dummy) relations for LTI model parameters (*pars*), initial values of the state variables (*data*0), and system inputs to be used for model training or predictions (*data*); and relations that represent simulated system states and outputs (*simul*). This model is fairly useless without actual model parameters and data being specified. Therefore, SolveDB proposes 3 specialized "conside yet powerful" operations on shared problem models: *instantiation*, *evaluation*, and *inlining*.

Model instantiation This operation instantiates a (generic) model into a (specific) problem model instance. This is done by allowing the user to redefine the input relation or any other CDTE in the problem model, along with their decision column list. For this, the operator << and another model are used, e.g.,

```
1 SELECT m << (SOLVEMODEL pars(b2) AS
2   (SELECT 0.995 AS a1, 0.001 AS b1, 0.2::float8 AS b2))
3 FROM model
```

In this example, a generic LTI model `m` is first selected from the table `model`. Then, `m` is instantiated using specifications of another model (say Δm) that is generated with **SOLVEMODEL** in the same query. Finally, the instantiation operator << replaces *pars* in m with *pars* in Δm while denoting $\{b2\}$ as a sole decision column with its initial value given in the table. The semantics of this operator is seen in Algorithm 1.

In general, as seen in Algorithm 1, model instantiation allows transferring an input relation, objective functions, constraint expressions, and any other CDTE expression from a *source model* to a *target model*. All entities that cannot be found using an *alias* in the target model are automatically added (instead of replaced) to the target model. This gives the possibility to inject data, different model parameters, objectives, constraints into a generic model.

Model Evaluation This operation allows accessing data from the input relation or any other CDTE inside the model. For this, SolveDB$^+$ introduces a new **MODELEVAL** clause:

```
MODELEVAL ( select_stmt ) IN ( select_stmt )
```

This clause retrieves a model instance by evaluating the 2^{nd} SELECT expression (`select_stmt`), then turns this model into a number of standard CTEs, and finally evaluates the 1^{st} SELECT expression in the context of these CTEs. Thus, the user can retrieve and inspect data specified by the model, e.g.,

```
MODELEVAL (SELECT a1, b1, b2 FROM pars)
       IN (SELECT m FROM model)
```

Model Inlining This operation allows embedding a model instance into another model instance – specified either by SOLVEMODEL or SOLVESELECT. To inline the model, the **INLINE** clause in **SOLVESELECT** or **SOLVEMODEL** is used, e.g.:

```
SOLVESELECT t(a1,b1,b2) AS
            (SELECT 0.5 AS a1,0 AS b1,0.5 AS b2)
     INLINE m AS (SELECT m <<
(SOLVEMODEL params AS (SELECT a1, b1, b2 FROM t)
       WITH  data0 AS (SELECT 25.0::float8 AS inTemp),
              data AS (SELECT * FROM input
              WHERE hload IS NOT NULL ))  FROM model)
MINIMIZE  (SELECT sum((x-inTemp)^2) FROM m_simulation)
SUBJECTTO (SELECT 0<=a1<=1, 0<=b1<=1, 0<=b2<=1 FROM t)
USING swarmops.sa()
```

This query specifies the problem of *least squares* to fit the LTI model parameters a_1, b_1, b_2 to the given data (Table 1). Here, the INLINE clause specifies that this problem depends on the shared problem model m from the table *model*. Before applying m to the outer problem, the model m has to be first instantiated with new LTI model parameters (line 4), a new initial value of the state variable (line 5), and new training dataset (line 6-7). Note, the decision columns (variables) from the outer problem (a1,b1,b2) are passed to the inner model during the instantiation, so their values can be used in computations defined by the inner model. Given this query, SolveDB$^+$ generates a new (outer) problem instance, making all internal model relations ($m.D$, $m.R$) available to the constraint expressions of the outer problem (lines 8-9) using the prefix $m\_$, where m is the assigned model alias (line 3).

The injection of the decision variables through model instantiation is not the only way to interconnect inner and outer problems in SolveDB$^+$. Another way is to declare that some of the inner model relations (CDTEs) contain decision columns. Consider the optimization/scheduling step of the PA process (P4 in Figure 1). To solve the cost minimization problem, SolveDB$^+$ allows defining the following query:

```
1  SOLVESELECT t(hload, iTemp) AS
2        (SELECT time, outTemp, inTemp, hLoad, pvSupply
3         FROM input WHERE hload IS NULL)
4  INLINE m AS (SELECT m << (SOLVEMODEL
5   data AS (SELECT time,outTemp,0 AS inTemp,hLoad FROM t)
6   WITH data0(inTemp) AS (SELECT NULL::float8 AS itemp))
7                FROM model)
8  MINIMIZE (SELECT sum((hload - pvsupply)*0.12) FROM t)
9  SUBJECTTO
10  -- Bind inner and outer problem variables
11  (SELECT t.inTemp = m_simul.x    FROM m_simul, t
12    WHERE t.time   = m_simul.time),
13  -- Initial conditions
14  (SELECT iTemp=20 FROM m_data0),
15   -- Comfort and HP power constraints
16  (SELECT 20<=intemp<=25, 0<=t.hpload<=17000 FROM t)
17 USING solverlp.cbc();
```

As seen here, model instantiation is used to declare that the attribute `inTemp` in the CDTE `data0` of the model m should be treated as decision column (line 6). Thus, a new decision variable(-s) will be introduced in the inner problem and made available to the specification of the outer problem (line 14).

Algorithm 2 elaborates the semantics of this **INLINE** clause. As seen in the algorithm, SolveDB$^+$ imports the input relation, CDTEs, and rule expressions from the inner model m into the outer model o. Each such expression receives a new prefixed alias for use in the outer problem to prevent naming collisions (lines 3,7). Further, table access scopes of these expressions are reworked such that the new relations (with new aliases) in the outer model can be accessed from the inner model expressions using the initial aliases, and without the need to modify the actual expressions (lines 5,9). In SolveDB$^+$, this is done by introducing additional CTEs in inner model expressions, e.g., **WITH** `data0` **AS** (**SELECT** * **FROM** `m_data0`), where m_data0 becomes a part of the outer model, but $data0$ is used in the inner model instead.

Algorithm 2: Problem model inlining

Input: o - a model instance before inlining; m - a model instance to be inlined; ma - a model alias;
Output: o' - a model instance after inlining

1 $prefix \leftarrow ma +' \_'$;
2 **for** $i \leftarrow 1 : |m_i.D|$ **do**
3 $\quad d^{prefix+a} \leftarrow \{d_i^a | d_i^a \in m.D\}$;
4 $\quad o.D \leftarrow o.D \cup \{d^{prefix+a}\}$;
5 $\quad scope(d^{prefix+a}) \leftarrow \{a_j \mapsto d^{prefix+a_j} | d_j^{a_j} \in m.D, j < i, d^{prefix+a_j} \in o.D\}$;
6 **for** $i \leftarrow 1 : |m_i.R|$ **do**
7 $\quad r^{prefix+a} \leftarrow \{r_i^a | r_i^a \in m.R\}$;
8 $\quad o.R \leftarrow o.R \cup \{r^{prefix+a}\}$;
9 $\quad scope(r^{prefix+a}) \leftarrow \{a_j \mapsto d^{prefix+a_j} | d_j^{a_j} \in m.D, d^{prefix+a_j} \in o.D\}$;
10 **return** *(o.D, o.R, o.s, o.m)*

Finally, as seen above, SolveDB$^+$ can "seamlessly integrate" the RC1-RC3 contributions of Sec. 3 and 4 and thus address RC4, allowing the user o specify a complete PA workflow as an extended SQL query. SolveDB$^+$ offers efficient in-DBMS processing by optimally using the DBMS query optimization and execution machinery for processing solver inputs and outputs, allowing for integrated (cache-aware) and optimized processing of PA workflows. The effects of using SolveDB$^+$ and its novel extensions are evaluated next.

5 EXPERIMENTAL EVALUATION

In this section, we first present results from a SolveDB$^+$ usability study involving a group of data scientists. To support the end user claims about SolveDB$^+$, we also evaluated SolveDB$^+$ on two typical PA use-cases from the fields of *energy* and *supply chain management*. Lastly, we used these use-cases to compare SolveDB$^+$ against SolveDB.

Table 6: Strong and Weak Points of SolveDB$^+$

Strong points
"*Syntax very SQL-like, queries feel natural, intuitive from a SQL users perspective. This also makes it **very** easy to pick up for anyone familiar with basic SQL.*"
"*I liked the syntax that makes you feel you are still working inside the database sphere while solving optimization problems without the need to jump between different solutions/languages*"
"*SolveDB+ is still a database system, meaning that it would be possible to to use it even in legacy systems...*"
"*I think SolveDB+ is a great tool! ... For any professionals I see this type of tool as the only tool for fast analytics.*"
"*... great idea and great tool. I have already suggested one of my students to check it out also...I am surprised how easy it was to implement and solve problems - definitely not the last time I will work with SolveDB+*"
"*Seems like a much more streamlined development experience.*"
"*Easy to use in a database-context*"
"*I do think python is more intuitive, but SolveDB+ is very close.*"
"*The simplicity, readability, easy to adapt and learn.*"
"*Fewer lines of code needed to solve the same problem...*"
"*SolveDB+ was faster than MADlib+pIPython*"
Weak points
"*...for some optimization problems, we need to put some "extra" effort to produce a good "representation" of the problem so it that can be handled by SolveDB+ (e.g. Sudoku solver). SolveDB+ needs a big community, and more detailed documentations and examples.*"
"*Needs to be updated on every PostgreSQL release*"
"*Due to relational nature of SQL syntax, some expressions are longer than they ideally should be*"

5.1 Usability Study

We conducted a study where the usability of SolveDB$^+$ was evaluated by a group of highly skilled data scientists, namely the 7 participants of the 2.5 day PhD course *Aspects of Advanced Analytics*, organized by Aalborg University in Dec. 2020. Each participant pre-reported strong competences in SQL, Python, PostgreSQL, and optimization problem solving. The participants used SolveDB$^+$ to solve their chosen subset of five simple optimization problems (Knapsack, production planning, Sudoku, curve fitting, and hypothetical DB deletes/inserts) and two more advanced PA problems (demand and supply balancing, heat-pump power optimization)[30]. In all cases, the initial data and the solution had to be stored in a database. For comparison, the participants had to use another in-DBMS analytics stack of their own choice for solving these problems. They agreed to use the stack based on PostgreSQL, the *PyMathProg* Python library for high-level optimization problem modeling, *PL/Python* language extension for in-DBMS Python programming, and the widely used PostgreSQL extension *MADlib*[5] for in-DBMS machine learning. Afterwards, the participants reflected on their experiences.

The study demonstrated that they solved their chosen problems with approx. 1.5-3.5 times less code and approx. 2 times faster SolveDB runtimes when using SolveDB$^+$. They identified a number of strong and weak points of SolveDB$^+$ - see Table 6. They also reflected on the new SolveDB$^+$ features, e.g., "*The SolveDB+ shared model concept is interesting...*", "*I think it [shared models] fits well with the rest of the system, ... can be incredibly useful in specific use cases...*" , "*...it is a great idea to incorporate the opportunity to do simulation models within the dbms... however, when doing this, my experience is that I need a lot of flexibility - and im not sure the compact style of solveDB+ will benefit me there. At least not yet*". In summary, the study confirmed our expectations that SolveDB$^+$ has good usability, explainability, developer productivity, and performance, even for new users. The next subsections dig deeper into these aspects.

5.2 Experimental Setup

To support the claims about SolveDB$^+$ (Section 5.1), we further evaluated SolveDB$^+$ in two typical PA use-cases from the fields of *energy* and *supply chain management*, covering the phases P1-P4 shown in Figure 1. For both use-cases, we implemented two PA technology stacks: 1) a stack consisting of a standard DBMS and relevant state-of-the-art PA tools and 2) a SolveDB$^+$ stack with a number of standard and specialized built-in solvers (used in place of the PA tools). In both configurations, input data is read from the database and the solution is stored back to the database. We compared these two technology stacks by measuring the Effective Lines of Code (eLOC)[24] (relevant since we are comparing high-level languages and eLoc is used in similar comparisons [28, 31]) of the full implementations and their inherent P1-P4 parts. We also compared them in terms of *execution time*, by encompassing database I/O time as well as prediction, model fitting, and optimization problem solving time. Lastly, these use-cases were used to compare SolveDB$^+$ against SolveDB by evaluating novel SolveDB$^+$ features, including *CDTEs*, *shared models*, and the *predictive framework*. In all experiments, we used SolveDB$^+$/SolveDB on top of PostgreSQL 11.2 in the default configuration and native SolveDB solvers for LP/MIP/Blackbox problems [31].

5.3 Energy Planning (UC1)

We evaluated the impact of using SolveDB$^+$ to solve the energy planning problem from the running example, denoted as UC1, using the NIST dataset [4] – containing 8737 hourly aggregates from PV, HVAC, temperature sensors, all from a high precision lab-home. We compared with two different PA technology stacks using either *specialized tools* or *general modeling tools*.

Specialized tools Here, we used standard PostgreSQL, Matlab R2015b, and three powerful specialized libraries, *Statistics and Machine Learning Toolbox*, *System Identification Toolbox*, and *Multi-Parametric Toolbox* (MPT), for *Linear Regression (LR) forecasting*, *state-space (SS) model fitting*, and *dynamical system optimization*, respectively. Specifically, we used a Matlab implementation that uses the following native library functions: `fitlm` to estimate the LR model coefficients, `predict` to produce PV supply forecasts, and `ssest` to fit HVAC state-space model parameters to the given data. The implementation uses the outputs of these functions to define an MPC (model-predictive control) controller with a number of constraints on the system input and state variables and the PV supply amounts used as a reference for minimizing electricity cost. The size of this implementation in eLOC is given in Figure 3(a) as **`Matlab-native`**. As this configuration is the most comprehensive, it is used as a *reference* for this comparison.

General-purpose modeling tools In this configuration, we utilized a standard DBMS, Matlab R2015b, and YALMIP – a Matlab toolbox for rapid prototyping of optimization problems. Like SolveDB$^+$, YALMIP is provided with a variety of solvers for different problem classes. By using both YALMIP and SolveDB$^+$, we modeled *LR model estimation* (P2), *state-space model fitting*

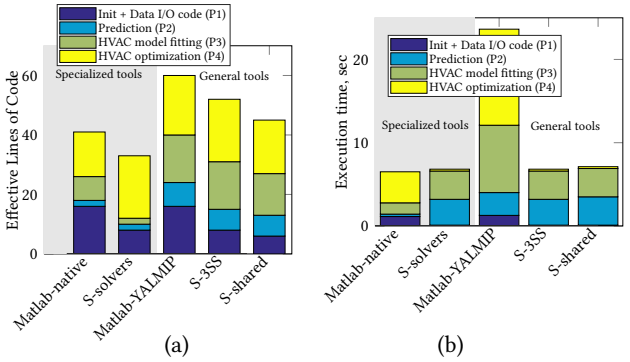

Figure 3: Implementation sizes (a) and run time (b) of UC1

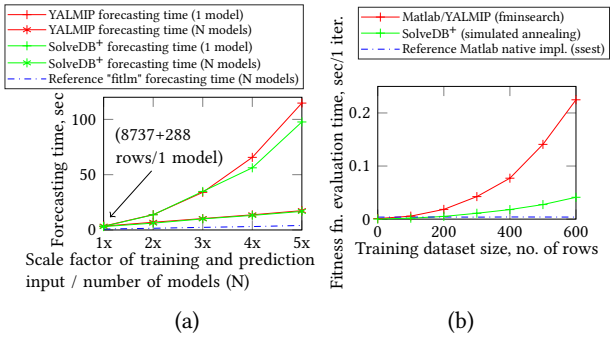

Figure 4: Scalability of prediction (P2) and model fitting (P3) using general-purpose (YALMIP, SolveDB$^+$) and specialized tools (P2: fitlm, P3: ssest)

(P3), and *dynamical system optimization* (P4) problems as explicit LP/nonlinear optimization problems using Matlab/YALMIP programs and SolveDB$^+$ queries, respectively. Specifically, P2 is modeled as an LP optimization problem by minimizing the forecasting error to compute regression model parameters. To solve this problem, SolveDB$^+$ and YALMIP use the Coin-OR CBC solver for the actual computations. Similarly, P3 is specified as a non-linear problem (NLP) of minimizing prediction error of a linear dynamical system using time domain data and *HVAC power levels* and *inside temperatures* as decision variables. To solve this problem, Matlab/YALMIP uses *fminsearch* and SolveDB$^+$ uses *simulated annealing*. These are two distinct NLP solvers that solve the problem in a non-deterministic way. Since they typically give different solutions each time, we only measure average time required for a single solving iteration (fitness function evaluation, Figure 4(b)). Lastly, P4 is modeled as a linear cost minimization problem, where the cost of electricity is minimized under a number of constraints on the HVAC system state and input, and by taking PV supply forecasts into account (based on the LR model). SolveDB$^+$ and YALMIP use CBC to solve this problem. The size of YALMIP implementation in eLOC is given in Figure 3(a) as **`Matlab-YALMIP`**. In SolveDB$^+$, the complete PA workflow, encompassing P2-P4, were implemented in 3 different ways:

-**`S-3SS`** P2-P4 were implemented as three independent **`SOLVESELECT`**s linked using temporary tables (P1).

-**`S-shared`** To be able to reuse the HVAC model parts repeating in P3 and P4, we defined the complete PA problem as a single **`SOLVESELECT`** using a SolveDB$^+$ *shared model*. The model captures indoor temperature dynamics, with P2 and P3 **`SOLVESELECT`** specifications embedded into the model. Note, the size of the model is equally shared by the respective parts in Figure 3(a).

-**`S-solvers`** To relieve the user from the need to specify detailed **`SOLVESELECT`** queries for P2 and P3, we implemented two *composite solvers* which hide respective problem specification details. As these solvers are conceptually similar to the library functions (`Matlab-native`), the overall PA workflow is simplified to a single **`SOLVESELECT`** invoking the composite solvers.

Comparison to specialized tools As seen in Figure 3, the complete PA problem can be specified in just 41 lines of Matlab code and solved in 6.5 secs using specialized tools (`Matlab-native`). Here, around 40% of code and 18% of time is used for initializing libraries and accessing the database, the rest is spent on forming required inputs for, and invoking, the black-box library functions (all considered as P1). As seen for `S-solvers`, this I/O overhead as well as optimization time can be reduced by more than one order of magnitude if all computations are pushed inside the DBMS. This also reduces the PA problem (code) size when SolveDB$^+$ with specialized (composite) solvers are used. As seen in Figure 5 (SolveDB$^+$ vs. MPT), this optimization (P4) performance improvement comes from the reduced model generation time – time spent by MPT to translate the problem to YALMIP, and for YALMIP to aggregate problem constraints and build an optimization (P4) model instance in the binary representation (required by CBC). However, as seen in Figure 3(b), native prediction (P2) and SS model fitting (P3) functions are hard to outperform using general-purpose solvers (`Matlab-native` v.s. `S-solvers`). Figure **??** hint that specialized SolveDB$^+$ solvers for prediction and model fitting are required for larger input datasets. Considering the prediction alone, LR model fitting (P2) using the general-purpose solvers scale *linearly* with respect to independent model count and *exponentially* with respect to training and prediction input size, and therefore might still be useful for some smaller PA cases.

Comparison to general-purpose tools Compared to the native tools (`Matlab-native`), general modeling tools (`Matlab-YALMIP`, `S-3SS` and `S-shared` – all using general-purpose solvers) offer a single language and the full control of how the three PA subproblems P2-P4 are specified. However, explicitly specifying these sub-problems requires up to 45% more code (see Figure 3(a)). Further, computations are up to 3.6 times slower (see Figure 3(b)) and they do not scale (linearly) as in the native case (see Figures 4–5). Comparing YALMIP to SolveDB$^+$, SolveDB$^+$ solves the complete PA problem 3.5 times faster due to significantly reduced data I/O and HVAC optimization time. This can also be seen in Figure 5, which shows that SolveDB$^+$ exhibits up to 2 order of magnitude less data I/O and up to 3 orders of magnitude less model generation time, which is spent translating high-level constraint and objective function specifications into the binary format required by CBC. Both YALMIP and SolveDB$^+$ exhibit somewhat comparable forecasting (P2) and model fitting performance (P3). In the P2 case, YALMIP model generation time is less significant as model constraints can be vectorized (defined without "'for"' loops) and, in the P3 case, just 3 decision variables (a_1, b_1, and b_2) are used. Still, as shown in Figure 4(a), SolveDB$^+$ implementation offers up to 18% lower forecasting time for larger input dataset due to more efficient processing of linear constraints. This difference is less evident when several independent forecasting models need to be estimated using smaller training datasets. Lastly, in addition to these performance benefits, SolveDB$^+$ offers up to 33% smaller implementation sizes as shown in Figure 3(a).

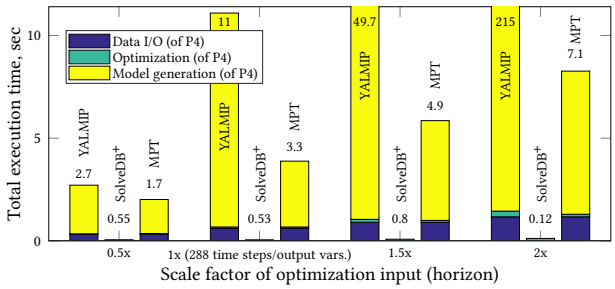

Figure 5: Scalability of HVAC energy optimization (P4)

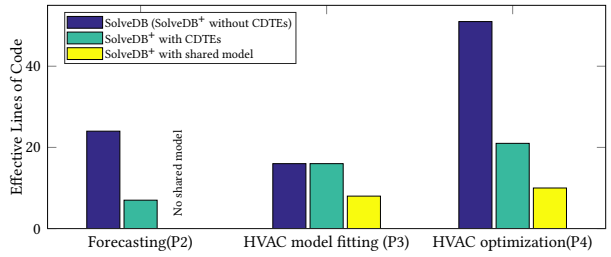

Figure 6: Sizes of SolveDB$^+$ implementations with and without CDTEs and Shared Models

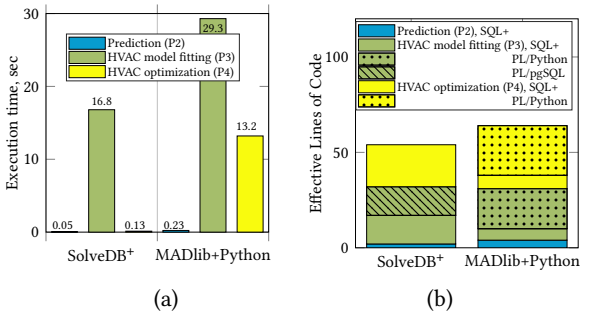

Figure 7: UC1 performance (a) and implementation sizes (b) when using SolveDB$^+$ and existing in-DBMS tools

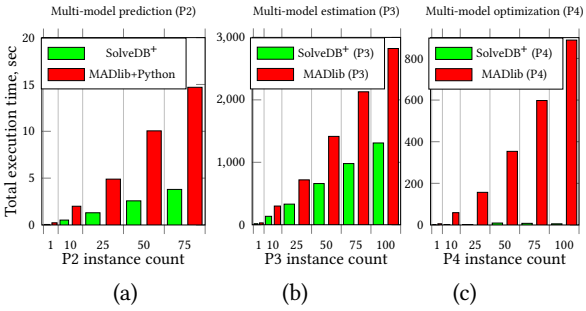

Figure 8: Scalability of In-DBMS UC1 implementations

Comparison to in-DBMS analytics tools Next, we compared SolveDB$^+$ against the in-DBMS analytics stack from the usability study (Section 5.1). We used MADlib's in-DBMS *linear regression* (*linregr_train* UDF) for P2. Since MADlib alone cannot be used to solve the HVAC model fitting and optimization sub-problems (P3-4), we implemented two in-DBMS Python (*PL/Python*) programs for HVAC model fitting (P3) and HVAC operation optimization (P4) by utilizing the *Swarmops* and *PyMathProg* Python libraries, respectively. These libraries offer high-level optimization problem modeling capabilities (required for P3-4) and, under the hood, invoke the low level solvers *Differential Evolution* and *GLPK*, respectively. A SolveDB$^+$ implementation uses three **SOLVESELECT** statements that define the P2-P4 sub-problems and invoke the (same) *linear regression*, *Swarmops*, *GLPK* low-level solvers using SolveDB$^+$'s high-level solvers (incl., *solverlp* and *swarmops* – see Section 3.2 and Section 4.1). The SolveDB$^+$ implementation also uses a *PL/pgSQL* UDF to compute prediction error (being minimized) given (solver-)supplied candidate values of the HVAC model parameters (P3). The goal of this experiment was to compare implementation sizes and runtimes of individual phases (P2-P4) when solving a number of UC1 instances using the same set of low-level solvers (i.e., linear regression, differential evolution, GLPK) running inside a DBMS. Thus, we aimed at comparing the two stacks in terms of *how P2-P4 are specified by the user, how well these (high-level) problem specifications are translated to (low-level) solver inputs*, and *how fast data, solver inputs and outputs are processed by the two in-DBMS stacks.*

As seen in Figure 7(b), *MADlib+Python* required 64 eLOC of mixed SQL and PL/Python code and SolveDB$^+$ required 47 eLOC of (extended) SQL and PL/pgSQL code. While implementation sizes are somewhat comparable, SolveDB$^+$ required very little non-SQL code (15 lines of PL/pgSQL only) to specify the iterative P3 computations. Note, we have also implemented UC1 using pure (extended) SQL (in total 42 lines) with a recursive CTE query for P3. However, this implementation with a recursive query for HVAC simulations might be less intuitive for inexperienced users. In terms of performance, as seen in Figure 7(a), a single instance of UC1 can be solved with SolveDB$^+$ more than twice as fast as with MADlib+Python (19.9 vs 42.7sec). Here, significant gains are observed primarily for P3 (16.8 vs 29.3sec) and P4 (0.13 vs 13.2 sec). For P3, SwarmOPS (in C++) was able to reevaluate the fitness function specified as a SELECT expression from **SOLVESELECT** (that calls a `PL/pgSQL` function) approx. 1.7 time faster that pure Python implementation, where both the solver (SwarmOPS) and the fitness function were implemented in Python. For P4, SolveDB$^+$ offers faster processing of P4 problem symbolic descriptors (*solverlp* vs *PyMathProg*), to be consumed by the same low-level solver (GLPK in C). As seen in Figure 8 (a-c), this gain is more significant when scaling the number of UC1 instances to be solved, i.e., scaling the number of parameters need to be estimated for P3, and predictions and optimization (P2, P4) need to be made for multiple independent HVAC installations. Here, SolveDB$^+$ offered 3.6x faster predictions (P2, Figure 8(a)) since it did not need to create intermediate tables for model parameters and summaries, unlike MADlib; 2.1x faster model parameter estimation, primarily, due to faster evaluation of the fitness function (P3, Figure 8(b)); and 161x faster optimization (P4, Figure 8(c)) primarily due to efficient manipulation of symbolic optimization models and automatic problem partitioning. All in all, SolveDB$^+$ had 2.8x faster execution of the complete PA workflow using less and less complex code, showing its clear advantage over MADlib+Python and confirming the claims about SolveDB$^+$ usability (and performance, see Section 5.1).

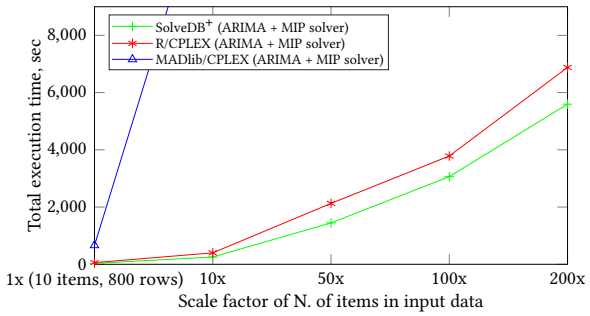

Figure 9: Scalability of combined P1-P4 for UC2

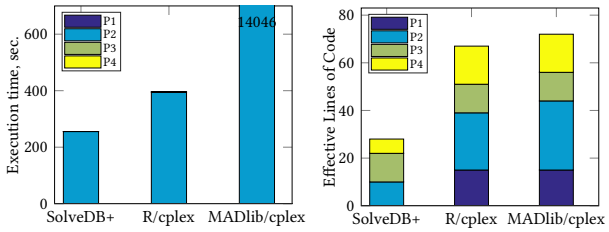

Figure 10: UC2 performance (a) and eLOC (b) comparison

5.4 Supply Chain Management (UC2)

As a second use case (UC2), we considered a common supply chain management scenario. We used the TPC-H dataset [26] containing production supply chain items with the information associated to these items, e.g., orders in the last months, parts needed to assemble the items, size of the parts, price, suppliers, etc. The objective in this use case is to increase revenue by producing in advance the items that will be the most profitable in the next month. The warehouse of the production facility has a limited *volume capacity*, so the decision on which items to produce and store has to be optimized subject to this constraint. This PA workflow requires predicting expected item demand for the next month (P2), modeling *expected profit* for the items by weighting item profit by the probability that the item is ordered in the next month (P3), and solving a variant of the *knapsack problem*, where the warehouse's capacity constraint is respected (P4).

We compared PA stacks with SolveDB$^+$ and both *standalone* and *integrated DBMS analytics* tools. For SolveDB$^+$, we used the predictive framework with a built-in ARIMA solver based on the Statsmodels 0.8.0 package [29] for P2, PL/pgSQL function for P3, and a pre-installed MIP solver from the GNU Linear Programming Kit (GLPK) v4.47 for P4. For standalone tools, we used a configuration with a standard PostgreSQL 9.6.1 (P1, P3), an ARIMA model in R 3.2.3 (P2), and a MIP solver in CPLEX 12.7.1 (P4). For the integrated DBMS analytics tools, we utilized PostgreSQL 9.6.1(P1, P3) with the MADlib [5] extension for in-DBMS machine learning using SQL (P2), and the same MIP solver in CPLEX 12.7.1 (P4). We used 5 different UC2 sizes, scaling the number of items in the dataset. Each item is associated with a time series containing 80 rows of monthly orders.

Figure 10(a) shows the results on the UC2 instance with 100 items. In all implementations, the prediction process accounted almost exclusively for the total execution time, as up to 10000 ARIMA models are trained: 100 per item in R and MADlib, 10 particles with 10 iterations per item in SolveDB$^+$. However, the SolveDB$^+$ implementation was approximately 30% faster than R, and 2 orders of magnitude faster than MADlib, thanks to the efficient use of particle swarm optimization solver for cross validation of the model parameters. Specifically, MADlib does not provide efficient support for cross-validating the forecasting models (ARIMA), with multiple write/read operations accounting for as much as 60% of the total execution time. Figure 10(b) shows the size for the three implementations (implementation size is identical across instances), with SolveDB$^+$ being approximately 50% smaller than the R/MADlib and CPLEX implementations.

The performance results for the different UC2 instances in Figure 9, together with Figure 10(b), show that SolveDB$^+$ allows for a more compact problem definition and execution times that are between 20% and 30% faster than the R configuration, and orders of magnitude faster than the MADlib setup. SolveDB$^+$ outperforms the other two systems thanks to a reduced number of I/O operations and the use of the native local search solvers for hyper-parameters optimization in the model training phase. All in all, UC2 also confirms the end-user claims about SolveDB$^+$ usability (and performance) (Section 5.1).

5.5 SolveDB$^+$ Feature Evaluation (Comparison to SolveDB)

SolveDB$^+$ inherits features and advantages from SolveDB [31]. Specifically, both offer wider applicability and significantly increased tool productivity and usability (order of magnitude less code), while in most cases providing much (up to > 2 orders of magnitude) better performance than systems such as LogicBlox or Tiresias (seeSection 2). We now evaluated the novel SolveDB$^+$ features that distinguish SolveDB$^+$ from SolveDB using the energy and supply chain management use-cases, UC1 and UC2.

Common Decision Table Expressions (CDTEs) As explained in Section 4, CDTEs extend the SOLVESELECT clause like Common Table Expressions (CTEs) extend the simple SELECT in standard SQL. In contrast to CTEs, CDTEs allow annotating some table attributes as *decision columns*, the values of which are evaluated as part of a (much better organized) single SOLVESELECT problem. As seen in Figure 6, CDTEs have a major impact on SolveDB$^+$ usability. Specifying LR model estimation/prediction problems and HVAC optimization problems from the energy planning use-case without CDTEs (SolveDB) requires up to 3 times more **SOLVESELECT** code compared to using CDTEs (SolveDB$^+$). In this case, the HVAC model fitting problem does not benefit from CDTEs, as it uses just a single collection of decision variables, which can be well arranged in a single table. Our experiments also showed that CDTEs do not introduce significant performance overhead to the overall PA workflow.

Shared Optimization Models As explained in Section 4, shared optimization models allow reusing data, objective, and constraint specifications across several optimization problems. UC1 can benefit from such models, by reducing the amount of **SOLVESELECT** code 2 times (Figure 6) for HVAC model fitting and optimization sub-problems alone, and 16% for the complete PA application (see `S-3SS` and `S-shared` in Figure 3(a)), which also includes the shared model specifications. As can be seen in Figure 3(b), shared models do not introduce significant performance overhead to the overall PA workflow.

Predictive Framework As discussed in Section 4, the predictive framework of SolveDB$^+$ offers two ways to integrate new

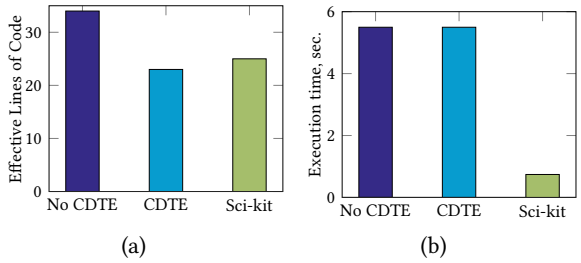

Figure 11: LR code size (a) and execution time (b)

forecasting models. The user can either manually specify forecasting models as SOLVESELECT queries and/or specialized solvers, or install them as "wrappers" over third-party general purpose forecasting libraries. We now compare these two approaches.

For this experiment, we developed the linear regression model as a SOLVESELECT query a) with CDTEs, and b) with no CDTEs wrapped into the respective solvers within the predictive framework. Additionally, we c) installed a general purpose linear regression model from the Sci-kit learn library [3] as a wrapper in SolveDB$^+$. Figure 11(a) shows the implementation size for these three cases. While the size of the Sci-kit implementation is approximately the same as the CDTE implementation, the no CDTE implementation is approximately 30% larger than the other two. Still, the Sci-kit solver implementation is conceptually simpler as it just uses a library function. Furthermore, Figure 11(b) shows that the specialized SolveDB$^+$ implementation is almost 8 times faster than the manual SOLVESELECT implementation (CDTEs do not affect performance), as it combines both in-DBMS execution and a highly specialized machine learning library.

6 CONCLUSION AND FUTURE WORK

This paper presented SolveDB$^+$, the first SQL-based DBMS to provide an extensible and efficient eco-system for all Prescriptive Analytics (PA) phases. SolveDB$^+$ reduces the complexities and inefficiencies of existing PA application stacks, which consist of many specialized, independent, poorly connected systems with different APIs and languages. SolveDB$^+$ acts as a "*swiss-army knife*" system for PA, effectively supporting all 5 phases of PA development: *P1: data management*, *P2: prediction/forecasting*, *P3: system modeling*, *P4: optimization problem solving*, and *P5: solution analysis*. SolveDB$^+$ provides extensibility, allowing developers to add new custom functionalities for specialized PA cases. SolveDB$^+$'s common SQL-based language can express an entire PA workflow in a single SQL-based query. SolveDB$^+$ offers faster PA workflow execution due to its in-DBMS PA algorithms.

Compared to the earlier (SolveDB) tool, SolveDB$^+$ provides a number of novel modeling features, including *common decision table expressions* and *shared optimization models*, enabling a significant size reduction of complex PA problem specifications. It also introduces a new *predictive framework*, which is a generic and extensible in-DBMS platform for the use and development of time series forecasting methods. With all its features, SolveDB$^+$ offers convenient and efficient ways to use and extend the eco-system of forecasting models and optimization problem solvers, thus adapting the system to virtually unlimited PA scenarios.

Our experiments showed that the new SolveDB$^+$ features yield up to 5 times smaller problem specifications (better productivity and explainability) and up to 6 times faster forecasting time, compared to SolveDB. Overall, SolveDB$^+$ offers up to three orders of magnitude better performance for individual PA steps, and up to 3.5 times faster execution times and 3 times smaller implementation sizes for the full PA workflow, compared to state-of-the-art baselines. SolveDB$^+$ scales well in its chosen in-DBMS setting.

Future work will redesign SolveDB$^+$ for distributed Big Data processing and integrate What-If analysis for hypothetical scenarios, and support more data formats, operators on shared models, and further ML models.

ABSTRACT

Influence Maximization (IM) is the problem of finding a set of influential users in a social network, so that their aggregated influence is maximized. The classic IM problem focuses on the single objective of maximizing *the overall number of influenced users*. While this serves the goal of reaching a large audience, users often have multiple specific sub-populations they would like to reach within a single campaign, and consequently multiple influence maximization objectives. As we show, maximizing the influence over one group may come at the cost of significantly reducing the influence over the others. To address this, we propose IM-Balanced, a system that allows users to explicitly declare the desired balance between the objectives. IM-Balanced employs a refined notion of the classic IM problem, called Multi-Objective IM, where all objectives except one are turned into constraints, and the remaining objective is optimized subject to these constraints. We prove Multi-Objective IM to be harder to approximate than the original IM problem, and correspondingly provide two complementary approximation algorithms, each suiting a different prioritization pertaining to the inherent trade-off between the objectives. In our experiments we compare our solutions both to existing IM algorithms as well as to alternative approaches, demonstrating the advantages of our algorithms.

1 INTRODUCTION

Social networks attracting millions of people, such as Twitter and LinkedIn, have emerged recently as a prominent marketing medium. *Influence Maximization* (IM) is the problem of finding a set of influential network users (termed a *seed-set*), so that their aggregated influence is maximized [23]. IM has a natural application in viral marketing, where companies promote their brands through the word-of-mouth propagation. This has motivated extensive research [7, 26], emphasizing the development of scalable algorithms [20, 33].

The classic IM problem focuses on the single objective of maximizing *the overall number of influenced users*, given a bound on the seed-set size. While this serves the goal of reaching a large audience, IM algorithms may obliviously focus on certain well-connected populations, at the expense of other demographics of interest. Indeed, marketing campaigns often have multiple objectives, and consequently multiple subpopulations they would like to reach within a single campaign. In this paper we refer to the subpopulations of interest as *emphasized groups*, and assume the existence of boolean functions over user profile attributes, which identify these groups. We introduce the Multi-Objective IM problem, which refines the IM problem, handling multiple emphasized groups.

Ideally, one would like to find a seed-set which simultaneously maximizes the influence over all emphasized groups. However, as we demonstrate, maximizing influence over one group may come at the cost of significantly reducing the influence over another group. Hence, we devise a framework enabling users to explicitly specify the desired trade-off. Concretely, our system, called IM-Balanced, allows the user to prioritize the objectives and declare what portion of the influence over specific groups she is willing to compromise, in order to increase influence over the others.

For simplicity of presentation, we initially focus on the case where the user has two (possibly overlapping) emphasized groups, denoted as g_1 and g_2, and she is willing to compromise a certain percentage of the maximal possible influence over one group for an influence increase over the other. We then extend our discussion to multiple groups, and shortly discuss alternative problem definitions.

We illustrate the problem that we study in this paper via the following two examples.

Example 1.1. Consider a government office aiming to spread a message regarding a new vaccination policy, across a social network. The main goal is to reach the largest possible number of users, but at the same time, it is also desirable to maximize the number of reached anti-vaccination users. Here g_1 consists of all users, and g_2 is the group of anti-vaccination users. A standard IM algorithm will maximize the overall influence (g_1), possibly at the expense of not reaching sufficient g_2 members. A partial solution can be found in targeted IM algorithms (e.g., [9]), which maximize the influence over a particular group (here - g_2). But if this (possibly small) group is somewhat socially isolated, the message may not reach a sufficient number of users overall.

Example 1.2. Consider a tech company running a recruitment campaign over a social network, with the goal of hiring both engineers (g_1) and researchers (g_2). Assume that there are far more engineers than researchers, and that the two groups are not strongly connected socially (though some users may belong to both groups). A targeted IM algorithm focusing, e.g., on users belonging to the union of the groups, may fail to reach a sufficiently large fraction of the researchers. On the other hand, a targeted IM focusing on the researchers may result in too few engineers being reached.

In both examples, there is a trade-off between the influence over two groups of interest. One simple solution is to split the budget (i.e., seed-set size) and run two separate (single-objective) targeted IM algorithms. However, it is not clear how to split the seed-set to obtain the desired balance between the objectives. An alternative approach to tackle multi-objective optimization problems is the weighted-sum approach, where the objectives are combined into a single objective. In the IM setting this involves assigning each user a weight depending on the groups(s) to which she belongs (e.g. [26, 31]). A main difficulty in applying this approach is assigning the weights that achieve a desired influence balance [21]. Indeed, as we demonstrate in our experiments, the exploration for the optimal weights results in poor runtime performance.

Another more direct approach to multi-objective optimization problems is the constraints method [12], where all objectives except one are transformed into constraints, and the remaining

objective is optimized subject to these constraints. Our work employs this approach for IM. Concretely, in IM-Balanced users can define the emphasized groups, and specify for each group the fraction of its optimal influence that they are willing to compromise in order to increase influence over other groups. An easily operated UI allows users to view the maximal possible influence for each group (and what influence it entails over other groups), specify the constraints, and view the corresponding derived influence.

Continuing with Example 1.1, if the UI indicates that the overall number of users that can be influenced is rather high, one may be willing to sacrifice a certain amount in order to increase the influence over anti-vaccination users. In Example 1.2, assuming that the company is interested in recruiting a small number of researchers and a larger number of engineers, one can set a constraint on the minimal number of researchers to be informed, and maximize the influence over engineers under this constraint.

Next, we provide a brief overview of our contributions.

Multi-Objective IM. To allow users to balance the objectives we formalize the Multi-Objective IM problem, which extends the IM problem as follows. Given two emphasized groups g_1 and g_2 and a threshold $0 \leq t \leq 1$, we add a requirement that the solution must exceed a t-fraction of the optimal influence over g_2. Then, subject to this constraint, we maximize the influence over g_1. For $t = 0$ one gets a single-objective targeted IM problem solely over g_1 users, whereas for $t = 1$ one gets a single-objective targeted IM solely over g_2 users (Section 3).

Approximation lower bound. We prove that, like IM, Multi-Objective IM is *NP*-hard. We show that when the constraint threshold t is $> (1 - \frac{1}{e})$, then no seed-set satisfying the constraint can be found in PTIME. Moreover, we prove that the $(1 - \frac{1}{e})$-approximation factor for g_1, which is optimal in the (unconstrained) IM problem, is unattainable in our setting. We show however that it can nevertheless be achieved if the constraint imposed on g_2 is also approximated by a $(1 - \frac{1}{e})$ factor. This bound exposes the trade-off between the approximation factor for the g_1 users and the relaxation of the constraint imposed on the g_2 users. We therefore provide two approximation algorithms, each suiting a different prioritization pertaining to this trade-off.

The MOIM algorithm. Our first algorithm is simple yet highly efficient. It follows the budget splitting approach mentioned above, but rather than requiring the user to specify the partition, it derives it by itself. MOIM runs two single-objective targeted IM algorithms, each focusing on a different group, and combines their outputs. It guarantees that the constraint is fully satisfied, while providing a $(1 - \frac{1}{e \cdot (1-t)})$-approximation for the g_1 users, which equals $1 - \frac{1}{e}$ for $t = 0$, but decreases as t increases. A key advantage of MOIM is its modularity: MOIM maintains the properties of its input IM algorithm, carrying over all of its optimizations, and therefore it achieves near linear time performance. Such good performance is critical for scaling successfully to massive networks (Section 4).

The RMOIM algorithm. To get a tighter approximation ratio one needs to compromise on (i) how strictly the constraint is maintained, and (ii) performance. The RMOIM algorithm relaxes the constraint, allowing its approximation by a $(1 - \frac{1}{e})$ factor, achieving in return near optimal approximation ratio for the influence over g_1. RMOIM extends a Linear program (LP) for Maximum Coverage [38], and thus its performance becomes polynomial (but still practical for real-life social networks including tens of thousands users, as our experiments indicate). One point to note is that building the LP assumes knowledge of the optimal influence over the constrained g_2 group. As this value is incomputable in PTIME, we approximate it, and provide worst case guarantees for this as well.

Implementation and Experimental study. We have implemented our algorithms as part of the IM-Balanced system and experimentally compare our algorithms to (targeted) IM algorithm and alternative approaches. We show that while the weighted-sum approach, *when assigned optimal weights*, is able to achieve results of quality close to ours, our algorithms are significantly more efficient. In terms of runtime performance, we show that the quality advantage comes with a reasonable performance cost for MOIM, which scales well for massive networks. For RMOIM the decrease in scalability turns out to be moderate, proving it practical for non-massive networks, while often exceeding worst-case guarantees to satisfy the constraint (Section 6).

A demonstration of IM-Balanced's usability and its suitability to end-to-end employment was presented in [16]. The short paper accompanying the demonstration provides only a brief, high-level description of the system, whereas the present paper provides the theoretical foundations and algorithms underlying the demonstrated system, as well as the experimental study.

For space constraints, all proofs are deferred to our technical report [3].

2 PRELIMINARIES

This section presents the standard IM problem, and introduces the auxiliary problem of *Group-Oriented IM*. Our multi-objective variant of the IM problem is then presented in the next section.

2.1 Influence Maximization

We model a social network as a weighted graph $G{=}(V, E, W)$, where V is the set of nodes and every edge $(u, v){\in}E$ is associated with a weight $W(u, v){\in}[0, 1]$, which models the probability that u will influence v. Given a function $I(\cdot)$ dictating how influence is propagated in the network, the IM problem [23] is defined as follows.

Definition 2.1 (IM [23]). Given a weighted directed graph G and a natural number $k \leq |V|$, find a set O that satisfies: $O = argmax_{\{T:T\subseteq V,|T|=k\}} I(T)$, where $I(T)$ is the expected number of nodes influenced by the seed set T.

Naturally, every node v in a seed set T is influenced by itself, and hence, by definition, T is influenced by T with probability 1. In what follows, we refer to influenced nodes as *covered*.

The function $I(\cdot)$ is defined by the influence propagation model. The majority of existing IM algorithms apply for the two most researched models [7, 20], the Independent Cascade (IC) and the Linear Threshold (LT) models. Both models define the function $I(\cdot)$ as non-negative, submodular and monotonically rising. Our results hold under both models. For simplicity of presentation, in our numeric examples throughout the paper we focus on the LT model.

In the LT model, each node v chooses a threshold $\theta_v{\in}[0, 1]$ uniformly at random, which represents the weighted fraction of v's neighbors that must become covered in order for v to become covered. Given a random choice of thresholds and an initial set of seed nodes, the diffusion process unfolds deterministically in discrete steps: in step t, all nodes that were covered in step

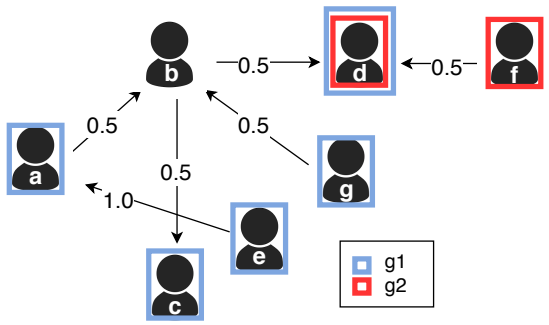

Figure 1: Example social network with two emphasized groups.

$t-1$ remain covered, and we cover any node v for which the total weight of its covered neighbors is at least θ_v. To illustrate, consider the example network presented in Figure 1, ignoring for now the users' border colors. For k=2, the optimal 2-size solution is O=$\{e, g\}$, where $I(O)$=5. Throughout the paper, the threshold for each node was sampled uniformly at random from $[0, 1]$.

Existing IM algorithms. Selecting the optimal seed set is NP-hard, and hard to approximate beyond a factor of $(1-\frac{1}{e})$ [23].The subsequent work on IM following [23], which had already achieved the optimal approximation, has focused on scalability [7, 13, 29]. In what follows, whenever we refer to an IM algorithm, we in fact refer to a probabilistic algorithm, which, given the parameters $0 \leq \epsilon, \delta \leq 1$, achieves, with probability $\geq (1-\delta)$, the optimal approximation factor up to an additive error of ϵ. To ease the presentation, we omit the discussion of ϵ and δ whenever possible.

State-of-the-art IM algorithms are based on the Reverse Influence Sampling (RIS) framework, achieving near optimal time complexity [33] of $\tilde{\Theta}(k \cdot (|V|+|E|))$. The RIS framework utilizes sampling over the transpose graph, to reduce the problem to an instance of the *Maximum Coverage* (MC) problem [38]. For completeness of this paper, we formally define this problem.

Definition 2.2 (MC [38]). Given subsets $S_1, ..., S_m$ of elements from $U = \{u_1, ..., u_n\}$ and a natural number $k \leq m$, the goal is to find k subsets from $S_1, ..., S_m$ so as to maximize the number of covered elements in their union.

The well-known MC problem has a simple greedy approximation procedure [38], achieving an optimal approximation factor of $(1-\frac{1}{e})$. The RIS framework consists of two steps: First, θ nodes are sampled uniformly, then, for each sampled node u, a backward influence propagation is simulated from it, with all nodes covered in a simulation constituting a *Reverse Reachability* (*RR*) set. This *RR* set plays the role of possible influence sources for u. Next, each node is associated with the set of *RR* sets containing it, then, using a greedy algorithm, k nodes are selected with the goal of maximizing the number of covered *RR* sets. The observation underpinning this approach is that influential nodes will appear more frequently in *RR* sets, and that the share of *RR* sets covered by a seed set implies an unbiased estimator for its influence.

Example 2.3. Let k=2, θ=4 and four random *RR* sets G_{d_1}=$\{b, d, f\}$, G_e=$\{e\}$, G_{d_2}=$\{d, f\}$ and G_b=$\{a, b, e\}$ are generated from the graph depicted in Figure 1 (d was sampled twice). The corresponding MC instance is: S_b=$\{G_{d_1}, G_b\}$, S_d=$\{G_{d_1}, G_{d_2}\}$, S_f=$\{G_{d_1}, G_{d_2}\}$, S_e=$\{G_b, G_e\}$, S_a=$\{G_b\}$. W.h.p. the sets S_e, S_f will be selected by the greedy algorithm for MC, as they cover all *RR* sets, and hence the nodes e, f will be selected as the seed nodes.

Most recent works focused on optimizing this approach by minimizing the number of sampled *RR* sets [20, 28, 34].

An important observation is that the second step of RIS can also be achieved using Linear Programming (LP), yielding the same guarantees. However, in terms of time complexity, IM algorithms are nearly linear, compared to PTIME LP solvers [22].

2.2 Group-Oriented IM

In our setting users are associated with profile properties such as their profession or political opinion. Characterized by these properties, the end-user provides her *emphasized groups*, i.e., groups which she wishes to ensure are sufficiently covered. An emphasized group may be defined using a boolean query over (multiple) user profile attributes. Figure 1 depicts two emphasized groups: the group of users with red border (g_1), and the group of users with blue border (g_2). In this example, user d belongs to both groups and user b to none.

Recall that $I(S)$ denotes the expected number of nodes covered by a seed-set S. Let $g \subseteq V$ be a group of emphasized users, and $I_g(S)$ denote the expected number of g members covered by S, referred to as the g-cover. We present the auxiliary *Group-Oriented IM* problem, denoted as IM_g, which instead of maximizing $I(\cdot)$, maximizes $I_g(\cdot)$.

Definition 2.4 (The IM_g problem). Given a group $g \subseteq V$ and a number $k \leq |V|$, find a set O_g satisfying: $O_g = argmax_{\{T:T\subseteq V,|T|=k\}} I_g(T)$.

To illustrate, consider the following example.

Example 2.5. Consider again Figure 1 and assume that k=2. The optimal solution for g_2 is O_{g_2}=$\{d, f\}$, where $I(O_{g_2})$=$I_{g_2}(O_{g_2})$=2 and $I_{g_1}(O_{g_2})$=0. The solution that maximizes the g_1-cover is O_{g_1}=$\{e, g\}$, where $I_{g_1}(O_{g_1})$=4 and $I_{g_2}(O_{g_1})$=0.5. Observe that covering a greater number of users from one group may come at the cost of significantly reducing the cover size of users from another group.

The hardness result of IM also applies to this variant, following a straightforward reduction from IM, where g=V.

Proposition 2.6. *The IM_g problem is hard to approximate beyond a factor of $(1-\frac{1}{e})$ in PTIME.*

In Section 4.1 we explain how a given IM algorithm can be adapted to its group-oriented version, retaining all its theoretical properties. Note that this variant can be seen as a special case of the *Targeted IM* problem [26], where the goal is to maximize influence over a targeted group of users, with relevance of users modeled by weights in $[0, 1]$. The IM_g problem is further imposing a dichotomy where the weights are in $\{0, 1\}$, modeling discrete properties.

3 PROBLEM FORMULATION

As mentioned, our results support multiple, possibly overlapping, emphasized groups. However, for simplicity, we initially focus on the two groups scenario and imposed a size constraint on one group. In Section 5.1 we extend our results to multiple emphasized groups, and discuss alternative problem definitions.

3.1 Multi-Objective IM

Let g_1, g_2 to be two emphasized groups. Our goal is to assure the obtained solution will ensure sufficient cover of the two groups. To this end, we add a constraint on the IM_{g_2} problem (pertaining to the g_2 group), which explicitly models how much the user is willing to settle on the g_2-cover, in order to increase the g_1-cover.

Definition 3.1 (Multi-Objective IM). Given a network G, two emphasized groups $g_1, g_2 \subseteq V$, a threshold parameter $0 \leq t \leq 1$ and a number k, find a k-size seed-set O^* that maximizes the g_1-cover size, subject to the constraint on the g_2-cover being above a t-fraction of its optimal size. Namely, find a set O^* s.t:

$$O^* = argmax_{\{T:|T|=k, I_{g_2}(T) \geq t \cdot I_{g_2}(O_{g_2})\}} I_{g_1}(T)$$

where $I_{g_1}(T)$ (resp., $I_{g_2}(T)$) denote the expected size of the g_1 (resp., g_2) cover by T, and O_{g_2} denotes the optimal k-size solution for g_2.

Throughout the paper, we refer to the expected g_1 and g_2 influences, resp., as the objective and the constraint. To illustrate, in Example 1.1, one may wish to maximize the influence over the anti-vaccination users, while ensuring that the influence over all users is at least 60% of its optimal value. Alternately, continuing with Example 1.2, a user may wish to maximize the influence over engineers, while ensuring that the influence over researchers is no less than 50% of its optimal value.

To illustrate how the constraint affects the selected seed-set, consider the following example.

Example 3.2. Consider again Figure 1 and let $k = 2$. For $t = 0.1$ the optimal solution is $S = \{e, g\}$ since $I_{g_2}(S) = 0.5 \geq 0.1 \cdot I_{g_2}(O_{g_2}) = 0.2$ (O_{g_2} is the optimal solution for g_2), and among all 2-size seed-sets satisfying the constraint, its g_1-cover size is maximal with $I_{g_1}(S) = 4$. However, for $t = 0.5$, S no longer satisfies the constraint, and $S' = \{e, d\}$ becomes the optimal solution, with $I_{g_1}(S') = 3.25$ and $I_{g_2}(S') = 1$. This demonstrates that higher values of t put more emphasis on the g_2-cover, possibly at the expense of eliminating seed-sets with high approximation factor for the g_1-cover.

Recall that the IM problem is closely related to the MC problem, as explained in Section 2.1. We define the *Multi-Objective MC* problem, analogous to Multi-Objective IM, which will serve us for deriving our lower bound and for devising the RMOIM algorithm.

Definition 3.3 (Multi-Objective MC). Given subsets $S_1, \ldots, S_m$ of elements from $U = \{u_1, \ldots, u_n\}$, two groups of elements $g_1, g_2 \subseteq U$, a threshold parameter $0 \leq t \leq 1$, and a number $k \leq m$, a constraint is imposed on the number of covered elements from g_2, requiring it to exceed a t-fraction of the optimal cover size. The goal is to find, among all k sets from $S_1, \ldots, S_m$ satisfying the constraint, the one covering a maximal number of elements belong to g_1.

The constraint threshold. Before presenting our algorithms, let us highlight important properties of the constraint threshold parameter t.

First, consider again Example 3.2, demonstrating that setting higher values for t restricts the solution space and diminishes the optimal value for the objective among remaining k-size seed-set. This exposes the inherent trade-off between the objective and the constraint threshold. A higher threshold is at odds with optimizing the main objective.

We note that the actual value of the optimal g_2-cover size, $I_{g_2}(O_{g_2})$, can only be approximated up to a $(1 - \frac{1}{e})$ factor in PTIME. Thus, the exact value can only be referred to implicitly. Hence, to allow the user to make an informed decision for the value of t, our system uses an IM_g algorithm (as we explain in Section 4), yielding the optimal PTIME approximation for $I_{g_2}(O_{g_2})$.

Observe that setting t to 0 nullifies the constraint, producing the IM_g problem for g_1. Therefore, we only examine cases where $t > 0$. Moreover, it is easy to show that for $t > 1 - \frac{1}{e}$, following the hardness results of IM [23], merely finding a single (not necessarily optimal) k-size seed set satisfying the constraint cannot be done in PTIME.

Corollary 3.4. *A k-size seed set satisfying the constraint can always be found in PTIME only if $0 \leq t \leq (1 - \frac{1}{e})$. For higher t values, this claim no longer holds.*

We therefore restrict our attention to cases where $0 \leq t \leq (1 - \frac{1}{e})$. In cases where the user is interested in higher values of t, as no PTIME algorithm which satisfies the constraint exists, one would need to employ an exhaustive search over the $|V|^k$ possible k-size seed-sets to find the optimal solution.

3.2 Approximation lower bound

In order to devise efficient algorithms for Multi-Objective IM, it is useful to understand which properties are attainable for a PTIME algorithm. We next formally define the solution space, then present a lower bound for Multi-Objective IM.

The solution space. We generalize the solution space to *bicriteria approximation*, where an algorithm approximates the objective and may also approximate the constraint, up to multiplicative factors of α and β, resp. For β=1 the solution strictly satisfies the constraint. To accommodate practical algorithms we consider, as in standard IM, randomized algorithms that may add an error margin ϵ to the approximation factors, while requiring the stated factors to hold with probability $\geq(1-\delta)$. Formally, given $0 \leq \epsilon, \delta \leq 1$, an algorithm computes a (α, β)-solution S, with $0 \leq \alpha, \beta \leq 1$, if for every instance (G, g_1, g_2, k, t) of Multi-Objective IM, the following holds with probability $\geq 1-\delta$: $I_{g_2}(S) \geq (\beta-\epsilon) \cdot t \cdot I_{g_2}(O_{g_2})$ and $I_{g_1}(S) \geq (\alpha-\epsilon) I_{g_1}(O^*)$, where O^* is the optimal constrained solution w.r.t. Def. 3.1. We assume ϵ and δ are implicitly provided. However, for simplicity, we omit discussions of these parameters whenever possible.

We emphasize that α is derived from comparing the returned solution not to the optimal unconstrained solution, but rather to an optimal solution which satisfies the constraint. This highlights the difference between approximating the constraint by a factor of β and replacing t with $\beta \cdot t$, as the solution space is affected only in the latter case. Namely, when examining a seed-set which relaxes the constraint, the optimal value for the objective is still taken only over the subset of solutions satisfying the constraint. We refer to an algorithm *as dominant over another algorithm* if it computes an approximated solution for higher values of at least one parameter (α, β), with the other parameter being at least equal. We refer to a tuple (α, β) as an *optimum*, if no (PTIME) algorithm that generates an approximated solution dominant over it exists. One immediate such optimum is $(1 - \frac{1}{e}, 1)$, which follows directly from the hardness result of IM [23]. However, as we prove, there exists no PTIME algorithm which can achieve this bound. Moreover, we show that to achieve $\alpha = (1 - \frac{1}{e})$, β must be reduced to $(1 - \frac{1}{e})$ as well.

Hardness of approximation. As mentioned, the optimal objective approximation of Multi-Objective IM is α=$1-\frac{1}{e}$. We next prove that in order to achieve this optimal α value, a relaxation of the constraint is necessary. Concretely, we prove that Multi-Objective IM has no PTIME algorithm with approximation guarantees (even in expectation) dominant over $(1 - \frac{1}{e}, 1 - \frac{1}{e})$, via a reduction from MC. This result is independent of t, yet, surprisingly, holds for all its values in $(0, 1 - \frac{1}{e}]$.

Theorem 3.5. *Multi-Objective IM has no approximation factor dominant over* $(1-\frac{1}{e}, 1-\frac{1}{e})$ *(unless NP = BPP).*

Next, we provide a proof sketch for Theorem 3.5 using a novel reduction from MC.

Proof. (sketch). Given an MC instance along with k and t, let k_t denote the smallest natural number s.t. $I(O_{k_t}) \geq t \cdot I(O_k)$. We first fix any arbitrary k and $t \in (0, 1-\frac{1}{e}]$, then sample two disjoint MC instances, $\mathcal{I}_1$ and $\mathcal{I}_2$, s.t. the seed set size requirements are $k-k_t$ and k_t, resp. We construct a Multi-Objective MC instance by taking the union of both collection of sets, and defining the g_1 and g_2 groups as follows: g_1 comprises of all elements of $\mathcal{I}_1$, and g_2 comprises of all elements of $\mathcal{I}_2$. The cardinality constraint is k along with threshold t. This construction implies a dichotomy where choosing sets from the g_1 collection only affects the objective, while choosing sets from the g_2 collection only affects the constraint. We show that, in the worst case, one needs to choose as many g_2 sets as in the optimal solution (i.e. k_t sets), up to a $o(1)$ factor, to achieve a $(1-\frac{1}{e})$ approximation of the constraint, and therefore with the remaining slots one cannot guarantee any factor beyond $(1-\frac{1}{e})$ for the objective.

Last, we extend this result to Multi-Objective IM via a reduction from Multi-Objective MC. In essence, we reduce a given Multi-Objective MC instance to a graph s.t. each element is mapped to a new node, carrying over any membership in g_1 and g_2 groups. Additionally, for each subset S_i, we create a new node, and add an edge from it into every nodes corresponding to an element in this set, with the constant edge weight of 1. □

Note that this lower bound holds even for the easier version of the problem, where explicit values are known for both the constraint threshold and the constrained optimum for the objective.

4 ALGORITHMS

As mentioned, the approximation factor of the objective depends on how strictly the constraint is preserved. We, therefore, provide two complementary algorithms for Multi-Objective IM. Our first algorithm, named *the Multi-Objective IM (MOIM) algorithm*, finds a seed-set that strictly satisfies the constraint, at the cost of influence decrease for the objective. Its key advantage is that it achieves near-linear time complexity, which, as we show, is critical for scaling successfully to massive networks. To get a tighter approximation ratio for the objective, our second algorithm, named *the Relaxed Multi-Objective IM (RMOIM) algorithm*, relaxes the constraint, allowing its approximation by a $(1-\frac{1}{e})$-factor, achieving in return near optimal approximation for the objective. This however comes at the cost of performance - its time complexity is polynomial.

4.1 The MOIM algorithm

MOIM is a simple yet efficient algorithm achieving state-of-the-art performance by leveraging existing IM algorithms. Intuitively, using a modular approach where given an IM algorithm, it generically modifies it to create two group-oriented versions of it, then combines them together to produce a single seed set. We next detail our modification of a given IM algorithm, followed by the full algorithm scheme.

Given an IM algorithm $\mathcal{A}$ and an emphasized group g, we define $\mathcal{A}_g$ as its IM_g counterpart - an analogous algorithm that maximizes $I_g(\cdot)$ instead of $I(\cdot)$. Any RIS-based algorithm, $\mathcal{A}$, can be adapted to $\mathcal{A}_g$ via a single modification: the *RR* sets are generated from nodes from g only, independently and uniformly as before. We can prove that $\mathcal{A}_g$ outputs a seed-set covering at least $(1-\frac{1}{e}) \cdot I_g(O_g)$ nodes from g, which is optimal [23].

A method of weighted RIS sampling for solving Targeted IM was presented in [26]. Concretely, instead of using the uniform distribution, nodes are sampled according to their weights, which model their relevance to a given context. Our adaptation for IM_g can be seen as a special case of this method with binary weights. Nonetheless, the authors of [26] have focused in cases where there is only one emphasized group. As we show in our experiments, choosing the weights achieving sufficient covers for more than one group requires further effort.

Algorithm 1 The MOIM algorithm.

1: **Input:** A network G; emphasized groups $g_1, g_2 \subseteq V$; $k \in [n]$; $t \leq 1-\frac{1}{e}$; an IM algorithm $\mathcal{A}$.
2: **Output:** A k-size seed set S.
3: We run independently the following two procedures:
   i $S_1 \leftarrow$ Run algorithm $\mathcal{A}_{g_2}$, where the seed set size is fixed to $\lceil -\ln(1-t) \cdot k \rceil$.
   ii $S_2 \leftarrow$ Run algorithm $\mathcal{A}_{g_1}$, where the seed set size is fixed to $\lfloor (1+\ln(1-t)) \cdot k \rfloor$.
4: $S \leftarrow S_1 \cup S_2$
5: **if** $|S| < k$ **then**
6: Run $\mathcal{A}_{g_1}$ on the residual network until enough seeds are gathered.
7: **end if**
8: **return** S

The MOIM algorithm is depicted in Algorithm 1. MOIM runs independently two procedures: The first ensures satisfaction of the constraint (line 3.i), while the second maximizes the objective (line 3.ii). We return the union S of the selected seeds (line 4). If S contains less than k seeds, we run $\mathcal{A}_{g_1}$ on the residual problem (by eliminating the respective sets of the seeds selected so far), s.t. additional nodes are added to S (lines 5-7). In practice, this could be achieved by initially running $\mathcal{A}$. Note that this can only improve the accuracy guarantees. In our analysis we assume that the returned set is of size exactly k.

We now state the approximation factor of MOIM.

Theorem 4.1. *For* $0 \leq t \leq 1-\frac{1}{e}$, *MOIM provides a* $(1-\frac{1}{e \cdot (1-t)}, 1)$*-approximation to the Multi-Objective IM problem.*

Example 4.2. Consider again Figure 1, and let k=2. Recall that the optimal solution for g_2 is O_{g_2}=$\{d, f\}$, with $I_{g_2}(O_{g_2})$=2. For t=$1-\frac{1}{e}$, MOIM would be equivalent to running $\mathcal{A}_{g_2}$ with k=2. It would w.h.p. output, if not O_{g_2}, then a set S, s.t. $I_{g_2}(S) \geq 2 \cdot (1-\frac{1}{e}) \approx 1.26$, with no particular regard for g_1 cover, which may be as small as 1.5 (for S=$\{c, f\}$), or as high as 3 (for S=$\{e, f\}$). For t=$1-\frac{1}{\sqrt{e}}$, MOIM runs $\mathcal{A}_{g_1}$ and $\mathcal{A}_{g_2}$ while setting k=1 for both, which would presumably output $\{e\}$ and $\{f\}$ resp., combining for a seed set S s.t $I_{g_1}(S)$=3 and $I_{g_2}(S)$=1.75. This approximated solution comes close to both O_{g_1} and O_{g_2}, in terms of g_1/g_2 cover size, resp.

The time complexity of MOIM depends only on that of its input IM algorithm $\mathcal{A}$, which is assumed to be near optimal [33].

4.2 The RMOIM algorithm

We first describe a theoretical algorithm which, given the optimal cover size of g_2, $I_{g_2}(O_{g_2})$, exactly matches our hardness bound. We then discuss the practical case where $I_{g_2}(O_{g_2})$ is unknown (and can only be approximated in PTIME), proving that the scale of the reduction in the approximation factors is not too high.

Theorem 4.3. *There exists a PTIME randomized algorithm that, given $I_{g_2}(O_{g_2})$, in expectation, outputs a $(1-\frac{1}{e}, 1-\frac{1}{e})$ approximation for the Multi-Objective IM problem.*

We described the reduction from IM to MC suggested in [7], utilized by the RIS framework. We extend this reduction to the multi-objective variants, implying that any algorithm for Multi-objective MC can be extended to Multi-Objective IM, retaining the same guarantees. Therefore, all that is left to prove is that one can get a $(1-\frac{1}{e}, 1-\frac{1}{e})$-approximation for Multi-Objective MC.

Given an instance $\mathcal{I}$ of Multi-Objective MC with m subsets $S_1, ..., S_m$ and two groups $g_1, g_2 \subseteq U$, we construct LP($\mathcal{I}$), the corresponding LP instance, where $Y=|g_2 \setminus g_1|, Z=|g_1 \setminus g_2|, W=|g_1 \cap g_2|$:
variables: $x_1, \ldots, x_m, y_1, \ldots, y_Y, z_1, \ldots, z_Z, w_1, \ldots, w_W$ (x_i is an indicator for selecting S_i, y_i for covering element in $g_2 \setminus g_1$, z_i for covering element in $g_1 \setminus g_2$, and w_i for covering elements in $g_1 \bigcup g_2$)
constraints: $\sum_{i=1}^{m} x_i = k$ (cardinality constraint)

$$\sum_{i:u_j \in S_i} x_i \geq y_j, \sum_{i:u_j \in S_i} x_i \geq z_j, \sum_{i:u_j \in S_i} x_i \geq w_j \text{ (coverage constraint)}$$

$$(\sum_{i=1}^{Y'} y_i \cdot \frac{Y}{Y'} + \sum_{i=1}^{W'} w_i \cdot \frac{W'}{W}) \geq t \cdot I_{g_2}(O_{g_2}) \text{ (size constraint)}$$

$$\forall i \in \{1, ..., m\}, 0 \leq x_i \leq 1; \forall i \in \{1, \ldots, W'\}, 0 \leq w_i \leq 1$$

$$\forall i \in \{1, \ldots, Y'\}, 0 \leq y_i \leq 1; \forall i \in \{1, \ldots, Z'\}, 0 \leq z_i \leq 1$$

objective: maximize $\sum_{i=1}^{Z'} z_i + \sum_{i=1}^{W'} w_i$.
where $I_{g_2}(O_{g_2})$ is the optimal g_2-cover size and Y', Z', W' are the number of sampled nodes from $g_2 \setminus g_1$, $g_1 \setminus g_2$ and $g_1 \cap g_2$, resp.

The solution is determined by the values of the variables x_i, indicating the selected sets. This LP relaxes the Integer LP which precisely models the Multi-Objective MC problem. We can compute an optimal solution by using any LP solver, then apply the following randomized rounding procedure [30]: (1) Interpret the numbers $\frac{x_1}{k}, .., \frac{x_m}{k}$ as probabilities corresponding to $S_1, .., S_m$, resp. (2) Choose k sets independently w.r.t. the probabilities. By adapting the proof in [32], we show that this procedure yields a seed set whose cover, in expectation, for each group separately, is at least a $1-\frac{1}{e}$ fraction of the corresponding optimal cover size, thus proving Theorem 4.3.

Omitting the optimal-value knowledge assumption. As mentioned, the optimal value of the g_2-cover is uncomputable in PTIME. We, therefore, first run a IM_{g_2} algorithm which outputs a seed set S, s.t. $I_{g_2}(O_{g_2}) \cdot (1-\frac{1}{e}) \leq I_{g_2}(S) \leq I_{g_2}(O_{g_2})$. We then set the constraint threshold in $LP(\mathcal{I})$ to $t \cdot (1-\frac{1}{e})^{-1} \cdot I_{g_2}(S)$ instead of $t \cdot I_{g_2}(O_{g_2})$, with the rest of the algorithm remaining the same. This substitution can only increase the constraint threshold, which in turn, reduces the set of valid solutions, possibly diminishing the objective value of the optimal solution subject to the stricter constraint. However, as we prove, the scale of the reduction in α is not arbitrarily large.

The RMOIM algorithm is depicted in Algorithm 2. Given an IM algorithm $\mathcal{A}$, we first run $\mathcal{A}_{g_2}$ to estimate $I_{g_2}(O_{g_2})$ (line 3). Next, using $\mathcal{A}$, we sample the *RR* sets needed for constructing the Multi-Objective MC instance, and build the corresponding LP (lines 4 – 5). Then, we employ an LP solver, obtaining the fractional solution (line 6). Last, we employ the rounding procedure to select k sets for the Multi-Objective MC instance, and return their corresponding nodes as the selected seed-set S (lines 7 – 8).

Given an IM_g algorithm, let S denote its output. We define $\lambda \in [0, \frac{1}{e-1}]$ s.t. $I_g(S) = (1+\lambda) \cdot (1-\frac{1}{e}) \cdot I_g(O_g)$.

Algorithm 2 The RMOIM algorithm.

1: **Input:** A network G; emphasized groups $g_1, g_2 \subseteq V$; $k \in [n]$; $t \leq 1-\frac{1}{e}$; an RIS-based IM algorithm $\mathcal{A}$ and an LP solver.
2: **Output:** A k-size seed set S.
3: $I_{g_2}(\tilde{O_{g_2}}) \leftarrow$ Run $\mathcal{A}_{g_2}$ on the input.
4: RR $\leftarrow$ Construct the *RR* sets using $\mathcal{A}$.
5: LP($\mathcal{I}$) $\leftarrow$ Construct the LP from RR, replacing $t \cdot I_{g_2}(O_{g_2})$ with $t \cdot (1-\frac{1}{e})^{-1} \cdot I_{g_2}(\tilde{O}_{g_2})$.
6: $\vec{X} \leftarrow$ Solve LP($\mathcal{I}$), and output the values for the x_i variables.
7: $S \leftarrow$ Run the randomized rounding procedure on $\vec{X}$.
8: **return** S

Theorem 4.4. *The RMOIM algorithm provides, in expectation, a $((1-\frac{1}{e}) \cdot (1-t \cdot (1+\lambda)), (1+\lambda) \cdot (1-\frac{1}{e}))$ approximation to Multi-Objective IM, where $\lambda \in [0, \frac{1}{e-1}]$.*

The time complexity of RMOIM is dominated by its input LP solver, whose complexity is polynomial in the input size [22].

5 EXTENSIONS

We present an extension of our results to multiple groups, then briefly discuss on alternative problem definitions. We conclude with a discussion regarding a well-studied related problem.

5.1 Multiple Emphasized Groups

The Multi-Objective IM problem naturally extends to multiple groups. Given m emphasized groups, the user can impose size constraints on all but one groups, and subject to these constraints, maximize the cover size of the remaining group. W.l.o.g. let us assume that the user imposed size constraints on the last $m-1$ groups. Given the $m-1$ constraint threshold parameters $t_2, ..., t_m$, analogously to the binary scenario, we can show that a k-size seed set satisfying all constraints can always be found in PTIME if $0 \leq \sum_i t_i \leq (1-\frac{1}{e})$. We prove that in PTIME, one cannot attain an approximation factor dominant over $(1-\frac{1}{e}, \ldots, 1-\frac{1}{e})$. Moreover, our generalized random algorithm matches our lower bound for multiple groups.

Both our algorithms can be generalized to solve the multiple groups scenario. In MOIM we run (independently) $m-1$ IM_{g_i}, $i \in [2, m]$ algorithms, where the seed set size in each algorithm is fixed to $\lceil -\ln(1-t_i) \cdot k \rceil$, and run an $\mathcal{IM}_{g_1}$ algorithm, where the seed set size is fixed to $\lfloor (1+\ln(1-\sum_i t_i)) \cdot k \rfloor$. As in Algorithm 1, we then return the union of the selected seeds. We can show that this algorithm provides a $(1-\frac{1}{e \cdot (1-\sum_i t_i)}, 1, \ldots, 1)$-approximation to Multi-Objective IM with m emphasized groups.

In RMOIM, we first estimate the $I_{g_i}(O_{g_i})$ values for the constrained $m-1$ groups, to include these values in the LP described in Section 4.2. Given an IM_{g_i} algorithm, let S_i denote its output. Recall that $\lambda_i \in [0, \frac{1}{e-1}]$ was defined s.t. $I_{g_i}(S_i) = (1+\lambda_i) \cdot (1-\frac{1}{e}) \cdot I_{g_i}(O_{g_i})$. We prove that RMOIM provides, in expectation, a $((1-\frac{1}{e}) \cdot (1-\sum_i t_i \cdot (1+\sum_i \lambda_i)), (1+\lambda_1) \cdot (1-\frac{1}{e}), \ldots, (1+\lambda_{m-1}) \cdot (1-\frac{1}{e}))$-approximation to Multi-Objective IM with m emphasized groups.

5.2 Alternative problem definitions

We next briefly discuss alternative problem definitions. An alternative variant of Multi-Objective IM is where the user specifies an explicit value constraint (rather than specifying a fraction of the optimal possible value). For instance, continuing with Example 1.2, one may request to maximize the cover over engineers, subject to a constraint requiring that at least 1K researchers

are influenced. Both our algorithms support this variant as well. Specifically, in MOIM, we can run an IM_{g_2} algorithm until it exceeds the constraint value, and with the remaining seeds we run an IM_{g_1} algorithm, which can only improve the guarantees as we no longer overestimate the constraint. In RMOIM, the problem becomes much simpler, since now the exact value for the size constraint is known. Therefore, here RMOIM is optimal as it matches our lower bound (which holds here as well). We focus on the implicit size constraint variant, as the analysis of the explicit value constraint variant is contained in it as a simpler case.

Our definition provides cardinality guarantees over the emphasized groups. An alternative definition may be to constrain the *ratio* of different cover cardinalities. We note that this definition is essentially different form our definition, as maximizing the ratio between the cover cardinalities can dramatically reduce the number of covered users from each group. Therefore, such definition is ill-suited to our motivation where the underlying goal is to reach as many as possible users from the emphasized groups. We further note that the analysis of such ratio-based definitions differs from the one we have provided, and therefore we leave the study of ratio-based constraints for future research.

In our analysis so far the user imposes constraints on all but one group. Our results also support the case where the user imposes constraints on all emphasized groups (see details in [3]).

5.3 Connection to the RSOS problem

The closely related problem of multi-objective maximization of monotone submodular functions subject to a cardinality constraint (known as the RSOS problem) was introduced in [24].

Given m monotone submodular functions $f_i(\cdot), i \in \{1, .., m\}$ and a target value V_i for each function f_i, the goal in the RSOS problem is to find a k-size set A s.t. $\forall i : f_i(A) \geq V_i$, or provide a certificate that there is no feasible solution. A solution S is an $alpha$-approximation if $\forall i : f_i(S) \geq \alpha \cdot V_i$.

In contrast to Multi-Objective IM, where users can specify for each group the *fraction* of the optimal influence that they wish to retain, in RSOS only explicit values can be used. Nonetheless, we establish the connection between the two problems. Specifically, we prove that the two problems are equally hard, and that any algorithm solving RSOS, could in principle also solve Multi-Objective IM. However, as we show in our experiments, top performing RSOS algorithms can only process small networks.

We next briefly present our main results.We restrict our analysis of the RSOS problem to its applicability in an IM setting, s.t. all functions are IM-functions. To simply the presentation, we focus here on the two groups scenario, and defer the analogous results regarding multiple groups to [3].

We reduce RSOS to Multi-Objective IM, showing that any (α, α)-approximation to Multi-Objective IM implies an α-approximation to RSOS. It follows that leveraging existing techniques in RSOS works yields at best an $(1-\frac{1}{e}, 1-\frac{1}{e})$-approximation for Multi-Objective IM, which is an optimum we have already achieved with RMOIM.

Theorem 5.1. *RSOS $\leq_p$ Multi-Objective IM.*

We further provide a reduction in the other direction, showing that any α-approximation algorithm for RSOS, implies an (α, α)-approximation algorithm for Multi-Objective IM.

Theorem 5.2. *Multi-Objective IM $\leq_p$ RSOS.*

Table 1: Datasets.

Datasets	Dimensions	Profile properties
Facebook	|V|=4K, |E|=168K	Gender, Education type.
DBLP	|V|=80K, |E|=514K	Gender, country, age, h-index.
Pokec	|V|=1M, |E|=14M	Gender, age, region
Weibo-Net	|V|=1.5M, |E|=369M	Gender, city.
YouTube	|V|=1M, |E|=3M	-
LiveJournal	|V|=4.8M, |E|=69M	-

However, to do so, we need to know both the optimal cover size of the constrained group $I_{g_2}(O_{g_2})$ (as in RMOIM), and (additionally) the constrained optimal objective value $I_{g_1}(O^*)$. $I_{g_2}(O_{g_2})$ may be estimated, as done in RMOIM, by running an IM_{g_2} algorithm. Here again, we may overestimate this value by a $(1-\frac{1}{e})$ factor, yielding the same guarantees as RMOIM. To efficiently estimate $I_{g_1}(O^*)$, we can examine only $O(log(n))$ guesses for $I_{g_1}(O^*)$, which increases the time complexity of an RSOS algorithm by an $O(log(n))$ factor.

A state-of-the-art algorithm for RSOS, which achieves the optimal $(1-\frac{1}{e})$-approximation, has been introduced in [36]. As we show in our experiments, this algorithm can only process small networks (even without the $log(n)$ multiplicative overhead).

6 EXPERIMENTAL STUDY

We have implemented our prototype in Python 2.7. We use as the input IM algorithm, for both of our algorithms, IMM[1] [33], a top performing IM algorithm. We solve the LP in RMOIM using Gurobi LP solver [2][2]. We have conducted an experimental study to evaluate (1) The quality of results achieved by our algorithms. We demonstrate the advantages of our algorithms in multiple scenarios over real-life datasets, compared to existing and alternatives approaches; (2) The performance of our algorithms in terms of execution times and scalability.

6.1 Experimental setup

We conducted all experiments on a Linux server with a 2.1GHz CPU and 96GB memory. Next, we describe the examined datasets, the considered emphasized groups, the competing algorithms, and the parameters setup.

Datasets. We have focused on social networks which include user profile properties, to characterize the emphasized groups. We have examined 6 commonly used datasets: Facebook, DBLP, Pokec, Weibo-Net, Twitter and Google+ (extracted from [4, 25]). For space constraints, we omit the results over Twitter and Google+, as they were similar to those obtained over the other 4 datasets (depicted in Table 1). To further examine our algorithms scalability, we considered two additional large-scale datasets: YouTube and LiveJournal [25]. These datasets do not include user properties. To nevertheless examine them in our context, we randomly assigned users to emphasized groups (see details below). Following the conventional method as in [28, 34], we set the weight of each edge (u, v) as $w(u, v) = \frac{1}{d_{in}(v)}$, where $d_{in}(v)$ denotes the in-degree of v. To ensure uniformity, undirected networks were made directed by considering, for each edge, the arcs in both directions (as was done in [5]).

[1] We used the corrected version described in [10].
[2] Our code will be publicly available upon acceptance.

Emphasized groups. The benefit that our approach brings is in particular critical for subpopulations that are typically not covered by standard IM algorithms. To identify such groups, we have run, for each network, a grid search over the extracted profile properties. We have considered all groups that are characterized by a single or a combination of two profile properties. For each such group g, we have examined the expected g-cover size of standard IM algorithms, as well as the expected g-cover size of their IM_g counterparts. We are focusing here only on groups in which the results showed that standard IM algorithms tend to overlook their users, while targeted IM algorithms showed that a different choice of seed-set significantly increase their expected cover size. Interestingly, our experiments indicate that all analyzed datasets include several such groups. For example, female Indian researchers in DBLP and females over the age of 50 in Pokec, are typically neglected by standard IM algorithms. Additional examples are provided in [3]. For YouTube and LiveJornal, we have considered random emphasized groups, defined as follows. Given a number $c \in (0, 1]$ (sampled uniformly at random), every node $v \in V$ is a member of the emphasized group with probability of c. Note that this simple definition allows for overlapping emphasized groups of different cardinalities.

Examined scenarios. We examine the following two scenarios: ***Scenario I***. In this scenario the user wishes to maximize the overall influence (g_1), subject to a constraint requiring that at least a given portion of a group's members (g_2) are influenced (a scenario analogous to that of Example 1.1). We focus on this particular scenario as it allows to compare, in a single setting, algorithms for standard IM (that maximize the overall influence), targeted IM (that maximize the influence solely over the g_2 members), and ours. We present the results while setting g_2 to be a group which is not covered by standard IM algorithms (see full details in [3]). We have also run all experiments while choosing all possible pairs of g_1 and g_2 to be groups that are typically not covered by standard IM algorithms. We report that all experiments show similar trends and therefore we omit from presentation these results. ***Scenario II***. Next we consider multiple-groups, to demonstrate the effect of multiple objectives on performance. We present a scenario where the user provides 5 emphasized groups, specifies constraints on 4 of them, and asks to maximize the influence over the remaining group, subject to these constraints. We have also experimented with other numbers of emphasized groups and report that all results have shown similar trends. In real-life scenarios, the number of emphasized groups is typically small [26, 36] and thus we focus on realistic number ranges ($2 - 10$). Here again we have considered groups that are typically not covered by standard IM algorithm.

Competing algorithms. We consider the following baselines.
Standard IM algorithms. We have examined the results of *IMM* [33] and SSA [28], top preforming RIS-based algorithms, as well as SKIM [13] and Celf++ [17], greedy-based IM algorithms. As all algorithms demonstrated similar trends, we detail here only *IMM*.
(Single objective) Targeted IM algorithms. We examine IMM_g, a variant of *IMM* (based on [26]) which maximizes exclusively the cover of a given emphasized group g. In scenario *II* we have defined the target group to be the union of all emphasized groups.
Weighted IM. An alternative is to assign different weights to users, reflecting their relevance to the objectives. The authors of [26] introduced a weighted RIS sampling method, that maximizes the influence over a targeted group. We examined the results for Weighted *IMM* (*WIMM*), a variant of *IMM* which is based on a weighted RIS sampling method presented in [26]. We apply a (multi-dimensional) binary search to find the optimal weights[3]. We examined the results while substituting the weights of users in the constrained group(s) and the objective group with c_i and $1 - \sum_i c_i$, resp[4]., for varying values of $c_i \in [0, 1]$.
We have also examined a variant of *WIMM* that skips the search and instead uses some default weights given as input. **RSOS algorithms.** We examine the RSOS algorithm of [36] (used to solve Multi-Objective IM). Additionally, the authors of [36] have studied the problem of fair resource allocation in IM, and proposed two fairness concepts: *MaxMin*, which maximizes the minimum fraction of users within each group that are influenced, and Diversity Constraints (*DC*), which guarantees that every group receives influence proportional to what it could have generated on its own, based on a number of seeds proportional to its size. They have shown that both fairness concepts can be reduced to RSOS, for which they provided the state-of-the-art algorithm. For completeness, we have included the *MAXMIN* and *DC* baselines. As we show, all RSOS-based algorithms can only process small networks. A more recent fairness-aware IM framework was presented in [15]. However, in this work as well, only small-size networks were examined[5].

Parameter Settings. Recall that RMOIM requires to estimate $I_{g_i}(O_{g_i})$, the optimal cover cardinality for all constrained groups g_i. For that we use the following estimation strategy (as described in Section 4.2): for each emphasized group g we ran IMM_g for 10 times, selecting the minimal obtained value to derive an estimate for $I_g(O_g)$. Unless mentioned otherwise, we set $k = 20$, and $\epsilon = 0.1$. In scenario *I* we have set the threshold parameter $t = 0.5 \cdot (1 - \frac{1}{e})$, and in scenario *II* we have set the threshold parameters $t_i = 0.25 \cdot (1 - \frac{1}{e}), \forall i \in 1, ..., 4$. We also use, as a default setting, the LT model (when setting uniformly random threshold for every node). In all experiments, the time-out limit is 24 hours (or out of memory exception). For the RSOS baselines, we use the default parameters as provided in [1]. We report for each baseline the averaged measurements of 10 runs.

6.2 Quality Evaluation

Scenario I results. The results are depicted in Figure 2, where the x and y axes represent, resp., the g_1 and g_2 influences, and red lines are the estimated constraint thresholds. A desirable solution should be above (or near) the red lines (i.e., satisfying the constraint), and, at the same time, the right as much as possible (i.e., covering as many g_1 users as possible). For *WIMM*, we present the results obtained by selecting the optimal weights for each dataset (pink points). We have also examined multiple settings of default weights for *WIMM*, however, none of these options yielded satisfying results across all datasets. In particular, the optimal weights per network were different, and to illustrate that, we show how the optimal weights for DBLP operate on the other datasets (yellow points).

In all cases, MOIM managed to match (and sometimes even exceed) the results of *WIMM*, which uses the optimal weights for each dataset. For example, over Facebook, while *WIMM* and MOIM influenced almost the same number of g_1 users (601 and

[3]The optimal choice is the one that satisfies all constraints, while maximizing the value for the objective.
[4]Users belong to multiple groups are assigned with the sum of weights of their groups.
[5]In both [36] and [15], the largest examined network included 500 nodes.

Figure 3: Expected influence with 5 emphasized groups. The red horizontal lines represent the estimated constraints.

599, resp.), MOIM succeeded in covering more g_2 users (19 vs. 12 for MOIM and *WIMM*, resp.). Observe that using the optimal weights for DBLP over Pokec for *WIMM*, result in not satisfying the constraint. The exploration of *WIMM* for optimal weights significantly increases its runtime, making it impractical for massive networks like Weibo-Net, YouTube and LiveJournal (exceeded our time cutoff). In all cases, not only did MOIM satisfy the constraint, it also came very close to the results of IMM_{g_2} in terms of covering g_2 users, which returns the optimal solution. For example, over Pokec, where IMM_{g_2} covered 189 g_2 users, MOIM covers 159, as opposed to *IMM* covering only 73 such users.

Although RMOIM allows for some relaxation of the constraint, it in-fact fully satisfied it in most cases. Moreover, its overall influence was consistently higher than those of *WIMM* and MOIM. In particular, in all but one of the cases, the g_1 influence of RMOIM was very close to that of *IMM*. For example, over DBLP, RMOIM and *IMM* covered 1,661 and 1,712 users, resp., with RMOIM covering over 6 times more g_2 members. RMOIM is incapable of processing massive networks like Weibo-Net (out of memory).

Not surprisingly, the results RMOIM and *RSOS* were similar. Nonetheless, as opposed to RMOIM, all RSOS-based baselines were incapable of even processing medium-size networks (exceeded our time cutoff). Recall that *MAXMIN* aims to maximize the minimum influence over the emphasized groups, and therefore here it behaves similarly to IMM_{g_2} (as $g_2 \subseteq g_1$). As for *DC*, since it guarantees that every group receives influence proportional to what it could have generated on its own, it ignores the constraint. This demonstrates that *MAXMIN* and *DC* are ill-suited for Multi-Objective IM.

Observe that the single objective algorithms were either far from satisfying the constraint (*IMM*) or covered significantly less g_1 users (IMM_{g_2}). Contrarily, both our algorithms succeeded in covering almost as many g_1 users as *IMM*, and almost as many g_2 users as IMM_{g_2}. For example, over DBLP, *IMM* covered only 2 g_2 users and 1,712 users in total (g_1 users), whereas IMM_{g_2} covered 33 g_2 users, and less than 155 in total. MOIM and RMOIM covered 20 and 13 g_2 users, resp., and covered each more than 1,050 users in total. This demonstrates the advantage of our approach over solutions which are focused only on a single objective.

Last, consider Figures 2 (e) and (f). Among all competitors that satisfy the constraints, MOIM has influenced the largest number of users. Interestingly, even though the emphasized groups were randomly generated, *IMM* did not satisfy the constraints. As for IMM_{g_i}, it influences significantly less users than MOIM. This demonstrates that existing single-objective IM algorithms do not ensure the desired balance between the objectives. Note that here the differences in the cover cardinalities among all competitors

were smaller than in other networks. This stems from the fact that the benefit our approach provides is particularly critical for groups that are typically not covered by standard IM algorithms (which is mostly not the case in random emphasized groups).

Scenario II results. The results are depicted in Figure 3, where the y-axis is the influence over the emphasized groups, and red lines represent the estimated constraint thresholds. A desirable solution should be above (or near) the red lines for the constrained groups $g_1, \ldots, g_4$ groups, and, at the same time, should be as high as possible for g_5 (i.e., maximizing the objective). For the *WIMM* baseline we only present the results obtained by using default weights set to 0.2 for all 5 groups (we report that similar results were obtained when using other weighting schemes), as the search for the optimal weights was infeasible in all cases (it exceeded our time cutoff).

MOIM is the only algorithm satisfying all constraints over each dataset. On top of that, its g_5 influence (i.e., objective value) competes nicely with all competitors. For example, over Weibo-Net, MOIM succeeded to cover the greatest number of g_5 members, while over YouTube it covered 510 g_5 members, compared with the best competitor (here - IMM_{g_i}) that covered 810 g_5 users (yet did not satisfy the constraints). In the datasets which RMOIM has managed to process, its g_5 influence was the best or slightly below the best value achieved. E.g., over Pokec, RMOIM and IMM_{g_i} covered 4036 and 4090 g_5 users, resp., while over Facebook and DBLP RMOIM covered the greatest number of g_5 users.

Here again, all RSOS baselines could only process the small Facebook network (exceeded our time cutoff in other datasets), and, as expected, the results of *RSOS* and RMOIM were similar. Here, *MAXMIN* also behaves similarly to RMOIM, however, as noted above, in other scenarios it may behave differently. This stems from the fact that *MAXMIN* optimizes for equality of outcomes, which may be undesirable when some groups are much better connected than others. For instance, if one group is poorly connected, *MAXMIN* would require that a large number of seeds is "spent" on reaching it, even though these seeds may have a relatively small impact on other groups. As the *DC* baseline ignores the constraints, it did not satisfy them.

As opposed to the binary scenario where the objective was to maximize the overall influence, here *IMM* has no advantage over the competitors. Indeed, in all except one of the examined cases, *IMM*'s objective value was the lowest among all algorithms. Furthermore, regarding IMM_{g_i}, as can be seen, covering a greater number of users from one group may come at the cost of significantly reducing the cover sizes of users from other groups. For example, in LiveJournal (Figure 3 (F)), while the g_4 and g_5 cover sizes of IMM_{g_i} were the largest, its g_1 and g_2 cover sizes were significantly lower than the competitors (and below the required constraints). This demonstrates that existing (single-objective) IM algorithms do not ensure the desired balance between the objectives.

6.3 Parameter Tuning

Next, we examine how varying the input parameters affects the results. To illustrate, we present here the results using a range of values for k and t over the DBLP dataset (the other datasets show similar trends). We note that a desirable behavior of a Multi-Objective IM algorithm is as follows. As k increases, we expect both the g_1 (i.e., overall) and the g_2 (i.e., emphasized group) influences to increase as well. As t increases, i.e., the constraint threshold is elevated, the g_2 influence should increase, possibly at the cost of reducing the g_1 (i.e., overall) influence. Naturally, as only our algorithms and *WIMM* take into account the parameter t, other competitors are indifferent to it.

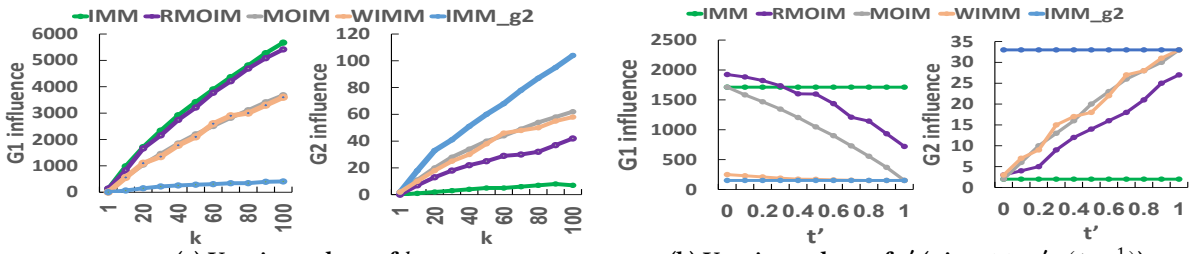
The results are depicted in Figure 4. We first examine Figure 4(a). Interestingly, for all examined k values, the targeted IM algorithm, IMM_g, has shown almost no growth in the overall number of influenced users (less than 400), compared to *IMM* and RMOIM, which, already for $k = 10$, are influencing twice as many users (more than 800). Analogously, for all k values, there is almost no increase in the number of emphasized users influenced by *IMM* (8 such users at most), while IMM_g, already for $k = 10$, influenced twice as many emphasized users (more than 18 such users). Contrarily, MOIM, RMOIM and *WIMM* have demonstrated the desired behavior when k increases. As expected, MOIM, RMOIM and *WIMM*, as t increases, cover a greater number of g_2 users, and fewer users in total, as illustrated in Figure 4(b). Note that in these experiments *WIMM* exhibit the desired behavior, almost identical to that of MOIM. However, as we will see next, its execution times are significantly longer.

6.4 Performance Evaluation

We next measure the cost of enriching the IM problem by incorporating multiple objectives, studying how different parameters affect running times of our algorithms. For brevity, we present the results only for scenario *II*, as the results for scenario *I* show similar trends (see [3]).

Recall that MOIM runs targeted IM algorithms (i.e., IMM_g) as subroutines. As we show, the overhead for MOIM turns out to be negligible compared to IMM_g, and it can process massive networks efficiently. Naturally, MOIM behaves similarly to its current input algorithm *IMM*, whose optimizations and shortcomings both carry over to MOIM. In particular, as mentioned in [33], when k decreases, so does the optimal expected influence, $I(O)$ (resp. $I_g(O_g)$), in which case it is more challenging for *IMM* (resp. IMM_g) to estimate $I(O)$ (resp. $I_g(O_g)$). Contrarily, for larger k values, *IMM* (resp. IMM_g) is optimized to reuse *RR* sets produced in earlier stages. Thus, the two main factors affecting *IMM* (resp. IMM_g) are k and $I(O)$ (resp. $I_g(O_g)$). Consequently, these factors have a similar effect on MOIM. Regarding RMOIM, we show that solving an LP is indeed costlier than employing an IM algorithm. We will see that when it comes to medium or large scale networks, RMOIM's overhead turns out to be moderate, but when it comes to massive networks it is incapable of processing them. We further show that RMOIM's scalability is not affected by the same factors as MOIM, and its running times are barely affected by those of its input IM algorithm.

Network size. . We first report the running times for the cases presented above in Figure 5(a). Naturally, all competitors' running times increase for larger networks. Although we see that MOIM and RMOIM are naturally slower than *IMM* and IMM_g, they run in approximately 2 and 7 minutes, resp., even on Pokec, which includes 1M nodes and 14M edges. That is, both our algorithms can process large-scale networks in feasible running times. Importantly, note that the running times of MOIM are very close to those of IMM_{g_i} (i.e., MOIM and IMM_{g_i} have processed YouTube in 5.7 and 5.3 minutes, resp.). When it comes to massive networks such as Weibo-Net, while MOIM processed it in less than 49 minutes (in comparison, IMM_{g_i} processed it in 47 minutes), RMOIM can not process it, since the LP program was too big for the LP solver to handle (out of memory). According to our experiments, RMOIM is feasible for graphs including up



(a) Varying values of k. (b) Varying values of t' (t is set to $t' \cdot (1 - \frac{1}{e})$).

(a) Network size. (b) Propagation model.

(c) Seed-set size k. (d) Constraint threshold.

Figure 5: Averaged execution times (for scenario *II*).

to 20M edges and nodes. Regarding *WIMM*, as it searches for optimal weights, its running times were significantly longer than both our algorithms. For example, on Facebook, it took *WIMM* 16 seconds - almost 4 times slower than MOIM (which ended after 4.5 seconds). Observe that all RSOS-based algorithms ran in more than 6 hours, even on the small Facebook instance network.

In what follows we focus on the Pokec dataset, as this is the largest dataset RMOIM can process. We omit the results of the RSOS-based and *WIMM* baselines, as they cannot process it.

Propagation model. We present the effect of the propagation model on running times in Figure 5(b). As reported in [5], while *IMM* scales well under the LT model, it shows inferior performance under the IC model, as it samples more *RR* sets. Consequently, all *IMM* variants, MOIM included, run slower under the IC model. Indeed, it took all *IMM* variants almost twice the time to process Pokec when using the IC model. Contrarily, as RMOIM is less sensitive to the increase in the number of *RR* sets, and it behaves similarly under both propagation models (the difference was less than a minute). As explained in [5], besides *IMM*, multiple top performing IM algorithms are not robust across different propagation models (e.g., [18], [34]). This property of *IMM* is naturally carried over to MOIM. In cases where the user is interested in a different propagation model, she can take a different IM algorithm optimized for this model (e.g., [13] for IC) as an input for MOIM.

Seed-set size. . In Figure 5(c) we examine the effect of the parameter k on running times. As mentioned, when k increases *IMM* employs an optimized computation and hence we observe almost no change in running times for all *IMM* variants, MOIM included. This behavior of MOIM is a consequence of employing *IMM*, and therefore using an alternative IM algorithm (e.g., [17]) could lead to a linear growth in running times. As expected, RMOIM demonstrates nearly linear growth as a function of k, as more k-size seed sets are considered.

Constraint threshold parameter. . In Figure 5(d) we examine how the parameters $t_i, i \in [1, 4]$ affect performance. Here we tested all t_i values of the form $t_i = 0.25 \cdot t' \cdot (1 - \frac{1}{e})$, where $t' \in [0.1, 0.2, \ldots, 1]$. Note that this parameter only affects the behavior of our algorithms. In MOIM it dictates the required seed-set size for the procedures it employs. Observe that when all $t_i = 0$ MOIM only runs IMM_{g_5}, while for other t_i values it employs 5 versions of IMM_{g_i} with smaller k values, therefore it cannot use *IMM* optimizations for large k values. On the other hand, as the solution space becomes smaller for higher t_i values (i.e., less k-size seed-sets satisfy the constraint), the running time of RMOIM decreases.

7 RELATED WORK

The seminal work of [23], the first to formulate the IM problem, has motivated extensive research [5, 13], which can be classified into three main approaches: (i) The greedy framework [18, 23, 29], which iteratively adds nodes to the seed-set, maximizing the expected marginal influence gain; (ii) The RIS framework [7], where, while retaining optimal accuracy, running times were gradually improved, resulting in highly scalable algorithms [20, 28, 33]; (iii) In cases where scalability is preferred over accuracy, there are heuristic algorithms that have been shown to perform well in practice (e.g., [11]), despite not having theoretical guarantees. Any greedy or RIS-based IM algorithm can be embedded in MOIM, retaining the same features and drawbacks. In our experiments we have examined the results of top performing IM algorithms (e.g., [17, 33]), showing them all to be ill-suited for the Multi-Objective IM problem.

An extension of IM, which we also examined in our experiments, is *targeted IM*, where the goal is to maximize the influence over a target group of users [6, 9, 26]. As demonstrated, this extension as well is ill-suited for the Multi-Objective IM problem, as maximizing the influence over one group of users may come at the cost of influence decrease for other groups. Therefore, unlike our solutions, it does not provide theoretical guarantees for the influence over each emphasized group separately.

Multi-Objective optimization problems (also known as Pareto optimization) involve several (possibly conflicting) objectives, which are required to be optimized simultaneously. Such problems have been studied in numerous fields, including economics [27], finance [35], social-network analysis [19] and engineering [14]. A classic approach to tackle such problems, which was adopted by targeted IM algorithms [26, 31]), is the weighted-sum method (e.g., [21]), which scalarizes the objectives into a single objective, by assigning to each objective a user-defined weight (which is chosen in proportion to its relative importance). In the IM setting, the relative weights of users in the overall influence sum are altered in accordance with a context-based function

[6, 9, 26]. The main disadvantage of this method is the difficultly in setting the weights obtaining the desired trade-off between the objectives. Indeed, as we show in our experiments, adopting the weighted-sum approach for our context requires an exploration for the optimal weights which strike the desired balance. Hence, this solution results in poor performance.

An alternative, more direct approach to multi-objective optimization problems is the *constraints method* (e.g., [12]), that transforms all except one objectives into constraints, optimizing the remaining objective subject to these constraints. A typical challenge when applying this method is that the constraints have to be chosen within the minimum/maximum values of the individual objectives (which are generally unknown). Our solution follows this approach, which enables the user to prioritize her objectives and provides lower bound guarantees for all of them. As mentioned, to assist the user in choosing the minimum values of the objectives, IM-Balanced indicates to the user the range of possible constraints per objective.

We have discussed on the connection between Multi-Objective IM and the RSOS problem [24]. The authors of [8] provided an optimal $(1-\frac{1}{e})$-approximation algorithm for RSOS (assuming that number of objectives is $m = \Omega(k)$), which runs in $O(n^8)$. Udwani [37] has recently introduced two more efficient algorithms. The first is an optimal $(1-\frac{1}{e})$-approximation algorithm, which runs in $\tilde{O}(mn^8)$. The second is a more efficient algorithm which runs in $O(n \log m \log n)$, yet achieves only a $(1-\frac{1}{e})^2$ approximation. More recently, the authors of [36] remedy this gap by providing an optimal $(1-\frac{1}{e})$-approximation algorithm, whose runtime is comparable to the second algorithm of Udwani. As mentioned, we have included this algorithm in the experimental study, showing that, unlike our algorithms, it fails to process large networks.

8 CONCLUSION AND FUTURE WORK

We have presented the IM-Balanced system, which employs Multi-Objective IM, a refined notion of the IM problem, handling multiple objectives. We motivate the practical relevance of this problem, and propose two algorithms: MOIM and RMOIM. IM-Balanced employs RMOIM for social networks including up to 20M users and links, and MOIM for larger networks. Our experimental study demonstrates the advantages of our algorithms in multiple real-life scenarios, compared to alternative approaches.

We are currently pursuing complementary Multi-Objective IM definitions, e.g., definitions aiming to maximize the *ratio* of different cover cardinalities, inspired by recent work on fairness-aware IM [15, 36]. We identify several interesting directions for future research, which include confirming the tightness of MOIM, and identifying other optimum values for Multi-Objective IM.

ABSTRACT

Online users are becoming increasingly dependent on Web services in choosing among products and services. This recent trend is motivated by the integration of conversational agents which took the human-machine interaction to unprecedented levels of ease, using natural language as a communication medium. Given the success of these systems, users are constantly switching to experiential search, providing utterances that are intrinsically subjective such as looking for a restaurant with a romantic ambiance, creative cooking or nice staff. Current Web services are unfortunately unable to decipher the subjective signals present in user utterances and only support objective attributes that are listed in service descriptions (e.g., restaurant address, cuisine, price range).

To make the most of dialog systems, they must be able to detect subjective attributes in user utterances and filter responses according to user subjective preferences. This paper presents a framework and techniques that augment conversational search services with capabilities to understand and reason about subjective user utterances. We propose novel subjective tag-based indexing of information services. We discuss automatic subjective tag extraction from both user utterances and online reviews using state of the art machine learning techniques such as BERT, adversarial training and data programming. Experiments show that the proposed techniques outperform existing information retrieval systems and the search mechanisms provided by well-known web search services such as Yelp.

1 INTRODUCTION

Digital services and online reviews are widely used in day-to-day decisions [14], such as providing recommendations or opinions regarding which restaurant to eat, which research paper to read or even who to vote for in elections. When we make decisions, recent studies show that we are prone to lean toward subjective data focusing on past experiences rather than relying solely on objective information (e.g., type of food served by a restaurant or an address of a restaurant) [31]. For example, when we set out to choose between two restaurants, we are attracted by the ones offering great experiences such as delicious food, brilliant atmosphere, friendly staff or romantic ambiance in addition to deciding based on factual information such as restaurant locations or specific types of cuisine [39]. Often, we find experiential and subjective information in online reviews because they reflect user opinions and experiences [14]. Techniques from opinion mining and information retrieval (IR) [32] can be used to extract knowledge from reviews. However, such techniques usually lack the necessary precision to obtain meaningful and accurate subjective information due to their keyword-based search nature [31]. On the other hand, online reviews are expressed in natural language which is very nuanced and intricate, thus needing more effective extraction techniques. In the same line of argument, information retrieval systems are heavily manual for the users given that users need to try different combinations of keywords and query styles before having to compare between the results in a manual and labor-intensive way. Hence, decisions made through traditional information retrieval systems are generally sub-optimal [14].

Capturing and reasoning about subjective information has been explored at various levels [31]. Some techniques explored ratings (e.g., star ratings) to represent aggregated user opinions on entities or services [59]. Rating-based techniques do not consider reviews content but they rather provide aggregated numerical or symbolic values which are hard for users to express accurately. For example, a star rating of three out of five might give the impression that the restaurant is average in all aspects but in reality, it may serve delicious food but employs unhelpful waitstaff, which made the reviewer balance out her final rating. Another line of subjectivity-related research translates numerical attribute values to linguistic values (e.g., translation of prices to linguistic values, such as {"cheap", "fair", "costly", "expensive"}) using insights from fuzzy logic [26]. Nonetheless, such methods involve objective attributes, whose values are to be translated into subjective linguistic variations, leaving the space of the inherently subjective attributes untouched.

More recently, [31] proposed techniques extending database systems to account for both objective and subjective attributes and support subjective database queries. Nevertheless, in order to use [31], the database schema, and hence the subjective attributes, must be defined beforehand. Unfortunately, it is not always easy to identify which attributes to include in the schema and what their precise meaning is [14]. Besides, while such extensions [31] augment structured query languages with subjectivity support, they presuppose technical expertise comparable to that of professional database users, who can express (complex) SQL queries. Therefore, there is a need for more advanced techniques to empower all users to benefit from subjectivity-aware services in performing their day-to-day activities in a digitally enabled world.

At the same time, conversational Artificial Intelligence (AI) and its instantiation in the form of messaging or chat bots (also called task-oriented conversational bots) emerged as a new paradigm to naturally access services and perform tasks through natural language (text or voice) conversations with software services and humans. Thousands of bots have already been used in a variety of significant use cases, e.g. tourism, travel, office tasks, healthcare, e-commerce, education, and e-government services. On the downside, the current generation of conversational bots does not handle subjective information users ought to include in their utterances and often ignores them, leading to user dissatisfaction.

In this work, we propose *SACCS* (Subjectivity Aware Conversational Search Service), consisting of a Natural Language Understanding (NLU) framework and techniques, that combine the usefulness of including subjective information in the search utterances and the flexibility of utilizing natural conversations to interact with users. A key feature of *SACCS* is the ability to automatically and dynamically extract subjective information from user utterances and online reviews without explicitly defining them beforehand. Achieving such an objective faces several difficult issues, the most challenging of which is due to the expressiveness and complexity of natural language, i.e. the same subjective information can be expressed using various phrases. For instance, both *"The food is phenomenal"*, *"Very tasty plates of food"* or *"Really good food"* denote the deliciousness of food. To address this issue, we introduce the concept of *subjective tags*. Briefly stated, a subjective tag denotes subjective information in user utterances and online reviews. For example, the review sentence *"This restaurant serves really good food and the service is really quick"*, is tagged with {*delicious food*, *quick service*} subjective tags. The use of tags provides a powerful mechanism to reason about subjective information in user utterances and online reviews (e.g., organization, navigation, summarization, matching and understanding of subjective information). Building upon advances in opinion extraction, in our approach a subjective tag is represented as concatenation of an *aspect* term and an *opinion* term [32]. The aspect term denotes the feature being described and the opinion term characterizes this feature. For example, *delicious food* is a subjective tag wherein *food* is the aspect while *delicious* is the opinion. *SACCS* marks each review with a corresponding set of subjective tags.

In this paper we make the following contributions to overcome challenges related to extracting subjective tags from user utterances and online reviews as well as using them to support subjectivity-aware human-bot natural language conversations:

- We introduce a framework that augments task-oriented dialog systems with subjective filters. Search services are augmented with subjective tag based search and indexing [36]. Each subjective tag in the index is mapped to a list of reviews and entities (e.g. restaurants, books, hotels...).
- We provide a novel subjective tag extraction pipeline that is robust against variations of natural language. Tagging labels each word in a natural language sentence as being either an aspect, an opinion or neither. We train a subjective tag extraction model (called extractor) in an adversarial fashion, wherein the adversary [13, 38] adds *informed* perturbations to natural language sentences. This allows the tag extraction model to learn the possible variations in language and update its parameters accordingly.
- After the aspects and opinions have been extracted, there is a need to pair each aspect with its corresponding opinion in order to construct subjective tags. We propose two novel heuristics for pairing an aspect to an opinion. These heuristics aim to overcome the limitation of word-based distance approaches for pairing an aspect term to an opinion term [31, 56]. The first heuristic relies on the distance between aspects and opinions in the review parse trees [24, 25, 41]. For example, the opinion *professional* would be wrongfully paired with the aspect *decor* in the review *"The staff is friendly, helpful and professional. The decor is beautiful"* when relying on word distance alone. However, when using a parse tree to represent the above review, the two sentences *"The staff is friendly, helpful and professional"* and *"The decor is beautiful"* belong to two separate sub-trees. Consequently, the opinion *professional* will be closer to the aspect *staff* than the aspect *decor* because *professional* and *staff* belong to the same sub-tree. While more effective than traditional word distance techniques, this heuristic has the following limitations: (i) In long sentences, the different aspects and opinions may not be separated into their own sub-trees. In this case, this heuristic provides the same result as word distance methods. (ii) The generated parse tree will be incorrect when there are typos or punctuation errors in the review. The second heuristic is proposed to overcome these limitations. It relies on attention mechanism [3, 17, 54] to distribute the attention of an aspect term among the different opinion terms. These heuristics are combined using a data programming paradigm [2, 49] to : (i) pair opinion and aspect terms in natural language sentences in an unsupervised model, or (ii) automatically generate training data from online reviews to build a supervised pairing model.
- We evaluate the performance of the proposed techniques using crowd sourced data. Experiments show that *SACCS* provides better results than IR systems. Besides, the tagger improves upon state of the art by up to 4.93% in F1 scores while the supervised pairing method adds 3.03 points in accuracy.

This paper is organized as follows: We first discuss related work. We then introduce the architecture of *SACCS* in Section 3. The extraction of subjective tags is discussed in Sections 4 and 5. Section 4 describes the tagging while Section 5 details pairing. Finally, Section 6 discusses the evaluation of the proposed techniques.

2 RELATED WORK

Our work lies at the intersection of two areas: Subjectivity search, and aspect/opinion extraction.

Subjectivity Search. Despite the overwhelming importance of subjective information in the decision making process, relatively little effort focused on understanding and measuring the effect of subjectivity in user decisions [31]. This task has been traditionally delegated to standard information retrieval systems which provide a keyword-based search, and a synonym expansion at best [36, 52]. Systems that incorporate subjective filters in their data models attracted the attention of the research community only recently. Perhaps the closest work to ours is [31] which aimed to augment traditional database systems with subjective attributes. Their approach is different from ours in that their

subjective attributes are part of a database schema itself, which should be explicitly defined by a database designer beforehand. The query interfaces require the users to have precise knowledge about source schemas too. In our approach, subjective tags are dynamically extracted from user utterances as they interact with the system, thus increasing flexibility and productivity.

[27] built a tunable high-precision knowledge base with both factual and subjective attributes. To do so, they predefined a list of attributes (e.g. GOOD_VIEW, KID_FRIENDLY, HAS_HIGH_CHAIRS) and asked crowd workers to assess whether an entity (in their case, they used locations in Google Maps) has each attribute or not. They then modeled user consensus with Beta distributions. The major limitation of this approach is the increasing cost of crowd workers when adding new locations, new attributes or even changing the domain. Besides, crowd-sourced data suffers from data quality problems, mainly due but not limited to the inherent subjectivity in the task at hand. Also, the subjective attributes in [27] are set at design time and not learned from user interactions as we do.

Prior works also tackled the problem of subjectivity and opinions in various domains [29, 37, 59]. Most of them capture a narrow aspect of subjectivity by prompting the reviewers to rate the objects they write about. We often find these in e-commerce services in the form of star ratings which aggregate opinions of all sub-parts of the object and act as a proxy for the overall user satisfaction. This suffers from coarse granularity because the star rating skips the details we might be interested in and only gives one global assessment of the reviewer's true feeling.

Another body of research aims to translate objective facts into subjective phrases [20, 26, 50, 60]. The dominant example is the price which is mapped to a set of subjective phrases such as {"cheap", "fair", "costly", "expensive"} depending on comparisons between the price value and a set of thresholds. This approach only deals with translating objective attributes whose values are indisputable. It leaves the space of the inherently subjective attributes such as food deliciousness or room cleanliness untouched.

Aspect Opinion Extraction. The problem of extracting aspects from review texts is a long standing one in the Natural Language Processing (NLP) literature [32]. However, most previous work focused on identifying the aspects only and measuring their quantitative sentiment polarity (as being positive, negative or somewhere in between). This task is often referred to as *Aspect-Based Sentiment Analysis* (ABSA) [32].

Existing approaches include rule-based, feature-engineering-based and deep-learning-based approaches [56]. In a rule-based approach, to classify the aspect terms as positive or negative, a lexicon is used along with handcrafted sentiment values [18, 19]. Feature-based approaches [22, 30] train a classifier to extract the aspect terms with manually defined features. Both rule-based and feature-based solutions are labor-intensive and highly demanding in terms of effort and time. Deep-learning-based approaches [33, 55, 56], aside from having superior performance than the previous two methods, extend the extraction to opinion terms as well. While [55] used recursive neural networks, [56] employed an attention-based architecture. The motivation behind both approaches is the necessity to link aspects to opinions. [31] employed BERT sentence embeddings [7] with a standard classifier that classifies each word in the sentence into either Aspect, Opinion or Other. In the same spirit, we use BERT as an embedding layer along with a BiLSTM-CRF classification model. We also leverage adversarial training to handle potential variations in the language. Experiments show that *SACCS* 's extractor yields better performance in various test benchmarks.

Table 1: An example of an inverted index with degrees of truth for each subjective tag and restaurant pair

Tag	Restaurants
good food	Vue du Monde (0.89) Anchovy (0.76) Pizza Hut (0.82)
nice staff	Vue du Monde (0.92) Pizza Hut (0.63)
creative cooking	Anchovy (0.94) Pizza Hut (0.34) Kazuki's (0.85)
fast delivery	Anchovy (0.13) Pizza Hut (0.75) McDonald's (0.74)

3 SUBJECTIVE TAG BASED INDEXING AND FILTERING IN CONVERSATIONAL SEARCH SERVICES

To describe the pipeline of *SACCS* , we begin with illustrating how subjective tags are used. We then move on to show how *SACCS* constructs these tags and how it uses them to answer complex and subjective user utterances. It should be noted that, while the proposed techniques are not domain specific, we choose the restaurants domain as a use case in this paper in order to illustrate the components of the proposed pipeline. We also assume that the underlying dialog system is already equipped with intent recognition [15, 23, 46] and slot filling techniques [4, 12]. Briefly stated, intent recognition allows the identification of user intents from user utterances. For instance, from the following user utterance: *"I want to eat Italian food near Lyon in a romantic ambiance"*, the dialog system identifies that the user is searching for a restaurant. Once an intent is identified, the system also extracts what is called slots (e.g., the type of cuisine (Italian), the location of the restaurant (Lyon)). The chatbot then delegates the search intent to a search API that retrieves a list of restaurants filtered by objective criteria. The goal of *SACCS* is to re-filter this list to only keep the restaurants which offer a romantic ambiance.

3.1 Subjective Tag Index

In order to use subjective tags, *SACCS* leverages an inverted index data structure [36]. Table 1 shows a snippet of what the index might look like [1]. Each subjective tag points to a set of entities (in this case restaurants) whose reviews include mentions of the subjective tag. For example, *good food* in Table 1 points to *Vue du Monde*, *Anchovy* and *Pizza Hut*, meaning that the reviews of these restaurants mention the deliciousness of the food cooked there. Also, every entity is accompanied by a degree of truth. Informally, a degree of truth associated to a tag measures the degree of certainty that *SACCS* exhibits when marking an entity with the tag. In the case of Table 1, *Vue du Monde* is more likely to have a nice staff than *Pizza Hut* (a degree of truth of 0.92 compared to 0.63). The degrees of truth are computed automatically by *SACCS* .

[1] The degrees of truth reported in the table are for illustration only and do not reflect the quality of these restaurants in the real world

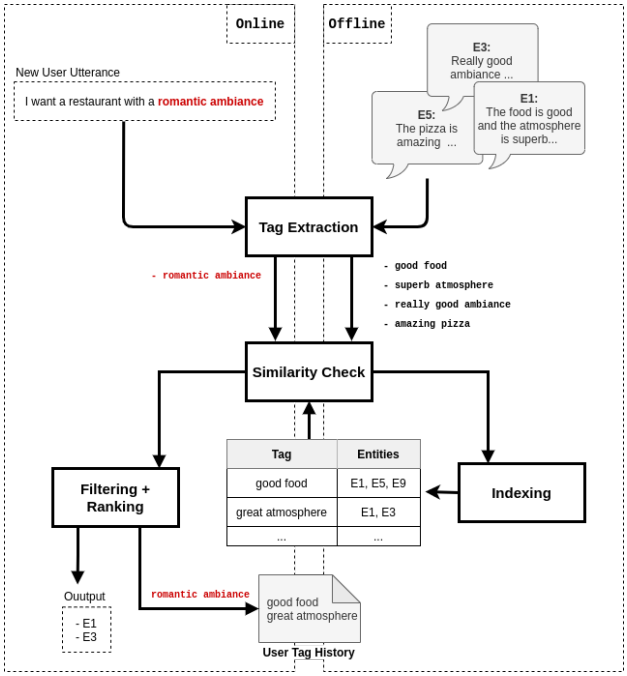

Figure 1: Architecture of *SACCS*

After collecting the set of subjective tags, *SACCS* needs to associate each tag with a set of entities, as depicted in Table 1. Association, or mapping, between a tag and an entity is based on similarity scores [53]: *SACCS* reads online reviews of the entity and extracts all subjective mentions from it. It then proceeds to compute similarities between the subjective tags in the index with those extracted from the reviews. If the similarity exceeds a predefined threshold, *SACCS* includes the corresponding entity to the index. Figure 1 illustrates this process.

The index in Figure 1 contains two subjective tags: *good food* and *great atmosphere*. Suppose we have three entities (*E1, E3* and *E5*) each having only one review. The extractor component extracts subjective tags from the reviews, in this case *good food*, *superb atmosphere*, *really good ambiance*. In the next step, the similarity checker computes similarity scores between the review tags and the index tags. Each time a similarity exceeds a specified threshold, the indexer adds the corresponding entity to the appropriate subjective tag in the index. Following the same example in Figure 1, *E1* and *E5* are both included as mappings to the subjective tag *good food* because their reviews both mention it (*good food* and *amazing pizza* for *E1* and *E5* respectively). However, the review of *E3* only mentions the ambiance; hence *SACCS* does not add it as a mapping to *good food*. We use conceptual similarity which, in addition to the individual meaning of words, also considers their nature or concept, for example pizza being a type of food [2]. Conceptual similarity has been shown to work better on short phrases such as subjective tags than cosine similarity. When building the index, *SACCS* automatically computes the degrees of truth of an entity e with respect to *tag*. The exact formula is shown in Equation 1.

[2]Conceptual similarity is outside the scope of this paper and may be subject to another submission

$$Deg\_truth(tag, e) = \frac{log(|R_e| + 1)}{|T_e^{tag}|} * \sum_{t \in T_e^{tag}} Sim(tag, t) \quad (1)$$

Where R_e is the set of entity e's reviews and T_e^{tag} is the set of subjective tags automatically extracted from R_e and whose similarity score exceeds a predefined threshold θ_{index} when compared to the tag *tag*. $|R_e|$ and $|T_e^{tag}|$ are the number of elements in both R_e and T_e^{tag} respectively. Equation 1 finds all review tags which are similar to *tag* and computes the arithmetic mean of their similarity scores, weighted by the number of reviews. The motivation of multiplying the mean with the number of reviews for each entity is that the more reviews there are, the more statistically significant the degrees of truth become. That is why *SACCS* privileges the entities having more reviews.

Going back to the example in Figure 1, when the user submits a new utterance *"I want a restaurant with a romantic ambiance"*, *SACCS* extracts *romantic ambiance* from the utterance. Because this tag is unknown to *SACCS* , it adds it to the user tag history. Consequently, in the next indexing round, *SACCS* includes *romantic ambiance* to the index and computes its entity mappings along with their degrees of truth as has been explained above. This mechanism enables *SACCS* to adapt to new user needs.

3.2 Filtering

In this section, we provide details about how *SACCS* utilizes subjective tags to answer users subjective utterances.

Processing user utterances. Suppose the user submits a new utterance: *"I want an Italian restaurant in Melbourne that serves delicious food and has a nice staff"*. *SACCS* forwards this utterance to the underlying dialog system which finds the user intent (in this case *searchRestaurant*) and calls a corresponding search API (e.g. TripAdvisor, Yelp...). In this example, *SACCS* expects the API to return the set of restaurants that are in Melbourne and serve Italian food. We call this set $\mathcal{S}_{api}$. As mentioned before, neither the dialog system nor the search API understand subjective information in the utterance such as *delicious food* and *nice staff*, thereby ignoring them completely. *SACCS* extracts these tags from the utterance and use them to filter and rank $\mathcal{S}_{api}$ before showing the final results to the user.

Probing the index. If the subjective tags extracted from the user utterance exist in the index, the corresponding entities with their degrees of truth are directly taken from the index. For instance, in the previous utterance, *nice staff* exists in the index depicted in Table 1, and thus the matching set ("Vue du Monde", 0.92), ("Pizza Hut", 0.63) is extracted as is. We call this set $\mathcal{S}_{t1}$, where t1 = *"nice staff"*.

On the other hand, if the subjective tag is not found in the index, *SACCS* adds it to the user tag history as discussed in Section 3.1 and Figure 1 for later indexing. However, in order to provide a good answer to the user in real time, *SACCS* combines mappings of similar tags which are already in the index. To illustrate this, we go back to the previous example. *Delicious food* does not exist in the index of Table 1, but is similar to *good food* and *creative cooking*. In this case, *SACCS* calculates the union of the mappings corresponding to these two tags and multiply their degrees of truth by the similarity score of *delicious food* with each of the two subjective tags. Assume that:

$$s_1 = similarity(\textit{delicious food}, \textit{good food}) \quad (2)$$

$$s_2 = similarity(\textit{delicious food}, \textit{creative cooking}) \quad (3)$$

The set of entities that *SACCS* finds for *delicious food* is then $\mathcal{S}_{t2} = \{(\textit{"Vue du Monde"}, s_1 \times 0.89), (\textit{"Anchovy"}, s_1 \times 0.76 + s_2 \times 0.94), (\textit{"Pizza Hut"}, s_1 \times 0.82 + s_2 \times 0.34), (\textit{"Kazuki's"}, s_2 \times 0.85)\}$

After the construction of $\mathcal{S}_{api}$, $\mathcal{S}_{t1}$ and $\mathcal{S}_{t2}$, *SACCS* needs to aggregate the entities coming from the search API, plus the ones recovered from each subjective tag in the utterance. In other words, *SACCS* computes the **intersection** of these sets of entities according to Algorithm 1. It is worth noting that the function *search_api* takes the user utterance as input parameter and relies on the underlying dialog system and the search API to provide results filtered by objective attributes alone. On the other hand, the function *extract_tags* takes the user utterance as input parameter and returns the list of subjective tags using the extraction pipeline which we describe in Sections 4 and 5.

Algorithm 1 Filtering & Ranking

1: Let **u** be the user utterance
2: Let **index** be the inverted index
3: Let θ_{filter} be the similarity threshold
4: $\mathcal{S}_{api} \leftarrow search\_api(u)$
5: $tags \leftarrow extract\_tags(u)$
6: **for** t in tags **do**
7: **if** $t \in index.keys$ **then**
8: $\mathcal{S}_t \leftarrow index[t]$
9: **else**
10: $\mathcal{S}_t \leftarrow \bigcup_{tag \in index.keys} \{\text{index[tag]}\}$ such that $similarity(t, tag) > \theta_{filter}$
11: $\mathcal{R} \leftarrow \bigcap_{t \in tags} \{\mathcal{S}_{api}, \mathcal{S}_t\}$
12: **Return** $sort(aggregate\_scores(\mathcal{R}))$

3.3 Ranking

SACCS ranks the filtered set of entities according to their degrees of truth across all subjective tags. We identify two situations for ranking.

One subjective tag. If the user expresses a single subjective filter in her utterance, the ranking is straight forward. *SACCS* sorts the entities according to their degrees of truth in descending order, so that the top results are the ones whose reviews strongly mention the subjective tag.

Many subjective tags. In this case, *SACCS* has a separate set of entities with their degrees of truth for each subjective tag. However, an entity can belong to many of such sets. Thus, before ranking becomes feasible, *SACCS* must aggregate the degrees of truth for each entity across all subjective tags. Aggregation is done via computing the arithmetic mean over all tags. We also experimented with other aggregation methods such as the product or min operators, but the arithmetic mean works better in practice. *SACCS* then sorts the entities in descending order. Algorithm 1 combines the filtering and ranking stages. In line 12, the function *aggregate_scores* computes the arithmetic mean of degrees of truth across the tags.

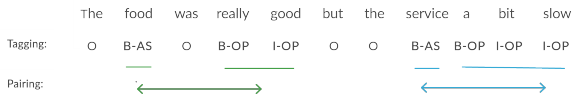

Figure 2: Token Tagging and Pairing

As mentioned before, a subjective tag is the concatenation of two terms: the **aspect** term and the **opinion** term. Following previous effort [31], we formulate the task of extracting subjective tags from a given input sentence as a two-stage process: tagging and pairing, as illustrated in Figure 2. Each word in the sentence is first tagged as being an aspect (AS), an opinion (OP) or neither (O). Then, every aspect term gets paired with its corresponding opinion term to build the set of subjective tags from the input sentence. In the following, we describe the techniques we propose for tagging and pairing tasks. We describe tagging in Section 4 and pairing in Section 5.

4 TAGGING

We denote by r_i a review sentence which consists of a sequence of tokens $r_i = \{w_{i1}, w_{i2}, ..., w_{in}\}$. We use the IOB encoding scheme [47] with the following classes: B-AS (Beginning of Aspect), I-AS (Inside of Aspect), B-OP (Beginning of Opinion), I-OP (Inside of Opinion) and O (Outside). The set of tags is thus L = {B-AS, I-AS, B-OP, I-OP, O}. The objective of tagging is to classify each token w_{ij} in the sentence r_i, into a class $c_{ij} \in L$. The components of *SACCS* 's tagging model are detailed below.

4.1 Baseline for the Tagging Pipeline

Figure 3 depicts the base architecture for tagging words into aspects and opinions. We use BERT [7], the recently-developed language model, as the embedding layer thanks to its proven superior quality when compared to other embedding models [7]. As illustrated in Figure 3, BERT embeddings serve as input to the Bidirectional LSTM (BiLSTM) layer [16], which encodes the past context (all words prior to any given word in the sentence) and the future context (all words following a given word) of each word. Following [8, 35], we encode the text sequence from both left to right (forward) and right to left (backward). We then concatenate the resulting representations to form the final output of the BiLSTM.

Finally, the BiLSTM output flows to the Conditional Random Field (CRF) layer [28], which is paramount to encode dependencies between the different labels of L. For example, I-OP cannot follow I-AS in the label sequence. More generally, I-AS (or I-OP) must either follow B-AS or I-AS (B-OP or I-OP). Given an input sequence $z = \{z_1, z_2, ..., z_n\}$, CRFs effectively utilize correlations between labels to predict the best label sequence $y = \{y_1, y_2, ..., y_n\}$. Formally, the conditional probability function of CRFs is given by:

$$P(y|z, W, b) = \frac{\prod_{i=1}^{n} \psi_i(y_{i-1}, y_i, z)}{\sum_{y' \in Y(z)} \prod_{i=1}^{n} \psi_i(y'_{i-1}, y'_i, z)} \quad (4)$$

where $Y(z)$ denotes the set of possible labels for the sequence z and $\psi_i(y_{i-1}, y_i, z) = exp(W^T_{y',y} z_i + b_{y',y})$ are potential functions to be learned with $W_{y',y}$ and $b_{y',y}$ being the weight and bias vectors respectively. Decoding (i.e. solving the tagging task using

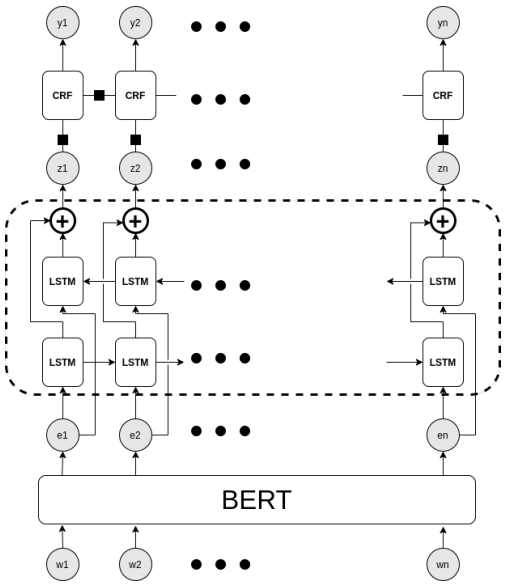

Figure 3: Sequence tagging model based on BERT + BiLSTM + CRF

a CRF layer) consists in finding the best sequence of labels y that maximizes the log-likelihood given the input sequence z:

$$y^* = \underset{y' \in Y(z)}{\text{argmax}}\, P(y'|z, W, b) \tag{5}$$

In this work, we use linear-chain CRFs, where only interactions between two successive labels are taken into consideration. We also adopt the Viterbi algorithm [10] along with beam search for efficient decoding of the label sequence.

4.2 Extending the Baseline with Domain Adaptation

In *"La carte of this restaurant is a killer"*, *SACCS* should be able to tag *la carte* as an aspect and *a killer* as an opinion. However, opinions are mostly adjectives whereas *a killer* is a noun, thereby *SACCS* might fail to recognize it as an opinion, or even mark it as an aspect. Moreover, *la carte* is a rare word in the english vocabulary, thus the tagger might not understand the word altogether. This limitation is largely due to the fact that BERT has been pre-trained on general Wikipedia articles [7]. As a consequence, it does not know that *a killer* is a widely used idiom in the restaurant jargon to characterize something as overly good. It also ignores that *la carte* in this case means *the menu*, which is an important aspect to be extracted. Hence, standard BERT embeddings are blind to the domain and may hinder the tagging performance of *SACCS* .

To make the embeddings more domain-aware, we follow the guidelines of [58] who post-trained BERT on domain-specific review corpora in order to make it understand opinion text rather than generic Wikipedia articles. We use reviews about restaurants as a post-training dataset in our case. [58] also added another fine-tuning iteration to make BERT aware of the task (e.g. aspect/opinion extraction), but on out-of-domain data. We find that using domain knowledge alone works better in our case than when leveraging both domain- and task-awareness. Experiments show that domain adaptation adds up to 2.93 F1 score points over the baseline.

4.3 Adversarial Learning for Dealing with Language Expressiveness

Natural language is very nuanced, and introducing subtle changes to the input sentences can change the meaning dramatically. For example, adding *not* before the verb or changing *always* with *never* reverse the meaning of the sentences completely. Unfortunately, such changes happen frequently when using the trained model with new sentences, unseen during training. This is particularly alarming when the changes are subtle, or insignificant when assessed by a human evaluator, for example changing a word with its synonym. However, word embeddings do not always align with human perception. For instance, two synonymous words might be far apart in the embedding space [9, 21, 40]. Even if they are close to each other, the tiny distance between the embeddings can be enough to mislead the trained model [38]. Adversarial examples have long been used to make trained models robust against small input differences and perturbations (noise). It has been shown to provide additional regularization capabilities beyond that brought by the use of dropout alone [13].

We leverage adversarial learning to enhance the robustness of *SACCS* 's tagger against input noise. We generate adversarial examples that are close to the original inputs and that should share the same label sequence (i.e. aspect/opinion tags), yet are specifically designed to fool the model into tagging them otherwise. The creation of these adversarial inputs is enabled by the introduction of small *worst case* perturbations bounded by a chosen perturbation set, to decrease the model's ability to predict correctly. The tagger is then trained on a mixture of clean and adversarial examples to enhance its stability and robustness against potential input perturbation. The objective function is thus the following:

$$\underset{\theta}{\text{Min}}[\alpha.l(h_\theta(x), y) + (1-\alpha).\underset{\delta \in \Delta(x)}{\text{Max}}\, l(h_\theta(x+\delta), y)] \tag{6}$$

where h_θ is the tagging model with θ being the corresponding parameters. l is the loss function and $\Delta(x)$ is the set of perturbations allowed for the input sequence x. In this work, we use the l_∞ ball: $\Delta(x) = \{\delta : ||\delta||_\infty < \epsilon\}$ where ϵ is a hyperparameter to be tuned. Equation 6 assumes the perturbations to be applied directly on the embeddings as has been done in [38]. Solving such an objective function exactly is intractable in complex networks. Consequently, by leveraging Danskin's theorem [6], we can first solve the inner maximization independently to find δ^* that maximizes the adversarial loss, and then adding δ^* to the input to solve the outer minimization objective.

$$\delta^* = \underset{||\delta||_\infty < \epsilon}{\text{argmax}}\, l(h_\theta(x+\delta), y) \tag{7}$$

$$\underset{\theta}{\text{Min}}[\alpha.l(h_\theta(x), y) + (1-\alpha).l(h_\theta(x+\delta^*), y)] \tag{8}$$

Finding an exact solution for δ^* is also an intractable problem for complex models. We approximate δ^* by assuming a *linear* tendency for the adversarial loss inside the norm-ball. We thus use the Fast Gradient Sign Method (FGSM) suggested by [13] to find a decent solution in an efficient way. The computation of δ^* is given by:

$$\delta^* = \epsilon.sign(g) \tag{9}$$

where $g = \nabla_\delta l(h_\theta(x+\delta), y)$. In Equation 8, the first loss is the clean loss, while the second loss represents its adversarial counterpart. The parameter α denotes how much weight we

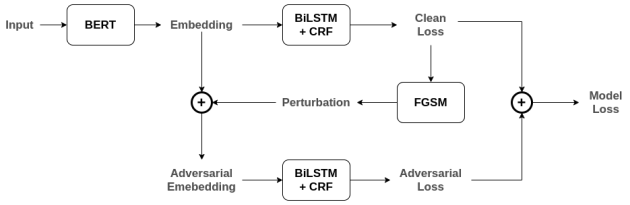

Figure 4: Architecture for Adversarial learning using BERT

give to the adversarial example with respect to the original one. Figure 4 illustrates the entire adversarial learning component.

5 PAIRING

In Figure 2, *food* is paired with *really good*, and *service* with *a bit slow* [3] in order to create the corresponding subjective tags. Most previous work [55, 56] employ simple heuristics such as word distance to pair aspects and opinions. However, such techniques fall short of the expected accuracy especially on complex and tricky input sentences. For example, the opinion *professional* would be wrongfully paired with the aspect *decor* in the review *"The staff is friendly, helpful and professional. The decor is beautiful"* when relying on word distance alone, because *professional* is closer to *decor* than to *staff*.

In this section, we first describe the two novel heuristics that we propose to pair aspects with opinions (Section 5.1). Although these heuristics can be directly used as an unsupervised pairing model, in Section 5.2, we discuss how they are used in a supervised model.

5.1 Pairing Heuristics

We design two types of unsupervised heuristics for pairing. The first category is based on constituency parse trees [24, 25, 41] while the second utilizes the attention mechanism [17].

Heuristic based on parse trees. The first method is a rule-based method. The intuition behind it is that associated aspects and opinions should be close to each other in the parse tree of the input sentence. We start by building the parse tree and then apply a greedy strategy that maps every aspect term to the "closest" opinion term in the parse tree. Given that a single aspect can be mapped to multiple opinions [4], we use this heuristic twice: from aspects to opinions and then from opinions to aspects. For example, in *"The staff is friendly and professional"*, *friendly* is closer to *staff* than *professional* is in the parse tree. Hence, the first version outputs the pair (*staff*, *friendly*). On the other hand, the second run starts from opinions and looks for the closest aspect. It would thus give the pairs (*staff*, *friendly*) and (*staff*, *professional*).

Heuristic based on BERT attention heads. The idea behind using BERT attention heads for pairing is motivated by the need to assign relevance scores to aspects and opinions. Ideally, we want each aspect term to focus more on its corresponding opinion (high relevance score) and ignores the rest (low relevance scores). Attention can be leveraged to approximate relevance. First introduced to enhance neural machine translation

[3] A multi-word aspect (or opinion) is regarded as a single aspect (opinion) term
[4] The reverse also applies: An opinion term can be paired with multiple aspects as well

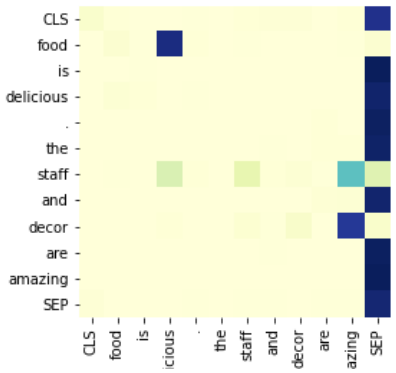

Figure 5: BERT attention head for pairing aspect and opinion terms

[3] and later adapted to nearly every other NLP task, attention is a mechanism to assign importance values to every token in the sequence given a query term. We say that the query term attends to the tokens which have the highest attention scores. In our case, the query term is the aspect term, and the sequence is the input sentence. Using this method, the goal is to distribute the attention of every aspect term so that it attends to the rightful opinion (that of the highest attention).

Fortunately, BERT is an attention-based model, and we have it already trained on aspect/opinion extraction as explained in Section 4. We hypothesize that, while learning the downstream task of tagging aspects and opinions, BERT leverages its attention heads in a way that makes aspects attend to the rightful opinions, and vice versa. Figure 5 confirms our hypothesis. It illustrates one attention head of BERT. Each row in the figure is the attention distribution of the corresponding word over the entire input sequence; the darker the color, the higher the attention. In the figure, *food* is darkest at *delicious*, meaning that *food*'s attention to *delicious* is very high. In the same spirit, both *staff* and *decor* attend to *amazing*. Thus, BERT attention heads act as simple no-training-required classifiers that, given an aspect, output the most attended to opinion. We find that BERT heads capture various linguistic properties, some of which correspond remarkably well to the notion of pairing aspects with opinions. The best head we found for pairing has an accuracy of 82.62% on the pairing test set (Section6.4), which is excellent given the quasi-none effort this method needs.

5.2 Supervised Learning-based Approach for Pairing

We also provide a supervised learning alternative to the problem of pairing. We formulate our pairing objective as a classification problem. Given an input sentence s_i (e.g., *"The food is delicious and the staff are friendly"*) and a short phrase p_i (e.g., *"delicious food"*)[5], the classifier classifies p_i as being a correct extraction from s_i or not. To use this classifier with *SACCS* , we first use the tagger to extract aspects and opinions from s_i. We then construct all possible pairs from the sets of aspects and opinions regardless of their soundness. For example, suppose we have *food* and *staff* as aspects, and *delicious* and *friendly* as opinions. The list of all possible pairings is: P_{all} = [*"delicious food"*, *"delicious staff"*,

[5] In the context of this work, these short phrases are subjective tags

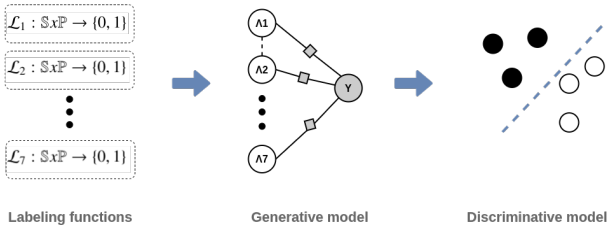

Figure 6: Data Programming pipeline for pairing

"friendly food", *"friendly staff"*]. We feed s_i with each pair from P_{all} into the classifier, and consider it as a correct extraction if the classifier returns a positive label.

We use data programming [2, 49] in order to create the dataset necessary to train such a classifier. The entire pipeline is illustrated in Figure 6. First, a set of labeling functions [2, 48, 49] use the heuristics described in Section 5.1 in order to independently assign a label to every (s_i, p_i) pair. These labeling functions are considered weak supervision sources.

The second step in the pipeline aggregates the labels from the labeling functions to construct a single overall label for every (s_i, p_i) pair, based on agreements and disagreements between labeling functions. This is generally achieved with generative models which, by aggregating enough datapoints, end up creating a decent labeled training dataset. Finally, we use this dataset to train a discriminative model. In our case, it's the classifier discussed above. It is important to note that, in our case, we have a working solution for pairing aspects with opinions at each step of the pipeline. However, experiments show that committing to the entirety of the pipeline and using the discriminative model (and thus the supervised model) drives a considerable boost in pairing accuracy when compared to the unsupervised methods.

In the following, we describe the labeling functions, the generative and discriminative models we use in the supervised learning-based pairing pipeline.

Labeling functions for the pairing pipeline. A labeling function in *SACCS* 's pairing module has the same interface as the classifier, i.e. expects a sentence s_i and a phrase p_i as input, and outputs a binary label telling whether p_i is a legit extraction from s_i. All labeling functions are based on the heuristics presented in Section 5.1. To transform each heuristic H_j into a labeling function L_j, we follow the procedure below:

(1) Extract all aspects and opinions from s_i using *SACCS* 's tagger.
(2) Use H_j to find the pairs $P_{H_j^i}$ as detailed in Section 5.1.
(3) If the short phrase p_i belongs to the set of constructed pairs $P_{H_j^i}$, output 1. Otherwise, return 0.

We use seven different labeling functions: two are based on the parse tree method (the first from aspects to opinions, the second the other way around) while the remaining five rely on BERT attention scores employing different heads. The choice of attention heads has been made after a qualitative analysis.

Generative model for the pairing pipeline. We use the generative model proposed by Snorkel [48] in our pipeline. Snorkel is a data programming framework that integrates the noisy signals of multiple labeling functions to estimate the true label class[48]. Snorkel offers two mechanisms for aggregation. The simplest is a majority vote model where each labeling function is regarded as an independent voter. The chosen label for each datapoint is the most agreed upon by labeling functions. The other method incorporates statistical properties of labeling functions such as accuracies and correlations. Snorkel then trains a probabilistic graphical model to *generate* the true labels without access to ground truth data. Training is based on agreements and disagreements between the different labeling functions as dictated by data programming. Although the authors of Snorkel state that the probabilistic generative model works better in practice than the majority vote, we found the latter to be more accurate.

We can directly use the generative model to extract subjective tags from review sentences. However, a better use of data programming lies in the automatic creation of labelled training data to train a subsequent discriminative model. The advantages of doing so are twofold: First, the discriminative model generalizes beyond the scope of examples fed to the labeling functions. Second, the discriminative model is faster to execute because the generative model loops through all labeling functions and aggregates their outputs, whereas the discriminative model only uses one forward pass in case of neural networks.

Discriminative model for the pairing pipeline. We train a simple two-layer neural network with a sigmoid activation function. We encode s_i and p_i using BERT embeddings. We train the classifier with the training data that has been automatically created with the procedure explained in the previous sections. Our experiments confirm that the discriminative model outperforms the generative one, as has been found in [48].

6 EXPERIMENTS

We first begin by showing our experimental settings before describing the experiments that we conducted. The first set of experiments evaluates the overall performance of *SACCS* and compares it to two baselines (Section 6.2). We then move to assess the quality of *SACCS* components. We evaluate the sequence tagger in Section 6.3 and the pairing mechanism in Section 6.4.

6.1 Experimental Settings

Datasets. We apply *SACCS* to the domain of restaurants whose online reviews we get from the publicly available Yelp Dataset [1]. Since it covers a wide array of businesses, we filter it to only keep reviews about Italian restaurants in Montreal, resulting in 280 entities (restaurants) with 7061 reviews. To train the aspect/opinion tagger, we use the training dataset created by [31] that contains 800 sentences, wherein each token is accompanied by its label. For pairing, we use the same training dataset as in [31] but without the labels since we augment the data and infer the labels with Snorkel [48].

Processing. We implemented *SACCS* in Python using standard packages such as PyTorch [42] for neural networks, HuggingFace transformers library [57] for BERT, NLTK [34] for textual preprocessing and Scikit-Learn [43] for evaluation metrics. In order to incorporate domain knowledge into BERT, we directly use the models for restaurants published on Huggingface community hub by [58]. For adversarial training, we fix the value of α to 0.5 (Equation 8) while we vary ϵ between {0.1, 0.2, 0.5, 1.0, 2.0}.

6.2 Comparing *SACCS* with Baselines

In this experiment, we evaluate the overall performance of *SACCS* , and then compare it to two strong baselines. The evaluation works as follows: we first prepare a set of subjective tags as a test set. Each system that we want to evaluate takes the tags as input and returns an ordered list of results, sorted by their degree of relevance with respect to the subjective tags. The result of each system is then compared to the ideal ordering of entities. The system whose ordering is "closest" to the ideal one is deemed the best. We apply this experiment to the domain of restaurants.

Preparing subjective tags. Since there is no benchmark for subjective tags, we had to create our own. [39] identified the most important features restaurant seekers consider when choosing a restaurant. These features include *"delicious food"*, *"creative cooking"*, *"varied menu"*, *"romantic ambiance"*... We chose 18 of them to serve as our subjective tags for testing purposes. We then construct combinations of these tags by uniform random sampling. Each combination will form a potential subjective user utterance. For example, if random sampling puts together the tags *"clean plates"* and *"quick service"*, it works as if a user gave the following utterance to the system: *"I am looking for a restaurant that delivers a quick service with clean plates."*. The number of tags per combination depends on the level of difficulty of the query (utterance). In this experiment, we set 3 levels of difficulty: Short with either 1 or 2 tags; Medium with 3 or 4; Long with 5 or 6 tags. Each set (level of difficulty) contains 100 queries (combinations).

Evaluation metrics. To measure how well the entities returned by *SACCS* and the baselines satisfy the queries in the test set, we use the well-known Normalized Discounted Cumulative Gain (NDCG) [5] which is a measure of ranking quality. Formally, this metric computes the quality of a ranked list and divides it by that of the ideal ordering, thus giving a score between 0 and 1, the higher the better. For illustration purposes, assume that subjective query Q has n subjective tags: $Q = \{q_1, q_2, ..., q_n\}$ and that we input Q to *SACCS* . The latter returns a list of top-k entities $E = \{e_1, e_2, ..., e_k\}$. We define $sat(q_i, e_j) \in [0, 1]$ as the degree with which entity e_j satisfies the subjective tag q_i. The NDCG score is computed as follows:

$$DCG(Q, E) = \sum_{j=1}^{k} (2^{\frac{1}{m}\sum_{i=1}^{m} sat(q_i, e_j)} - 1)/log_2(j+1) \quad (10)$$

$$NDCG(Q, E) = DCG(Q, E)/iDCG(Q) \quad (11)$$

Intuitively, a highly relevant entity (that with $sat(q_i, e_j)$ scores close to 1) should be at the top in order for the DCG to be high. iDCG in Equation 11 corresponds to the DCG score of the ideal ordering. It is fairly easy to get the iDCG as it is only a matter of sorting the entities with respect to the sum of their $sat(q_i, e_j)$ scores and then computing the DCG. Finally, we take the arithmetic mean over all queries to compute the quality of the entire test set.

Ground truth. We obtain the ground truth $sat(q_i, e_j)$ of subjective tag q_i and entity e_j via crowdsourcing. We give each worker a tag q_i and one review r_j^k from the set of online reviews corresponding to entity e_j. The crowdsourcing task is to inspect the review r_j^k and tell whether it mentions the tag q_i or not. The worker must assign each pair of review/tag a relevance score among the following: 0 for no relevance, $\frac{1}{3}$ for weak relevance, $\frac{2}{3}$ for strong relevance and 1 for perfect relevance. As an example, given the review sentence *"The food is very delicious but the service is terrible"*, the tag *great food* should be marked as perfectly relevant, *nice decor* not relevant while *slow service* as weakly relevant because the slowness of the service is somewhat related to it being terrible. For each review/tag pair, we ask three different workers to provide labels, from which we take the majority vote, resulting in $sat(q_i, r_j^k)$ relevance scores. To obtain $sat(q_i, e_j)$, we take the mean of $sat(q_i, r_j^k)$ across the reviews of the same entity e_j. The crowdsourcing experiment has been conducted on Yandex Toloka platform[6].

Table 2: Comparing *SACCS* to baselines

System	Short	Medium	Long
IR	0.829	0.896	0.916
SIM - 1 att	0.828	0.886	0.907
SIM - 2 atts	0.837	0.891	0.909
SACCS - 6 tags	0.815	0.874	0.896
SACCS - 12 tags	0.825	0.882	0.902
SACCS - 18 tags	**0.854**	**0.911**	**0.928**

Baselines. We compare *SACCS* to two baselines: an Information Retrieval (IR) system and a custom simulation (SIM). The IR baseline uses Okapi BM25 [5] retrieval model. We follow the work of [11] and add the capability to expand the terms of the query into synonymous and related terms, as well as select the best query combination method they found to make the IR system more competitive.

SIM represents what a determined and tireless user can get from Yelp or other similar online services. Because these services provide a set of queryable attributes (such as NoiseLevel, Ambiance or GoodForGroups), the user might filter the search results with the attributes she thinks closely resemble her subjective preferences. For example, if she is interested in quiet restaurants, she can set the attribute NoiseLevel to *calm* and the attribute GoodForGroups to *False* in Yelp's interface. She can also rank the results by star rating. SIM is a simulation of such behavior. We assume that the user can choose one or two attributes from Yelp's interface at a time. SIM computes all possible combinations of attribute values and selects the one that maximizes the NDCG score, thus finding the best top-k results that satisfy the subjective queries. It's needless to say that SIM constitutes a very strong baseline to compare *SACCS* against.

Comparison and analysis. Table 2 reports the NDCG scores of the three systems on the test set. Each column corresponds to the level of difficulty, that is Short, Medium or Long. The first row shows the quality of the IR system. The following two lines are variations of SIM using only one attribute, or a combination of two separate attributes. The last 3 rows describe the performance of *SACCS* , each time with a different number of subjective tags present in the index. This is to simulate the adaptive capability of *SACCS* as interactions with users unfold.

In all difficulty levels, *SACCS* outperforms the information retrieval system with a margin between 1.2% and 2.5%. This is not surprising because the IR system is based on keywords and looks for exact match whereas *SACCS* models subjective

[6] https://toloka.yandex.com

Table 3: Dataset Descriptions with number of sentences for train and test

Dataset	Description	Train	Test	Total
S1	SemEval-14 Restaurants	3041	800	3841
S2	SemEval-14 Electronics	3045	800	3845
S3	SemEval-15 Restaurants	1315	685	2000
S4	Booking.com Hotels	800	112	912

attributes with subjective tags. Table 2 shows that *SACCS* is superior to keyword-based systems even when the latter are bulked with query expansion and adequate predicate aggregation techniques. On the other front, SIM simulates the behavior of a determined user that runs through all possible combinations of queryable attributes that online services such as Yelp offer. To make the evaluation challenging, we take the combination that maximizes the NDCG score, thus reflecting the best result a user can have when interacting with Yelp's interface. As shown on the table, considering two attributes yields better results than one attribute, but with diminishing returns. That is why we don't bother searching the space of more than two attributes, which adds a non-negligible amount of computation. *SACCS* outruns SIM with 2 attributes by a margin between 1.7% and 2.0%.

Even with a small number of tags in the index, the performance of *SACCS* is comparable to that of IR or SIM. This is especially the case at the initialization of the index, where it finds itself nearly empty (in Table 2, the index contains 6 tags only). However, as *SACCS* interacts with users, it extracts new subjective tags from user utterances and adds them to the index in a dynamic and adaptive way. This experiment demonstrates that adding more tags to the index improves the overall accuracy (improvement between 3.2% and 3.9%), and confirms that *SACCS* adapts to new user needs.

We also observe that, for all three systems, accuracy increases with a higher number of subjective criteria. We hypothesize that with more subjective tags, the list of restaurants which verify all the subjective filters shrinks, leading to a lower margin for error in all systems; thus a higher NDCG score. Nonetheless, *SACCS* is still the best no matter the number of subjective tags to be considered. We also observe that the largest improvement happens with short queries (1 or 2 subjective tags therein). This result reinforces the integration of *SACCS* to task-oriented dialog systems where utterances are short and usually span a small number of subjective filters.

6.3 Sequence Tagging Evaluation

We show that the aspect and opinion tagger of *SACCS* is of better quality than that of state of the art, especially when the training dataset is small. We evaluate the sequence tagging model with 4 different datasets summarised in Table 3. The first three datasets are from SemEval competitions: SemEval 2014 Task 4 (Restaurants and Electronics)[45] and SemEval 2015 Task 12 (Restaurants)[44]. Each dataset contains a set of sentences where each token is labeled as being an aspect, an opinion or neither, following IOB coding scheme [47]. The original SemEval datasets contain labels for aspects only. However, we use the versions of [31, 55, 56] who added labels for opinions to the original sentences. The last dataset has been created and labeled by [31]. The goal of this experiment is to compare *SACCS* 's tagger with the strongest previous works in the literature, using datasets of different sizes and domains as well.

Table 4: Evaluation of aspect/opinion tagger

Models	S1	S2	S3	S4
OpineDB	81.82	75.44	72.30	67.41
OpineDB + DK	83.06	75.42	73.86	69.64
Adversarial ($\epsilon = 0.1$)	81.23	76.56	**74.63**	70.16
Adversarial ($\epsilon = 0.2$)	83.46	**76.97**	73.64	**72.34**
Adversarial ($\epsilon = 0.5$)	**84.43**	75.36	72.28	70.32
Adversarial ($\epsilon = 1.0$)	82.80	67.50	73.47	70.38
Adversarial ($\epsilon = 2.0$)	82.93	71.39	73.27	68.42

Other extraction tasks such as Named Entity Recognition (NER) [51] employ F1 to measure the quality of tagging. In the same spirit, Table 4 reports F1 scores of the extraction quality. For an aspect (or opinion) to be counted as correctly extracted, it needs to match the exact terms present in the ground truth. We compare our tagger against two strong baselines: OpineDB's tagger [31] which is a BERT-based solution that outperformed previous works in the literature [55, 56] and currently enjoys state of the art performance. We also enhance OpineDB's tagger with the domain-specific fine-tuning strategy suggested by [58] to make it even stronger (**OpineDB + DK** in Table 4). We evaluate our adversarial tagging model with different sizes of perturbations (ϵ values) as shown in Table4, but we fix $\alpha = 0.5$ (Equation 8) across all runs. The models are trained for 15 epochs.

The adversarial tagging model beats state of the art performance in all four datasets with an improvement ranging from 1.53% to 4.93%. As shown in the table, fine-tuning BERT with domain knowledge (DK) improves the performance by up to 2.23%, confirming the findings of [58] on aspect-based sentiment analysis. However, the boost of domain fine-tuning is not enough to outperform the adversarial training component, motivating the integration of adversarial examples in deep learning models. We also note that the adversarial component works better for smaller datasets (S4). We believe this is due to the regularization capabilities adversarial training provides as a counter-measure against overfitting beyond what is already ensured with dropout. We also notice that the tagging model performs best with lower perturbation sizes ($\epsilon \in \{0.1, 0.2, 0.5\}$), in which case the adversarial examples remain "closer" to the original ones, in contrast to large perturbation sizes ($\epsilon \in \{1.0, 2.0\}$) that can lead the model to exhibit poor accuracy. The issue of large ϵ values is especially noticeable with the Electronics dataset (S2) where $\epsilon = 1.0$ makes the adversarial model worse than OpineDB's baseline. We hypothesize that, since the Electronics dataset contains many technical terms such as brand names and numerical references, adding slight perturbations can change the meaning of terms completely while keeping the same labels, leading to the model's poor performance.

These results are very promising in the context of task-oriented dialog systems. Since chatbots should cover a wide array of domains, they need to be trained and fine-tuned for every single one of them. This task implies the creation of various datasets that are large enough to ensure a decent learning. Fortunately, Table 4 shows that our tagging model is efficient even with small training data (S4), thus eliminating the need to build large and costly datasets.

Table 5: Evaluation of the pairing models

Models	Accuracy	Precision	Recall	F1
OpineDB	83.87	/	/	/
lf_bert_7:10	82.62	95.02	78.36	85.89
lf_bert_3:10	74.56	91.54	68.66	78.46
lf_bert_3:8	68.26	91.76	58.21	71.23
lf_bert_4:6	75.82	93.00	69.40	79.49
lf_bert_8:9	77.33	94.95	70.15	80.69
lf_tree_op	74.06	92.31	67.16	77.75
lf_tree_as	76.07	91.00	71.64	80.17
Majority Vote	84.10	97.20	78.70	87.00
Probablistic Model	82.40	**98.10**	75.40	85.20
Discriminative	**86.90**	92.52	**87.69**	**90.04**

6.4 Pairing Evaluation

In this section, we evaluate the accuracy of the pairing model. We use the test benchmark created by [31] and employed to conduct their own experiments. Each test example consists of a review sentence (e.g., *"The food is delicious and the staff is helpful"*), a tag (*"delicious staff"*) and the label is whether the tag is a correct extraction from the review sentence. The test set contains 397 sentences with a fairly equal amount of positive and negative examples. We compare the accuracy of *SACCS* 's pairing model with that of [31] in Table 5. To highlight the effectiveness of data programming in the context of pairing and motivate the use of both generative and discriminative models, we also assess the quality of every step in the data programming pipeline presented in Section 5.2. Thus, Table 5 reports the accuracy, precision, recall and F1 scores of all seven labeling functions that we used in our solution, both types of generative models (Majority vote and the probabilistic graphical model) and the supervised discriminative classifier.

We take the accuracy score of OpineDB pairing method directly from their paper [31] as we use the same test set. However, they do not report their precision, recall and F1 scores. In Table 5, lf_bert_**l**:**h** corresponds to the labeling function that is based on BERT using the attention head number **h** at layer **l**. lf_tree_op is the labeling function that uses the parse tree and that goes from each opinion to its closest aspect. lf_tree_as travels from aspects to opinions. We train the model with Booking.com dataset for hotels.

SACCS 's pairing model outperforms that of [31] by a margin of 3.03% in accuracy. This result confirms the effectiveness of data programming and weak supervision, and shows that really robust and efficient deep learning models can be designed with little effort and much less resources rather than relying on costly manual annotation. In Table 5, the labeling functions have different accuracies but they all suffer from low recall. We believe this phenomenon is due to the fact that labeling functions are simple heuristics in the first place, and thus fail to cover the entirety of the input space. On the other hand, they all enjoy very high precision, ranging from 91.00% to 95.02%. This insight sheds some light on the nature of our labeling functions and suggests to direct future work on designing heuristics that are less-precise but wide-reaching in order to balance precision and recall ratios. The generative models in Table 5 inherit the high precision of the labeling functions, with the probabilistic model scoring an outstanding 98.10%. However, they also drag the low recall, but are better in general than labeling functions when taken separately. This is due to the nature of generative models which maximize the benefits of labeling functions while minimizing their risk by combining and integrating their respective labels. Our findings support the original statements of [48]. Nevertheless, the experiment shows that the majority vote model surpasses the probabilistic graphical model in terms of accuracy, unlike what [48] reported. One explanation for this is that our labeling functions are already accurate enough and have comparable F1 scores, leading to similar votes. Thus, consensus should be relatively easier to reach, translating to better accuracy. Finally, we find that the discriminative model is the top scoring model in both accuracy, recall and F1, because it has been trained in a supervised fashion. Rather than depending on labeling functions to provide noisy labels, the discriminative model analyzes the feature space and generalizes its classification decisions to new and potentially unseen input; hence the high recall.

7 CONCLUSION

We proposed *SACCS* : a Natural Language Understanding module for task-oriented dialog systems which allows to recognize the subjective signals in user utterances and filter search results accordingly. *SACCS* is based on the inverted index data structure and mines subjective information from online reviews. We propose a novel subjective tag extraction pipeline that is robust against variations of natural language. We also propose two novel heuristics for pairing an aspect to an opinion. These heuristics aim to overcome the limitation of word-based distance approaches for pairing an aspect term to an opinion term. We also performed extensive evaluation of the proposed subjective tag extraction and pairing techniques. The performed experiments show that these techniques outperform existing approaches.

The advancements brought by *SACCS* are promising, albeit far from perfect. As future work, we plan to investigate the incorporation of search automata as a substitute for inverted indexes. Subjective digital assistants should be able to take into account user profiles and adjust their search and interaction behavior accordingly. We also plan to extend the robustness of the proposed techniques to cater for biased or fraudulent online reviews. For instance, a reviewer might have been paid by a business owner to write positive reviews about it, or negative reviews about its competitors. We have to differentiate between truthful and fake reviews in order to provide a transparent search experience for users. Finally, given the importance of thresholds in similarity assessments, it would be useful for *SACCS* to adjust these dynamically depending on the semantics of the subjective tags being compared.

ACKNOWLEDGEMENT

This work was partially supported by the PICASSO (IDEX/FEL/2018/01 - 18IA102UDL) project at LIRIS centre.

ABSTRACT

As individual traffic and public transport in cities are changing, city authorities need to analyze urban geospatial data to improve transportation and infrastructure. To that end, they highly rely on spatial aggregation queries that extract summarized information from point data (e.g., Uber rides) contained in a given polygonal region (e.g., a city neighborhood). To support such queries, current analysis tools either allow only predefined aggregates on predefined regions and are thus unsuitable for exploratory analyses, or access the raw data to compute aggregate results on-the-fly, which severely limits the interactivity. At the same time, existing pre-aggregation techniques are inadequate since they maintain aggregates over rectangular regions. As a result, when applied over arbitrary polygonal regions, they induce an approximation error that cannot be bounded.

In this paper, we introduce GeoBlocks, a novel pre-aggregating data structure that supports spatial aggregation over arbitrary polygons. GeoBlocks closely approximate polygons using a set of fine-grained grid cells and, in contrast to prior work, allow to bound the approximation error by adjusting the cell size. Furthermore, GeoBlocks employ a trie-like cache that caches aggregate results of frequently queried regions, thereby dynamically adapting to the skew inherently present in query workloads and improving performance over time. In summary, GeoBlocks outperform on-the-fly aggregation by up to three orders of magnitude, achieving the sub-second query latencies required for interactive exploratory analytics.

1 INTRODUCTION

Nowadays, the amount of geospatial data collected in cities is increasing rapidly, thanks to the widespread use of mobility applications such as Uber [53]. To analyze this data and make data-driven decisions, city officials and planners often rely on visualization frameworks that allow users to visualize data of interest at different spatial and temporal resolutions [4, 8, 41, 50, 53]. To generate common visualizations, such as heatmaps, visual tools perform *spatial aggregation queries* that partition the data over different polygonal-shaped regions and then compute summarized aggregate information for each region. To support *exploratory analyses*, visual tools must provide interactive response times as high latency reduces the rate at which users make observations, draw generalizations, and generate hypotheses [22]. However, the sheer size of the data combined with the complexity of spatial queries prohibit interactivity, which severely limits analyses. As shown in [28], current tools operating over raw geospatial data cannot produce results fast enough for interactive analysis.

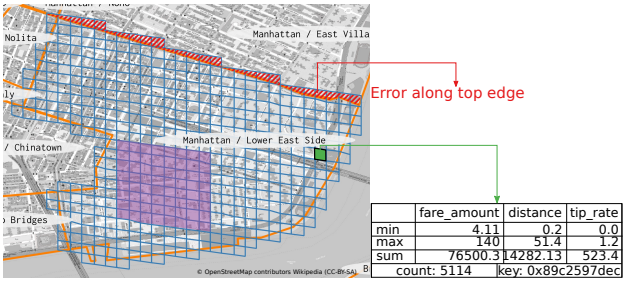

Figure 1: Cell covering (blue) of the Lower East Side (border in orange) with bounded error (red), a cell aggregate (green), and a cached commonly queried region (purple).

On the bright side, interactive analyses are often repetitive in nature. Analysts, for example, typically run multiple aggregate queries for the same area (e.g., the city center) in a sequence, changing only the aggregate function (e.g., count, sum) or the data attribute over which the aggregation is performed. Furthermore, they often focus on certain geospatial regions during their analysis. They might, for example, iteratively resize the boundary of the spatial region of interest, extracting an aggregate every time, or calculate aggregates for neighboring, potentially overlapping, regions. Such analyses can greatly benefit from query-driven materialization approaches that store and reuse intermediate or even full query results.

Naturally, in classical OLAP settings, query-driven materialization and result recycling are widely used and well understood [24, 35, 42, 45]. However, these methods do not address multi-dimensional spatial data. While methods have also been proposed for spatio-temporal OLAP queries, such as nanocubes [21] and the aR-tree [30, 31], these do not provide *precision guarantees* for spatial aggregation queries over *arbitrary polygons*. Both nanocubes and the aR-tree store aggregate information in a hierarchy of rectangles, maintained using a quadtree and an R-tree, respectively. Therefore, they are designed for aggregate queries over rectangular regions while their precision depends on the granularity of the underlying index structure. Using them to compute aggregates over *polygonal* regions introduces an approximation error, which *cannot be bounded*. There are also some analysis tools, such as Uber Movement [53], that rely on precomputation to provide exact results for spatial aggregations over polygons. However, they require the polygonal regions to be pre-defined at aggregation time. This assumes a priori knowledge of the workload and is thus not applicable in *exploratory* analyses, where the query polygons are chosen *ad-hoc*.

We propose GeoBlocks, a novel pre-aggregating data structure for geospatial point data that guarantees error-bounded results for spatial aggregation queries over arbitrarily shaped polygons. Essentially, GeoBlocks are materialized views on geospatial point data that pre-compute filters and aggregations on pre-defined

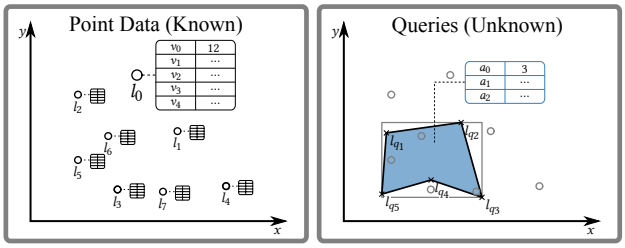

Figure 2: Problem overview: Calculating unknown aggregates a from known points P contained within an unknown query polygon R (specified by its vertices l_q).

columns. Instead of pre-computing aggregates over a hierarchy of rectangles as in prior work, GeoBlocks pre-compute aggregates over *fine-grained grid cells*. As depicted in Figure 1, GeoBlocks subdivide the spatial domain into grid cells, keeping aggregates for each individual cell. We allow the user to specify the geospatial granularity, and thereby *bound* the spatial approximation error. In addition, we propose a trie-like data structure that caches aggregates for commonly queried regions in a compact manner, enabling even faster response times. GeoBlocks are designed for historical point data and are thus write-once/read-only. However, while GeoBlocks currently do not support updates, they can be adapted to do so, as we briefly discuss in Section 5. Our contributions are summarized as follows:

- We propose GeoBlocks, the first, to the best of our knowledge, data structure that supports spatial aggregation over arbitrary polygons, while guaranteeing a bounded error.
- We develop a query-driven caching mechanism that further accelerates aggregate queries by leveraging the skew commonly found in exploratory query workloads.

The advantages of our approach are amply clear from our extensive experimental evaluation on real-world data. The results show that GeoBlocks achieve up to three orders of magnitude speedup compared to on-the-fly aggregation approaches and support sub-second response times.

In the remainder of this paper, we first formalize the problem in Section 2. Section 3 describes our approach, which we then experimentally evaluate in Section 4. Section 5 summarizes the key points discovered in the evaluation and discusses updates for GeoBlocks. Finally, we present an overview of related work in Section 6 before concluding in Section 7.

2 PROBLEM STATEMENT

In this paper, we propose a new data structure to speed up the execution of spatial aggregation queries. Formally, the query can be defined in SQL-like notation as follows:

```
SELECT AGG(P.v0), . . . , AGG(P.vk) FROM P
WHERE P.l INSIDE R(lq1, lq2, . . . , lqm) [AND filterCondition]*
```

Given a set of annotated points of the form P($l, v_0, v_1, \ldots, v_n$), where $l = (x_l, y_l)$ is the location of the point and v_i are numerical or temporal attributes, this query extracts multiple aggregates $a_i = AGG(v_i)$ over all the points contained in a query region R. The query region can be any *arbitrary polygon*, and its geometry is defined by the locations of the polygon's vertices $l_{q1}, l_{q2}, \ldots, l_{qm}$. The aggregates are non-holistic functions such as count, sum, min, max, or average. Finally, the query can have zero or more `filterConditions` on the attributes.

cell	Rectangular area, hierarchically subdividable into four children
cell level	Number of subdivisions performed on the spatial domain to obtain the cell
cell id/spatial key	Unique one-dimensional identifier of a cell
block level	Level of grid cells in a GeoBlock
cell aggregate	Aggregates of all tuples of a grid cell
cell covering	Error-bounded approximation of a polygon using cells

Table 1: Terminology

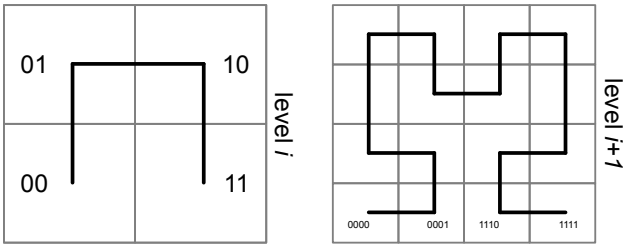

Figure 3: Hierarchical cell decomposition [16].

In exploratory interactive analyses, users can dynamically and unpredictably change not only the filtering conditions and the requested aggregates but also the polygonal query region. The data points, on the other hand, are known a priori. Figure 2 presents an example of this scenario: The left-hand side shows the input points that are located at $(l_0, \ldots, l_7)$ and have five attributes each. The right-hand side shows the query; the polygonal region is marked in blue, while three different aggregates are extracted. As can be seen in the figure, this query applies the aggregation over the three points that are contained in the query region, located at l_5, l_6, and l_7.

Existing approaches for spatial aggregation queries, such as the aR-tree [30, 31], are designed for rectangular regions, and thus *do not support arbitrary polygons*. Applying them to the example of Figure 2 requires to approximate the query polygon with a minimum bounding rectangle, displayed in grey, over which the aggregation is performed. This introduces an extra point in the results, l_3, which is outside the actual query region.

3 GEOBLOCKS

In this section, we first present the geospatial decomposition that forms the basis of our approach. We then discuss how we can quantify and *bound* the error that this decomposition introduces. Next, we explain the core concepts of GeoBlocks, their storage layout, and the efficient evaluation of spatial aggregation queries using GeoBlocks. Finally, Section 3.6 outlines our query-driven caching mechanism that further improves performance by leveraging the characteristics of the query workload. Table 1 provides an overview of the concepts introduced in this section.

3.1 Geospatial Decomposition

GeoBlocks rely on a hierarchical, quadtree-based spatial decomposition. In this decomposition, a given area (cf. the outer rectangle in Figure 3) is recursively subdivided into equally-sized smaller areas that we call cells. Each cell has four children, which

leads to an exponentially growing number of 4^n cells after recursively subdividing a cell n times. We encode each subdivision using two bits, which allows us to uniquely identify a cell at level n by concatenating the encoding of levels 0 to n. Equivalently, all cells at a given level can be enumerated using an *order-preserving space-filling curve*. Since children cells share a common prefix with their parent cell, containment tests are reduced to efficient bitwise operations. This encoding further allows storing cell ids in prefix-encoded index structures such as radix trees [16, 17] or in learned indices [52] to speed up containment queries. Figure 3 shows the decomposition of a cell in four (level i) and 16 (level $i+1$) sub-cells, and the corresponding enumeration with a Hilbert curve. Applying our decomposition strategy to the Earth's surface, we only need 64 bits to address every single square centimeter. That way, we map two-dimensional geospatial locations (lat/long coordinates) to one-dimensional 64-bit keys. In our implementation, we use the Google S2 library [38] to perform the spatial decomposition and cell enumeration. Note, however, that our approach is not restricted to S2 or the Hilbert curve. Any other framework that supports recursive geospatial subdivisions and order-preserving cell enumerations can be used instead.

Point Approximation. We map locations (i.e., *points*) to the smallest cell that contains them. The imprecision introduced by this approximation (e.g., at most 6.1 mm for any point in the US) is negligible, as the imprecision of GPS data is often orders of magnitude worse [54].

Polygon Approximation. Similarly, we approximate the query polygons on-the-fly by mapping them to a set of cells, possibly at different levels, as shown in Figure 4 (center and right). We call this geometric approximation a *cell covering*. In our implementation, we calculate cell coverings using the S2 library.

3.2 Bounded Error

Similarly to all geometric approximations, our cell covering introduces a spatial error. This is because all the cells that intersect the polygon outline, even minimally, are considered to be part of the polygon. However, in contrast to other coverings like the widely used minimum bounding rectangle (MBR), our cell covering is much more fine-grained. As can be seen in Figure 4, the cell covering approximates the polygon outline much more closely compared to the MBR. More importantly, the introduced approximation error can be bounded. In fact, any point on the cell covering is within a distance $\sqrt{\epsilon_1^2 + \epsilon_2^2}$ from the polygon outline, where ϵ_1, ϵ_2 are the side lengths of the cell. Clearly, the smaller the cell size, the smaller the approximation error. Consequently, our cell covering can *guarantee* a user-defined error bound, i.e., a bound on the spatial distance between the approximate and the original polygon, by using an appropriately small cell size. The MBR cannot guarantee such a bound, because its spatial extent, and thus its distance from the polygon outline, depends on the polygon's minimum and maximum coordinates in each dimension and cannot be controlled [52]. The user can specify the error bound by choosing an appropriate cell level[1] so that the cell's diagonal is not greater than her desired error. This user-controlled and bounded spatial error is the only error in GeoBlocks. All further operations are exact and do not introduce any additional error. While the error bound should be the driving factor when selecting a cell level, there are other points to consider: (1) The cell diagonal is the maximum error, and the average error can be expected to be lower. (2) The cost of reducing the error is not linear. Per each level, the diagonal, and thereby the error bound, reduces by a factor of 2. At the same time, the number of grid cells, and thus the query input, grows by a factor of 4.

[1]From the table at https://s2geometry.io/resources/s2cell_statistics

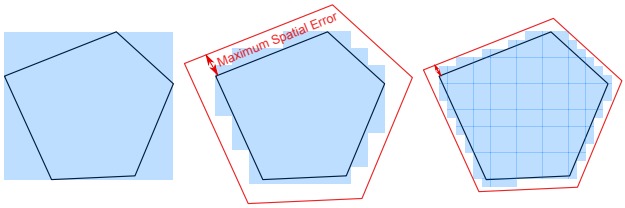

Figure 4: MBR (left) and two cell coverings with increasingly fine-grained resolution.

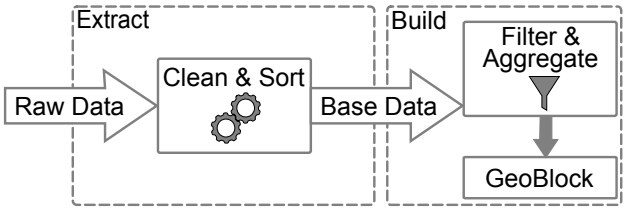

Figure 5: Creation of a GeoBlock in two phases. The extract phase is run once per dataset. The build phase is run for each filter and error bound combination.

3.3 Preprocessing

In addition to transforming the two-dimensional input space to one-dimensional spatial keys, we perform some additional preprocessing steps on the known point data. Our process, outlined in Figure 5, consists of two phases, extract and build, and is similar to the ETL process traditionally applied in OLAP settings. In the first phase, we prepare the raw data by filtering outliers in the often dirty datasets and limiting the columns to those relevant and suitable for analysis. We furthermore sort the data by the generated one-dimensional spatial key. This extract phase is run exactly once per dataset and allows us to cheaply build GeoBlocks from the extracted base data. The second phase, build, utilizes the clean and sorted base data to generate a GeoBlock in a single pass and thus in linear time.

Updates and Filters. An important part of data analysis is filtering to gain insights into the desired subsets of the data. In our process, we could apply filters either before or after sorting the raw data. While the first option seems tempting, as it would reduce the number of tuples over which the expensive sorting has to be performed, we decided to filter the data in the build phase. This way, we can utilize the sorted base data to quickly build GeoBlocks for different filter predicates, aggregates, and grid resolutions in a single pass. Building new GeoBlocks quickly is especially useful in exploratory analyses, where the data and filters of interest might not be fully known a priori. However, the increased cost of sorting all data has to be amortized over multiple GeoBlocks and filter predicates. In reality, the sorting cost might be amortized immediately, as some exploratory queries might need to compare a subset of the data with the total. Consider, for example, a query comparing the tip rate of expensive taxi rides (`WHERE fare_amount > 20`) with that of all rides. In this case, we would need to build a GeoBlock for all rides, and therefore sort the entire dataset anyway.

Given k different filter predicates with average selectivity s and a total input size of n tuples, we can calculate the runtime of building isolated GeoBlocks with filters before sorting, and incremental builds from sorted base data as follows:

$$k * (O(n) + O(sn * log(sn)) + O(sn)) \quad (1)$$

$$O(n * log(n)) + k * O(n) \quad (2)$$

The isolated build (1) has three phases, cleaning and filtering in $O(n)$, sorting in $O(sn * log(sn))$, and finally aggregating in $O(sn)$. Incremental builds (2) have a fixed component composed of cleaning and sorting in $O(n * log(n))$, followed by the incremental filtering and aggregation of the GeoBlock in $O(n)$. For incremental builds to pay off, the sorting cost of the regular builds ($k * (O(sn * log(sn)))$) has to outweigh the initial cost of the incremental builds ($O(n * log(n))$). As we only have runtime classes for each variant and de-facto runtimes will vary between systems and datasets, we cannot determine when amortization is reached solely depending on k and s. However, we provide an in-depth experimental analysis of the amortization in Section 4.

3.4 Storage Layout

Once the filtering of the base data is completed, we can start aggregating and building a GeoBlock. To build a GeoBlock, for each grid cell in the decomposed space, we compute a number of aggregates over all the tuples that it contains. Empty cells that do not contain any tuples are omitted during aggregation as they would needlessly consume space. We refer to the aggregates of a grid cell as *cell aggregates*. A GeoBlock stores cell aggregates in ascending order of the cell's spatial key, which is the same sorting order as the one applied to the base data. Moreover, a GeoBlock maintains a global header that combines all cell aggregates into a single GeoBlock-wide aggregate and contains additional metadata required for querying, such as the minimum and maximum cell id in the GeoBlock.

Cell Aggregate. Each cell aggregate stores pre-computed answers for spatial aggregation queries at the grid cell level. A cell aggregate consists of the cell's spatial key, the base data offset of the first tuple contained in the cell, and the number of contained tuples. Furthermore, it maintains aggregates for all columns (both numeric and temporal attributes) in the extracted data. The maintained aggregates are the minimum, maximum, and sum of all values contained in the cell. Note that using the sum together with the tuple count allows us to also compute the average as sum/count. Furthermore, the cell aggregate stores the minimum and maximum keys of the spatial column. The table in Figure 1 shows an example of a cell aggregate.

Aggregate Granularity. As described in Section 3.2, the block level (i.e., the granularity of the space decomposition) is defined by the user at build time. However, it is also possible to adapt the granularity at a later time. Building a more coarse-grained GeoBlock from an existing one is rather straightforward and does not require re-scanning the base data. We can easily combine all cell aggregates of the finer-grained GeoBlock corresponding to a more coarse-grained grid cell in a single pass over the aggregates. On the other hand, building a more fine-grained GeoBlock requires scanning and further subdividing the base data.

3.5 Querying

GeoBlocks support two variants of spatial aggregation queries. On the one hand, they support regular SQL `SELECT` queries that take a query polygon and produce a user-defined subset of the available aggregates. On the other hand, they support a specialized efficient implementation of `COUNT` queries that only report the number of points contained in a query polygon. Such `COUNT` queries are commonly used in analytics, especially in the context of visualization. Figure 1 shows an example query that extracts a set of aggregates over the Lower East Side region, which is approximated by a cell covering (marked in blue). The answer is calculated by extracting and combining all the aggregates contained in the blue cells.

```
1  lastAgg = 0
2  def selectQuery(polygon):
3    queryCells = s2.coverPolygon(polygon)
4    # Prune search range
5    queryCells.pruneLess(globalHeader.minCell)
6    queryCells.pruneGreater(globalHeader.maxCell)
7
8    lastAgg = 0
9    resultAggregates = initial
10   for qcell in queryCells:
11     # Map qCell to smaller childCells at the block level
12     childCells = s2.childrenAtLvl(qcell, BLOCK_LVL)
13     for cell in childCells:
14         getAggregates(cell, resultAggregates)
15   return result
16
17 def getAggregates(cell, result):
18   # Check the last results successor
19   if lastAgg == 0:
20     # Search initial header
21     aggregate = allAggregates.upperBound(cell).prev
22     if aggregate.cell == cell:
23       combineAggergates(aggregate, result)
24     lastAgg = aggregate
25   else:
26     if lastAgg.next.cell == cell:
27       lastAgg = lastAgg.next
28       combineAggregates(lastAgg, result)
```

Listing 1: SELECT query

To answer a spatial aggregation query over a polygonal region (Figure 6a), the polygon is approximated using a cell covering, as discussed in Section 3.1. We compute a cell covering that conforms to the error bound (Figure 6b). Note that the cell covering can have cells at different levels, and some of them might be larger than our grid cells. Such larger cells can be easily mapped to smaller grid cells (Figure 6c) in the GeoBlock and offer further optimization potential, as discussed next. The cell covering, however, cannot contain any cells smaller than the cells of the GeoBlock. Once we obtain the cell covering, we query the GeoBlock for each of the covering cells, as visualized for a `SELECT` query in Figure 6d. We then combine these partial results to compute the final result for the entire query polygon. In the following, we describe the query process for each cell of the covering. First, we use the GeoBlock's header to check if the cell overlaps with the GeoBlock at all. Thanks to the prefix-based containment checks, this is possible in constant time using the minimum and maximum cell id in the GeoBlock. Only if there is a possible overlap, we continue with the specific checks for `SELECT` and `COUNT` queries as follows:

`SELECT` Queries. `SELECT` queries have to look at all cell aggregates contained in the query cell. Listing 1 presents the pseudocode of the algorithm. After a query cell has passed the first check, we try to further limit the search space to the overlapping area (Lines 5 & 6). After splitting the query cell to smaller cells that match the GeoBlock's granularity if needed (Line 12), we locate the first intersecting grid cell using an upper-bound binary search (Lines 21 - 24). For all the following cells, we exploit the

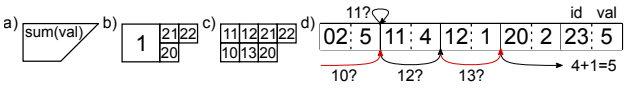

Figure 6: Query overview: Query polygon (a), cell covering (b), grid-cell representation of covering (c), and subquery for covering cell *1* in the cell aggregates (d, Listing 1 Line 12 and following).

```
1  def countQuery(polygon):
2    queryCells = s2.coverPolygon(polygon)
3    result = 0
4    for c in queryCells:
5      f_child = c.firstChildAtLvl(cell, BLOCK_LVL)
6      l_child = c.lastChildAtLvl(cell, BLOCK_LVL)
7      # Get first & last contained aggregate
8      first = allAggregates.lowerBound(f_child)
9      last = allAggregates.upperBound(l_child, first)
10

13   return result
```

Listing 2: `COUNT` query

fact that cell aggregates are stored contiguously in ascending order. This allows us to iterate over the cell aggregates (Lines 25 - 28) until we reach a grid cell not contained in the query cell, combining all cell aggregates along the way into the query result.

`COUNT` Queries. Intuitively, we can answer `COUNT` queries faster than `SELECT` queries, as we can exploit the sorted order of the cell aggregates to calculate the count without accessing the cell aggregates of all grid cells that are contained in the query cell. Specifically, `COUNT` queries can be answered using the count and offset values of only the first and the last cell aggregates that are contained in the query cell, as outlined in Listing 2. Note that here we benefit from having larger query cells. The larger the cells used in the covering, the fewer cell aggregates we need to access overall. To find the first and last cell aggregates, we calculate the id of the first and last child of the query cell at our grid level. We then locate the first child in the aggregates using a lower bound binary search (Line 8). Then, we use the position of the first child as a search start to locate the last child, again with a binary search (Line 9). Once we have located the aggregates of the first and last contained child, we can calculate (Line 11) the resulting count in a range-sum manner as:

$$\text{child}_{\text{last}}.\mathit{offset} + \text{child}_{\text{last}}.\mathit{count} - \text{child}_{\text{first}}.\mathit{offset}$$

3.6 Query-Cache Acceleration

While our cell aggregates can speedup queries significantly, there is further potential in pre-computing aggregates for frequently queried areas. This is based on the following key observations:

(1) Exploratory analyses are often repetitive in nature. Analysts, e.g., may run consecutive queries for the same area to extract different aggregates (i.e., using a different aggregate function, or aggregating over a different attribute).
(2) Furthermore, analysts might only iteratively change the shape or size of the query polygon. Consequently, part of the polygon's interior area remains unchanged.
(3) Lastly, analytical queries often focus on a geographic subset of the whole data. For the analysis of the NYC taxi data, e.g., the focus lies mostly on Manhattan, Brooklyn, and the airport regions, ignoring most suburbs [40].

In all the above cases, it is reasonable to pre-aggregate small grid cells that are often queried together to avoid costly scans of individual cells. In our example in Figure 1, e.g., we want to keep a single aggregate for the purple region, instead of having to consult all 64 contained cell aggregates.

Determining Relevant Aggregates. We want to determine the relevant areas that are worth being additionally pre-aggregated and cached, without making any assumptions about the expected query workload or the semantics of the indexed data. To achieve that, we use all previously seen queries as hints. Precisely, to determine whether an area is worth aggregating, we consider (i) the number of times it was queried, and (ii) its cell level.

For each query cell that intersects with the GeoBlock, we keep track of the number of times it was queried in a trie-like structure. We then use these statistics to calculate cell scores. The score of a cell is the sum of the cell's hits and the hits of its parent. This score takes into account that child cells can be used to speed up queries for parent cells. We then sort all cells by descending score. When scores are identical, we sort by ascending level (coarser-grained cells come first). As the last criterion, to ensure determinism, we sort by spatial key. We chose the above metric as it is sufficient to properly and repeatably represent the skew in the experiments in our evaluation while being easy to understand and implement. However, we also identified some weaknesses of our metric:

- Smaller cells might overshadow slightly less frequently queried bigger cells. Consider, for example, the green and purple cells of Figure 1 and assume that the green cell is queried just once more than the purple one. Based on our metric, we would then aggregate the green cell even if the purple cell could have an up to 64× bigger impact.
- The parent-child relationship is simplified: Children only cover parts of their parent but are treated as equally useful. Furthermore, we do not consider calculating aggregates by combining the aggregates of the parent and siblings of a cell. For example, the count for a cell could be calculated by subtracting the count of its sibling cells from the count of its parent cell.

Our evaluation showed that these shortcomings have a minor impact, but we plan to investigate them further and address them, if needed, in our future work.

Aggregate Storage. We cache aggregates in a trie-like cache, which we call AggregateTrie. Further, we allow the user to control the maximum size of the storage available for caching, and we store the AggregateTrie in-place with our cell aggregates and the filtered base data. As the cells are strictly ordered, we can simply insert the most relevant unaggregated cell until the reserved area is filled. Figure 7 shows an example AggregateTrie.

The storage for the aggregates is split into two parts. The first part (up until `0x90`) contains the trie structure, while the second part stores the actual aggregates. The root of the trie corresponds to the cell level that can enclose our input data, which is typically just a small fraction of the possible earth-wide input space. Each following trie-level encodes exactly one cell level, resulting in a fanout of 4. Since we store the AggregateTrie in-place, we chose a compact encoding storing all nodes contiguously. Nodes consist of just two 32-bit integers. The first one is the pointer to the first child in the AggregateTrie. The second one is the pointer to the corresponding aggregate in the aggregate storage (e.g., `0xb8`). Pointers are encoded as 32-bit offsets from the start of the allocated memory region. Both aggregates and nodes can be sufficiently encoded with an offset, as they are of fixed size.

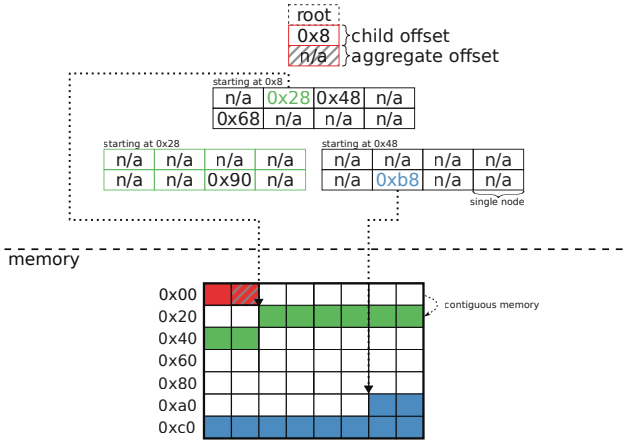

Figure 7: AggregateTrie with 40 byte aggregates and in-memory representation. Non-existent children (or aggregates) are marked with *n/a* and are encoded as `0x0`.

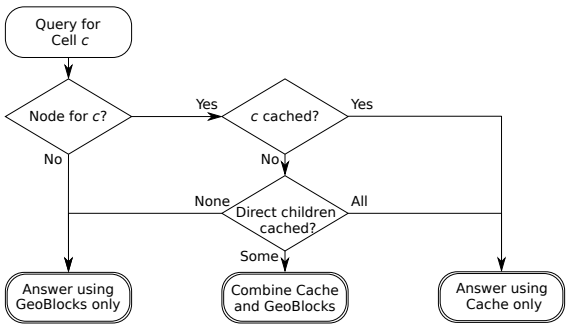

Figure 8: Overview of adapted query algorithm.

Nodes occupy 8 bytes, while the size of the aggregates depends on the schema. Since we store only the offset to the first child, we need to always allocate space for all children in a node, even for children that do not exist in the cache. This can be seen for the node starting at `0x28`, where only one child has an aggregate and no other children or aggregates exist. While this seems wasteful at first, the alternative would be to store four individual child offsets per node. As children are only created and stored if they are needed, our encoding never occupies more storage than this alternative. In fact, our design is more space-efficient in all cases, except for this worst-case in the example above, where only one out of four children is required.

Adapted Query Algorithm. We integrate the cached aggregates into the query algorithm (cf. Section 3.5). As the runtime of `COUNT` queries is mostly independent of the cell level since only the first and last grid cells are relevant, we do not expect noticeable speedups for them. Therefore, the adapted process, highlighted in Figure 8, is only used for `SELECT` queries.

Once the pre-query checks are completed, we first probe the query cache and resort to the old algorithm only when necessary. For each query cell, we traverse the AggregateTrie to locate the corresponding node. If there is no node for this cell, we abort probing and answer the query with the old algorithm. Once the node corresponding to the cell is reached, there are two possible ways forward. If the cell is cached, i.e., if it has a valid aggregate offset, the aggregate is extracted as a result. If the cell is not cached, there has to be at least one child at any level residing in our cache, as nodes are only created on demand. While, theoretically, all children could be used to reduce the number of grid cells of the GeoBlock to query, the number drops with each level, while keeping track of the missing children gets increasingly expensive. Therefore, we only consider direct children for this optimization. If some of the direct children are cached, we combine their aggregates with the results of the old algorithm for the non-aggregated ones to obtain the final result.

4 EXPERIMENTAL EVALUATION

We compare GeoBlocks with on-the-fly aggregation approaches on real-world data. To show that our advantage is not dependent on the indexing strategy, we use different strategies to index the base data of the on-the-fly approaches. We also compare GeoBlocks against a pre-aggregating approach, the aR-tree [30, 31]. However, we do not include the aR-tree in all experiments, as it is designed for rectangular queries and does not directly support polygonal ones.

4.1 Experimental Setup

Baselines. To keep the experiments as fair as possible, we use the mapping from geospatial space to linear space for the baselines as an index key unless specified otherwise. Furthermore, we keep all data in a columnar layout. Below, we describe the three strategies that we use to index the raw data, as well as our pre-aggregating baseline:

BinarySearch: This is the simplest baseline. Instead of indexing the data, we use binary search to locate the first and last contained raw tuple in the data. Afterward, we loop over all tuples in between and compute the requested aggregates. GeoBlocks use binary search to locate the cell aggregate in a similar way.

BTree: We use the BTree as a secondary index over the raw data. For the experiments, we use an open-source B-tree implementation by Google [7]. We probe the tree for the first child and scan the sorted raw data until no further tuple qualifies.[2]

PHTree: Our last non-aggregating baseline is a multidimensional point index structure, the PH-tree [56]. Instead of the one-dimensional spatial key, we use the latitude and longitude of the points to index the data. As the PH-tree only supports rectangular range queries, we use S2 to get the interior rectangle of the query polygon and use this as a query region. This way, we hope to keep the comparison fair, if not favorable for the PHTree, as this interior rectangle covers fewer points than our approach. As a consequence, the PHTree's query results differ from the results of the other approaches. For the measurements, we use an open-source C++ implementation [36].

aRTree: We implement the aR-tree [30, 31] based on the boost R-tree [5]. To minimize overlaps between nodes and thereby optimize the query performance, we use the R^* algorithm. In our implementation, each node covers a region r and has up to 16 child nodes, which further subdivide r into smaller areas. For each node, we store the aggregates in a cell aggregate corresponding to the region covered by the node, and reference it with an offset (cf. Figure 9). That way, we can modify the RTree query logic by adding *early abortion* exactly like in the aR-tree. Given a search area s and a node of the aR-tree that covers a region r, we distinguish three cases, as shown in Listing 3: (a) If s is completely contained by the covered region r_c of one of n's

[2]We first tried the PointIndex of the S2 library (https://s2geometry.io/devguide/cpp/quickstart.html#s2pointindex) that uses the same b-tree as point storage. Initial measurements showed that our optimized BTree implementation outperformed the PointIndex by 3×, so we opted for our implementation.

```
def queryARTree(node, searchArea, result):
  partiallyOverlappingNodes = []

  for child in node:
    if child.contains(searchArea):
      return queryARTree(child, searchArea, result)
    if searchArea.contains(child):
      result += child.aggregatedResult
    else if searchArea.intersects(child):
      partiallyOverlappingNodes.append(child)

  for child in partiallyOverlappingNodes:
    result += queryARTree(child, searchArea, result)
  return result
```

Listing 3: aR-tree lookup query

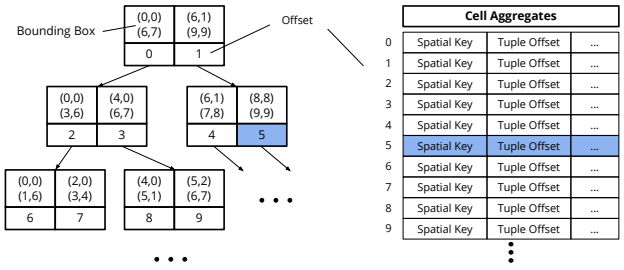

Figure 9: Illustration of aRTree with node size two and offsets into the cell aggregates.

child nodes, we recursively continue the search at the child node and do not consider other overlapping child nodes as this would result in counting values multiple times. (b) If the region covered by a child node is completely contained within the search area, we add its aggregated value to the overall result and continue processing the next child node. (c) If s and the child node region intersect, we *mark* the child node to be processed later *iff* no other child node fulfills criterion (a).

By accepting that points are counted multiple times in the case of overlapping internal nodes, our aR-tree implementation follows the query algorithm of the original aR-tree that does not consider overlapping children. While the implementation delivers an upper-bound of the result, it visits the internal nodes in the same way the aR-tree does, thus achieving the same performance.

Implementation. We implement GeoBlocks in C++ as described in Section 3. Our implementation, as well as that of all baselines, is single-threaded. Throughout this section, especially in all figures, we will refer to GeoBlocks as Block. Furthermore, we will differentiate between the regular Block and Block^{QC}. Block denotes GeoBlocks without query caching using the basic query algorithm. Block^{QC} is GeoBlocks using query caching with the AggregateTrie and adapted query process outlined in Figure 8.

Hardware. All experiments are run on a server machine with two Intel Xeon E5-2680 v4 processors clocked at 2.4 GHz. The machine is equipped with 256 GiB of DDR4-2400 RAM. All performed experiments fit entirely into main memory.

Dataset. The primary dataset used in the experiments is composed of trip records from 12 million NYC yellow cab rides in the time between January and March 2015, which we cleaned of outliers. It is openly available for download from the NYC Taxi and Limousine Commission (TLC) [49]. It contains data from individual rides like pickup and drop-off location and time, passenger count as well as trip distance.

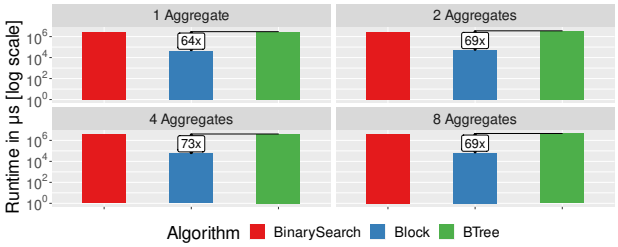

Figure 10: Runtime with increasing number of aggregates.

Unless otherwise specified, the queries consist of polygons representing NYC neighborhoods taken from [25]. As a base workload, we build a query containing each polygon once. For the skewed workload, we select 10% of neighborhoods uniformly at random and query them multiple times. We select 7 aggregates, requesting each column at least once, as query output.

In addition, we use 8 million geotagged tweets from the contiguous US and query them using polygons representing US states. Finally, we use an extract of 389 million OpenStreetMap (OSM) points in the Americas and query them with polygons representing countries. Both these datasets have randomly generated integer values as payload. For both, we fix the level at 11 (~7km diagonal). Unless otherwise specified, all experiments are conducted on the primary dataset only.

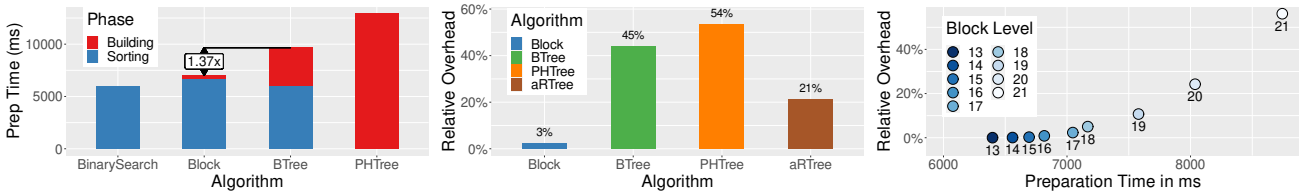
4.2 Baseline Comparison

Impact of Number of Aggregates. To show the impact of the number of aggregates on the performance of the baselines and the Blocks, we use a combined workload consisting of once the base and four times the skewed workload. We query this workload for 1, 2, 4, and 8 aggregates and report the results in Figure 10.

As one can easily see, GeoBlocks outperform both the BTree and BinarySearch baseline in all cases. We omitted the PHTree and aRTree from these experiments, as the imprecise rectangular approximation of the skewed workload lead to a drastic increase in their runtime. Even for the base workload, the PHTree was slower by a factor of about 3× while covering fewer tuples.

Indexing Overhead. We compare the build time, i.e., the preparation time required prior to running any query, in Figure 11a, with the block level set to 17 (~100m diagonal). The reported times for sorting are measured once for the optimized out-of-place sorting for the Blocks and reported for each baseline. This step is completely identical in all sorting baselines. There is a noticeable gap in the sorting phase between the BTree/BinarySearch and the Block. This gap is caused by the collection of grid cell ids to aggregate that we piggybacked on the sorting process to save an additional pass on the data. Overall, the Block is built faster than the BTree and the PHTree, and slightly slower than the BinarySearch, which only needs to sort the input data. We exclude the aRTree baseline from this experiment as we only optimized the implementation for query performance, and the build time was multiple orders of magnitude slower than the others described. Most notably, the majority of the Block preparation is spent on sorting, indicating that once the data is sorted, building additional Blocks with different filter sets is reasonably cheap.

The relative space overhead of each algorithm is depicted in Figure 11b. BinarySearch was omitted as it does not require any additional storage. One could argue that this is not a fair comparison to the BTree and PHTree as they index individual points, but



(a) Build time of GeoBlocks and baselines. **(b) Size overhead of GeoBlocks and baselines.** **(c) Level influence on GeoBlocks overhead.**

Figure 11: Index overhead in build time and space.

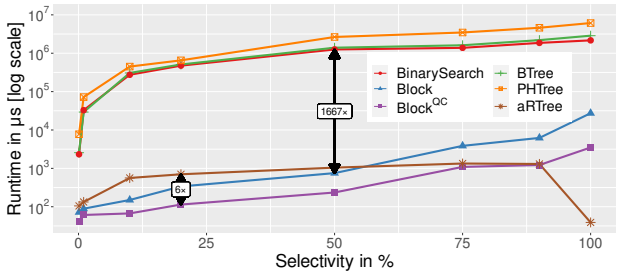


Figure 12: Query runtime for varying selectivity.

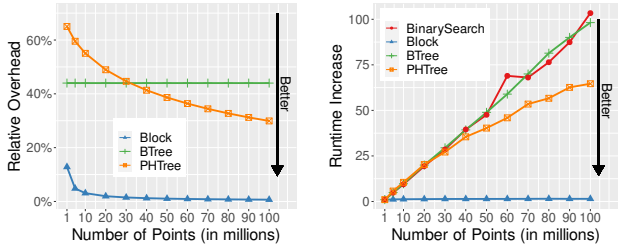

(a) Size overhead of GeoBlocks and baselines.

(b) Relative runtime increase of GeoBlocks and competitors compared to 1M points.

Figure 13: Scaling with increasing input sizes.

as our goal is to provide approximate results, we wanted to show that storing intermediate results is less space-consuming than one would assume for such fine-grained aggregates. While the aRTree is more space-saving when compared to the single-point indices, it still introduces an order of magnitude higher storage overhead than GeoBlocks.

Impact of Selectivity. Selectivity is usually defined based on a single query, but in our context, it is hard to specify what a single query is. We break down query polygons, e.g., the orange bordered Lower East Side in Figure 1, to different-sized cells covering the polygon (e.g., the purple cell), which in turn are broken down into equally sized cells to query (blue cells). While the intermediate cells of the query polygon's covering are the best representation of individual queries, as each index is probed once for them, they are artificial concepts introduced by our algorithm. Furthermore, these are hard to map to the rectangular query regions of the PHTree and the aRTree. Therefore, we define selectivity based on query polygons. For this experiment, we artificially select polygons covering a part of NYC, which contains a certain percentage of the total rides. Figure 12 reports the runtime of the base workload at different selectivities using a logarithmic scale. PHTree's and aRTree's measured selectivities differ slightly from the reported ones due to the less precise covering using an interior rectangle. As this covering contains fewer points, this should slightly skew the experiment in favor of the PHTree and aRTree. Even though GeoBlocks can handle rectangular queries as well, since rectangles are just constrained polygons, we opted for the most-precise covering where possible.

While runtime rises quickly for all baselines for selectivities above 1%, the increase is much softer for both Block variants. Even though the workload is not skewed, and we only use 2% of additional storage for query caching, Block^{QC} still outperforms the non-caching Block across all selectivities. This is likely explained by the shape of the polygons that are often simple quadrilaterals or pentagons. These can be covered using few cells and, therefore, most of these cells can be pre-aggregated. BinarySearch can keep up with the BTree, reporting similar runtimes independent of selectivity, while the PHTree lags behind quickly. Even if the relative runtime gap narrows for higher selectivity, the absolute gap still favors GeoBlocks. The aRTree, our implementation of the aR-tree, outperforms the on-the-fly aggregating benchmarks easily while staying behind GeoBlocks for lower selectivities. However, it can catch up with Block at around 50% selectivity. At 100% selectivity, the aRTree needs to only access the root aggregate, explaining the sharp drop in runtime. Overall, GeoBlocks outperform the non-aggregating baselines by at least two and up to three orders of magnitude, performing on-par with the aR-tree while delivering far more precise results.

Scalability. To study the performance for different-sized datasets, we collect 100M taxi rides spanning all of 2015 and build and query the approaches for an increasing subset of these rides. We omit the aRTree as the build time exceeded reasonable limits upward of 30 million points. As the build time is dominated by the sorting process, which is shared and identical in all approaches, they scale identically in build time. When comparing the size overhead in Figure 13a, we can see that the BTree overhead is constant as expected. For the PHTree, we see the positive impact of the integrated compression strategies for bigger datasets. Still, the near fixed-size grid aggregates - the size of a GeoBlock is determined by the spatial distribution of points, not their number - enables even smaller overheads for GeoBlocks. To focus on the individual scalability for queries, we analyze the query runtime normalized to the runtime of each approach for one million points. As shown in Figure 13b, both the BTree and the BinarySearch scale linearly with the input size, as the on-the-fly aggregation dominates the runtime. We expect a similar behavior from the PHTree, but as the covering is less accurate and chosen deliberately smaller, the increase is not fully linear. For GeoBlocks, the runtime stays nearly constant, since it depends on the number of maintained aggregates, and not on the number of individual points. The number of aggregates is in turn determined by the spatial distribution of the input. Since one million

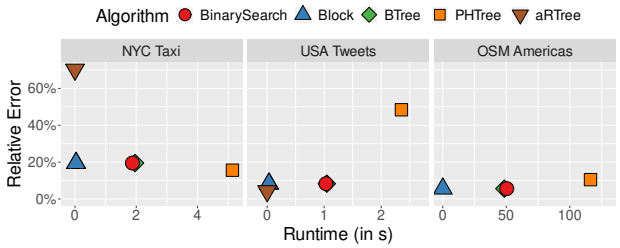

Figure 14: Query runtime and relative error for varying datasets.

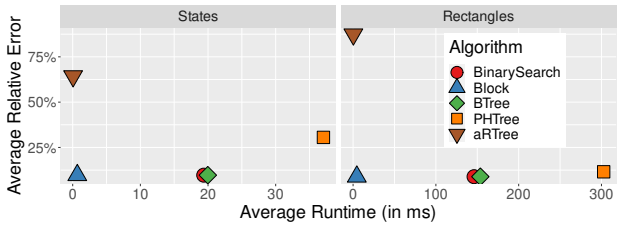

Figure 15: Query runtime and relative error for US states and generated rectangles on the Twitter dataset.

points already cover most areas in NYC, the distribution does not change when further increasing the number of points, i.e., the number of aggregates does not increase significantly. This explains why query latency remains nearly constant for bigger datasets.

Datasets. To show that our approach is not limited to the NYC taxi dataset, we evaluate it on the two additional datasets in Figure 14. We again query the whole area represented by the individual polygons and report runtime, as well as the average error defined as $\frac{|\text{\# tuples in query result} - \text{\# tuples in polygon}|}{\text{\# tuples in polygon}}$. For the OSM dataset, the aRTree again was excluded because of its excessive build time. As the Block, BinarySearch, and BTree use the same covering, the result and error are identical. While the aRtree and PHTree use an identical rectangular representation, the pre-aggregated nodes of the aRTree lead to a different result, and therefore error. Overall, the aRTree and Block are similarly fast with a slight advantage for the aRTree, outperforming the non-aggregating approaches easily. However, the error for Block is far more stable.

Accuracy. Finally, we want to study the influence of smaller individual polygons, as well as rectangular areas, on both runtime and relative error. Therefore, we query all US states and 51 randomly generated rectangles within the US on the Twitter dataset and report the average runtime and error in Figure 15. In contrast to the previous experiment, we query all areas individually. For both polygons and rectangles, the same overall trends are visible. The aRTree is slightly faster than Blocks as the large polygons can be answered in the upper levels of the tree. However, this leads to high imprecision even for rectangular queries as partially overlapping internal nodes might be counted multiple times. Besides, we see that the individual errors canceled out in Figure 14, leading to a seemingly good error bound. While the PHTree error also improves considerably for the rectangular workload, we expected it to be exact. We suspect this is caused by our transformation of the coordinates to integer space, which is necessary for efficient queries. As expected, the performance

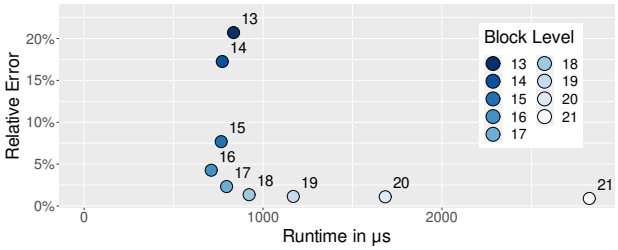

Figure 16: Relative error and runtime at varying levels.

Level	13	14	15	16	17	18	19	20	21
Sorting	6020	6008	6317	6459	6633	6754	7028	7344	7666
Building	376	499	376	356	411	408	538	666	1025

Table 2: Index build times in ms at varying levels.

of Blocks and the other approximating baselines does not degrade for rectangular areas. The aggregating approaches again far outperform the point indexing approaches in runtime.

4.3 Sensitivity Analysis

After showing that GeoBlocks easily outperform all baselines, we study the impact that the configuration of GeoBlocks has on throughput, as well as the impact of data skew on the adaptive Block version. The Block configuration is specified by three parameters: The first setting we study is the level of the Block, i.e., the resolution of the grid overlying the spatial domain. Next, we take a look at the impact of skew on both Block and Block^{QC}. Finally, we examine how the size of the AggregateTrie influences the runtime of unskewed and skewed workloads.

Impact of Block Level. We vary the block levels from 13 to 21 (between ~1.5km and ~6m diagonal) while keeping the other configuration parameters fixed. From a runtime-only point of view, lower-level (coarser-grained) blocks are always preferable, as the query algorithm needs to take fewer cells into account. However, this comes at the price of precision loss. Figure 16 illustrates the connection between the block level, the runtime, and the relative error introduced by the cell covering. The cell covering can introduce only false positive results, i.e., some reported results are not contained in the actual polygon. The figure clearly shows the expected overall trend: the higher the level, the lower the relative error and the higher the runtime. However, after a certain point, decreasing the level further does not pay off. Further, we see that the correlation between error and runtime is not linear, as we already suspected in Section 3.2. The correlation does not even follow the discussed influences completely, which is likely caused by missing sparse children, and the non-uniform distribution of points leading to a gap between the relative error and the configurable spatial error.

The block level influences not only the relative error and the runtime, but also the build time and size of GeoBlocks. Figure 11c depicts the build time and size overhead for GeoBlocks from levels 13 to 21. The build time seems to be only slightly affected by the level, rising slowly with it. Table 2 splits the runtime into two parts: sorting and building. There is a noticeable increase in sort time along with the block level, in addition to the expected increase in build time. This increase in sorting can be explained through our grid cell extraction that we piggybacked to the sorting process, which has to extract more finer-grained

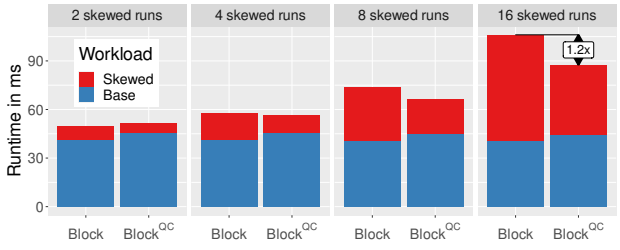

Figure 17: Query runtime with increasing workload skew.

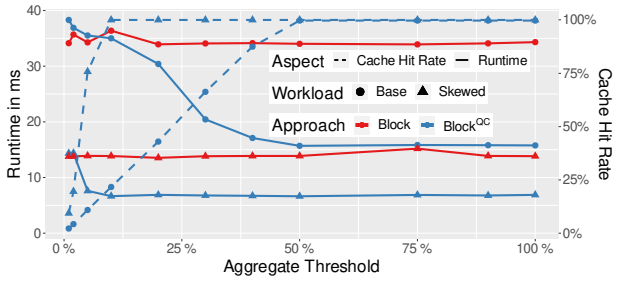

Figure 18: Impact of threshold on workload runtime (solid line) and cache hit rate (dashed line).

cells. The size overhead, however, grows exponentially due to the exponentially growing number of cells along with the level.

Impact of Skew. To study the impact of data skew on the effectiveness of query caching, we measure the query runtime when running the NYC workload once, and the skewed workload multiple times. The number of times we run the skewed workload varies in each experiment. We fix the block level to 17 (~100m diagonal) and the size of the cache to 5% of the cell aggregates, which roughly corresponds to aggregating all cells of the skewed workload. Figure 17 displays the absolute runtime for both the base and the skewed part of the workload. One can see that after four skewed runs, the cached aggregates start to pay off. With even more skew in the total workload, our query-caching Block^{QC} quickly starts to outperform Block. Furthermore, as expected, the runtime for the base workload stays nearly constant, and is always slightly faster for Block. This is easily explained by the overhead of probing the AggregateTrie for each cell, regardless of whether the cell is aggregated or not.

Impact of Aggregate Threshold. Having studied the impact of skew, we want to examine how the aggregate threshold, and thereby the size of the query cache (in Block^{QC}), influences the runtime of the base and the skewed workload. The aggregate threshold denotes the relative size overhead that the query cache, the AggregateTrie, introduces compared to the size of the cell aggregates in the regular GeoBlock. We again fix the block level to 17, and the number of skewed runs to four. Figure 18 depicts the measured runtimes and cache hit rates. The runtime of Block is unaffected by the changed threshold and only acts as a baseline to highlight the influence on Block^{QC}. Up until a threshold of around 5%, only queries from the skewed workload can be answered using the AggregateTrie. The small speedup in the base workload can be explained by the inclusion of the skewed workload in the base workload. Once all cells in the skewed workload are cached, and the cache hit rate for the skewed part reaches 100%, other query cells of the base workload start to get cached

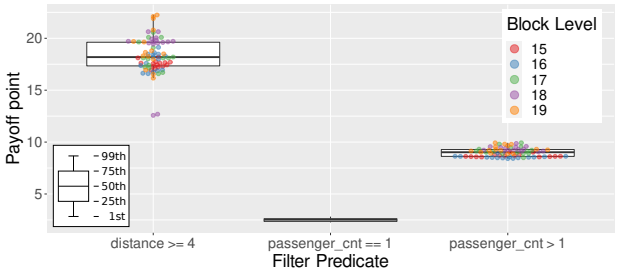

Figure 19: Payoff point: Number of incremental builds required to amortize the cost of sorting the raw data.

as well. While this, of course, leads to further runtime improvements, it is undesirable, especially when memory is scarce. In our experiments, at around 50%, the cache hit rate reaches 100% for both workloads, and there is no further speedup, even when the cache size is doubled. The cache hit rate, illustrated by the dashed line and shown on the right axis, shows the desired effect. The skewed part is cached almost immediately, and the hit rate for the unskewed workload grows linear with increasing cache size. The average lookup time slowly grows from 58ns at 1% to 81ns at 100%. As the lookup time depends on the number of levels (30 in the maximum) and not on the size, this growth is attributable to more complex access patterns for larger cache trees.

4.4 Changing Filters

Finally, we compare our process of Figure 5, wherein we build multiple GeoBlocks from the sorted base data, against building isolated GeoBlocks from scratch. We vary the block level from 15 to 19 (between ~420m and ~27m diagonal), and build 15 GeoBlocks per level using three different predicates of varying selectivity:

- **distance >= 4:** Long taxi trips, selectivity of ~16%
- **passenger_cnt == 1:** Solo taxi trips, selectivity of ~70%
- **passenger_cnt > 1:** Shared taxi trips, selectivity of ~30%

For this, we want to analyze how many different filter and level combinations are required to amortize the initial cost of sorting. Figure 19 shows the payoff point of filter changes for our three filter predicates. The payoff point is the number of incremental builds required to be, in sum, faster by creating incremental builds than building individual GeoBlocks from the raw data and filtering before sorting. We omitted the individual runtimes for the `passenger_cnt == 1` predicate as they would be too densely packed vertically.

As expected, the more selective the filter, the lower the speedup. Once all tuples in the raw data have been filtered according to the predicate, the qualifying tuples have to be sorted. More selective predicates take longer to amortize as sorting few tuples is cheap , whereas for the 70% selectivity query `passenger_cnt == 1`, the more expensive sorting is amortized almost immediately. There is a correlation between the block level and amortization, most notably for the most selective predicate `distance >= 4`. Given that the payoff point drastically rises with lower selectivity, we expect that incremental builds will only pay off when the new filters are less selective. If only a few highly selective queries are expected, building regular GeoBlocks directly from the raw data will still be the fastest option. However, the time to switch to a new filter, and therefore the individual query latency, will always be lower for incremental builds.

5 DISCUSSION

In this section, we discuss the takeaways of the evaluation as well as updates for GeoBlocks.

Evaluation Summary. First, we showed that pre-aggregation in a spatial context pays off when a limited and bounded spatial error is acceptable, independently of the number of aggregates queried and the selectivity of the query polygons. Furthermore, GeoBlocks can be built fast, introducing only a small overhead compared to the simple BinarySearch baseline. Even when the data is already indexed with one of our baselines (i.e., without taking the index build time into account), GeoBlock's build time of around 7 seconds can be amortized by fewer than 30 polygon queries with a selectivity of 10% (cf. Figures 11a and 12). In addition, building multiple GeoBlocks once the data is sorted is possible within one second for our dataset, cf. Figure 11a. Building new GeoBlocks for different filters is even faster when using sorted base data, often amortizing the initial extra cost of sorting all data in less than 10 filter changes (cf. Figure 19). Even though not all configurations are optimal for GeoBlocks, there are acceptable error-runtime trade-offs, in our case around levels 17 and 18. While the level does not significantly impact the index build time, the size overhead growth is almost exponential, cf. Figure 11c, indicating that it is wise to think about which error is acceptable for the given query workload when memory is scarce.

Updates. Up until now, we considered GeoBlocks to be read-only as they are designed for historical point data. However, the layout of GeoBlocks allows us to integrate updates easily, as long as a cell aggregate for the region of the newly arriving tuple already exists. For the non-adaptive version, all we have to do is locate the cell aggregate containing the tuple and update all stored aggregates. In the adaptive version, we additionally need to update all cached parents of the grid cell in the AggregateTrie as well. Thanks to the prefix-based indexing property of the trie, we can do this in a single depth-first traversal. Only if tuples arrive for a new, previously unaggregated region, we have to rebuild the aggregate layout, as we rely on the cell aggregates to be sorted. However, as we have shown in the evaluation, recalculating the cell aggregates is often possible within a second, so this operation would not induce too much delay when updates are implemented in batches instead of single tuples. Other indexing approaches on the cell aggregates (e.g., a clustered B-tree) could eliminate the need to rebuild by reserving storage for new aggregates. Preliminary experiments using `std::map` and a B-tree as an index showed similar lookup performance at the cost of increased size overhead.

6 RELATED WORK

Our approach builds on seminal work from decades of research on spatial indexing. Decomposing space into hierarchical grid cells [1, 9, 39], as well as approximating polygons using simpler shapes [18], are all well-known approaches. Likewise, enumerating cells using a space-filling curve such as Hilbert or Z order [26, 27] and storing aggregate information within cells [20, 30, 46] are ideas that have been around for some time. However, while building on these established concepts, GeoBlocks present the first pre-aggregating data structure that supports a *bounded, distance-based error* on the results of *polygonal queries*. Specifically, prior work on pre-aggregation [14, 30, 31, 34] is limited to rectangular queries and requires an expensive post-processing (refinement) step to answer polygonal queries. GeoBlocks, on the other hand, yield error-bounded results and do not require expensive refinement.

Spatial Aggregation. Past work has proposed several approaches for spatial aggregation queries [23]. These approaches mainly rely on pre-aggregation [14, 34]: they pre-aggregate records at various spatial resolutions and store this summarized information in a hierarchy of rectangular regions, maintained using a spatial index like the quadtree or the R-tree [19, 30–32]. For instance, the aRtree [30, 31] enhances the R-tree by storing aggregate information for each node. This allows to directly extract the aggregate of all the records contained in a node, if the node's MBR is fully enclosed in the query region. Being a variant of the R-tree, the aRtree constrains the supported queries to only rectangular regions. Furthermore, the computed aggregates are approximate and the error *cannot be bounded*, since the accuracy depends on the resolution of the rectangular R-tree nodes. Providing precision guarantees for arbitrary polygons requires accessing the raw data and involves additional processing. There are also approaches that store aggregates inside a data cube [6, 37], or using sketches [48]. Nanocubes [21], for example, store the CUBE operator for spatio-temporal datasets, and are specifically designed for visualization systems. The data cube-based approaches suffer from the same limitations as the aRtree, since they also rely on a hierarchy of rectangular regions. Besides, accessing the raw data to refine the aggregates might require additional indices, as the cube does not store individual records. Vorona et al. [55] approximate the distribution of geospatial points with an autoregressive deep learning model to answer arbitrary polygonal queries, but they cannot provide any error bounds. Pandey et al. [29] propose to use learned indices for query-efficient spatial indexing, albeit limited to range queries. Finally, Raster Join [51] uses GPU rendering to compute aggregates over a point-polygon join. In contrast, GeoBlocks support aggregation over spatial selections.

Prefix sums [10] can be used in addition to pre-aggregation to enable fast range-sums. This is achieved by only inspecting the aggregates in the two corners of a query region, rather than every aggregate inside the query region. An example of this is our `COUNT` algorithm. However, in contrast to our `SELECT` queries, these range-sums are unable to extract min and max aggregates.

Materialized Views and OLAP Cubes. GeoBlocks are essentially materialized views over geospatial data with support for filters and aggregations. In contrast to regular views [12, 44], GeoBlocks are designed for historical spatial data and can adapt to the query workload at a fine-grained level using a trie-like cache. Work on materialized view selection [2] also makes materialization decisions based on the query workload, but at a much coarser granularity (e.g., what columns to aggregate). There has also been a lot of work on data cubes and query caching [11, 15, 42], but these do not support geospatial data as a first-class citizen.

Spatial Point Indexing. Spatial point indexing approaches typically index points using a hierarchy of MBRs, most notably the R-tree [13], or by subdividing grid cells into equally-sized children, e.g., the quadtree [9, 39]. Both of these index structures are queried using the dimension-wise min/max values, i.e., the query regions are rectangular. Other approaches, like the UB-tree [3], assign univariate keys to the indexed regions first and rely on these keys for data access. While the UB-tree does not specify how these keys have to generated, most approaches use space-filling curves like the Z order [26, 27].

Based on these concepts, more specialized indices have been developed. The PH-tree [56] combines a quadtree with hypercubes to allow splitting all dimensions in each node, providing a space-efficient index structure for multidimensional data. The space efficiency can be partly attributed to the utilization of prefix

sharing, similar to the one used in our trie-like cache. Alternating the indexed dimensions in an in-memory tree structure, the BB-tree [47] offers fast point and range queries for multidimensional data. While these structures require the index to be built a priori, there are others like QUASII [33], where the index is built incrementally as a side product of query execution. As a result, QUASII can adapt to the query workload at runtime. However, QUASII only supports spatial range (window) queries. Recently, Shin et al. [43] proposed integrating grid indices into a tree structure to achieve faster node accesses and point operations.

7 CONCLUSIONS

We have introduced GeoBlocks, a novel pre-aggregating data structure for geospatial data. GeoBlocks pre-compute aggregates over fine-grained grid cells, thereby supporting arbitrarily shaped polygons. Using these aggregates, GeoBlocks can provide fast query results with a user-controlled spatial error. Furthermore, GeoBlocks can speed up aggregate queries for commonly queried regions by dynamically adapting to any given workload using limited additional storage.

Comparing GeoBlocks with on-the-fly aggregating indexing baselines, we have shown that we can outperform them for any number of aggregates, in parts by three orders of magnitude. The introduced storage overhead is comparable, and often even lower, to that of traditional indexing structures, while GeoBlocks can be built equally fast. Looking at GeoBlocks' configuration options, we have shown how they can be adapted to the given dataset and workload, and how they influence the runtime, the overhead, and the error in the result. Overall, GeoBlocks are materialized views over geospatial data that support filter predicates and aggregates while enabling fine-grained adaptation to the query workload.

ABSTRACT

To support indoor spatial queries and indoor location-based services (LBS), multiple techniques including model/indexes and search algorithms have been proposed. In this work, we conduct an extensive experimental study on existing proposals for indoor spatial queries. We survey five model/indexes, compare their algorithmic characteristics, and analyze their space and time complexities. We also design an in-depth benchmark with real and synthetic datasets, evaluation tasks and performance metrics. Enabled by the benchmark, we obtain and report the performance results of all model/indexes under investigation. By analyzing the results, we summarize the pros and cons of all techniques and suggest the best choice for typical scenarios.

1 INTRODUCTION

Indoor location-based services (LBS) are becoming increasingly popular [6, 9]. Relevant applications, such as POI search [22, 28] and routing [11, 13, 14], are often built on top of typical spatial queries like range query, k nearest neighbor query, shortest path query, and shortest distance query. Therefore, the efficiency of processing such typical indoor spatial queries plays a key role in the success of indoor LBS.

To facilitate query processing for indoor LBS, space models, indexes and algorithms have been proposed. They all deal with indoor entities, e.g., rooms, doors, walls and floors. These entities form distinct topology that determines indoor distances and impacts indoor movement. As a result, the distances in indoor spatial queries must be measured appropriately, e.g., without involving straight line segments through walls. Also, indoor routing in shortest path/distance queries must consider connectivity and reachability between indoor locations.

To support indoor distance computation, existing models and indexes [27, 31, 37, 38] employ different approaches to integrate the geometry and topology information of an indoor space. Though all these approaches can be used to process the aforementioned indoor spatial queries, a comprehensive experimental study on all these proposals is still missing. Consequently, indoor LBS application developers inevitably encounter difficulties in choosing the appropriate technique for a given indoor space scenario.

To bridge this gap for LBS application development and disclose insights for further research on indoor data management, we conduct a comprehensive experimental study in this work. Our study focuses on five existing model/indexes that support typical indoor spatial queries on static indoor objects (e.g., POIs) or indoor shortest paths/distances. We compare the five proposals theoretically and empirically. Our contributions are as follows.

- We survey the five proposals by scrutinizing their structures, algorithmic characteristics, and space and time complexities.
- We design an in-depth benchmark with datasets, evaluation tasks, and performance metrics. The datasets consist of real and synthetic data characterized by distinctive indoor topology.
- Within the benchmark, we conduct extensive experiments to evaluate the performance of the five proposals in terms of construction cost and query efficiency.
- By analyzing the results, we disclose the pros and cons of the proposals, analyze the impact of different conditions, and recommend the best choice for typical application scenarios.

All code, data and test cases are open-sourced [1]. To the best of our knowledge, this work is the first that comparatively analyzes and evaluates the existing techniques under a unified framework.

The paper is organized as follows. Section 2 introduces indoor spatial queries and related work. Sections 3 and 4 present the indoor space model/indexes and query processing, respectively. Section 5 details the experimentation benchmark. Section 6 reports and analyzes the evaluation results. Section 7 concludes the paper.

2 INDOOR SPATIAL QUERIES

Table 1 lists the frequently used notations.

Table 1: Notations

Symbol	Meaning
$\mathbb{I}$	An indoor space
$p, q \in \mathbb{I}$	Indoor points
$o \in O$	A static indoor object
$d \in D$	A door
$v \in V$	An indoor partition
$\|p, q\|_I$	Indoor distance from p to q
$\langle p, d_i, \ldots, d_j, q \rangle$	An indoor path
$L(\phi)$	Length of a path ϕ

2.1 Indoor Space Concepts

Indoor space features distinct entities such as walls, doors, and rooms, which altogether form complex indoor topology that enables and constrains movements. Naturally, an indoor space is divided by walls and doors into **indoor partitions** like rooms, hallways or staircases. Two indoor partitions can be connected by a door or an open segment between them. Referring to the example floorplan in Figure 1, partitions 30 and 40 (denoted as v_{30} and v_{40}, respectively) are connected by an open segment d_3, In this paper, we refer to both doors and open segments as doors. We do not consider the width of a door and represent a door by its center point. In other words, each door can be generally regarded as an indoor point. Furthermore, a door can be unidirectional such as a security checkpoint at the airport. The door directionality makes the indoor distance between two points asymmetric. Referring to Figure 1, the shortest indoor path from p to p' and that from p' to p are different due to the unidirectionality of d_{12}.

Topology renders the indoor distance more complex than Euclidean distance. In Figure 1, the indoor distance $|p, o_1|_I$ from p to

o_1 is not subject to the straight line segment between them; it is the total length of the polyline $p \rightarrow d_{11} \rightarrow o_1$.

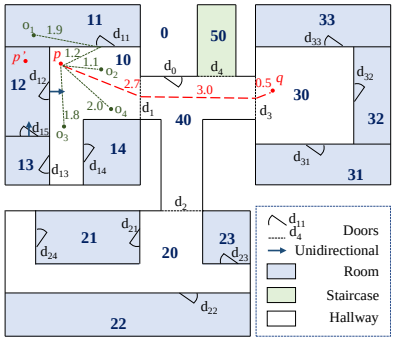

Figure 1: Example Floorplan

Lu et al. [27] proposes mappings to capture the relationships between indoor partitions and doors. In particular, $D2P_{\sqsupset}(d_i)$ gives the set of partitions that one can enter through door d_i and $D2P_{\sqsubset}(d_j)$ gives those that one can leave through door d_j. Besides, $D2P(d_i)$ gives a set of a partition pair (v_j, v_k) such that one can go through door d_i from partition v_j to v_k. Moreover, $P2D_{\sqsupset}(v_k)$ gives the set of enterable doors through which one can enter partition v_k, and $P2D_{\sqsubset}(v_k)$ gives the set of leaveable doors through which one can leave partition v_k. When doors are bidirectional, we use $P2D(v_k) = P2D_{\sqsupset}(v_k) \cup P2D_{\sqsubset}(v_k)$ to denote the set of doors associated to partition v_k.

Example 1. *In Figure 1, given the unidirectional door d_{12}, we have $D2P_{\sqsupset}(d_{12}) = \{v_{10}\}$, $D2P_{\sqsubset}(d_{12}) = \{v_{12}\}$, and $D2P(d_{12}) = \{(v_{12}, v_{10})\}$. Moreover, we have $P2D_{\sqsupset}(v_{12}) = \{d_{15}\}$, $P2D_{\sqsubset}(v_{12}) = \{d_{12}\}$, and $P2D(v_{12}) = \{d_{15}, d_{12}\}$.*

2.2 Indoor Spatial Query Types

We focus on *static* indoor objects such as POIs and facilities. Our study covers four fundamental indoor spatial query types.

Definition 1 (Range Query (RQ)). *Given an indoor point $p \in \mathbb{I}$, a set O of indoor objects, and a distance value r, a* range query *$\mathsf{RQ}(p, r)$ returns all indoor objects from O whose indoor distance from p is within r. Formally, $\mathsf{RQ}(p, r) = \{o \mid |p, o|_I \leq r, o \in O\}$.*

Definition 2 (k Nearest Neighbor Query (kNNQ)). *Given an indoor point $p \in \mathbb{I}$, a set O of indoor objects, and an integer value k, a k* nearest neighbor query *$k\mathsf{NNQ}(p)$ returns a set O' of k indoor objects whose indoor distances from p are the smallest, i.e., $|O'| = k$ and $\forall o_i \in O', o_j \in O \setminus O', |p, o_i|_I \leq |p, o_j|_I$.*

In Figure 1 where $O = \{o_1, \ldots, o_4\}$, a query $\mathsf{RQ}(p, 1.9\text{m})$ returns $\{o_2, o_3\}$ since the distances from p to o_1 and o_4 both exceed 1.9m.[1] Furthermore, a query $3\mathsf{NNQ}(p)$ returns $\{o_2, o_3, o_4\}$, since o_1's distance from p is the longest among all.

Definition 3 (Shortest Path Query (SPQ)). *Given a source point $p \in \mathbb{I}$, a target point $q \in \mathbb{I}$, a* shortest path query *$\mathsf{SPQ}(p, q)$ returns the shortest path $\phi = \langle p, d_i, \ldots, d_j, q \rangle$ from p to q such that 1) $d_i, \ldots, d_j$ are door sequences and each two consecutive doors are associated to the same partition, 2) p is in the partition having d_i as a leavable door, 3) q is in the partition having d_j as an enterable door, and 4) $\forall \phi'$ from p to q, $L(\phi) \leq L(\phi')$.*[2]

Definition 4 (Shortest Distance Query (SDQ)). *Given a source point $p \in \mathbb{I}$, a target point $q \in \mathbb{I}$, a* shortest distance query *$\mathsf{SDQ}(p, q)$ returns the shortest indoor distance from p to q, i.e., the length of $\mathsf{SPQ}(p, q)$.*

[1] Meter is the distance unit in all examples in this paper.

[2] $L(\phi) = \sum_{k=0}^{k=j} |d_k, d_{k+1}|_I$ where $d_0 = p$ and $d_{j+1} = q$.

As indicated by the red dashed polyline in Figure 1, a query $\mathsf{SPQ}(p, q)$ returns $\phi = \langle p, d_1, d_3, q \rangle$ as the shortest path from p to q, and the result of $\mathsf{SDQ}(p, q)$ is 2.7m + 3.0m + 0.5m = 6.2m.

2.3 Related Work

Indoor Space Modeling. Many indoor space models [7, 15, 20, 35, 36] focus on symbolic modeling of topological relationships between indoor partitions. Lacking of indoor distances, they cannot support the aforementioned distance-aware queries.

Indoor Moving Objects. Alamri et al. [4] propose an index tree for indoor moving objects based on connectivity between indoor cellular units. Kim et al. [19] propose to index indoor moving objects based on grid cells. Lin et al. [24] design an indoor moving object index to speed up complex semantic queries in multi-floor spaces. In the context of RFID indoor tracking, Yang et al. study continuous range monitoring queries [39] and probabilistic k nearest neighbor queries [40]. To improve the query result, Yu et al. [41] propose a particle filter-based method to infer the undetected locations of indoor moving objects. Assuming a probabilistic sample based location data format, Xie et al. [37, 38] process kNN query and range query for indoor moving objects. Considering uncertain object movements between observed time and query time, Li et al. [22] study searching the current top-k indoor dense regions. These works consider indoor moving objects with uncertain positions at a particular time. Unlike all these works on indoor moving objects, this study concerns spatial queries on static indoor objects, e.g., printers or ATMs.

Indoor Trajectories. Jensen et al. [15] study historical trajectories of RFID-tracked indoor objects. Delafontaine et al. [12] find sequential visiting patterns within historical Bluetooth tracking data. Given a past time or a time interval, Lu et al. define spatio-temporal joins [29] to find moving object pairs in the same indoor partition, and top-k queries [28] to find the most frequently visited indoor POIs. Ahmed et al. [2, 3] define threshold density query to find dense indoor semantic locations in a historical time interval. Assuming probabilistic sample based location records, Li et al. [23] find the top-k most popular indoor semantic regions with the highest object flow values. Jin et al. [17] study the similarity search over indoor trajectories, considering both spatial and semantic properties. By analyzing spatial constraints of indoor POIs, Jiang et al. [16] study the restoration of indoor trajectories. Li et al. [21] propose a coupled conditional Markov model to enrich indoor uncertain trajectories with mobility events and stay regions. Unlike these works, the queries studied in this paper focus on static objects or indoor paths.

Indoor Path Planning. Goetz and Zipf [14] study user-adaptive length-optimal indoor routing based on a weighted routing graph. Salgado et al. [30] study indoor keyword-aware skyline route query, considering the number of covered keywords and route distances. Feng et al. [13] study indoor keyword-aware routing queries to find shortest paths covering user-specified semantic keywords. Costa et al. [11] propose the context-aware indoor-outdoor path recommendation that minimizes the outdoor exposure and path distance. To enable navigation through movable obstacles, Sun et al. [33] study semantic assisted path planning over a gridded map of an indoor environment. Wang et al. [34] propose an obstacle-avoiding path planning algorithm to automate indoor robots. These techniques consider additional query semantics, and thus are different from the fundamental, pure shortest path/distance queries studied in this paper.

3 MODEL AND INDEXES

The aforementioned indoor spatial queries all involve indoor distances. To facilitate such queries, indoor distances must be considered in modeling and indexing indoor space.

3.1 Indoor Distance-Aware Model

Indoor distance-aware model [27] (IDMODEL) is a graph $G_{\text{dist}}(V, E_a, L, f_{\text{dv}}, f_{\text{d2d}})$. The first three elements capture indoor topology in an *accessibility base graph* $G_{\text{accs}}(V, E_a, L)$, where V is the set of vertexes each referring to an indoor partition, $E_a = \{(v_i, v_j, d_k) \mid d_k \in D, v_i \in D2P_{\sqsupset}(d_k) \wedge v_j \in D2P_{\sqsubset}(d_k)\}$ is a set of labeled, directed edges, and L is the set of edge labels each corresponding to a door in D. The additional two are mapping functions defined as follows.

$$f_{\text{dv}}(d_i, v_j) = \begin{cases} \max_{p \in v_j} ||d_i, p||_{v_j}, & \text{if } v_j \in D2P_{\sqsupset}(d_i); \\ \infty, & \text{otherwise.} \end{cases}$$

Here, $||p, q||_{v_j}$ is the indoor distance from a point p to a point q within the partition v_j. Note that $||p, q||_{v_j}$ is not necessarily a Euclidean distance because even within the same partition there may be obstacles in the line of sight between p and q. Specifically, *door-to-partition distance mapping* $f_{\text{dv}}(d_i, v_j)$ returns the longest distance one can reach within partition v_j from door d_i, if v_j is an enterable partition of d_i. Otherwise, it returns ∞.

$$f_{\text{d2d}}(v_j, d_i, d_j) = \begin{cases} ||d_i, d_j||_{v_j}, & \text{if } d_i \in P2D_{\sqsupset}(v_j) \\ & \text{and } d_j \in P2D_{\sqsubset}(v_j); \\ 0, & \text{if } d_i = d_j \\ & \text{and } d_i, d_j \in P2D(v_j); \\ \infty, & \text{otherwise.} \end{cases}$$

The *door-to-door distance mapping* $f_{\text{d2d}}(v_j, d_i, d_j)$ maps a partition v_j and two doors d_i and d_j to a distance value. If both doors are associated to v_j, it returns the distance from d_i to d_j within v_j, i.e., $||d_i, d_j||_{v_j}$. If d_i and d_j are identical and associated to v_j, we stipulate $f_{\text{d2d}}(v_j, d_i, d_j) = 0$. Otherwise, $f_{\text{d2d}}(v_j, d_i, d_j)$ returns ∞, indicating that one cannot go from d_i to d_j via v_j only.

Figure 2 illustrates the IDMODEL for the example shown in Figure 1. The outdoor space is captured in a special graph vertex v_0. Two hashmaps implement the mappings $f_{\text{dv}}(d_i, v_j)$ and $f_{\text{d2d}}(v_j, d_i, d_j)$. With directed edges, IDMODEL can support doors' directionality and temporal variation when needed.

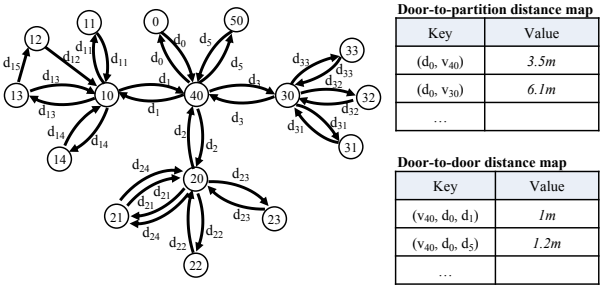

Figure 2: An Example of IDMODEL

With the two mappings $f_{\text{dv}}(d_i, v_j)$ and $f_{\text{d2d}}(v_k, d_i, d_j)$, a graph traversal algorithm [27] on IDMODEL is designed to compute the shortest door-to-door distance $\text{d2d}(d_s, d_t)$ from a source door d_s to a target door d_t. The basic idea is to keep expanding to unvisited doors based on the current shortest path until reaching the target door. Further, the shortest indoor distance from any point p to any point q can be computed by finding the minimum value of the distance summation $||p, d_p||_{v_p} + \text{d2d}(d_p, d_q) + ||d_q, q||_{v_q}$, where v_p and v_q are the partitions that host p and q, respectively, $d_p \in P2D_{\sqsubset}(v_p)$, and $d_q \in P2D_{\sqsupset}(v_q)$.

However, IDMODEL does not support fast determination of the host partition of a query/source point. It boils down to sequential scanning of all partitions if no additional index, e.g., R-tree, is used for the partitions. Also, to manage indoor static objects, IDMODEL needs additional object buckets each for a partition.

3.2 Indoor Distance-Aware Index

IDMODEL only captures the door-to-door and door-to-partition distances within a local partition, which entails extra search to compute the indoor distance for two points in different partitions.

To cut such costs, indoor distance-aware index [27] (IDINDEX) stores extra information on top of IDMODEL, namely, precomputed global door-to-door distances and their ordering in two matrices. The **door-to-door distance matrix** M_{d2d} is an N-by-N matrix where $\text{N} = |D|$ is the total number of doors and $M_{\text{d2d}}[d_i, d_j]$ gives the precomputed shortest indoor distance from d_i to d_j. The **distance index matrix** M_{idx} is also an N-by-N matrix such that $M_{\text{idx}}[d_i, k]$ gives the identifier of a door whose indoor distance from d_i is the k-th shortest among all the N doors.

The IDINDEX matrices for the top-left part in Figure 1 is illustrated in Figure 3. Here, we have $M_{\text{d2d}}[d_1, d_{15}] = 4.6\text{m}$. The first row of M_{d2d} shows that d_{15} has the longest indoor distance from d_1. Accordingly, we have $M_{\text{idx}}[d_1, 6] = d_{15}$ in M_{idx}.

$$\begin{pmatrix} & d_1 & d_{11} & d_{12} & d_{13} & d_{14} & d_{15} \\ d_1 & 0 & 1.7 & 2.7 & 3.6 & 2.8 & 4.6 \\ d_{11} & 1.7 & 0 & 1.9 & 3.6 & 2.8 & 4.6 \\ d_{12} & 2.7 & 1.9 & 0 & 2.6 & 1.8 & 1.6 \\ d_{13} & 3.2 & 3.4 & 2 & 0 & 2 & 1 \\ d_{14} & 2.8 & 2.8 & 1.8 & 1 & 0 & 2 \\ d_{15} & 4.3 & 3.5 & 1.6 & 1 & 2 & 0 \end{pmatrix} \qquad \begin{pmatrix} & 1 & 2 & 3 & 4 & 5 & 6 \\ d_1 & d_1 & d_{11} & d_{12} & d_{14} & d_{13} & d_{15} \\ d_{11} & d_{11} & d_1 & d_{12} & d_{14} & d_{13} & d_{15} \\ d_{12} & d_{12} & d_{15} & d_{14} & d_{11} & d_{13} & d_1 \\ d_{13} & d_{13} & d_{15} & d_{12} & d_{14} & d_1 & d_{11} \\ d_{14} & d_{14} & d_{13} & d_{12} & d_{15} & d_1 & d_{11} \\ d_{15} & d_{15} & d_{13} & d_{12} & d_{14} & d_{11} & d_1 \end{pmatrix}$$

(a) Distance Matrix M_{d2d} (b) Distance Index Matrix M_{idx}

Figure 3: An Example of IDINDEX

As the shortest indoor distances to all doors are precomputed and sorted for each door in IDINDEX, it is faster to compute the shortest indoor distance between any two points p and q in the indoor space. To support the shortest path query, in addition to the shortest distance value between any two points, IDINDEX also keeps the first-hop door of the corresponding shortest path. In this way, the complete shortest path between two points can be constructed by recursively concatenating the first-hop doors.

3.3 Composite Indoor Index

Composite indoor index [37] (CINDEX) is a layered structure for indexing indoor partitions and moving objects. It consists of three layers: geometric layer, topological layer, and object layer. In this study, we adapt the object layer to index static indoor objects. A partial example CINDEX for Figure 1 is given in Figure 4.

The **geometric layer** uses an R*-tree [8] to index all indoor partitions, with an additional skeleton tier to maintain the distances between staircases at different floors. To ease the geometrical computations, it decomposes each irregular partition[3] into regular ones using a decomposition algorithm [37]. Referring to the bottom-right of Figure 4, the hallway v_{10} is divided into two regular indoor partitions v_{10a} and v_{10b} by a door d_{16}. Afterwards, each regular partition is represented by a *Minimum Bounding Rectangle* (MBR). The MBRs are indexed by the R*-tree. As shown in the top-left of Figure 4, a non-leaf node R_1 is composed of six partitions in the leaf level, i.e., v_{10a}, v_{10b}, and v_{11}-v_{14}.

[3] A partition is irregular if it is non-convex or imbalanced (long in one dimension but short in the other).

The **topological layer** stores the connectivity information among indoor partitions, and it is integrated to the tree by inter-partition links. In particular, a leaf node v_i in the R*-tree is linked with a pointer record $(d_k, \uparrow v_j)$ to indicate that one can move from a partition v_i to another partition v_j through door d_k. As shown in the top-right of Figure 4, the two pointer records for v_{13} mean that v_{13} is adjacent to v_{10b} and v_{12} via d_{13} and d_{15}, respectively.

The **object layer** maintains a number of object buckets each for an indoor partition at the leaf node level of the R*-tree. Each indoor object o is kept in the bucket of the partition in which o is located. In addition, an object hashtable o-table : $O \rightarrow {}^*V$ maps each object to its host partition's pointer. Unlike [37, 38], the object buckets store static objects in this study. As shown in the bottom-left of Figure 4, the leaf node v_{10a} is linked to its object bucket with two static objects o_2 and o_4. Also, two corresponding records are kept in the object hashtable (o-table).

The R*-tree in CINDEX organizes partitions hierarchically, and thus enables search space pruning for distance relevant computations. As a result, CINDEX does not cache the precomputed door-to-door distances as IDINDEX does. Moreover, as the topological layer maintains the links between partitions and doors, which form an implicit graph structure, CINDEX does not need an explicit graph model to keep connectivity information. The topological layer's dynamic link updating makes CINDEX adaptive to possible temporal variations of doors.

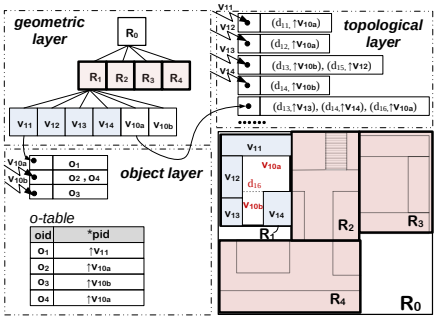

Figure 4: CINDEX Example (Adapted from [37])

3.4 IP-Tree and VIP-Tree

Indoor partitioning tree [31] (IP-TREE) is a tree-based indoor partition index with a number of matrices each materializing the door-to-door distances within a local range. In particular, each leaf node of IP-TREE covers a number of topologically adjacent indoor partitions. The adjacent leaf nodes are combined to form a non-leaf node, and adjacent non-leaf nodes are combined hierarchically until a root node is formed. Each node N has a **distance matrix** and a number of **access doors**. An access door is a border door that connects N to its external space. AD(N) denotes N's access door set. The distance matrix for a leaf node stores the shortest distance (as well as the first-hop door on the shortest path) between every door of the leaf node to every access door of the leaf node. The distance matrix for a non-leaf node only stores the shortest distances and first-hop door between each pair of access doors of its child nodes. To compute the indoor distance from a point p to a point q, IP-TREE locates the lowest common ancestor of the leaf nodes `Leaf`(p) and `Leaf`(q), finds the access doors constituting the shortest path in that ancestor, and connects the materialized indoor distances involving p, the found access doors, and q.

Figure 5 shows an example of IP-TREE corresponding to Figure 1. The topologically adjacent partitions v_{10}-v_{14} form a leaf node N_1. Another leaf node N_2 is composed of partitions v_{40} and v_{50}. As N_1 and N_2 are connected by a border door d_1, d_1 is put into AD(N_1) and AD(N_2). For the leaf node N_1, the distance matrix stores the distances from each of its doors to the access door d_1 of N_1. For instance, the distance from N_1's only door d_{15} to access door d_1 contained by N_1 is 4.3m. Moreover, as the shortest path from d_{15} to d_1 is $\langle d_{15}, d_{12}, d_1 \rangle$, the first-hop door of the path is kept as d_{12} in the matrix. Differently, for the non-leaf node N_0, the distance matrix only keeps the distances between each pair of access doors. In the running example, each pair of access doors are directly connected. Therefore, no first-hop door is recorded. The storage space of each distance matrix will double when the door directionality needs to be considered, i.e., both the distances d2d(d_i, d_j) and d2d(d_j, d_i) are kept in each node.

As a variant of IP-TREE, vivid IP-Tree (VIP-TREE) [31] further accelerates the distance computation by materializing more precomputed information. Specifically, each leaf node N additionally maintains the shortest distance between each door contained by N and each access door in N's all ancestor nodes, along with the corresponding first-hop door information.

IP-TREE and VIP-TREE materialize a small number of distances only related to access doors that are critical in the overall topology of an indoor space. This design eases the on-the-fly distance related computations in spatial query processing.

	d_0	d_1	d_2	d_3
d_0	0	1.4	2	3.9

Distance Matrix for $\mathbf{N_1}$ (a leaf node)

Figure 5: An Example of IP-TREE

4 QUERY PROCESSING

All the aforementioned model/indexes can be used to process indoor spatial queries. Although query processing differs for different query types, all algorithms share a general paradigm as follows. First, an algorithm finds the initial indoor partition for a query. The initialization decides the indoor partition in which the query (or source) point p is located for a given RQ(p, r) (kNNQ(p), SPQ(p, q), or SDQ(p, q)). Subsequently, an algorithm expands from the initial partition, searching adjacent partitions via doors. Finally, the expansion stops when the search range is beyond the query range r for a RQ(p, r), or kNNs have been found for a kNNQ(p), or the target point q is met for a SPQ(p, q) or SDQ(p, q). Algorithms based on different model/indexes differ in their initializations and expansions. Below, we present a comprehensive analytical comparison of all model/indexes.

4.1 Algorithmic Comparison

Table 2 summarizes the comparison.

Distance Precomputation. IDMODEL and CINDEX do not precompute any indoor distances, whereas IDINDEX and IP-TREE/VIP-TREE maintain some door-to-door distances before query processing. In particular, IDINDEX precomputes the shortest indoor distances between every pair of doors, but IP-TREE/VIP-TREE only keeps a small number of distances in each tree node.

Model/Index Structure. IDMODEL is a labeled graph with distance mapping functions, whereas IDINDEX materializes two matrices for global door-to-door distances. Employing a tree-based structure, CINDEX keeps topological information incrementally by maintaining inter-partition links, whereas IP-TREE/VIP-TREE augments each tree node with a local distance matrix. More importantly, CINDEX forms the non-leaf tree nodes according to the

geometrical proximity of partitions, whereas IP-Tree/VIP-Tree do so based on the topological proximity of partitions.

Query Types. All model/indexes can support all the four query types. However, IDModel [27] does not provide RQ and kNNQ algorithms. Therefore, we implement the two algorithms and refer readers to the appendix in [26]. Also, there are no off-the-shelf SPQ/SDQ algorithms for IDIndex and CIndex. Nevertheless, the global door-to-door distances and the corresponding last-hop door information in IDModel can be used to expand path searching in SPQ/SDQ algorithms for IDIndex. For CIndex, the inter-partition links can be used for path expansion.

Initialization. To decide the initial indoor partition for a query, IDModel and IDIndex sequentially scan all partitions. Enabled by the R*-tree indexing partitions, CIndex can quickly find the host partition of any indoor point. In contrast, IP-Tree and VIP-Tree are based on pure topological relationships among partitions, and thus they also sequentially scan all partitions.

Expansion. As a graph-based model, IDModel expands to the next unvisited door in the spirit of Dijkstra's algorithm [18]. CIndex does so as well since the next-hop doors are captured in the inter-partition links on the topological layer. Instead of expanding via directly connected doors, IP-Tree/VIP-Tree finds the lowest common ancestor (LCA) node of p and q and locates the intermediate access doors on the shortest path straightforwardly. It is noteworthy that IDIndex alone cannot support topological door expansion. Instead, IDIndex relies on an underlying IDModel to loop through relevant indoor partitions' doors.

4.2 Complexity Analysis

Let V, D, O be the total number of indoor partitions, doors, and indoor objects, respectively. Let d and o be the average door number and average object number per partition, respectively. Let w be the average number of door nodes on a shortest path. For IP-Tree/VIP-Tree, we use f to denote the fan-out of the tree node, ρ the average access door number per node, and L the total number of leaf nodes. Table 2 summarizes the space complexity of all model/indexes and their time complexity for queries.

Space Complexity. IDModel $(V, E_a, L, f_{\mathrm{dv}}, f_{\mathrm{d2d}})$'s space complexity is $O(\mathtt{V}+\mathtt{Vd}+\mathtt{D}+\mathtt{Vd}+\mathtt{Vd}^2)=O(\mathtt{Vd}^2)$. IDIndex's space complexity is $O(2\mathtt{D}^2)=O(\mathtt{D}^2)$ as it consists of two door matrices. CIndex's space complexity is $O(\mathtt{V}+\mathtt{Vd}+\mathtt{O})=O(\mathtt{Vd}+\mathtt{O})$ where V, Vd, and O correspond to partition R*-tree, inter-partition links, and object hashtable, respectively. IP-Tree's space cost mainly consists of the distance matrices for leaf nodes and those for non-leaf nodes. The former's complexity is $O(\rho\mathtt{D})$ and the latter's is $O((\rho\mathtt{f})^2\mathtt{L})$ where ρf corresponds to the number of access doors from a child node and L reflects the number of non-leaf nodes. In contrast, VIP-Tree's space cost on the distance matrices for leaf nodes is $O(\rho\mathtt{D}\log_\mathtt{f}\mathtt{L})$, where $\log_\mathtt{f}\mathtt{L}$ corresponds to the ancestor number of each leaf node.

Time Complexity for RQ and kNNQ. RQ and kNNQ have similar time complexity as they both prune objects based on shortest distances. IDModel's search expands via qualified doors by graph traversal in $O(\mathtt{V}\log\mathtt{D})$ and iterates on the objects in each visited partition in $O(\mathtt{o})$. Also based on graph traversal, the search on CIndex obtains a subgraph in $O(\mathtt{V}\log\mathtt{D})$ and visits all objects in each partition of the subgraph in $O(\mathtt{o})$. IDIndex's search expands to the nearest partitions based on the sorted result in M_{idx}, and loops through each object in the expanded partition. So its time complexity is $O(\mathtt{od}\log\mathtt{D})$. The searches via IP-Tree and VIP-Tree work similarly. They prune a tree node based on its distance from the query point in $O(\log_\mathtt{f}\mathtt{L}\cdot\rho\cdot c)$, where c is the unit SDQ cost. Then, they qualify each object in the remaining nodes in $O(\log_\mathtt{f}\mathtt{L}\cdot\mathtt{V}/\mathtt{L}\cdot\mathtt{o}\cdot c)$. Given the SDQ complexity $O(\rho^2\log_\mathtt{f}\mathtt{L})$ for IP-Tree and $O(\rho^2)$ for VIP-Tree (to be detailed below), their RQ and kNNQ complexities are $O((\rho\log_\mathtt{f}\mathtt{L})^2(\mathtt{Vo}/\mathtt{L}+\rho))$ and $O(\rho^2\log_\mathtt{f}\mathtt{L}(\mathtt{Vo}/\mathtt{L}+\rho))$, respectively.

Time Complexity for SDQ and SPQ. For the graph traversal algorithms of IDModel and CIndex, the SDQ complexity is $O(\mathtt{V}\log\mathtt{D})$ and SPQ complexity is $O(\mathtt{V}\log\mathtt{D}+\mathtt{w})$ with additional cost to backtrack the shortest path in w hops. For IDIndex, the only cost of SDQ is to loop through two door sets corresponding to p and q by a complexity of $O(\mathtt{d}^2)$. The extra cost of SPQ to concatenate shortest path is of $O(\mathtt{w})$. For IP-Tree, SDQ needs to search the lowest common ancestor and then find a pair of access doors from that ancestor node, resulting in a complexity of $O(\rho^2\log_\mathtt{f}\mathtt{L})$. In contrast, VIP-Tree materializes the distances from a leaf node to each access door in the ancestors. Its SDQ complexity is $O(\rho^2)$. The additional cost to construct shortest path in SPQ is $O(\mathtt{w}\log_\mathtt{f}\mathtt{L})$ for IP-Tree and $O(\mathtt{w})$ for VIP-Tree.

4.3 Extensibility Analysis

Table 3 summarizes the extensibility of all model/indexes.

Temporal Variation. Indoor topology may feature temporal variations, e.g., doors have open and close hours. To support indoor spatial queries in such cases, temporal variations like open and close time of doors can be maintained as a table attached to the accessibility base graph of IDModel or the topological layer of CIndex [25]. However, frequent temporal variations are hard to handle for IDIndex and IP-Tree/VIP-Tree as they need to precompute door-to-door distances globally or locally.

Moving Objects. CIndex [37, 38] is designed for managing indoor moving objects. It supports distance-aware queries like kNNQ and RQ, and also distance-aware joins like semi-range join and semi-neighborhood join. All other model/indexes can also index moving objects by maintaining dynamic object buckets

attached to indoor partitions in a way similar to how we handle the static objects. Nevertheless, the buckets need to be updated appropriately for indoor moving objects.

Uncertain Locations. In some settings, indoor points or objects are represented as uncertain regions. To process indoor spatial queries over uncertain locations, a model/index should support geometric operations on partitions. As a result, only CINDEX with partition R*-tree excels at handling uncertain locations [37, 38].

Keywords. A spatial keyword query [10] returns objects or paths that are spatially and textually relevant to the user-specified location(s) and keyword(s). Such queries can be supported if we extend the model/indexes by additionally maintaining mappings between partitions/objects and keywords. Especially, top-k keyword-aware shortest path queries have been supported based on IDMODEL [13], and boolean kNN spatial keyword queries have been supported based on VIP-TREE [32].

5 BENCHMARK

In this section, we detail the benchmark for evaluating the indoor spatial query techniques (model/indexes and algorithms). All code, data, and test cases are available online [1].

5.1 Datasets

We use four very different indoor space datasets, each featuring a distinctive indoor topology. The floorplans are briefly represented and illustrated in Figure 6. The data statistics are given in Table 5.

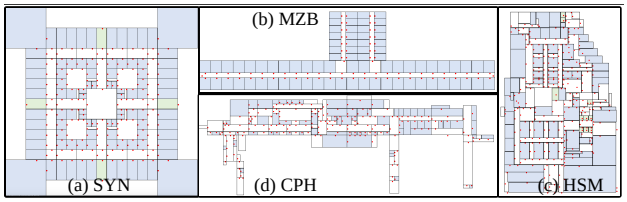

Figure 6: Floorplan of Datasets.

Synthetic Building (**SYN**) is a n-floor building. Its each floor is from a real-world floorplan [4] of 1368m × 1368m with 141 partitions and 216 doors. Its each two adjacent floors are connected by four 20m long stairways. By default, we set $n = 5$ and get the default dataset SYN5. To study the effect of topological changes, from SYN5 we derived SYN5$^-$ with fewer doors and SYN5$^+$ with more doors. Note that varying the door number will significantly change the connectivity and accessibility of the partitions, leading to a major topological change. We also form SYN5^0 in which the hallways are not decomposed [5].

Menzies Building (**MZB**) [6] is a landmark building at Clayton campus of Monash University. Each floor takes approximately 125m × 35m and connects to adjacent floors by two or four stairways each being 5m long. In total, there are 1344 partitions (including 34 staircases and 85 hallways) and 1375 doors. By changing the hallway decomposition, we form MZB^0 in which the hallways are not decomposed and MZB$^\Delta$ in which the hallways are decomposed into more partitions than default.

Hangzhou Shopping Mall (**HSM**) is a 7-floor mall in Hangzhou, China, occupying 2700m × 2000m. Ten stairways connect each two adjacent floors. Each floor contains 150 partitions and 299 doors on average. In total, there are 1050 partitions (including 70 staircases and 133 hallways) and 2093 doors.

[4] https://deviantart.com/mjponso/art/Floor-Plan-for-a-Shopping-Mall-86396406

[5] We precompute the door-to-door distance matrix for each hallway when it is not decomposed. The hallways are of irregular and concave shapes, and thus the door-to-door distance in a hallway can not use the Euclidean distance.

[6] https://www.monash.edu/virtual-tours/menzies-building

Copenhagen Airport (**CPH**) refers to the ground floor of Copenhagen Airport [7], taking around 2000m × 600m with 147 partitions (including 25 hallways) and 211 doors.

Overall Analysis of Different Datasets. The statistics of the datasets are given in Table 5. We use $\#dv$ to denote the number of doors in a partition, and conduct quartile statistics [5] on $\#dv$. In Table 5, Q1($\#dv$), Q2($\#dv$), and Q3($\#dv$) denote the first, second, third quartiles of $\#dv$, respectively, and max($\#dv$) denotes the maximum value of $\#dv$. In addition, we also plot the distributions of $\#dv$ over all partitions in each dataset in Figure 7.

Table 5: Statistics of Datasets

Datasets	SYN	MZB	HZM	CPH	SYN5$^-$	SYN5$^+$	SYN5^0	MZB^0	MZB$^\Delta$

Q3($\#dv$)	4	1	5	4	3	4	3	1	1
max($\#dv$)	10	56	17	12	10	10	132	82	47

Based on the space scale information and door distribution information from Table 5 and Figure 7, we summarize the characteristics of each dataset as follows.

- SYN: The overall space is square and regular. The number of doors and partitions in each floor is medium (216 doors and 141 partitions per floor). The door density within each partition is small (with Q2 equals only 2).
- MZB: The overall space is long and narrow with large scale crucial partitions (*C-Pars* for short). The number of doors and partitions in each floor is relatively small (80.4 doors and 76.8 partitions on average), whereas the overall size of doors and partitions is large due to the floor number. The planning of doors is rather skewed in that most partitions have only 1 or 2 doors while there are some C-Pars that accommodate 56 doors (as shown in Figure 7(b)).
- HSM: The overall space is long and relatively narrow. The number of doors and partitions in each floor is medium and the overall size of doors and partitions is large. The planning of doors is regular and door density in each partition is medium (Q2 and Q3 are equal to 4 and 5, respectively).
- CPH: The space is long, narrow yet open, resulting in a small number of doors and partitions. The door distribution is regular and door density in each partition is small (Q2 equals 2).

5.2 Object/Query Workload Generation

For each dataset, we randomly generated a set O of valid points as static objects, each object in O falling in an indoor partition. To test the effect of different object numbers, we vary $|O|$ as 500, 1000, 1500, 2000 and 2500.

The augment generation for each query type is detailed below.

RQ(p, r). We vary the range value r according to the predefined values in Table 6 (default values in bold). For each r, we generate ten RQ instances with a random p in the indoor space.

kNNQ(p). Similar to RQ generation, we generate ten random kNNQ instances for each k value given in Table 6.

As SPQ and SDQ can be integrated into one search procedure, we use SPDQ(p, q) to denote the integrated query that returns the shortest path from p to q along with the corresponding shortest distance value. In the following sections, we evaluate search performance of SPDQ only.

-	decomposition method	B7	b1, b2, b3 (only for SPDQ)	RQ, kNNQ, SPDQ	SYN MZB	SYN5^0, SYN5 MZB^0, MZB, MZB$^\Delta$

SPDQ(p, q). We use a parameter s2t to control the shortest distance from the source p and target q. Its parameter values are listed in Table 6. For each s2t, we generate ten different (p, q) pairs to form SPDQ instances as follows. First, we randomly select an indoor point p and find a door d whose indoor distance from p approximates s2t. Next, we expand from d to find a random point q whose indoor distance from p approximates s2t.

5.3 Model/Index Settings

IDMODEL. For each partition v_i, we implemented the door-to-door distance mapping $f_{\text{d2d}}(v_i, \cdot, \cdot)$ as a 2D array, and door-to-partition distance mapping $f_{\text{dv}}(\cdot, v_i)$ as an 1D array. Besides, the partition mappings $P2D_{\sqsupset}(v_i)$ and $P2D_{\sqsubset}(v_i)$ (cf. Section 2.1) were implemented as lists associated to v_i. Moreover, the door mappings $D2P(d_i)$, $D2P_{\sqsupset}(d_i)$, and $D2P_{\sqsubset}(d_i)$ were implemented as lists associated to the door d_i.

IDINDEX. The distance matrix and distance index matrix were implemented as 2D arrays.

CINDEX. Since the partitions in the datasets rarely intersect, we used an R-tree instead of R*-tree to index partitions while preserving roughly the same spatial search performance. We set the tree fan-out to 20 as suggested in a previous work [37]. Each partition's inter-partition links were maintained in an inner list.

IP-TREE and VIP-TREE. We set the minimum fanout to 2 for non-leaf tree nodes, as suggested in [31]. As each leaf node maintains the shortest distance for each pair of doors in it, the computation will be complicated if a leaf node contains too many C-Pars that each has many doors. Following work [31], we designate that each leaf node can only contain one crucial partition and regard a partition as crucial partition if its door number exceeds a threshold γ. Through tuning, we got optimal γ as 6, 4, 7, and 5 for SYN, MZB, HZM, and CPH, respectively.

5.4 Performance Evaluation Procedure

Concerning model construction and query processing, the following tasks are implemented to evaluate each model/index. For each task, a parameter is varied with others fixed to default. Table 6 lists all the evaluation settings. The code of following evaluation procedures and their query instances are also available online [1].

A **Model Construction.** For each model/index, we evaluate its (**a1**) model/index size and (**a2**) construction time. In this task, we vary the number of floors in synthetic datasets.

B **Query Processing.** We evaluate the search efficiency of a given query type. The metrics are (**b1**) running time, (**b2**) memory use, and (**b3**) number of visited doors (NVD) for SPDQ.

B1 **Effect of Floor Number n.** Using SYN with floor number n varied from 3 to 9, we test the search efficiency for each indoor spatial query algorithm.

B2 **Effect of Object Number $|O|$.** To test RQ and kNNQ, we vary $|O|$ from 500 to 2500 in all datasets.

B3 **Effect of Range Distance r.** We vary and test the augment r of RQ. In particular, we vary r from 200m to 1000m in SYN5, HZM and CPH, and from 20m to 100m in MZB.

B4 **Effect of k.** We vary and test kNNQ's augment k from 1 to 100 in all datasets.

B5 **Effect of Source-Target Distance s2t.** To test SPDQ, we vary s2t from 1100m to 1900m in SYN5, HZM, and CPH, and from 30m to 150m in MZB.

B6 **Effect of Topological Change.** We vary indoor topology by changing the door number from 840 to 1280 in SYN5 and obtain SYN5$^-$ and SYN5$^+$.

B7 **Effect of Hallway's Decomposition Method.** We use SYN5 and MZB with the derived datasets, SYN5^0, MZB^0 and MZB$^\Delta$.

6 RESULTS ANALYSIS

This section reports and analyzes the experimental results. All experiments are implemented in Java and run on a MAC with a 2.30GHz Intel i5 CPU and 16 GB memory.

6.1 Model/Index Construction

We vary the floor number n on SYN and obtain four variants SYN3, SYN5, SYN7, and SYN9. We construct the five model/indexes (cf. Section 3) and report their size and construction time in Figures 8 and 9. The cost of maintaining static objects is excluded as it is the same for all model/indexes.

- According to the results on SYN3 to SYN9 in Figure 8, each model/index's size increases steadily with a larger floor number.

When there are more doors and partitions, more storage space is needed to handle the indoor space.

- Among all, IDMODEL construction requires the least costs on storage (Figure 8) and time (Figure 9). This is because IDMODEL is extended based on a simple graph model and maintains only a small amount of geometric information locally. For large-scale and complex-topology spaces (e.g., SYN9, MZB, and HZM), IDMODEL has clearer advantages over the tree-based indexes (i.e., IP-TREE and VIP-TREE).
- As expected, IDINDEX always takes much time and storage to construct due to its global door-to-door distance precomputation. When there are many doors, it is difficult to fit the corresponding matrices in memory. In comparison, IP-TREE and VIP-TREE precompute less information and therefore their consumptions on time and storage are medium.
- In addition to maintaining the topology, CINDEX needs to construct a partition R-tree. Therefore, it incurs extra time and space overheads compared to IDMODEL.

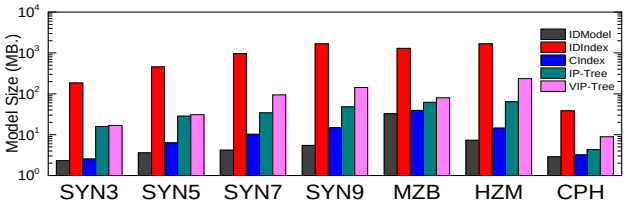

Figure 8: Model Size

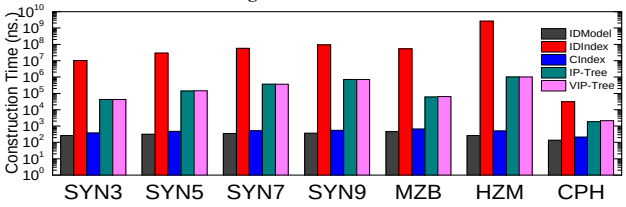

Figure 9: Construction Time

6.2 Query Processing

All results are averaged over 10 queries (cf. Section 5.2).

B1 Effect of Floor Number n (using SYN)

RQ and kNNQ: The query time and memory use for RQ are reported in Figures 10 and 11, respectively, and those for kNNQ are reported in Figures 12 and 13, respectively.

- For both query types, IDINDEX always runs fastest as shown in Figures 10 and 12, unaffected by the varying floor number n. The price behind this is to maintain the memory-resident distance matrices, which increases rapidly with n. Referring to Figures 11 and 13, when n grows to 9, IDINDEX requires up to 1600MB of memory on both queries.
- On each SYN dataset, IP-TREE and VIP-TREE need more time to complete the two queries. Through analysis, we found that the two indexes need to prune tree nodes when searching for qualified objects. In the absence of global door-to-door distances, they need a lot of on-the-fly calculations to get the shortest distance from a query point to a tree node. Being consistent with the complexity analysis in Table 4, VIP-TREE outperforms IP-TREE for both queries. However, due to the good scalability of the tree structure, both indexes' running time is relatively stable as shown in Figures 10 and 12.
- IDMODEL and CINDEX perform similarly, and their execution time increases with a larger n (Figures 10 and 12). When n increases, IDMODEL has a slight advantage as CINDEX costs more time in space pruning. In terms of memory overhead, the two indexes are almost the same.

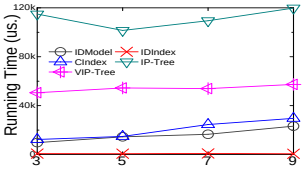

Figure 10: RQ Time vs. n

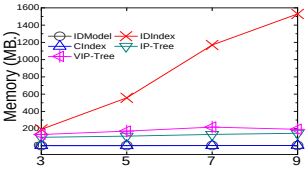

Figure 11: RQ Memory vs. n

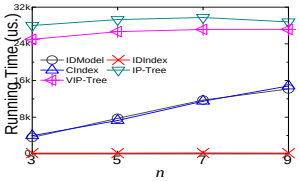

Figure 12: kNNQ Time vs. n

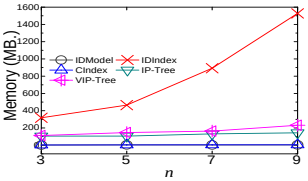

Figure 13: kNNQ Memory vs. n

SPDQ: The running time, memory use, and number of visited doors (NVD) are reported in Figures 14, 15, and 16, respectively.

- IDINDEX's running time and NVD are insensitive to the increasing floor number n. However, its memory use grows moderately as n increases. In the case of SPQ and SDQ, we recommend using IDINDEX when the door size is relatively small.
- In contrast to IDINDEX, the memory of IDMODEL and CINDEX is relatively stable (Figure 15), and their query performance deteriorates as the space scale increases (Figure 14).
- IP-TREE and VIP-TREE achieve clearly good performance on SPDQ, in both running time and memory use. Unlike IDINDEX that precomputes global door-to-door distances or IDMODEL and CINDEX that compute distances on the fly, IP-TREE and VIP-TREE cache relevant distance information only for those access doors on shortest paths. Thus, without degrading query performance, they only incur slightly more memory overhead than IDMODEL and CINDEX (Figures 14 and 15).

B2 Effect of Object Number $|O|$

RQ: With different sizes of O, the running time and memory use are reported in Figures 17 and 18, respectively.

- Algorithms based on different model/indexes are almost insensitive to $|O|$ in running time, implying that each can prune irrelevant objects effectively and stop searching early. A larger $|O|$ results in higher object density. This tends to increase the query processing time in general, as the query algorithms need to process larger object buckets. However, this impact is negligible according to the results in Figure 17. This implies that all model/indexes are good at pruning indoor partitions and thus object buckets when processing RQ.
- Referring to Figure 17, IDINDEX runs faster than others by several orders of magnitude in all datasets, thanks to its precomputed global door-to-door distances. However, it also requires memory an order of magnitude higher to store the distance matrix (Figure 18). A special case occurs on CPH (Figure 18(d)) that IP-TREE and VIP-TREE consume more memory than others. First, the door number of CPH is quite small such that the matrices of IDINDEX are not large. Second, as there are fewer access doors, IP-TREE/VIP-TREE involves heavy on-the-fly computations on distances between doors and non-leaf nodes and thus needs more memory for the intermediate results.
- On each dataset, IDMODEL and CINDEX incur almost the same execution time (see Figure 17), as they both use graph traversal to search for objects. Under complex indoor topology, CINDEX using R-tree does not have much advantage in spatial pruning.
- IP-TREE and VIP-TREE perform differently on different datasets. They outperform IDMODEL and CINDEX on MZB but are

worse on the others (see Figure 17). Recall that MZB features some C-Pars having up to 56 doors. In such a case, the efficiency of graph traversal is much lower than searching on the tree structure. On the contrary, when the number of candidate doors for the next hop is relatively small, the graph-based search algorithms are advantaged in range queries. Therefore, we recommend using IP-TREE/VIP-TREE to perform RQ in spaces with very large main corridors.

- Referring to Figure 17, VIP-TREE is generally faster than IP-TREE because of more cached distances. IP-TREE needs to compute more intermediate results on the fly. However, memory use is close between the two (see Figure 18).

*k*NNQ: Figures 19 and 20 report $|O|$'s impact on the time and memory costs, respectively. In general, each model/index's performance on *k*NNQ exhibits similar trend as that on RQ.

- Referring to Figure 19, the time cost of each algorithm on each dataset remains stable, showing that large object workloads (and high object density) have little effect on all models.
- On datasets with relatively large numbers of doors and partitions (i.e., SYN5, MZB, and HSM), IDINDEX runs faster by orders of magnitude. However, its memory use is clearly larger.
- On one-floor CPH with small numbers of doors and partitions, IP-TREE and VIP-TREE incur more running time as well as higher memory use (Figures 19(d) and 20(d)). However, they run faster on MZB (Figure 19(b)) in which many access doors exist due to many C-Pars (see Table 5).
- IDMODEL and CINDEX perform comparably as shown in Figures 19 and 20. Without a specially designed partition R-tree, IDMODEL achieves quite good object pruning due to the efficient distance mapping maintained in its edges and vertexes.

B3 Effect of Range Distance *r*

RQ: The time and memory costs with respect to varied *r* are reported in Figures 21 and 22, respectively.

- On SYN5, MZB, and HSM with complex indoor topology, IDINDEX's running time reported in Figure 21 increases slowly with a growing *r*. In contrast, on the simple-topology CPH, the advantage of IDINDEX over others is not marked.
- IDMODEL and CINDEX perform well on all datasets, except on MZB (Figure 21(b)) that has a large number of C-Pars. This again reflects the disadvantages of the graph-based traversal algorithms when dealing with this particular topology type. Nevertheless, through efficient node search and on-the-fly distance computation, these two model/indexes always have the smallest memory overhead.
- When increasing *r*, the running time of IP-TREE and VIP-TREE in Figure 21 increase steadily on all datasets. A larger *r* needs to consider a tree node farther from the node where the query point is located, and thus introduces more computations on the distance from a door to some non-leaf nodes. As the distance to the access door of each ancestor node is materialized at the leaf node, VIP-TREE runs faster than IP-TREE.

B4 Effect of *k*

*k*NNQ: The time and memory costs with respect to different *k* values are reported in Figures 23 and 24, respectively.

- Similar to increasing *r* value in RQ, increasing *k* leads to more search time by each model/index according to the results reported in Figure 23. Among them, IDINDEX's running time increases slowest. In addition, IP-TREE/VIP-TREE show exponential growth on SYN, HSM, and CPH. This is because the two indexes need to access the topologically far-away partitions and compute the distances to them on the fly when *k* is large.
- Considering both time and memory costs, IDMODEL and CINDEX achieve a good balance when searching for nearest neighbor objects (see Figures 23 and 24).

B5 Effect of Source-Target Distance s2t

SPDQ: The time cost, memory use, and NVD for different s2t values are reported in Figures 25, 26, and 27, respectively.

- IDINDEX runs the fastest and is not affected by s2t as reported in Figure 25. As only a small number of doors are required to process after the source point and before the target point, its NVD is always small (Figure 27). Nevertheless, its global distance matrix takes up a lot of memory (Figure 26).
- IDMODEL and CINDEX use the same graph search process. Note that because the Euclidean distance is no larger than the indoor distance, using R-tree to prune space by Euclidean distance does not really reduce the number of doors to visit. Therefore, the two models' NVDs in Figure 27 are almost the same. Also, as s2t increases, the candidate space becomes larger and the running time of the two becomes longer (see Figure 25).
- On MZB and HSM (Figure 25(b) and (c)), VIP-TREE achieves query performance comparable to IDINDEX that precomputes door-to-door distances. Both MZB and HSM are large-scale and have over 1000 doors. In the routing process based on VIP-TREE, the precomputed distances in non-leaf nodes greatly accelerate the expansion to the target point. Therefore, VIP-TREE is particularly suitable for the shortest path search in indoor spaces with complex structures.

VIP-TREE	2349	2369	2493	55	43	105	52	61	90

B6 Effect of Topological Change

RQ and *k*NNQ: The time cost and memory use with respect to topology characteristics are reported in Tables 7 and 8 respectively.

- IDINDEX runs fastest, but it needs large memory to store the door-to-door distance matrix. With increasing number of doors, its time cost and memory use increase steadily.
- IDMODEL and CINDEX use the smallest memory when processing RQ and *k*NNQ. Regarding the time cost, they perform medium. When the topology becomes more complex, the memory use keeps stable and the time cost increases slightly.
- IP-TREE and VIP-TREE cost more time to process RQ and *k*NNQ. Moreover, when the topology becomes more complex, the time cost rises rapidly. E.g., RQ's time cost using IP-TREE grows nearly 20 times from SYN5$^-$ to SYN5$^+$.

SPDQ: The time cost, memory use and NVD with respect to different topology characteristics are reported in Table 9.

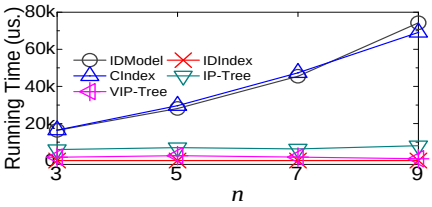

Figure 14: SPDQ Time vs. n

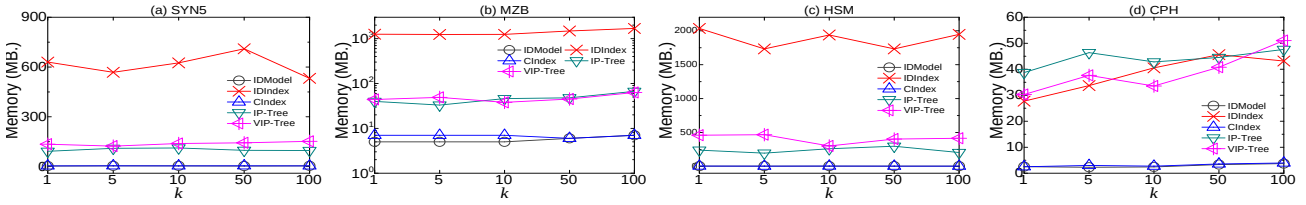

Figure 24: kNNQ Memory vs. k

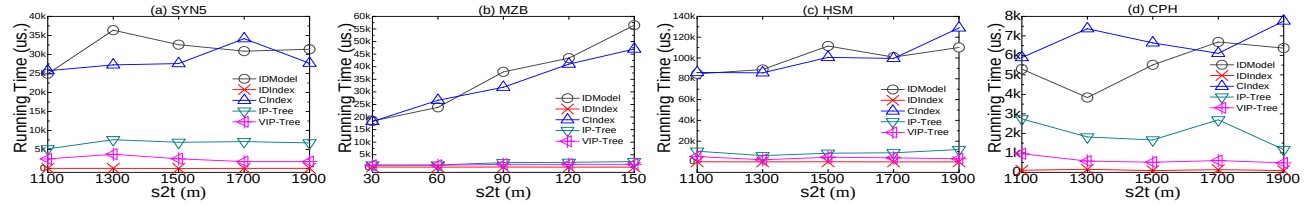

Figure 25: SPDQ Time vs. s2t

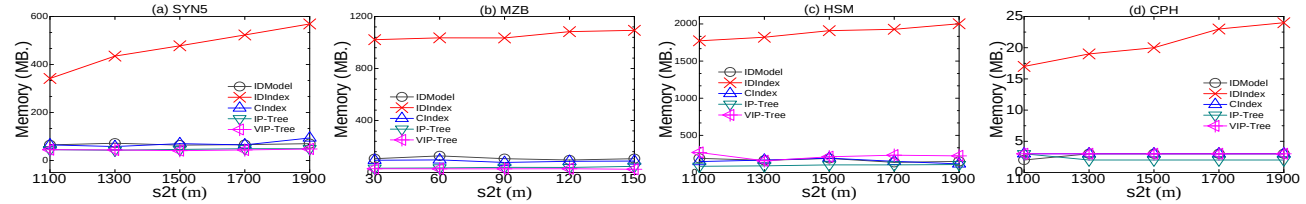

Figure 26: SPDQ Memory vs. s2t

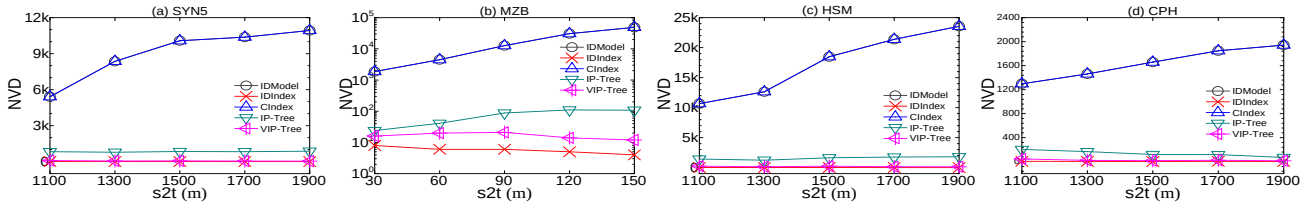

Figure 27: NVD in SPDQ vs. s2t

- Like in the other cases, IDINDEX performs best in terms of the time cost but costs most memory compared with others. When the topology becomes complex, IDINDEX's time cost increases relatively slightly, while the memory use grows fast.
- IP-TREE/VIP-TREE perform best with relatively less time cost and smaller memory use. For time cost, VIP-TREE always outperforms IP-TREE because of the extra precomputation, but it needs more memory. With the doors increasing, their time and memory costs rise slightly.
- IDMODEL and CINDEX performs worst in both time and memory costs because they have to visit many doors in search.

B7 Effect of Decomposition Methods for Hallways

RQ, kNNQ and SPDQ: For RQ and kNNQ, their time cost and memory use with respect to different decomposition methods are reported in Tables 10 and 11. For SPDQ, its time cost, memory use and NVD are reported in Table 12.

- IDINDEX runs fastest when processing RQ and kNNQ but uses most memory. When hallways are decomposed into more partitions, IDINDEX's time cost keeps nearly stable but its memory cost increases. This is because there are more doors connecting increased numbers of partitions, which leads to more door-to-door pairs stored in the distance matrix.
- IDMODEL and CINDEX use the least memory but runs slowest. With more partitions, both time cost and memory use decrease because hallways are decomposed into more partitions each having less doors to process.
- IP-TREE and VIP-TREE perform best considering both time cost and memory use. However, when hallways are decomposed into more partitions, the two methods need more time and memory to process RQ and kNNQ. Regarding the performance in RQ, IP-TREE and VIP-TREE cost more time than IDMODEL. There are more nodes in IP-TREE and VIP-TREE when hallways are decomposed into more partitions, which entails more on-the-fly computations to prune tree nodes when processing RQ and kNNQ. Moreover, the time cost of IP-TREE and VIP-TREE rises faster when processing RQ and kNNQ than processing SPDQ. That is because there is some extra cost to prune nodes when processing RQ and kNNQ. As the nodes increase, this extra cost increases fast.

6.3 Summary of Findings

We summarize all five model/indexes' performance in Table 13 where more stars imply a better performance (lower cost). IDMODEL incurs minimum time and space costs in construction. It

Table 12: Results of SPDQ with Decomposition Method

Model	Time (us.)					Memory (MB.)					NVD				
	SYN5^0	SYN5	MZB^0	MZB	MZB$^\Delta$	SYN5^0	SYN5	MZB^0	MZB	MZB$^\Delta$	SYN5^0	SYN5	MZB^0	MZB	MZB$^\Delta$
IDMODEL	31242	31855	36220	33503	32396	44	63	54	73	92	82574	10074	24877	12718	4243
IDINDEX	138	75	71	69	73	388	396	1096	1273	1489	58	8	22	9	8
CINDEX	32823	26900	35307	33238	31806	43	65	52	97	110	82574	10074	24877	12718	4243
IP-TREE	1610	7523	1252	1893	3257	59	44	31	39	44	416	843	97	87	139
VIP-TREE	856	2379	1091	1126	1474	64	42	54	39	55	136	61	37	24	26

works well for RQ and kNNQ, and its performance for SPQ/SDQ even improves when hallways are decomposed into more partitions. IDINDEX runs fastest for all types of indoor spatial queries while requiring significantly large time to construct offline and high memory consumptions during search. CINDEX performs only comparably to IDMODEL when processing the queries. IP-TREE and VIP-TREE are optimized for SPQ/SDQ tasks—they stand out when there are many C-Pars connected by so-called access doors; they decline when decomposition reduces C-Pars.

In short, IDINDEX is preferred for small-scale spaces. VIP-TREE is recommended if routing is the task or the space accommodates many C-Pars. Otherwise, IDMODEL is recommended for non-routing queries due to its low construction cost and good balance between storage and query time costs.

7 CONCLUSION AND FUTURE WORK

This work reports on an extensive experimental evaluation of five indoor space model/indexes that support four typical indoor spatial queries. Our evaluation concerns the costs in model/index construction and query processing using a model/index. By analyzing the results, we summarize the pros and cons of all techniques and suggest the best choice for typical scenarios.

For future work, changes to existing methods may improve their performance. First, heuristics like A* and IDA* algorithms can replace the Dijkstra-based expansion in IDMODEL and CINDEX to speed up SPDQ processing. Second, intra-partition indexes like grids can be combined with CINDEX and IP-TREE/VIP-TREE to achieve local object pruning in processing RQ and kNNQ. Third, strategies to select crucial doors/partitions can be developed to reduce the storage of door-to-door distances in CINDEX and IP-TREE/VIP-TREE while preserving their search efficiency.

ABSTRACT

Numerous data are stored in semi-structured files with ad-hoc layout. Such data are valuable digital assets for various data-driven applications. This work introduces the notion of *verbose CSV files*. Verbose CSV files include content serving different purposes in various positions. They are designed for human visual inspection or statistical report collection. An important preliminary task for extracting information from such files is *structure detection*, in particular classifying lines or cells by their purpose. As manual efforts are infeasible and error-prone for large files or large sets of files, automatic approaches are desirable.

This work addresses both the *line* and the *cell classification* problems on verbose CSV files. Strudel is a supervised learning approach based on a random forest classifier, combined with a set of novel features that fall into three categories: content features, contextual features, and computational features. We annotated five real-world datasets from various domains, on which we tested our approach. Our in-depth experiments show the advantages of Strudel over baseline and state-of-the-art approaches in both line and cell classification tasks.

1 INTRODUCTION

The rapidly growing amount of data promises to be of great value for everyone's day-to-day life, for example, assisting doctors in personalizing healthcare solutions to their patients, scientists conducting open data-based citizen researches, and enterprises making better business decisions. To enable such applications, raw data must be properly processed and analyzed before generating insights. While some data are saved in well-defined formats, such as relational tables or as key-value pairs, that can be readily parsed by dedicated tools, a large quantity of other data are stored in documents with unique structures, for example, CSV files. CSV files are comma-separated values files that provide a great number of data sources for various data-driven tasks, such as data profiling [10, 24], data curation [22, 26, 30], and information extraction [9, 16]. Although there is a standard[1] that stipulates how data shall be stored in CSV files in theory, in practice users and applications do not always conform to it, producing documents with very unique structures.

This work addresses one such type of document: verbose CSV files. Later, we formally define a comma-separated value file as *verbose* if its raw values serve various purposes, such as data, metadata, group headers or notes, and appear in various positions. An example of a real-world verbose CSV file from the "Crime In the US" (CIUS) dataset is given in Figure 1, where groups of cells with different roles are highlighted. This file cannot be directly

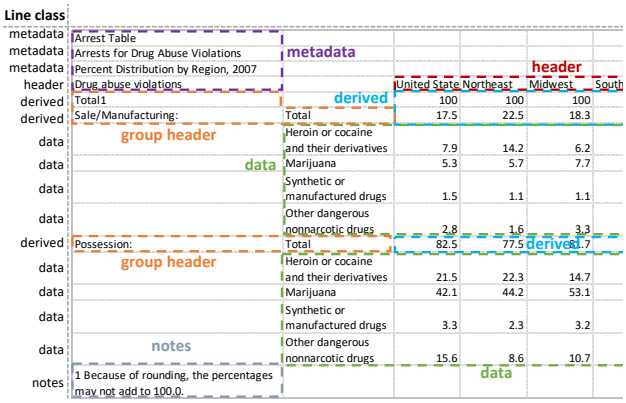

Figure 1: A real-world verbose CSV file with different cell-level and line-level content classes. Here, the line-class is determined by the majority of its cell classes.

ingested by common RDBMS tools, as it contains much additional information, aside from a table with its header and data rows.

While standard CSV files contain data in the form of a structured table, a verbose CSV file is more similar to a spreadsheet, in terms of its flexible content layout. Researchers have suggested that only a minority of spreadsheets (22% of 200 randomly selected spreadsheets) can be directly converted to relational tables [6]. A similar observation by Dong et al. states that less than 3% of spreadsheet tables are "machine-friendly" [11]. Spreadsheets are not the only source for verbose CSV files. We randomly selected 26,140 files from data that we crawled from the Mendeley data portal[2], and manually checked their file types. We grouped all files into three broad categories: (i) application-specific files, such as Microsoft office files; (ii) plain-text files; (iii) multi-media files. Amongst all plain-text files, we are interested in those with at least one table. Out of these files with tabular structures, there are 4,459 files that are verbose, accounting for around 20% of all inspected plain-text files. These verbose plain-text files can be easily transformed to CSV files by applying file-specific delimiters. In our experiments, we tested our approach on verbose CSV files derived from both spreadsheets and arbitrary plain-text files that contain data lines/cells.

Verbose CSV files are prevalent media to store data that aim at aiding human visual inspection or collecting statistical reports. These data often need to be shared amongst communities. Therefore, plain-text files, such as CSV files, are favored due to their generality over those with proprietary file types, such as spreadsheets, that are used by specific applications. However, compared to application-specific files, verbose CSV files are harder to parse, as they do not necessarily follow a specific format. Various open data portals include such files, sometimes labeled as 'ASCII' data[3].

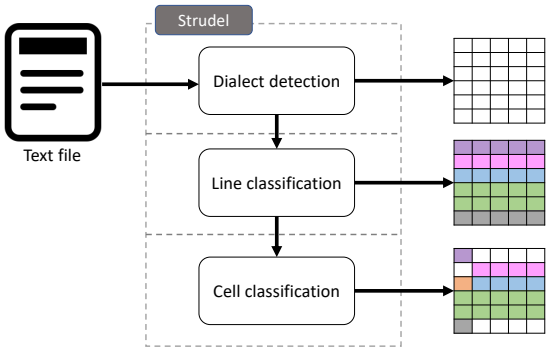

Figure 2: Architecture of the Strudel algorithm.

To obtain insightful information from these files, the first step is to understand their structure, i.e., detect the types of cells, lines, or data blocks. In practice, this is a challenging task due to (i) the wide range of ad-hoc layout variants that can be found and (ii) the lack of rich stylistic features that have been exploited by previous work [2, 11, 18]. Manual inspection to recognize file structure and acquire valuable information is extremely time-consuming for many and large verbose CSV files; automatic methods can support this task.

Information in verbose CSV files is usually organized in a tabular fashion, where each cell is an atomic content unit. File structure is often reflected in the sequence of classes of horizontal lines, as data organized in verbose CSV files usually conforms to the common top-to-bottom data presentation logic. For example, consider the line class labels of the example file in Figure 1. These classes show a natural logic of organizing information: metadata, such as captions, come first, followed by the main body of a table incorporating table headers, derived (aggregated) lines and data lines, and finally a few footnote lines conclude the file. In this work, we aim at *verbose CSV file structure detection* by means of classifying file content in two granularities: *lines* and *cells*.

Obtaining manually labeled datasets with known line and cell annotations to evaluate an approach for the structure detection problem is difficult, as ascertaining these classes in a verbose CSV file is a difficult task even for experienced practitioners. In our study, even by using a tool with a sophisticated graphical interface, practitioners 1) took on average of two minutes to label the lines in a single file, because they needed to spend a lot of time understanding the unique structure of each file; 2) at times disagreed with each other on the annotations of individual lines. These observations highlight the challenge of automatically classifying lines and cells in verbose CSV files.

To address the line/cell classification problem, we propose the Structure Detection in Verbose CSV Files (Strudel) approach, which is grounded on a multi-class random forest classifier. Figure 2 shows the architecture of the approach. It first detects the dialect of a text file, and creates a verbose CSV file from it, based on the dialect. Then Strudel classifies first lines and then cells therein with the proposed feature sets. Cells of different types are distinguished by colors. Sections 4 and 5 describe Strudel for line and cell classification, respectively. We propose sophisticated features to model the individual classes for both classification tasks. The features can be categorized into three groups: 1) *content features* parsing the values of cells or lines, such as cell length and amount of words; 2) *contextual features* comparing the inspected cell or line with its neighbors, such as the similarity of data types between lines/cells; 3) *computational features* seeking to connect lines/cells with each other by inspecting arithmetic correlations between them. The contributions of this work are summarized as follows:

(1) A supervised learning approach with novel features to address the structure detection problem for verbose CSV files.
(2) A dataset with more than 97,000 annotated lines in 226 files, reforged labels of datasets from related work based on our perspective on cell classes, and a dataset with 62 files transformed from plain-text files.
(3) An experimental comparison of Strudel with baseline and state-of-the-art approaches.

In the next section, we introduce the related work on line and cell classification tasks and other relevant areas. In Section 3, we formally define the classification problem and introduce the set of line and cell classes. Section 4 and 5 describe the core idea of Strudel, followed by Section 6, where we present the results and analysis of our experiments. We conclude in Section 7.

2 RELATED WORK

Extracting information from semi-structured documents has been a growing research field in recent years. Relevant research questions include how to locate tabular content in documents such as PDF files [20], and spreadsheets [12], how to distinguish relational tables from non-relational tables [4, 29], and how to extract relational tables from heterogeneous sources [5, 13, 14, 25].

Prior to extracting information from a semi-structured document, understanding its structure is necessary. Some techniques have been proposed to address the structure detection problem on various documents, such as web tables and spreadsheets, which include tabular material and have flexible layout. We summarize these works focusing on structure detection by classifying lines or cells, respectively.

2.1 Line classification

Pinto et al. suggest a conditional random field (CRF) learning approach to predict the label for lines of plain-text documents crawled from a open data portal [23]. For each document, a sequence of features is computed for its lines. The sequences of all documents are used by the CRF classifier to infer the label. This approach was later adopted to infer spreadsheet table schemata [28] and extract relational data from spreadsheets [5]. Moreover, it was extended by Adelfio et al. to recognize line classes in web tables and spreadsheets [2]. The authors suggest feature binning to generalize the training data and show the effectiveness of their approach on recognizing line classes in both HTML tables and spreadsheets crawled from several open data portals. However, the approach assumes the presence of stylistic features, such as font styles, or built-in spreadsheet formula features, which are not available in verbose CSV files.

A recent work has proposed the rule-based approach Pytheas for CSV file line classification [8]. To classify lines in a CSV file, the approach first determines for each line whether it is data or non-data by consulting a set of fuzzy rules, whose weights have been learned beforehand with a training dataset. These binary results are then used to determine the top/bottom borders of tables in the file. Finally, the approach exploits additional class-specific rules on the discovered table/non-table areas to further ascertain the class of each line. The core of this approach is the

design of the fuzzy rule set, which significantly impacts the consequences of table border discovery, and also line classification. However, such a fixed set of rules might fail to generalize to new circumstances in unseen data.

2.2 Cell classification

Finer-grained cell classification in tabular documents has been the subject of academic interest in recent years. Abraham et al. developed the UCheck framework, which includes a component to detect "cell roles", such as header and footer, in spreadsheets using several heuristics [1]. Cell roles are then used by the system to detect spreadsheet errors. The goal of their approach is to correlate cells in a table with their corresponding headers, thus they assume spreadsheets with only table regions as input data.

Koci et al. suggest a supervised learning approach with a post-processing component to repair classification errors [19]. The authors introduce five misclassification patterns and suggest that the occurrence of them in the results hints at a misclassification.

To reduce the amount of manual annotation effort, Chen et al. integrated an active learning technique into their spreadsheet cell classification approach [7]. In their iterative algorithm, a sheet selector presents the most uncertain spreadsheet to human labelers. The sheet is then labeled and included into a training set that is used to train a spreadsheet property classifier.

Ghasemi-Gol et al. suggest a recursive neural network (RNN) architecture on two seperately trained cell embeddings that capture the contextual and the stylistic semantics of cells, respectively [18]. Even though the authors mention the contextual impact on a cell from both neighboring and distant cells, they considered only the former ones in their approach. They built the stylistic features upon those suggested by [19].

In summary, these works all make use of stylistic features of their input. However, no such information can be obtained in verbose CSV files. In this work, we compare our approach with the RNN-based approach of [18], as it was reported to outperform the other approaches. In spite of using stylistics features to solve the task, the authors also reported the performance of their algorithm without their usage, enabling a direct comparison to our approach.

3 DEFINITIONS AND PROBLEM STATEMENT

We first define the notion of verbose CSV files. Then, we present the taxonomy of element classes used to label our datasets and present the detailed definition of each class. Based on these concepts, we formally state the problem addressed by our approach.

3.1 Verbose CSV files

A standard CSV file, according to RFC 4180, contains an optional header line at the beginning of the file, followed by a number of data lines. In contrast to that, a *verbose CSV file* may include elements of heterogeneous classes (which will be introduced in Section 3.2), possibly with empty visual separators. Here, an *element* is either a non-empty cell or a line that includes at least one non-empty cell.

Definition. *A* verbose CSV file *is a comma-separated values file with values including one or more of metadata, header, group, data, derived, and notes at arbitrary positions. Each line of the file may be composed of cells of one or more classes. Empty cells may represent either missing values or serve layout purposes.*

A standard CSV file stores a single table that is machine-readable, whereas a verbose CSV file may include multiple tables, and make use of empty cells and further cell types to improve human readability, leading to various configurations. Information of different kinds may be organized as connected clusters of cells throughout the file: each such cluster may include information of different types, such as data, metadata, or aggregations; a table may be divided by blank visual separators into several table fractions; etc.

3.2 Class taxonomy

Our taxonomy includes six semantic classes and is similar to that of [2], which addressed the line classification problem on web tables and spreadsheets. While in principle content of any class may appear at any location in a verbose CSV file, we enforce a few practical constraints on their possible position, reflecting the usual reading convention: from left to right and from top to bottom, assuming that tables are stacked only vertically. We describe in detail each class in the following list.

- **metadata.** Metadata are the descriptive text *above* a table. Such text may include the title of a table, or additional information on the content of the table. A metadata area may span across one or more lines and columns.
- **group.** In verbose CSV files, tables are often split into several fractions, each including data of a particular group. A group (a.k.a. group header) element serves as the label of such a fraction. We have seen in our datasets the group elements appearing both *above* and *below* header areas. Therefore, we allow both cases in our definition. Group cell may also serve as the leftmost string cells in a derived line, e.g., the 'Sale/Manufacturing:' cell in Figure 1.
- **header.** Headers are the column labels in the top area of a table (or table fraction). Headers may span multiple cells. In our definition, the header elements are located *above* the data area, and *below* any metadata block of the table.
- **data.** Data elements are the content of a table that cannot be derived from any other elements. Because they constitute the main body of a table, data elements of a section of a table are always *below* header and group elements that indicate this section.
- **derived.** A derived cell aggregates the values of some other numeric cells in the same table. In verbose CSV files, derived cells are usually organized as the top- or bottom-most lines, or the left/right-most columns of the data area of a table.
- **notes.** Notes are descriptive text that follow a table. They may give explanations of particular parts of a table, explain the meaning of marks used in the table, or indicate the data source origin.

Any line or cell in a verbose CSV file can be associated with exactly one of the classes introduced above. We address the following problem: *Given a verbose CSV file and the group of possible element classes, how can we determine the classes of all elements?* We consider elements of two natures addressing two sub-problems under the same problem definition: *lines*, reflecting the usual vertical arrangement within a file, and *cells*, as the most fine-grained element of a structured file.

4 LINE CLASSIFICATION

In this section, we describe *Strudel*^{L} – the Strudel approach to deal with the line classification problem. *Strudel*^{L} is based on a

multi-class random forest classifier. Its input includes a set of features extracted from the two-dimensional tabular data.

Various kinds of features have been proposed by previous work to address the line classification problem, including content features, contextual features, spreadsheet formula features, and stylistic features [2]. In our case, formula and stylistic features cannot be applied, as CSV files do not preserve these rich-text information. Instead, we design a set of content features, contextual features, as well as computational features. We build the features of *Strudel*^{L} on top of the applicable features from the previous work [2]. Table 1 lists our complete set of features, divided into the three groups. The context features can include information from both the line above and the line below. Thus, the features marked by a star are applied twice – once for the line above and once for the line below. To distinguish derived cells from data cells, we propose novel *computational* features that check whether the value of a numerical cell can be calculated by applying a specific aggregation function on the numbers in the vicinity, i.e., the cells in the same row or column.

Table 1: Line classification features: '∗' marks contextual features applied to both lines above and below the inspected line; '†' are adapted from [19].

Category	Feature	Value
Content	EmptyCellRatio†	[0.0, 1.0]
	DiscountedCumulativeGain	[0.0, 1.0]
	AggregationWord†	0/1
	WordAmount	[0.0, 1.0]
	NumericalCellRatio†	[0.0, 1.0]
	StringCellRatio†	[0.0, 1.0]
	LinePosition†	[0.0, 1.0]
Contextual	DataTypeMatching*	[0.0, 1.0]
	EmptyNeighboringLines*	[0.0, 1.0]
	CellLengthDifference*	[0.0, 1.0]
Computational	DerivedCoverage	[0.0, 1.0]

Here, we describe and explain only the novel features used in our approach and refer to related work for the others.

- DiscountedCumulativeGain (DCG) calculates the discounted cumulative gain on a vector created from the cells of a line. The vector has the same length as the number of cells in a line. An element is set to '1' if the corresponding cell in the line is non-empty, or '0' if it's empty. This feature is exploited to model the pattern of empty cells. DCG gives more weight to left-more positions than to right-more positions, modeling users laying out data from left to right.
- AggregationWord checks whether a line contains any word that belongs to a pre-made dictionary of terms associated with aggregation in tables (case-insensitive): `total`, `all`, `sum`, `average`, `avg`, `mean`, and `median`. An existence of any keyword gives '1' to this feature, otherwise '0'. Using a dictionary of such kind of keywords proves to be effective [19].
- WordAmount calculates the number of words in all cells of a line. A word is a sequence of alphanumeric characters. The feature values are normalized per file by using a min-max normalization strategy.
- DataTypeMatching calculates the percentage of line cells whose data types match with those of the adjacent line (above or below). Note that some files insert an empty line between every pair of non-empty lines to visually highlight the content. However, comparing the data type of a line with an empty adjacent line does not carry much information. Therefore, an adjacent line refers to the closest non-empty line. Data and derived lines tend to have numerical cells while header lines usually contain alphanumeric values. Other functional lines, such as metadata, notes, and group lines tend to have many empty cells, as they often contain values for only the first cell in a line.
- EmptyNeighboringLines calculates the percentage of empty lines in the five lines above or below the inspected line. Empty lines are often used as visual separators in verbose CSV files. Using such a separator between data lines within a table is uncommon, but placing them between two classes of lines, such as header-data and derived-notes is more common.
- CellLengthDifference calculates the cell value length difference between two adjacent lines by calculating the Bhattacharyya histogram difference on the sequence of cell value length of the two lines. When computing this feature, we compare only a line with its closest non-empty neighboring line, similar to that applied for the DataTypeMatching feature. While data lines tend to have similar cell-wise value lengths, as they usually describe the same property and thus draw values from the same domain and range, non-data lines might have natural language form values that are of arbitrary value lengths.
- DerivedCoverage counts the number of numeric cells that are recognized as derived cells by the derived cell detection Algorithm 2 in the next section. The feature is normalized by the number of numeric cells in this line.

Note that these line classification features are all local features, i.e., describing the characteristics of individual lines. We have tested a few global features that reflect properties of the entire file, namely percentage of empty lines in a file, width and length of a file, and the number of empty line blocks in a file. However, our experiments show no positive impact on the classification problem.

All features are normalized and passed to a random forest classifier that predicts one class for each line. When used as the Line class probability feature in *Strudel*^{C} (Section 5.4), the output is a set of vectors, each of which stands for a probability vector of all classes for a line.

5 CELL CLASSIFICATION

Our cell classification approach *Strudel*^{C} is, like *Strudel*^{L}, based on a multi-class random forest classifier. For the input of this classification task, we have again constructed a set of features that include both the effective ones from previous work, and novel ones. The predictions for line classes are used as a set of features in *Strudel*^{C}. Therefore, the *Strudel*^{L} approach is executed beforehand to obtain the line prediction probabilities that are then transformed into the features of *Strudel*^{C}. We leave the detailed description to Section 5.4.

5.1 Feature extraction

Previous work has proven the effectiveness of content features, stylistic features, spreadsheet formula features, and contextual features [18, 19]. We ignore spreadsheet-specific formula features and stylistic features, as they cannot be constructed from verbose CSV files. Table 2 lists all features involved in our approach, which fall into three groups: content, contextual, and computational features.

Table 2: Cell classification features; '∗' marks contextual features applied to each of the eight surrounding cells of the inspected cell; '†' marks features from related work.

Category	Feature	Value
Content	ValueLength†	[0.0, 1.0]
	DataType†	[0..4]
	HasDerivedKeywords†	0/1

	NeighborDataType*	[0..5]
Computational	IsAggregation	0/1

The features marked with '†' in Table 2 are based on those used in [18, 19]. Some of the original features are integrated in our feature set without modification, such as ValueLength and DataType, while others are adapted to a certain extent. For instance, a Boolean feature used to mark the existence of derived cell keywords is extended to a row or a column (RowHasDerivedKeywords and ColumnHasDerivedKeywords), i.e., whether the row or the column that contains the inspected cell contains any derived cell keywords. Features without '†' are new. ValueLength counts the number of characters in the value of the cell. DataType in this work has four possible values, corresponding to four data types: int, float, string, and date. In the next subsections, we explain the intuition and implementation of the four most sophisticated of them.

5.2 Block size

A verbose CSV file may contain multiple tables in various positions, rather than a single relational table. Apart from tables, a verbose CSV files may contain non-data regions composed of aggregation cells, notes, or metadata cells. In our datasets, non-data regions are usually smaller than tables.

To model this phenomenon, we create for each non-empty cell a BlockSize feature, which is calculated as the size of the connected component that contains this cell. A connected component is composed of a group of connected, non-empty cells. Two cells are connected if they are either vertically or horizontally adjacent to each other, or there is at least one connective path between them. Algorithm 1 describes how the value of this feature is produced for each cell in a given verbose CSV file. It takes all non-empty cells in a table as input, and outputs key-value pairs where keys are these non-empty cells and values are their respective block sizes. To obtain the block size for all non-empty cells, the algorithm employs a depth-first strategy to iterate over all of them in a given file. It starts from a single cell block (line 4-7), and continuously adds adjacent cells to expand the block until no more non-empty adjacent cell can be found (line 8-13). The block size is normalized to $[0, 1]$ by the size of the file (line 14). The algorithm terminates once all cells have been touched. Regarding the complexity of this algorithm, assume there are n non-empty cells in a verbose CSV file. On the one hand, each cell will be visited once and only once, resulting a $O(n)$ complexity. On the other hand, the four directions of a cell are checked once the cell is visited, leading to a $O(4n)$ complexity. Therefore, the overall algorithm complexity is $O(n) + O(4n) = O(n)$.

Algorithm 1: Block size calculation

Input: The set of non-empty cells in a table C
Output: The set of key-value pairs BS from cells to block size

1 $BS \leftarrow \{\}$;
2 $V \leftarrow \{\}$ # *visited cells* ;
3 **while** $C - V \neq \emptyset$ **do**
4 $\quad c \leftarrow$ random cell in $C - V$;
5 $\quad bs \leftarrow 1$;
6 $\quad V \leftarrow V \cup c$;
7 $\quad B \leftarrow \{c\}$;
8 $\quad$ **while** *there exist cells in* $C - V$ *adjacent to* B **do**
9 $\quad\quad c_{adj} \leftarrow$ an adjacent cell in C;
10 $\quad\quad bs \leftarrow bs + 1$;
11 $\quad\quad V \leftarrow V \cup c_{adj}$;
12 $\quad\quad B \leftarrow B \cup \{c_{adj}\}$;
13 $\quad$ **end**
14 $\quad bs \leftarrow$ normalize(bs);
15 $\quad$ **foreach** $c \in B$ **do**
16 $\quad\quad BS \leftarrow BS \cup \{c : bs\}$;
17 $\quad$ **end**
18 **end**
19 **return** BS

5.3 Neighbor profile

Cells of some classes may be likely to have particular kinds of neighboring cells. For example, to highlight group header cells, users often separate them from other cells with empty cells, or they place derived cells at the margin of a table, as a way to summarize data. These observations bring our focus on the adjacency context of a cell: for each cell, we gather the data types and value lengths of all eight surrounding cells and present each as a single feature in the feature vector. The neighbor profile of a cell includes all these NeighborValueLength and NeighborDataType features. For the cells on the margins of a file, some adjacent cells do not exist. We set a default value for these non-existent adjacent cells, i.e., -1 for value length and data type.

5.4 Line class probability

Despite the possible flexible layout, verbose CSV files are usually organized in some structurally meaningful way. Lines tend to organize mostly homogeneous types of cells to ease human understanding. For example, a data line contains mostly data cells, while a header line contains mostly header cells. Table 3 displays statistics about the *cell class diversity degree* of all lines in our datasets. The cell class diversity degree of a line is its number of distinct non-empty cell classes. We observe that most lines a have diversity degree of 1: for the cells in these lines, their classes are trivially determined by the class of the line. Therefore, when determining the class of a cell, the class of the line it is located in

is likely a useful feature. In fact, we use this feature alone as one of our baselines.

Table 3: Percentage of lines under different diversity degrees.

	Diversity degree				
Dataset	1	2	3	4	5
SAUS	86.3%	13.7%	0%	0%	0%
CIUS	88.7%	11.2%	0.1%	0%	0%
DeEx	95.3%	4.6%	0.1%	0%	0%

To obtain the line class information, we first run $Strudel^L$ to obtain the prediction for each line. The result of this execution is, however, a probability vector of all classes, instead of a single predicted class. We interpret this probability vector as the classifier's confidence for these classes. Each element of the 6-dimensional vector accounts for a feature for the cell class detection.

5.5 Derived cell detection

If a cell is indeed a derived cell, it should be possible to derive its value by aggregating values of some other neighboring cells. This fact has not been considered by previous work, possibly due to computational cost. We propose a derived cell detection algorithm that seeks to identify derived cells by arithmetically correlating their values with other numeric cells.

We made three observations while investigating the datasets: (i) a derived cell usually aggregates the values of cells from its own row or column; (ii) a derived cell tends to aggregate values close to it; (iii) sum and mean are the two dominant aggregation functions used in verbose CSV files. We integrate these insights into our Algorithm 2. For conciseness, it shows only the approach for detecting derived sum cells.

The algorithm takes as input a table as a two dimensional array, the derived keyword dictionary to look for anchoring cells, an aggregation delta d to give some slack to aggregation results, and a coverage threshold c that controls the generality of aggregation results. Executing the algorithm produces all detected derived cells.

We first determine derived cell candidates, as calculating all aggregation possibilities for all numeric cells is prohibitively expensive. We found that some indicative words usually appear in a cell in the same row or column where there exist many derived cells. For example, for a row with many summing cells, words such as 'Total' are likely to appear in a cell of this row. Therefore, we mark those cells with any of our aggregation keywords (introduced in Section 4) as anchoring cells (line 2). Based on our first observation, only numeric cells in the same row or column as an anchoring cell are treated as derived cell candidates (line 6-8).

For the candidates in the same row as the anchoring cell, the algorithm looks first upwards and then downwards for possible aggregating relationships (line 9-19), whereas for the candidates in the same column as the anchoring cell, the algorithm looks left or right (line 20-30). When looking upwards, the algorithm adds numeric values of a row each time to the sum vector correspondingly, and inspects whether the current sum vector is element-wise close enough (according to d) to the candidates. If the coverage of the close enough elements in the sum vector surpasses c, the candidate is treated as a derived cell (line 14-17). Due to our second observation, a row closer to the row where the candidates are is inspected earlier than a row farther away.

Algorithm 2: Derived cell detection

Input: Table T, keywords K, aggregation delta d, coverage c
Output: All detected derived cell C_D

1 $C_D \leftarrow \{\}$;
2 $A \leftarrow$getAnchoringCells(T, K);
3 **if** *A is empty* **then**
4 **return** C_D;
5 **foreach** *a in A* **do**
6 $i_a, j_a \leftarrow$ row index of a, column index of a;
7 $C_R, cc_{ind} \leftarrow$ the list of numeric cells in row i_a and their column indices;
8 $C_C, rc_{ind} \leftarrow$ the list of numeric cells in column j_a and their row indices;
  /* line 9-19 for upwards detection */
9 $sum \leftarrow (0...0)$;
10 **for** $i = 1$ **to** ∞ **do**
11 **if** $i_a - i < 0$ **then**
12 **break**;
13 **else**
14 $v_o \leftarrow$ numeric values at cc_{ind} in row $(i_a - i)$;
15 $sum \leftarrow sum + v_o$;
16 **if** *coverage of* $(C_R - sum < d) > c$ **then**
17 $C_D \leftarrow C_D \cup C_R$
18 **end**
19 **end**
  /* repeat line 9-19 for downwards detection */
  /* line 20-30 for leftwards detection */
20 $sum \leftarrow (0...0)$;
21 **for** $i = 1$ **to** ∞ **do**
22 **if** $j_a - i < 0$ **then**
23 **break**;
24 **else**
25 $v_o \leftarrow$ numeric values at rc_{ind} in column $(j_a - i)$;
26 $sum \leftarrow sum + v_o$;
27 **if** *coverage of* $(C_C - sum < d) > c$ **then**
28 $C_D \leftarrow C_D \cup C_C$
29 **end**
30 **end**
  /* repeat line 20-30 for rightwards detection */
31 **end**
32 **return** C_D

6 EVALUATION

In this section, we first describe the datasets and all algorithms used in our experiments. After that, we present our experimental evaluation on Strudel, including its comparison with referenced approaches, analysis of feature importance and four advanced features on cell classification, and difficult case study for both line and cell classification tasks.

6.1 Datasets and experimental setup

This section first lists the datasets used in our evaluations, and the preprocessing steps applied thereon. In practice, verbose CSV files may have unique dialects. The dialect of a file specifies the delimiter, quoting character, and escape character, enabling to parse the lines and cells correctly. Therefore, as a general preprocessing, we first applied dialect detection on each file with the approach of van den Burg et al. [27]. This approach takes a text file as input, and produces its detected dialect. The scope of each cell or line is determined by that dialect. The second part of this section describes the list of baseline and competing approaches,

our Strudel approach, and their respective configurations for evaluation.

6.1.1 Datasets. Our datasets with verbose CSV files come from various sources, as summarized in Table 4. Only non-empty lines and cells are counted. The content of our datasets is given in the English language and follows a top-bottom / left-right organisation. Non-Western verbose CSV files might organize the content in a different fashion, which could be an interesting future work.

We created the dataset *GovUK* by crawling all data files in Microsoft Excel format (both in .xls and .xlsx) from an open data portal[4] and transforming them into corresponding CSV format with the Apache POI library[5]. While converting them to CSV files, we omitted both files that contain macros or were not otherwise processable by the library and empty sheets. We randomly selected a subset of 226 files from the dataset, and created a line-level ground truth for them. To perform the actual annotation, we implemented a tool to annotate each line as one of our element classes. Each line of each file in the created dataset was annotated by three human experts. In case of disagreement, which affected only 1% of the annotated lines, we used majority-vote to determine the annotation. For the lines with complete disagreement (fewer than 250 lines in our dataset), we employed an independent fourth annotator to determine which one of the three answers to apply. In the end, we obtained the ground truth for in total more than 110,000 annotated lines. We make all datasets publicly available[6].

Table 4: The dataset overview.

Dataset	# files	# lines	# cells
GovUK	226	97,212	1,382,704
SAUS	223	11,598	157,767
CIUS	269	34,556	367,172
DeEx	444	77,852	784,229
Mendeley	62	195,598	1,359,810
Troy	200	4,348	23,077

Three other datasets *SAUS*, *CIUS*, and *DeEx* were created and annotated by Ghasemi-Go et al. for cell classification [18]. The first two are administrative datasets, while the last one is a business dataset. More detailed descriptions of each dataset can be found in their original paper. The datasets were annotated by the original authors with a slightly different taxonomy. To reconcile their annotations to ours, we partly re-annotate their labels. In summary, they annotated all left-most headers of a table as *attributes*, while we consider them as data of their columns. In the example of Figure 1, they treat the cells that indicate the drug types in the second column as *attributes*, while we annotate them as *data*, as we model them as a data column of the table without a header. We also note that some clearly derived cells were marked as data: understandable errors due to their similarity, which we corrected. In many cases, derived cells form an entire line, with the exception of the leading cell, which is usually textual. This textual cell often includes keywords, such as 'Total', and is neither a derived cell nor a header cell. We treat it as *group* in our system, because a derived line often serves as a section separator in a table. Table 5 presents the class distribution of these three datasets with the reforged annotations.

Table 5: The number of lines or cells per class in the dataset *SAUS*, *CIUS*, and *DeEx* as a whole.

class	# lines	# cells	# cells per line
metadata	2,213	2,479	1.12
header	2,232	19,047	8.53
group	1,767	6,143	3.48
data	114,354	1,202,058	10.51
derived	1,406	76,996	54.76
notes	2,036	2,445	1.20
Overall	124,006	1,309,168	-

Our *Mendeley* data is a set of plain-text files collected from Mendeley's data sharing platform[7] of experimental data. These data are stored in research projects. We crawled all 2,214 projects whose data are stored on Mendeley's own server and that contain at least one plain-text file, i.e., whose MIME type is "text/*". This MIME type corresponds to a wide variety of actual file formats: not only files with table structures and verbose information, such as verbose CSV files, but also programming scripts, HTML pages, etc. We randomly selected 100 projects that include at least one suitable verbose text file, and obtain one such file from each project. Given the intricate dialects of these plain-text files, the dialect detection approach of [27] cannot reliably discover the correct dialect for all files. A file is *parse-able* if the dialect for the table region (including header, data, group, and derived) is correct. For our experiments, we kept the 62 parse-able verbose CSV files. Note that this dataset is used only to verify the performance of our approach on verbose plain-text files and is not part of. the training set. We observe a high line-to-file and cell-to-file ratio, because the files of this dataset are mostly used to store data, e.g., experimental results, rather than presenting statistical tables.

The last dataset, *Troy*, contains 200 CSV files collected from various government websites [17]. Embley et al. used this dataset in their work to convert different statistical tables to relational tuples [15]. We kept the dataset unseen during the design of Strudel to test the out-of-domain generalizability of our approach with this dataset.

In our data preparation process, we cropped each file by removing the marginal empty lines or columns, as some of our features are sensitive to the number of empty cells in the lines, and leading/trailing empty lines are trivial cases. Values of spanning cells in original spreadsheets are copied only to the top-left cell in the CSV file, instead of to all covered cells for two reasons: (i) the top-left is well-defined for all shapes of spanning cells and (ii) copying the values to all covered cells creates too many repeated characters, confusing the models that cause unnecessary over-fittings towards these values. To ease future study on this topic, we will publish all datasets and their annotations.

6.1.2 Setup of experiments. The list below contains all algorithms used in the evaluation, along with their corresponding configurations. All algorithms were implemented in Python with the scikit-learn library[8]. The superscript in the name of an algorithm indicates the type of elements detected by this algorithm, i.e., 'L' and 'C' represent line and cell classification, respectively.

- CRF^L is a conditional random field-based learning approach dedicated to line classification from the work of Adelfio et al. [2] as the current state of the art. We applied this approach with the logarithmic binning technique introduced by the authors, as this setting was reported to gain the best performance.
- $Pytheas^L$ is a rule-based approach that discover the locations of tables, and further classifies the lines in CSV files [8]. We use the parameter values introduced in the original paper for our experiments.
- $Strudel^L$ is our proposed approach for line classification. The underlying random forest classifier used the default settings in the scikit-learn library.
- $Line^C$ is a baseline approach for cell classification. This approach simply extends the predicted class of a line from the result of a $Strudel^L$ execution to each non-empty cell in this line.
- RNN^C is based on the state of the art by Ghasemi-Gol et al., which classifies cell types with a recursive neural network using pre-trained cell embeddings [18]. For our experiment, we used the same settings as introduced in the original paper.
- $Strudel^C$ is our approach for cell classification. Again, we used the default settings of the random forest classifier in the scikit-learn library. In our experiment, we do not observe a substantial difference in the result with different values of the aggregation delta d and coverage c. We set them to 0.1 and 0.5, respectively.

Apart from using content and spatial features, both original CRF^L and RNN^C applied stylistic or spreadsheet formula features. Because the input data in our use-case are style-less, verbose CSV files, we remove all stylistic features from the two approaches so as to conduct fair comparisons. Each algorithm is evaluated using 10-fold cross validation. When creating the folds, our process ensures that all elements from a single file appear in either the training or the test set. We repeat the 10-fold cross validation ten times to reduce bias leaning to particular fold splits. The results of all repetitions are averaged to obtain the final score.

We have tested several classification algorithms for Strudel, including Naïve Bayes, KNN, SVM, and random forest. Random forest consistently outperformed the other candidate algorithms on our datasets for both classification tasks. Therefore, we chose it as the backbone supervised learning algorithm of Strudel. The advantage of random forest over the other algorithms is that it reduces the risk of over-fitting by considering the results from multiple base classifiers, which is crucial for unbalanced datasets, such as verbose CSV files.

6.2 Comparative evaluation

This section presents the comparative evaluation results between Strudel and the referenced approaches. We use the F1 measure to evaluate the classification correctness of each approach for both line and cell classification tasks. When comparing the overall result amongst algorithms, we focus on the macro average, which does not weigh the average score with the support of individual classes, thus avoiding the bias from the number of

per-class instances, which is crucial for supervised learning tasks on imbalanced data.

6.2.1 Line classification. We compared *Strudel*^{L} with *CRF*^{L} and *Pytheas*^{L}. *CRF*^{L} uses a set of features, including content features, contextual features, and stylistic features to train a conditional random field based classifier on web tables and spreadsheets. *Pytheas*^{L} uses a number of weighted rules to decide whether a line is data or non-data. The binary results are used to draw the table top/bottom boundaries, on top of which the approach utilizes some additional rules to determine line classes.

Table 6 (top) reports the per-class and macro-average F1 scores, and accuracy for the three approaches. Note that *Pytheas*^{L} can classify a line as one of only five classes that correspond respectively to ours, missing the derived class. Therefore, when calculating the measurements for this approach, we leave out the derived lines from our datasets. Overall, our approach leads on macro-average for all datasets. *Pytheas*^{L} does not perform well in general on the minority classes in all but the *SAUS* datasets, as its proposed rules are not suitable for these datasets: they produce poor results already for the binary data/non-data classification, which disrupts the subsequent table discovery and line classification. Group lines are particularly difficult for *Pytheas*^{L}: the scope of group lines is constrained to lines between data lines and has only the leftmost cell non-empty. While the group lines in *SAUS* mostly follow this definition, those in the other datasets do not. Most header lines of both *SAUS* and *CIUS* are across few lines and with simple structures. Therefore, recognizing those headers correctly is easier. Since the rule used to determine metadata lines is dependent only on the positions of headers, it is also easier to recognize metadata in these two datasets.

For *CRF*^{L} and *Strudel*^{L}, classifying header, group, derived and notes correctly is in general more challenging, compared to metadata and data, according to the per-class scores. Both algorithms perform better on *CIUS* than on the other datasets, because many files in this dataset are essentially the reports from different years on the same themes with the same templates – there are few file structure outliers. Both approaches do not work well on *derived* in *SAUS*, because the dataset has many unanchored derived cells. *GovUK* and *DeEx* are difficult to both approaches, because they both have many heterogeneous files regarding their structures.

In summary, *Strudel*^{L} outperforms *CRF*^{L} without using its stylistic features on our datasets, showing that our approach is more effective when fewer assumptions can be made about the input. *Strudel*^{L} is also more flexible than rule-based approaches such as *Pytheas*^{L} in predicting cases that are not covered by the given rule set.

6.2.2 Cell classification. For the cell classification task, we compare *Strudel*^{C} with two aforementioned algorithms: (i) *Line*^{C} provides a reasonable baseline, as most lines have homogeneous cells; (ii) *RNN*^{C} is based on an advanced deep learning architecture. The authors of *RNN*^{C} evaluated their approach also without stylistic features, which allows a fair comparison to *Strudel*^{C}. Table 6 (bottom) summarizes the comparative result in terms of the per-class and macro-average F1 score, and accuracy. *Strudel*^{C} surpasses its competitors . Meanwhile, the macro-average of *RNN*^{C} shows an advantage against the baseline approach, although the per-class scores of the two approaches are on par with each other. Even though cell classification is a more imbalanced task than line classification, the performance of our *Strudel*^{C} approach is comparable to its line counterpart.

Similar to the line classification problem, metadata, group, derived and notes are the difficult classes in general. *Group* cells are challenging for all approaches, as cells of this class are particularly rare. However, unlike other rare classes, such as metadata and notes, group cells are more likely to co-occur in the same line with data cells. *Line*^{C} reported low F1 score particularly on group and derived cells across datasets. In fact, both group and derived cells often co-occur with other types in the same lines: some tables contain a group cell in a line with several derived cells; other tables have derived columns rather than lines, therefore causing the few derived cells in a same line with multiple data cells. Group and derived cells usually account for a minor amount in these cases.

Line^C applies a majority-take-all strategy to extend the line prediction result of a line to all its non-empty cells, and therefore causes false negative for group and derived cells in the above two cases. *RNN*^{C} shows a low F1 score on the group class, which is not considered in the original paper [18], showing that the approach cannot be directly adapted to it. The set of the reforged derived cells, many of which were misplaced in the original annotations, is also troublesome for *RNN*^{C}, which does not involve value calculation mechanisms to detect them.

6.3 Strudel performance evaluation

In this section, we present experimental results to gain insights on the following questions: (i) When does Strudel mis-classify an instance of a particular class, and which class is most likely to be considered? (ii) Whether our approaches generalize to plain-text files that do not stem from spreadsheets? (iii) How do the features exploited in this work affect performance? (iv) What are the typical reasons that cause these incorrect predictions?

6.3.1 Line classification. Table 6 has introduced the per-class and overall F1 results of *Strudel*^{L}. In this section, we present our analysis of the classification results by using the confusion matrix. Figure 3 (top) shows the confusion matrix on executing *Strudel*^{L} per dataset. Due to space limitations, we leave out the matrix for *SAUS*, which is very similar to that for *GovUK*. To create a confusion matrix with the repeated 10-fold cross validation setting, we concatenate for each line in the files the predictions of all repetitions, and construct an ensemble prediction for it with the majority voting strategy. To resolve possible ties, we stipulate that the fewer instances of a class included in the dataset, the more prior the class is. We normalize the confusion matrix by the number of instances with particular classes.

Correctly identifying derived lines is the most challenging task across all datasets. These lines are mostly misclassified as data. The two main reasons for this are the lack of derived line training instances and the high similarity between derived and data lines, w.r.t. data types and spatial characteristics. Around 11.4% of the derived lines are treated as headers for *GovUK*. We observed this to happen in many tables where derived lines are between header and data areas and separated from these two areas by empty lines. Note that when a line of a minority (non-data) class is misclassified, the wrong prediction tends to be 'data', as the data class has much more instances than any other class. Apart from derived lines, header, group, and notes lines in *DeEx* also incorrectly lean towards the data class, because this dataset contains many tables of complicated structures. We discuss the kinds of mistakes in these categories in Section 6.3.6.

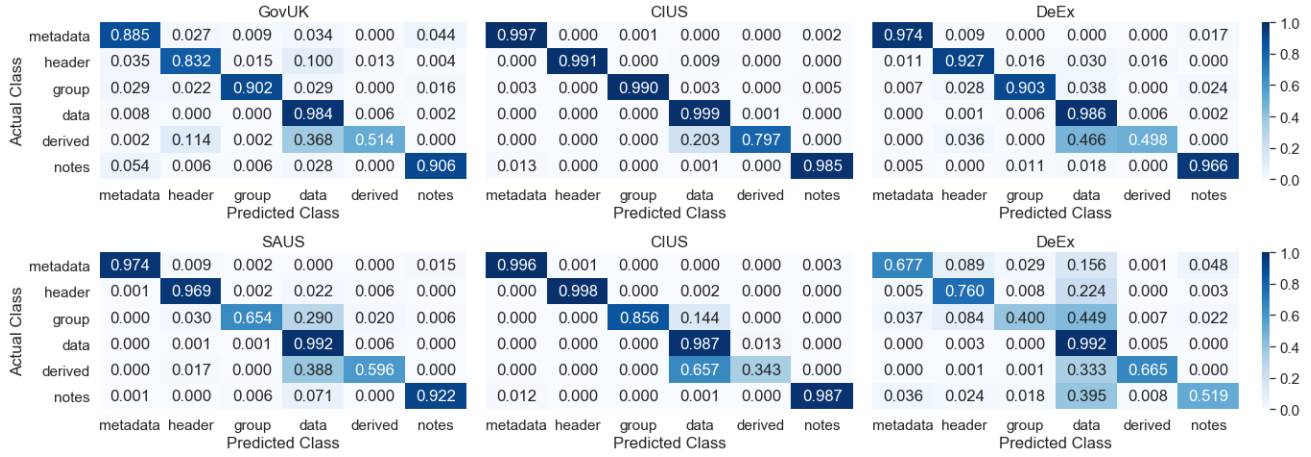

Figure 3: Confusion matrices to describe the pair-wise performance of *Strudel*^{L} (top) and *Strudel*^{C} (bottom) on individual datasets. The numbers are normalized by the amount of instances per class.

6.3.2 Cell classification. Similar to line classification experiments, we performed a set of experiments for evaluating *Strudel*^{C} and show the results in this section. Figure 3 (bottom) depicts the per-dataset confusion matrix on executing *Strudel*^{C}. To create it, we applied on the repeated cross validation results the same procedure used to create the confusion matrix for *Strudel*^{L}.

Compared to the confusion matrix of *Strudel*^{L}, more classes have a higher mis-classification ratio for all three datasets, showing that cell classification is a more challenging task than its line counterpart. On the one hand, the tendency to mark the instances of the minority classes as data is still prevalent. On the other hand, as the complexity of the problem increases, we do not observe many classification errors between two non-data classes, showing the effectiveness of our approach to distinguish between pairs of elements belonging to minority classes. About two-thirds of the derived cells are treated as data for *CIUS*. This is because a number of files share a fixed table schema that uses no keywords to indicate derived columns. Therefore, they are effectively ignored by the derived cell detection component.

6.3.3 Out-of-domain classification performance. To test the out-of-domain classification performance of Strudel, we kept the *Troy* dataset unseen during its design. We used a model trained on the collection of *SAUS*, *CIUS*, *DeEx* datasets to predict the line and cell classes of each file in this dataset.

The results in Table 7 show that group and derived cells are challenging for Strudel. After inspection, we found out that most of the derived cells lay in the lines that do not contain any derived keyword, such as 'total'. These derived cells are excluded from the candidate set, because our derived cell detection algorithm (Algorithm 2) relies on these keywords to anchor the candidates in order to reduce the search space. A typical derived line contains few group cells (usually the left-most) with indicative strings, such as 'total' and a number of numerical derived cells. Many of these derived lines are mis-classified as data, leading to the group cells therein also being mistaken.

6.3.4 Performance on plain-text files. To verify the effects of our Strudel algorithms on more difficult plain-text files that are not converted from spreadsheets, we tested the Strudel algorithm on the *Mendeley* dataset. We trained a model of our algorithm on the collection of *SAUS*, *CIUS*, and *DeEx* datasets, using the whole *Mendeley* dataset for testing.

Table 7: Per-class and overall F1 score on the *Troy* dataset.

	Strudel^L	*# lines*	*Strudel*^{C}	*# cells*
metadata	.935	317	.921	321
header	.798	278	.840	1,341
group	.667	42	.232	294
data	.937	2,898	.936	18,600
derived	.070	239	.216	1,935
notes	.971	575	.952	592
macro-avg	.730	4349	.683	23,083

Table 8 displays the per-class and overall F1 score for this experiment. As mentioned above, files of the *Mendeley* dataset are mostly used to store (tabular) data. Therefore, the minority classes in the *Mendeley* dataset have very few instances.

While the overall F1 scores in this experiment are inferior to the respective ones shown in Table 6, they do show that even for such difficult files our approaches are well able to distinguish data from non-data. The values in *Mendeley*'s plain-text files show properties different from traditional spreadsheets, e.g., length of metadata and notes areas, width of files. The second reason is that no data from *Mendeley* was included in the training phase. Therefore, dataset-specific properties are not learned properly by the classifiers. Last but not least, different areas in a plain-text file might have their own delimiters. As the delimiter of the table areas is used across the file, it is possible to destroy the intrinsic structures of other areas, e.g., when using comma as the delimiter, the value of a note line is split across multiple cells.

Regarding the results of individual classes, our model treats quite a few metadata lines as data, as the delimiter of metadata and data areas are different. At times, the delimiter dilemma also confuses our model of header lines in files where these lines are not split correctly. Out of the few derived cells, most are located in a single file, where the derived cells form a table by themselves, and aggregate on the values from another table, which is not recognizable by our model.

As the *Mendeley* dataset holds the biggest files across all our datasets, we also tested the scalability of our approach. The overall runtime on classifying cells of a file includes that of dialect

detection, feature creation, and cell class prediction. Our experiments show that the overall runtime is linear to the file size. For a file of around 10MB, the whole procedure takes around 256s on a 1.4 GHz MacBook Pro with 16GB RAM. Most of the time is spent on creating the feature vectors, which could be easily parallelized if possible. While we have few big files of such size, most files are only several kilobytes, probably because files with verbose information are usually used to show limited key information, rather than store a big amount of data.

Table 8: Per-class and overall F1 score for *Mendeley*.

	Strudel^L	# lines	*Strudel*^{C}	# cells
metadata	.623	604	.245	2,152
header	.406	86	.629	769
group	.263	27	.303	44
data	.999	194,786	.999	1,356,635
derived	.364	9	.051	99
notes	.448	86	.380	111
macro-avg	.517	195,598	.435	1,359810

6.3.5 Feature analysis. To understand which features exert more influence than others on particular classes, we calculated the feature importance for both *Strudel*^{L} and *Strudel*^{C} models. There are a variety of techniques to calculate feature importance [3, 21]. As many of our features are low-cardinality categorical features, we exploited permutation feature importance, because it does not favor high cardinality features [3]. Permutation feature importance indicates the ability of one feature to distinguish instances of one class from those of another in a binary classification scenario. To adapt this metric to our multiclass classification problem, we trained a model for each class in a one-vs.-rest fashion, and use the permutation feature importance of each such binary classifier to represent the ability of our model to detect instances of the particular class. The permutation of each feature was repeated five times and averaged.

Figure 4 illustrates the per-class feature importance for *Strudel*^{L} (top) and *Strudel*^{C} (bottom) with 100% stacked bars. The models are trained on the collection of *SAUS*, *CIUS*, and *DeEx*. We grouped all neighbor profile features (Section 5.3) into neighbor value length and neighbor data type to reduce the complexity of the figure, as each individual feature has little importance on the cell classification task. Up to five most important features whose proportions are higher than 10% are highlighted.

The line type probability feature is the most crucial feature for notes, metadata, and header. The percentage of empty cells in the row is also quite useful for notes and metadata. The percentage of empty cells in a column is most important to discover group cells: many group cells are in the left-most column (also indicated by the importance of the column position feature) of a file and span multiple rows. Neighbor profile features are most useful on discovering group cells, proving that group cells tend to locate in specific places. The novel feature signifying whether the value of a cell is the aggregation of other cells in the same line or column plays a great role in detecting derived cells, proving its effectiveness. Besides that, the existence of derived keywords, such as 'total' in the same column is also important, indicating that users tend to use these words to mark the derived columns. However, the existence of derived keywords in the same line shows quite limited importance in our experiment, although we expected similar importance of it as its column counterpart.

6.3.6 Analysis of difficult cases. The confusion matrices shed light on which classes are most commonly mis-predicted, either in the line or cell classification task. Here, we identify typical causes of those errors. The list below describes the pairs of common mis-classification cases (with > 10% incorrect classification in the class), e.g., mis-classifying 'derived as data', each followed by an error analysis after manually inspecting the results.

- **Derived as data.** Errors of this type usually happen because derived lines without keywords, such as 'total', in any of the cells are ignored by the derived cell detection algorithm, which uses these words to determine candidates, or because derived lines aggregate values from non-consecutive lines, which are ignored by the detection algorithm.
- **Header as data.** A header line with a number of non-textual values adjacent to a data line may be mis-classified as part of the data area. Examples include numeric headers, such as year and date. Files with multiple vertically-stacked tables may also be affected by this sort of error, as the headers of the tables towards the bottom of the stack have unusual line positions.
- **Notes as data.** Organizing notes as a small table is not uncommon, particularly in *DeEx*. Therefore, these tables of notes are likely to be treated as data. In some cases, authors place notes to the right of a table. Therefore, they are likely to be treated as data areas during cell classification.
- **Group as data.** One reason for this type of error is that some files have multi-level group columns, such as 'country-state-city', to the left of a table, followed by a number of data columns to the right. As most tables have few group columns, the classifier may mis-interpret these rare cases as data. Another reason is that these group cells lay in the same lines as those derived cells, who are not captured by the derived cell detection algorithm, because there is no keyword in the same row or column.
- **Metadata as data.** Tables may have elaborate metadata organized as small tables. Due to the tabular features of these metadata tables, Strudel tends to interpret them as data cells.

In summary, there are three aspects that mostly affect the correctness of our approach: (i) the geographical characteristic of vertically stacked multi-table files; (ii) the arithmetic calculation method for derived lines; (iii) the similarity between numeric header lines and data lines. These facts offer directions for improving our approach in the future work.

7 CONCLUSIONS

Often, valuable data are stored in semi-structured documents and cannot be directly parsed by common data management tools. Prior to extracting information from these files, it is necessary to understand their structure, by means of element classification, at either line or cell level. Previous works have addressed the line or cell classification problem for style-enriched documents, such as web tables or spreadsheets. In this work, we address both tasks on verbose CSV files that, similar to spreadsheets, organize data in a flexible layout, yet lack rich-text features. We addressed the two classification problems separately and designed a set of features for each of them, including content features, contextual features, and computational features.

Based on the experimental evidence, we discovered that with well-designed features, it is possible to reach decent performance of classifying lines and cells in a verbose CSV file and spreadsheets even if the stylistic features are not available. To conduct fair comparison between Strudel and related work, we use only the non-stylistic features. We summarize a handful of reasons that

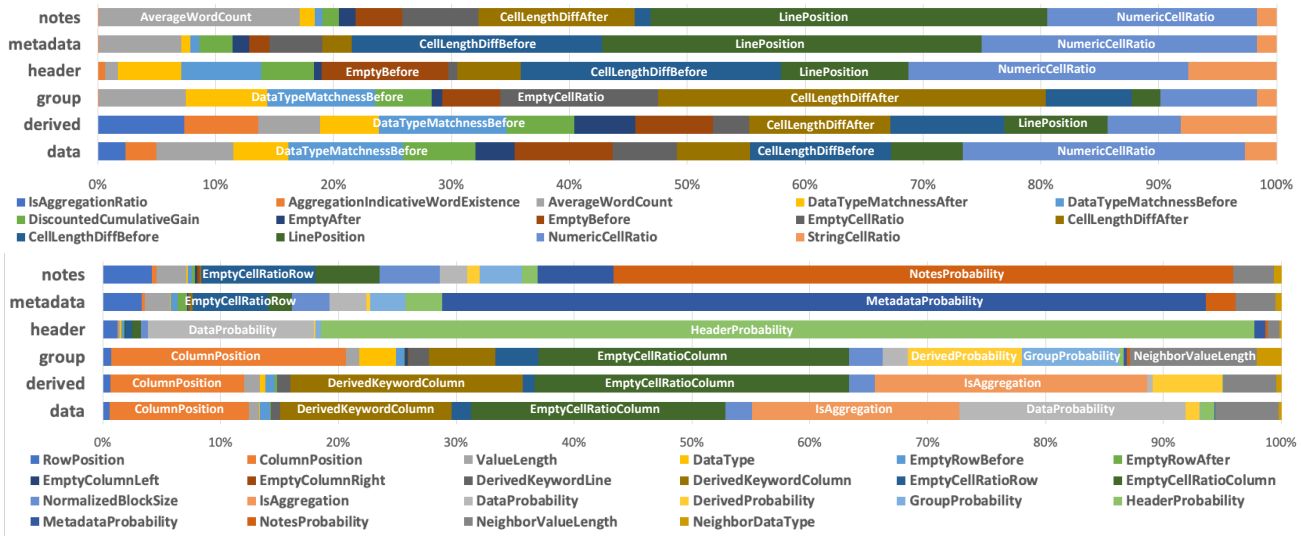

Figure 4: Feature importance of *Strudel*^{L} (top) and *Strudel*^{C} (bottom) trained on the collection of *SAUS*, *CIUS*, and *DeEx*. Several most important features for each class are highlighted.

cause common misclassification cases, and recognize the effectiveness of computational features that are neglected by former studies, drawing key insights for further structure understanding research: (i) how to improve the prediction quality with semantic features; (ii) how can we extend the derived cell detection algorithm by recognizing more aggregation functions; (iii) whether column classification can help boost the classification quality.

FRESQUE: A Scalable Ingestion Framework for Secure Range Query Processing on Clouds

[1]Univ Rennes & CNRS & IRISA, [2]UC Santa Barbara, [3]Can Tho University

ABSTRACT

Performing non-aggregate range queries over encrypted data stored on untrusted clouds has been considered by a large body of work over the last years. However, prior schemes mainly concentrate on improving query performance while the scalability dimension still remains challenging. Due to heavily pre-processing incoming data at a trusted component such as encrypting data and building secure indexes, existing solutions cannot provide a satisfactory ingestion throughput. In this paper, we overcome this limitation by introducing a framework for secure range query processing, FRESQUE, that enables a scalable consumption throughput while still maintaining strong privacy protection for outsourced data. Our experiments on real-world datasets show that FRESQUE can support over 160 thousand record insertions in a second, when running on a 12-computing node cluster. It also significantly outperforms one of the most efficient schemes such as PINED-RQ++ by 43 times on ingestion throughput.

1 INTRODUCTION

With the prosperity of online social networks and web-based services, a large amount of personal data is collected every second. To achieve analytical and administrative purposes, it becomes increasingly desirable for modern systems to support not only low-latency queries, but also intensive ingestion throughput over incoming data. For instance, to reduce the impact of seasonal epidemics (e.g., influenza), participatory surveillance systems, to name few, have been deployed in recent years such as Flu Near You [2] in North America, Influenzanet [16] in Europe, and FluTracking [3, 9] in Australia and New Zealand. These systems weekly collect symptoms from their participants to track influenza nation-wide. Such systems are expected to receive a huge number of records every second.

Due to the significant costs necessary for building and maintaining such systems (e.g., computing and scalability requirements, human resources), it may be worth to outsource user data to a cloud service, that can provide lower costs and enable elastic scaling [14]. However, parts of the data may be sensitive, e.g., participants' symptoms, and sociodemographic data (age, gender, etc.). Managing sensitive data on a public cloud increases the risk of unauthorized disclosure since its infrastructure may be compromised by an adversary. According to a recent survey, 52% of companies use cloud services that have experienced a data breach [18].

This paper considers the following cloud computing model (Figure 1): a collector receives data from multiple data sources and stores them on a cloud while a client retrieves the data by using queries. For a simple example, Flu survey participants submit electronic medical records to a Center for Disease Control and Prevention (CDC) that stores the collected data on a cloud. An epidemiologist queries these records from the cloud. In this model, only the cloud is untrusted while the others are trusted.

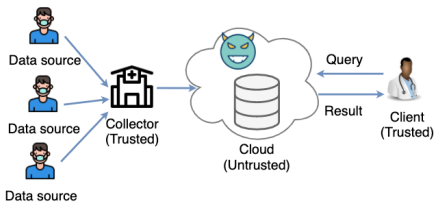

Figure 1: An architecture of cloud computing

Encryption is a standard technique to ensure the confidentiality of data stored on untrusted environments like clouds [29, 32, 35]. In this study, we focus on non-aggregate range queries over encrypted data since they are fundamental operations. For example, a doctor, Alice, wants to get encrypted electric records of the patients whose ages are between a and b. One example of a range query (expressed with SQL) can be: SELECT * FROM database WHERE age $\geq$ a AND age $\leq$ b.

Although many studies in this line of work have been done over the last years [5–8, 10, 19, 20, 24, 26, 30, 31, 36], none of them satisfies real-life scalability requirements. It is also non-trivial to scale these schemes due to their own limitations. For instance, Hidden Vector Encryption (HVE) methods [8, 36] use bilinear groups equipped with bilinear maps and hide attributes in an encrypted vector. However, they suffer from high latency because it is extremely costly to compute exponentiation and pairing in a composite-order group. Meanwhile, some recent schemes [10, 23, 24] attempt to maintain secure indexes, that rely on *Searchable Symmetric Encryption*, for efficiency. Unfortunately, the secure indexes not only create high space overhead, but also require at least hundreds of second for construction that may lead to bottlenecks. Even though ArxRange [30] does not experience long index building time, it incurs prohibitive storage overhead and only supports a modest ingestion throughput, e.g., about 450 writes per second with caching. Recently, solutions based on differential privacy [11], e.g., the PINED-RQ family [33, 34], have been considered and achieve very good performance in terms of computation and space requirements, however, they do not render a satisfactory ingestion throughput. In particular, PINED-RQ [33] incurs congestion as incoming data rate is high. Meanwhile, PINED-RQ++ [34] experiences modest throughput, ~46K records/s.

Therefore, we aim at developing a scalable ingestion framework dedicated to secure range query processing. To the best of our knowledge, this is the first paper about the architecture of such system. Our solution is developed based on the PINED-RQ family [33, 34]. This choice is motivated by the fact that this family can achieve both fast range queries and provable security guarantees while the secure index requires small space. More specifically, we re-design the architecture of PINED-RQ++ [34] in order to make it fully distributed. That is, we attempt to distributively process all heavy tasks (e.g., parsing and encrypting data) on a

set of *shared-nothing* machines[1]. By relying on such architecture, the system can easily scale. Additionally, we introduce a data representation and an asynchronous publishing method to decrease throughput degradation as much as possible. By precisely coordinating all of them together, our framework can enable intensive ingestion throughput. Experimental results show that as compared to (non-)parallel PINED-RQ++ [34], the throughput is improved by (~43×) ~5.6× respectively (NASA dataset [1]). Furthermore, we also present a new noise management mechanism to cope with strong online attackers having background knowledge about the time distribution of incoming data. This method also improves the practicality of FRESQUE since it does not require a pre-defined timestamp distribution as in PINED-RQ++ (see Section 4.1). In this study, we develop **FRESQUE**, a scalable ingestion **fr**am**e**work for **s**ecure range **que**ry processing on cloud, including the following contributions.

(1) We thoroughly analyze the architecture of the PINED-RQ family [33, 34], and point out obstacles that prevent the existing architecture from achieving a high ingestion throughput. Also, we propose an approach to cope with offline and online attackers while minimizing the required knowledge of the collector.
(2) We design an ingestion architecture that enables to distribute all heavy jobs to multiple workers (computing nodes) of a cluster. Besides, we present and integrate a data representation and an asynchronous publishing method to this architecture, mitigating throughput degradation.
(3) We extensively evaluate FRESQUE on real-world datasets to demonstrate its scalability. Particularly, the throughput of FRESQUE is about 43× higher than that of PINED-RQ++ and being at least one order of magnitude higher than that of other efficient solutions such as [6, 30, 31].
(4) We formally analyze the security of FRESQUE.

The paper is structured as follows. In Section 2, we briefly introduce the problem statement. Section 3 reviews the related work. We analyze the architecture of the PINED-RQ family in Section 4. We then describe our framework in Section 5. Section 6 gives security analyses while Section 7 presents our experimental results. We discuss an application of our solution in Section 8. Section 9 concludes the paper and gives future work.

2 PROBLEM STATEMENT

We assume that data sources produce a set of records where all records have the same number of attributes. These records are immediately sent to the collector. The dataset stored at the collector is a relation $D(A_1, \ldots, A_n)$, where A_i is an attribute. Queries are non-aggregate one-dimensional range queries. A query Q is evaluated over the attribute A_q of D, which contains numerical values. Periodically, the collector pre-processes the dataset, e.g., building a secure index over the dataset and encrypting it, prior to sending it to the cloud.
In this study, we concentrate on the scalability dimension of the system in terms of ingestion throughput. This metric measures how many records a system is able to consume within a time period. The target solution should meet additional requirements, namely formal security guarantees, supporting updates, and incurring practical storage overhead.

[1]We take the shared-nothing architecture into account since it is highly scalable.

2.1 Threat model

We consider the *honest-but-curious* model [15]. In this model, an attacker examines data stored on the cloud to glean sensitive information, but follows the protocol as specified and does not change the datasets or query results. Also, we consider three types of attackers : (1) the *offline* attacker is able to access a copy of the encrypted datasets and secure indices (e.g., by stealing the hard drives), (2) the *online* attacker is able to observe any information available at the cloud or being exchanged between the cloud and the trusted components, and (3) the *informed online* attacker is an online attacker that further has background knowledge about the data distribution of the incoming time of real data.

2.2 Security

2.2.1 Differential privacy. The ϵ-differential privacy model [11] requires that any possible individual record can only have a limited impact on the output distribution of an ϵ-differentially private function. This model considers a very strong adversary that is not computationally-bounded (information-theoretic guarantees). Definition 1 gives a formal definition.
Definition 1 (ϵ-differential privacy [11, 13]): A randomized mechanism $\mathcal{M}$ satisfies ϵ-differential privacy, if for any set $O \in Range(\mathcal{M})$, and any datasets $\mathcal{D}$ and $\mathcal{D}'$ s.t. $\mathcal{D}$ is $\mathcal{D}'$ with one record more or one record less,

$$Pr[\mathcal{M}(\mathcal{D}) = O] \leq e^{\epsilon} \cdot Pr[\mathcal{M}(\mathcal{D}') = O]$$

where ϵ represents the privacy level. A smaller ϵ means stronger privacy level. The Laplace mechanism is the most common method to achieve ϵ-differential privacy.
Laplace Mechanism [12]: Let $\mathcal{D}$ and $\mathcal{D}'$ be two datasets such that $\mathcal{D}$ is $\mathcal{D}'$ with one record more or one record less. Let $Lap(\beta)$ be a random variable that has a Laplace distribution with the probability density function $pdf(x, \beta) = \frac{1}{2\beta} e^{-|x|/\beta}$. Let f be a real-valued function, the Laplace mechanism adds $Lap(max \parallel f(\mathcal{D}) - f(\mathcal{D}') \parallel_1 / \epsilon)$ to the output of f, where $\epsilon > 0$.
Theorem 1 (Sequential Composition [27]): Let $\mathcal{M}_1, \mathcal{M}_2, \ldots, \mathcal{M}_r$ denote a set of mechanisms and each $\mathcal{M}_i$ gives ϵ_i-differential privacy. Let $\mathcal{M}$ be another mechanism that executes the sequence of $\mathcal{M}_1(\mathcal{D}), \mathcal{M}_2(\mathcal{D}), \ldots, \mathcal{M}_r(\mathcal{D})$. Then $\mathcal{M}$ satisfies $(\sum_{i=1}^{r} \epsilon_i)$-differential privacy.

2.2.2 Semantic Security. Loosely speaking, a cryptosystem is semantically secure if it is infeasible for a computationally-bounded adversary, i.e., a probabilistic polynomial algorithm, to derive significant information about plaintext from its ciphertext and any auxiliary information, e.g., obtained from external sources. Today, AES (in CBC mode) is the common instance of efficient private key encryption schemes satisfying semantic security.
Definition 2 (Semantic security [15]): A private key encryption algorithm E_χ, where χ is the secret key, is semantically secure if for every probabilistic polynomial time algorithm A there exists a probabilistic polynomial time algorithm A' such that for every input dataset $\mathcal{D}$, every auxiliary background knowledge $\zeta \in \{0,1\}^*$, every polynomially bounded function $g : \{0,1\}^* \rightarrow \{0,1\}^*$, every polynomial $p(\cdot)$, every sufficiently large $n \in N$, it holds that:

$$Pr[A_n(E_\chi(\mathcal{D}), |\mathcal{D}|, \zeta) = g(\mathcal{D})] < Pr[A'_n(|\mathcal{D}|, \zeta) = g(\mathcal{D})] + \frac{1}{p(n)}$$

2.2.3 Unified privacy model. Sahin *et al.* [33] is based on a probabilistic relaxation of a variant of differential privacy that considers computationally bounded adversaries [28] and that considers the cryptographically-negligible leaks due to the use of efficient real-world encryption schemes, i.e., AES in CBC mode. Definition 3 is a simplification of ϵ_n-SIM-CDP, the simulation-based computational differential privacy model proposed in [28].

Definition 3 (ϵ_n-SIM-CDP privacy [28]): The randomized function f_n provides ϵ_n-SIM-CDP if there exists a function F_n that satisfies ϵ_n-differential-privacy and a polynomial $p(\cdot)$, such that for every input dataset $\mathcal{D}$, every probabilistic polynomial time adversary A, every auxiliary background knowledge $\zeta \in \{0,1\}^*$, and every sufficiently large $n \in N$, it holds that:

$$Pr[A_n(f_n(\mathcal{D},\zeta)) = 1] - Pr[A_n(F_n(\mathcal{D},\zeta)) = 1] \leq \frac{1}{p(n)}$$

Definition 4 ((ϵ,δ)-Probabilistic-SIM-CDP [33]): A randomized function f_n satisfies (ϵ,δ)-Probabilistic-SIM-CDP, if it provides ϵ_n-SIM-CDP to each individual with probability greater than or equal to δ, where $\delta \in [0,1]$.

3 RELATED WORK

In this section, we briefly review prior schemes with respect to the target requirements. Table 1 gives the corresponding summary.

Table 1: Prior schemes with respect to target requirements

PINED-RQ family [33, 34]	✓	✓	✓	✓

Hidden vector encryption (HVE) methods [8, 36] employ asymmetric cryptography to conceal attributes in an encrypted vector. A range predicate is privately evaluated on such vector. However, these schemes incur prohibitive computation and storage costs.

Bucketization approaches [17, 19, 20] partition an attribute domain into a finite number of buckets. Each bucket is then assigned by a random tag (bucket-id). When the client sends a range query to the server, the buckets that intersect the query are determined by using the index tag stored at the client. All contents of the intersecting buckets are finally returned to the client. These approaches lack formal privacy guarantee.

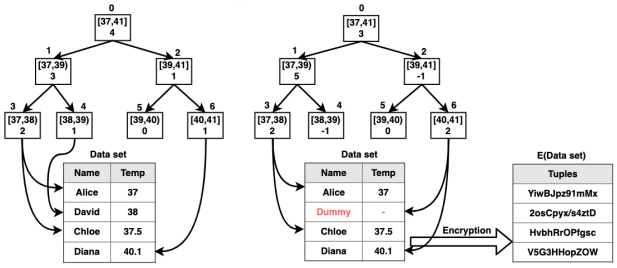
Order-preserving encryption schemes (OPE) [5–7, 26, 31] transform plaintexts into ciphertexts so that the relative order of their plaintexts is preserved. This property enables to efficiently execute range predicate evaluation on encrypted data. Unfortunately, OPE schemes disclose the underlying data distribution, and hence they are vulnerable to statistical attacks.

Recently, a few works have taken indexing solutions into account such as [10, 23, 24, 30, 33]. These schemes seek to maintain a secure index over outsourced data for fast range query processing. However, most of them [10, 23, 24, 30] suffer from prohibitive storage overhead. On the other hand, Sahin et al. [33] introduce an approach constructing *clear* secure indexes, called PINED-RQ indexes, for serving efficient range queries. The efficiency is enabled by the secure index while the security relies on computational differential privacy guarantees. Although PINED-RQ index is small in space, this scheme publishes data in batches, hence suffering from bottlenecks in the system as data arrives at high speed. Tran et al. [34] later introduce an index template-based approach, PINED-RQ++, to handle this limitation. Similar to prior schemes, high ingestion throughput still remains challenging for these solutions.

As shown in Table 1, the PINED-RQ family outperforms its counterparts with regard to the target requirements. To achieve our goal, we thus develop our solution based on this family. Particularly, we address the drawback of modest throughput in PINED-RQ.

4 ANALYSIS OF THE PINED-RQ FAMILY

This section gives thorough analyses of the PINED-RQ family [33, 34] and points out their drawbacks. Based on them, we develop our solutions in the Section 5.



(a) Clear index **(b) Perturbed index**

Figure 2: Sample PINED-RQ index

4.1 Overview

Building index. There are two primary steps to build a secure PINED-RQ index.

Step 1 - Building an index. PINED-RQ is inspired from B+Trees. In PINED-RQ, the set of all nodes is defined as a histogram covering the domain of an indexed attribute (e.g., the participants' body temperature (Temp)), as illustrated in Figure 2a. Each leaf node has a count that represents the number of records falling within its interval. It also keeps pointers to those records. Likewise, the root and any internal node have a range and a count, combining the intervals and the counts of their children, respectively.

Step 2 - Perturbing an index. All counts in the index are independently perturbed by Laplace noise [12]. The noise may be positive or negative, thereby after this step, the count of a node may increase or decrease, respectively. As shown in Figure 2b, the count of node 4 changes from 1 to -1 while the count of node 6 changes from 1 to 2. Such changes consequently lead to inconsistencies between the noisy count of a leaf node and the number of pointers it holds. To address this issue, PINED-RQ adds dummy records to the dataset when a leaf node receives positive noise, otherwise, if a leaf node receives negative noise, real records are removed from the dataset. The records removed are then inserted into the corresponding *overflow array* which is a fixed-size array. This overflow array is filled with dummy records if it has free space. As illustrated in Figure 2b, the record (David) belonging to node 4 is removed from the dataset while one dummy record is added and linked to node 6. Lastly, the perturbed index, the encrypted dataset, and the overflow arrays are published to the cloud.

Query processing on indexed data. A range query will start from the root of an index. It then traverses the child of any node that has a non-negative count and intersects with the query range. This is repeated recursively until the leaves of the index are reached. At the leaves that overlap the query range, their records and overflow arrays are returned.

Building index with index template. To adapt PINED-RQ to

the context of high rate of incoming data, Tran et al. [34] have previously developed PINED-RQ++ that builds a secure index based on the notion of *index template*. In particular, the collector initially creates an index template and perturbs it by using Laplace noise. This means that the count of bins at first contains only noise. The real count of bins will be updated during a *publishing time interval*, which is defined as the period from when an index template is created to when it is published. During a publishing time interval, whenever a new record arrives, the index template is updated with the record. Next, the collector encrypts and forwards this record to the cloud. At the end of each publishing time interval, the updated index template is published, and the cloud associates it with earlier published records to produce a secure index.

To manage positive noise, being represented by dummy records, the collector can send dummy records to the cloud according to the actual distribution of the sending time of the real records. On the other hand, for negative noise, if a leaf node initially receives negative noise c, the collector moves the first c records (when they arrive) of that leaf node to the corresponding overflow array.

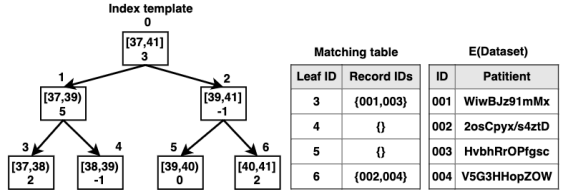


Figure 3: Perturbed index template and matching table (the corresponding PINED-RQ index is presented in Figure 2b)

To privately keep the relationships between published records and index template leaves, PINED-RQ++ utilizes a *matching table* (see Figure 3). In particular, a record is tagged by a random number instead of the real id of a leaf prior to being sent to the cloud. When the matching table is published at the end of each publishing time interval, the cloud uses it to reconstruct pointers between leaves and published data.

Generally, the workflow at the collector starts with initiating a new index template. When new data arrives, it sequentially passes a series of components, as depicted in Figure 4.

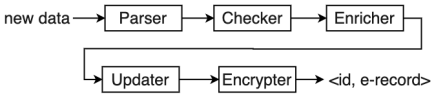

Figure 4: Workflow at the collector of PINED-RQ++

- **Parser** transforms incoming data into a pre-defined format.
- **Checker** buffers the parsed record at the collector as its indexed attribute belongs to a negative leaf. The index template is then updated. Otherwise, that record is forwarded to the next component.
- **Enricher** adds a random number (id) to the record.
- **Updater** updates the index template and matching table based on the record.
- **Encrypter** encrypts the record and gets e-record (encrypted record). The encrypter finally sends a pair of <id, e-record> to the cloud.

Parallel architecture of PINED-RQ++. Since the heavy workflow greatly degrades the throughput at the collector, Tran et al. [34] have introduced a parallel version of PINED-RQ++. Its overview architecture is depicted in Figure 5. Parallel PINED-RQ++ distributively processes heavy tasks on a set of independent

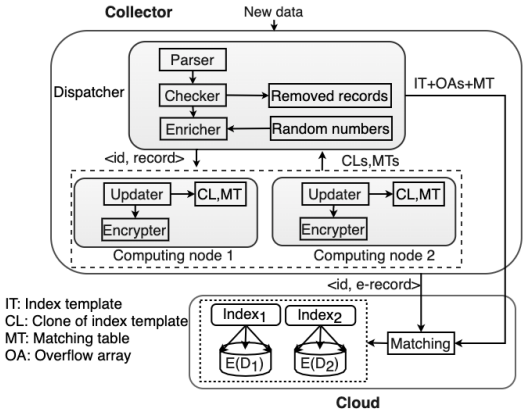

Figure 5: Architecture of parallel PINED-RQ++

machines (e.g., computing nodes), namely updater and encrypter. As a result, ingestion throughput exhibits a significant improvement. Nonetheless, several challenges still remain in this architecture. We now identify the obstacles that hinder PINED-RQ++ from achieving a scalable solution.

4.2 Limitations

Partial parallelism. In PINED-RQ++, the index template is proposed to temporarily store information that is necessary to build the secure index later. By doing it, the count variables of the index template are updated and referenced by the updater and the checker, respectively, during a publishing time interval. The index template is thus considered as a *shared* data structure, that does not run simultaneously in parallel PINED-RQ++. Furthermore, the checker depends on the parser for the checking operation. Hence, both parser and checker are organized to run in sequence at the collector (see Figure 5). Unfortunately, the parsing task usually takes time, especially in case of large record size. Thus, the parser mainly makes the ingestion throughput of the parallel PINED-RQ++ incredibly degraded. For instance, our experiments shows that the parsing task reduces the throughput of the collector by over 50% when we use NASA dataset [1].

Heavily updating index template. Since PINED-RQ++ uses the whole index template for updating and checking incoming data, there are some unnecessary overheads at the collector in terms of memory usage and computation. For example, an update always requires traversing from the root to leaves of the index template, having a complexity of $O(\log_k n)$, where n is the number of leaves and k is the branching factor. Likely, the checker faces the same complexity for checking a record whether it belongs to negative leaf or not. These tasks will take time to process records and diminish the ingestion ability of the system, especially when the domain of index template is huge. The situation is even worse when all tasks which reference the index template have to be processed sequentially.

Synchronous publication. Both PINED-RQ++ and its parallel version are designed to *synchronously* publish datasets to the cloud. In other words, they will start a new publication only if the current publication is sent to the cloud. This mechanism may create congestion in some circumstances. For instance, at the end of each publishing time interval, the collector needs to generate overflow arrays whose size primarily relies upon several configurable parameters, namely domain size, security level (e.g., ϵ), and bin interval. These parameters vary for different applications, thereby the size of overflow arrays will also change accordingly. As the size of overflow arrays is large, the collector

spends long time for generating overflow arrays, giving a heavy burden on the ingestion performance or even bottlenecks at this component.

5 INGESTION FRAMEWORK FOR SECURE RANGE QUERY (FRESQUE)

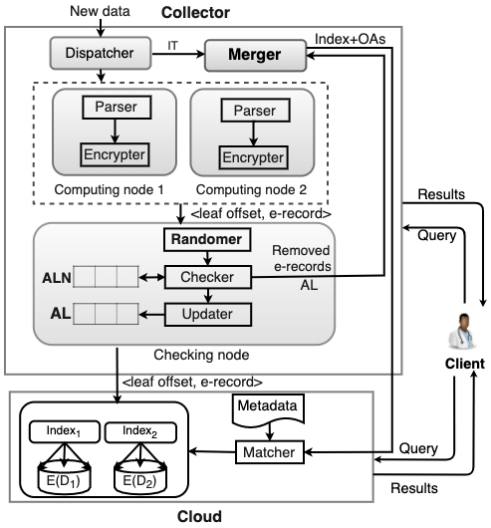

Figure 6: Architecture of FRESQUE

We first present below the key design features of FRESQUE that tackle the main limitations of PINED-RQ++ [34] (see Section 4.2). Then we describe how FRESQUE copes with the informed online attacker (see Section 2.1). Finally we present the complete architecture of FRESQUE.

5.1 Key Design Features

(a) A fully parallel architecture. As stated earlier, **partial parallelism** mainly causes low ingestion throughput in PINED-RQ++. To deal with that, we aim at making the collector fully distributed by parallelizing all heavy jobs (e.g., parser and encrypter) on a cluster of computing nodes.

The difficulty is that the checker, that resides between the parser and the encrypter in the workflow, cannot be parallelized since it relies not only on the parser but also on a shared data structure (e.g., index template). This means that the checker should be positioned after the parser and cannot be run in parallel. In fact, we can run the parser and the encrypter on multiple computing nodes while the checker runs sequentially at another node[2]. After incoming records are parsed at the instances of the parser, they are sent to the checker. These records are then checked by the checker before being sent back to the instances of the encrypter. Nevertheless, this approach would increase unnecessary communication overheads among components at the collector. Instead, we position the checker after the parser and the encrypter in the workflow, as illustrated in Figure 6. This approach allows to scale the intake ability of the collector without creating unnecessary transmission overheads. We then add additional information (e.g., leaf offset) to the ciphertext of the record so that the checker can know which leaf the record belongs to.

(b) Array representation of Leaves (AL). To address the problem of **heavily updating index template**, we replace the index template by an *array representation* of its leaves for the updating and checking operations in our new architecture. Such array representation is small to keeps in memory and accessing array elements requires constant time, $O(1)$. Particularly, the collector maintains two arrays of integers, one with noise (ALN) and the other without noise (AL). The former is used to check whether a record falls within a negative leaf or not while the latter is mainly used to count the number of real records passing the collector. Each element of AL/ALN represents the true count/noise of a leaf, respectively. The size of the two arrays is equal to the number of leaves of the index template. Note that the AL contains the true count of leaves while the IT only contains noise, thereby the two components are sufficient to compute the secure index.

To integrate such data representation into the new architecture, for a given value, the collector needs to know the *leaf offset* of the corresponding element in AL(N). Thanks to the strongly constrained shape of the PINED-RQ index, the leaf offset of a record can be easily obtained based on the configurable parameters of the system. Given parameters, namely domain min (d_{min}), domain max (d_{max}), bin interval (I_b), and an indexed attribute value (v), the leaf offset (O_v) of v can be achieved as follows.

$$O_v \leftarrow min(\lfloor (v - d_{min})/I_b \rfloor, \lfloor (d_{max} - d_{min})/I_b \rfloor - 1)$$

With such an approach, the checker is lightweight enough to avoid performance bottlenecks even if it runs sequentially.

(c) Asynchronously publishing mechanism. To address the issues of the **synchronous publishing** mechanism, we design our new architecture to *asynchronously* publish datasets. To this purpose, we add a new component to our architecture, named merger, that runs independently of the ingestion component (e.g., dispatcher), as depicted in Figure 6. The merger is only responsible for *publishing tasks*, namely building overflow arrays and combining a secure index from the AL and the IT (Index Templates). At the end of each publishing time interval, the publishing tasks are shifted to the merger, and a new publication is immediately initiated at the dispatcher. With this approach, while the dispatcher ingests data for a new publication, the merger performs the publishing tasks for the previous one. This eliminates the burden of the publishing tasks on the ingesting component and prevents potential bottlenecks at the collector. More importantly, the asynchronous publishing method allows the system to continuously consume incoming data with a very small latency for starting a new publication. Such property partially improves the ingestion throughput.

By using the asynchronous publication strategy, all components in FRESQUE, including the dispatcher and the merger, run independently. To ensure data consistency among publications, e.g., how a component determines to which publication a record belongs, we mark each publication with a unique *monotonic* number, named publication number.

5.2 Upgrading PINED-RQ++ for Coping with Informed Online Attackers

Information about the noise injected, e.g. dummy/removed records of a publication, may be disclosed to the informed online attacker if the order of the incoming data at the cloud is the same as the order of the incoming data at the collector. Indeed, since the informed online attacker has the time at which records (dummy or true) arrive at the cloud, his background knowledge on the time distribution of real data can enable him to distinguish (probabilistically) between incoming true records and incoming dummy records (positive noise), or to gain partial knowledge of the number of removed records (negative noise). First, the records removed by the checker at the collector (if they fall in the interval of a negative leaf - see Section 4) do not leave the collector before

[2]The encrypter can further benefit from hardware cryptographic modules.

the end of the publishing time interval. Their absence may reveal to the informed online attacker information about the values of negative noises. Second, the arrival of records at the cloud at unexpected times makes them more likely to be dummy record (information about positive noises). In PINED-RQ++, the collector releases dummy records according to the true distribution of the incoming time of real data for confusing the informed online attacker. This obviously requires to know the distribution in advance, which may be difficult to achieve in real-life applications. We now seek to design a new noise management method that mitigates privacy leaks against the informed online attacker and does not depend on any pre-defined distribution of the incoming time of real data.

To address this issue, we introduce a new component, called *randomer*, to our architecture (see Figure 6). It aims at *perturbing* the distribution of the incoming time of real data at the collector so that the insertion of dummy records or the deletion of real records are hidden from the adversary. The randomer consists of a *fixed-size buffer* and a *trigger* function. The former is used to *mix* incoming real and dummy records together while the latter is used to control the size of the buffer. In particular, all dummy records of a publication are first generated and are *uniformly at random* sent to the buffer of the randomer during a publishing time interval. For example, suppose a publication has 100 dummy records, then 100 time points are chosen uniformly at random over the current publishing time interval, and one dummy record is released at each time point. When a record (real/dummy) arrives at the randomer, it is buffered here. If the randomer buffer is full, then the randomer randomly picks one record in the buffer and releases it to the next component. Note that at any time point when one record is picked and released, it may be a real or dummy record. As a result, if a new record arrives the cloud at an improbable time point, the adversary cannot conclude with certainty whether it is dummy or not. Similarly, when the adversary does not see any record at an expected time point at the cloud, she/he cannot be sure it is removed or not due to the uncertainty caused by the randomer. The leakage caused by dealing naively with positive or negative noise (i.e., dummy records or removed true records) is thus addressed by the randomer. Moreover, FRESQUE does not require knowing in advance any data distribution.

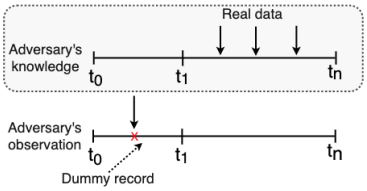

Figure 7: Randomer : Possible Issue of a Tiny Buffer

Challenges of randomer. One of the challenges of using randomer is how to choose a right size for its buffer. Intuitively, a large buffer gives high security. However, if the chosen size is too big, the system may confront bottlenecks at collector, particularly at the checking node. Otherwise, a tiny buffer may result above leak (the extreme case being a buffer of size 1). As an example depicted in Figure 7, we first assume that no real data is present during the period between t_0 and t_1 (the publishing time interval is $[t_0, t_n]$) and the size of the buffer is much smaller than the total number of dummy records. Since all dummy records are randomly released over a publishing time interval, it may happen that the buffer is full of dummy records, e.g., during the period $[t_0, t_1]$. The trigger function is thus activated and dummy records in the buffer are released before t_1. These dummy records will be recognized by the adversary who has prior knowledge about real data distribution. Fortunately, such situation only happens as the randomer buffer is much smaller than the total number of dummy records. Otherwise, if the randomer buffer is large enough, no record will appear at the cloud in that period. Therefore, the buffer size must be chosen to be sufficiently larger than the total number of dummy records of the publication.

A straightforward solution is to determine the buffer size by multiplying the actual number of the dummy records of a publication by several times. However, since we will publish the whole buffer at the end of the publishing time interval, the adversary may infer the size of the buffer, and hence the actual number of dummy records can be leaked. So the method of determining buffer size must (*) not depend on the real number of dummy records and (**) being larger than the number of the dummy records of a publication.

Note that since dummy records are generated due to the Laplace noise, the number of dummy records varies with each publication. It is thus difficult to choose a right capacity for the randomer buffer while meeting both (*) and (**). Fortunately, the noise in FRESQUE is sampled from the Laplace distribution, we can then choose buffer size based on the inverse CDF of the Laplace distribution with a very high probability, δ'. Intuitively, this approach gives an upper bound on the number of dummy records. Given a set of m leaves, denoted $L = \{l_1, ..., l_m\}$, we probabilistically compute the maximum number of dummy records of leaf l_i based on the inverse CDF of the Laplace distribution, considered as s_i. Then, $T = \sum_{i=1}^{m} s_i$ is viewed as the *maximum* number of dummy records of an index. To guarantee the buffer size is larger than T, we multiply it by a configurable coefficient, α. To ensure the buffer size is larger than the total number of dummy records, we suggest to set $\alpha \geq 2$. Then, the buffer size, S, of the randomer is: $S = \sum_{i=1}^{m} s_i \times \alpha$ (or $S = T \times \alpha$), where $\alpha \geq 2$.

Finally, the position of the randomer within the architecture of the collector is important as well: it must be put before the checker and the updater (so that it processes all records, including the removed ones) and after the parser and the encrypter (for obvious latency reasons).

5.3 Architecture of FRESQUE

Following the key design features in Section 5.1, we now detail our ingestion framework to support efficient range query processing over encrypted data. Especially, we describe the orchestration of different components in this architecture.

(a) Ingestion life cycle. The collector of FRESQUE runs on a small cluster of commodity machines (see Figure 6). At the collector, one (and only one) node runs the Dispatcher (D) and all worker nodes in the cluster run a Computing Node (CN) while the randomer, the checker, and the updater run on the same Checking node (C).

When new records arrive to the dispatcher, they are immediately sent to the computing nodes according to a round robbin approach. This approach is used for the sake of load balancing. The computing node first pre-processes incoming data to get pairs of <leaf offset, e-record>. These pairs are then sent to the checking node. After being randomized and checked at the checking node, such pairs are forwarded to the cloud or the merger. Note that the dispatcher, the computing node, the merger, and the checking node can coexist on the same node.

(b) Instantiation of FRESQUE. In order to demonstrate how data

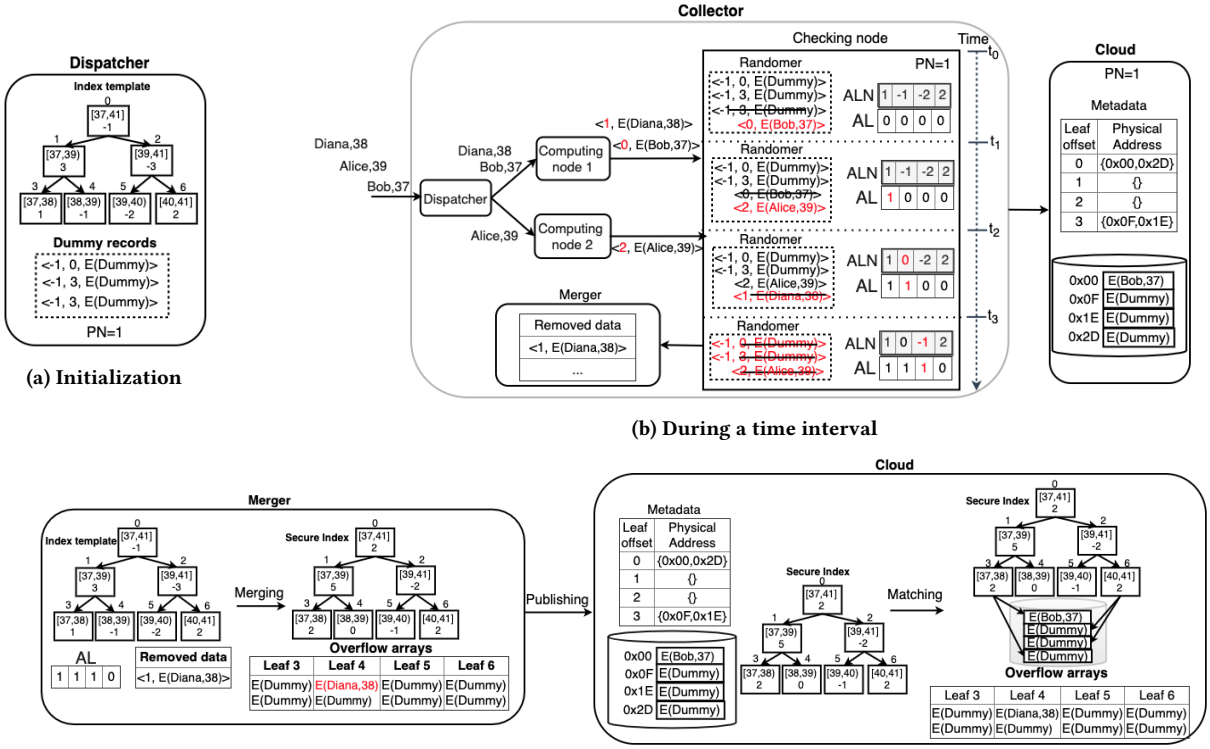

Figure 8: An example demonstrating how FRESQUE processes incoming data by using two computing nodes. Assume that the size of randomer buffer is 4 pairs of e-record.

is processed at the collector and transported to the cloud, Figure 6 shows the composition of FRESQUE running on five nodes at the collector and Figure 8 gives a running example.

Dispatcher (D): At the beginning of a publishing time interval, the dispatcher initiates an Index Template (IT), dummy records, and a Publication Number (PN), as illustrated in Figure 8a. The dispatcher then sends the IT, PN and all dummy records to the checking node. During a publishing time interval, whenever the dispatcher receives new data from data sources, it distributes the data to the computing nodes in a round-robin fashion. As an example shown in Figure 8b, there are three records, (Bob,37), (Alice,39), (Diana,38), arriving in order at the dispatcher. These records are then distributed to the two computing nodes. At the end of each publishing time interval, the dispatcher sends a *publishing* message to all available computing nodes and to the checker. By using the asynchronous publishing method, a new publication is immediately started after a *publishing* message is sent instead of waiting for the publishing tasks to be done. This allows the system to continuously ingest arrivals. By completely removing heavy jobs (e.g., parsing, encrypting, and checking) from the dispatcher and using the asynchronous publishing method, throughput ingestion is maximized at this component.

Computing Node (CN): During a publishing time interval, when new data comes, the computing node parses the raw data into a record, calculates the leaf offset, and encrypts it. Then, a pair of <leaf offset, e-record> is transferred to the checking node. As showed in Figure 8b, after passing the two computing nodes, three records are now parsed, encrypted, and associated with the corresponding leaf offsets, 0, 2, 1, respectively. When the computing node receives a *publishing* message from the dispatcher, it waits for a *done* message from the checking node. Notably, during the meantime, all incoming data will be processed and stored in local in-memory buffers at the computing nodes. By doing it, the delay of performing heavy tasks on buffered data is reduced when a new publication is started.

As mentioned earlier, the parser and the encrypter mainly cause throughput degradation in the system. With the parallel approach, the degradation is reduced significantly and only relies on the number of the computing nodes used. Interestingly, this approach not only allows to easily scale the throughput up, but also shortens the publishing time at the collector. For instance, PINED-RQ++ has to sequentially encrypt removed records and insert them into overflow arrays at the end of each publishing time interval, whereas they are now encrypted in a parallel manner by a set of networked machines during that period. As a result, at the end of each publishing time interval, the collector only randomly inserts removed encrypted records into the corresponding overflow arrays before transferring them to the cloud, reducing the publishing time in FRESQUE.

Checking node (C): At the beginning of a publishing time interval, the checking node receives Index Template (IT) and Publication Number (PN) from the dispatcher. It first initiates the corresponding AL and ALN (see Figure 8b). The checking node then forwards the IT to the merger while the PN is sent to the cloud. During a publishing time interval, when a pair of <leaf offset, e-record> arrives, it stores that pair in the buffer of the randomer. If the buffer is full, one of them is randomly picked and passed to the checker. Next, the checker gets its leaf offset (e.g., i) from the selected pair. If the i^{th} element of ALN is less than zero, the checker increases the value of the i^{th} element of both ALN and AL by one, and then sends that pair to the merger

as removed. Otherwise, that pair is sent to the updater, and only the value of the i^{th} element of AL is increased by one. Finally, that pair is sent to the cloud. As the example presented in Figure 8b, when the pair <0, (Bob,37)> comes to the checking node at timestamp t_0, it is inserted into the randomer's buffer. When this pair is released at timestamp t_1, the 0^{th} element of AL is increased by one since the 0^{th} element of ALN is positive. Otherwise, at timestamp t_2, when the pair <1, (Diana,38)> is considered, since it belongs to a negative element of ALN, the 1^{st} element of AL and ALN are both increased by one and this pair is then sent to the merger.

When the checking node receives *publishing* messages from all available computing nodes, it will send the updated AL to the merger (see Figure 8c). We emphasize that the condition of receiving publishing messages from all computing nodes needs to be guaranteed so that the consistency of publications is achieved. In other words, it makes sure that all (dummy/real) data of the current publication, that are sent by the dispatcher, are received by the checking node. The randomer buffer is then shuffled and published to the cloud. Finally, the checking node sends a *done* message back to the computing nodes.

It is worth noting that the checker and the updater will ignore the dummy records when they pass the checking node. This means that the counts of AL and ALN are independent of such dummy data. To achieve it, the checker and the updater need to perceive which incoming record is dummy in order to ignore it during the updating process. Nonetheless, the difficulty is that they all become ciphertexts after being encrypting by the computing nodes. To address it, we add to dummy records a *special* flag (e.g., -1) to distinguish them from real data. This straightforward technique allows the checker and the updater to know which record is dummy or real. As shown in Figure 8b, at timestamp t_0, a dummy pair is released by the checking node, and does not lead to any update on AL and ALN.

Even if all tasks at the checking node are designed to run sequentially such as the checker and the updater, they do not have much impact on the ingestion throughput at the collector. Moreover, thanks to the array representation, our architecture diminishes the complexity of the updating and checking tasks from $O(\log_k n)$ to $O(1)$, and hence shortening the delay of processing a record and boosting the consumption throughput.

Merger (M): At the beginning of each publishing time interval, the merger receives IT and PN from the checking node, then keeps them in memory. During a publishing time interval, the merger may receive removed records from the checker. Whenever the merger receives the updated AL, it triggers a new merging job that performs publishing tasks, e.g., combining IT and AL to achieve the complete secure index, generating overflow arrays (OAs) to conceal the removed records. Finally, the merger sends them to the cloud with the corresponding PN, as shown in Figure 8c.

Cloud: When the cloud receives a new PN from the checking node, it creates a new file for storing the incoming data. However, when its secure index is published by the merger, the published data will be read from the file on disk for a matching process and finally written back to disk again. Such approach gives rise to high I/O overhead. Instead, we keep small information about the published data, e.g., *metadata*, that is used for the matching process. Specifically, when a pair of <leaf offset, e-record> arrives, the cloud writes the e-record to disk, gets its physical address, and caches a pair of <leaf offset, physical location> in memory. To boost the matching process, we organize *metadata* in the form of <leaf offset, list of physical locations>, as demonstrated in Figure 8b. Such *metadata* is relatively small and independent of the size of e-records. When a publication comes from the merger, the matching process immediately associates the physical address of e-records with leaves based on the cached metadata. The metadata is finally destroyed (see Figure 8c).

(c) Query processing. In FRESQUE, when a query comes at the cloud, it is evaluated on both indexed and unindexed data. With regard to indexed data, the query processing strategy is applied as in Section 4.1. Meanwhile, unindexed data are processed one by one based on the query range. The (removed) records have a range overlapping the query range at the cloud, the randomer, and the merger are returned to the client.

6 SECURITY ANALYSIS

We develop FRESQUE that builds a PINED-RQ index [33] during a publishing time interval. With such an approach, at the end of each publishing time interval, all parts of the index (e.g., IT, AL, and removed e-records) are combined at the merger to get a secure index and overflow arrays. In other words, this process only occurs at the trusted collector, and hence FRESQUE apparently inherits the privacy protection level of the PINED-RQ index and trivially satisfies (ϵ, δ)-Probabilistic-SIM-CDP against offline attackers and (simple) online attackers.

The main difference between FRESQUE and PINED-RQ with respect to the index creation function is that FRESQUE publishes encrypted records immediately. Informed online attackers may be able to gain information about positive or negative noises based on the expected time distribution of incoming real records. However, thanks to the randomer, this leakage is mitigated. Theorem 2 claims the security of FRESQUE.

Theorem 2 (Security of FRESQUE*):* The index creation function of FRESQUE satisfies (ϵ, δ)-Probabilistic-SIM-CDP [33] against offline attackers and (simple) online attackers, and mitigates the information leak against informed online attackers.

Proof. *(Sketch)* We only consider informed online attackers because the two other attackers are trivial.

Considering dummy records (information leak about positive noises). First, we consider the case where a record arrives at the cloud at the time point at which there is real data. Since real/dummy records are randomly mixed together before being released, the adversary is unable to distinguish dummy records from real ones and does not obtain additional useful information about the values of the positive noises.

Second, we consider the case where a record arrives at the cloud at an unlikely time point at which there is no real data. This situation happens when a dummy record is inserted into a full randomer buffer. This means that with high probability the randomer buffer contains both real and dummy records. When receiving a record recently picked from the buffer, the cloud is thus unable to distinguish dummy records from real ones and does not learn additional information about the values of the positive noises.

Third, we consider the case where the checking node sends the full randomer buffer to the cloud at the end of a publishing time interval. Dummy records are mixed with real ones at the randomer during a publishing time interval. Additionally, the ratio between real and dummy data at any time point is hidden from the adversary (see Section 5.2), hence the adversary does not

obtain additional useful information about the values of the positive noises from this case.

Fourth, we consider the case where the randomer contains only dummy records and no real ones. Note that such situation only occurs if all dummy records are released before real data arrives at the collector. If the buffer of the randomer were allowed to be smaller than or equal to the total number of dummy records, a dummy record would be picked with certainty and released to the cloud. As a result, the adversary would learn with certainty that it is dummy. However, FRESQUE requires that the buffer of the randomer is chosen to be much larger than the total number of dummy records of a publication, with (tunable) high probability (see Section 5.2). This makes this case highly improbable.

Considering removed records (information leak about negative noises). Since dummy records will not be deleted by the checking node, we only focus on real records. Recall that the decision to remove a real record is taken by the checker, after the randomer, and that removed records are buffered by the merger in order to be published within the overflow arrays at the end of the publishing time interval. Without randomer, the artificial removal of records due to negative noise may impact the number of records sent to the cloud and thus, slightly, the time distribution of the records sent to the cloud. However, first, the additional dummy records mitigate the decrease in the number of records overall (recall that the Laplace distribution used for generating the noises is symmetric around 0), and second, with the randomer, the delay introduced by the randomer buffer in releasing both dummy and real records also impacts the time distribution of records to the cloud, similar to the removal of true records, which mitigates the information leak about the values of the negative noises. □

Comparison with PINED-RQ [33]. The highest security of FRESQUE is achieved when the coefficient α is chosen so that the randomer buffer can contain the whole dataset and all dummy records. In that case, at the end of each publishing time interval, the randomer shuffles and sends the buffer to the cloud along with a secure index and overflow arrays. It is easy to see that this is exactly the publishing process of PINED-RQ. Thus, in that case, FRESQUE has the same level of privacy against informed online attackers as PINED-RQ, and thus also satisfies exactly (ϵ, δ)-Probabilistic-SIM-CDP against all attackers.

7 EVALUATION

We evaluate FRESQUE against PINED-RQ++ due to its outperformance compared to other prior schemes (see Table 1). We mainly focus on the metrics contributing to the scalability of the system, namely ingestion throughput and publishing latency at the collector as well as at the cloud.

7.1 Benchmark Environment

Table 2: Experimental environment

Component	CPU (2.4 GHz)	Memory (GB)	Disk (GB)
Dispatcher	4	8	80
Merger	4	8	80
Checking node	4	8	80
Computing node	2	2	20
Data source	4	16	80
Cloud	16	64	160

We implemented FRESQUE in Java 1.8.0[3]. Data was encrypted by the Java package (javax.crypto). We ran our experiments on the Galactica platform [4] and organized FRESQUE as a cluster of 17 nodes, including 12 computing nodes, running on Ubuntu 14.04.4 LTS. Each node was used to run one component of FRESQUE. The configurations of nodes are detailed in Table 2. The TCP socket was used for exchanging data among the components of FRESQUE.

[3]The code is available at https://gitlab.inria.fr/vtran/fresque.git.

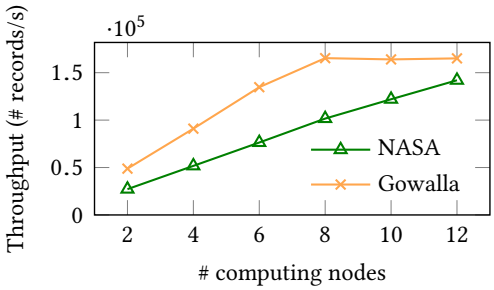

Figure 9: Ingestion throughput of FRESQUE

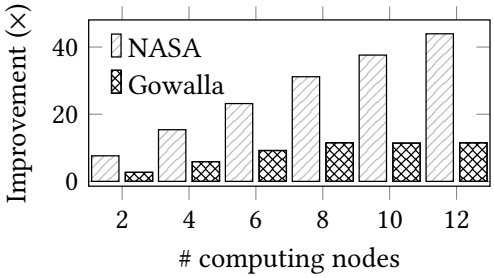

Figure 10: FRESQUE's improvement compared to PINED-RQ++

We evaluate our solution on two real datasets: NASA log [1] (1, 569, 898 records, five attributes) and Gowalla [22] (6, 442, 892 records, three attributes). We use the reply byte and check-in time as indexed attributes, respectively. Based on these datasets, the domain of the reply byte is divided into 3421 bins and each bin interval represents 1 KB. Meanwhile, the domain of the check-in time is 626 bins and each bin interval implies one hour. The fanout is set to 16. We use a publishing time interval of 60 seconds and incoming data rate is 200k records per second. The initial privacy budget and coefficient is set to 1 and 2, respectively, for all experiments unless otherwise stated. Both δ and δ' are set to 99% and every experiment was run over ten minutes. Then, we present the averaged results of ten publications in Section 7.2.

7.2 Results

Ingestion throughput. We first present the ingestion throughput of FRESQUE with a varied number of computing nodes. Then we compare its ingestion throughput to those of the (non-)parallel PINED-RQ++. The results in Figure 9 show that the throughput of FRESQUE significantly increases as the number of computing nodes goes up. Especially, the highest throughput is reached at ~142k records/second (NASA) and at ~165k records/second (Gowalla) with 12 and 8 computing nodes respectively. As compared to ArxRange [30], one of the state-of-the-art solutions, FRESQUE reaches an ingestion throughput that is at least two orders of magnitude higher.

(a) Comparison with non-parallel PINED-RQ++. With the given settings, non-parallel PINED-RQ++ is able to ingest only 3,159 records/s in NASA and 13,223 records/s in Gowalla. Such ingestion throughputs are substantially lower than those of FRESQUE. The results in Figure 10 demonstrate the outperformance of

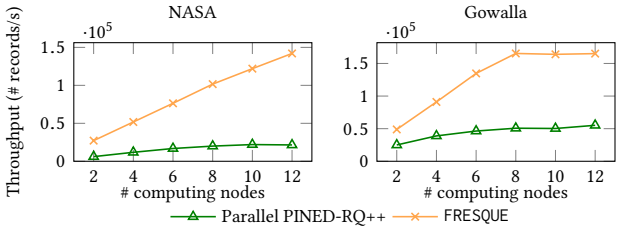

Figure 11: Comparison of ingestion throughput with parallel PINED-RQ++

FRESQUE compared to non-parallel PINED-RQ++. The enhancement goes up as the number of computing nodes grows. The highest improvement can be seen as the collector is configured as a 12-computing node cluster, and the ingestion throughput is improved by ~11× and ~43× in Gowalla and NASA dataset, respectively. Even if only two computing nodes are used, FRESQUE can achieve the improvement of 7.61× (NASA) and 2.69× (Gowalla). Compared to Gowalla, NASA always exhibits higher improvement with the same number of computing nodes. The major source of this gap comes from the fact that the record size and the domain of NASA record are larger than those of Gowalla. Based on such observation, we can conclude that FRESQUE would be more beneficial as datasets have larger size and/or domain.

(b) Comparison with parallel PINED-RQ++. The throughput of FRESQUE is always higher than that of parallel PINED-RQ++ as we vary the number of computing nodes at the collector, as shown in Figure 11. The setting of 12-computing node cluster gives the biggest gap, the throughput of FRESQUE is ~5.6× (NASA) and ~2.2× (Gowalla) better than that of parallel PINED-RQ++. Noted that since the throughput in FRESQUE reaches the peak as we use 8 computing nodes in Gowalla, the use of more computing nodes does not bring more benefit.

Throughput degradation. We measure the throughput degradation at the collector of the three prototypes. Such metric is obtained by comparing their maximum ingestion throughput with the maximum incoming throughput (without any processing on incoming data) at the collector. As shown in Figure 12, FRESQUE experiences the lowest throughput degradation among the three prototypes, with a reduction of at least ~3.9× (compared to parallel PINED-RQ++) in NASA, and at most ~7.9× (compared to PINED-RQ++) in Gowalla.

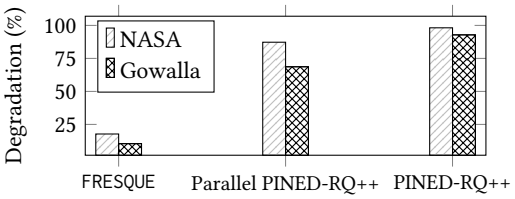

Figure 12: Throughput degradation at the collector

Publishing time. We now turn our attention to the publishing time metric, i.e., the time required to publish a dataset with FRESQUE and with parallel PINED-RQ++. Noted that FRESQUE consists of the three main components, namely the dispatcher, the checking node, and the merger which mainly decide the publishing time at the collector. We thus measure the delay of the three components separately. Additionally, we consider the time needed to perform a matching process at the cloud. This is because a long delay of this process might also lead to bottlenecks.

(a) Publishing time at the dispatcher. As shown in Figure 13, the time is always lower than 520ms with NASA and 200ms with

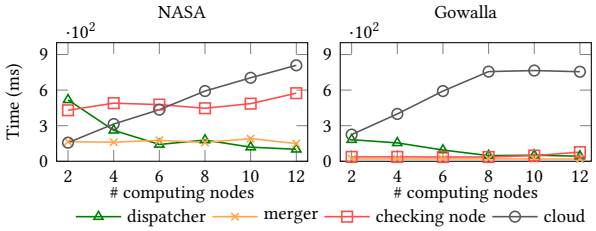

Figure 13: Publishing time in FRESQUE

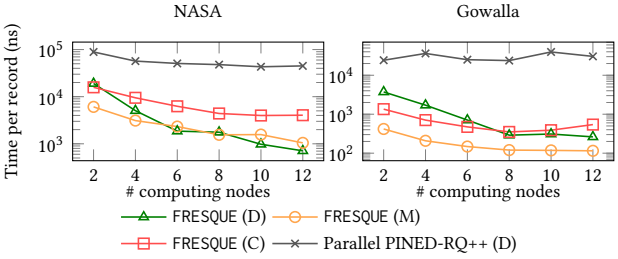

Figure 14: Comparison of publishing time at collector with parallel PINED-RQ++

Gowalla. The delay even gradually decreases as the number of computing nodes increases. In particular, the dispatcher takes only 101ms (NASA) and 19ms (Gowalla) for performing the publishing tasks in a 12-computing node cluster.

(b) Publishing time at the merger. The results in Figure 13 indicates that the time is virtually unchanged in the two datasets as their size changes. Specifically, the time with NASA fluctuates between 149ms and 191ms while that with Gowalla varies between 18ms and 20ms. Since the domain size of NASA (3421 bins) is larger than the one of Gowalla (626 bins), the NASA experiences a higher publishing time than that of the Gowalla dataset.

(c) Publishing time at the checking node. In this study, we attempt to design FRESQUE so that the checking node has a lightweight publishing job and has a reduced impact on the ingestion performance. In particular, the checking node only sends the buffer of the randomer to the cloud and the updated AL to the merger at the end of each publishing time interval. The results in Figure 13 show that the time is under 600ms with NASA and 80ms with Gowalla. It can be understood that the publishing time at the checking node is mainly represented by the time of sending the randomer buffer that varies according to the required level of security. A huge randomer buffer results in long publishing time at this component. Fortunately, since the computing nodes always process and cache incoming data during the meantime, the impact on the ingestion throughput is negligible. We will evaluate the randomer below in the latest part of this section.

(d) Matching time at the cloud. To show the efficiency of FRESQUE at the cloud side, we measure the time required to associate *metadata* (physical locations of records) with published index. As depicted in Figure 13, the time in FRESQUE goes up according to data size. Nonetheless, FRESQUE spends only 877ms and 837ms on matching the large dataset of 8.1M records (NASA) and 9.8M records (Gowalla), respectively. These performances come from the deletion of the matching table from FRESQUE's architecture.

(e) Comparison with parallel PINED-RQ++. We now compare publishing time at the collector between FRESQUE and parallel PINED-RQ++. Since the different numbers of computing nodes used result in different publication sizes, we consider the time is required to publish a record instead of a whole dataset. The results in Figure 14 show that parallel PINED-RQ++ (dispatcher) takes longer delay than FRESQUE (dispatcher, checking node, and merger) for

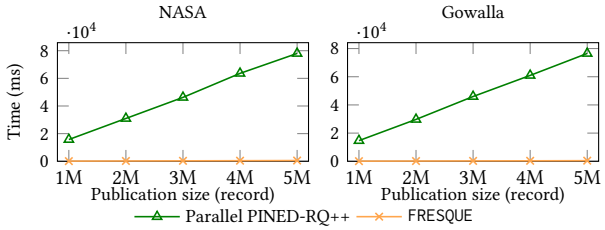

Figure 15: Comparison of matching time at cloud with parallel PINED-RQ++

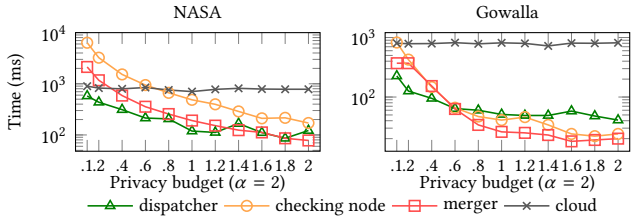

Figure 16: Publishing time with different privacy budgets

the two datasets used. Regarding the dispatcher, the publishing time of FRESQUE is at most ~62× and ~127× lower with NASA and Gowalla, respectively, compared to parallel PINED-RQ++.

Matching time. We also evaluate the matching time needed to process a publication between parallel PINED-RQ++ and FRESQUE. The results in Figure 15 show that the time of parallel PINED-RQ++ increases when publications are larger. For example, when a dataset of 5M records is used, the matching time in parallel PINED-RQ++ reaches ~78s (NASA) and ~76s (Gowalla). In contrast, FRESQUE constantly maintains a short time for processing a publication at the cloud, with a maximum is ~54ms (NASA) and ~43ms (Gowalla). The matching time of FRESQUE is at least two orders of magnitude shorter than that of parallel PINED-RQ++.

Impact of the randomer. For mitigating the information disclosed to the informed online attacker, the randomer maintains a local buffer for perturbing incoming data. A large buffer may introduce a bottleneck at the collector. We thus evaluate the impact of this component here. Indeed, the buffer size is mainly determined by two configurable parameters, namely privacy budget ϵ and coefficient α. Hence, we run various experiments with varied values of the two parameters to evaluate the impact of the randomer. We use a configuration of 10 computing nodes.

(a) Privacy budget ϵ. We now consider the impact of the randomer in terms of publishing time as we use different privacy budgets, ranging from 0.1 to 2.0, for a publication. In these experiments, we record the publishing time at the collector (dispatcher, checking node, and merger), and the matching time at the cloud. The results in Figure 16 show that the privacy budget influences the publishing time at the three components. Indeed, as a smaller privacy budget is used, their publishing time goes up. The highest increase is witnessed at the checking node, approximately 7s (NASA) and about 0.8s (Gowalla) for the budget of 0.1. Similarly, as the privacy budget declines, the size of overflow arrays and the number of dummy/removed records go up, causing a slight increase of the publishing time at the dispatcher and the merger.

(b) Coefficient α. We adjust the value of α to see the impact of randomer on publishing time at the checking node, the merger and the cloud. As expected, when we increase the value of α, the publishing time grows (see Figure 17). However, even if α is set to 20, the checking node only takes about 6s (NASA) and 0.8s (Gowalla). Also, the time does not change much at the dispatcher,

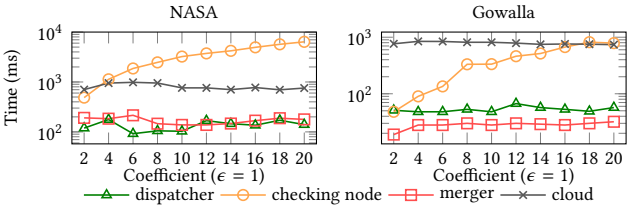

Figure 17: Publishing time with different coefficients

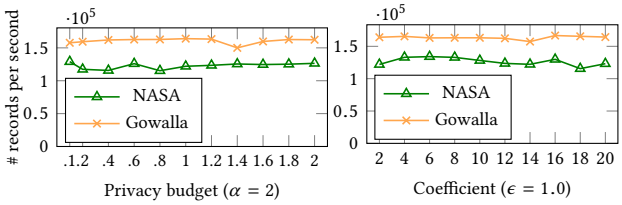

(a) Varying privacy budgets **(b) Varying coefficients**

Figure 18: Ingestion throughput of FRESQUE with randomer

the merger and the cloud.

(c) Impact of the randomer on ingestion throughput. We also consider the ingestion throughput at the collector as we vary the two parameters ϵ and α. Although the publishing time at the checking node goes up as we use smaller privacy budget and/or larger coefficient, the ingestion throughput at the collector is relatively stable. This is because while the checking node prepares publish the current dataset, including the sending of randomer to the cloud, incoming data of the new publication is still processed and buffered at the computing nodes. As it can be seen in Figure 18a and Figure 18b, the results show that the throughput with the NASA dataset fluctuates between ~115k records/s and ~134k records/s while that of Gowalla ranges from ~150k records/s to ~166k records/s.

8 DISCUSSION

We present a possible real-life application of FRESQUE based on the FluTracking use-case [3].

Flutracking is a web-based survey of influenza-like illness. This system weekly sends a link via email to all participants who will then submit required information via a web interface. The submitted data can be managed in a cloud and accessed by authorized users for analysis and prediction.

Although our description of FRESQUE focuses on the insertion of one record per individual, it is simple to extend our approach to the case of multiple records per individual. For example, in Flutracking [3], an individual can submit personal data several times to the database, at most once for a week. For such case, an important question is how to manage privacy budget over multiple insertions of the same individual.

In the targeted use case, it is unlikely to have multiple records of the same individual over a short period (e.g., weekly). Therefore, we can assume that a dataset of each period (e.g., week) is published with a secure index, and this publication consists of at most one record per individual. For each dataset, the system uses a portion of the total privacy budget ϵ_{total} for constructing a secure index. To determine how much budget is spent for a publication, an admin may necessarily determine how long the system needs secure indices for fast range query processing. ϵ_{total} is then divided according to the determined period. For instance, if the system must maintain indices for one year (52 weeks), then an admin can divide the total privacy budget ϵ_{total} into 52 equal

portions, $\epsilon_1, ..., \epsilon_{52}$, so that $\epsilon_{total} = \sum_{i=1}^{52} \epsilon_i$. Each of which is used to publish dataset of one week. Certainly, the system needs to make sure that an individual contributes at most one record per publication. Fortunately, thanks to the existing collecting method of the Flutracking, this work can simply be achieved. In particular, a unique link can be sent to all participants every Monday. The link is set to expired and a dataset is published before the next Monday. This ensures that a participant links to at most one record per publication.

9 CONCLUSION

This paper presents FRESQUE, a scalable ingestion framework for secure range query processing over encrypted data on clouds. We thoroughly analyze and identify the problems of the-state-of-the-art solutions related to the degradation of the ingestion throughput, with a special focus on PINED-RQ++. To address these drawbacks, we design a new architecture that is fully distributed at the collector. Additionally, we introduce a data representation as well as an asynchronous publication mechanism. All of them together allows FRESQUE to achieve intensive consumption throughput, reaching over 160K records/s. Moreover, we introduce and carefully integrate the randomer into our new architecture to improve the practicality and security of FRESQUE as compared to PINED-RQ++. We formally analyse the security guarantees of FRESQUE. Lastly, we discuss a potential application of FRESQUE based on a real-life example. Future works include coping with multiple records per individual and designing alternative indexes based on well-known highly concurrent data structures (e.g., Masstree [25] and ART [21]).

ABSTRACT

Distributed caches are widely deployed to serve social networks and web applications at billion-user scales. This paper presents *Cache-on-Track* (CoT), a decentralized, elastic, and predictive caching framework for cloud environments. CoT proposes a new cache replacement policy specifically tailored for small front-end caches that serve skewed workloads with small update percentage. Small front-end caches are mainly used to mitigate the load-imbalance across servers in the distributed caching layer. Front-end servers use a heavy hitter tracking algorithm to continuously track the top-k hot keys. CoT dynamically caches the top-C hot keys out of the tracked keys. CoT's main advantage over other replacement policies is its ability to dynamically adapt its tracker and cache sizes in response to workload distribution changes. Our experiments show that CoT's replacement policy consistently outperforms the hit-rates of LRU, LFU, and ARC for the same cache size on different skewed workloads. Also, CoT slightly outperforms the hit-rate of LRU-2 when both policies are configured with the same tracking (history) size. CoT achieves server size load-balance with 50% to 93.75% less front-end cache in comparison to other replacement policies. Finally, experiments show that CoT's resizing algorithm successfully auto-configures the tracker and cache sizes to achieve back-end load-balance in the presence of workload distribution changes.

1 INTRODUCTION

Social networks, the web, and mobile applications have attracted hundreds of millions of users who need to be served in timely personalized way [9]. To enable this real-time experience, the underlying storage systems have to provide efficient, scalable, and highly available access to big data.

Figure 1 presents a typical web and social network system deployment [9] where user-data is stored in a distributed back-end storage layer in the cloud. The back-end storage layer consists of a distributed in-memory caching layer deployed on top of a distributed persistent storage layer. The caching layer aims to improve the request latency and system throughput and to alleviate the load on the persistent storage layer at scale [44]. Distributed caching systems such as Memcached [3] and Redis [4] are widely adopted by cloud service providers such as Amazon ElastiCache [1] and Azure Redis Cache [2]. As shown in Figure 1, hundreds of millions of end-users send streams of page-load and page-update requests to thousands of stateless front-end servers. These front-end servers are either deployed in the same core datacenter as the back-end storage layer or distributed among other core and edge datacenters near end-users. Each end-user request results in hundreds of data object lookups and updates served from the back-end storage layer. According to Facebook

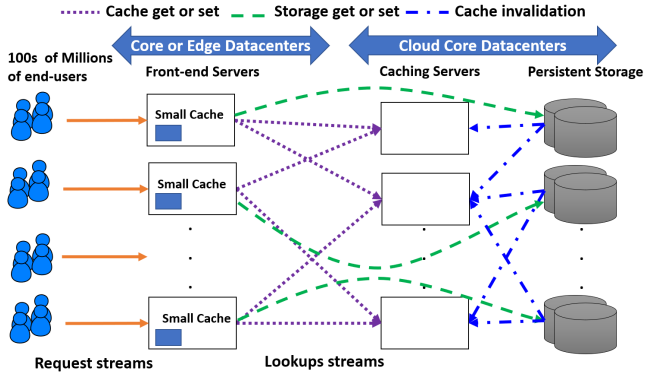

Figure 1: A typical web and social network system deployment

Tao [9], 99.8% of the accesses are reads and 0.2% of them are writes. Therefore, the storage system has to be **read optimized** to efficiently handle end-user requests at scale.

Redis and Memcached use consistent hashing [30] to distribute keys among several caching servers. Although consistent hashing ensures a fair distribution of the number of keys assigned to each caching shard, it does not consider the workload per key in the assignment process. Real-world workloads are typically skewed with few keys being significantly hotter than other keys [25]. This skew causes load-imbalance among caching servers.

Load imbalance in the caching layer can have significant impact on the overall application performance. In particular, it may cause drastic increases in the latency of operations at the tail end of the access frequency distribution [24]. In addition, the average throughput decreases and the average latency increases when the workload skew increases [11]. This increase in the average and tail latency is amplified for real workloads when operations are executed in chains of dependent data objects. A single page-load results in retrieving hundreds of objects in multiple rounds of data fetching operations [9, 38]. Finally, solutions that equally overprovision the caching layer resources to handle the most loaded caching server suffer from resource under-utilization in the least loaded caching servers.

In this paper, we propose Cache-on-Track (CoT); a decentralized, elastic, and predictive heavy hitter caching at front-end servers. CoT proposes a new cache replacement policy specifically tailored for small front-end caches that serve skewed workloads with small update percentage. CoT uses a small front-end cache to solve back-end load-imbalance as introduced in [20]. However, CoT does not assume perfect caching at the front-end. CoT uses the space saving algorithm [37] to track the top-k *heavy hitters*. The tracking information allows CoT to *cache* the exact top-C hot keys out of the approximate top-k tracked keys preventing cold and noisy keys from the long tail to replace hot keys in the cache. CoT is decentralized in the sense that each front-end independently determines its hot key set based on the key access

distribution served at this specific front-end. This allows CoT to address back-end load-imbalance without introducing single points of failure or bottlenecks that typically come with centralized solutions. In addition, this allows CoT to scale to thousands of front-end servers, a common requirement of social network and modern web applications. Unlike traditional replacement policies, CoT is elastic in the sense that each front-end uses its local load information to monitor its contribution to the back-end load-imbalance. Each front-end elastically adjusts its tracker and cache sizes to reduce the load-imbalance caused by this front-end. In the presence of workload changes, CoT dynamically adjusts front-end tracker to cache ratio in addition to both the tracker and cache sizes to eliminate any back-end load-imbalance.

In traditional architectures, memory sizes are static and caching algorithms strive to achieve the best usage of all the available resources. However, in cloud settings where there are theoretically infinite memory and processing resources and cloud instance migration is the norm, cloud end-users aim to achieve their SLOs while reducing the required cloud resources and thus decreasing their monetary deployment costs. CoT's main goal is to reduce the necessary front-end cache size *independently* at each front-end to eliminate server-side load-imbalance. In addition, CoT strives to dynamically find this minimum front-end cache size as the workload distribution changes. Reducing front-end cache size is crucial for the following reasons: 1) it reduces the monetary cost of deploying front-end caches. For this, we quote David Lomet in his recent works [33–35] where he shows that cost/performance is usually more important than sheer performance: *"the argument here is not that there is insufficient main memory to hold the data, but that there is a less costly way to manage data."*. 2) In the presence of data updates and when data consistency is a requirement, increasing front-end cache sizes significantly increases the cost of the data consistency management technique. Note that social networks and modern web applications run on thousands of front-end servers. Increasing front-end cache size not only multiplies the cost of deploying bigger cache by the number of front-end servers, but also increases several costs in the consistency management pipeline including a) the cost of tracking key incarnations in different front-end servers and b) the network and processing costs to propagate updates to front-end servers. 3) Since the workload is skewed, our experiments clearly demonstrate that the relative benefit of adding more front-end cache-lines, measured by the average cache-hits per cache-line and back-end load-imbalance reduction, drastically decreases as front-end cache sizes increase.

CoT's resizing algorithm dynamically increases or decreases front-end allocated memory in response to dynamic workload changes. CoT's dynamic resizing algorithm is valuable in different cloud settings where all front-end servers are deployed in the same datacenter or in different datacenters at the *edge*. These front-end servers obtain workloads of the same dynamically evolving distributions or different distributions. In particular, CoT aims to capture local trends from each individual front-end server perspective. In social network applications, front-end servers that serve different geographical regions might experience different key access distributions and different local trends (e.g., #miami vs. #ny).

We summarize our contributions in this paper as follows.

- Design and implement Cache-on-Track (CoT), a front-end cache replacement policy specifically tailored for small caches that serve skewed workloads with small update percentages.
- Design and implement CoT's resizing algorithm. The resizing algorithm dynamically minimizes the required front-end cache size to achieve back-end load-balance. CoT's built-in elasticity is a key novel advantage over other replacement policies.
- Evaluate CoT's replacement policy hit-rates to the hit-rates of traditional as well as state-of-the-art replacement policies, namely, LFU, LRU, ARC, and LRU-2. In addition, experimentally show that CoT achieves server size load-balance for different workload with **50% to 93.75%** less front-end cache in comparison to other replacement policies.
- Experimentally evaluate CoT's resizing algorithm showing that CoT successfully adjust its tracker and cache sizes in response to workload distribution changes.
- Report a *bug* at YCSB's [15] ScrambledZipfian workload generator. This generator generates workloads that are significantly less-skewed than the promised Zipfian distribution.

The rest of the paper is organized as follows. The related work is discussed in Section 2. In Section 3, the data model is explained. Section 4 further motivates CoT by presenting the main advantages and limitations of using LRU, LFU, ARC, and LRU-k caches at the front-end. We present the details of CoT in Section 5. In Section 6, we evaluate the performance and the overhead of CoT and the paper is concluded in Section 7.

2 RELATED WORK

Distributed caches are widely deployed to serve social networks and the web at scale [9, 38, 44]. Load-imbalancing among caching servers negatively affects the overall performance of the caching layer. Therefore, significant research has addressed the load-imbalacing problem from different angles. Solutions use different load-monitoring techniques (e.g., centralized tracking [6, 7, 26, 43], server-side tracking [11, 24], and client-side tracking [20, 28]). Based on the load-monitoring, different solutions redistribute keys among caching servers at different granularities. The following summarizes the related works under different categories.

Centralized load-monitoring: Slicer [7] and Centrifuge [6] are examples of centralized load-monitoring where a centralized control plane is separated from the data plane. Centrifuge uses consistent hashing to map keys to servers. However, Slicer propagates the key assignments from the control plane to the front-end servers. Slicer's control plane collects metadata about shard accesses and server workload. The control plane periodically runs an optimization algorithm that decides to redistribute, repartition, or replicate slices of the key space to achieve better back-end load-balance. Also, Slicer replicates the centralized control plane to achieve high availability and to solve the fault-tolerance problem in both Centrifuge [6] and in [11]. CoT is complementary to systems like Slicer and Centrifuge since CoT operates on a *fine-grain key* level at front-end servers while solutions like Slicer [7] operate on coarser grain slices or shards at the caching servers. Our goal is to cache heavy hitters at front-end servers to reduce key skew at back-end caching servers and hence, reduce Slicer's initiated re-configurations. Also, CoT is distributed and front-end driven that does not require any system component to develop a

global view of the workload. This allows CoT to scale to thousands of front-end servers without introducing any centralized points of failure or bottlenecks.

Server side load-monitoring: Another approach to load-monitoring is to distribute the load-monitoring among the caching shard servers. In [24], each caching server tracks its own hot-spots. When the hotness of a key surpasses a certain threshold, this key is replicated to γ caching servers and the replication decision is broadcast to all the front-end servers. Any further accesses on this hot key shall be equally distributed among these γ servers. Cheng et al. [11] extend the work in [24] to allow moving coarse-grain key cachelets (shards) among threads and caching servers. Our approach reduces the need for server side load-monitoring. Instead, load-monitoring happens at the edge. This allows individual front-end servers to independently identify their local trends and cache them without adding the monitoring overhead to the caching layer, a critical layer for the performance of the overall system.

Client side load-monitoring: Fan et al. [20] use a distributed front-end load-monitoring approach. This approach shows that adding a small perfect cache in the front-end servers has significant impact on solving the back-end load-imbalance. Fan et al. *theoretically* show through analysis and simulation that a small *perfect cache* at each front-end solves the back-end load-imbalance problem. Following [20], Gavrielatos et al. [21] propose *symmetric caching* to track and cache the hot-most items at every front-end server. Symmetric caching assumes that all front-end servers obtain the same access distribution and hence statically allocates the same cache size to all front-end servers. However, different front-end servers might serve different geographical regions and therefore observe different access distributions. CoT discovers the workload access distribution independently at each front-end server and adjusts the cache size to achieve some target load-balance among caching servers. NetCache [28] uses programmable switches to implement heavy hitter tracking and caching at the network level. Like symmetric caching, NetCache assumes a fixed cache size for different access distributions. To the best of our knowledge, CoT is the first front-end caching algorithm that exploits the cloud elasticity allowing each front-end server to independently reduce the necessary required front-end cache memory to achieve back-end load-balance.

Other works in the literature focus on maximizing cache hit rates for fixed memory sizes. Cidon et al. [12, 13] redistribute available memory among memory slabs to maximize memory utilization and reduce cache miss rates. Fan et al. [19] use cuckoo hashing [41] to increase memory utilization. Lim et al. [32] increase memory locality by assigning requests that access the same data item to the same CPU. Bechmann et al. [8] propose Least Hit Density (LHD), a new cache replacement policy. LHD predicts the expected hit density of each object and evicts the object with the lowest hit density. LHD aims to evict objects that contribute low hit rates with respect to the cache space they occupy. Unlike these works, CoT does not assume a static cache size. In contrast, CoT maximizes the hit rate of the available cache and exploits the cloud elasticity allowing front-end servers to independently expand or shrink their cache memory sizes as needed.

3 DATA MODEL

We assume a typical key/value store interface between the front-end servers and the storage layer. The API consists of the following calls:

- *v = get(k)* retrieves value *v* corresponding to key *k*.
- *set(k, v)* assigns value *v* to key *k*. *set(k, null)* to delete *k*.

Front-end servers use *consistent hashing* [30] to locate keys in the caching layer. Consistent hashing solves the *key discovery* problem and reduces key churn when a caching server is added to or removed from the caching layer. We extend this model by adding an additional layer in the cache hierarchy. As shown in Figure 1, each front-end server maintains a small cache of its hot keys. This cache is populated according to the accesses that are served by each front-end server.

We assume a client driven caching protocol similar to the protocol implemented by **Memcached** [3]. A cache client library is deployed in the front-end servers. *Get* requests are initially attempted to be served from the local cache. If the requested key is in the local cache, the *value* is returned and the request is marked as served. Otherwise, a *null* value is returned and the front-end has to request this key from the caching layer **at the back-end storage layer**. If the key is cached in the caching layer, its value is returned to the front-end. Otherwise, a *null* value is returned and the front-end has to request this key from the persistent storage layer and upon receiving the corresponding value, the front-end inserts the value in its front-end local cache and in the server-side caching layer as well. As in [38], a *set*, or an update, request invalidates the key in both the local cache and the caching layer. Updates are directly sent to the persistent storage, local values are set to null, and delete requests are sent to the caching layer to invalidate the updated keys. The Memcached client driven approach allows the deployment of a *stateless* caching layer. As requests are driven by the client, a caching server does not need to maintain the state of any request. This simplifies scaling and tolerating failures at the caching layer. Although, we adopt the Memcached client driven request handling protocol, our model works as well with write-through request handling protocols.

Our model is not tied to any replica consistency model. Each key can have multiple incarnations in the storage layer and the caching layer. Updates can be synchronously propagated if *strong consistency* guarantees are needed or asynchronously propagated if *weak consistency* guarantees suffice. Since the assumed workload is mostly read requests with very few update requests, we do not address consistency of updates in this paper. Achieving strong consistency guarantees among replicas of the same object has been widely studied in [11, 24]. Ghandeharizadeh et al. [22, 23] propose several complementary techniques to CoT to deal with consistency in the presence of updates and configuration changes. These techniques can be adopted in our model according to the application requirements. We understand that deploying an additional vertical layer of cache increases potential data inconsistencies and hence increases update propagation and synchronization overheads. Therefore, our goal in this paper is to reduce the front-end cache size in order to limit the inconsistencies and the synchronization overheads that result from deploying front-end caches, while maximizing their benefits on back-end load-imbalance.

4 FRONT-END CACHE ALTERNATIVES

Fan et al. [20] show that a small perfect cache in the front-end servers has big impact on the caching layer load-balance. A **perfect cache** of C cache-lines is defined such that accesses to the C hot-most keys always hit the cache while accesses to any other keys always miss the cache. The perfect caching assumption is impractical especially for dynamically changing and evolving workloads. Several replacement policies have been developed to

approximate perfect caching for different workloads. This section discusses the workload assumptions and various client caching objectives. This is followed by a discussion of the advantages and limitations of common caching replacement policies.

Workload assumptions: Real-world workloads are typically skewed with few keys being significantly hotter than other keys. In this paper, we assume skewed mostly read workloads with periods of stability (where hot keys remain hot during these periods).

Client caching objectives: Front-end servers construct their perspective of the key hotness distribution based on the requests they serve. Front-end servers aim to achieve the following caching objectives:

- The cache replacement policy should prevent cold keys from replacing hotter keys in the cache.
- Front-end caches should adapt to the changes in the workload. In particular, front-end servers should have a way to retire hot keys that are no longer accessed. In addition, front-end caches should have a mechanism to expand or shrink their local caches in response to changes in workload distribution. For example, front-end servers that serve uniform access distributions should dynamically shrink their cache size to *zero* since caching is of no value in this situation. On the other hand, front-end servers that serve highly skewed Zipfian (e.g., s = 1.5) should dynamically expand their cache size to capture all the hot keys that cause load-imbalance among the back-end caching servers.

A popular policy for implementing client caching is the LRU replacement policy. Least Recently Used (LRU) costs O(1) per access and caches keys based on their recency of access. This may allow cold keys that are recently accessed to replace hotter cached keys. Also, LRU cannot distinguish well between frequently and infrequently accessed keys [31]. Alternatively, Least Frequently Used (LFU) can be used as a replacement policy. LFU costs $O(log(C))$ per access where C is the cache size. LFU is typically implemented using a min-heap and allows cold keys to replace hotter keys at the top levels of the heap. Also, LFU cannot distinguish between old references and recent ones. This means that LFU cannot adapt to changes in workload. Both LRU and LFU are limited in their knowledge to the content of the cache and cannot develop a wider perspective about the hotness distribution outside of their static cache size.

Adaptive Replacement Cache (ARC) [36] tries to realize the benefits of both LRU and LFU policies by maintaining two caching lists: one for *recency* and one for *frequency*. ARC dynamically changes the number of cache-lines allocated for each list to either favor recency or frequency of access in response to workload changes. In addition, ARC uses shadow queues to track more keys beyond the cache size. This helps ARC to maintain a broader perspective of the access distribution beyond the cache size. ARC is designed to find the fine balance between recent and frequent accesses. As a result, ARC pays the cost of caching every new cold key in the recency list evicting a hot key from the frequency list. This cost is significant especially when the cache size is much smaller than the key space and the workload is skewed favoring frequency over recency.

LRU-k [39] tracks the last k accesses of each cached key, in addition to a pre-configured *manually* fixed size history that includes the access information of the recently evicted keys from the cache. New keys replace the cached key with the least recently k^{th} access. The evicted key is moved to the history, which is typically implemented using LRU. LRU-k is a suitable strategy to mock perfect caching of periodically stable skewed workloads when its cache and history sizes are perfectly pre-configured for this specific workload. However, due to the lack of LRU-k's dynamic resizing and elasticity of both its cache and history sizes, we choose to introduce CoT that is designed with native resizing and elasticity functionality. This functionality allows CoT to adapt its cache and tracker sizes in response to workload changes.

5 CACHE ON TRACK (COT)

Front-end caches serve two main purposes: *1) decrease the load on the back-end caching layer* and *2) reduce the load-imbalance among the back-end caching servers*. CoT focuses on the latter goal and considers back-end load reduction a complementary side effect. CoT's design philosophy is to track more keys beyond the cache size. This tracking serves as a filter that prevents cold keys from populating the small cache and therefore, only hot keys can populate the cache. In addition, the tracker and the cache are dynamically and adaptively resized to ensure that the load served by the back-end layer follows a load-balance target.

The idea of tracking more keys beyond the cache size has been widely used in replacement policies such as 2Q [29], MQ [45], LRU-k [39, 40], and ARC [36]. Both 2Q and MQ use multiple LRU queues to overcome the weaknesses of LRU of allowing cold keys to replace warmer keys in the cache. All these policies are desgined for fixed memory size environments. However, in a cloud environment where elastic resources can be requested on-demand, a new cache replacement policy is needed to take advantage of this elasticity.

CoT presents a new cache replacement policy that uses a *shadow heap* to track more keys beyond the cache size. Previous works have established the efficiency of heaps in tracking frequent items [37]. In this section, we explain how CoT uses tracking beyond the cache size to achieve the caching objectives listed in Section 4. In particular, CoT answers the following questions: 1) *how to prevent cold keys from replacing hotter keys in the cache?*, 2) *how to reduce the required front-end cache size that achieves lookup load-balance?*, 3) *how to adaptively resize the cache in response to changes in the workload distribution?* and finally 4) *how to dynamically retire old heavy hitters?*.

5.1 Notation

The key space, denoted by S, is assumed to be large in the scale of trillions of keys. Each front-end server maintains a cache of size $C <<< S$. The set of cached keys is denoted by S_c. To capture the top-C hottest keys, each front-end server tracks $K > C$ keys. The set of tracked key is denoted by S_k. Front-end servers cache the top-C hottest keys where $S_c \subset S_k$. A key hotness h_k is determined using the dual cost model introduced in [18]. In this model, read accesses increase a key hotness by a read weight r_w while update accesses decrease it by an update weight u_w. As update accesses cause cache invalidations. Therefore, frequently updated keys should not be cached and thus an update access decreases a key's hotness. For each tracked key, the read count $k.r_c$ and the update count $k.u_c$ are maintained to capture the number of read and update accesses of this key. Equation 1 shows how the hotness of key k is calculated. We use $r_w = u_w = 1$ in our experiments.

$$h_k = k.r_c \times r_w - k.u_c \times u_w \quad (1)$$

h_{min} refers to the minimum key hotness in the cache. h_{min} splits the tracked keys into *two* subsets: 1) the set of cached keys (also tracked) S_c of size C and 2) the set of tracked but not cached

S	key space
K	number of tracked keys at the front-end
C	number of cached keys at the front-end
h_k	hotness of a key k
$k.r_c$	read count of a key k
$k.u_c$	update count of a key k
r_w	the weight of a read operation
u_w	the weight of an update operation
h_{min}	the minimum hotness of keys in the cache
S_k	the set of all tracked keys
S_c	the set of cached keys (these keys are also tracked)
S_{k-c}	the set of tracked but not cached keys
I_c	the current local lookup load-imbalance
I_t	the target lookup load-imbalance
α	the average hit-rate per cache-line in an epoch
E	Epoch: a configurable number of accesses

Table 1: Summary of notation.

keys S_{k-c} of size $K-C$. The current local load-imbalance among caching servers lookup load is denoted by I_c. I_c is a local variable at each front-end that determines the current contribution of this front-end to the back-end load-imbalance. I_c is defined as the workload ratio between the most loaded back-end server and the least loaded back-end server as observed at a front-end server. For example, if a front-end server sends, during an epoch, a maximum of 5K key lookups to some back-end server and, during the same epoch, a minimum of 1K key lookups to another back-end server then I_c, at this front-end, equals 5. I_t is the target load-imbalance among the caching servers. I_t is the only input parameter set by the system administrator and is used by front-end servers to dynamically adjust their cache and tracker sizes. Ideally I_t should be set close to 1. $I_t = 1.1$ means that back-end load-balance is achieved if the most loaded server observes at most 10% more key lookups than the least loaded server. Finally, we define another **local auto-adjusted** parameter α. α is the average hits per cache-line and it determines the quality of the cached keys. A cache-line, or entry, contains one cached key and its corresponding value and α determines the average hits per cache-line during an epoch. For example, if a cache consists of 10 cache-lines and they cumulatively observe 2000 hits in an epoch, we consider α to be 200. α helps detect changes in workload and adjust the cache size accordingly. Note that CoT automatically infers the value of α based on the observed workload. Hence, the system administrator does not need to set the value of α. E is an epoch parameter defined by a configurable number of accesses. CoT runs its dynamic resizing algorithm every E accesses. Table 1 summarizes the notation.

5.2 Space-Saving Tracking Algorithm

CoT uses the *space-saving* algorithm introduced in [37] to track the key hotness at front-end servers. Space-saving uses a min-heap to order keys based on their hotness and a hashmap to lookup keys in the tracker in *O(1)*. The space-saving algorithm is shown in Algorithm 1. If the accessed key k is not in the tracker (Line 1), it replaces the key with minimum hotness at the root of the min-heap (Lines 2, 3, and 4). The algorithm gives the newly added key the benefit of doubt and assigns it the hotness of the replaced key. As a result, the newly added key gets the opportunity to survive immediate replacement in the tracker. Whether the accessed key k was in the tracker or is newly added to the tracker, the hotness of the key is updated based on the access type according to Equation 1 (Line 6) and the heap is accordingly adjusted (Line 7).

Algorithm 1 The space-saving algorithm: track_key(key k, access_type t).

State: S_k: keys in the tracker.
Input: (key k, access_type t)

1: **if** $k \notin S_k$ **then**
2: let k' be the root of the min-heap
3: replace k' with k
4: $h_k := h_{k'}$
5: **end if**
6: h_k := update_hotness(k, t)
7: adjust_heap(k)
8: return h_k

5.3 CoT: Cache Replacement Policy

CoT's tracker captures the approximate top K hot keys. Each front-end server should cache the exact top C keys out of the tracked K keys where $C < K$. The exactness of the top C cached keys is considered with respect to the approximation of the top K tracked keys. Caching the exact top C keys prevents cold and noisy keys from replacing hotter keys in the cache and achieves the first caching objective. To determine the exact top C keys, CoT maintains a cache of size C in a min-heap structure. Cached keys are partially ordered in the min-heap based on their hotness. The root of the cache min-heap gives the minimum hotness, h_{min}, among the cached keys. h_{min} splits the tracked keys into *two unordered* subsets S_c and S_{k-c} such that:

- $|S_c| = C$ and $\forall_{x \in S_c} h_x \geq h_{min}$
- $|S_{k-c}| = K - C$ and $\forall_{x \in S_{k-c}} h_x < h_{min}$

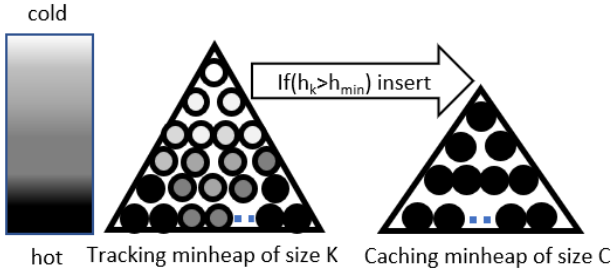

Figure 2: CoT: a key is inserted to the cache if its hotness exceeds the minimum hotness of the cached keys.

For every key access, the hotness information of the accessed key is updated in the tracker. If the accessed key is cached, its hotness information is updated in the cache as well. However, if the accessed key is not cached, its hotness is compared against h_{min}. As shown in Figure 2, the accessed key is inserted into the cache only if its hotness exceeds h_{min}. Algorithm 2 explains the details of CoT's cache replacement algorithm.

For every key access, the *track_key* function of Algorithm 1 is called (Line 1) to update the tracking information and the hotness of the accessed key. Then, a key access is served from the local cache only if the key is in the cache (Lines 3). Otherwise, the access is served from the caching server (Line 5). Serving an access from the local cache implicitly updates the accessed key hotness and location in the cache min-heap. If the accessed key

Algorithm 2 CoT's caching algorithm

State: S_k: keys in the tracker and S_c: keys in the cache.
Input: (key k, access_type t)

```
1:  h_k = track_key(k, t) as in Algorithm 1
2:  if k ∈ S_c then
3:      let v = access(S_c, k) // local cache access
4:  else
5:      let v = server_access(k) // caching server access
6:      if h_k > h_min then
7:          insert(S_c, k, v) // local cache insert
8:      end if
9:  end if
10: return v
```

is not cached, its hotness is compared against h_{min} (Line 6). The accessed key is inserted to the local cache if its hotness exceeds h_{min} (Line 7). This happens only if there is a tracked but not cached key that is hotter than one of the cached keys. Keys are inserted to the cache together with their tracked hotness information. Inserting keys into the cache follows the LFU replacement policy. This implies that a local cache insert (Line 7) would result in the replacement of the coldest key in the cache (the root of the cache heap) if the local cache is full.

5.4 CoT: Adaptive Cache Resizing

This section explains CoT's resizing algorithm. This algorithm reduces the necessary front-end cache size that achieves back-end lookup load-balance. In addition, this algorithm dynamically expands or shrinks CoT's tracker and cache sizes when the served workload changes. Also, this algorithm detects changes in the set of hot keys and retires old hot keys that are not hot any more. As explained in Section 1, reducing the front-end cache size decreases the front-end cache monetary cost, limits the overheads of data consistency management techniques, and maximizes the benefit of front-end caches measured by the average cache-hits per cache-line and back-end load-imbalance reduction.

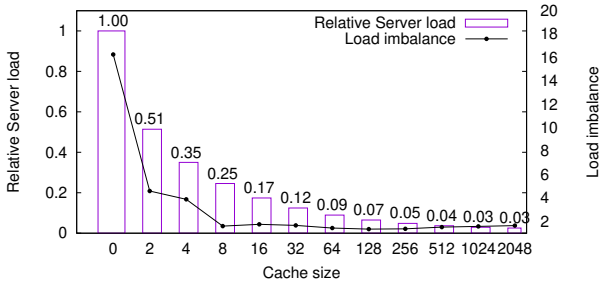

Figure 3: Reduction in relative server load and load-imbalance among caching servers as front-end cache size increases.

The Need for Cache Resizing: Figure 3 experimentally shows the effect of increasing the front-end cache size on both back-end *load-imbalance reduction* and decreasing the workload at the back-end. In this experiment, 8 memcached shards are deployed to serve back-end lookups and 20 clients send lookup requests following a significantly skewed Zipfian distribution (s = 1.5). The size of the key space is 1 million and the total number of lookups is 10 millions. The front-end cache size at each client is varied from 0 cachelines (no cache) to 2048 cachelines (≈0.2% of the key space). Front-end caches use CoT's replacement policy and a ratio of 4:1 is maintained between CoT's tracker size and CoT's cache size. We define back-end load-imbalance as the workload ratio between the most loaded server and the least loaded server. The target load-imbalance I_t is set to 1.5. As shown in Figure 3, processing all the lookups from the back-end caching servers (front-end cache size = 0) leads to a significant load-imbalance of 16.26 among the caching servers. This means that the most loaded caching server receives 16.26 times the number of lookup requests received by the least loaded caching server. As the front-end cache size increases, the server size load-imbalance drastically decreases. As shown, a front-end cache of size 64 cache lines at each client reduces the load-imbalance to 1.44 (an order of magnitude less load-imbalance across the caching servers) achieving the target load-imbalance I_t = 1.5. Increasing the front-end cache size beyond 64 cache lines only reduces the back-end aggregated load but not the back-end load-imbalance. The *relative server load* is calculated by comparing the server load for a given front-end cache size to the server load when there is no front-end caching (cache size = 0). Figure 3 demonstrates the reduction in the relative server load as the front-end cache size increases. However, the benefit of doubling the cache size proportionally decays with the key hotness distribution. As shown in Figure 3, the first 64 cachelines reduce the relative server load by 91% while the second 64 cachelines reduce the relative server load by only 2% more.

The failure of the "one size fits all" design strategy suggests that statically allocating fixed cache and tracker sizes to all front-end servers is not ideal. Each front-end server should independently and adaptively be configured according to the key access distribution it serves. Also, changes in workloads can alter the key access distribution, the skew level, or the set of hot keys. For example, social networks and web front-end servers that serve different geographical regions might experience different key access distributions and different local trends (e.g., #miami vs. #ny). Therefore, CoT's cache resizing algorithm learns the key access distribution independently at each front-end and dynamically resizes the cache and the tracker to achieve lookup load-imbalance target I_t. CoT is designed to reduce the front-end cache size that achieves I_t. Any increase in the front-end cache size beyond CoT's recommendation mainly decreases back-end load and should consider other conflicting parameters such as the additional cost of the memory cost, the cost of updates and maintaining the additional cached keys, and the percentage of back-end load reduction that results from allocating additional front-end caches.

Cache Resizing Algorithm (parameter configuration): Front-end servers use CoT to minimize the cache size that achieves a target load-imbalance I_t. Initially, front-end servers are configured with no front-end caches. The system administrator configures CoT by an input *target load-imbalance* parameter I_t that determines the maximum tolerable imbalance between the most loaded and least loaded back-end caching servers. Afterwards, CoT expands both tracker and cache sizes until the current load-imbalance achieves the inequality $I_c \leq I_t$.

Algorithm 3 describes CoT's cache resizing algorithm. CoT divides the timeline into epochs and each epoch consists of E accesses. Algorithm 3 is executed at the end of each epoch. The epoch size E is proportional to the tracker size K and is dynamically updated to guarantee that $E \geq K$ (Line 3). This condition helps ensure that CoT does not trigger consecutive resizes before the cache and the tracker are warmed up with keys. During each epoch, CoT tracks the number of lookups sent to every back-end caching server. In addition, CoT tracks the total number of cache

hits and tracker hits during this epoch. At the end of each epoch, CoT calculates the current load-imbalance I_c as the ratio between the highest and the lowest load on back-end servers during this epoch. Also, CoT calculates the current average hit per cached key α_c. α_c equals the total cache hits in the current epoch divided by the cache size. Similarly, CoT calculates the current average hit per tracked but not cache key α_{k-c}. CoT compares I_c to I_t and decides on a resizing action as follows.

(1) $I_c > I_t$ and $\alpha_c \geq \alpha_{k-c}$ (Line 1), this means that the target load-imbalance is not achieved and cached keys observe more hits than the keys in the tracker. CoT follows the binary search algorithm in searching for the front-end cache size that achieves I_t. Therefore, CoT decides to double the front-end cache size (Line 2). As a result, CoT doubles the tracker size as well to maintain a tracker to cache size ratio of at least 2, $K \geq 2 \cdot C$ (Line 2). The cache and tracker sizes are doubled until either I_t is achieved or a configurable upper limit cache size is hit. In addition, CoT uses a local variable α_t to capture the quality of the cached keys when I_t is first achieved. Initially, $\alpha_t = 0$. CoT then sets α_t to the average hits per cache-line α_c during the current epoch (Line 4). In subsequent epochs, α_t is used to detect changes in workload.

(2) $I_c \leq I_t$ (Line 5), this means that the target load-imbalance has been achieved. However, changes in workload could alter the quality of the cached keys. Therefore, CoT uses α_t to detect and handle changes in workload in future epochs as explained below.

Algorithm 3 CoT's elastic resizing algorithm.

State: S_c: keys in the cache, S_k: keys in the tracker, C: cache capacity, K: tracker capacity, α_c: average hits per key in S_c in the current epoch, α_{k-c}: average hits per key in S_{k-c} in the current epoch, I_c: current load-imbalance, and α_t: target average hit per key

Input: I_t

```
1:  if I_c > I_t && α_c >= α_{k-c} then
2:      resize(S_c, 2 × C) , resize(S_k, 2 × K)
3:      E := max (E, K)
4:      Let α_t = α_c
5:  else
6:      if α_c < (1 − ε).α_t and α_{k-c} < (1 − ε).α_t then
7:          resize(S_c, C/2), resize(S_k, K/2)
8:      else if α_c < (1 − ε).α_t and α_{k-c} > (1 − ε).α_t then
9:          half_life_time_decay()
10:     end if
11: end if
```

α_t is reset whenever the inequality $I_c \leq I_t$ is violated and Algorithm 3 expands cache and tracker sizes. Ideally, when the inequality $I_c \leq I_t$ holds, keys in the cache (the set S_c) achieve α_t hits per cache-line during every epoch while keys in the tracker but not in the cache (the set S_{k-c}) do not achieve α_t. This happens because keys in the set S_{k-c} are colder than keys in the set S_c. α_t represents a target hit-rate per cache-line for future epochs. Therefore, if keys in the cache do not meet the target α_t in a following epoch, this indicates that the quality of the cached keys has changed and an action needs to be taken as follows.

(1) Case 1: keys in S_c, on the average, do not achieve α_t hits per cacheline and keys in S_{k-c} do not achieve α_t hits as well (Line 6). This indicates that the quality of the cached keys decreased. In response. CoT shrinks both the cache and the tracker sizes (Line 7). If shrinking both cache and tracker sizes results in a violation of the inequality $I_c < I_t$, Algorithm 3 doubles both tracker and cache sizes in the following epoch and α_t is reset as a result. In Line 6, we compare the average hits per key in both S_c and S_{k-c} to $(1 - \epsilon) \cdot \alpha_t$ instead of α_t. Note that ϵ is a small constant $<<<$ 1 that is used to avoid unnecessary resizing actions due to insignificant statistical variations.

(2) Case 2: keys in S_c do not achieve α_t while keys in S_{k-c} achieve α_t (Line 8). This signals that the set of hot keys is changing and keys in S_{k-c} are becoming hotter than keys in S_c. For this, CoT triggers a half-life time decaying algorithm that halves the hotness of all cached and tracked keys (Line 9). This decaying algorithm aims to forget old trends that are no longer hot to be cached (e.g., Gangnam style song). Different decaying algorithms have been developed in the literature [14, 16, 17]. Therefore, this paper only focuses on the resizing algorithm details without implementing a specific decaying algorithm.

(3) Case 3: keys in S_c achieve α_t while keys in S_{k-c} do not achieve α_t. This means that the quality of the cached keys has not changed and therefore, CoT does not take any action. Similarly, if keys in both sets S_c and S_{k-c} achieve α_t, CoT does not take any action as long as the inequality $I_c < I_t$ holds.

6 EXPERIMENTAL EVALUATION

This section evaluates both CoT's caching and adaptive resizing algorithms. We choose to compare CoT to traditional and widely used replacement policies like LRU and LFU. In addition, we compare CoT to both ARC [36] and LRU-k [39]. As stated in [36], ARC, in its online auto-configuration setting, achieves comparable performance to LRU-2 (which is the most responsive LRU-k) [39, 40], 2Q [29], LRFU [31], and LIRS [27] even when these policies are perfectly tuned offline. Also, ARC outperforms the online adaptive replacement policy MQ [45]. Therefore, we compare with ARC and LRU-2 as representatives of these different polices. Section 6.1 explains the experimental setup. First, we compare the hit rates of CoT's cache algorithm to LRU, LFU, ARC, and LRU-2 hit rates for different front-end cache sizes in Section 6.2. Then, we compare the required front-end cache size for each replacement policy to achieve a target back-end load-imbalance I_t in Section 6.3. In Section 6.4, we provide an end-to-end evaluation of front-end caches comparing the end-to-end performance of CoT, LRU, LFU, ARC, and LRU-2 on different workloads with the configuration where no front-end cache is deployed. Finally, CoT's resizing algorithm is evaluated in Section 6.5.

6.1 Experiment Setup

We deploy 8 instances of memcached [3] on a small cluster of 4 caching servers (2 memcached instance per server). Each caching server has an Intel(R) Xeon(R) CPU E3-1235 (8MB Cache and 16GB RAM) with 4GB RAM dedicated to each memcached instance. Caching servers and clients run ubuntu 18.04 and connected to the same 10Gbps Ethernet network. No explicit network or OS optimization are used.

A dedicated client machine with Intel(R) Core(TM) i7-6700HQ CPU and 16GB of RAM is used to generate client workloads. The client machine executes multiple client threads to submit workloads to caching servers. Client threads use Spymemcached

2.11.4 [5], a Java-based memcached client, to communicate with memcached cluster. Spymemcached provides communication abstractions that distribute workload among caching servers using *consistent hashing* [30]. We slightly modified Spymemcached to monitor the workload per back-end server at each front-end. Client threads use Yahoo! Cloud Serving Benchmark (YCSB) [15] to generate workloads for the experiments. YCSB is a standard key/value store benchmarking framework. YCSB is used to generate key/value store requests such as *Get*, *Set*, and *Insert*. YCSB enables configuring the ratio between read (Get) and write (Set) accesses. Also, YCSB allows the generation of accesses that follow different access distributions. As YCSB is CPU-intensive, the client machine runs at most 20 client threads per machine to avoid contention among client threads. During our experiments, we realized that YCSB's ScrambledZipfian workload generator has a bug as it generates Zipfian workload distributions with significantly less skew than the skew level it is configured with. Therefore, we use YCSB's Zipfian generator instead of YCSB's ScrambledZipfian. Figure 4 shows the hits per key generated for the top 1024 out 1 million keys and 100 million samples of a zipfian 0.99 distribution from YCSB-Zipfian, YCSB-ScambledZipfian, and theoretical zipfian generators. As shown, YCSB-Zipfian generator (CDF 0.512) is almost identical to the theoretical generator (CDF 0.504) while YCSB-ScrambledZipfian generator (CDF 0.30) has much less skew than the theoretical zipfian generator (40% less hits in the top 1024 keys than the theoretical distribution).

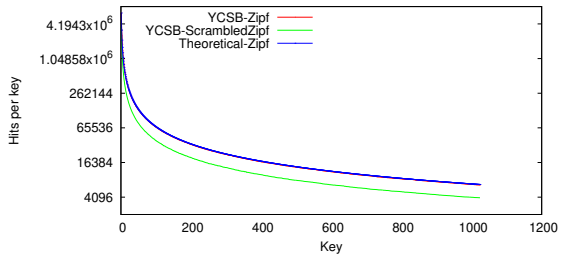

Figure 4: YCSB-Zipf vs ScrambledZipf vs Theoretical-Zipf

Our experiments use different variations of YCSB core workloads. Workloads consist of 1 million key/value pairs. Each key consists of a common prefix *"usertable:"* and a unique ID. We use a value size of 750 KB making a dataset of size 715GB. Experiments use read intensive workloads that follow Tao's [9] read-to-write ratio of 99.8% reads and 0.2% updates. Unless otherwise specified, experiments consist of 10 million key accesses sampled from different access distributions such as Zipfian (s = 0.90, 0.99, or 1.2) and uniform. Client threads submit access requests back-to-back. Each client thread can have only one outgoing request. Clients submit a new request as soon as they receive an acknowledgement for their outgoing request.

6.2 Hit Rate

The first experiment compares CoT's hit rate to LRU, LFU, ARC, and LRU-2 hit rates using equal cache sizes for all replacement policies. 20 client threads are provisioned on one client machine and each cache client thread maintains its own cache. **Configuration:** The cache size is varied from a very small cache of 2 cache-lines to 2048 cache-lines. The hit rate is compared using different Zipfian access distributions with skew parameter values s = 0.90, 0.99, and 1.2 as shown in Figures 5(a), 5(b), and 5(c) respectively. In addition, 14 days of Wikipedia's real traces, collected by [42], are used to compare CoT to other replacement policies, including LHD [8], as shown in Figure 5(d). CoT's tracker to cache size ratio determines how many tracking nodes are used for every cache-line. CoT automatically detects the ideal tracker to cache ratio for any workload by fixing the cache size and doubling the tracker size until the observed hit-rate gains from increasing the tracker size are insignificant i.e., the observed hit-rate saturates. The tracker to cache size ratio decreases as the workload skew increases. A workload with high skew simplifies the task of distinguishing hot keys from cold keys and hence, CoT requires a smaller tracker size to successfully filter hot keys from cold keys. Note that LRU-2 is also configured with the same history to cache size as CoT's tracker to cache size. In this experiment, for each skew level, CoT's tracker to cache size ratio is varied as follows: 16:1 for Zipfian 0.9 and Wikipedia, 8:1 for Zipfian 0.99, and 4:1 for Zipfian 1.2. Note that CoT's tracker maintains only the meta-data of tracked keys. Each tracker node consists of a read counter and a write counter with 8 bytes of memory overhead per tracking node. In real-world workloads, value sizes vary from tens of KBs to few MBs. For example, Google's Bigtable [10] uses a value size of 64 KB. Therefore, a memory overhead of at most $\frac{1}{8}$ KB (16 tracker nodes * 8 bytes) per cache-line is negligible (0.2%).

In Figures 5, the *x-axis* represents the cache size expressed as the number of cache-lines. The *y-axis* represents the front-end cache hit rate (%) as a percentage of the total workload size. At each cache size, the cache hit rates are reported for LRU, LFU, ARC, LRU-2, and CoT cache replacement policies. In addition, TPC represents the theoretically calculated hit-rate from the Zipfian distribution CDF if a perfect cache with the same cache size is deployed. For each experiment, the TPC is configured with the same key space size N = (1 million keys), the same sample generated size (10 million samples), the same skew parameter s (e.g., 0.9, 0.99, 1.2) of the experiment, and k equals to the cache size (ranging from 2 – 2048). For example, a perfect cache of size 2 cache-lines stores the top-2 hot keys and hence any access to these 2 keys results in a cache hit while accesses to other keys result in cache misses. For Wikipedia traces, the TPC is the cumulative accesses of the top-C keys.

Analysis: As shown in Figure 5(a), CoT surpasses LRU, LFU, ARC, and LRU-2 hit rates at all cache sizes. In fact, CoT achieves almost similar hit-rate to the TPC hit-rate. In Figure 5(a), CoT outperforms TPC for some cache size which is counter intuitive. This happens as TPC is theoretically calculated using the Zipfian CDF while CoT's hit-rate is calculated out of YCSB's sampled distributions which are approximate distributions. In addition, CoT achieves higher hit-rates than both LRU and LFU with **75% less cache-lines**. As shown, CoT with 512 cache-lines achieves 10% more hits than both LRU and LFU with 2048 cache-lines. Also, CoT achieves higher hit rate than ARC using **50% less cache-lines**. In fact, CoT configured with 512 cache-lines achieves 2% more hits than ARC with 1024 cache-lines. Taking tracking memory overhead into account, CoT maintains a tracker to cache size ratio of 16:1 for this workload (Zipfian 0.9). This means that CoT adds an overhead of 128 bytes (16 tracking nodes * 8 bytes each) per cache-line. The percentage of CoT's tracking memory overhead decreases as the cache-line size increases. For example, CoT introduces a tracking overhead of 0.02% when the cache-line size is 750KB. Finally, CoT consistently achieves 8-10% higher hit-rate than LRU-2 configured with the same history and cache sizes as CoT's tracker and cache sizes.

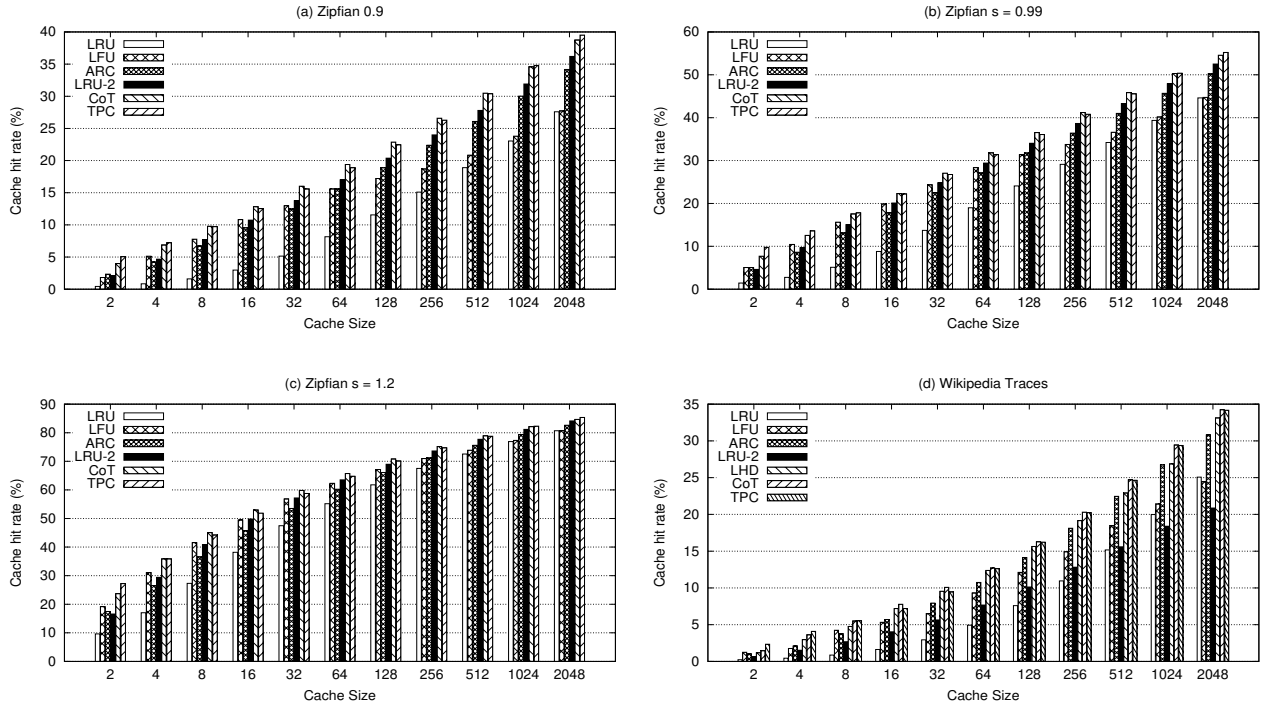

Figure 5: Comparison of LRU, LFU, ARC, LRU-2, LHD, CoT and TPC's hit rates using various Zipfian and Wikipedia traces

Similarly, as illustrated in Figures 5(b) and 5(c), CoT outpaces LRU, LFU, ARC, and LRU-2 hit rates at all different cache sizes. Figure 5(b) shows that a configuration of CoT using 512 cache-lines achieves 3% more hits than both configurations of LRU and LFU with 2048 cache-lines. Also, CoT consistently outperforms ARC's hit rate with 50% less cache-lines. Finally, CoT achieves 3-7% higher hit-rate than LRU-2 configured with the same history and cache sizes. Figures 5(b) and 5(c) highlight that increasing workload skew decreases the advantage of CoT. As workload skew increases, the ability of LRU, LFU, ARC, LRU-2 to distinguish between hot and cold keys increases and hence CoT's preeminence decreases.

In addition to YCSB synthetic traces, Wikipedia real traces show in Figure 5(d) that CoT significantly outperforms other replacement policies at every cache size. This Wikipedia real traces comparison includes LHD [8], a recently proposed caching policy specifically for cloud applications. As Figure 5(d) shows, CoT is the only replacement policy that achieves almost the same hit rate of the cumulative top-C keys beating LRU, LFU, ARC, LRU-2, and LHD by 23-84%, 14-51%, 9-42%, 37-58%, and 4-24% respectively for different cache sizes.

6.3 Back-End Load-Imbalance

In this section, we compare the required front-end cache sizes for different replacement policies to achieve a back-end load-imbalance target I_t. **Configuration:** Different skewed workloads are used, namely, Zipfian s = 0.9, s = 0.99, and s = 1.2. For each distribution, we first measure the back-end load-imbalance when no front-end cache is used. A back-end load-imbalance target I_t is set to $I_t = 1.1$. This means that the back-end is load balanced if the most loaded back-end server processes at most 10% more lookups than the least loaded back-end server. We evaluate the back-end load-imbalance while increasing the front-end cache size using different cache replacement policies, namely, LRU, LFU, ARC, LRU-2, and CoT. In this experiment, CoT uses the same tracker-to-cache size ratio as in Section 6.2. For each replacement policy, we report the minimum required number of cache-lines to achieve I_t.

Dist.	Load-imbalance	Number of cache-lines to achieve $I_t = 1.1$				
	No cache	LRU	LFU	ARC	LRU-2	CoT
Zipf 0.9	1.35	64	16	16	8	8
Zipf 0.99	1.73	128	16	16	16	8
Zipf 1.20	4.18	2048	2048	1024	1024	512

Table 2: The minimum required number of cache-lines for different replacement policies to achieve a back-end load-imbalance target $I_t = 1.1$ for different workload distributions.

Analysis: Table 2 summarizes the reported results for different distributions using LRU, LFU, ARC, LRU-2, and CoT replacement policies. For each distribution, the initial back-end load-imbalance is measured using no front-end cache. As shown, the initial load-imbalances for Zipf 0.9, Zipf 0.99, and Zipf 1.20 are 1.35, 1.73, and 4.18 respectively. For each distribution, the minimum required number of cache-lines for LRU, LFU, ARC, and CoT to achieve a target load-imbalance of $I_t = 1.1$ is reported. As shown, CoT requires **50% to 93.75% less cache-lines** than other replacement policies to achieve I_t. Since LRU-2 is configured with a history size equals to CoT's tracker size, LRU-2 requires the second least number of cache-lines to achieve I_t.

6.4 End-to-End Evaluation

In this section, we evaluate the effect of front-end caches using LRU, LFU, ARC, LRU-2, and CoT replacement policies on

the overall running time of different workloads. This experiment also demonstrates the overhead of front-end caches on the overall running time. **Configuration:** This experiment uses 3 different workload distributions, namely, uniform, Zipfian (s = 0.99), and Zipfian (s = 1.2) distributions as shown in Figure 6. For all the three workloads, each replacement policy is configured with 512 cache-lines. Also, CoT and LRU-2 maintain a tracker (history) to cache size ratio of 8:1 for Zipfian 0.99 and 4:1 for both Zipfian 1.2 and uniform distributions. In this experiment, a total of 1M accesses are sent to the caching servers by 20 client threads running on one client machine. Each experiment is executed 10 times and the average overall running time with 95% confidence intervals are reported.

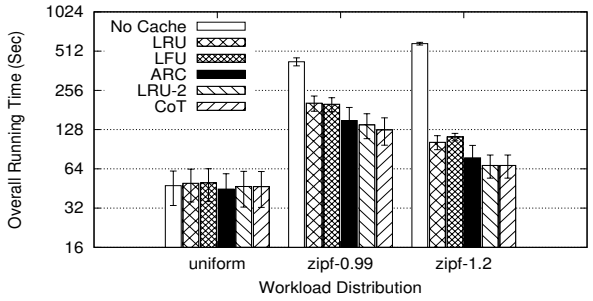

Figure 6: Front-end caching effect on the end-to-end overall running time using different workload distributions.

In this experiment, the front-end servers are allocated in the same cluster as the back-end servers. The average Round-Trip Time (RTT) between front-end machines and back-end machines is 244μs. This small RTT allows us to fairly measure the overhead of front-end caches by minimizing the performance advantages achieved by front-end cache hits. In real-world deployments where front-end servers are deployed in edge-datacenters and the RTT between front-end servers and back-end servers is in order of milliseconds, front-end caches achieve more significant performance gains.

Analysis: The uniform workload is used to measure the overhead of front-end caches. In a uniform workload, all keys in the key space are equally hot and front-end caches cannot take any advantage of workload skew to benefit some keys over others. Therefore, front-end caches only introduce the overhead of maintaining the cache without achieving any significant performance gains. As shown in Figure 6, there is no significant statistical difference between the overall run time when there is no front-end cache and when there is a small front-end cache with different replacement policies. Adding a small front-end cache does not incur run time overhead even for replacement policies that use a heap, e.g., LFU, LRU-2, and CoT.

The workloads Zipfian 0.99 and Zipfian 1.2 are used to show the advantage of front-end caches even when the network delays between front-end servers and back-end servers are minimal. As shown in Figure 6, workload skew results in significant overall running time overhead in the absence of front-end caches. This happens because the most loaded server introduces a performance bottleneck especially under thrashing (managing 20 connections, one from each client thread). As the load-imbalance increases, the effect of this bottleneck is worsen. Specifically, in Figure 6, the overall running time of Zipfian 0.99 and Zipfian 1.2 workloads are respectively 8.9x and 12.27x of the uniform workload when no front-end cache is deployed. Deploying a small front-end cache of 512 cachelines significantly reduces the effect of back-end bottlenecks. Deploying a CoT small cache in the front-end results in 70% running time reduction for Zipfian 0.99 and 88% running time reduction for Zipfian 1.2 in comparison to having no front-end cache. Other replacement policies achieve running time reductions of 52% to 67% for Zipfian 0.99 and 80% to 88% for Zipfian 1.2. LRU-2 achieves the second best average overall running time after CoT with no significant statistical difference between the two policies. Since both policies use the same tracker (history) size, this again suggests that having a bigger tracker helps separate cold and noisy keys from hot keys. Since the ideal tracker to cache size ratio differs from one workload to another, having an automatic and dynamic way to configure this ratio at run-time while serving workload gives CoT a big leap over statically configured replacement policies.

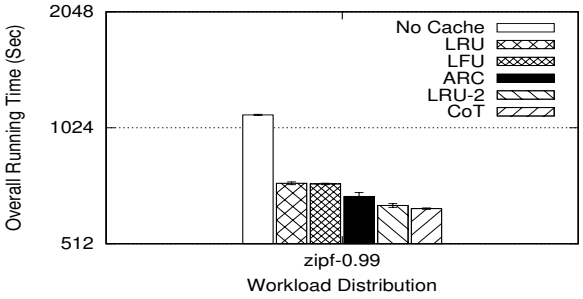

Figure 7: Front-end caching effect on the end-to-end overall running time in Amazon EC2 cloud.

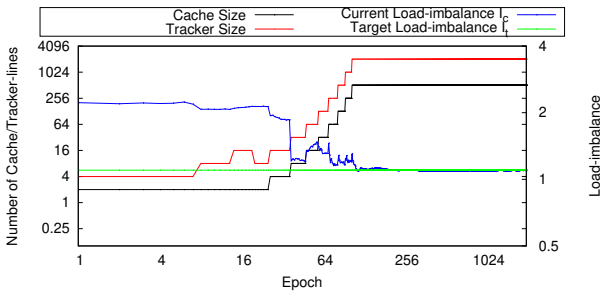
Similar results have been observed in a cloud setup as well. We run the same end-to-end evaluation on Amazon EC2's cloud. 20 client threads run on a t2.xlarge machine in California to send 1M requests following zipfian 0.99 distribution to 8 m3.medium ElastiCache cluster in Oregon. Front-end cache and tracker sizes are similar to the local experiments configuration. The key space consists of 1M keys and each key has a value of 10KB (smaller values are used since network latency is large in comparison to local experiments). As shown in Figure 7, a small front-end cache of 512 cache-lines has significant performance gains in comparison to the setup where no front-end cache is deployed. Also, both CoT and LRU-2 outperform other front-end cache replacement policies. Also, CoT slightly outperforms LRU-2 achieving 2% performance gain on the average. The main advantage of CoT over LRU-2 is its ability to dynamically discover the ideal cache and tracker sizes that achieve backend load-balance as the workload distribution changes. The following section illustrates CoT's performance in response to workload changes.

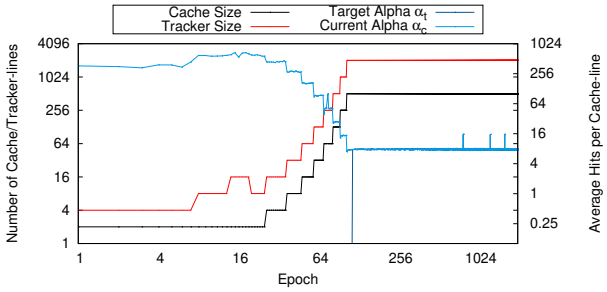
6.5 Adaptive Resizing

This section evaluates CoT's auto-configure and resizing algorithms. **Configuration:** *First*, we configure a front-end client that serves a Zipfian 1.2 workload with a tiny cache of size *two* cachelines and a tracker of size of *four* tracking entries. This experiment aims to show how CoT expands cache and tracker sizes to achieve a target load-imbalance I_t as shown in Figure 8. After CoT reaches the cache size that achieves I_t, the average hit per cache-line α_t is recorded as explained in Algorithm 3. *Second*, we alter the workload distribution to uniform and monitors how CoT shrinks tracker and cache sizes in response to workload changes without violating the load-imbalance target I_t in Figure 9. In both experiments, I_t is set to 1.1 and the epoch

size is 5000 accesses. In both Figures 8a and 9a, the x-axis represents the epoch number, the left y-axis represents the number of tracker and cache lines, and the right y-axis represents the load-imbalance. The black and red lines represent cache and tracker sizes respectively with respect to the left y-axis. The blue and green lines represent the current load-imbalance and the target load-imbalance respectively with respect to the right y-axis. Same axis description applies for both Figures 8b and 9b except that the right y-axis represents the average hit per cache-line during each epoch. Also, the light blue and the dark blue lines represent the current average hit per cache-line and the target hit per cache-line at each epoch with respect to the right y-axis.



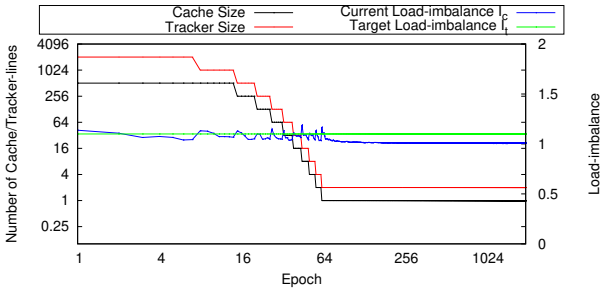
(a) Changes in cache and tracker sizes and the current load-imbalance I_c over epochs.



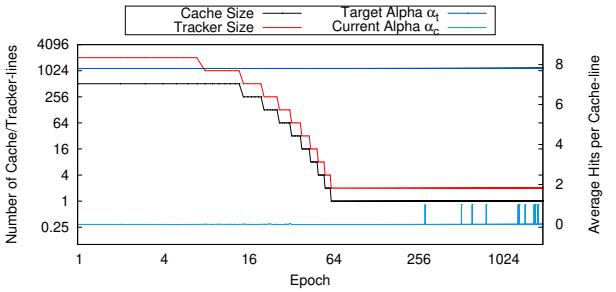
(b) Changes in cache and tracker sizes and the current hit rate per cacheline α_c over epochs.

Figure 8: CoT adaptively expands tracker and cache sizes to achieve a target load-imbalance $I_t = 1.1$ for a Zipfian 1.2 workload.

Analysis: In Figure 8a, CoT is initially configured with a cache of size 2 and a tracker of size 4. CoT's resizing algorithm runs in 2 phases. In the first phase, CoT discovers the ideal tracker-to-cache size ratio that maximizes the hit rate for a fixed cache size for the current workload. For this, CoT fixes the cache size and doubles the tracker size until doubling the tracker size achieves no significant benefit on the hit rate. This is shown in Figure 8b in the first 15 epochs. CoT allows a warm up period of 5 epochs after each tracker or cache resizing decision. Notice that increasing the tracker size while fixing the cache size reduces the current load-imbalance I_c (shown in Figure 8a) and increases the current observed hit per cache-line α_c (shown in Figure 8b). Figure 8b shows that CoT first expands the tracker size to 16 and during the warm up epochs (epochs 10-15), CoT observes no significant benefit in terms of α_c when compared to a tracker size of 8. In response, CoT therefore shrinks the tracker size to 8 as shown in the dip in the red line in Figure 8b at epoch 16. Afterwards, CoT starts phase 2 searching for the smallest cache size that achieves I_t. For this, CoT doubles the tracker and caches sizes until the target load-imbalance is achieved and the inequality $I_c \leq I_t$ holds as shown in Figure 8a. CoT captures α_t when I_t is first achieved. α_t determines the quality of the cached keys when I_t is reached for the first time. In this experiment, CoT does not trigger resizing if I_c is within 2% of I_t. Also, as the cache size increases, α_c decreases as the skew of the additionally cached keys decreases. For a Zipfian 1.2 workload and to achieve $I_t = 1.1$, CoT requires 512 cache-lines and 2048 tracker lines and achieves an average hit per cache-line of $\alpha_t = 7.8$ per epoch.



(a) Changes in cache and tracker sizes and the current load-imbalance I_c over epochs.



(b) Changes in cache and tracker sizes and the current hit rate per cache-line α_c over epochs.

Figure 9: CoT adaptively shrinks tracker and cache sizes in response to changing the workload to uniform.

Figure 9 shows how CoT successfully shrinks tracker and cache sizes in response to workload skew drop without violating I_t. After running the experiment in Figure 8, we alter the workload to uniform. Therefore, CoT detects a drop in the current average hit per cache-line as shown in Figure 9b. At the same time, CoT observe that the current load-imbalance I_c achieves the inequality $I_c \leq I_t = 1.1$. Therefore, CoT decides to shrink both the tracker and cache sizes until either $\alpha_c \approx \alpha_t = 7.8$ or I_t is violated or until cache and tracker sizes are negligible. First, CoT resets the tracker to cache size ratio to 2:1 and then searches for the right tracker to cache size ratio for the current workload. Since the workload is uniform, expanding the tracker size beyond double the cache size achieves no hit-rate gains as shown in Figure 9b. Therefore, CoT moves to the second phase of shrinking both tracker and cache sizes as long α_t is not achieved and I_t is not violated. As shown, in Figure 9, CoT shrinks both the tracker and the cache sizes until front-end cache size becomes negligible. As shown in Figure 9a, CoT shrinks cache and tracker sizes while ensuring that the target load-imbalance is not violated.

7 CONCLUSION

Cache on Track (CoT) is a decentralized, elastic and predictive cache at the edge of a distributed cloud-based caching infrastructure. CoT's novel cache replacement policy is specifically tailored

for small front-end caches that serve skewed workloads. Using CoT, system administrators do not need to statically specify the cache size at each front-end. Instead, they specify a target back-end load-imbalance I_t and CoT dynamically adjusts front-end cache sizes to achieve I_t. Our experiments show that CoT's replacement policy outperforms the hit-rates of LRU, LFU, ARC, and LRU-2 for the same cache size on different skewed workloads. CoT achieves a target server size load-imbalance with 50% to 93.75% less front-end cache in comparison to other replacement policies. Finally, our experiments show that CoT successfully auto-configures the size of front-end caches in the presence of workload distribution changes.

8 ACKNOWLEDGEMENT

We would like to thank Prabal Saha for his help setting up the experiments on EC2 instances. This work is funded by NSF grants CNS-1703560 and CNS-1815733.

ABSTRACT

Edge computing emerges as an innovative platform for services requiring low latency decision making. Its success partly depends on the existence of efficient data management systems. We consider that knowledge graph management systems have a key role to play in this context due to their data integration and reasoning features. In this paper, we present SuccinctEdge that can answer SPARQL queries, including those requiring reasoning services associated to some ontology. We provide details on its design and implementation before demonstrating its efficiency on real-world and synthetic data sets.

1 INTRODUCTION

Edge computing[2] corresponds to a processing paradigm that brings storage, management, and processing of huge amounts of data closer to the location where it needs to be performed. As such, this emerging trend complements a cloud computing approach by supporting the design of highly local context aware and responsive services, hence eliminating round trips to the Cloud, as well as mask cloud computing outages. A key challenge for systems designed for edge computing is an efficient data management in the context of mobile devices and sensors/actuators which generally have stringent requirements on energy consumption as well as memory, CPU usages and network bandwidth.

Our prototype system, SuccinctEdge[1], has been designed for edge computing from the get go and adopts the Resource Description Framework (RDF). The adoption of this data model is motivated by the data integration and reasoning facilities it provides. Considering the former, the Linked Data principles[2] together with the large set of Knowledge Graphs (KGs) available via the Linked Open Data initiatives[3] ease the design of Internet of Things (IoT) applications. For instance, ontologies such as the Sensor, Observation, Sample, Actuator (SOSA [4]), Quantities, Units, Dimensions, and Types (QUDT) [5] or Smart Applicances Reference (SAREF)[6] considerably simplify the task of describing, manipulating and connecting sensors and actuators. These ontologies also serve smart measure management when reasoning services are introduced in SPARQL queries to infer implicit consequences from explicitly represented knowledge.

SuccinctEdge favors a compressed, single index storage approach to a solution based on multiple indexes that could potentially improve query execution but at the cost of a higher memory footprint. The applications we are targeting with SuccinctEdge are the processing of a flow of RDF graphs (sent from sensors or actuators) which are sharing a common topology. These graphs are continuously queried by a set of SPARQL queries. In a typical use case, these queries are searching for anomalies occurring over a network of sensors (see Section sec:example for a motivating example). As a result, these queries are executed once per graph instance.

Our system makes an intensive use of succinct data structures (SDS)[8], a family of data structures that adopts a compression rate close to theoretical optimum, but simultaneously allows efficient decompression-free query operations on the compressed data. Together with our single index approach, SDS guarantees a low memory footprint that fits with an in-memory storage approach. The decompression-free aspects also tends to reduce the number of CPU cycles on standard queries and inferences.

SuccinctEdge's reasoning services are based on the LiteMat encoding solution[4]. This approach prevents inference materialization and reduces the cost of the SPARQL query rewriting task, the two most frequent reasoning solutions in RDF stores. As a result of encoding most triple entries with integer values, this approach improves the efficiency of graph pattern matching and compresses RDF data sets, thus limiting the memory footprint of a given graph.

SuccinctEdge is addressing the compact storage and efficient querying of RDF data via SPARQL queries in the presence of RDFS reasoning in an edge computing environment. The main contributions of this paper are to (i) present a self-index, compact, in-memory storage layout based on the bitmap and wavelet tree SDSs, (ii) propose a decompression-free (*i.e.*, the SDS compressed graph does not need any decompression step to enable query execution), efficient query processing and optimization of SPARQL BGPs which are transformed into access, rank and select SDS operations, (iii) support reasoning during query processing using a smart encoding approach and (iv) propose a simple and automatic approach to express complex queries requiring inferences by preventing end-users to learn the details of used ontologies and ontology annotations used at each sensor.

We demonstrate the efficiency of our implementation on an evaluation conducted on real-world and synthetic data sets. This paper is organized as follows. In Section 2, we motivate our approach with a real-world example in an industrial setting. In Section 3, we provide some background knowledge. Section 4 presents the overall architecture of SuccinctEdge. The query optimizer and processor is presented in Section 5. Section 6 relates our research to existing work and Section 7 provides a detailed experimentation. We conclude the paper and present directions for future work in Section 8.

2 MOTIVATING EXAMPLE

In this paper, we consider an upcoming deployment of SuccinctEdge at some of ENGIE's buildings where an IoT network is

[6]https://ontology.tno.nl/saref.ttl

deployed. ENGIE is a multinational company operating in fields such as energy transition, generation and distribution.

Our running example focuses on data harvested from a building management system with a first focus on potable water distribution. Intuitively, a flow of measures are obtained from a network of sensors. A thorough analysis permits to detect anomalies such as leaks or other abnormal situations from, for instance, pressure and flow measurements. The measures are usually represented as text files (*e.g.*, CSV) but, thanks to some mapping assertions and dedicated digital services deployed through APIs, are transformed into a form of RDF graph (to be detailed later in this paper) and annotated with concepts and properties of a domain ontology.

Figure 1 presents an extract of such a graph which concerns pressure and chemistry measures related to the water distribution management. Given such graph instances, our SuccinctEdge system executes queries that can detect some patterns such as anomalies linked to the water management system, *e.g.*, incorrect chemistry properties, network leak, etc. In a non edge computing context, each measure would transit on a computing network to a more powerful machine that could process the anomaly detection. Such an approach as several drawbacks: (i) it makes an intensive use of the computing and communication network which can rapidly be overloaded, *e.g.*, devices on the edge of the network generally have low bandwidth, (ii) the high-end computing machine also risks to be overcharged and stressed from the amount of data received (potentially from hundreds to thousands of sensors) and (iii) sending these data packets over the network is not cost-free for these sensors, *e.g.*, in terms of energy consumption.

In a context where anomalies are the exception, it makes sense to detect anomalies as close as possible to the sensors since it would require to (i) send fewer data over the computing network as that would occur only in anomaly cases, (ii) reduce decision latency and (iii) keep the high-end computing machine unstressed.

In our experimentation at ENGIE, we are designing a query-based anomaly detection approach that does not require from the end-users a high level of expertise on the underlying domain ontologies and its reasoning services. Hence these users only express queries in relatively high concept terms and do not have to worry about the inferences which are handled automatically by the system. Expressing a query with abstract concepts, *i.e.*, high in the concept hierarchy, permits to write a single query that can tackle sensors performing similar measures but annotated with different concepts and possibly with different measure units. This is an important requisite for our use case where different sensor brands and types can coexist in a given network. The simplicity of this approach was expected from ENGIE for productivity reasons. In fact, it enables its sensor personnel to concentrate on their tasks and not on adapting a given query to the potentially large number of sensors in an industrial setting. For instance, in the following real-world example, 2 sensor platforms are measuring similar values, *e.g.*, pressure and chemistry-related, but each sensor annotates them with different concepts. Considering Station1 the pressure and chemistry are respectively annotated with $qudt : PressureOrStressUnit$ and $qudt : Chemistry$, while for Station2, it is resp. $qudt : Pressure$ and $qudt : AmountOfSubstanceUnit$. Moreover, the pressure value in Station1 is expressed in Bar while it is measured in HectoPascal in Station2.

Since, the QUDT ontology[7] states that:

$qudt : AmountOfSubstanceUnit \sqsubseteq qudt : Chemistry \sqsubseteq qudt : ScienceUnit$ and $qudt : PressureOrStressUnit \sqsubseteq qudt : PressureUnit \sqsubseteq qudt : MechanicsUnit$, a single SPARQL query can be written to address the peculiarities of each sensor at these 2 stations. The following query detects anomalies related to an incorrect pressure value (either expressed in Bar or HectoPascal) for sensors of stations 1 and 2:

```
SELECT ?x ?s ?ts ?v1 WHERE {
?x a sosa:Platform; sosa:hosts ?s.
?s sosa:observes ?o; a sosa:Sensor.
?o sosa:hasResult ?y; a sosa:Observation;
sosa:resultTime ?ts. ?y a sosa:Result;
qudt:numericValue ?v1; qudt:unit ?u1.
?u1 a qudt:PressureUnit. FILTER (?newV<3.00 || ?newV>4.50)
BIND(if(regex(str(?u1),"http://qudt.org/vocab/unit/BAR"),?v1,
if(regex(str(?u1),"http://qudt.org/vocab/unit/HectoPA")
,?v1/1000,0)) as ?newV) }
```

3 BACKGROUND KNOWLEDGE

3.1 Semantic Web standards

RDF is the W3C recommendation schema-free data model that supports the description of data on the Web. It takes the form of a graph consisting of a set of triples. Each triple is composed of a subject, a predicate and an object. Properties can be qualified as object or datatype. They both related a URI (or blank node) to respectively a URI (or blank node) and a literal. SPARQL, another W3C recommendation, enables to express queries over RDF data. The syntax is inspired by SQL's SELECT-FROM-WHERE but it uses an approach based on matching a BGP, *i.e.*, a set of triple patterns (TP), on an RDF graph to retrieve query answer sets. Finally, RDF Schema (RDFS) and Web Ontology Languages (OWL) enable the description of vocabulary semantics used in RDF data sets. They support inference services based on their respective expressiveness.

3.2 LiteMat

LiteMat is a semantic-aware encoding scheme that compresses RDF data sets and supports reasoning services associated to the RDFS ontology language. In this work, we focus on the ρdf[7] subset of RDFS, *i.e.*, inferences associated to the `rdfs:range`, `rdfs:domain`, `rdfs:subClassOf` and `rdfs:subPropertyOf` properties. To address inferences drawn from these last two RDFS predicates, we attribute numerical identifiers to ontology terms, *i.e.*, concepts and predicates, that are supporting the semantics. This is performed by prefixing the encoding of a term with the encoding of its direct parent. This encoding is computed using a binary representation and all binary encoding entries are all of the same length. The encoding is performed using a top-down approach, *e.g.*, starting from the most specific concept of the hierarchy (typically `owl:Thing`, `owl:topObjectProperty` and `owl:topDataProperty` for respectively the concept, object property and datatype property hierarchies), until all leaves are processed. Then a normalization is performed to guarantee that all encoding entries have the same length, *i.e.*, by setting right-most bits to 0.

We now provide an example on a concept hierarchy (a similar approach is used for property hierarchies). In Figure 2, we consider a small ontology extract containing the following axioms: $A \sqsubseteq Thing$, $B \sqsubseteq Thing$, $C \sqsubseteq B$ and $D \sqsubseteq B$. Figure 2a

[7] https://qudt.org/

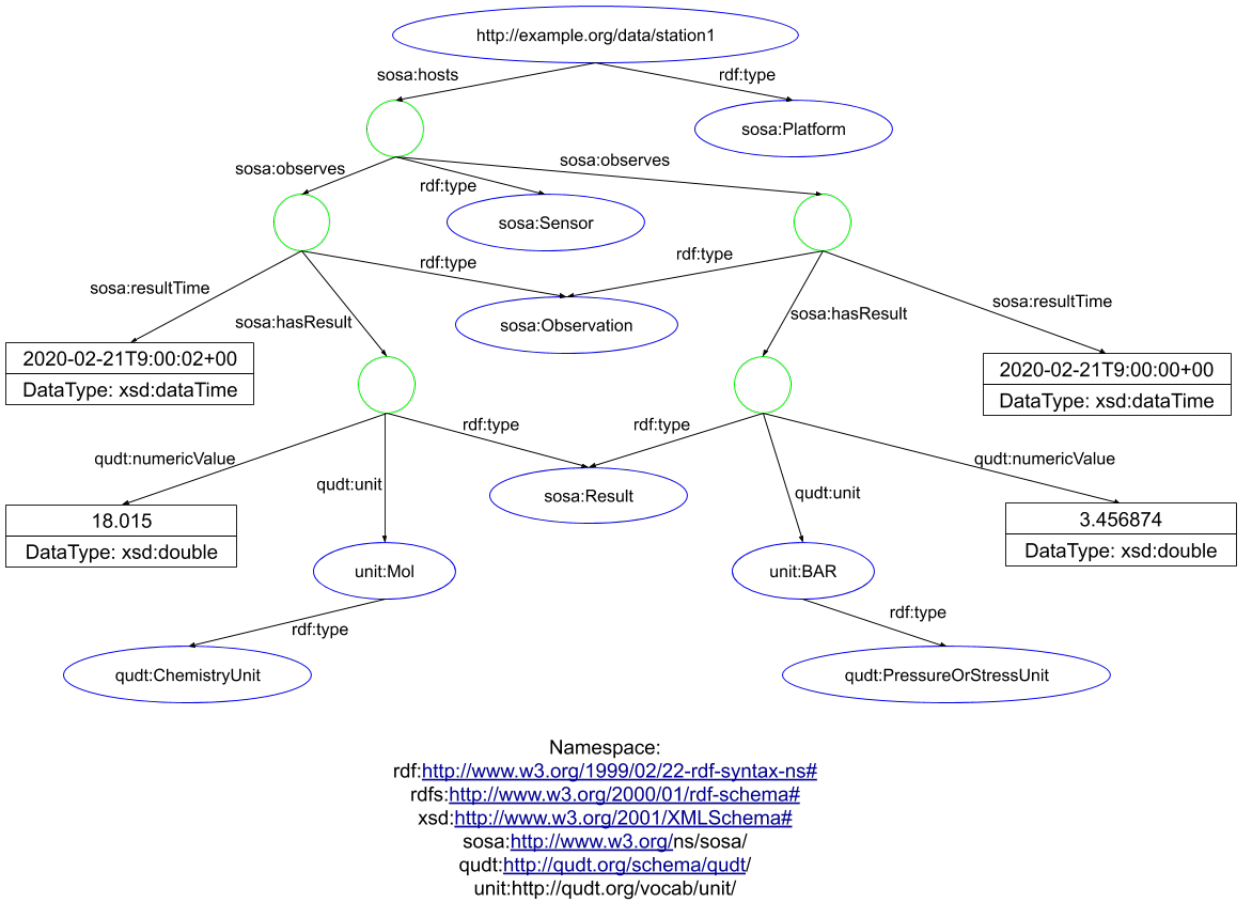

Figure 1: Graph extract of our use-case (green nodes are blank nodes)

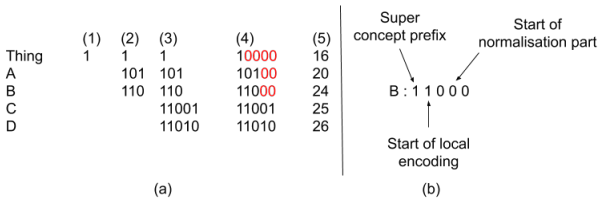

Figure 2: LiteMat encoding example

highlights the top-down encoding approach with (1) setting the local identifier of *Thing*, (2) its direct sub-concepts (*A* and *B*) and *B*'s sub-concepts in (3). Then, in (4) the normalization step is performed, *i.e.*, added right-most bits are written in red. Column (5) provides the integer values attributed to each concept.

The mapping between URIs and their identifiers are stored in dictionaries, two for the concepts and two for the properties to support a bidirectional retrieval, *i.e.*, from a URI to its identifier and from an identifier to its URI. Moreover, in the former dictionaries, additional identifier metadata are stored. For instance, the local length (binary length before the normalization phase) of each dictionary entry is stored along the final identifier entry.

Figure 2(b) emphasizes the different metadata of the LiteMat encoding for the *B* concept: super concept identifier part, start of local encoding and start of the normalization part.

The semantic encoding of concepts and predicates supports reasoning services usually required at query processing time. For instance, consider a query asking for the pressure value of sensors of type `S1`. This would be expressed as the two following TPs: `?x pressureValue ?v. ?x type S1`. In the case sensor concept `S1` has n sub-concepts, then a naive query reformulation requires to run the union of n+1 queries. With LiteMat's semantic-aware encoding, we are able, using two bit-shift operations and an addition, to compute the identifier interval, *i.e.*, [lowerBound, upperBound), of all direct and indirect sub-concepts of `S1`. And thus we can compute this query with a simple reformulation: (i) replacing the concept `S1` with a new variable : `?x type ?newVar` and (ii) introducing a filter clause constraining values of this variable: `FILTER (?newVar>=lowerBound && ?newVar<upperBound)`.

Considering the instance dictionary, each distinct entry is assigned an arbitrary unique integer value.

3.3 Succinct Data structures

SDS represents a family of data structures that stores data in a compact way, but still allows some efficient data access operations without decompression. There are different types of SDS, among which we consider Wavelet Tree (WT) and BitMap (BM).

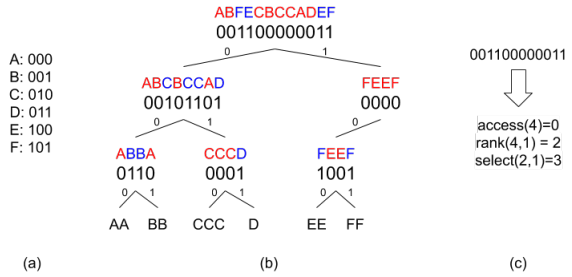

Figure 3: Wavelet Tree example with its dictionary

SuccinctEdge represents an RDF graph into a combination of these two structures to reach a very compact size without loss of query efficiency.

BM is the most basic SDS we are using in SuccinctEdge. It is a sequence of bits with some extra information to support the efficient execution of SDS operations. BM is the basic building block of WT's nodes (as each node in the tree is a BM), but it also relates different WTs in SuccinctEdge's triple representation (further details in Section 4).

WT [8], whose name reveals some affinity with the idea of the wavelet packet decomposition in signal processing, refers to a data structure which decomposes a data sequence into a set of nodes of a balanced binary tree. An example of a WT is given in Figure 3b. Suppose that we have a sequence *ABFECBCCADEF*, where each letter is mapped with an identifier in an incremental order, *e.g.*, *A* is denoted with 0, *B* is denoted with 1 (see dictionary in Figure 3a. A tree structure is constructed from this sequence as follows: each level of this tree divides the sequence of previous nodes into two sub-sequences by the corresponding bit. For example, from root to the first level, *ABFECBCCADEF* is divided into *ABCBCCAD* and *FEEF* by the first bit of each identifier entry. This strategy is applied recursively until each leaf is computed.

SDS support three operations to access data: *Rank*, *Select* and *Access*. Given a sequence *S*, the operation $S.Access(i)$ (also denoted as $S[i]$) refers to the $(i+1)^{th}$ element in *S*. $S.Rank(i,c)$ returns the number of occurrences of *c* from *S*'s beginning to index *i*. Finally, $S.Select(i,c)$ returns the index of i^{th} occurrence of element *c* in *S*. These operations can be computed in O(1) for BM and O(log n) for WT where n is the size of the vocabulary. Figure 3c provides an example over a simple BM. Dedicated algorithms permit to compute these 3 operations over WT.

4 ARCHITECTURE OVERVIEW

Before providing an overview of the SuccinctEdge RDF store, we describe a standard running setting at an ENGIE building. Typically, the person responsible for the building maintenance supervises a set of IoT devices from a SuccinctEdge server. From this central computer, the administrator is able to register new IoT devices installed in this set of buildings. Each IoT device typically runs a SuccinctEdge instance (client) which can execute many SPARQL queries. The administrator receives alerts from SuccinctEdge instances has abnormal sensor measures are occurring. Hence, each sensor modification (*e.g.*, a sensor is replaced due to a failure, a sensor data schema is modified) must go through an administration step which is performed on a central computer. Apart from such maintenance operations, this server also performs the pre-processing task consisting of encoding ontologies using the LiteMat scheme. In this context, and we consider in a large number of industrial settings, the ontologies are stable and thus rarely change. As explained previously, in SuccinctEdge, these ontologies take the form of a set of dictionaries (since their semantics are encoded via the use of LiteMat). These dictionaries are broadcasted to the different SuccinctEdge instances running at the edge.

An overview of SuccinctEdge's architecture is presented in Figure 4. Like most RDF stores, all triples are encoded according to some dictionaries. The underlying basic concept of a dictionary is to provide a bijective function mapping long terms (*e.g.*, URIs, blank nodes or literals) to short identifiers (*e.g.*, integers). More precisely, a dictionary should provide two basics operations : `string-to-id` and `id-to-string` (also referred in the literature as `locate` and `extract` operations). In a typical use of SuccinctEdge, the query engine will call the `locate` operation to rewrite the query into a list to match the data encoding, while the `extract` operation will be called to translate the result into the original format. In our case, we are using LiteMat (see Section 3.2) to generate the concept, property and individual dictionaries.

The Triple store component adopts a single index based on the predicate, subject, object (PSO) triple permutation. That is, the triples of the graph are sorted in ascending order over the P, S and O values of our dictionaries. The PSO order is motivated by the fact that the basic graph pattern of queries submitted to SuccinctEdge have predicates filled in with URIs (as opposed to variables). This corresponds to typical IoT use cases where queries are retrieving information from measures rather than serving to discover patterns in the graphs. In fact, there is no need for discovery since the graph patterns are well known in advance and are very rarely modified (*i.e.*, mostly due to sensor failure in industrial use-cases).

The Triple store component also highlights that we make a distinction between object (expect `rdf:type`) and datatype properties. In the former, objects are individuals and thus encoded with the respective instance dictionary while in the latter, objects are literals and stored using a flat data structure to store literals. This last data structure is motivated by the fact that it is not reasonable to create an entry in the instance dictionary for each new literal value. Intuitively, a sensor generally sends numerical values corresponding to physical measurement at a given time. Depending on the precision of these measures, the amount of different values to store in the instance dictionary is potentially infinite. So, we prefer to store the values as they have been sent by sensors, possibly with some redundancy, in order to prevent a complex and costly individual dictionary management.

In terms of data structures, WTs are used for the property and subject layers as well as the object layer for object properties. In order to relate a WT of one layer to another, we are using a BM. Figure 5b represents the triple set of Figure 5a where a WT corresponds to balanced tree of BMs. Intuitively the PS (respectively SO) bitmap permits to link a given P (resp. S) to several S (resp. O) values. In Figure 5b, p1 is connected to s1, s2 and s4 because the PS bitmap starts with a 100 sequence: '1' states that the sequence of p1 starts with a given subject (s1) and the '00' states that 2 other subjects are linked to p1. Moreover, the 4th bit in the PS BM (*i.e.*, set to '1') starts the sequence of the second property entry in the P WT (*i.e.*, p2).

Finally, triples containing a `rdf:type` property are stored in the RDFType store layout. These triples generally represent an important proportion of the triple set in real-world RDF data sets. We simply store them in a red-black tree in order to maintain the

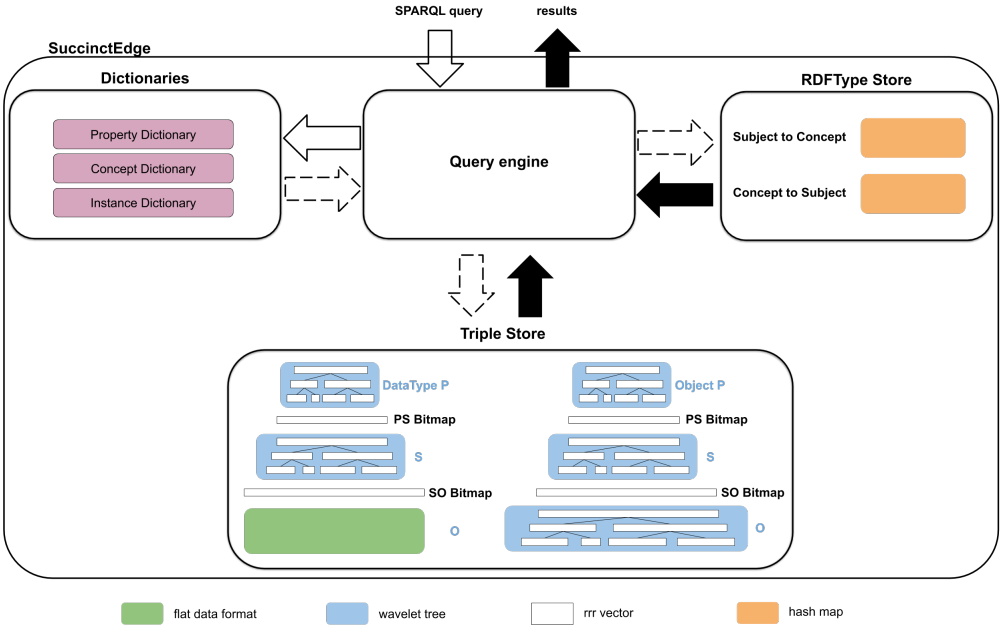

Figure 4: Architecture overview of SuccinctEdge

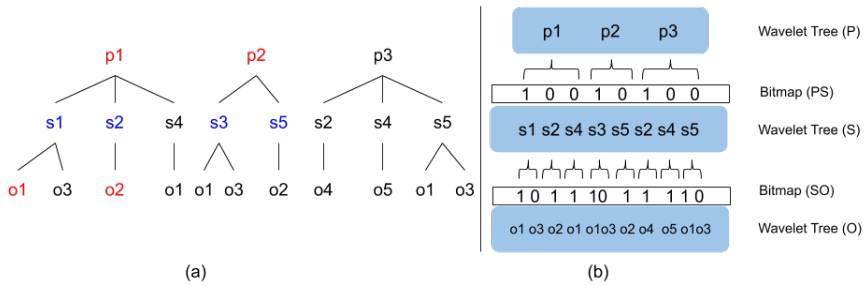

Figure 5: RDF graph representation: (a) as a PSO-based forest and (b) in SuccinctEdge as a combination of wavelet trees and bitmaps (only considering object properties)

search complexity to O(log(n)) while being fast when we insert `rdf:type` triples during database construction.

5 QUERY PROCESSING AND OPTIMIZATION

In this section, we present the query optimization and processing solutions developed for SuccinctEdge. Their main goals are respectively to define an efficient TP join ordering, by combining heuristic and cost-based approaches, and to generate a physical plan composed of SDS operations (*i.e.*, access, rank and select).

5.1 Query Optimization

The design of our query optimizer considers the limitations of the devices on which SuccinctEdge is running on, *i.e.*, limited memory space and computing power. Due to these constraints, our system only generates left-deep join trees which generally reduce the amount of memory used by the search process.

As stated in [10], join ordering is the most crucial issue in SPARQL query optimization. This is mainly due to the potentially high number of triple patterns and thus of join operations that one can find in BGPs. For instance, in our IoT building management experimentation, we have frequently encountered queries in the range of 10 joins.

In order to optimize a given SPARQL query, our query engine constructs a query graph where each TP of the SPARQL query corresponds to a node of the query graph. Each query graph node is also annotated to state whether its property is rdf:type or not. The nodes in this graph are connected if they share a common variable, hence forming a join. Moreover, the edges of this query graph are labeled with a join type, either SO or SS for respectively subject-object and subject-subject joins.

Example 5.1. Figure 6b displays the query graph associated with the SPARQL query presented in Figure 6a. This query contains 7 TPs, denoted tp1 .. tp7. The dotted nodes in the query graph correspond to rdf:type TPs.

Given a query graph, our optimizer uses Algorithm 1 to produce a join order. Intuitively, starting from a given TP, it invokes an overloaded *getMostSelective* method to search for the next TP to join with. This method uses a set of static rules together with some data statistics. In terms of the former, we have been influenced by Heuristic 1 of [12] which defines an execution

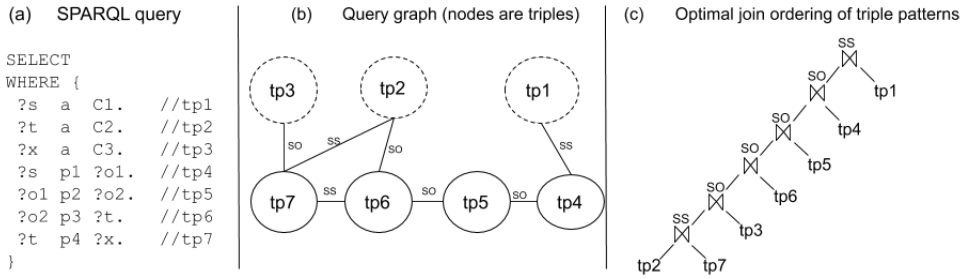

Figure 6: Query, query graph and join ordering

order for the 8 possible TP combinations. In the context of SuccinctEdge, we do not need to consider all combinations since TPs with either zero or three variables, *i.e.*, (s, p, o) and $(?s, ?p, ?o)$, are highly unlikely to occur in a real-world IoT SPARQL query. Intuitively, this heuristic states that TPs with the fewest variables should be executed first. Our adaptation re-orders the original proposition by taking into account the fact that our access paths are limited to PSO for non `rdf:type` properties and to SO/OS paths for `rdf:type` triples. As presented in Section 4, the latter access path (SO/OS on `rdf:type`) is more efficient than the one based on the SDS structures. Our TP order is thus:

(s,rdf:type,?o)>(?s,rdf:type,o)>(s,p,?o)>(?s,p,o)>(?s,p,?o), where p denotes any property different from rdf:type and the relation tp1 > tp2 states that tp1 should be executed before tp2. The (s,p,?o)>(?s,p,o) order is due to the navigation mode in our multi-layer SDS triple representation which is PSO based, *i.e.*, it is more efficient to retrieve objects given a subject/property pair than to compute subjects from a property/object pair. The (?s rdf:type ?o) TP is not considered relevant in a practical IoT context.

This first heuristic is generally not sufficient to decide which TP to execute first among a set of other TPs. Hence, we are considering a second heuristic that takes into consideration the linearity required by a left-deep join tree and examines the types of join possible between TPs. Due to the PSO self-index SDS structure used for non-rdf:type triples, SS joins are preferred over SO joins, *i.e.*, $S \bowtie S > S \bowtie O$. Other forms of joins, *i.e.*, SP, OP, PP have a lower priority since they are rarely encountered in the setting where SuccinctEdge is relevant.

In order to minimize intermediate results, the optimizer also relies on a set of statistics computed at dictionary creation-time. Intuitively, each dictionary persists the number of occurrences of each of its entries, *i.e.*, concept, property and non-literal individuals. Our statistic approach considers the hierarchy position of a given concept or property when computing the total number of triples it is involved in. For example, with the following concept hierarchy $C_2 \sqsubseteq C_1 \sqsubseteq C_0$ and $C_3 \sqsubseteq C_0$, the set of triples involving instances of concept C_0 will be the set of instances of type C_i with i $\in (0, 1, 2, 3)$. A similar process is applied to get the correct statistics for properties involved in a property hierarchy. Finally, some statistics are also computed at run-time, *e.g.*, the BM and WT data structures facilitate the computation of certain statistics. For instance, Algorithm 2 computes the number of triples containing a certain property.

Algorithm 1 first starts with the identification of the most selective rdf:type TP with an SS join. In the case it does not find an rdf:type TP or finds only rdf:type TP connected with SO joins, it then selects a non-rdf:type TP to start with. In the case several TPs satisfy our constraint, the statistics permit to take a decision. That first TP is appended to our *tpOrder* sequence. We then loop over the remaining nodes of the query graph until all TPs have been added to the sequence. At each iteration of the loop, the *getMostSelective* method considers TPs in the *tpOrder* sequence and searches for the next TP to append to this sequence. This search is again based on our two heuristics and the usage of statistics.

Example 5.2. The left-deep join tree displayed in Figure 6c has been defined using Algorithm 1 considering that tp2 is more selective than tp1, *i.e.*, the number of occurrences of C2 is lower than the one of C1. Once tp2 has been selected, the optimizer has the choice to join it with tp6 or tp7. tp7 is chosen since a SS join is preferred to a SO join. At this stage, the number of occurrences of concept C3, *i.e.*, tp3, can be lower than the number of already computed binding for ?x, and thus tp3 is selected. Given that tp2, tp7 and tp3 have already been considered, tp6 is the only alternative that can be considered and similarly for the remaining TPs, *i.e.*, tp5, tp4 and tp1.

Algorithm 1: Computation of a TP order

Input: query graph G
Output: ordered sequence of TPs

```
tpOrder ← ∅;
n ← getMostSelective(rdf : type);
tpOrder ← tpOrder + n;
while not all G nodes are in tpOrder do
    n ← getMostSelective(tpOrder);
    tpOrder ← tpOrder + n;
end
return tpOrder;
```

5.2 Query processing

Once an order is defined by SuccinctEdge's query optimizer, our system translates TPs into SDS's standard operations: access, rank and select. We are using an additional function, namely $rangeSearch(a, b, c)$, which finds all the occurrences of value c in the interval (a, b). It uses a binary search, *i.e.*, due to the ordering imposed on subjects for a given property, and returns the indexes of matching values. The use of this function speeds up query execution since it efficiently prunes searches by just computing the boundaries of the Subject WT, *i.e.*, first and last subject values of a given property, instead of scanning all values of that interval. A similar optimization is used when searching objects of given property/subject pair, *i.e.*, using the boundary of Object WT.

Algorithm 2: Compute the number of triples corresponding to a certain predicate.

Input: Predicate p
Output: Number n

$id_p \leftarrow FindIdFromDictionary(p)$;
$index_p \leftarrow wt_p.select(1, id_p)$;
$index_{sBegin} \leftarrow bitmap_{ps}.select(index_p + 1, 1)$;
$index_{sEnd} \leftarrow bitmap_{ps}.select(index_p + 2, 1)$;
$index_{oBegin} \leftarrow bitmap_{so}.select(index_{sBegin} + 1, 1)$;
$index_{oEnd} \leftarrow bitmap_{so}.select(index_{sEnd} + 2, 1)$;
$n \leftarrow index_{oEnd} - index_{oBegin}$;
return n;

We now present two translation examples in Algorithm 3 and 4 for resp. the $(s, p, ?o)$ and $(?s, p, o)$ TPs. Algorithm 3 shows how to retrieve an answer set with a $(s, p, ?o)$ TP. The idea is to first compute an interval of object values related to a given predicate and subject pair. This is performed by navigating through our BM and WT structures. All the objects in this interval are the results of this TP. Algorithm 4 retrieves all the subjects of a $(?s, p, o)$ TP. Unlike Algorithm 3, we can not locate all the subjects directly. So our strategy is to get the interval of all the objects corresponding to the known predicate top-down, after which we locate the object in this interval (there may be multiple appearances) and get the corresponding subjects.

Algorithm 3: Search the triple pattern $(s, p, ?o)$

Input: Predicate s,p
Output: Results res

$id_p \leftarrow FindIdFromDictionary(p)$;
$id_s \leftarrow FindIdFromDictionary(s)$;
$index_p \leftarrow wt_p.select(1, id_p)$;
$index_{sBegin} \leftarrow bitmap_{ps}.select(index_p + 1, 1)$;
$index_{sEnd} \leftarrow bitmap_{ps}.select(index_p + 2, 1)$;
for $index_s$ *in* $wt_s.rangeSearch(index_{sBegin}, index_{sEnd}, id_s)$ **do**
  $index_{oBegin} \leftarrow bitmap_{so}.select(index_{sBegin} + 1, 1)$;
  $index_{oEnd} \leftarrow bitmap_{so}.select(index_{sEnd} + 2, 1)$;
  for $index_o \leftarrow index_{oBegin}$ **to** $index_{oEnd}$ **do**
    $id_o \leftarrow wt_o[index_o]$;
    add (id_s, id_p, id_o) into res;
  end
end
return res;

In cases where reasoning services are necessary to provide an exhaustive answer set, we can replace $index_p$ with a continuous interval corresponding to a LiteMat interval. This interval is efficiently computed given the order imposed on leaves of a certain WT, *e.g.*, Property WT for the property hierarchy. The larger and deeper a property hierarchy, the more efficient this optimization approach since it prevents from navigating in the complete tree of a given WT.

TPs containing `rdf:type` are processed differently using the RDFType store component, where some simple structure look-ups permit to efficiently retrieve to subjects of a given concept or the concepts of a given subject.

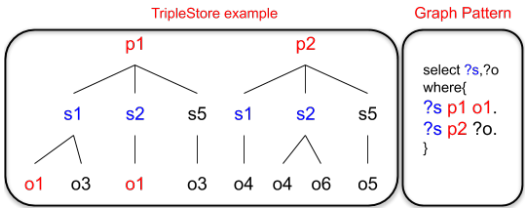

Figure 7: Merge join example

The next step corresponds to joining the results obtained from the execution of TPs. This occurs when different TPs share a common variable. One of our joining approach amounts to propagate variable assignments from one TP to another. Consider the triple set of Figure 5a and TPs $(?s, p1, o1)$ and $(?s, p2, ?o)$. The first TP gets the following assignments: $?s : \{s1, s2\}$ which will serve to dynamically generate $(s1, p2, ?o)$ and $(s2, p2, ?o)$ for the second triple.

During the join operation, we can benefit from a merge join (due to the original PSO value order) in certain cases when the values assigned to a joining variable to the TP are kept in order. For instance, in the case of a star-shaped BGP, *e.g.*, $(?s, p1, o1)$ and $(?s, p2, ?o)$, thanks to the facts that all the subjects connected to a certain predicate are ordered and that all the objects connected to one certain subject are also ordered, we can perform a merge join on the subject variable. Figure 7 provides a graph pattern (on the right side) and an RDF Graph (left side). From the first TP, we can retrieve $\{(p1, s1, o1), (p1, s2, o1)\}$ as the answer set. Clearly, since the subjects are ordered for a given predicate, the system can easily use a merge join with the 2nd TP of the query. In cases where the order is not guaranteed, we use nested loop joins.

Algorithm 4: Search the triple pattern $(?s, p, o)$

Input: Predicate p
Output: Results res

$id_p \leftarrow FindIdFromDictionary(p)$;
$index_p \leftarrow wt_p.select(1, id_p)$;
$index_{sBegin} \leftarrow bitmap_{ps}.select(index_p + 1, 1)$;
$index_{sEnd} \leftarrow bitmap_{ps}.select(index_p + 2, 1)$;
$index_{oBegin} \leftarrow bitmap_{so}.select(index_{sBegin} + 1, 1)$;
$index_{oEnd} \leftarrow bitmap_{so}.select(index_{sEnd} + 2, 1)$;
for $index_o$ *in* $wt_o.rangeSearch(index_{oBegin}, index_{oEnd}, id_o)$ **do**
  $index_s \leftarrow bitmap_{so}.rank(index_o + 1, 1) - 1$;
  $id_s \leftarrow wt_s[index_s]$;
  add (id_s, id_p, id_o) into res;
end
return res;

Previous executions steps are repeated until all the TPs have been processed. Then the answer set of the query is translated using our dictionaries and presented to the end-user or application.

6 RELATED WORK

Header Dictionary Triples (HDT)[6] is a compact data structure and binary serialization for RDF data. The Triples component of HDT requires that triples are sorted in a specific order, *e.g.*, SPO.

The triples are stored in so-called Bitmap Triples which represents a forest of RDF trees, *e.g.*, each tree is rooted with a given subject value. The remaining tree layers, *e.g.*, for P and O, each correspond to a sequence of identifiers and a bit sequence which connects layers like our BMs. Like HDT, SuccinctEdge represents RDF triples as trees but it makes an extensive use of WTs and depends on three different storage approaches, namely Object-triple-store, Datatype-triple-store and RDFType-store. Moreover, SuccinctEdge is equipped with a full-fledged query processing component and supports RDFS reasoning within SPARQL queries.

In [11], a so-called Semantic Index is proposed for Ontology-Based Data Access (OBDA) systems. In this approach, each entity (concept or property) in the corresponding hierarchy is assigned a numerical value according to a breadth-first search traversing of the hierarchy. Provided with this assignment, one is ensured that any sub-hierarchy is associated to a consecutive set of numerical values (*i.e.*, an interval). Intuitively, each entity is associated to an interval covering the indices of all its sub-entities. This approach is related to the LiteMat encoding scheme but the integration in SuccinctEdge permits a high compression rate with a decompression-free approach at query execution time. Moreover, Semantic Index is just an encoding scheme for a knowledge base and is not a complete query processor.

WaterFowl[3] was designed as a first attempt to use SDS for RDF storage and query processing. Although its compactness can be used in an edge computing setting, it lacks the different object storage implementation and query processing (including optimization) features of SuccinctEdge.

RDF4Led is an RDF store designed for edge computing. Compared to our system, RDF4led is disk-based, *i.e.*, it stores data on a SD card, and depends on multiple indexes which imply a high memory footprint. Moreover, it doesn't support reasoning services nor SPARQL's UNION clause which prevents to apply a query rewriting in order to support reasoning services.

ZipG[5] is a distributed graph store designed for the property graph data model. Hence it does not provide support for SPARQL (or any declarative query language) or reasoning services. Its storage layout is based on the Succinct[1] system and is mainly composed of flat binary unstructured files. ZipG is not compatible with devices located at the edge of a network. In fact, it thrives in a cloud computing setting.

TerminusDB[8] is an open-source general-purpose graph database. It aims to store very large graphs in main memory by scaling vertically. Such an approach is not compatible with the edge computing ecosystem that we are targeting. Moreover, TerminusDB does not support Semantic Web standards and hence can not benefit from the existence of a large set of available ontologies to support data integration or support reasoning services associated to RDFS or OWL ontology languages.

7 EVALUATION

7.1 Experimental setting

Our experimentation is conducted on a Raspberry Pi 3B+ which can be considered as a typical edge computing device on which we can run some sophisticated programs. This small computer is equipped with a Cortex-A53 (ARMv7l) 32-bit SoC 1.4GHz CPU and 1GB LPDDR2 SDRAM. A SD-card, a widely used memory solution on such devices, of 8GB is used as persistent storage.

Considering the evolution of technology, it is widely accepted that edge computing devices will be more and more powerful in the near future. Hence, it is quite obvious that devices with sufficient calculation power and memory, *e.g.*, Raspberry Pis, Odroids, etc. , will be deployed at the edge of networks.

SuccinctEdge is implemented in C++14 and the SDS-lite C++ library[9] is required during compilation. More details can be found on github[10]. We are comparing SuccinctEdge against RDF4Led[13], two Apache Jena[11] (version 3.15) database implementations and RDF4J's Memory Store[12] (version 3.4.0) . RDF4Led is to the best of our knowledge the only RDF store specifically designed for edge computing. It is characterized by a small memory footprint, although the database system does not reside in the main-memory. The two Apache Jena stores are TDB2 and the in-memory store. They are both open-source relatively lightweight and robust RDF stores. RDF4J (originally Sesame) is an open-source Java Framework for managing RDF data. The core RDF4J databases are mainly intended for small to medium-sized data sets and thus it makes sense to consider them for Edge computing. We also considered RDFox [9], a main-memory, centralized RDF store that is designed on a shared-memory architecture, but could not make it work on our raspberry Pi 3B+ since we only had access to a 64-bit pre-compiled version. Systems like Ontotext GraphDB[13], Stardog[14], MarkLogic[15], AllegroGraph[16], AWS Neptune[17] have not been considered since they have been designed for massive loads and scalability on high-end servers or Cloud computing.

7.2 Datasets and queries

The experimentation uses both synthetic and real-world data sets. This duality is motivated by the current lack of large graphs emitted from sensors at our industrial partner. In fact, our real-world data sets, which correspond to the water management distribution in ENGIE's building, consist of 250 and 500 triples. They are denoted with their number of triples in this experimentation.

Due to these size limitations, it is not possible to stress SuccinctEdge in terms of graph sizes. Hence, we are also experimenting with the synthetic Lehigh University Benchmark (LUBM)[18] which can be easily configured to produce large data sets. Starting from a LUBM with one university, *i.e.*, composed of over 103.000 triples (denoted 100K), we created several triple subsets of 1.000, 5.000, 10.000, 25.000 and 50.000 triples which are respectively denoted as 1K, 5K, 10K, 25K and 50K in the remaining of this section. They are used to evaluate the behaviors of the five evaluated data management systems. Note that some of these synthetic data sets have triple set size way beyond what most sensors are currently emitting in real-world industrial use-cases. All submitted queries are detailed in Section A and data sets are available on the system's Github page.

7.3 Experimentation results

In this section, we are aiming to compare the previously mentioned RDF stores (*i.e.*, Jena TDB, Jena in-memory, RDF4Led, RDF4J and SuccinctEdge) on the following dimensions: graph construction time, memory footprint (*i.e.*, the storage space taken

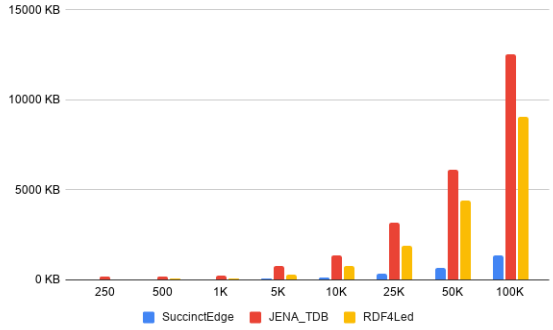

Figure 10: Storage size without dictionary comparison

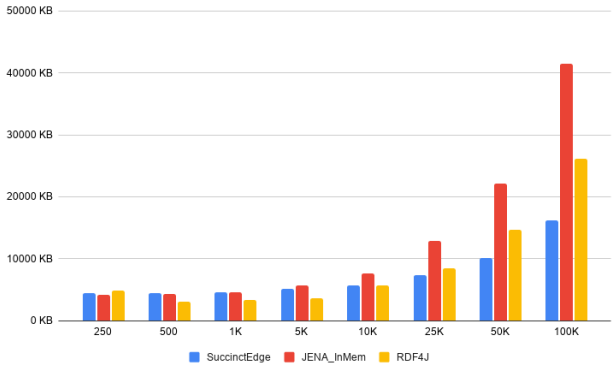

Figure 11: RAM footprint comparison

by different systems with the previous data sets), query execution performances on different triple patterns and basic graph patterns. Lastly, we evaluate the performance (duration time) of queries which necessitate reasoning services to produce an exhaustive answer set.

7.3.1 Back-end construction time. The back-end construction time corresponds to the time taken by each system to read the data set file and to construct its proper storage layout (including indexes in the case of all systems except SuccinctEdge which is self-index) on which queries can be asked.

In order to fully evaluate the performances of all the systems, we compare the back-end construction time of these systems with data sets ranging from 250 to over 100.000 triples. Figure 8 provides details on this experimentation. SuccinctEdge doesn't show much advantage when data set is rather small (up to 1.000 triples). We attribute this to the fact that the SDS-Lite library which is responsible for creating SuccinctEdge's BMs and WTs has an important start-up overhead that is relatively important compared to the effective duration of the structures. We consider that this may be optimized in future work, but it is out of the scope of this paper. However, as the data sets grow larger, our system outperforms all other systems.

7.3.2 Storage size. As SuccinctEdge is an in-memory RDF system, it is difficult to directly compare the memory occupation against Jena TDB and RDF4Led (which are both disk-based RDF stores). We persisted all the data structures existing in SuccinctEdge to disk in order to make a fair comparison.

We separately consider the dictionary and triple storage spaces. Figure 9 provides the three systems' dictionary sizes for all 8 data sets. In all cases, Jena TDB requires the largest memory footprint and SuccinctEdge takes about half of the size of RDF4Led.

Considering the triple storage space, displayed in Figure 10, SuccinctEdge consumes much smaller space thanks to its SDS-based storage implementation and self-index approach. This enables to reach one of our goal which is to store as much data as possible in a given amount of RAM.

We are also comparing the main-memory footprint of SuccinctEdge with the in-memory systems, *i.e.*, RDF4J and Jena_InMem. In this evaluation, it is not possible to distinguish between the space used for the dictionaries and the data sets. So we provide the total space amount. Figure 11 yields the experiment results. We can see that as the amount of data grows, SuccinctEdge gradually shows its strength in saving memory space. We mainly attribute this to the size of the indexes stored by both RDF4J and Jena_InMem.

7.3.3 Triple pattern query. Considering query processing, we start the evaluation with single triple patterns,*i.e.*, excluding the cost of join operations, in order to directly compare the performance of data retrieval in different systems.

We first consider the two interesting triple patterns containing a single variable in the context of SuccinctEdge: **S,P,?o** (queries S1 to S5) and **?s,P,O** (queries S6 to S10) . Moreover, we consider these two triple patterns with different selectivity, *i.e.*, result sets ranging from 4 to 521 tuples. Table 1 and 2 provide the results of this experimentation for the LUBM1 dataset (over 100.000 triples).

Table 1: Data retrieval for a single S,P,?o TP. The first row represents the number of triples in the answer set. All times in ms. Bold times are a column's most efficient.

	Query performance				
Query name	S6	S7	S8	S9	S10
Selectivity	4	66	129	257	513
SuccinctEdge	**0.3**	**3.5**	**6.2**	**10.9**	23.3
RDF4Led	12	28	33	47	84
Jena TDB	7	16	22	27	33
Jena_InMem	5	11	15	19	29
RDF4J	3	6	10	11.1	**13**

Table 2: Data retrieval for a single ?s,P,O TP. The first row represents the number of triples in the answer set. All times in ms. Bold times are a column's most efficient.

	Query performance				
Query name	S1	S2	S3	S4	S5
Selectivity	5	17	135	283	521
SuccinctEdge	**0.7**	**1.5**	**10.1**	20.7	32.0
RDF4Led	6	9	51	71	81
Jena TDB	7	8	30	32	41
Jena_InMem	7	8	15	21	27
RDF4J	3	3	11	**16**	**21**

As said previously, in an IoT setting, we are mainly interested in executing a query on the freshest data and such a query is generally execute only once per graph instance. Hence, we are only considering hot runs.

SuccinctEdge outperforms other systems on almost all query selectivity. It is only on relatively non-selective, at least considering an IoT context, that SuccinctEdge gets beaten by RDF4J (S4, S5 and S10). Considering our potable water distribution running example, the answer set of each query is clearly very selective. That is only a small set of tuples are retrieved from a specific query out of a given measure. We consider that this will be the case for many industrial situations. Thus, high selective queries is clearly the main playground for RDF stores running in Edge computing. In the case of selective queries, SuccinctEdge can be up to one order of magnitude faster than its RDF4J most direct competitor, *e.g.*, Table 1 S6 with a result set of size 4.

Figure 12 shows the results of several randomly picked **?s,P,?o** queries (triple patterns with a constant predicate and variable subject and object, denoted S11 to S15). We can see from the results that SuccinctEdge outperforms the other systems. Clearly, the conclusion obtained on single triple patterns with a single variable that the more selective, the more efficient SuccinctEdge is compared to the other systems, is confirmed. We attribute this to SuccinctEdge's in-memory approach and structure which is **?s,P,?o**-friendly due to its PSO self-index approach. Moreover Jena TDB and RDF4Led also have PSO or POS indexes but are disk-based database, for whom, loading data from disk takes a non-negligible time. The numbers of triples in the answer sets of our single variable TP experimentation are much smaller than that of the **?s,P,?o**. This leads to greater differences between the different systems. This is again due to the fact that RDF4Led and Jena TDB are loading data from disk. Nevertheless, we can consider that retrieving over 500 tuples at a time from a single sensor is already quite unusual for an IoT use case. The comparison

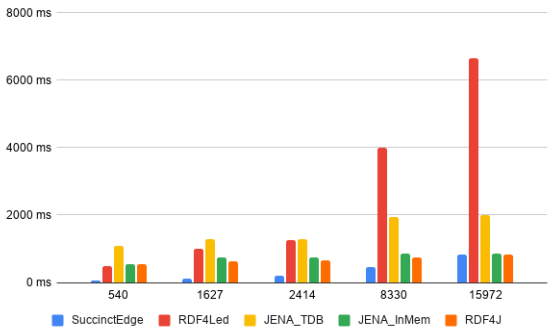

Figure 12: Data retrieval of queries with only one triple pattern of type ?s,P,?o, the x-axis represents the number of triples in the answer set.

with in-memory stores (RDF_InMem and RDJ4) highlights that SuccinctEdge is faster for answer sets lower than 10.000 tuples. At 16.000 result set tuples, The three systems behave similarly. Again, from the point of view of our experimentation partner, this is currently unusual for real-world industrial IoT use cases.

7.3.4 Graph pattern query. We now compare performances over queries containing multiple triple patterns, *i.e.*, requiring joins. Four queries with different selectivity values (answer sets ranging from 540 to close to 8.000 tuples) have been executed. They are denoted M1 to M5 and contain up to 10 TPs in the BGP. We can see in Figure 13 that RDF4Led and SuccinctEdge are always outperforming Jena TDB. SuccinctEdge is either more efficient than RDF4Led or slightly less efficient that RDF4Led. This showcases that in some cases RDF4Led finds a better TP query ordering strategy than SuccinctEdge and/or benefits from its large set of available indexes. Considering the latter, it is a price we are willing to pay for a lower memory footprint. Nevertheless, the former reason emphasizes that we can improve our query optimizer.

The comparison with the in-memory RDF stores emphasizes that the three systems behave similarly except for highly selective queries where SuccinctEdge is again more efficient. The differences between the query executions depend on the patterns used in the BGP of these five queries. Overall, we are satisfied that our system, with a single index, is at least at the same level than the two other systems.

7.3.5 Queries with RDFS reasoning. Our final experimentation concerns queries requiring some reasoning services. We have generated six queries (denoted R1 to R6) containing a mixture of RDFS:subClassOf and RDFS:subPropertyOf inferences. These queries present different selectivity characteristics, ranging from 15 to 8.345 tuples in the answer sets and contain up to 10 TPs in the BGP.

For SuccinctEdge, the reasoning service is automatically supported by LiteMat's encoding and is hence native in the system. This is not the case for the other systems for which we have rewritten each query as the union of all the possible sub-queries. Since RDF4Led doesn't support the SPARQL UNION clause no results are presented in Figure 14 for this system. Obviously, SuccinctEdge is much more efficient than Jena TDB. It is quite logical that the more entailments the query requires, the more efficient SuccinctEdge is compared to a system like Jena TDB.

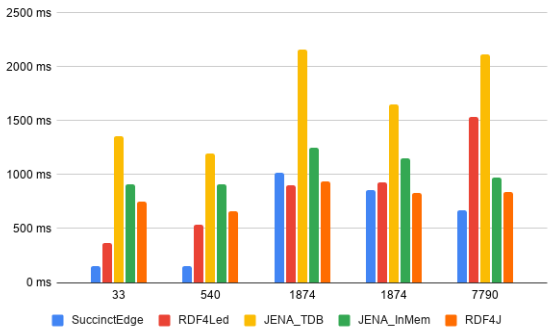

Figure 13: Queries with multiple triple pattern (x-axis corresponds to the number of tuples in the answer set)

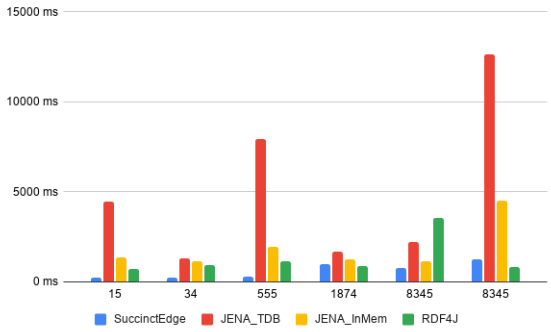

Figure 14: Queries with RDFS reasoning (x-axis corresponds to the number of tuples in the answer set)

As for Jena_InMem, it performs better than Jena TDB while still falling behind SuccinctEdge. When compared with RDF4J, SuccinctEdge performs better or similarly depending on the complexity of the reasoning services, *i.e.*, number of SPARQL UNION clauses. Note that we provide manual query rewriting to the Jena and RDF4J systems while these systems could implement the reasoning task with their APIs. In doing so, we provide a clear advantage to these systems since they do not have to load the ontology to perform the reasoning. Moreover, the extra cost of computing the UNION rewriting is not considered in the times of the Jena and RDF4J executions.

8 CONCLUSION

We have presented the first, to the best of our knowledge, KG inference-enabled data management system designed for Edge computing. Due to its unique index, compact, in-memory approach, we have demonstrated that SuccinctEdge outperforms its direct competitors on the following dimensions: query performance on different query patterns, efficiency of reasoning services, back-end size and creation time. The system is currently being deployed at some large building facilities at ENGIE and should help in detecting anomalies in water distribution and energy consumption. Due to its generic nature, SuccinctEdge is relevant for many IoT use cases such as anomaly and risk detection, supervising energy production and distribution. In the future, we are aiming to improve the query optimizer and support queries ranging several graphs. We are also considering to design a more efficient management of objects linked to datatype properties and to increase the expressiveness of supported ontology languages, *e.g.*, RDFS++ and OWL2RL. Moreover, we are considering the possibility of exchanging information with a larger graph portion that would reside in a cloud store.

A QUERIES

A total of 26 queries have been evaluated over a LUBM data set consisting of over 100.000 triples. They can be dispatched into 2 groups: whether their contain a single triple pattern or multiple ones. In this section, we list only the most prominent queries and provide templates for the other ones. Moreover, we present their main characteristics. The interested reader can access all of them on the paper companion GitHub page[19]. The following prefixes apply to all queries: lubm <http://swat.cse.lehigh.edu/onto/univ-bench.owl#>, rdf <http://www.w3.org/1999/02/22-rdf-syntax-ns#>

[19] https://github.com/xwq610728213/SuccinctEdge

Table 3: Query summary with the following notations: 'SS' and 'OS' respectively correspond to subject, subject and object,subject joins; 'Co' for concept hierarchy inferences, 'Pr' for property hierarchy inferences

	Query performance													
Systems	S1-5	S6-10	S11-15	M1	M2	M3	M4	M5	R1	R2	R3	R4	R5	R6
TP number	1	1	1	2	3	5	3	11	5	5	3	6	3	11
TP type(s)	sp?	?po	?p?	?p?	?p? ?po	?p? ?po	?p? ?po sp?o	?p? ?po	?p? ?po	?p? ?spo	?p? ?po	?p? ?po	?p?	?p? ?spo sp?
Join type	-	-	-	SS	SS	SS,OS	OS	SS,OS OO	SS,OS	SS,OS	SS	SS,OS	OS	SS,OS OO

Derived triples	0	0	0	0	0	0	0	0	15	540	1874	1874	555	1
Reasoning type	-	-	-	-	-	-	-	-	Co	Co Pr	Co Pr	Co Pr	Pr	Pr

A.1 Single triple pattern queries

This first set of queries contain a single triple pattern in the WHERE clause. We distinguish between queries with a single variable, either at the object (denoted sp?) or subject (denoted ?po) position, from queries with two variables (denoted ?p?). As explained in the paper, we do not consider that variables at the property position make sense in SuccinctEdge's use cases.

A.1.1 SP?o queries. The identification of these 5 queries range from S1 to S5. We used the following query template:

```
SELECT ?X WHERE {X1 P1 ?X}
```

For S1, P1 binds to the lubm:takesCourse property and X1 is an undergraduate student constant. For queries S2 to S5, P1 binds to lubm:publicationAuthor and the X1 bind to different publication instances. The selectivity of these queries are in Table 1.

A.1.2 ?sPO queries. These queries are identified from S6 to S10 and correspond to the following query template:

```
SELECT ?X WHERE { ?X P1 O1 }
```

P1 and O1 correspond to property and individual constants which for S6 to S10 respectively take the values (all properties are in the lubm namespace) : advisor/assistant professor constant, takesCourse/ course constant, worksFor/department constant, name/ publication constant, memberOf/ department constant.

A.1.3 ?sP?o queries.

```
S11: SELECT ?X ?Y ?Z WHERE { ?X lubm:worksFor ?Z }
S12: SELECT ?X ?Y ?Z WHERE { ?X lubm:teacherOf ?Y}
S13: SELECT ?X ?Y ?Z WHERE {
     ?X lubm:undergraduateDegreeFrom ?Y .}
S14: SELECT ?X ?Y ?Z WHERE { ?X lubm:emailAddress ?Y }
S15: SELECT ?X ?Y ?Z WHERE { ?X lubm:name ?Y }
```

A.2 Multiple triple patterns queries

In this set of queries, the BGP is composed of several triple patterns. The 11 queries in this category can be decomposed into those requiring or not some reasoning services (either based on concept or property hierarchies).

A.2.1 Non-inference queries. All prefixed with 'M'.

```
M1: SELECT ?X ?Y ?Z WHERE { ?X lubm:worksFor ?Z .
 ?X lubm:name ?Y .}
M2: SELECT ?X ?Y ?Z WHERE { ?X lubm:memberOf ?Z .
 ?X rdf:type lubm:GraduateStudent .
 ?X lubm:undergraduateDegreeFrom ?Y .}
M3:  SELECT ?X ?Y ?Z WHERE { ?X lubm:memberOf ?Z .
 ?X rdf:type lubm:GraduateStudent .
 ?Z rdf:type lubm:Department .
 ?Z lubm:subOrganizationOf ?Y .
 ?Y rdf:type lubm:University .}
M4: SELECT ?X ?Y ?Z WHERE { ?X lubm:memberOf ?Z .
 ?Z lubm:subOrganizationOf ?Y .
 ?Y rdf:type lubm:University }
M5: SELECT * WHERE {
 <http://www.Department0...Publication14>
 lubm:publicationAuthor ?p. ?st lubm:memberOf ?o2.
 ?p a lubm:AssociateProfessor. ?p lubm:worksFor ?o.
 ?o a lubm:department. ?o lubm:subOrganizationOf ?u.
 ?u a lubm:University. ?p lubm:teacherOf ?te.
 ?te a lubm:Course. ?st lubm:takesCourse ?te.
 ?st a lubm:UndergraduateStudent. }
```

A.2.2 Inference queries. The identifier of these queries is prefixed with an 'R' since they involve a form of reasoning.

```
R1: SELECT ?X ?Y ?Z WHERE { ?X rdf:type lubm:Person .
 ?Z rdf:type lubm:Department . ?X lubm:headOf ?Z .
 ?Z lubm:subOrganizationOf ?Y .
 ?Y rdf:type lubm:University .}
R2: SELECT ?X ?Y ?Z WHERE { ?X rdf:type lubm:Person .
 ?Z rdf:type lubm:Department .  ?X lubm:worksFor ?Z .
 ?Z lubm:subOrganizationOf ?Y .
 ?Y rdf:type lubm:University .}
R3: SELECT ?X ?Y ?Z WHERE { ?X lubm:memberOf ?Z .
 ?X rdf:type lubm:Student .
 ?X lubm:undergraduateDegreeFrom ?Y .}
R4: SELECT ?X ?Y ?Z ?N WHERE { ?X rdf:type lubm:Person .
 ?Z rdf:type lubm:Department . ?X lubm:memberOf ?Z .
 ?Z lubm:subOrganizationOf ?Y .  ?Y lubm:name ?N.
 ?Y rdf:type lubm:University . }
R5: identical to M4 but computes inferences  over the
memberOf property
R6: identical to M5 but computes inferences over the
memberOf and worksFor properties.
```

PolyFit: Polynomial-based Indexing Approach for Fast Approximate Range Aggregate Queries*

ABSTRACT

Range aggregate queries find frequent application in data analytics. In many use cases, approximate results are preferred over accurate results if they can be computed rapidly and satisfy approximation guarantees. Inspired by a recent indexing approach, we provide means of representing a discrete point dataset by continuous functions that can then serve as compact index structures. More specifically, we develop a polynomial-based indexing approach, called PolyFit, for processing approximate range aggregate queries. PolyFit is capable of supporting multiple types of range aggregate queries, including COUNT, SUM, MIN and MAX aggregates, with guaranteed absolute and relative error bounds. Experimental results show that PolyFit is faster and more accurate and compact than existing learned index structures.

1 INTRODUCTION

A *range aggregate query* [38] retrieves records in a dataset that belong to a given key range and then applies an aggregate function (e.g., SUM, COUNT, MIN, MAX) to an attribute of those records. Range aggregate queries are used in OLAP [38, 69] and data analytics applications, e.g., for outlier detection [72, 74], data visualization [24], and tweet analysis [54]. For example, network intrusion detection systems [74] utilize range COUNT queries to monitor a network for anomalous activities. Furthermore, applications with huge numbers of users are expected to receive queries frequently. For instance, Foursquare, with more than 50 million monthly active users [4], helps users find the number of specific POIs (e.g., restaurants) within given regions [3]. In many application scenarios, users accept approximate results provided that (i) they can be computed quickly and (ii) they are sufficiently accurate (e.g., within 5% error). We target such applications and focus on error-bounded evaluation of range aggregate queries.

A recent indexing approach represents the values of attributes in a dataset by continuous functions, which then serve to enable compact index structures [28, 44]. When compared to traditional index structures, this approach is able to yield a smaller index size and faster response time. The existing studies [28, 44] focus on computing exact results for point and range queries on 1-dimensional data. In contrast, we conduct a **comprehensive study of approximate range aggregate queries, supporting many aggregate functions and multi-dimensional data**.

The idea that underlies our proposal for using functions to answer approximate range aggregate queries may be explained as follows. Consider a stock market index (e.g., the Hong Kong Hang Seng Index) at different times as a dataset $\mathcal{D}$ consisting of records of the form (index value, timestamp), where the former is our measure and the latter is our key that is used for specifying query ranges—see Figure 1(a). A user can find the average stock market index value in a specified time range $[l_q, u_q]$ by issuing a range SUM query (and divide by $u_q - l_q + 1$). We propose to construct the cumulative function of $\mathcal{D}$ as shown in Figure 1(b). If we can approximate this function well by a polynomial function $\mathbb{P}(x)$ then the range SUM query can be approximated as $\mathbb{P}(u_q) - \mathbb{P}(l_q)$, which takes $O(1)$ time. As another example, the user may wish to find the maximum stock market index in a specified time range. The timestamped index values in $\mathcal{D}$ can be modeled by the continuous function shown in Figure 1(c). Again, if we can approximate this function well using a polynomial function $\mathbb{P}(x)$ then the range MAX query can be answered quickly using mathematical tools, e.g., by applying differentiation to identify maxima in $\mathbb{P}(x)$.

Regarding the two-dimensional case, consider the dataset of tweets' locations as shown in Figure 9(a) in Section 6, where each data point has a longitude (as key 1) and a latitude (as key 2). Suppose that the user wishes to count the number of tweets in a geographical region. Our idea is to derive the cumulative count function shown in Figure 9(b), and then approximate this function with a polynomial function $\mathbb{P}(x_1, x_2)$ (of two variables). This enables us to answer a two-dimensional range COUNT query in $O(1)$ time.

Another difference between our work and existing studies [28, 44] is the types of functions used for approximation. Our proposal uses piecewise polynomial functions, rather than piecewise linear functions [28, 44]. As we will show in Section 4, using polynomial functions yields lower fitting errors than using linear functions. Thus, our proposal leads to smaller index sizes and faster queries.

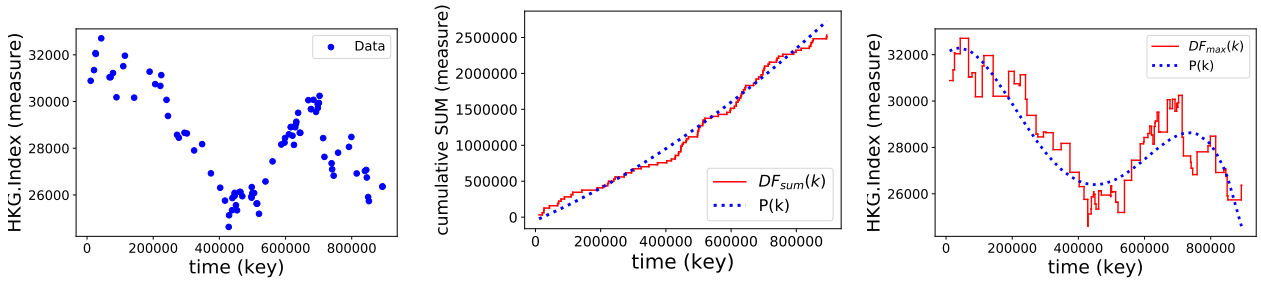
The key technical challenges are as follows. (1) How to find polynomial functions with low approximation error efficiently? (2) How to answer range aggregate queries with error guarantees? (3) How to support common aggregate functions (e.g., COUNT, SUM, MIN, MAX) and multi-dimensional data?

To tackle these challenges, we develop a polynomial-based indexing approach (PolyFit) for processing approximate range aggregate queries. Our contributions are summarized as follows.

- To the best of our knowledge, this is the first study that utilizes polynomial functions to learn indexes that support approximate range aggregate queries.
- PolyFit supports multiple types of range aggregate queries, including COUNT, SUM, MIN and MAX with guaranteed deterministic absolute and relative error bounds.
- Experiment results show that PolyFit achieves significant speedups, compared with the closest related works [28, 44], and traditional exact/approximate methods. For instance, for the OpenStreetMap dataset with 100M records, our index occupies only 4 MBytes and offers 5 μs query response time (per 2-dimensional range COUNT query).

The rest of the paper is organized as follows. We first review the related work in Section 2. Next, we introduce preliminaries in Section 3. Then, we present our index construction techniques in Section 4 and cover how to answer approximate range aggregate

*This work was supported by grant GRF 152050/19E from the Hong Kong RGC.



(a) timestamped index values (b) function for range SUM queries (c) function for range MAX queries

Figure 1: Stock market index values, 1-dimensional keys: discrete data points vs. continuous function

queries in Section 5. Next, we extend our proposal to datasets with two keys in Section 6. Lastly, we present experiments in Section 7 and conclude in Section 8.

2 RELATED WORK

Range aggregate queries are used frequently in analytics applications and constitute important functionality in OLAP and data warehousing [11, 12, 20, 23, 38, 40, 56, 69]. Exact solutions are based on prefix-sum arrays [38] or aggregate R-trees [59]. Due to the need for real-time performance in some applications (e.g., μs-level response time [74]), many proposals exist that aim to improve the efficiency of range aggregate queries. These proposals can be classified as being either data-driven or query-driven. In addition, we also review some other studies, including learned indexes, and time series databases, which are also related to this work.

Data-driven proposals build statistical models of a dataset for estimating query selectivity or the results of range aggregate queries. These models employ multi-dimensional histograms [39, 52, 57, 68], data sampling [9, 34, 36, 51, 60, 65], or kernel density estimation [32, 33, 37]. Although such proposals that compute approximate results are much faster than exact solutions, e.g., achieving ms (10^{-3}) level response time [61], they still do not offer real-time performance (e.g., μs level [74]). Furthermore, these proposals do not offer theoretical approximation error guarantees.

The **query-driven approaches** utilize query workloads to build statistical models of datasets. Typical methods include error-feedback histograms [8, 10, 49], max-entropy histograms [55, 64], and learning-based models [53, 66]. In addition, Park et al. [61] explore the approach of using mixture probabilistic models. These methods assume that new queries follow historical query workload distributions. However, as one study [13] observes, this assumption may not always hold in practice. Further, even when this assumption is valid, the number of queries that are similar to those used for training may be much smaller if the queries follow a power law distribution [73], which can cause poor accuracy and may render it impossible to obtain useful approximation error guarantees for range aggregate queries.

Recently, **learning-based methods** have been used to construct more compact and effective index structure, that hold potential to accelerate database operations. Kraska et al. [44] propose the RMI index, which incorporates different machine learning models, e.g., linear regression and deep-learning, to improve the efficiency of range queries. Galakatos et al. [28] develop the FITing-tree, which is a segment-tree-like structure [22, 71] that can significantly improve the efficiency of exact point queries. Ferragina et al. [27] further support efficient update operations for range queries. Wang et al. [70] extend this learning-based approach to the spatial domain with their learned Z-order model that aims to support fast spatial indexing. However, there are two main differences between these proposals and our proposal. First, they either support range queries [27, 44, 70] or point queries [28], but not range aggregate queries. Second, we are the first to exploit polynomial functions to build index structures for approximate range aggregate queries.

In the **time series database** community, some research studies utilize mathematical models to approximate time series data. Representative approaches include piecewise linear approximation [25, 41–43, 50], discrete wavelet transform [15, 62], discrete Fourier transform [26, 63], and their combinations [40, 58]. However, these studies focus on either time series similarity search (e.g., range or nearest neighbor queries) or time series compression and they are not designed to answer the range aggregate queries we target. Some of these studies also utilize piecewise linear approximation [25, 41, 42, 50] to approximate time-series, which we also do. In contrast, we achieve better performance by utilizing nonlinear (polynomial) functions to approximate curves, which can reduce the number of segments dramatically. Furthermore, we can also support the segmentation of surfaces (e.g., Figure 9(b)), rather than only 1-D curves.

3 PRELIMINARIES

First, we define range aggregate queries and their approximate versions in Section 3.1. Then, we discuss the baselines for answering exact range aggregate queries in Section 3.2. Table 1 summarizes frequently used symbols in this paper.

Table 1: Symbols

Symbol	Description
$\mathcal{D}$	dataset
n	number of records in $\mathcal{D}$
R_{count}	range COUNT query
R_{sum}	range SUM query
R_{min}	range MIN query
R_{max}	range MAX query
CF_{sum}	cumulative function for range SUM query
DF_{max}	key-measure function for range MAX query
$\mathbb{P}(k)$	polynomial function
I	interval
deg	degree of polynomial function

3.1 Problem Definition

We focus on the setting that a range aggregate query specifies a *key* attribute (for range selection) and a *measure* attribute for

aggregation. We shall consider the setting of two keys in Section 6. As such, the dataset $\mathcal{D}$ is a set of $(key, measure)$ records, i.e., $\mathcal{D} = \{(k_1, m_1), (k_2, m_2), ..., (k_n, m_n)\}$. For ease of discussion, we assume that key values are distinct and measure values are numerical. We leave the discussion of repeated keys and negative measure values in Appendices A.3 and A.4 [48]. Then we define a range aggregate query as follows.

Definition 3.1. Let $\mathcal{G}$ be an aggregate function (e.g., COUNT, SUM, MIN, MAX) on a measure attribute. Given a dataset $\mathcal{D}$ and a key range $[l_q, u_q]$, we define V as the following multi-set

$$V = \{m \mid (k, m) \in \mathcal{D} \wedge l_q \leq k \leq u_q\}$$

and then define the result of the range aggregate query as

$$R_{\mathcal{G}}(\mathcal{D}, [l_q, u_q]) = \mathcal{G}(V). \tag{1}$$

We aim to develop efficient methods for obtaining an approximate result of $R_{\mathcal{G}}(\mathcal{D}, [l_q, u_q])$ with two types of error guarantees [29, 30], namely the absolute error guarantee (cf. Problem 1) and the relative error guarantee (cf. Problem 2).

Problem 1 (Q_{abs}). *Given an absolute error ε_{abs} and a range aggregate query, we ask for an approximate result A_{abs} such that:*

$$|A_{abs} - R_{\mathcal{G}}(\mathcal{D}, [l_q, u_q])| \leq \varepsilon_{abs} \tag{2}$$

Problem 2 (Q_{rel}). *Given a relative error ε_{rel} and a range aggregate query, we ask for an approximate result A_{rel} such that:*

$$\left| \frac{A_{rel} - R_{\mathcal{G}}(\mathcal{D}, [l_q, u_q])}{R_{\mathcal{G}}(\mathcal{D}, [l_q, u_q])} \right| \leq \varepsilon_{rel} \tag{3}$$

3.2 Baselines: Exact Methods

We proceed to discuss exact methods for answering range SUM queries and range MAX queries. These methods can be easily extended to support COUNT and MIN, respectively.

3.2.1 **Exact method for range SUM queries**. First, we define the key cumulative function as $CF_{sum}(k)$:

$$CF_{sum}(k) = R_{sum}(\mathcal{D}, [-\infty, k]). \tag{4}$$

The additive property of CF_{sum} enables us to compute the exact result of the range SUM query as:

$$R_{sum}(\mathcal{D}, [l_q, u_q]) = CF_{sum}(u_q) - CF_{sum}(l_q). \tag{5}$$

Then, we discuss how to obtain the terms $CF_{sum}(l_q)$ and $CF_{sum}(u_q)$ efficiently. Although CF_{sum} is a continuous function, it can be expressed by a discrete data structure in finite space. Specifically, we presort dataset $\mathcal{D}$ in ascending key order and then follow this order to construct a key-cumulative array of entries $(k, CF_{sum}(k))$. At query time, the terms $CF_{sum}(l_q)$ and $CF_{sum}(u_q)$ are obtained by performing binary search on the above key-cumulative array. This step takes $O(\log n)$ time.

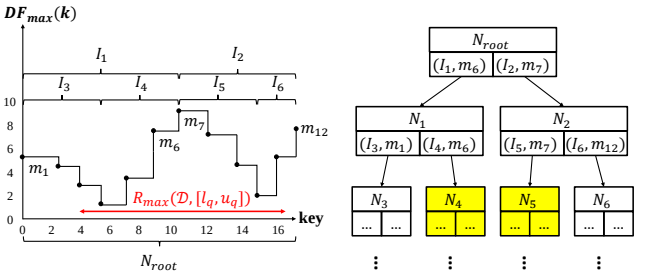
As a remark, this key-cumulative array is similar to the prefix-sum array [38]. The difference is that our array allows floating-point search keys, while the prefix-sum array does not.

3.2.2 **Exact method for range MAX queries**. First, we define the key-measure function $DF_{max}(k)$ in Equation 6 to capture the data distribution in the dataset $\mathcal{D}$. In the definition, we assume that each pair (k_i, m_i) in $\mathcal{D}$ is arranged in ascending order by the key.

$$DF_{max}(k) = \begin{cases} m_1 & \text{if } k_1 \leq k < k_2 \\ \vdots & \vdots \\ m_i & \text{if } k_i \leq k < k_{i+1} \\ \vdots & \vdots \\ m_n & \text{if } k = k_n \\ -\infty & \text{otherwise} \end{cases} \tag{6}$$

Figure 2(a) exemplifies the function $DF_{max}(k)$.

An aggregate max-tree [59] (cf. Figure 2(b)) can be built to answer range MAX queries. In this tree, each internal node stores two entries, where each entry stores an interval and the maximum measure within that interval (e.g., (I_1, m_6) and (I_2, m_7) are two entries of the root node N_{root}). We then explain how to process the query $R_{max}(\mathcal{D}, [l_q, u_q])$, whose query range is indicated by the red line in Figure 2(a). In Figure 2(b), we start from the root of the tree. If the interval of an entry intersects with the query range (e.g., I_1 and I_2 in Figure 2(a)), we visit its child nodes (e.g., N_1 and N_2). When the interval of an entry (e.g., I_4 and I_5 in Figure 2a) is covered by the query range, we directly use its stored aggregate value without visiting its child nodes (e.g., yellow nodes in Figure 2b). During the traversal, we keep track of the maximum measure seen so far. This procedure takes $O(\log n)$ time as we check at most two branches per level.



(a) (key, measure)-pairs, red line denotes the max query

(b) Hierarchical max-tree, yellow nodes are skipped during traversal

Figure 2: Aggregate MAX tree

4 INDEX CONSTRUCTION

Traditional index structures (e.g., B-tree [21]) need to store n keys, where n is the cardinality of the dataset $\mathcal{D}$. Thus, the index size grows linearly with the data size. To reduce the index size dramatically, we plan to index a limited number of functions (instead of n keys).

As a case study, we compare existing fitting functions [28, 44] with our fitting function (polynomial) on a real dataset (the Hong Kong 40 Index in 2018 [5]) in Figure 3. The exact key-measure function $DF_{max}(k)$ exhibits a complex shape. Observe that linear functions, e.g., linear regression $LR(k)$ [44] and linear segment $FIT(k)$ [28], cannot accurately approximate the exact function. In this paper, we adopt the polynomial function $\mathbb{P}(k)$, which captures the nonlinear property[1] and achieves a better approximation of $DF_{\max}(k)$. In this example, $\mathbb{P}(k)$ is a degree-4 polynomial function (blue dotted line).

We introduce our indexing framework in Figure 4. First, we convert the dataset into the following exact function $F(k)$ based

[1] As a remark, other types of nonlinear functions (e.g., logarithmic and trigonometric functions) require higher computation cost than polynomial functions. Thus, we leave other types of nonlinear functions as future work.

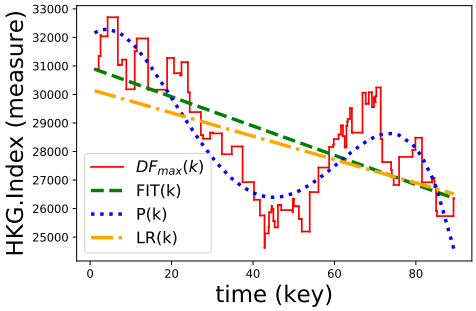


Figure 3: Curve fitting of the HKG 40 Index in 2018 [5]

on the aggregate function $\mathcal{G}$ and the functions in Section 3.2.

$$F(k) = \begin{cases} CF_{sum}(k) & \text{if } \mathcal{G} = \texttt{SUM} \\ DF_{max}(k) & \text{if } \mathcal{G} = \texttt{MAX} \end{cases} \tag{7}$$

We plan to compute an error-bounded approximation of $F(k)$ by using a sequence of polynomial functions. In Section 4.1, we examine how to find the best polynomial fitting of $F(k)$ in a given key interval I. Then, in Section 4.2, we propose a segmentation method for $F(k)$ in order to minimize the index size subject to a given deviation threshold. Finally, in Section 4.3, we discuss how to build an index for a sequence of polynomial functions.

4.1 Polynomial Fitting in a Key Interval

We discuss how to find the best fitting polynomial function of $F(k)$ in a given key interval I. First, we express a polynomial function $\mathbb{P}(k)$ as follows:

$$\mathbb{P}(k) = \sum_{j=0}^{deg} a_j k^j, \tag{8}$$

where deg is the degree and each a_j is a coefficient. Note that the choice of deg entails tradeoffs between the fitting error and the online query evaluation cost. We discuss the choice of deg in Section 5.3.

We formulate the following optimization problem in order to minimize the fitting error between $\mathbb{P}(k)$ and $F(k)$.

Definition 4.1. Let $F(k)$ be the exact function and I be a given key interval. Let $k_1, k_2, \cdots, k_\ell$ be the keys of $\mathcal{D}$ in interval I. We aim to find polynomial coefficients, $a_0, a_1, \cdots, a_{deg}$ that minimize the following error:

$$E(I) = \min_{a_0, a_1, \ldots, a_{deg} \in \mathbb{R}} \max_{1 \le i \le \ell} |F(k_i) - \mathbb{P}(k_i)| \tag{9}$$

This is equivalent to the following linear programming problem, where the coefficients $a_0, a_1, \cdots, a_{deg}$ and t are variables.

$$\begin{cases} \text{MINIMIZE} \quad t \\ \text{SUBJECT TO:} \\ -t \le F(k_1) - (a_{deg} k_1^{deg} + \ldots + a_2 k_1^2 + a_1 k_1 + a_0) \le t \\ -t \le F(k_2) - (a_{deg} k_2^{deg} + \ldots + a_2 k_2^2 + a_1 k_2 + a_0) \le t \\ \ldots \\ -t \le F(k_\ell) - (a_{deg} k_\ell^{deg} + \ldots + a_2 k_\ell^2 + a_1 k_\ell + a_0) \le t \\ \forall a_i \in \mathbb{R} \end{cases} \tag{10}$$

It takes $O(\ell^{2.5})$ time to solve the above linear programming problem (Equation 10) [46]. In our experimental study, we adopt the IBM CPLEX linear programming library as the LP Solver, which is believed to be the most reliable and efficient among other implementations [31]. We discuss some subtle issues like precision limitations in Section 5.3.

4.2 Minimal Index Size with Bounded Error

To support approximate query evaluation (in Section 5), we require that the fitting polynomial functions should satisfy a given error constraint. However, a single polynomial function is unlikely to fit accurately for the entire key domain. Thus, we propose to partition the key domain into intervals $I_1, I_2, \cdots, I_h$ so that each interval I_i satisfies the following requirement:

$$E(I) \le \delta,$$

where δ is a given deviation threshold. For instance, in Figure 5, the key domain is partitioned into two intervals I_1 and I_2 so that the best fitting polynomial function in each interval satisfies the error requirement.

To achieve a small index size, we aim to minimize the number of intervals (i.e., h in Figure 4). An existing dynamic programming (DP) approach [47], though designed for piecewise linear functions, can be adapted to solve our partitioning problem of $F(k)$. However, this method takes $O(n^2 \times \ell_{max}^{2.5})$ time[2], where ℓ_{max} is the maximum number of keys covered by any interval. Obviously, this method does not scale well with the data size n.

In Section 4.2.1, we present a more efficient method, called greedy segmentation (GS), to segment the exact function $F(k)$. As we show later, the time complexity of GS is $O(n \times \ell_{max}^{2.5})$, which scales well with the data size n. Then, in Section 4.2.2, we show that GS is guaranteed to return the optimal solution.

4.2.1 **Greedy Segmentation (GS) Method.** We present the pseudo-code of the Greedy Segmentation (GS) method in Algorithm 1. It examines the key domain from left to right (line 2). In each iteration, it expands the interval I by including the next key (line 3), calls an LP solver on the interval I to obtain a fitting function $\mathbb{P}_{now}$ (line 4), and tests whether it fulfills the error requirement. When this test fails (i.e., $E(I) > \delta$), we conclude that the previous interval is a maximal interval and thus insert its corresponding fitting function $\mathbb{P}_{prev}$ into the result. The above procedure is repeated until all keys are covered.

Algorithm 1 Greedy Segmentation (GS)

Input: function $F(k)$, degree deg, deviation threshold δ
Output: sequence of polynomial functions $\text{Seq}_{\mathbb{P}}$

```
1: Seq_P ← ∅;  l ← 1;  P_prev ← null
2: for u ← 2 to n do
3:     I ← [k_l, k_u]                    ▷ the interval for polynomial function P
4:     P_now ← call LP solver on I       ▷ Equation 10
5:     if E(I) > δ or u = n then         ▷ Equation 9
6:         insert P_prev into Seq_P
7:         l ← u
8:     P_prev ← P_now
9: return Seq_P
```

The time complexity of GS is $O(n\ell_{max}^{2.5})$ because it invokes $O(n)$ calls to the LP solver, where each call takes $O(\ell_{max}^{2.5})$ time [46]. We further accelerate GS by applying an existing exponential search technique [14], which can reduce the number of LP calls per interval by $\frac{\ell}{\log \ell}$ times. With this technique, GS takes only 70 seconds (cf. Section 7.2.2) to complete for a real dataset with 1 million data points. This is acceptable for many data analytics tasks (with static datasets) in OLAP. In our experiments, we find that ℓ_{max} usually ranges between hundreds and thousands, thus

[2]Recall that the state-of-the-art linear programming solver [46] takes $O(\ell_{max}^{2.5})$ time for each curve-fitting problem (cf. Equation 10).

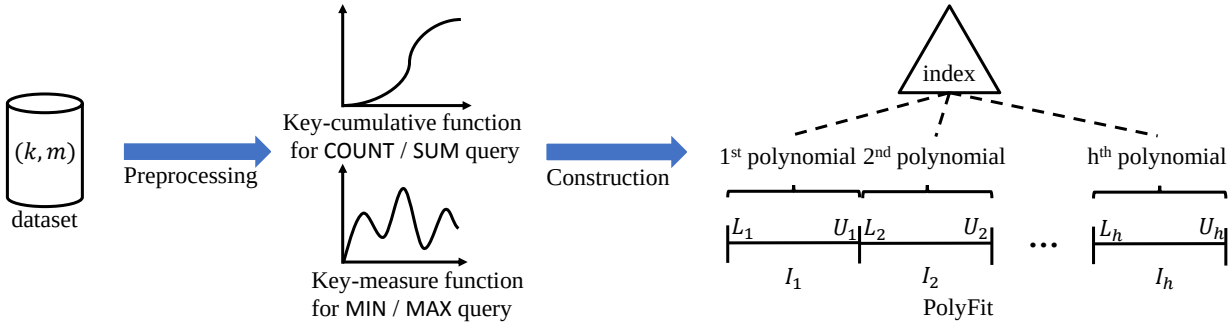

Figure 4: Indexing framework for PolyFit, each leaf entry stores a polynomial function

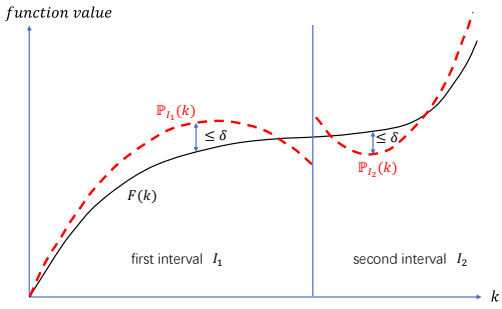

Figure 5: Fitting $F(k)$ with multiple polynomial functions, subject to the deviation threshold δ

the term $O(\ell_{max}^{2.5})$ is acceptable in practice. In Appendix [48], we discuss how to utilize parallel computation to further improve the construction time.

4.2.2 **GS is Optimal**. We first prove the following property (Lemma 4.2) of our curve fitting problem (cf. Definition 4.1).

Lemma 4.2. *Let I_l and I_u be two intervals, which contain two sets of keys S_l and S_u, respectively. If $S_l \subseteq S_u$, then $E(I_l) \leq E(I_u)$.*

Proof. Recall that the value of $E(I)$ (cf. Equation 9) is equal to the minimum value of the optimization problem (Equation 10). Since S_l is a subset of S_u, the set of constraints for solving $E(I_l)$ is also the subset of constraints for solving $E(I_u)$. Thus, for the minimization problem in Equation 10, the possible solution space for S_l is a superset of the possible solution space for S_u. Therefore, we conclude that $E(I_l) \leq E(I_u)$. □

Based on Lemma 4.2, we then show that GS produces the fewest polynomial functions (cf. Theorem 4.3), i.e., the optimal solution.

Theorem 4.3. *GS always produces the optimal number of functions (with respect to the given parameters deg and δ).*

Proof. We denote the minimum key and the maximum key of an interval I by $I.\min$ and $I.\max$, respectively.

Let $\mathcal{I}^*_{\text{OPT}} = (I^{(1)}_{\text{OPT}}, I^{(2)}_{\text{OPT}}, \cdots)$ and $\mathcal{I}^*_{\text{GS}} = (I^{(1)}_{\text{GS}}, I^{(2)}_{\text{GS}}, \cdots)$ be two ascending sequences of intervals for the optimal solution and our GS method, respectively (i.e., $I^{(i)}.\max < I^{(i+1)}.\min$ for $i = 1, 2, \ldots, n-1$). Every interval I in $\mathcal{I}^*_{\text{OPT}}$ and $\mathcal{I}^*_{\text{GS}}$ must satisfy $E(I) \leq \delta$. We now prove the theorem by mathematical induction.

In the base step, we consider the first interval in each sequence. Since both GS and OPT must cover the key domain, we have:

$$I^{(1)}_{\text{GS}}.\min = I^{(1)}_{\text{OPT}}.\min$$

According to GS, the first interval $I^{(1)}_{\text{GS}}$ is maximal, because a longer interval would violate the deviation threshold δ. Thus, we have:

$$I^{(1)}_{\text{GS}}.\max \geq I^{(1)}_{\text{OPT}}.\max \tag{11}$$

In the inductive step, assume that the first ℓ intervals of the two sequences satisfy the following property:

$$I^{(\ell)}_{\text{GS}}.\max \geq I^{(\ell)}_{\text{OPT}}.\max \tag{12}$$

Since $\mathcal{I}^*_{\text{OPT}}$ and $\mathcal{I}^*_{\text{GS}}$ are ascending sequences of intervals, Equation 12 implies the following:

$$I^{(\ell+1)}_{\text{GS}}.\min \geq I^{(\ell+1)}_{\text{OPT}}.\min \tag{13}$$

Now, we consider two cases for comparing $I^{(\ell+1)}_{\text{GS}}$ and $I^{(\ell+1)}_{\text{OPT}}$.

Case 1:

$$I^{(\ell+1)}_{\text{GS}}.\max \geq I^{(\ell+1)}_{\text{OPT}}.\max$$

In this case, the first $\ell+1$ intervals of GS cover all keys in the first $\ell+1$ intervals of OPT.

Case 2:

$$I^{(\ell+1)}_{\text{GS}}.\max < I^{(\ell+1)}_{\text{OPT}}.\max \tag{14}$$

Consider the interval $I' = [I^{(\ell+1)}_{\text{GS}}.\min, I^{(\ell+1)}_{\text{OPT}}.\max]$. By using Equations 13 and 14, we obtain: $I' \subset I^{(\ell+1)}_{\text{OPT}}$. By Lemma 4.2, we get: $E(I') \leq E(I^{(\ell+1)}_{\text{OPT}})$. Since $E(I^{(\ell+1)}_{\text{OPT}}) \leq \delta$, we get: $E(I') \leq \delta$.

Observe that I' has the same minimum key as $I^{(\ell+1)}_{\text{GS}}$ but a larger maximum key than $I^{(\ell+1)}_{\text{GS}}$. Since I' does not pass the error test in GS, we get $E(I') > \delta$. This contradicts the statement $E(I') \leq \delta$.

Therefore, only the first case is true, and we have:

$$I^{(\ell+1)}_{\text{GS}}.\max \geq I^{(\ell+1)}_{\text{OPT}}.\max$$

This means GS always covers no fewer keys than OPT with the same number of intervals. Thus, GS produces the optimal number of functions. □

4.3 Indexing of polynomial functions

In our experimental study, the number of intervals (for polynomial functions) ranges from 100 to 1000. We adopt existing index structures on these intervals to support fast query evaluation. Specifically, we employ an in-memory index called the STX B-tree [6] to index intervals. In each internal node entry, we maintain an additional attribute to store the aggregate value of its subtree. In each leaf node entry, we store an interval and its corresponding polynomial model (in the form of coefficients). In summary, this index is similar to the aggregate tree exemplified in Figure 2(b), except that we store polynomial models in leaf nodes.

5 APPROXIMATE QUERY EVALUATION

We present our framework for answering approximate range aggregate queries in Figure 6. The first step is to compute an initial approximate result quickly by using our index (PolyFit). Then, we check whether the error condition is satisfied and refine the approximate result if necessary. We discuss how to answer

the approximate range SUM query and the approximate range MAX query in Sections 5.1 and 5.2, respectively. Finally, in Section 5.3, we discuss how to tune our index parameters (e.g., deg, δ) in order to optimize the query response time.

5.1 Approximate range SUM Query

Given the query range $[l_q, u_q]$, we propose to compute the approximate result as:

$$\tilde{A}_{sum} = \mathbb{P}_{I_u}(u_q) - \mathbb{P}_{I_l}(l_q), \tag{15}$$

where I_l and I_u denote the intervals of $\mathbb{P}$ that contain the values l_q and u_q, respectively.

Then, we show the error conditions for Q_{abs} (cf. Problem 1) and Q_{rel} (cf. Problem 2).

Error condition for Q_{abs}

Given the absolute error ε_{abs}, we recommend to use the deviation threshold $\delta = \frac{\varepsilon_{abs}}{2}$ in constructing PolyFit. With this setting, the following lemma offers the absolute error guarantee for the approximate result $\tilde{A}_{sum}$ (in Equation 15).

Lemma 5.1. *If $\delta = \frac{\varepsilon_{abs}}{2}$, then $\tilde{A}_{sum}$ (in Equation 15) satisfies the absolute error guarantee with respect to ε_{abs}.*

Proof. Let I_l and I_u be two intervals (in PolyFit) which contain l_q and u_q (of the query range $[l_q, u_q]$), respectively. Based on the deviation threshold guarantee in Section 4.2.2, we obtain:

$$|CF_{sum}(l_q) - \mathbb{P}_{I_l}(l_q)| \leq \delta$$

$$|CF_{sum}(u_q) - \mathbb{P}_{I_u}(u_q)| \leq \delta$$

By combining them, we have:

$$CF_{sum}(u_q) - CF_{sum}(l_q) - 2\delta \leq \tilde{A}_{sum} \leq CF_{sum}(u_q) - CF_{sum}(l_q) + 2\delta$$

By using Equation 5, we have:

$$R_{sum}(\mathcal{D}, [l_q, u_q]) - 2\delta \leq \tilde{A}_{sum} \leq R_{sum}(\mathcal{D}, [l_q, u_q]) + 2\delta$$

Since $\delta = \frac{\varepsilon_{abs}}{2}$, $\tilde{A}_{sum}$ satisfies the absolute error guarantee ε_{abs}. □

Error condition for Q_{rel}

In this scenario, there is no specific preference for setting the deviation threshold δ when constructing PolyFit. The following lemma suggests a condition to test whether $\tilde{A}_{sum}$ satisfies the relative error guarantee. If this test fails, we resort to the exact method (cf. Section 3.2.1) to obtain the exact result.

Lemma 5.2. *If $\tilde{A}_{sum} \geq 2\delta(1 + \frac{1}{\varepsilon_{rel}})$, then $\tilde{A}_{sum}$ (in Equation 15) satisfies the relative error guarantee with respect to ε_{rel}.*

Proof. Like in the proof of Lemma 5.1, we can derive Equations 16 and 17.

$$|\tilde{A}_{sum} - R_{sum}(\mathcal{D}, [l_q, u_q])| \leq 2\delta \tag{16}$$

which also implies (by simple derivations):

$$R_{sum}(\mathcal{D}, [l_q, u_q]) \geq \tilde{A}_{sum} - 2\delta \tag{17}$$

Since δ and ε_{rel} must be positive, the given condition $\tilde{A}_{sum} \geq 2\delta(1 + \frac{1}{\varepsilon_{rel}})$ implies that $\tilde{A}_{sum} > 2\delta$ and $\frac{2\delta}{\tilde{A}_{sum} - 2\delta} \leq \varepsilon_{rel}$.

Dividing Equation 16 by Equation 17, we obtain the following inequality (under the condition $\tilde{A}_{sum} > 2\delta$).

$$\frac{|\tilde{A}_{sum} - R_{sum}(\mathcal{D}, [l_q, u_q])|}{R_{sum}(\mathcal{D}, [l_q, u_q])} \leq \frac{2\delta}{\tilde{A}_{sum} - 2\delta}$$

This completes the proof because $\frac{2\delta}{\tilde{A}_{sum} - 2\delta} \leq \varepsilon_{rel}$. □

The overall query algorithm

We summarize the query algorithm for both types of error guarantees in Algorithm 2. The processing for Q_{abs} is composed of two parts: index search T_1 (i.e., Lines 1-2) and function evaluation T_2 (i.e., Line 3). The processing for Q_{rel} includes T_1, T_2, and possible refinement T_3 (i.e., Lines 4-6). The time complexity of T_1, T_2, and T_3 are $O(\log(|\text{Seq}_{\mathbb{P}}|))$, $O(deg)$, and $O(\log|\mathcal{D}|)$ respectively.

Algorithm 2 Query Processing for SUM (or COUNT)

Input: $\text{Seq}_{\mathbb{P}}$ (output from Algorithm 1), l_q, u_q, $\mathcal{D}$, δ, Q_{type}
Output: Approximate query result A

1: $\mathbb{P}_{I_l} \leftarrow$ index search $\mathbb{P}$ from $\text{Seq}_{\mathbb{P}}$ that includes l_q
2: $\mathbb{P}_{I_u} \leftarrow$ index search $\mathbb{P}$ from $\text{Seq}_{\mathbb{P}}$ that includes u_q
3: $\tilde{A}_{sum} \leftarrow \mathbb{P}_{I_u}(u_q) - \mathbb{P}_{I_l}(l_q)$
4: **if** $Q_{type} = Q_{rel}$ **then**
5: **if** $\tilde{A}_{sum}$ fails the error condition of Lemma 5.2 **then**
6: $\tilde{A}_{sum} \leftarrow$ perform refinement on $\mathcal{D}$ ▷ Section 3.2.1
7: **return** $\tilde{A}_{sum}$

5.2 Approximate range MAX Query

The query method described in Section 3.2.2 can be applied here, except that we employ the index described in Section 4.3.

Given the query range $[l_q, u_q]$, we propose to compute the approximate result as:

$$\tilde{A}_{max} = \max\{\max_{k \in I_l, k \geq l_q} \mathbb{P}_{I_l}(k), \max_{k \in I_u, k \leq u_q} \mathbb{P}_{I_u}(k), \max_{N_j.I \subseteq [l_q, u_q]} N_j.max\} \tag{18}$$

where N_j denotes an internal node of the index built on top of $\text{Seq}_{\mathbb{P}}$. I_l and I_u denote the intervals of $\mathbb{P}$ that contain the values l_q and u_q, respectively.

The error conditions for Q_{abs} and Q_{rel} are presented in Lemmas 5.3 and 5.4 respectively. We omit their proofs; they are similar to the proofs of Lemmas 5.1 and 5.2.

Lemma 5.3. *If $\delta = \varepsilon_{abs}$, then $\tilde{A}_{max}$ (in Equation 18) satisfies the absolute error guarantee ε_{abs}.*

Lemma 5.4. *If $\tilde{A}_{max} \geq \delta(1 + \frac{1}{\varepsilon_{rel}})$, then $\tilde{A}_{max}$ (in Equation 18) satisfies the relative error guarantee ε_{rel}.*

We now discuss how to evaluate Equation 18 in greater detail. The third term is contributed by the inner nodes of the aggregate R-tree whose intervals are covered by $[l_q, u_q]$. Regarding the first two terms, it suffices to find the maximum values for $\mathbb{P}_{I_l}(k)$ and $\mathbb{P}_{I_u}(k)$ in regions $[l_q, U_{I_l}]$ and $[L_{I_u}, u_q]$, as shown in Figure 7, where U_{I_l} (L_{I_u}) is the upper (lower) end of the leaf node interval that l_q (u_q) overlaps. These values (i.e., red dots) can be calculated by checking the border points and the zero derivative points.

The overall query algorithm

We conclude the query algorithm for both types of error guarantees in Algorithm 3. The processing for Q_{abs} consists of two parts: index search T_1 (i.e., Line 3) and function evaluation T_2 (Lines 8-9). The processing for Q_{rel} includes T_1, T_2, and possible refinement T_3 (i.e., Lines 10-12). The time complexities of T_1 and T_3 are still $O(\log(|\text{Seq}_{\mathbb{P}}|))$ and $O(\log|\mathcal{D}|)$. However, for T_2, this includes calculating the zero derivative points within the intersection region. If the degree is between 1 and 5, closed-form equations exist, where the number of arithmetic operations in these cases are summarized in Table 2. Starting from degree 6, there is no closed-form equations, and thus require expensive

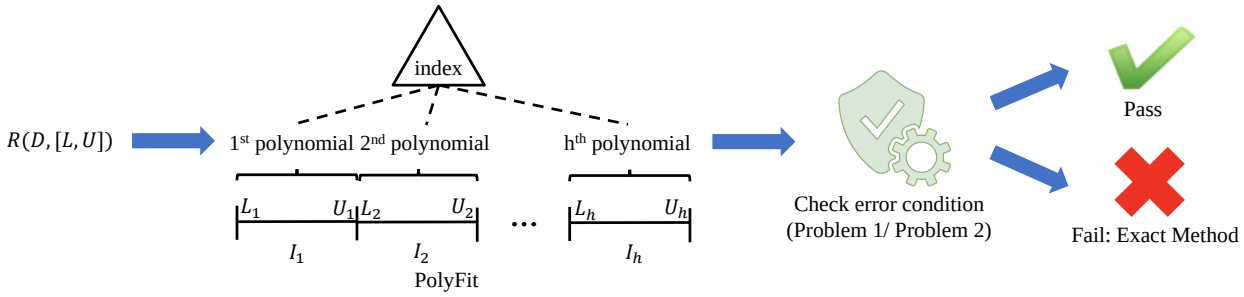

Figure 6: Querying framework for PolyFit

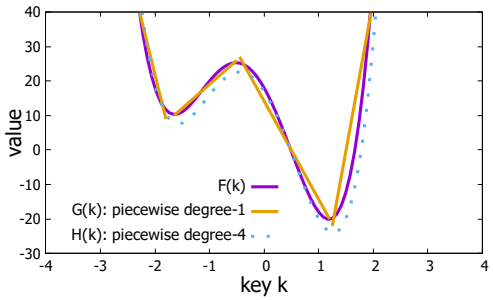

Figure 8: An example of degree selection

numerical evaluation methods like gradient descent [67]. In practice, we recommend to use degrees up to 3 for the approximate range MAX query.

Algorithm 3 Query Processing for MAX (or MIN)

Input: Aggregate R-tree N on $\text{Seq}_{\mathbb{P}}$, l_q, u_q, $\mathcal{D}$, δ, Q_{type}
Output: Approximate query result A

```
1:  Ã_max ← −∞
2:  if N is an internal node then
3:      update Ã_max based on aggregate R-tree's mechanism
4:  else
5:      for leaf element ℙ in N do
6:          if ℙ.I ∩ [l_q, u_q] ≠ ∅ then          ▷ the interval ℙ covered
7:              I* ← ℙ.I ∩ [l_q, u_q]
8:              β ← {x ∈ I* | ℙ'(x) = 0}          ▷ zero derivative points
9:              Ã_max ← max(Ã_max, max_{x∈β} ℙ(x), ℙ(I*.l), ℙ(I*.u)))
10: if N is root node and Q_type = Q_rel then
11:     if Ã_max fails the error condition of Lemma 5.4 then
12:         Ã_max ← perform refinement on 𝒟          ▷ Section 3.2.2
13: return A
```

degree	1	2	3	4	5
operations	0	2	up to 18	up to 261	up to 1612

5.3 Tuning *deg* and δ

We discuss the effect of our index parameters (i.e., *deg*, δ) on the query response time and examine how to tune them.

***How to tune the degree** deg?*

The exact function $F(k)$ is approximated by different polynomial functions with different degrees. For instance, in Figure 8, the exact function $F(k)$ is approximated, among others, by the following functions (within the deviation threshold δ): (i) a piecewise function $G(k)$ with four pieces of degree-1 functions, or (ii) a single-piece function $H(k)$ of degree-4. Based on our experimental findings (cf. Section 7.2.1), we recommend to set the degree to 2 or 3. In general, one could generate a random workload of queries to measure the performance of an index, and then test the performance of index structures using different degrees (e.g., from 1 to 4).

As a remark, it is not practical to use large degree, due to the limited precision of numeric data types in both the linear programming solver and the programming language [1, 2]. For example, IBM CPLEX uses κ (kappa) as a statistical measurement of numerical difficulties. In our experiments, the κ value of a degree-4 polynomial (1E+10) is much higher than that of a degree-1 polynomial (1E+05).

***How to tune** δ?*

The tuning of δ depends on the most frequent query type used in the given application. For Q_{abs} (i.e., Problem 1), if all users share the same absolute error threshold ε_{abs}, then it is used to derive the value of δ, according to Lemmas 5.1 and 5.3. Otherwise, we can select the value of δ such that it satisfies the error requirements for the majority of users (e.g., 80%).

For Q_{rel} (i.e., Problem 2), the processing includes three phases: index search, function evaluation, and refinement (cf. Algorithms 2 and 3). A large δ leads to fast index search but high refinement probability. In contrast, a small δ leads to slow index search but low refinement probability. Observe that refinement is often more expensive than index search. We recommend to pick a small δ such that most users avoid the refinement phase. In our experiments, we examine different values of δ (e.g., 25, 50, 100, 200, 500, and 1000) to identify the best setting in terms of the query response time.

6 EXTENSIONS: QUERIES WITH TWO KEYS

Previous sections consider range aggregate queries with a single key (cf. Definition 3.1). We now discuss how to support range aggregate queries with two keys (cf. Definition 6.1). Due to the space limit, we only consider the COUNT query. In Appendix A.5 [48], we discuss the case of more than two keys.

Definition 6.1. Let $\mathcal{D}$ be a set of records (u, v, w), where u, v, and w are the first key, the second key, and the measure, respectively. Given the query ranges $[l_q^{(1)}, u_q^{(1)}]$ and $[l_q^{(2)}, u_q^{(2)}]$ for u and v, respectively, we define the COUNT query as:

$$R_{count}(\mathcal{D}, [l_q^{(1)}, u_q^{(1)}][l_q^{(2)}, u_q^{(2)}]) = \text{COUNT}(V) \tag{19}$$

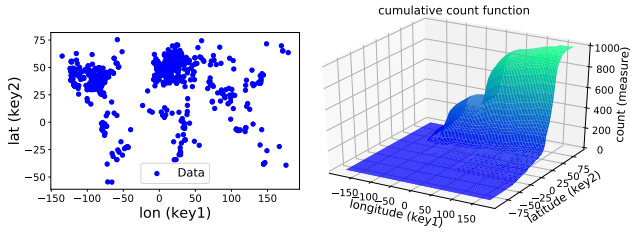
where V is the multi-set of measure values defined below:

$$V = \{m : (k^{(1)}, k^{(2)}, m) \in \mathcal{D}, l_q^{(1)} \leq k^{(1)} \leq u_q^{(1)}, l_q^{(2)} \leq k^{(2)} \leq u_q^{(2)}\}$$

We build the following key-cumulative function to represent the surface (cf. Figure 9), which is formulated in Definition 6.2.

Definition 6.2. The key-cumulative function with two keys for COUNT query is defined as $CF_{count}(u, v)$, where:

$$CF_{count}(u, v) = R_{count}(\mathcal{D}[-\infty, u][-\infty, v]) \tag{20}$$



(a) tweet locations as data points (b) function for range COUNT queries

Figure 9: Tweet locations, 2-dimensional keys: discrete data points vs. continuous function

The following equation enables us to answer the COUNT query quickly.

$$R_{count}(\mathcal{D}[l_q^{(1)}, u_q^{(1)}][l_q^{(2)}, u_q^{(2)}]) = CF_{count}(u_q^{(1)}, u_q^{(2)}) - CF_{count}(l_q^{(1)}, u_q^{(2)}) - CF_{count}(u_q^{(1)}, l_q^{(2)}) + CF_{count}(l_q^{(1)}, l_q^{(2)})$$

Then, we follow an idea similar to that used in Section 4.1 and utilize the polynomial surface $\mathbb{P}(u, v)$ to approximate the key cumulative function $CF_{count}(u, v)$ with two keys, where:

$$\mathbb{P}(u, v) = \sum_{i=0}^{deg} \sum_{j=0}^{deg} a_{ij} u^i v^j$$

By replacing $F(k_i)$ and $\mathbb{P}(k_i)$ in Equation 9 with $F(u_i, v_i)$ and $\mathbb{P}(u_i, v_i)$, respectively, we obtain a similar linear programming problem for obtaining the best parameters a_{ij}. However, unlike the one-dimensional case, it takes at least $O(n^2)$ to obtain the minimum number of segmentations when using the GS method (cf. Section 4.2.1), which is infeasible even for small-scale datasets (e.g., 10000 points). Instead, we propose a heuristics-based solution that performs quad-tree-like segmentations. As illustrated in Figure 10, when a region does not fulfill the error guarantee δ (e.g., white rectangles), it is decomposed into four smaller regions. This procedure terminates when all regions satisfy the error guarantee δ.

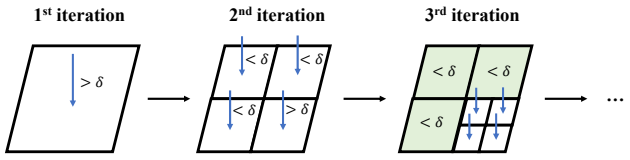


Figure 10: Quad-tree based approach for obtaining the segmentation

After building the PolyFit index structure, we utilize a similar approach in Section 5 to answer range aggregate queries with theoretical guarantees (cf. Lemmas 6.3 and 6.4).

Given the query range $[l_q^{(1)}, u_q^{(1)}]$ for u and $[l_q^{(2)}, u_q^{(2)}]$ for v, we propose to compute the approximate result as:

$$\tilde{A}_{count} = \mathbb{P}_{I_{uu}}(u_q^{(1)}, u_q^{(2)}) - \mathbb{P}_{I_{lu}}(l_q^{(1)}, u_q^{(2)}) - \mathbb{P}_{I_{ul}}(u_q^{(1)}, l_q^{(2)}) + \mathbb{P}_{I_{ll}}(l_q^{(1)}, l_q^{(2)}) \tag{21}$$

where I_{uu}, I_{lu}, I_{ul}, and I_{ll} denote the coverage regions of $\mathbb{P}$ that $(u_q^{(1)}, u_q^{(2)})$, $(l_q^{(1)}, u_q^{(2)})$, $(u_q^{(1)}, l_q^{(2)})$, and $(l_q^{(1)}, l_q^{(2)})$ overlap, respectively. These regions could be efficiently found with the same quad-tree index used in construction.

LEMMA 6.3. *If we set* $\delta = \frac{\varepsilon_{abs}}{4}$, *then* $\tilde{A}_{count}$ *satisfies the absolute error guarantee* ε_{abs}.

LEMMA 6.4. *If* $\tilde{A}_{count} \geq 4\delta(1 + \frac{1}{\varepsilon_{rel}})$, *then* $\tilde{A}_{count}$ *satisfies the relative error guarantee* ε_{rel}.

The proofs of Lemma 6.3 and 6.4 are similar to those of Lemmas 5.1 and 5.2, respectively.

7 EXPERIMENTAL EVALUATION

We introduce the experimental setting in Section 7.1. Then, we investigate the performance of PolyFit in Section 7.2. Next, we compare PolyFit and error-bounded competitors on real datasets in Section 7.3. After that, we compare the response time of PolyFit with other heuristic methods in Section 7.4. Lastly, we compare the construction times of all methods in Section 7.5.

7.1 Experimental Setting

We use three real large-scale datasets (0.9M to 100M records) to evaluate the performance. They are summarized in Table 3. For each dataset, we randomly generate 1000 queries. In the single-key case, we randomly choose two key values in the datasets as the start and end points of each query interval. In the two-key case, we randomly sample rectangles from the dataset as query regions. In our experiments, we focus on COUNT and MAX queries. Nevertheless, our methods are readily applicable to SUM and MIN queries.

Table 3: Datasets

Name	Size	Key(s)	Measure	Aggregate function
HKI [5]	0.9M	timestamp	index value	MAX
TWEET [19]	1M	latitude	# of tweets	COUNT
OSM [7]	100M	latitude, longitude	# of records	COUNT

Table 4 summarizes different methods for supporting range aggregate queries. We classify these methods based on five features: (i) whether it provides absolute error guarantees (cf. Problem 1 (Q_{abs})), (ii) whether it provides relative error guarantees (cf. Problem 2 (Q_{rel})), (iii) whether it supports queries with two keys (cf. Section 6), (iv) whether it supports the COUNT query, and (v) whether it supports the MAX query.

We first introduce the methods that can satisfy deterministic error guarantees (i.e., those with ✓ or △ in the Q_{abs} and Q_{rel} columns in Table 4). The aR-tree [59] is a traditional tree-based method for answering exact COUNT and MAX queries. The MRTree [45] extends the aR-tree by utilizing progressive lower and upper bounds to answer approximate COUNT and MAX queries with error guarantees. In addition, both the aR-tree and the MRTree can support the range aggregate queries with two keys. With simple modifications, the learned-index methods, including RMI [44], FITing-tree [28], and PGM [27], can be extended to support range aggregate queries with both absolute and relative error guarantees. However, they are unable to support queries with two keys and the MAX query. Due to the space limitation, we cover the modifications and parameter tuning in our technical report (cf. Appendix in [48]). PolyFit supports all these five features. By

Table 4: Methods for range aggregate queries

✓ Directly support △ Extend to support × Cannot support

Method	Q_{abs}	Q_{rel}	2 keys	COUNT	MAX
aR-tree [59]	✓	✓	✓	✓	✓
MRTree [45]	✓	✓	✓	✓	✓
RMI [44]	△	△	×	✓	×
FITing-tree [28]	△	△	×	✓	×
PGM [27]	△	△	×	✓	×
PolyFit (ours)	✓	✓	✓	✓	✓
Hist [68]	×	×	×	✓	×
S-tree [6]	×	×	×	✓	×
S2 [35]	×	×	✓	✓	×
VerdictDB [60]	×	×	✓	✓	×
DBest [53]	×	×	✓	✓	×
PLATO [50]	×	×	×	✓	×

default, we follow Lemmas 5.1, 5.3, and 6.3 to set the δ values in Problem 1 (Q_{abs}), for different absolute error threshold ε_{abs}. In addition, we adopt $\delta = 100$ in PolyFit for the experiments with two keys in Problem 2 (Q_{rel}).

We then discuss the methods that are unable to fulifll the deterministic error guarantee (i.e., the methods with × in the Q_{abs} and Q_{rel} columns in Table 4). Hist [68] adopts the entropy-based histogram for answering the COUNT query. The S-tree prebuilds the STX B-tree [6] on top of a sampled subset of each dataset. S2 [35] and VerdictDB [60] are sampling-based approaches that can only provide probabilistic error guarantees. By default, we set the probability to 0.9 in our experiments. Both DBest [53] and PLATO [50] are the state-of-the-art methods in approximate query processing and time series databases, respectively, that can be also adapted to answer approximate range aggregate queries. Since these methods cannot provide deterministic error guarantees, we regard them as heuristic methods.

We implemented all methods in C++ and conducted experiments on an Intel Core i7-8700 3.2GHz PC using WSL (Windows 10 Subsystem for Linux).

7.2 PolyFit Tuning

In this section, we investigate two research questions for PolyFit, namely (1) how does the degree *deg* affect the query response time of PolyFit? (2) how does the degree *deg* affect the construction time of PolyFit?

7.2.1 **Effect of *deg* on the query response time**. Recall that we need to select the degree *deg* in order to build PolyFit. It is thus important to understand how this parameter affects the query response time. Here, we use the form PolyFit-*deg* to represent the degree *deg* of PolyFit. Figure 11 shows the trends for the query response time for both COUNT (one key and two keys) and MAX (one key) queries, using the absolute error threshold $\varepsilon_{abs} = 100$. When we choose a larger degree *deg*, the polynomial function can provide better approximation for $F(k)$, and thus reduce the index size, which can reduce the response time for each query. However, the larger the degree *deg*, the larger the computation time for each node in PolyFit. Therefore, we can find that the response time increases (e.g., $deg = 3$ and 4 in Figure 11a), once we utilize a high degree *deg*. By default, in subsequent experiments, we choose deg = 2 for the COUNT query with a single key, and deg = 3 for the COUNT query with two keys and for the MAX query.

7.2.2 **Effect of *deg* on the construction time**. We further examine the construction time for PolyFit, varying the highest degree *deg* from 1 to 4 in the polynomial function (cf. Figure 12). Since a polynomial function with a higher degree can produce error guarantee for a longer interval I, i.e., $E(I) \leq \delta$, the GS method needs to call the LP solver with longer intervals (cf. line 4 in Algorithm 1), which can increase the construction time when using polynomial functions with higher degree *deg*.

7.3 Comparing with Error-Bounded Methods

In this section, we test the response time of the different methods that can fulfill the absolute and relative error guarantees. Here, we adopt the default settings for these methods (cf. Section 7.1) and use the datasets HKI, TWEET, and OSM for testing the performance of COUNT (single key), MAX (single key), and COUNT (two keys) queries, respectively. For Problem 1 (Q_{abs}), we fix the absolute error $\varepsilon_{abs} = 100$ and $\varepsilon_{abs} = 200$ for the experiments with one key and two keys, respectively. For Problem 2 (Q_{rel}), we fix the relative error $\varepsilon_{rel} = 0.01$. Table 5 shows the response time of different methods. Observe that PolyFit achieves the best performance for all the types of queries. For the COUNT query with two keys, PolyFit can achieve a speedup of at least two orders of magnitude over the existing methods.

Table 5: Response time (nanoseconds) for all methods with error guarantees

Error guarantee	Q_{abs}			Q_{rel}		
Query type	COUNT	MAX	COUNT	COUNT	MAX	COUNT
# of keys	1	1	2	1	1	2
aR-tree	590	3592	357457	590	3592	357457
MRTree	565	182	385391	335	138	98919
RMI	568	n/a	n/a	579	n/a	n/a
FITing-tree	135	n/a	n/a	147	n/a	n/a
PGM	104	n/a	n/a	118	n/a	n/a
Polyfit	**68**	**63**	**5274**	**79**	**65**	**5299**

Sensitivity of ε_{abs} for COUNT query. We investigate how the absolute error ε_{abs} affects the response times of different methods. For the COUNT query with single key, we choose five absolute error values for testing, which are 100, 200, 400, 1000, and 2000. Observe from Figure 13a that since PolyFit, FITing-tree, and PGM can provide more compact index structures for the datasets, these methods can significantly improve the efficiency, compared with the traditional index structures, i.e., the aR-tree and the MRTree. In addition, due to the better approximation with nonlinear polynomial functions ($deg = 2$), PolyFit can achieve 1.33x to 6x speedups, over the existing learned-index structures, including RMI, FITing-tree, and PGM. For the COUNT query with two keys, we choose 200, 400, 800, 2000, and 4000 as the absolute error values for testing. Since the state-of-the-art learned index structures (RMI, FITing-tree, and PGM) can only support queries with a single key, we omit these methods in this experiment. Figure 13b shows that PolyFit achieves at least one order of magnitude speedups compared with the existing methods (aR-tree and MRTree), which is due to its compact index structure and query processing method.

Sensitivity of ε_{rel} for COUNT query. We proceed to test how the relative error ε_{rel} affects the response time of the different methods. In this experiment, we choose five relative error values, which are 0.005, 0.01, 0.05, 0.1, and 0.2. Based on the more compact index structure, PolyFit is able to achieve better performance, compared with the existing methods (cf. Figure 14a). For the COUNT query with two keys, PolyFit significantly outperforms the existing methods, i.e., the aR-tree and the MRTree, by at least one order of magnitude (cf. Figure 14b).

Sensitivity of ε_{abs} and ε_{rel} for MAX query. In this experiment, we proceed to investigate how the absolute error ε_{abs} and

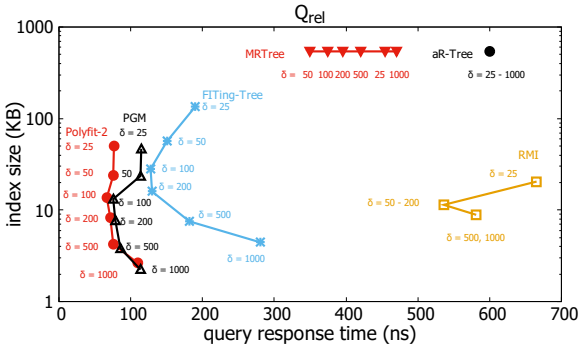

Figure 18: Trade-off between the query response time and index size of COUNT query (single key) in TWEET dataset, for Q_{rel} with $\varepsilon_{rel} = 0.01$, varying δ from 25 to 1000

methods. Observe from Figure 15, PolyFit can achieve at least 2x speedup, compared with other methods, even though the selected error is small.

Sensitivity of the selectivity for COUNT query. We further test the response time of the different methods, varying the selectivity of the COUNT query. Figure 16 shows that when we increase the selectivity of the COUNT query (i.e., each query covers a larger region), the query response time normally increases in different methods. Since all methods for the COUNT query with a single key have logarithmic time complexity, they are not sensitive to the selectivity (cf. Figure 16a). Unlike the single key case, both

the existing methods aR-tree and MRTree are sensitive to the selectivity, compared with PolyFit (cf. Figure 16b).

In both cases, PolyFit achieves better performance across different selectivities. Since the methods MRTree, aR-tree, and RMI always provide inferior efficiency in the single key case (cf. Figures 13a, 14a and 16a), compared with FITing-Tree, PGM and PolyFit, we omit their results in subsequent experiments.

Scalability to the dataset size. We proceed to test how the dataset size affects the efficiency of PolyFit and other methods. In this experiment, we choose the largest dataset OSM (with 100M records) for testing. Here, we focus on solving Problem 1 (Q_{abs}) for COUNT query, in which we adopt the default absolute errors, i.e., $\varepsilon_{abs} = 100$ and $\varepsilon_{abs} = 200$ for the cases in single key and two keys, respectively, and choose the latitude attribute as the key. To conduct this experiment, we choose five dataset sizes, which are 1M, 10M, 30M, and 100M. Figure 17 shows that PolyFit scales well with the dataset size and outperforms other methods.

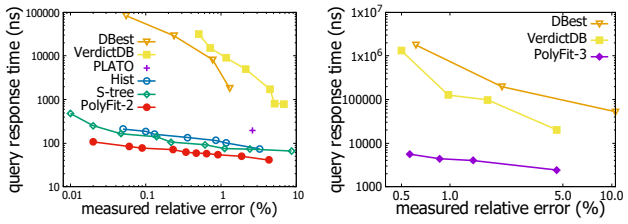
Trade-off between the query response time and index size. We proceed to investigate the trade-off between the query response time and index size of the different indexing methods. To conduct this experiment, we focus on Problem 2 (Q_{rel}) and choose 25, 50, 100, 200, 500, and 1000 as values of δ for testing. In Figure 18, since the changes to δ cannot affect the index construction methods of the aR-tree and MRTree, parameter δ cannot affect the index sizes of these two methods. We also notice that these index structures consistently provide inferior performance in terms of index size and query response time, compared with the FITing-tree, PGM, and the PolyFit methods. For the other methods, we can observe that the smaller the δ, the larger the index size and query response time. The reason is that smaller δ values lead to more leaf nodes in the index structures in the different methods (e.g., more intervals are generated by the GS method (cf. Algorithm 1) in PolyFit). On the other hand, if δ is too large, it is easier for an online query to violate the error condition for Q_{rel} (i.e., Lemma 5.2), and thus the query response time can also be larger. As such, all curves (except for the MRTree and aR-tree methods) in Figure 18 resemble the "C"-shape. In general, PolyFit-2 offers a better trade-off compared with other methods.

7.4 Comparing with Heuristic Methods

We compare the response time of PolyFit with other heuristic methods, which cannot fulfill deterministic error guarantees, i.e., Q_{abs} (cf. Problem 1) and Q_{rel} (cf. Problem 2). In this experiment, we adopt the default setting for the method PLATO [50], vary the bin size for the method Hist and vary the sampling size for the sampling-based methods, including S-tree, S2, VerdictDB, and DBest. Since S2 cannot achieve less than 100000ns query response time with 10% measured relative error, we omit the result of S2 in Figure 19a. In addition, we only report the results of the heuristic methods DBest and VerdictDB in Figure 19b, as the other heuristic methods cannot support COUNT queries with two keys (cf. Table 4). In these two figures, PolyFit yields the smallest query response time with similar relative error.

7.5 Comparing the Construction Time of All Methods

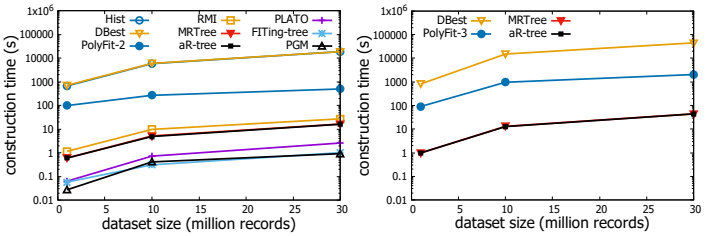
We proceed to investigate further how the construction times of all methods change across different dataset sizes. Here, we adopt the default degrees, i.e., $deg = 2$ and $deg = 3$, for the polynomial functions in the COUNT query with a single key and two keys, respectively. In Figure 20, PolyFit consistently achieves faster construction time than Hist and DBest. Although PolyFit may not achieve the fastest construction time, compared with



(a) COUNT query (single key) (b) COUNT query (two keys)

Figure 19: Response time between PolyFit and the heuristic methods for COUNT query with single key and two keys in TWEET and OSM datasets, respectively

some methods (e.g., the aR-tree and the MRTree), PolyFit takes less than 150s and 2500s (with default *deg*) in the construction stage with 1 million (TWEET) and 30 million records (OSM), respectively, which are acceptable in practice where the datasets are static during data analytics tasks.



(a) COUNT query (single key) (b) COUNT query (two keys)

Figure 20: Index construction time of methods for COUNT query with single key and two keys (using OSM dataset for both settings), varying the dataset size

8 CONCLUSION

In this paper, we study the range aggregate queries with two types of approximate guarantees, which are (1) absolute error guarantees (cf. Problem 1 (Q_{abs})) and (2) relative error guarantees (cf. Problem 2 (Q_{rel})). Unlike the existing methods, our work can efficiently support the most commonly used range aggregate queries (SUM, COUNT, MIN, MAX), fulfill the error guarantees, and support the setting of two keys.

In order to improve the efficiency of computing these queries, we utilize several polynomial functions to fit the data points and then build the compact index structure PolyFit on top of these polynomial functions. An experimental study shows that PolyFit can achieve significant speedups compared with existing learned-index methods and other traditional exact/ approximate methods for different query types. In particular, we can achieve at most 5μs query response time in a dataset with 30 million records, which cannot be achieved by the state-of-the-art methods.

In the future, we plan to further develop advanced techniques to improve the efficiency of constructing PolyFit, in order to handle updates of records in large-scale datasets. In addition, we aim to extend our methods to support other fundamental analytics operations, including standard deviation, median, etc. Moreover, we plan to investigate how to utilize the idea of PolyFit to further improve the efficiency of other types of statistics and machine learning models, e.g., kernel density estimation [16, 18], and support vector machines [17, 18].

Shift-Table: A Low-latency Learned Index for Range Queries using Model Correction

Ali Hadian
Imperial College London

Thomas Heinis
Imperial College London

ABSTRACT

Indexing large-scale databases in main memory is still challenging today. Learned index structures — in which the core components of classical indexes are replaced with machine learning models — have recently been suggested to significantly improve performance for read-only range queries.

However, a recent benchmark study shows that learned indexes only achieve limited performance improvements for real-world data on modern hardware. More specifically, a learned model cannot learn the micro-level details and fluctuations of data distributions thus resulting in poor accuracy; or it can fit to the data distribution at the cost of training a big model whose parameters cannot fit into cache. As a consequence, querying a learned index on real-world data takes a substantial number of memory lookups, thereby degrading performance.

In this paper, we adopt a different approach for modeling a data distribution that complements the model fitting approach of learned indexes. We propose *Shift-Table*, an algorithmic layer that captures the micro-level data distribution and resolves the local biases of a learned model at the cost of at most one memory lookup. Our suggested model combines the low latency of lookup tables with learned indexes and enables low-latency processing of range queries. Using Shift-Table, we achieve a speedup of 1.5X to 2X on real-world datasets compared to trained and tuned learned indexes.

1 INTRODUCTION

Trends in new hardware play a significant role in the way we design high-performance systems. A recent technological trend is the divergence of CPU and memory latencies, which encourages decreasing random memory access at the cost of doing more compute on cache-resident data [25, 42, 44].

A particularly interesting family of methods exploiting the memory/CPU latency gap are learned index structures. A learned index uses machine learning instead of algorithmic data structures to learn the patterns in data distribution and exploits the trained model to carry out the operations supported by an algorithmic index, e.g., determining the location of records on physical storage [7, 12, 18, 24, 25, 29]. If the learned index manages to build a model that is compact enough to fit in processor cache, then the results can ideally be fetched with a single access to main memory, hence outperforming algorithmic structures such as B-trees and hash tables.

In particular, learned index models have shown a great potential for range queries, e.g., retrieving all records where the key is in a certain range $A <$ key $< B$. To enable efficient retrieval of range queries, range indexes keep the records physically sorted. Therefore, retrieving the range query is equivalent to finding the first result and then sequentially scanning the records to retrieve the entire result set. Therefore, processing a range query $A <$ key $< B$ is equivalent to finding the first result, i.e., the smallest key in the dataset that is greater than or equal to A (similar to `lower_bound(A)` in the C++ Library standard). A learned index can be built by fitting a regression model to the cumulative distribution function (CDF) of the key distribution. The learned CDF model can be used to determine the physical location where the lower-bound of the query resides, i.e., $\texttt{pos}(\text{A}) = N \times F_\theta(\text{A})$ where N is the number of keys and F_θ is the learned CDF model with model parameters θ.

Learned indexes are very efficient for sequence-like data (e.g., machine-generated IDs), as well as synthetic data sampled from statistical distributions. However, a recent study using the Search-On-Sorted-Data benchmark (SOSD) [22] shows that for real-world data distributions, a learned index has the same or even poorer performance compared to algorithmic indexes. For many real-world data distributions, the CDF is too complex to be learned efficiently by a small cache-resident model. The data distribution of real-world data has "too much information" to be accurately represented by a small machine-learning model, while an accurate model is needed for an accurate prediction. One can of course use smaller models that fit in memory with the cost of lower prediction accuracy, but will end up in searching a larger set of records to find the actual result which consequently increases memory lookups and degrades performance. Alternatively, a high accuracy can be achieved by training a bigger model, but accessing the model parameters incurs multiple cache misses and also increases memory lookups, reducing the margins for performance improvement.

In this paper, we address the challenge of using learned models on real-world data and illustrate how the micro-level details (e.g., local variance) of a cumulative distribution can dramatically affect the performance of a range index. We also argue that a pure machine learning approach cannot shoulder the burden of learning the fine-grained details of an empirical data distribution and demonstrate that not much improvement can be achieved by tuning the complexity or size thresholds of the models.

We suggest that by going beyond mere machine learning models, the performance of a learned index architecture can be significantly improved using a complementary enhancement layer rather than over-emphasizing on the machine learning tasks. Our suggested layer, called *Shift-Table* is an algorithmic solution that improves the precision of a learned model and effectively accelerates the search performance. Shift-Table, targets the micro-level bias of the model and significantly improves the accuracy, at the cost of only one memory lookup. The suggested layer is optional and applied after the prediction; it can hence be switched on or off without re-training the model.

Our contributions can be summarized as follows:

- We identify the problem of learning a range index for real-world data, and illustrate the difficulty of learning from this data.

- We suggest the Shift-Table approach for correcting a learned index model, which complements a valid (monotonically increasing) CDF model by correcting its error.
- We show how, and in which circumstances, the suggested methods can be used for best performance.
- We suggest cost models that determine whether the Shift-Table layer can boost performance.
- The experimental results show that our suggested method can improve existing learned index structures and bring stable and almost-constant lookup time for real-world data distributions. Our enhancement layer achieves up to 3X performance improvement over existing learned indexes. More interestingly, we show that for non-skewed distributions, the Shift-Table layer is effective enough to help a dummy linear model outperform the state of the art learned indexes on real-world datasets

2 MOTIVATION

2.1 Lookup Cost for Learned Models

In modern hardware, the lookup times of in-memory range indexes and the binary search algorithm are mainly affected by their memory access pattern, most notably by how the algorithm uses the cache and the Last-Level-Cache (LLC) miss rate.

Processing a range query in a learned index has two stages: 1) **Prediction**: Running the learned model to predict the location of the first result for the range query; and 2) **Local search** (also known as *last-mile search*): searching around the predicted location to find the actual location of the first result. Figure 1a shows common search methods for the local search. If the learned model can determine a guaranteed range area around the predicted position, one can perform binary search. Otherwise, exponential or linear search should be used, starting from the predicted position.

A cache miss in a learned index can occur in the first stage for accessing the parameters of the model (if the model is too big to fit in cache), or in stage two for the local search. Key in understanding the cost of a learned index is that local search is done entirely over non-cached blocks of memory. A learned index built over millions of records could predict the location of records with an error of, say, 1000 records and yet achieve no performance gain over binary search algorithms or algorithmic indexes. This is because while the learned index fits the models in cache, its algorithmic competitors also fit the frequently-accessed parts of the data in cache, which limits the potential for improvement for a learned index.

2.2 Lookup Cost for Algorithmic Indexes

Classical algorithms, such as binary search, can be seen as a hierarchy of [non-learned] models, which take the middle-point as its parameter and predicts (accurately) which direction the search should follow. Specifically for the first few steps of binary search where the middle-points usually reside in cache, the functionality of binary search is the same as a learned model from a performance point of view.

In a pure binary search on the entire data, the first set of memory locations accessed by the algorithm (i.e., the median, quarters, etc.) will already be in the CPU cache after a few lookups. Therefore, the major bottleneck in binary search is for the latter stages of search where the middle elements are not in cache, causing last-level-cache (LLC) misses. Figure 1b shows a schematic illustration of how caching accelerates binary search.

In basic implementations of binary search, the "hot keys" are cached with their payload and nearby records in the same cache line, which wastes cache space. Binary search thus uses the cache poorly and there are more efficient algorithmic approaches whose performance is not sensitive to data distributions.

Cache-optimized versions of binary search, e.g., a binary search tree such as FAST [21], a read-only search tree that co-locates the hot keys but still follows the simple bisecting method of binary search, are up to 3X faster than binary search [22]. This is because FAST keeps more hot keys in the cache and hence it needs to scan a shorter range of records in the local search phase (cache-non-resident iterations of the search).

2.3 Preliminary Experimental Analysis

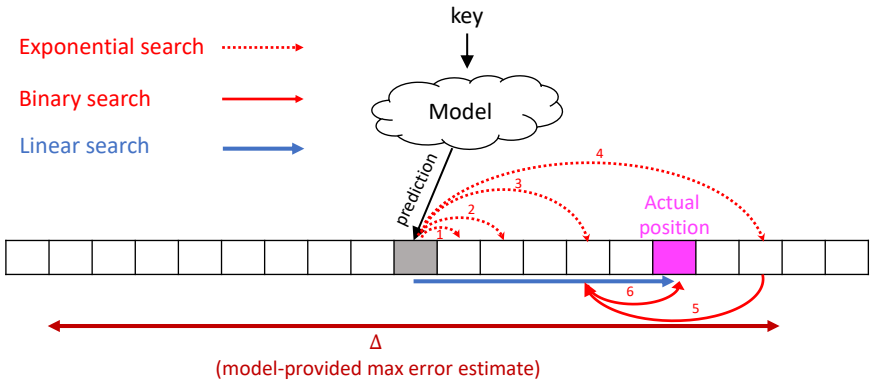
For a tangible discussion and to elaborate on the real cost of a learned model, we provide a micro-benchmark that measures the cost of errors in a learned index. We use the experimental configuration used in the SOSD benchmark [22], i.e., searching over 200M records with 32-bit keys and 64-bit payloads. Figure 2a shows the lookup time of the second phase (local search) in a learned model for different prediction errors. We include the lookup times for binary search, as well as FAST [21], over the whole array of 200M keys.

We are interested to see that if the position predicted by a learned index, say $\texttt{predicted\_pos}(x)$, has an error Δ, then how long does it take in the local phase to find the correct record. Thus, for each query x_i, we pre-compute the 'output' of the learned index with error Δ, i.e., $[\texttt{predicted\_pos}(x_i) \pm \Delta]$, and then run the benchmark given $\{x_i, [\texttt{predicted\_pos}(x_i) \pm \Delta]\}$ tuples.

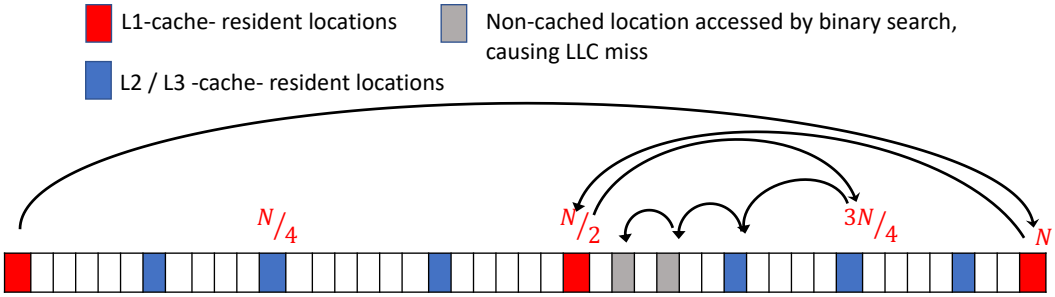
As shown in Figure 2a, if the error of the model is more than ~300 records on average, then FAST outperforms the learned model (with linear or exponential local search). Even if the learned model can give a guaranteed range around the predicted point to guide the local search and enable binary search, FAST outperforms it if the error exceeds 1000 records. The same trend can be seen for the LLC miss rates in Figure 2b.

Note that this micro-benchmark over-estimates the maximum error that the learned index can have because we only compare the time of *local search phase* in a learned index with the *total search time* of FAST and binary search. Considering the time taken to execute the model for predicting the location, a learned model needs to have a much lower error to compete with the generic, reliable, and distribution-independent algorithms such as binary search and FAST. For example, FAST takes 200 nanoseconds to search a key in the entire 200M-key dataset. If a learned index takes, say, 120 nanoseconds to run (for accessing model parameters and computing the prediction), then the local search can take at most 80 nanoseconds so that the learned index can outperform FAST, which means that the prediction error (Δ) must be less than 16 records (based on Figure 2a).

Tuning the learned index for a balance of model size and accuracy is a challenging task. Improving the local search time requires using a more accurate model with a higher learning capacity and more parameters. However, accessing such a big model typically incurs further cache misses during model execution, and consequently the lookup time. Therefore, if the data distribution cannot be learned efficiently with a small memory footprint (fitting into cache), outperforming cache-efficient algorithmic indexes is very challenging. This is indeed the case for most real-world datasets that cannot be modelled accurately with a small-sized model.



(a) Different "last-mile" search methods (performed after location prediction) in learned index. The locations predicted by the model depend on the query and are not known in advance. Since the last-mile search algorithms need to access different memory locations for each query, they cannot exploit the processor cache and the search algorithm incurs multiple cache misses



(b) Schematic illustration of processor caching in binary search. The locations accessed by the very early stage of binary search, such as the min, max, and the midpoint, are frequently accessed and available in the L1 cache. Further steps of binary access locations that are less frequently accessed and fit on lower levels of the memory hierarchy. Therefore, a deterministic search algorithm like binary search enjoys a high cache hit rate

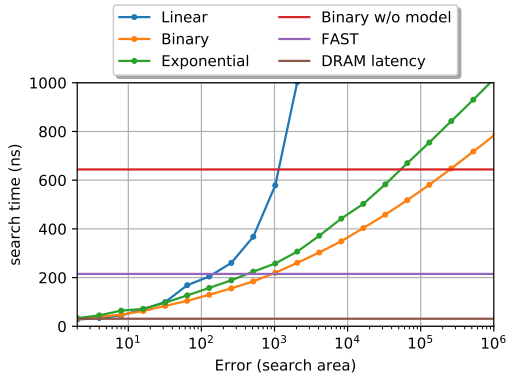
Figure 1: Comparison of patterns in binary search (partially cached) and local search in learned indices (non-cached).

2.4 Difficulty of Learning Real-world Data

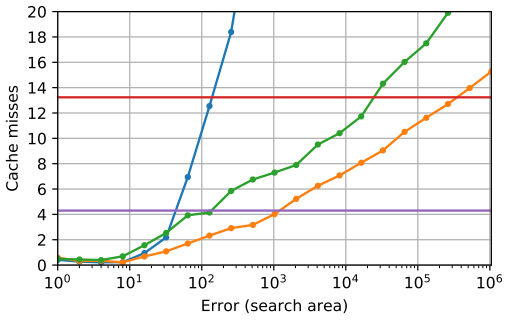
To use a learned index in a production system, it is essential to identify when learned indexes fail to achieve superior performance and what aspects of the data distribution contributes to the performance of a learned index model. We realized that a major challenge in understanding learned indexes is that the common practices of performance evaluation for indexing algorithms are misleading for learned indexes. For example, it is common to use the uniform and skewed distributions (such as log-normal) as arguably the two best- and worst-case extremes for a search task [25]. However, for evaluating search over sorted read-only data, the difficulty of the task is determined by the *unpredictability* of the data, which is not necessarily a factor of skewness or shape parameter of the data distribution. As we will show in this section, most statistical distributions are much easier to model than real-world data.

Distributions that matter. An interesting observation from the SOSD benchmark results is that even for datasets that have the same background distribution, e.g., both closely match a uniform distribution, the performance of a learned model can vary significantly, depending on the fine-grained details in the empirical CDFs. For example, consider Figures 3a and 3b, which represent two CDFs that are both close to uniform. The uniform data (`uden64` [22]) is comprised of dense integers that are synthetically sampled from a uniform distribution, and Facebook (`face64` [22]) is a Facebook user ID dataset. While both datasets match closely with the uniform distribution, face64 is significantly harder to model due to its fine-grained details in the CDF. The lookup time of learned indexes (both RMI and Radix-Splines) for face64 is 6-7× higher than that of uden64 (see Table 2) because there are many micro-level details (unpredictability) in the CDF, hence a huge model with a high learning capacity is needed to fit the CDF accurately. Using the RMI learned index, for example, the uden64 data is easily modelled with a simple line (two parameters) with near-zero error, while the best architecture found by the SOSD benchmark for modelling the face64 data is a hierarchy of two linear models, a huge model (136MB), with an average error of 202 records.

Generally speaking, real-world datasets are more difficult to learn compared to synthetic ones and the learned index built over them is not significantly faster than the algorithmic rivals. The main question remains what distinguishes a real-world data from a synthetic one? Consider the four distributions in Figure 3, where Figures 3a, 3c are synthetic (generated from uniform and log-normal distributions), and Figures 3b, 3d are real-world data. The mini-chart inside each CDF highlights the distribution in a small sub-range, i.e., a "zoomed-in" view of the CDF. For the synthetic data, the CDF is very smooth in any short sub-range of the whole CDF. Synthetic data (such as uniform, normal and log-normal) are built using a cumulative density function that is derivable, meaning that the at any small sub-range, the shape of the CDF is close to a straight line with a slope that is close to the derivation of the underlying CDF in that range. Such a



(a) Lookup time



(b) Cache misses

Figure 2: Cost of local search in a learned index

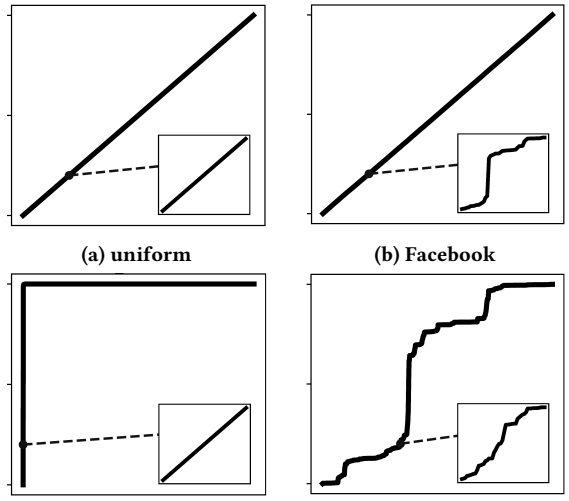
smooth CDF has less information to be compressed into a model. For example, a learned index model based on linear splines can accurately fit the whole CDF by fitting each part of the CDF to a line. Even for very skewed distributions, such as log-normal, the data is so predictable that it can be easily fitted to simple, linear models.

Real-world data, however, is much less predictable and has a much higher level of complexity in its patterns. Even if an ideal learning algorithm is used to model the real-world data, the model itself needs to be very big because the compressed version of the CDF (to be stored as a model) is still very big.

This explains why state-of-the-art learned indexes perform extremely well for datasets that are synthetically generated from a statistical distribution (such as uniform, normal, and log-normal), but perform comparably poor for real-world data that even almost match (shapewise) with those synthetic distributions [22]. On real-world datasets, learned indexes have a high cache miss rate and lookup time, contrary to their primary goal of having fewer cache misses.

Using learned models is beneficial when they are 1) accurate enough to predict a position within the same cache line that contains the data point, otherwise the lookup time will be adversely affected due to multiple cache misses, and 2) compact enough to fit in cache and not to cause LLC misses. With this in mind, we can argue that a pure machine-learning approach might fail to "learn the data perfectly" and "fit the model in cache" simultaneously, specifically in case of real-world datasets that contain a lot of underlying patterns like spikes and generally noise.

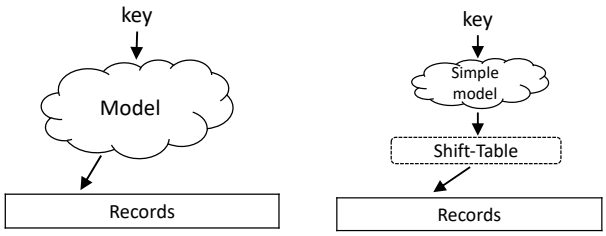
As a consequence, learned models are crucial to indexing but they cannot shoulder the burden of indexing the data alone. We hence suggest an algorithmic layer that can mitigate the difficulty



(a) uniform (b) Facebook

(c) Lognormal (d) OSMC

Figure 3: Example distributions with different complexities in micro and macro levels



(a) Learned index (b) Model + Shift-Table

Figure 4: Leveraging correction layers to a learned index

of learning the data distribution. In this approach, the learned model is allowed to learn an semi-accurate, small model that learns the holistic shape of the distribution, and the fine-tuned modelling is provided by the algorithmic layers.

2.5 Model Correction

While learned index models are powerful tools for describing a data distribution in a compact representation, merely focusing on learning a highly-accurate model does not necessarily lead to a high-performance index. In this paper, we suggest a new approach for boosting existing learned models with additional layers, specifically developed with hardware costs in mind.

The suggested helping layers add a small overhead when executing queries, but significantly reduce the overall lookup time of the learned index. The suggested layers are very powerful and consequently allow for using more lightweight models, yet ideally avoid computationally-expensive algorithms for training.

As Figure 4 illustrates, in addition to the learned index model we add a correction layer, an optional component, that can be added to improve the performance. We explore the potential of correction layers in the next sections.

3 SHIFT-TABLE

A learned model predicts a relative position $F_\theta(x)$ for a given query x. To calculate the position of the result, the estimated

relative position is multiplied by the number of keys, and truncated to an integer (the index), hence the predicted position is $[NF_\theta(x)]$. The actual position of the record, however, is $NF(x)$ where $F(x)$ is the empirical CDF of the data points, and N is the data size. Therefore, the result is $NF(x) - [NF_\theta(x)]$ records ahead of the predicted position. We identify $NF(x) - [NF_\theta(x)]$ as the *drift* of F_θ at key x, which is the signed error of the prediction, as opposed to the absolute error.

The idea of the Shift-Table layer is to have a lookup table that contains the drift values so that the drift of the prediction can be corrected. Capturing the drift for every value of x requires an auxiliary index, which is not feasible. However, we can use the *output* of the learned index model ($[NF_\theta(x)]$), which is in the range of $[0, N]$, and we construct a mapping from each possible output of the model, say k, to "how far ahead is the actual record if model predicts k's record", so that we can correct the predictions using this mapping. This means that for each prediction, we only need an extra lookup of k in a fixed array of size N.

To build the Shift-Table layer, we first partition the keys $x_0, \cdots, x_{N-1}$ into N partitions. We define P_k as the set of keys for which the model predicts k as the position:

$$P_k = \{x \mid [NF_\theta(x)] = k\} \quad (1)$$

Each of the indexed keys in P_k has an index, say $NF(x)$ and a prediction $k = [NF_\theta(x)]$. For each partition, we extract two parameters that specify the range for local search, namely Δ_k and C_k. Δ_k is defined as:

$$\Delta_k = \min\left(NF(x) - k\right) \quad \forall x \in P_k \quad (2)$$

which indicates that if the predicted location is k, the search should be started at point $k+\Delta_k$. Also, $C_k = |P_k|$ is the cardinality of P_k, i.e., the number of indexed keys for which the prediction predicts the k'th record, in other words, the length of the area that has to be searched in the local search phase.

To correct the prediction, we first compute the predicted position $k = [NF_\theta(x)]$, and then perform local search in the range of $[k + \Delta_k, k + \Delta_k + C_K - 1]$.

The number of partitions depends on the range of the output of the learned index, which should be $0, N)$. Therefore, The $<\Delta_k, C_k>$ pairs: pairs are stored in a single array of size N, so that the correction can be done using a single lookup into the array of pairs.

A Shift-Table layer is depicted in Figure 5. The index contains 100 elements in range [0,999]. The CDF model is a simple model: $F_\theta(x) = x/1000$, hence the prediction is simply $k = [x/10]$. If the query is 771, for example, the prediction of the model is $k = 77$. The correction information are $\Delta_{77} = -41$ and $C_{77} = 2$, which indicates that the result is -41 records ahead of the prediction, and the search area is of length 2. Therefore, the local search is performed on the indexes of range $[36, 37]$.

Algorithm 1 shows how Shift-Table is used to accelerate query processing. The Shift-Table layer reduces the prediction error of the model, but incurs an additional memory lookup.

Algorithm 1 Search with direct-mapped learned index

```
1:  procedure FIND_LOWER(q, model, Shift-Table)
2:      pos = model.predict(q)
3:      pos = Shift_Table.mapping[pos].startPoint
4:      range = Shift_Table.mapping[pos].range
5:      if range < linear_to_binary_threshold then
6:          pos = LinearSearch(start=data[pos],range)
7:      else
8:          pos = BinarySearch(start=data[pos],range)
9:      end if
10:     return pos
11: end procedure
```

3.1 Querying non-indexed keys

If the query is on the indexed keys, the result is in range $[k + \Delta_k\ ,\ k + \Delta_k + C_K - 1]$. In Figure 5, for example, querying 771 and 782 points to the correct range that contains the result. However, if the query is not among the indexed keys, then the query is either within the range, or in the position just after the range (at data$[k+\Delta_k+C_K]$. For example, in Figure 5, the record corresponding to queries 778 and 781 is the same, though the aforementioned model ($k = [q/10]$), maps 778 to range $[36, 37]$, and 781 to $[38, 39]$. In both cases, however, the local search algorithm (either binary or linear search) within the range computes the correct position of the result (i.e., 38). Notably for $q = 778$, a typical local search implementation realizes that the query is greater than the largest value in range and returns the first index right after the range of $[36, 37]$, which is 38.

Another issue that can arise for non-indexed keys is when the predicted position P_k has an empty partition that none of the indexed keys belongs to. In Figure 5, if the query is 15, then the predicted position is $k = [15/10] = 1$, but P_1 is empty because the model does not predict position 1 for any of the indexed keys. If the query is predicted to be in an empty partition, the result is the first record in the next non-empty partition, e.g., the result of query=15 is record 3. To make the Shift-Table layer consistent for the empty partitions, we put pseudo values for Δ, C in the mapping layer such that they refer to the same range as the next existing partition. If $P_{k^\varnothing}$ is an empty partition and P_k is the first non-empty partition after $P_{k^\varnothing}$, then $C_{k^\varnothing} = C_k$ and $\Delta_{k^\varnothing} = \Delta_k + (k - k^\varnothing)$. The pseudo Δ, C-values are depicted using dashed arrows in Figure 5.

3.2 CDF and duplicate values

It should be noted that the *empirical CDF* function, i.e., $F(X) = P(X \leq x)$ does not exactly identify the result of a range query on x. In this paper, we use the CDF (F(x)) notation as the index of the result corresponding to x. We consider range queries of type (`key <= query`), hence the CDF for a point x is the relative position of the *first* key in the indexed keys, as the range is scanned towards the right. More precisely, we assume that $NF(x_0) = 0$ and $NF(x_{N-1}) = N - 1$ (for the last key).

A range learned index built for a specific comparison operator, say $x \leq q$, can be used for other operators ($\geq, >,$, etc.) with a brief left/right scan. However, if there are too many duplicates in the indexed data, then the the performance of the learned index will be worse for queries that do not match the presumed definition of F(X). In such cases, it is more efficient to use the specific definition of $F(x)$ that reflects the position of the result of the query in the most common type of constraint in the queries. For example, if most of the queries are of type $x >= q$, then $F(x)$ should be defined such that $NF(x)$ identifies the index of the last key among the duplicate values.

3.3 Building the Shift-Table layer

Algorithm 2 describes how the mapping of the Shift-Table layer is built. In the first stage, it computes the Δ, C values and updates for the non-empty partitions, i.e., P_ks for which at least one of

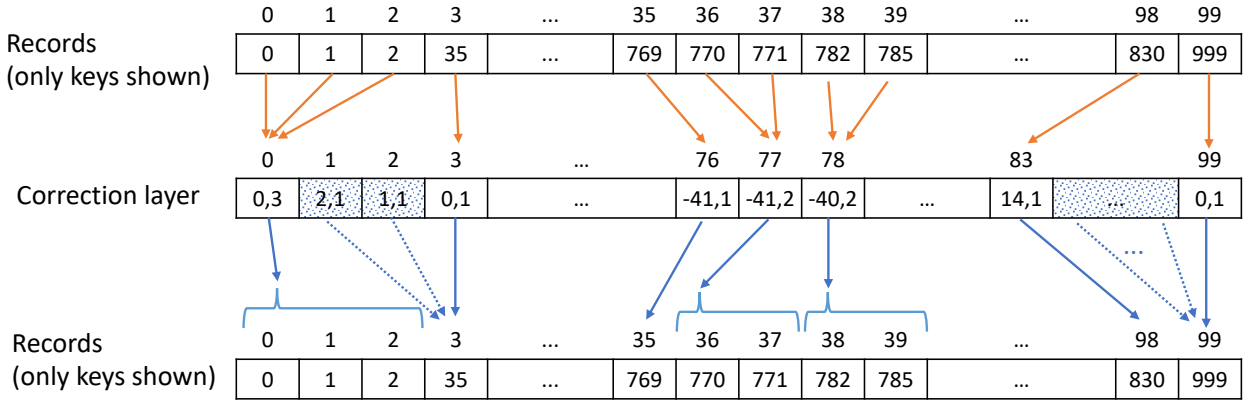


Figure 5: Shift-Table

the indexed keys is mapped to k. In the second stage, a backward traversal is performed on the Shift-Table layer and the compute the pseudo-values for the empty partitions (Algorithm 2, lines 10–14). Starting from the last entry, a pseudo-partition has the same count (C) as the first non-empty partition on its right side, but the shift Δ is adjusted so that they both point the the same region for local search.

The computational complexity of building the Shift-Table layer is $O(N) \times O(F_\theta)$ to compute the drifts and updating the mapping, as it only traverses the data and the Shift-Table layer once. In case that running the model is expensive, model executions can be parallelized for faster execution.

Algorithm 2 Building the Shift-Table layer

```
1:  procedure SHIFT-TABLE_BUILD(model (F_θ), data)
2:      Shift-Table = Array of tuples <Δ, C>, all set to zero
3:      for all x ∈ data do
4:          pos = NF(x)                          ▷ Position of x (sec 3.2)
5:          k = [NF_θ(data[i])]
6:          Δ = pos − k
7:          Shift_Table[k].Δ = min(Shift_Table[k].Δ, Δ)
8:          Shift-Table[k].C += 1
9:      end for
10:     for k ← N − 1 ··· 0 do
11:         if Shift_Table[k].C = 0 then          ▷ Empty partitions
12:             Shift_Table[k].C = Shift_Table[k-1].C
13:             Shift_Table[k].Δ = Shift_Table[k-1].Δ + 1
14:         end if
15:     end for
16:     return Shift_Table
17: end procedure
```

3.4 Compressing the Shift-Table layer

Correcting the prediction of the model using the Shift-Table layer takes a single DRAM lookup irrespective of the size of the index. However, it might be of interest to reduce the size of the layer. The Shift-Table layer is an array of size N, containing <Δ, C> tuples. Further compression can be used to decrease the memory footprint of the Shift-Table layer.

One approach is to keep a single parameter instead of the <Δ, C> tuples. In this regard, a predicted position k should be mapped to the key that is in the median point among the keys in P_k, which is

$$\bar{\Delta}_k = \left[\Delta_k + \frac{C_k}{2}\right] \tag{3}$$

To correct using the $\bar{\Delta}_k$ values, the final position is computed as $pos = k + \bar{\Delta}_k$, which indicates where the search should be started without specifying the guaranteed range that should be searched. Therefore, search algorithms that require the boundaries specified such as binary search cannot be used for local search. As discussed in section 2.4, linear or exponential search can be used for local search without boundaries, but they are slightly slower if the error is considerable after the correction.

A second approach that complements the first one, is to shrink the size of the Shift-Table layer by merging nearby partitions. We can extend the definition of $\mathcal{P} = \{P_1, \cdots, P_N\}$ to allow partitions that have a size of $M < N$. We define M partitions $\mathcal{P}^M = \{P_1^M, \cdots, P_M^M\}$ where each partition is defined as:

$$P_k^M = \{x \mid [MF_\theta(x)] = k\} \tag{4}$$

Similarly, Δ_k^M is the minimum "move to the right" shifts that each of the keys in P_K^M need:

$$\Delta_k^M = \min\left(NF(x) - [NF_\theta(x)]\right) \quad \forall x \in P_k^M \tag{5}$$

and C_k should be defined such that the boundary is valid for all keys in P_K^M, which is:

$$C_k^M = \max(NF(x) - \underbrace{([NF_\theta(x)] + \Delta_k^M)}_{\text{start of the search window}}) \quad \forall x \in P_k^M \tag{6}$$

To combine approaches to compact the Shift-Table layer, we can use average drifts $\bar{\Delta}_k^M$ instead of the <Δ_k^M, C_k^M> pairs:

$$\bar{\Delta}_k^M = \left[\frac{1}{|P_k^M|} \sum_{x \in P_k^M} (NF(x) - [NF_\theta(x)])\right] \tag{7}$$

and then use $[NF_\theta(x)] + \bar{\Delta}^M_{[MF_\theta(x)]}$ as the corrected prediction. Suppose the same data as in Figure 5, but instead of a Shift-Table layer of size N, we use only M=30 partitions. Table 1 shows how a compact Shift-Table layer is built and used for correction, on a portion of the index. We use the same model ($F_\theta = [x/1000]$), hence the prediction is $NF_\theta(x) = [0.1x]$, and the partition corresponding to a key is $NF_\theta(x) = [0.03x]$. All of the records from data[35..39] are assigned to the same partition P_{23}^{30} and their predictions are shifted 40 records backwards. Note that when

$M \neq N$, a partition does not specify a single point (or range) for all of the keys in the partition. Instead, the position of a key after correction depends on both $NF_\theta(x)$ (prediction) and $MF_\theta(x)$ (partition number). For example, all keys belonging to P_{23}^{30}, i.e., data$[35 \cdots 39]$ have the same correction of $\bar{\Delta}_{23}^{30} = -40$, but their final predictions are different. Therefore, the correction error of a compact Shift-Table layer is less than the number of elements in the partitions.

Table 1: Illustration of Shift-Table with $M = 30$ mapping entries on an index with $N = 100$ keys

Index	34	35	36	37	38	39	40	41
key (x)	752	769	770	771	782	785	820	830
Predicted index= [0.1 x]	75	76	77	77	78	78	82	83
Error before correction	-41	-41	-41	-40	-40	-39	-42	-42
Partition (k) = [0.03 x]	22	23					24	
$\bar{\Delta}_k^{30}$	-41	-40					-42	
Prediction after correction	34	36	37	37	38	38	40	41
Error after correction	0	1	1	0	0	-1	0	0

The drift of P_k^M, namely $\bar{\Delta}_k^M$ is the index of the median key among the members of P_k^M. This means that if the key is predicted to be in the k'th partition (among the M partitions), the local search is done around $[NF_\theta(x)] + \bar{\Delta}_k^M$.

Using a Shift-Table layer of size $K < N$ does not affect the complexity of building the layer, which is $O(N) \times O(F_\theta) + O(M)$. However, if the midpoint-values are used (correction without specifying the boundary), it is possible to construct the map using a sample of the indexed keys, which comes at the cost of the accuracy. Using a sample of size $S < N$, the layer can be built in $O(S) \times O(F_\theta) + O(K)$ time.

Nonetheless, keep in mind that the Shift-Table layer is designed for applications that favour latency to memory footprint, hence reducing the memory footprint of the Shift-Table layer by a large factor will limit its margin for improvement as the fine-grained details of the empirical CDF will be lost to some extent.

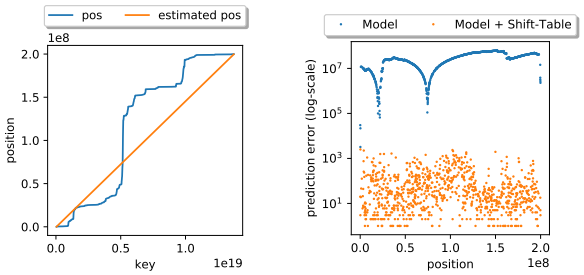
3.5 Measuring the error

Since the Shift-Table layer specifies a range for local search, the notion of error is not trivial. However, we can use the estimates without range ($\bar{\Delta}$), for which the correction picks the median value among the keys in the P_k. The error for the keys in each partition is $\left\{[\frac{C_k}{2}], \cdots, 0, \cdots, [\frac{C_k}{2}]\right\}$ if C_k is odd, and $\left\{[\frac{C_k}{2}] - 1, \cdots, 0, \cdots, [\frac{C_k}{2}]\right\}$ if C_k is even. The average error is approximately $C_k/4$.

In a learned index without Shift-Table, the error is the distance between $F(x)$ and $F_\theta(x)$. After correcting the model with the Shift-Table, however, the error only depends on the C_k values, i.e., a prediction error only occurs when $[F_\theta(x)]$ predicts the same position for multiple keys. Therefore, the local search range and the error are combinations of multiple step functions over the P_ks with $C_k > 1$.

The average error depends on the data distribution in the query workload. If the queries are uniformly sampled from the keys, then the average error is:

$$\bar{e} = \frac{1}{2N} \sum_{k \in \mathcal{P}} C_k^2 \tag{8}$$



(a) Example data & model **(b) Error**

Figure 6: Error correction using the Shift-Table layer

3.6 Behaviour of the Shift-Table layer

Figure 6 illustrates how the Shift-Table layer corrects the error of a linear interpolation model on the OSMC data. While the model is too simple to capture the patterns in data, the Shift-Table layer alone is effective for correcting the predictions. While the average error of the model is 28 million keys, Shift-Table reduces the error to only 129 keys.

Shift-Table corrects two types of error. First, when the model has a considerable local bias, which means that $NF(x)$ diverges significantly from $NF_\theta(x)$ in a sub-range of the data distribution. The second type of error is the fluctuations of the distribution between the nearby keys, for most of which the Shift-Table layer is very effective. The only type of error that can degrade the performance of the Shift-Table layer is when there is a congestion of keys in a small sub-range of values, leading to many of the keys being classified in a single layer, and hence having some partitions with high C_k.

The behavior of the Shift-Table layer and its error estimate indicates that it can be effective in eliminating different types of errors that models have. One common type of error is the local bias in the model, i.e., when the error of the model, i.e., $NF_\theta(x) - NF(x)$ has a considerable *bias* in some sub-ranges of the distribution, meaning that the F and F_θ diverge at some point. This happens when the model cannot capture the CDF in a local neighborhood. Table 2 shows that even if a single line is used as a model, which has a huge bias in most areas of the distribution, the Shift-Table layer can efficiently eliminate the huge bias of a fully linear model (a single line as a model), and reduces the error significantly such that the linear model outperforms all other algorithms for the real-world datasets, as well as the uspr dataset (sparse uniformly-distributed integers) which has a significantly higher variance than uniformly-distributed dense integers.

Another type of error that the Shift-Table layer eliminates is the local variance in the data, which is the fluctuations of the values between nearby keys. This type of error is very common in real-world data. For example, the *face, uspr, and uden* datasets all follow a uniform distribution, but they have different local variances, which is the amount of fluctuations in the nearby keys. The uden dataset is very easy to model using the learned indexes and does not require a helping layer such as Shift-Table. The other two datasets, however, are very hard to model using the learned index structures. This is because the Shift-Table model can easily correct the fluctuations of values (different increments between each two points), as long as the model does not predict a single record for a lot of nearby keys (resulting in a high C_k value).

3.7 Cost model of the Shift-Table layer

The accuracy of the model after correction with Shift-Table depends on the cardinalities of the partitions (C_i values). Ideally, if the records of each partition reside on a single cache line, the results will be retrieved in a single memory lookup. The cost of local search, i.e., the mapping between the accuracy in each partition and the latency to do local search depends on the hardware. As discussed in section 2.1, the latency of search for various ranges can be measured by a micro-benchmark over non-cached regions with different sizes. Let $L(s)$ be the measured latency of non-cached search over a range containing s records. The latency for looking up a key in a region of size s is $L(C_k)$. Assuming that the queries have the same distribution as the data points, the average lookup latency for the index is:

$$\text{Latency with Shift-Table} = \text{Latency}(F_\theta) + \frac{1}{N}\sum_{k\in\mathcal{P}} C_k L(C_k) \quad (9)$$

The cost model can also be used to estimate which of the local search algorithms should be used, by substituting in equation 9 the local search cost of each local search algorithm, i.e., $L(s)$ mappings for linear, binary, and exponential search; and for and their different implementations. Branch-optimized binary search would be the natural choice if the Shift-Table model can determine the boundary (if using the Δ_k, C_k pairs), otherwise either linear or exponential search should be chosen based on the latency estimate.

Taking the cost of running the Shift-Table layer into account, we should consider how much the correction improves the accuracy of the learned index model and hence estimate the speedup. The lookup time of the model without using the Shift-Table model can be estimated once the Shift-Table model is built, without running a speedup benchmark. The model error for each key is $\bar{\Delta}_k = \Delta_k + \frac{C_k}{2}$, therefore the estimated runtime of the index without correction is:

$$\text{Latency without Shift-Table} = \text{Latency}(F_\theta) + \frac{1}{N}\sum_{k\in\mathcal{P}} C_k L(\bar{\Delta}_k) \quad (10)$$

3.8 CDF model validity constraint

The correction layer requires the learned model to be a valid CDF function, i.e., $F_\theta(x)$ should be monotonically increasing: $x_i > x_j \longrightarrow F_\theta(x_i) >= F_\theta(x_j)$. Among our baselines, the RadixSplines learned index always produces a valid (increasing) CDF, but the RMI index does not always produce monotonically increasing predictions. In RMI, for example, the CDF model might decrease when using cubic models [30] or on the edge point between two models in the second-level. If $F_\theta(x)$ is not monotonically increasing, then the correction layer could identify a range that does not include the query result, because the values of x for which the learned model predicts k'th record are not in a contagious memory block.

A learned index model that is non-monotonic can still use the Shift-Table layer, as the output of the Shift-Table layer would still predict a position but it is not guaranteed that the position is in the predicted range. Therefore, the local search algorithm should check if the query is in the predicted range and perform a search outside of the range. Another hack for non-monotonic model is to use the $\bar{\Delta}$ midpoint-values instead of the Δ_k, C_k pairs, which predicts a location (instead of a range) to start the local search.

If the Shift-Table layer uses the $<\Delta_k^M, C_k^M>$ pairs, it can determine the range for local search and we can apply either linear or binary search, depending on the error range. We do linear search if the range is smaller than a threshold (8 keys, in our experiments), otherwise a binary search is performed. However, if it only contains the average shift values ($\bar{\Delta}_k$, it predicts a position without specifying the boundaries that contain the record; hence either linear or exponential search can be performed depending on the *average* error rate and performance objectives (average or worst-case latency).

3.9 Tuning the system

The Shift-Table layer is optional and adds overhead to the search. Therefore, enabling Shift-Table is only worthwhile if it can eventually accelerate the original learned index structure. An effective configuration of the index is a choice between 1) Using the model alone, 2) model + Shift-Table. Note that the Shift-Table layer is optional and can be deactivated with zero cost. The output of the model and the Shift-Table layer are of the same type and both represent a prediction of the records, hence if the Shift-Table layer is disabled, we can easily use the model alone for prediction of the records.

While tuning the system, the performance of each configuration can be directly measured using performance tests, or by measuring the model error and then using the cost model of the Shift-Table model on the bottom of the architecture (section 3.7).

The parameters of the architecture, i.e., the Shift-Table array size M and the parameters of the learned CDF model, can be tuned by computing the error estimate using Shift-Table's cost model, or alternatively, by running a performance tests on the built architecture. Our suggested default value for the Shift-Table layer is $M = N$, because using a mapping layer that has the same number of entries as the keys will ensures that the layer can exhibit its ultimate effect to eliminate the signed error, and does not have more latency compared to using smaller M values.

An advantage of Shift-Table is that the learned model does not need to be very accurate, as a correction will be applied anyway. Therefore, a more relaxed measure can be used instead of least-square error. In this paper, however, we do not learn the model w.r.t. the Shift-Table layer, for the sake of simplicity and to keep the Shift-Table layer detacheable (optional), preserving the assumption that the Shift-Table layer can be disabled to free up memory space on run-time while the model can still be used.

The accuracy of the learned model also determines the size of the entries of the Shift-Table layer. Each mapping entry should at most fit a Δ value of Δ_{MAX}, which is the maximum error of the model. If, for example, the error is smaller than $2^16/2$, then a 16-bit integer (`short` type) can be used.

4 EVALUATION

In this section, we compare the performance of our proposed method with the SOSD benchmark [1], which is a recent benchmark for search on sorted data. The benchmark includes learned indexes, classical indexes, and no-index search algorithms.

Experimental Setup. The algorithms are implemented in C++ and compiled with GCC 9.1. The experiments are performed on a system with 16 GB of memory and Intel Core i7-6700 (Skylake), which has four cores and is running at 3.4 GHz with 32 KB L1, 256 KB L2, and 8 MB L3 caches. The operating system is Ubuntu 18.04 with kernel version 4.15.0-65. In our setup, the LLC miss

[1] https://github.com/learnedsystems/SOSD/tree/mlforsys19

penalty measured by Intel Memory Latency Checker [2] is 36 ns, which is the minimum lookup time of an ideal index.

Note that all data resides in main memory. The range index finds the first indexed key that is equal to or bigger than the lookup key. Also, the keys on the physical layout are sorted (i.e., it is a clustered index), so that the entire result set of the range query can be returned once the first key is found. Similar to [22, 25], we only report the lookup time for the first result and do not include the scan times in our experiments because all indexes use the same layout for the data records.

Datasets. For the sake of reproducibility, we used the same datasets as in the SOSD benchmark, which contains four datasets synthetically generated from known distributions and four real-world ones. The synthetic data are generated from different distributions, namely *logn*: lognormal distribution $(0, 2)$, *norm*: normal distribution, *uden*: uniformly-generated dense integers, and *uspr*: uniformly-generated sparse integers. The real-world datasets are *face*: Facebook user IDs [42], *amzn*: book sale popularity from Amazon sales rank data [3], *osmc*: uniform sample of OpenStreetMap locations [4], and *wiki*: timestamps of edit actions on Wikipedia articles[5]. All datasets contain 200M unsigned integers.

Implementation details. Our experiments are based on the SOSD benchmark [22]. The baseline includes two learned indexes, namely RadixSpline [33] (RS), which uses linear splines; and Recursive Model Index (RMI), which uses a hierarchy of models. Note that RMI has a choice of different models and SOSD [22] specifically handpicked the best models for each of the datasets in the benchmark [6]. SOSD also includes no-index search algorithms such as binary search (BS), linear interpolation search (IS), and the recently suggested non-linear triple-point interpolation (TIP) [42]. We also compare against algorithmic index structures such as ART: Adaptive Radix Tree [26], FAST [21], RBS (Radix Binary Search): a two-stage algorithm in which a radix structure that maps a fixed-length key prefix to the range of all keys having that prefix and then a binary search is performed on the range [22], and STX implementation of B+tree [1]. Finally, we included four *On-the-fly* search algorithms, namely BS: Binary search (STL implementation), TIP: three-point interpolation [42], Interpolation search, which is similar to binary search but uses interpolated positions in each iteration, and IM: *Interpolation as a Model*: a dummy model that interpolates the key between the minimum and maximum value of the keys and then performs exponential search around the predicted key.

The experiments use either 32- or 64-bit unsigned integer IDs for the key (depending on the dataset), and 64-bytes for the payload.

4.1 The SOSD benchmark

To test the effectiveness of the suggested layers compared to learned indexes, we use a simple interpolation model (IM), i.e., $F_\theta(x) = (x - minVal)/(maxVal - minVal)$. Such a dummy model is deliberately chosen to purely delegate the burden of data modelling to the correction layers.

The Shift-Table layer has the same number of entries as the actual data, i.e., $M = N$. We followed the tuning procedure discussed in section 3.9: we start from the model (IM and RS) and consequently evaluate IM+Shift-Table and RS+Shift-Table. The cost of running the Shift-Table layer is around 40ns, which pays off by reducing the prediction error and thus lookup time. Therefore, based on the cost model of the Shift-Table layer (Section 3.7) and the error-to-latency micro-benchmark (Figure 2a), we should not add the Shift-Table layer if the error before adding the configuration is less than a threshold (10 records), or 2) the error of the index after adding the Shift-Table layer does not decrease by a factor of 10 (roughly equivalent to the 50-nanoseconds latency the additional layer, according to the error-to-latency micro-benchmark).

Table 2 compares the lookup times (nanoseconds per lookup) of the baseline algorithms with our dummy interpolation model (IM), and the two corrected versions, i.e., IM+Shift-Table and RS+Shift-Table. Note that ART does not support data with duplicate keys, and FAST does not support 64-bit keys. Also, interpolation search (IS) takes too much time on some datasets, because the execution time of interpolation search highly depends on the uniformity of data distribution, varying from O(loglogN) + O(1) iterations on uniform distributions, to O(N) iterations for very skew ones [42].

For the synthetic datasets, the difficulty of the datasets for our dummy linear interpolation model varies from very easy (uden64) to extremely hard (logn64). While the Shift-Table layer significantly improves a dummy layer on non-uniform data distributions, it cannot outperform the learned index models. This is not surprising, as all synthetic datasets (uniform, lognormal, and uniform) have a pattern derived from continuously differentiable density functions, hence the distribution is similar to a straight line on smaller sub-ranges as we "zoom in" the data distribution (e.g., see Figure 3c). Therefore, a learned index structure composed of linears at the bottom (including both RMI and RS) can effectively model the distribution using a very compact representation.

For the real-world data, however, the fluctuations in data severely affect both RMI and RS learned indexes. The Shift-Table layer, effectively corrects a highly inaccurate dummy IM model, such that it outperforms the RMI learned index by 1.5X to 2X on all datasets, while RS falls behind both. Keep in mind that RMI requires to be tuned with the best architecture and parameters, while Shift-Table does not require a manual training process and can even work with a simple model such as IM that is not trained, and yet deliver a lower latency.

Figure 7 shows the average build times of the indexes, along with the standard deviation bars indicating how the build time varies for different distributions. Please note that the RMI implementation used in the SOSD benchmark needs to be compiled for faster retrievals, however we did not include RMI's extra overhead for compiling the code and only reported the build time. IM+Shift-Table, the winner method latency-wise, also takes either the same or even less build time than the competing learned indexes.

4.2 Explaining the performance

The latencies reported in Table 2 present the fastest configuration for each learned index. In this section, we present the details of the tuning process to see the optimum performance of each learned index.

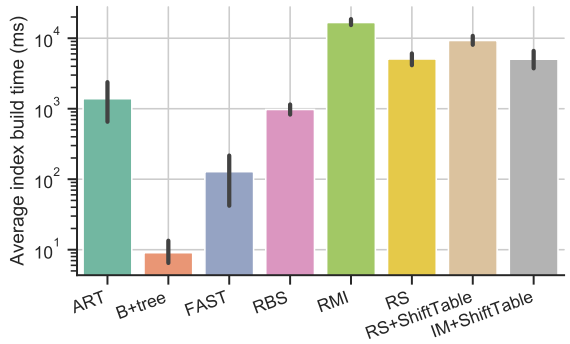

Figure 7: Build times (average time for all datasets)

For those indexes that have a parameter affecting the index size (such as the branching factor in B+tree, and the number of radix bits in ART, RS, and RBS), the performance can be tuned by evaluating the latency for different index sizes.

Figure 8 shows the latencies of the indexes for the face64 and osmc64 datasets, along with the average Log2 error, CPU instructions, and L1/LLC cache misses. IM+Shift-Table and RS+Shift-Table achieve faster lookup times on both datasets. For most indexes, except RMI and RBS, the latency does not improve beyond a certain optimum index size, after which the latency increases again. RBS has a much larger latency than both [IM/RS]-Shift-Table indexes of the same size, and extrapolating the RMI latencies also suggest that if we could extend RMI size to 1400MB (equal to Shift-Table's size), it could not achieve a game-changing performance on either of the datasets. Note that we could not run RMI with larger models because RMI embeds the parameters into the code, and the compile times for models larger than 400MB were astonishingly high.

Average Log2 errors indicate the average number of iterations in binary search for the last-mile search stage. Larger models result in lower Log2 errors in all indexes and lead to faster last-mile search, however, once the model exceeds the LLC cache sizes, cache-miss rate increases (when running the model), and hence the prediction time worsens. For RS, ART, and B+tree, the cache misses and extra overhead of running the models increases either the number of instruction, the cache misses, or both, enough to prevent the index from improving latency by increasing the footprint.

4.3 Layer size

As discussed in section 3.4, the Shift-Table layer can be compressed by merging multiple entries, hence reducing its footprint. Figure 9 shows the effect of the Shift-Table layer size on lookup time and prediction error. Shift-Table can operate in two modes: **R-1**: a full layer containing $<\Delta_k^M, C_k^M>$ pairs similar to Figure 5 that indicates the exact *range* for local search (hence enabling binary search); and **S-X**: a compressed single-entry map similar to Table 1 containing one $\bar{\Delta}_k^M$ entry per X records. Thus, S-X contains $M = N/X$ entries; and the memory footprint of S-1 is half the size of R-1.

The error of the S-1 Shift-Table is slightly more than that of R-1. This is due to the fact that S-1 is designed to draw boundaries for binary search; hence it always points to the first record of each partition; while R-1 always points to the middle of the partition and almost half the error of S-1. Performance-wise, however, S-1 always has the lowest latency, because its boundaries for the last-mile search operation do not need to be discovered using additional boundary-detection algorithms such as exponential search. As expected, compressing the Shift-Table by allocating one entry per X records increases the error and hence degrades

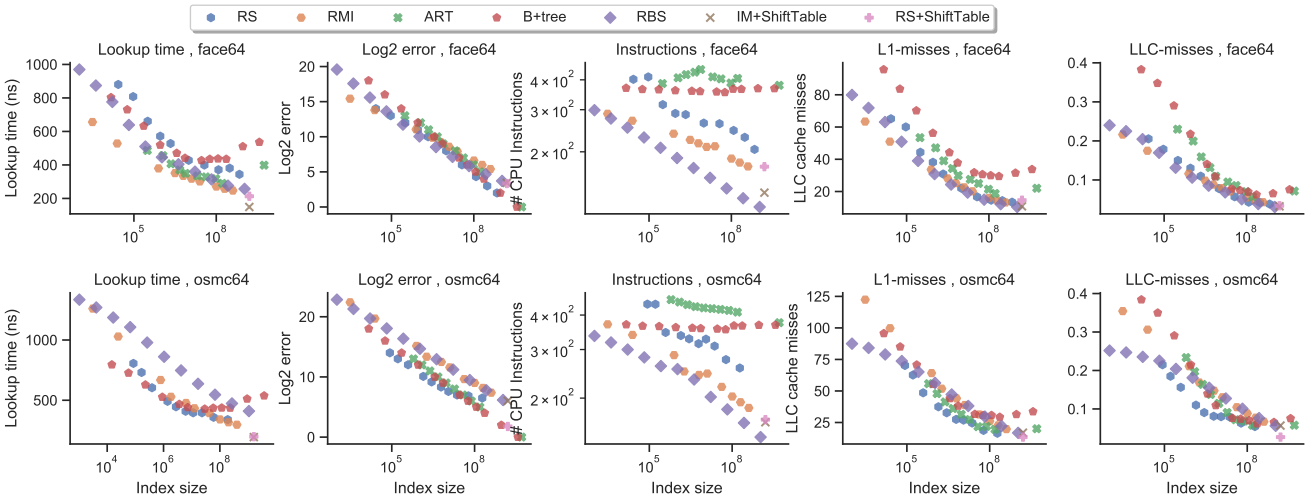

Figure 8: Analysis of the effect of index size on performance

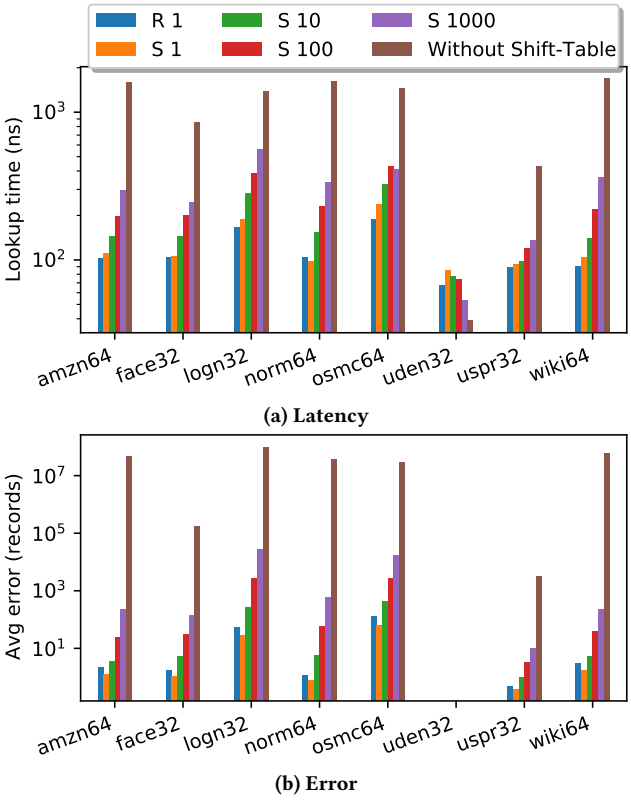

Figure 9: Analysis of the effect of Shift-Table layer size

the performance. This is due to the fact that with higher compression ratios, the ability of Shift-Table to "memorize" the fine-grained details of the data distribution degrades due to the loss of information after merging.

5 RELATED WORK

On-the-fly search on sorted data A fundamental problem that is studied for decades is how to find a key among a sorted list of items. The classic approach is binary search and numerous extensions have been suggested to improve it for special cases, most notably interpolation search [35] and exponential search [3]. For data distributions that are close to uniform, interpolation-search is shown to be very effective [13, 36, 42]. Due to the growing gap between CPU power and memory latency in the past decade, more advanced interpolation techniques such as three-point interpolation are becoming viable on modern hardware [42]. Exponential search enables binary search over an unbounded list. Exponential search is also extensively used in learned indexes when the key is more likely to be near a "guessed" location, but a guaranteed boundary around the guessed point that contains the data is not known [7, 25, 32].

Range indexes An alternative to on-the-fly binary search over sorted data is to keep the data in an index structure. Nonetheless, indexes that are built to answer range queries (such as B-trees) are similar to the binary search in that they need to keep the data sorted internally. Common index structures for range index include skiplists, B+trees, and radix-trees. The B+-tree is cache-efficient, but requires pointer chasing, which incurs multiple cache misses [14]. There has been a tremendous effort to make binary search trees and B+-trees efficient on modern hardware. For example, FAST [21] organizes tree elements efficiently to exploit modern hardware features such as the cache line and SIMD. Another common solution is to use compression techniques on the indexed keys, most notably as a radix-tree. Modern radix trees exploit hardware-efficient heuristics for fitting a distribution in memory (usually by building a heuristically-optimized compressed trie), such as adaptive radix index (ART) [5, 26], and Succinct Range Filter (SuRF) [44]. Skiplist is specifically efficient for concurrent updates workloads [41, 43].

Learned index structures Learned range indexes [7, 12, 25, 29, 33] have recently been suggested as an alternative to range indexes. In this approach, a model is trained from the data with the intent of capturing the data distribution and processing the queries more efficiently. We refer to the paper by Kraska et al. [25], which introduced the idea of the learned index. In a learned index, the CDF of the key distribution is learned by fitting a model, and the learned model is subsequently used as a replacement of the index (B+-trees or similar) for finding the location of the query results on the storage medium. Index learning frameworks such as the RMI model [25, 30] can learn arbitrary models [30], although a further theoretical study [9] as well as a recent experimental benchmark [22] have shown that simple

model like linear splines are very effective for datasets. Spline-based learned indexes include Piecewise Geometric Model index (PGM-index) [11], Fiting-tree [12], Model-Assisted B-tree (MAB-tree) [19], Radix-Spline [23], Interpolation-friendly B-tree (IF-Btree) [18] and some others [29, 40]. We refer to [10] for an extensive comparison of learned indexes. Recently, there has been numerous theoretical works [4, 27, 38, 39] on learned indexes. Also, numerous efforts have been made to handle practical challenges around using a learned index, including update-handling [7, 17] and designing a learned DBMS [24]. The idea of using a model of the data to boost an existing algorithmic index has been the center of focus in the past few years [14, 17, 19, 37]. In the multivariate area, learning from a sample workload has also shown interesting results [8, 20, 28, 32]. Aside from the main trend in learned indexes, which is on range indexing, machine learning has also inspired other indexing and retrieval tasks. This includes bloom filters [6, 31], multidimensional indexing on datasets with correlated attributes [15], and other applications [2, 16, 34].

6 CONCLUSION AND FUTURE WORK

Learning and modeling data distributions via machine learning approaches is a great idea for managing and analyzing data management systems. However, the approaches and objective functions that are common in machine learning problems are not necessarily optimal choices when the ultimate target is performance improvement. Instead of pushing machine learning model algorithm to its limits for highly accurate modeling of data distributions, it is more efficient if we only use ML models to approximate the high-level, generalizable "patterns" in data distribution (the holistic shape), and handle the fluctuations and fine-grained details of the distribution using a more hardware-efficient approach, outperforms learned models as well as algorithmic index structures even if a simple or somewhat dummy model such as min/max linear interpolation is used. The Shift-Table layer is effective in learning almost all distributions even without using models that require training from data, and takes only a single pass over the data points to build the layer. Our results show that even a simple linear model equipped with the Shift-Table enhancement layer outperforms trained and tuned learned indexes by 1.5X to 2X on real-world datasets.

Our current work only considers read-only workloads. We leave it as future work to adapt Shift-Table with workloads having updates. One idea is to capture the drifts in data distribution using update-tracking segments [17], and use Fenwick trees to estimate and correct the drifts in both the model and the Shift-Table.

ABSTRACT

Location data are widely used in mobile apps, ranging from location-based recommendations, to social media and navigation. A specific type of interaction is that of *location-based alerts*, where mobile users subscribe to a service provider (SP) in order to be notified when a certain event occurs nearby. Consider, for instance, the ongoing COVID-19 pandemic, where contact tracing has been singled out as an effective means to control the virus spread. Users wish to be notified if they came in proximity to an infected individual. However, serious privacy concerns arise if the users share their location history with the SP in plaintext.

To address privacy, recent work proposed several protocols that can securely implement location-based alerts. The users upload their encrypted locations to the SP, and the evaluation of location predicates is done directly on ciphertexts. When a certain individual is reported as infected, all matching ciphertexts are found (e.g., according to a predicate such as "10 feet proximity to any of the locations visited by the infected patient in the last week"), and the corresponding users notified. However, there are significant performance issues associated with existing protocols. The underlying searchable encryption primitives required to perform the matching on ciphertexts are expensive, and without a proper encoding of locations and search predicates, the performance can degrade a lot. In this paper, we propose a novel method for variable-length location encoding based on Huffman codes. By controlling the length required to represent encrypted locations and the corresponding matching predicates, we are able to significantly speed up performance. We provide a theoretical analysis of the gain achieved by using Huffman codes, and we show through extensive experiments that the improvement compared with fixed-length encoding methods is substantial.

1 INTRODUCTION

Location-based alerts are an emerging area of mobile apps that are very relevant to domains such as public safety, healthcare and transportation. For instance, users may want to subscribe to services that notify them whether an imminent danger exists in their close proximity (e.g., an active shooter situation). Or, in the recent context of COVID-19, mobile users wish to be notified if they came in close proximity to an individual who was diagnosed with the disease. While the advantages of location-based alerts are undeniable, they also introduce serious privacy concerns: in order to benefit from such services, users periodically upload their locations to a service provider (SP). The SP monitors large number of individuals, and evaluates spatial predicates to determine which individuals should be alerted. Disclosing individual locations can leak sensitive personal details to the SP, which may in turn share the data with third parties. And even in cases where the SP is fully trusted, it can be subject to cyber-attacks, or subpoenas by governments, resulting in the users' moving history being exposed.

Movement data can disclose sensitive details about an individual's health status, political orientation, alternative lifestyles, etc. Therefore, it is crucial to support location-based alerts while at the same time protecting user privacy. This problem has been recently studied in literature, and formulated in the context of *secure alert zones* [14, 21, 23], where users report their *encrypted* locations to the SP, and the SP evaluates alert predicates on encrypted data. These approaches require a special kind of encryption that allows predicate evaluation on ciphertexts, namely *searchable encryption (SE)* [5, 19, 24]. However, the SE primitives are not specifically designed for geospatial queries, but rather for arbitrary keyword or wildcard queries. As a result, a data mapping step must transform spatial queries to the primitive operations supported on ciphertexts. Due to this translation, the performance overhead can be significant.

Some solutions use *Symmetric Searchable Encryption (SSE)* [11, 19, 24], where a trusted entity knows the secret key of the transformation, and collects the location of all users before encrypting them and sending the ciphertext to the service provider. While the performance of SSE can be quite good, the system model that requires mobile users to share their cleartext locations with a trusted service is not adequate from a privacy perspective, since it still incurs a significant amount of disclosure.

Prior work in secure alert zones [14, 21, 23] uses *Hidden Vector Encryption (HVE)* [5], which is an *asymmetric* type of encryption that allows direct evaluation of predicates on top of ciphertexts. Each user encrypts her own location using the *public* key of the transformation, and no trusted component that accesses locations in clear is required. However, the performance overhead of HVE in the spatial domain remains high.

In existing HVE work for geospatial data [14], [21], the data domain is partitioned into a hierarchical data structure, and each node in this structure is assigned a binary string identifier. The binary representation of each node plays an important part in query encoding, and it influences the amount of computation that needs to be executed when evaluating predicates on ciphertexts. In [14], the earliest solution for secure alert zones, the impact of the specific encoding is not evaluated in-depth. In [23], the geospatial data domain is embedded to a high-dimensional hypercube, and then graph embedding [7] is applied to reduce the computation overhead in the predicate evaluation step.

However, all previous solutions use fixed-length encoding of locations and alert zones, meaning that the same number of bits is used to represent each location. In cases where the distribution of alert zones and/or locations is not uniform, using fixed-length encoding can introduce unnecessary overhead. Motivated by this fact, we propose techniques to reduce the computational overhead of HVE by using variable-length encoding. Specifically,

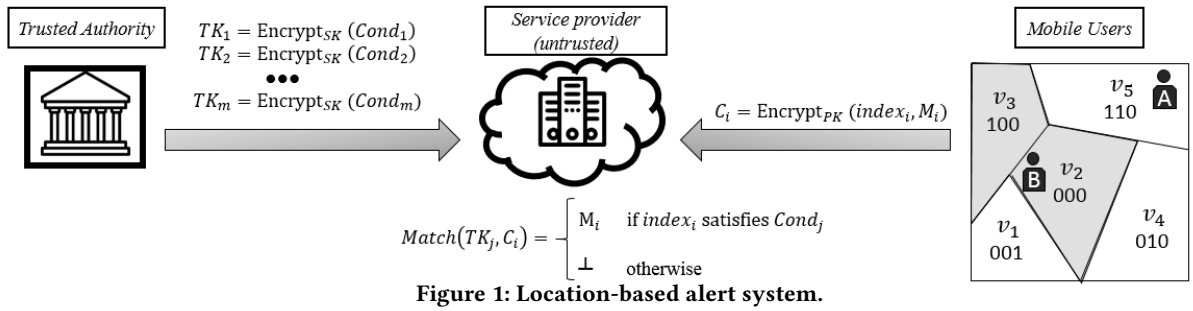

Figure 1: Location-based alert system.

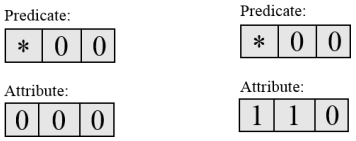

(a) Match **(b) Nonmatch**

Figure 2: HVE evaluation

we use Huffman compression codes to represent both user locations and alert predicates. Areas of the domain that are more popular, or more likely to result in a secure alert being triggered, are encoded with fewer bits than less popular areas. This allows us to perform spatial query execution on ciphertexts in a less computationally-intensive manner.

Our specific contributions are:

- We consider for the first time the use of variable-length encoding, specifically Huffman compression codes, for the problem of secure alert zones on encrypted location data;
- We devise specialized domain encoding techniques for both user locations and alert zones that take into account location popularity;
- We provide algorithms to evaluate the secure alert zone enclosure predicates directly on ciphertexts when both user locations and alert zones are represented using variable-length encoding;
- We perform an extensive experimental evaluation which shows that the proposed approach reduces considerably the performance overhead of secure alert zones compared to fixed-length encoding approaches.

The rest of the paper is organized as follows: Section 2 introduces necessary background and the system model. Section 3 provides the details of the proposed variable-length encoding techniques for user locations and alert zones. Section 4 generalizes our solution to non-binary identifiers. Section 5 analyzes the overhead of variable-length encoding on ciphertext size. Section 6 provides a security discussion, followed by evaluation of the proposed approach on both real and synthetic datasets in Section 7. We survey related work in Section 8 and conclude in Section 9.

2 BACKGROUND

Consider a map divided into a set of n non-overlapping partitions

$$\mathcal{V} = \{v_1, , v_2, ..., v_n\}. \quad (1)$$

Each partition v_i represents a spatial area on the map referred to as *cell*. Cells are identified by a unique binary code called *index*, and can have arbitrary shapes and sizes (although equal-size square cells are most likely in practice). We refer to the partitioning as a *grid*. The assignment of indexes to cells is referred to as *grid encoding*. All indexes must have the same length for security purposes (to prevent an adversary from distinguishing cells based on length). Fig. 1 shows a sample grid with five cells, each associated with an index of length three.

When an event of interest occurs, an *alert zone* is created, which spans a number of grid cells. We refer to such cells interchangeably as *alert cells* or *alerted cells*. In Fig. 1, cells v_3 and v_2 associated with the indexes 100 and 000 (shown highlighted) are alert cells. We denote the likelihood of cell v_i being alerted by $p(v_i)$, or alternatively p_i. Our goal is to exploit alert cell likelihoods in order to choose an encoding that reduces the computational complexity of HVE.

2.1 Hidden Vector Encryption

Hidden Vector Encryption (HVE) [5] is a searchable encryption system that supports predicates in the form of conjunctive equality, range and subset queries. Search on ciphertexts can be performed with respect to a number of *index attributes*. HVE represents an attribute as a bit vector (each element has value 0 or 1), and the search predicate as a *pattern* vector where each element can be 0, 1 or '*' that signifies a wildcard (or "don't care") value. Let l denote the HVE *width*, which is the bit length of the attribute, and consequently that of the search predicate. A predicate evaluates to $True$ for a ciphertext C if the attribute vector I used to encrypt C has the same values as the pattern vector of the predicate in all positions that are not '*' in the latter. Fig. 2 illustrates the two cases of *Match* and *Non-Match* for HVE.

HVE is built on top of a symmetrical bilinear map of composite order [5], which is a function $e : \mathbb{G}\times\mathbb{G} \rightarrow \mathbb{G}_T$ such that $\forall a, b \in G$ and $\forall u, v \in \mathbb{Z}$ it holds that $e(a^u, b^v) = e(a, b)^{uv}$. $\mathbb{G}$ and $\mathbb{G}_T$ are cyclic multiplicative groups of composite order $N = P \cdot Q$ where P and Q are large primes of equal bit length. We denote by $\mathbb{G}_p$, $\mathbb{G}_q$ the subgroups of $\mathbb{G}$ of orders P and Q, respectively. Let l denote the HVE *width*, which is the bit length of the attribute, and consequently that of the search predicate. HVE consists of the following phases:

Setup. The public/private (PK/SK) key pair has the form:

$$SK = (g_q \in \mathbb{G}_q, \quad a \in \mathbb{Z}_p, \quad \forall i \in [1..l] : u_i, h_i, w_i, g, v \in \mathbb{G}_p)$$

To generate PK, we first choose at random elements $R_{u,i}, R_{h,i}$, $R_{w,i} \in \mathbb{G}_q, \forall i \in [1..l]$ and $R_v \in \mathbb{G}_q$. Next, PK is determined as:

$$PK = (g_q, \quad V = vR_v, \quad A = e(g, v)^a,$$

$$\forall i \in [1..l] : U_i = u_i R_{u,i}, \quad H_i = h_i R_{h,i}, \quad W_i = w_i R_{w,i})$$

Encryption uses PK and takes as parameters index attribute I and message $M \in \mathbb{G}_T$. The following random elements are generated: $Z, Z_{i,1}, Z_{i,2} \in \mathbb{G}_q$ and $s \in \mathbb{Z}_n$. Then, the ciphertext is:

$$C = (C^{'} = MA^s, \quad C_0 = V^s Z,$$

$$\forall i \in [1..l] : C_{i,1} = (U_i^{I_i} H_i)^s Z_{i,1}, \quad C_{i,2} = W_i^s Z_{i,2})$$

Token Generation. Using SK, and given a search predicate encoded as pattern vector I_*, a search token TK is generated

as follows: let J be the set of all indexes i where $I_*[i] \neq *$. We randomly generate $r_{i,1}$ and $r_{i,2} \in \mathbb{Z}_p, \forall i \in J$. Then

$$TK = (I_*, K_0 = g^a \prod_{i \in J} (u_i^{I_*[i]} h_i)^{r_{i,1}} w_i^{r_{i,2}},$$

$$\forall i \in [1..l] : K_{i,1} = v^{r_{i,1}}, \quad K_{i,2} = v^{r_i,2})$$

Query is executed at the service provider, and evaluates if the predicate represented by TK holds for ciphertext C. The server attempts to determine the value of M as

$$M = C^{'} / (e(C_0, K_0) / \prod_{i \in J} e(C_{i,1}, K_{i,1}) e(C_{i,2}, K_{i,2}) \tag{2}$$

If the index I based on which C was computed satisfies TK, then the actual value of M is returned, otherwise a special number which is not in the valid message domain (denoted by $\perp$) is obtained.

The HVE query, or matching, is the most important operation in a location-based alert system, because it is executed every time an alert occurs, and it requires processing of a large number of ciphertexts. *Our goal is to reduce the overhead of matching, and the most direct way to do so is by reducing the number of non-star bits in a token, since the number of expensive bilinear maps is proportional to the count of non-star bits.*

2.2 System Model

The architecture of location-based alert systems is shown in Fig. 1. There are three types of entities: mobile users, a service provider (SP) and a trusted authority (TA).

Mobile users subscribe to the location-based alert system and periodically submit their encrypted location updates. Users want to be notified when they are in an alert cell, without their privacy being compromised. They the public key (PK) of the HVE cryptosystem to encrypt their locations before sending them to the SP. For example, users A and B on the grid encrypt their indexes 110 and 000, generating two ciphertexts C_A and C_B, respectively.

The **Trusted Authority (TA)** has the secret key (SK) of the HVE cryptosystem. In practice, the TA role could be played by a reputable organization such as a law enforcement agency, or the center for disease control, who issue *HVE search tokens* corresponding to alerts. The TA does *not* have access to user locations, and is assumed not to collude with the SP. The TA is acting in the interest of the general public, but does not have the infrastructure to run a complex alert system, which is why this service is outsourced to the SP. One important aspect when generating tokens is to minimize the number of non-star bits in a token, in order to reduce the computational overhead of matching. A common approach is to use binary minimization on the cell identifiers. For example, the two alerted indexes 100 and 000 are combined using binary expression minimization to obtain *00, then, the new index is encrypted using the SK to create a token with two non-star bits, instead of two tokens with three non-star bits each. The overhead is reduced from six sets of bilinear pairings to two.

The SP implements the alert service. It receives encrypted updates from users and tokens from the TA, and performs the matching to decide whether encrypted location C_i of user i falls within alert zone j represented by token TK_j. If the *matching* outcome is positive, the SP learns that the user is inside the alert zone, and notifies the user. For a matching process to result in a positive outcome, all the token's non-star bits should exactly match the user index. Star bits ('don't care' bits), as the name suggests, match with either a zero or one bit in the user index. Note that all received information from users and the TA is encrypted in the matching process, and the search happens over encrypted data only.

Table 1: Summary of notations.

Symbol	Description
n	Number of cells
$\mathcal{V} = \{\bigcup v_i\}$	Set of all cells
$p(v_i)$	Probability of cell v_i becoming alerted
C_j	Encrypted location of user j
TK_j	Token j
M_j	Message of user j
RL	Depth of prefix tree (reference length)
r_i	ith internal node of tree
Pois(λ)	Poisson distribution; occurrence rate λ
Σ	Identifier symbol alphabet
γ	*Euler-Mascheroni* constant
ϕ	Golden ratio
$a[i:j]$	Returns elements i to $j-1$ of array a
$\overline{x_1 x_2 ... x_l}$	Concatenation of symbols x_1 to x_l

Revisiting the example in Fig. 1, the outcome of matching between token *00 and user B's ciphertext corresponding to index 000 is positive (all the non-star bits match); however, the matching outcome between *00 and 110 (user A) is negative as the second bits do not match. From the mathematical derivation of HVE (2.1), the HVE system's computation complexity is proportional to the number of non-star bits in the tokens. Therefore, a good grid encoding reduces the overall number of non-star bits in tokens to minimize the HVE computational overhead.

2.3 Motivation and Scope

While prior work made important steps toward secure and scalable location-based alert systems, important performance issues still need to be addressed. The pioneering work in [14] was the first to use searchable HVE encryption in the context of locations, but assumed that all data domain regions are equally likely to be part of an alert zone. Later in [23], it was shown that if there are significant differences in likelihood of distinct regions to be part of an alert zone, then performance can be significantly boosted. However, both [14] and [23] use fixed-length encoding, i.e., the same number of bits are used to represent each cell. Hence, their performance overhead depends entirely on their ability to aggregate search tokens. When alert zones consist of a relatively large number of co-located alert cells, fixed-length encoding methods are able to perform effectively binary minimization of identifiers, and reduce overhead. This may be sufficient in some scenarios such as an active shooter, or a gas leak, where there is an epicenter of the event, and a range around the epicenter (often circular) within which users must be alerted. The range can be large, for instance in the order of hundreds of meters.

However, in other applications, alert zones may be compact and sparse. For instance, consider the case of contact tracing – an important task in controlling pandemics, such as COVID-19. In this case, there will be a number of distinct alert zones, corresponding to the set of locations visited by a COVID-19 patient. For each individual site, the range of the query is relatively small, for instance, several meters around the patient location for direct spread. Or, in the case of surface spread or aerosol transmission, the query may be restricted to a room, or a store, which may be in the order of $10-20$ meters in size. There are insufficient cells in the alert zones to allow for effective token aggregation with fixed encoding, and the performance obtained may be poor.

Our goal is to address this latter case, and we do so by using a novel variable-length encoding approach. In this case, it is important to use fewer representation bits for high-probability regions. While our advantage is greatest for small, sparse alert zones, we show in our empirical evaluation in Section 7 that variable-length encoding can outperform fixed-length approaches for a wide choice of alert zone sizes, and mixed-size workloads.

Normalizing the cell probability values over the domain space reveals how likely a cell is to be alerted compared to others. A typical stochastic distribution used to model sporadic events is *Poisson distribution*, characterized as follows.

Theorem 1. *If a random variable Y represents the number of alert cells on the grid, then, it approximately follows Poisson distribution (Pois(λ)) with the occurrence rate of one (λ = 1).*

Proof. An alert zone event on the map is a subset of cells $v_1, , v_2, ..., v_n$, where n is a large value and each probability $p(v_i)$ is relatively small. Moreover, the events are either independent or weakly dependent of each other. Let

$$Y = \sum_{i=1}^{n} I(v_i) \tag{3}$$

count how many of the cells are alerted, in which I is an indicator random variable having a value of one when the cell is alerted and zero otherwise. Based on the Poisson distribution, the random variable Y can be approximated with rate $\lambda = \sum_{i=1}^{n} p(v_i) = 1$. Therefore, the probability of having k alert cells is given by

$$p(Y = k) = \frac{e^{-1}}{k!}. \tag{4}$$

□

One can see from the Poisson distribution that the likelihood of having a large number of alert cells is low. The maximum probability corresponds to having only a single alert cell in a zone, and then it drops significantly. This motivates our technique for dealing effectively with cases where alert zones are compact.

3 LOCATION-BASED ALERTS WITH VARIABLE-LENGTH ENCODING

In Section 3.1 we provide an overview of Huffman codes; Section 3.2 presents the proposed location encoding scheme; Section 3.3 introduces the token minimization process.

3.1 Prefix and Huffman Codes

Generally, any uniquely-decodable representation used to transmit information is a *prefix code*, i.e., it follows the *prefix property*, which requires that no whole code can be part of any other code. For example, [000, 001, 01, 10, 11] is a prefix code as no code starts with any other code in the set. A well-known theorem based on *Kraft inequality* [10] states that any prefix over an alphabet of size two with string lengths of l_1 to l_n must satisfy the inequality

$$\sum_{i=1}^{n} \frac{1}{2^{l_i}} - 1 \leq 0, \tag{5}$$

and conversely, given a set of string lengths that satisfies the Kraft inequality, there exists a prefix code with these string lengths. Let the tuple $\mathcal{P} = (p_1, p_2, ..., p_n)$ defined over space partitioning $\mathcal{V}$ indicate the likelihood of cells $v_1, \cdots v_n$ becoming alert cells. Furthermore, suppose that the function $f(l_1, l_2, ..., l_n)$ returns the average symbol length with no minimization, and $f_M(l_1, l_2, ..., l_n)$ returns the average reduction in number of bits in the minimization process. Given the tuple of cells and probabilities, the objective of a minimal encoding is to generate a prefix code $C(\mathcal{P}) = (c_1, c_2, ..., c_n)$ as follows:

$$\begin{aligned} &\text{minimize} \quad L(C(\mathcal{P})) = \sum_{i=1}^{n} p(v_i) \times length(c_i) \\ &\text{subject to} \quad L(C(\mathcal{P})) \leq L(\mathcal{T}(\mathcal{P})) \text{ for any code } \mathcal{T}(\mathcal{P}) \end{aligned}$$

Note that f_M, which indicates the amount of minimization, is not necessarily a function. For example, a previously used minimization approach based on Karnaugh maps [14] does not always result in a unique output. The NP-hardness of the above problem based on fixed-length codes is shown in [23].

The most well-known prefix code is the *Huffman encoding*, widely used in communication systems as it results in optimal decodable average code length. The main idea behind Huffman codes is that more common symbols are represented with fewer bits compared with the less common symbols. In grid encoding, it is desirable to encode symbols that have higher probabilities of being in alert zones with fewer bits than the less likely ones. Given the tuple of cells and probabilities, the objective of Huffman encoding is to generate a prefix code that minimizes the average length of codewords:

$$\begin{aligned} &\text{minimize} \quad f(l_1, l_2, ..., l_n) - f_M(l_1, l_2, ..., l_n) \\ &\text{subject to} \quad \sum_{i=1}^{n} \frac{1}{2^{l_i}} - 1 \leq 0 \\ &\qquad\qquad l_i > 0, \quad \forall i = 1, .., n \end{aligned} \tag{6}$$

Prefix Trees. An intuitive way to discover whether the prefix property holds for a code is to draw its associated binary tree, called prefix tree. The prefix tree is constructed by assigning an empty character to the root and descending through the tree. At each branching point, we either choose to go left by adding a zero character or move to the right child by adding a character '1' to the root string. We call the tree's depth *reference length (RL)*. This number also indicates the maximum length of a prefix code. Moreover, the subtree roots are referred to as *interior nodes* of the prefix tree, and the leaf nodes are the *prefix codes*. Fig. 4b, shows a prefix tree with an RL of three. As an example, the prefix code '001' is generated by traversing nodes r_4, r_2, and r_1.

3.2 Proposed Coding Scheme

The focus of prior work on secure alert zones [14, 23] has been on fixed-length codes. Such codes are indeed a special case of prefix codes, in which the tree is balanced, and no assigned code can start with another. Next, we show how variable-length codes can be used in conjunction with HVE. An overview of the proposed approach is presented in Fig. 3. Based on a given prefix code, the TA generates grid indexes where each index is a unique identifier of a cell in the grid. In addition to grid indexes, a coding tree is generated for the purpose of token minimization. Given the set of indexes associated with the alert cells, the TA applies the proposed minimization algorithm and transmits the encrypted tokens to the SP. Fig. 4 serves as a running example.

Our approach consists of four steps:

I. Generation of Probabilities: Our coding scheme relies on a set of probabilities for each cell of the location domain to be part of an alert zone. This step is a prerequisite to our approach, and thus performed independently of the encoding. Such probabilities are application dependent, and can be generated based on a trained

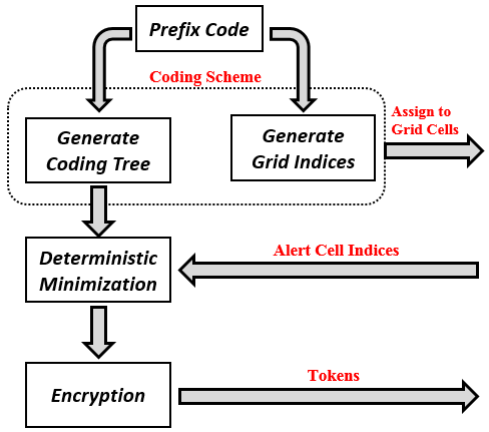

Figure 3: Overview of HVE with variable-length codes.

machine learning model. In the example of Fig. 4a, we have five cells $\mathcal{V} = (v_1, v_2, v_3\, v_4, v_5)$ with alert probabilities of

$$\mathcal{P}=(p(v_1)=0.1,\ p(v_2)=0.2,\ p(v_3)=0.5,\ p(v_4)=0.4,\ p(v_5)=0.6).$$

For grids entailing a high correlation between alert probabilities of cells, the setting in [23] or deep learning models such as [2] can be used to find the stationary distribution of probabilities, leading to a more accurate probabilistic model.

II. Prefix tree : An arbitrary prefix code defined over alphabet $\Sigma = \{0, 1\}$ can be represented by a binary tree with the prefix codes located on the leaves of the tree. We are not just interested in the generated prefix codes, but also in the codes associated with the internal nodes of the tree. Therefore, internal nodes are also stored as well as the generated prefix codes.

The topology of the tree is stored by recording five attributes of each node: left child (leftChild), right child (rightChild), parent node (parentNode), weight, and the associated code. The weight of a node represents its frequency. The leaf nodes have a frequency equal to their probability, and the weight of a parent node is found by the addition of its immediate children's weights (i.e., *Huffman mechanism*). The prefix tree is not used directly in the prefix coding scheme, but two sets of codes are generated based on the prefix tree; one is used for identifying grid cells referred to as cell *indexes*, and another is used by the TA to perform token minimization. Once the base codes are assigned for each node of the tree, two sets of *padding* are conducted, one for indexes assigned to the cells, and one used as a guideline for the token generation. The padding leads to a length of RL (i.e., equal length) for all codewords and indexes. Recall that equal ciphertext lengths is a requirement for security. However, the variable-length codes affect the ciphetexts and token contents in a way that allows fast processing. Furthermore, the padding prevents an adversary from distinguishing among ciphertexts.

III. *Grid indexes:* the prefix codes (leaves on the prefix tree) are padded from the right-hand side with zeros if they have a length less than RL. In our example, the generated prefix codes are $\{v_1 : 001, v_2 : 000, v_3 : 10, v_4 : 01, v_5 : 11\}$ which are transformed to $\{v_1 : 001, v_2 : 000, v_3 : 100, v_4 : 010, v_5 : 110\}$ after padding with zeros. We refer to zero-padded prefix codes as *indexes*. Once codes are created, they are assigned to corresponding cells identified by their probabilities. The assigned indexes to the sample grid are shown in Fig 4c. These are the indexes utilized by users to identify the cell they are enclosed by.

Algorithm 1 Coding Scheme

Input: Root; $\mathcal{V}$;

```
1:  //Root traversal to generate codes
2:  function TRAVERSE(Root)
3:      if Root has no children then
4:          return True
5:      else
6:          Root.leftChild = Root.code + '0'
7:          Root.rightChild = Root.code + '1'
8:          Traverse(leftChild)
9:          Traverse(rightChild)
10:
11: Traverse (Root)
12: //Generate indexes assigned to cells
13: RL ← depth of tree
14: for all leaf nodes do
15:     index = node.code
16:     while len(node.code) < RL do
17:         index = index +' 0'
18:     Assign index to v_i that has p(v_i) = node.weight
19:
20: //Generate coding tree
21: for all nodes do
22:     while len(node.code) < RL do
23:         node.code = node.code + '*'
24: //codingTree is the set of all nodes, alternatively Root can be
    returned
25: return codingTree
```

IV. *Coding tree:* the coding tree is used by the trusted authority to generate tokens. The coding tree is constructed by adding star bits on the right side of the prefix codes as well as the internal nodes on the prefix tree if they have a length less than RL. The padding for the sample grid is shown in Fig. 4d. The codes on the coding tree are referred to as *codewords*.

Algorithm 1 formally presents how indexes and the coding tree are generated for a given prefix tree. The inputs to the algorithm are the tree root, grid cells, and their probabilities. The tree root is sufficient for reconstructing the tree as children and parents are presumed to be recorded. The algorithm traverses through nodes to generate the prefix tree. Next, indexes of the grid are generated and assigned to the grid cells, and finally, the coding tree is completed and returned as the output of the algorithm.

Algorithm 2 presents how the Huffman tree is generated. The algorithm starts by creating a node (leaf node) for each cell of the grid, sorting them in ascending order based on their weights, and placing them in a priority queue. Recall that the weights of the leaf nodes are the probability of cells becoming alerted. Next, while the length of the queue is greater than one, the algorithm extracts two nodes with the minimum weights and creates a new internal node (newNode) with a weight equal to the addition of two extracted nodes. The new node is assigned as the parent of extracted nodes, and the extracted nodes are assigned as left and right children of the parent node. The new node's weight is inserted in the queue, and the process continues until only a single weight remains in the queue. The last node is the root of the tree and the output of the algorithm. The root node is used as input to Algorithm 1 to generate the coding tree and grid

Algorithm 2 Huffman Tree

Input: $\mathcal{V}$; $\mathcal{P}$

```
1: //Generate tree nodes
2: for v_i ∈ V do
3:     Create a newNode(leftChild=None, rightChild = None,
4:                      parent = None, weight = p(v_i), code = ' ')
5: Insert nodes into priority queue Q
6: while len(Q)>1 do
7:     Sort Q in ascending order of weights
8:     (node_1, node_2) ← Extract first two nodes in Q
9:     Create a newNode(leftChild= node_1, rightChild = node_2,
10:                     parent = None,
11:                     weight = n_1.weight + n_2.weight, code = ' ')
12:    n_1.parent, n_2.parent= newNode
13:    Insert newNode into Q
14: //The last nodes in Q is the tree root
15: return root
```

indexes. The algorithm is executed with the time complexity of $O(n(\log_2 n))$.

The following steps illustrate the generation of Huffman tree for the example presented in Fig. 4.

1. One node is generated for each cell (v_1, v_2, v_3, v_4, v_5) and their probabilities are inserted in a priority queue

Q=($p(v_1)$=0.2, $p(v_2)$=0.1, $p(v_3)$=0.5, $p(v_4)$=0.4, $p(v_5)$=0.6).

2. The queue is sorted in an ascending order:

Q=($p(v_2)$=0.1, $p(v_1)$=0.2, $p(v_4)$=0.4, $p(v_3)$=0.5, $p(v_5)$=0.6)

3. The two nodes with the minimum weights (v_1 and v_2) are extracted from the queue and a new parent node r_1 is generated with the weight of $p(v_2) + p(v_1) = 0.3$ and inserted into the queue:

$$Q=(p(r_1)=0.3,\ p(v_4)=0.4,\ p(v_3)=0.5,\ p(v_5)=0.6)$$

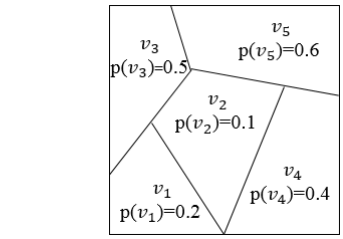
4. Similarly r_2, r_3, and r_4 are generated as

$$Q=(p(r_2)=0.7,\ p(v_3)=0.5,\ p(v_5)=0.6),$$
$$Q=(p(r_2)=0.7,\ p(r_3)=1.1),$$
$$Q=(p(r_4)=1.8).$$

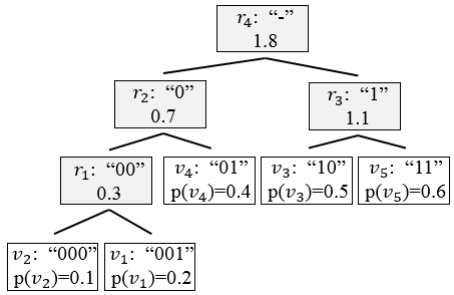
Another prefix tree evaluated in the experiments is called balanced tree. This prefix tree is used as a baseline to understand the improvement made by the Huffman tree. The balanced tree is a complete binary tree constructed in $log_2(n)$ steps. Given a tuple of probabilities corresponding to grid cells, they are sorted in ascending order and placed in a priority queue, i.e., Q. In the jth step, nodes $Q[2i]$ and $Q[2i+1]$ are paired for $i = 0, 1, ..., \lfloor n/2^j \rfloor - 1$, and each pair is replaced with a parent node in the queue. The weight of a parent is the addition of its immediate children's weights. The final remaining node in the queue is the tree's root.

3.3 Token Generation and Minimization

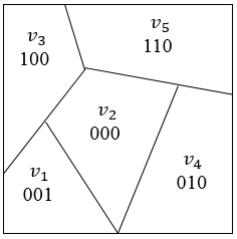
Prior work [14, 23] showed how the process of token generation for an alert zone can considerably improve the computation overhead, if the process of *token aggregation* is performed. Specifically, the binary codes corresponding to different regions of an alert zone can be aggregated to yield tokens with few non-star symbols, which in turn reduces the HVE overhead. Binary minimization on fixed-length codes is used for this purpose. For instance, suppose that the alert zone contains cells 0000, 0010, 0110, 0100,. Instead of separately encrypting the cell indexes and generating four



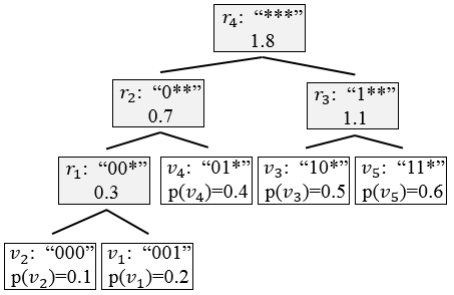
(a) Sample grid.



(b) Coding tree generated based on Huffman encoding.



(c) Assigned grid indexes.



(d) Coding tree.

Figure 4: Sample variable-length coding scheme

tokens, the TA uses binary minimization to generate a single token $0**0$, and the cost is reduced from twelve HVE operations to two. Binary minimization works when there are many cells in the alert zone, and when the placement of these cells permits code minimization. This approach is suitable when the number of alert cells is significant; however, in practice, alert zones may have cell configurations that do not permit efficient aggregation.

We propose a different token generation approach, where instead of performing binary minimization on fixed-length codes, we control the configuration of tokens based on the assignment of variable-length codes to cells. Algorithm 3 summarizes this process. Inputs to the algorithm are a set of alert cells and the coding tree. In the initialization phase, the algorithm defines:

- a dictionary of parent nodes (*parentDict*) with the number of leaf nodes in the corresponding subtree. This is done by traversing through children of parent nodes and counting the number of leaves located in that subtree. For the sample example, we have the dictionary as

$$[00* : 2,\ 0** : 3,\ 1** : 2,\ *** : 5]$$

- a list of leaf nodes denoted by *leaves*, ordered as they appear on the tree while traversing; no two edges of the tree cross path. Such a list for the sample tree is:

$$[v_2 : 000, v_1 : 001, v_4 : 01*, v_3 : 10*, v_5 : 11*].$$

The algorithm continues by converting alert cell indexes to codewords on the tree and recoding their associated codeword and the corresponding index in *leaves*. By default, the mapping process splits codewords into clusters that are located consecutively in *leaves*. It is important to note that mapping of alert cell indexes to codewords is unique, as demonstrated in Theorem 2. The theorem proves a bijective mapping between grid indexes and coding tree codewords. For instance, if the alert cells are $[001, 100, 110]$, then the mapping would result in leaves $[001, 10*, 11*]$ for the sample example. Next, the minimization process based on the coding scheme is conducted. The minimization's main idea is to find the common subtree roots that have maximum depths and use them as tokens. All leaves under a common subtree root must be alerted; otherwise, if a user is located in such a leaf node it will be falsely notified to be in an alert zone.

Continuing with the example and alert cells $[001, 10*, 11*]$, the algorithm generates two clusters $[10*, 11*]$ and $[001]$, and aims to identify the common subtree roots with the maximum depths in each cluster. This is done heuristically in lines 23- 37. Suppose that a cluster's length is L, the common left-hand side code in all L codewords is calculated and padded with '*' bits to ensure that the codeword length is RL. If the common codeword exists in the dictionary and the number of its children is L, the codeword is chosen as representative of its descendent leaves; otherwise, L is decremented by one, and now the first $L-1$ members are checked to see if there exists a common root associated with them. The process continues until the first subtree root is found. For the remaining codewords in the cluster, the algorithm is applied again until all tokens representing codewords in the cluster are selected. A similar approach is repeated for all clusters.

Algorithm 3 Deterministic Minimization

```
   Input: alertCells; codingTree;
1: parentDict = {}
2: for node ∈ codingTree do
3:     parentDict[node.code] = # descendent leaves
4: indexHolder, codewordHolder = []
5: leaves ← list of leaf codewords
6: for i ∈ alertCells do
7:     memCodeword ← Map i to a codeword in leaves
8:     codewordHolder = codewordHolder ∪{memCodeword}
9:     memIndex ← index of memCodeword in leaves
10:    indexHolder = indexHolder ∪{memIndex}
11: // Generate a two dimensional list of clusters
12: Clusters, c = []
13: c = c ∪ codewordHolder[0]
14: for i ∈ [1 : len(codewordHolder)] do
15:    if indexHolder[i] = indexHolder[i − 1] + 1 then
16:        c = c ∪ codewordHolder[i]
17:    else
18:        clusters = clusters ∪ c
19:        c = []
20:        c = c ∪ codewordHolder[i]
21: tokens = []
22: RL ← depth of tree
23: for cluster ∈ clusters do
24:    L = len(cluster)
25:    while L > 1 do
26:        code ← common bits in cluster[1 : L]
27:        if len(code) < RL then
28:            Pad with RL − len(code) star bits
29:        if code ∈ parentDict & parentDict[code] = L then
30:            tokens = tokens ∪ code
31:            cluster = cluster[L : len(cluster)]
32:            L = len(cluster)
33:        else
34:            L = L − 1
35:            if L = 1 then
36:                tokens = tokens ∪ cluster[L]
37:                cluster = cluster[L : len(cluster)]
38: return tokens
```

Theorem 2. *There exists a bijective function between grid indexes and the leaf nodes of the coding tree.*

Proof. We start by proving that for each index on the grid there exists a unique leaf node (codeword) on the tree. Let $\overline{x_1x_2...x_l}$ denote an arbitrary index on the map. There exists at least one leaf on the tree with the codeword $\overline{y_1y_2...y_{r_1} * ...*}$ such that $\overline{x_1x_2...x_{r_1}} = \overline{y_1y_2...y_{r_1}}$, as indexes have been generated from leaf nodes of the prefix tree. Suppose that there exist at least two leaf nodes with the codewords $\overline{y_1y_2...y_{r_1} * ...*}$ and $\overline{z_1z_2...z_{r2} * ...*}$ corresponding to the index $\overline{x_1x_2...x_l}$. Hence, we have the following relationship between the index and codewords on the tree.

$$\overline{x_1x_2...x_{r_1}} = \overline{y_1y_2...y_{r_1}} \tag{7}$$

$$\overline{x_1x_2...x_{r_2}} = \overline{z_1z_2...z_{r_2}} \tag{8}$$

Without loss of generality, assume that $r_2 \geq r_1$. Hence, equations 7 and 8 result in

$$\overline{y_1y_2...y_{r_1}} = \overline{z_1z_2...z_{r_1}}. \tag{9}$$

However, this contradicts the prefix property of the codes. Hence, there is a unique leaf node corresponding to each cell index. As there are an equal number of indexes and codewords, there exists a bijective mapping between indexes and codewords. □

4 EXTENSION TO NON-BINARY CODES

So far, we considered the alphabet of HVE operations to be limited to $\Sigma = \{0, 1\}$ and the extended alphabet as $\Sigma_* = \Sigma \cup \{*\}$. This is an intuitive way of looking at indexes as they are a series of zeros and ones. However, by extending the alphabet to $\Sigma = \{0, 1, ..., B-1\}$ for an arbitrary integer $B \in \{2, ..., n-1\}$, we could obtain more compact representations. The special character is also added as $\Sigma_* = \Sigma \cup \{*\}$. We re-visit the operations from the previous section for the extended alphabet with B symbols.

1. *Prefix tree:* We incorporate an extension of Huffman coding referred to as B-ary Huffman to generate the prefix tree. The main idea is to group B least probable symbols (instead of 2) at each substitution stage of the algorithm. The construction of the prefix tree for our running example grid is shown in Fig. 6a in which a 3-ary or Huffman code is used. Initially, the algorithm

(a) (b)

Figure 5: Expansion process.

starts by combining nodes v_2, v_1, and v_4, as they correspond to a group of three nodes with the minimum total weight, generating the node r_1. Next, the nodes r_1, v_3, and v_5 are combined, and the root node r_2 is generated. The weights and other characteristics of the nodes are stored and calculated in the same way as the binary Huffman tree. The codes associated with the tree are generated by assigning an empty character to the root node and then traversing the tree. At each branching node, when following the ith child edge, character $i-1$ is added to the root string. As an example, prefix code '02' is generated by adding character '0' at r_1, and character '2' by moving to node v_4. As in the case of the binary case, we are interested in codes assigned to internal nodes as well as the prefix codes generated at the leaves.

2. *Coding tree:* The generation of the coding tree requires an additional step compared to the binary Huffman tree. In the first step, codes are padded with star characters until they reach the same length as the RL. The padded prefix tree for our running example is shown in Fig. 6b. Next, we expand each character to an array of B bits. The character $i \in \Sigma$ is converted to B bits with the $(i+1)$-th bit set to 1 and star bits otherwise. The only exception is the star character, which will be mapped to a string of length B with all bits set to '*'. As an example, the expansion of $2*$ is shown in Fig. 5a.

Each original character essentially works as a placeholder for the expanded representation. The final coding tree generated for our example is shown in Fig. 6c.

3. *Indexes:* We generate indexes by padding the leaves in the prefix tree by zeros, and then expanding the codes. An interesting case occurs that gives the TA the opportunity to increase the grid's granularity further if desired. Consider the prefix code '2', which will be zero-padded to generate '20'. The expansion process requires two steps: (i) zeros generated by the padding process are mapped to B bits; (ii) each character $i \in \Sigma$ is expanded to B bits with the $(i+1)$-th bit set to 1, and star bits otherwise. The expansion of '20' is demonstrated in Fig. 5b.

The additional star bits in the index are converted to zeros. The advantage of the approach is revealed when we increase the granularity of a grid cell in a later stage in time. This can be done by exploiting the star bits generated in the last step without violating the structure of the grid or the coding tree. Consider the index '20' corresponding to cell v_5 one more time. This string was first converted to '**1000' and then to '001000'. Suppose, later on, the TA decides to increase the granularity of v_5 to four cells. This can simply be done by using four indexes '001000', '011000', '101000', '111000' generated based on star bits with all of them lying under character '2'. The coding tree is also updated accordingly via placeholders for the character '2' without violating the tree's prefix property.

5 ENCRYPTION OVERHEAD

Employing variable-length codes into HVE can significantly improve the computation complexity at the SP, but there is a a trade-off with respect to increased encryption time. When variable-length encoding is used, all ciphertexts submitted by the mobile users to the SP must have the maximum length of any existing code. Otherwise, the length of the ciphertext would enable the SP to pinpoint the location of the submitting user to one of the cells that are assigned a code with bit length equal to the one submitted. To thwart such attacks, all codes are padded before encryption to the maximum possible length, i.e. RL. In this section, we analyze this additional encryption overhead, and we show that it is not significant, especially compared to the savings at the SP. Furthermore, the additional computational load is spread over the user population, since each user encrypts its own location independently, and no bottleneck is created (as opposed to the alert matching overhead which is centrally incurred at the SP).

In our analysis, we make use of the following result:

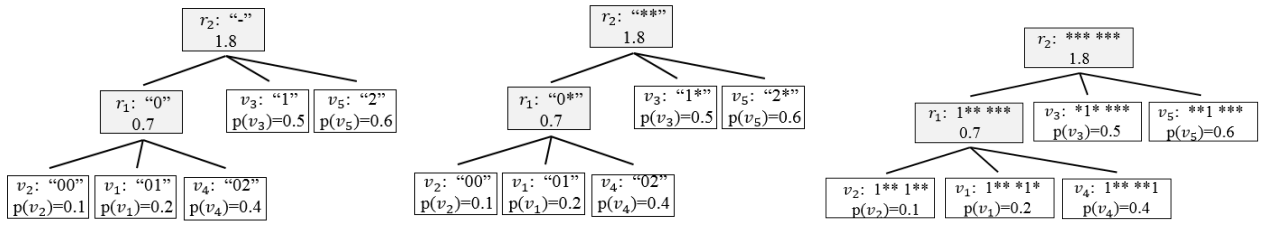
THEOREM 3. *The depth of a B-ary Huffman tree (RL) with n leaves is less than or equal to* $\lceil \frac{n-1}{B-1} \rceil$.

PROOF. The theorem can be proved by counting the number of internal nodes in a B-ary Huffman tree. Consider a tree with n leaves generated by the Huffman mechanism. At every run of the algorithm, B less likely remaining nodes in the priority queue are combined, and a new internal node is inserted. Suppose that the Huffman mechanism is conducted x times over the priority queue until a single node, i.e. root node, is left in the queue. The maximum value of integer x can be derived as:

$$\max_x \ \{n - x(B-1) \geq 1\} \rightarrow x = \lceil \frac{n-1}{B-1} \rceil \qquad (10)$$

Therefore, the maximum possible depth of a B-ary Huffman tree is $\lceil \frac{n-1}{B-1} \rceil$. □

Let L_E denote the difference between the RL of an encoding grid with n cells generated by Huffman coding and fixed-length codes. We start by deriving an upper bound for L_E when $\Sigma_* = \{0, 1\} \cup \{*\}$, and then extend the upper bound for an arbitrary size alphabet. Without loss of generality, consider that RL in the binary Huffman tree is l_n. The minimum possible value for l_n is



(a) Ternary Huffman coding tree. (b) Placeholders. (c) Coding tree.

Figure 6: Sample coding tree for extended framework.

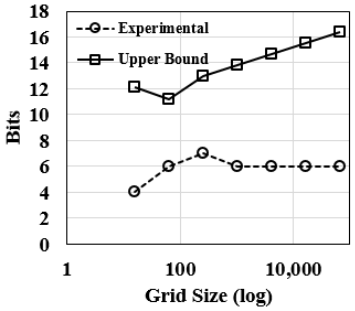


Figure 7: Upper bound of L_E for Binary Huffman codes.

$\lceil \log_2 n \rceil$. Based on Theorem 3, L_E can be written as:

$$L_E(B=2,n) = l_n - \lceil \log_2 n \rceil \leq \lceil \frac{n-1}{2-1} \rceil - \lceil \log_2 n \rceil = n-1-\lceil \log_2 n \rceil \tag{11}$$

A tighter upper-bound for RL in a binary Huffman tree can be derived based on the following theorem proven in [6] (we omit the proof for brevity):

Theorem 4. *Let p_n and l_n denote the minimum probability and its corresponding length existing on the Huffman tree. Then,*

$$l_n \leq log_\phi \frac{1}{p_n} \tag{12}$$

where ϕ denotes the golden ratio*, i.e., $\phi = (1+\sqrt{5})/2$.*

Therefore, a tighter upper-bound for L_E can be written as

$$L_E(B=2,n) \leq log_\phi \frac{1}{p_n} - \lceil \log_2 n \rceil \tag{13}$$

The numerical and analytical values of L_E are verified[1] for binary Huffman coding in Fig. 7.

Now let us extend the approach for B-ary Huffman codes generated with the alphabet $\Sigma_* = \{0, 1, ..., B-1\} \cup \{*\}$. Based on information theory, the minimum length of RL corresponding to fixed-length codes is derived as $\lceil \log_B n \rceil$. Therefore, the upper-bound for L_E can be computed as:

$$L_E(B,n) = B(l_n - \lceil \log_B n \rceil) \leq B(\lceil \frac{n-1}{B-1} \rceil - \lceil \log_B n \rceil) \tag{14}$$

$$\leq B(\frac{n-1}{B-1} + 1 - \lceil \log_B n \rceil) \tag{15}$$

The multiplier B is required to map the alphabet to 0s and 1s, used in the encryption.

$$E[L_E(n)] \leq \frac{1}{n-1}(\sum_{i=2}^{n} \frac{i(n-1)}{i-1} + \sum_{i=2}^{n} i - \sum_{i=2}^{n} i\lceil \log_i n \rceil) \tag{16}$$

The first and second summation in the upper-bound of $E[L_E(n)]$ can be further simplified as

$$\sum_{i=2}^{n} \frac{i(n-1)}{i-1} = (n-1) \times (n-1+\sum_{i=2}^{n} \frac{1}{i-1}) \tag{17}$$

$$\approx (n-1) \times (n-2+\ln(n-1) + \frac{1}{2(n-1)} + \gamma) \tag{18}$$

and,

$$\sum_{i=2}^{n} i = \frac{n^2+n-1}{2} \tag{19}$$

[1]Grid probabilities are generated with the parameters of sigmoid function set to $a = 0.95$ and $b = 20$. Please refer to Section 6 for details.

where $\gamma \approx 0.577$ is the *Euler-Mascheroni* constant. The approximation for the nth Harmonic can be derived by its asymptotic expansion in the *Hurwitz zeta* function [8].

6 SECURITY DISCUSSION

Our proposed technique uses as building block HVE primitives as introduced in [5], and hence inherits the security properties of HVE, namely IND-CCA under the bilinear Diffie-Hellman assumption. In terms of ciphertext processing semantics, the security achieved by our technique is similar to existing work in the area of secure computation, namely the only leakage that occurs as part of ciphertext matching is the evaluation outcome. Specifically, the SP learns only whether the user is included in the alert zone (which is a necessary condition for correctness), and no other information. The SP does not learn where exactly the user is located within the alert zone, if the match is successful; conversely, if the match is not successful, the SP learns only that the user is not inside the alert zone, but cannot further narrow down the user within the data domain.

Furthermore, our technique is guided by statistical information that is derived solely from public data. Namely, the heuristic on how to encode cells does not use any user location data, but strictly likelihood scores that are assigned to grid cells, based on public knowledge regarding the *alert zone* properties, such as site popularity, etc. No private information regarding any system user is included in the encoding process (not even aggregate data, such as user distribution, etc).

Finally, the encryption strength achieved by HVE depends on the underlying bilinear pairing curve used [5]. Modern elliptic-curve pairing-based cryptography can easily provide 128-bit security, which is on par with commercial database applications such as banking, or heathcare data security standards.

7 EXPERIMENTAL EVALUATION

We conduct our experiments on a 3.40GHz core-i7 Intel processor with 8GB RAM running 64-bit Windows 7 OS. The code is implemented in Python. We evaluate our methods on both real and synthetic datasets, as follows:

- *Chicago Crime Dataset.* This dataset is provided by the Chicago Police Department's CLEAR (Citizen Law Enforcement Analysis and Reporting) system [1]. The dataset consists of reported incidents of crime that occurred in the city of Chicago in 2015. We consider four categories of crime: homicide, sexual assault, sex offense, and kidnapping. Fig. 8 shows data statistics. A 32×32 grid is overlaid on top of the dataset, and a logistic regression model is trained with the crime data from January to November 2015, and tested on the December data. The accuracy of the model is 92.9% and the generated likelihood scores based on the model are used as input to our techniques.
- *Synthetic data.* We generate the likelihood of grid cells to be part of an alert zone using a sigmoid activation function $\mathcal{S}(X=x) = 1/(1+\exp^{-b(x-a)})$, where a and b are parameters controlling the function shape. For each data point (i.e., cell) x, a uniformly random number between zero and one is generated, i.e., $x \in X \sim$ uniform$(0,1)$. Then, the number is fed into the sigmoid activation function. The output is a value between zero and one indicating the likelihood of the cell to be inside an alert zone. The sigmoid function is a frequent model used in machine learning, and

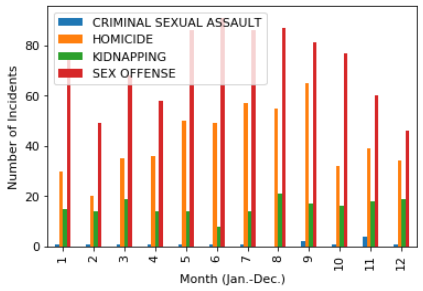

Figure 8: Chicago crime dataset statistics.

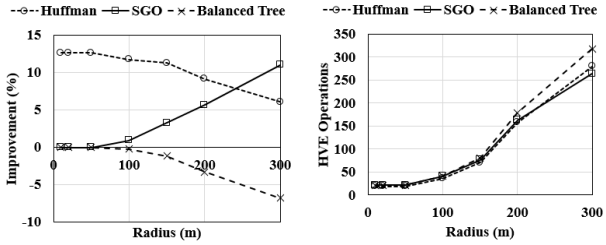

(a) (b)

Figure 9: Evaluation on Chicago crime dataset.

we choose it because we expect that, in practice, the probability of individual cells becoming part of an alert zone can be computed using such a model built on a regions' map of features (e.g., type of terrain, building designation, etc.). Parameter a of the sigmoid controls the *inflection* point of the curve, whereas b controls the gradient.

We compare our proposed variable-length encoding scheme with the state-of-the-art fixed-length approach scaled gray optimizer (SGO) from [23], which uses graph embedding to reflect cell probabilities in the way cell codes are chosen. We also consider as a second benchmark an approach that uses balanced trees, as opposed to Huffman trees.

We use as performance metric the number of HVE bilinear map pairing operations incurred by each technique (which are the most expensive component of the overhead). We present both absolute counts, as well the percentage of *improvement* compared to the original fixed-length encoding HVE approach introduced in [14] (which assumes all cells are equally likely to be alerted).

7.1 Evaluation on Real Dataset

Fig. 9 shows the performance results obtained on the real dataset. The x-axis in each graph indicates the size of the alert zone (expressed as radius). For low radii values, the SGO algorithm fails to provide significant improvement, due to the fact that the binary minimization process used by fixed-length encoding approaches is unable to aggregate tokens. In contrast, the proposed variable-length technique using Huffman encoding is able to provide gains of up to 15% compared to the baseline. In practice, we expect alert zones to be relatively compact compared to the data domain, hence this case is frequently occurring in practice. Furthermore, the results show the superiority of the Huffman code compared to generic variable-length encodings, as the balanced-tree approach benchmark does not produce any improvement.

As the size of alert zone increases, SGO improves, whereas the gain of Huffman encoding decreases. This is expected, since with very large alert zones, it is easy to aggregate tokens, by grouping together cells with low Hamming distance between their codes. However, such an improvement can only be reached when the alert zones are very large, which is not a realistic scenario in practice. In general, the size of alert zones is expected to be small, and their distribution in the data domain sparse, which would further diminish the potential of SGO (and other binary minimization approaches) to produce performance gains, as aggregation requires clustered cells with similar binary codes.

7.2 Evaluation on Synthetic Dataset

Performance evaluation results for synthetic data are summarized in Fig. 10. We use two inflection points for the sigmoid function $a = 0.90, 0.99$, as well as three gradient values $b = 10$, $b = 100$ and $b = 200$. A similar trend to the real dataset is observed. The Huffman tree approach achieves significantly better performance when the alert zones are compact, which is the expected case in practice.

Two other trends can be observed with respect to the parameters of the sigmoid function. First, a higher inflection point setting results in a more skewed distribution probability on the grid, and leads to a higher performance gain for Huffman encoding compared to competitor approaches. The performance gain can be as high as 50%. This is a positive aspect, since in real life one expects alert cell probabilities to be quite skewed, where more popular areas are visited by more individuals, hence there is more potential for alert events (e.g., public-safety alerts, or visits of a COVID-infected patient to points of interest). Second, an increase in the gradient of initial probabilities (b) also improves the performance gain of Huffman encoding.

We also conducted an experiment under mixed-workload conditions. We consider several mixes between short-radius (20 meters) and long-radius (300 meters) alert zones: *W1* (90% short-10% long); *W2* (75% short-25% long); *W3* (25% short-75% long); and *W4* (10% short-90% long). Results are summarized in Fig. 11. Our proposed technique outperforms SGO for all considered cases. For mostly-compact alert zones (*W1*), the improvement is much higher than that of SGO, with absolute values of up to 40%.

On the synthetic data, we are also able to perform more in-depth tests where we vary the parameter settings of our proposed approach. In Fig. 12, we vary the grid granularity. The results are obtained for $a = 0.95$ and $b = 20$. The results show that higher grid granularities lead to higher performance overhead, which is expected, since more cells need to be encoded and encrypted, and thus code lengths increase. We also observe an interesting trend: the improvement for a low number of alert cells decreases at higher granularity levels. As the number of grid cells grow, and considering the same sigmoid activation function parameters, there will be more cells with low probabilities of becoming an alert cell. Therefore, the Huffman tree tends to have higher depths. This can be observed more accurately in Fig. 13, where we show the ratio of average length to the maximum length of the Huffman tree for various grid sizes. Hence, the improvement achieved by deterministic minimization lags behind the logic minimization approach, leading to a smaller improvement percentage.

Finally, we present the run time required to generate indexes and the coding tree in Fig. 14. Note that, this is a one-time setup cost, as the process is only run when initializing the system, and has no effect on run-time performance. In the worst case, the process takes minutes for larger-granularity grids.

8 RELATED WORK

Location Privacy. Early works on location data privacy pivoted around the k-anonymity [25] model. The main idea is to hide users' location among at least k-1 other users to protect user privacy. A preliminary approach to achieve k-anonymity

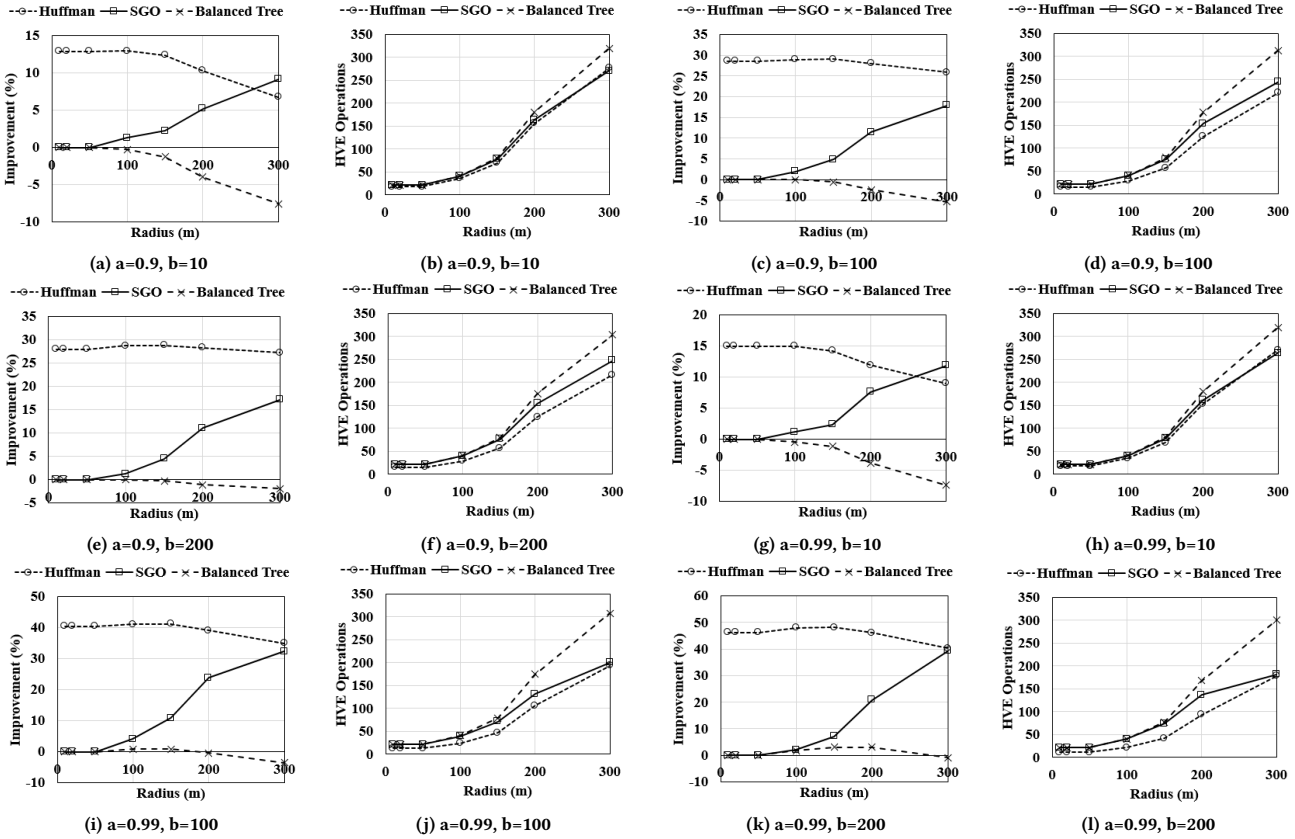

Figure 10: Performance evaluation on synthetic dataset.

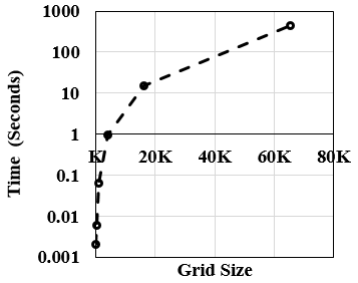

Figure 14: System Initialization Time

was focused on the generation dummy (fake) locations for data points [18]. Unfortunately, dummy generation algorithms are shown to be susceptible to inference attacks [22].

An alternative proposed method to achieve k-anonymity has been focused on the concept of *Cloaking Regions (CRs)* [15]. Most approaches in this category take advantage of a trusted anonymizer to generate a cluster of k user locations and query the area locations are enclosed by, achieving k-anonymity [13, 17, 20]. Approaches based on CRs are effective in a single snapshot [17]; however, once users are considered in trajectories, requiring continuous queries, privacy concerns are posed on the system by inference attacks. Moreover, large CRs are needed in trajectories, significantly reducing the utility of data [9] as well as posing privacy risks due to inference attacks. The authors in [12, 16]

aim at providing privacy by distinguishing between sensitive and non-sensitive locations based on user preferences.

Searchable Encryption The main motivation behind searchable encryption techniques is outsourcing the data management to a third party, such as cloud providers without the third party learning about data or queried information by users. The use of a searchable encryption was initially proposed in [24] for a secure cryptographic search of keywords. The approach supports comparison queries [4] as well as subset queries and conjunctions of equality [5]. The concept of HVE used in this paper was first proposed in [5] and later extended in [3]. The authors in [14] proposed the use of HVE to guarantee user privacy in location-based alert systems. Despite promising results of the approach, a major challenge is reducing the computation complexity of HVE at the server where the matching process is conducted. The work in [23] represents the current state-of-the art in location-based alerts with searchable encryption, and it takes into account probabilities of cells being part of an alert zone. A graph embedding technique is used to assign codes to cells in a manner that is aware of their likelihood of becoming alerted. The approach achieves significant improvement in performance compared to [14]. However, as our experimental evaluation shows, such improvements are reached only when a relatively large number of alert cells are part of an alert zone. For alert zones with few cells, our approach clearly outperforms that of [23].

9 CONCLUSIONS AND FUTURE WORK

We proposed a technique for secure location-based alerts that uses searchable encryption in conjunction with variable-length location encoding. Specifically, using Huffman compression codes, we showed that it is possible to significantly reduce the overhead of searchable encryption for cases where alert zones are compact and sparse, which is the case we believe to be most likely in practice. Extensive analytical and empirical evaluation results prove that our proposed approach significantly outperforms existing fixed-length encoding techniques, with only a small overhead in terms of additional encryption time.

In some cases, our approach may be limited by the lack of a systematic way of obtaining the probability values for various data domain regions. While having accurate probabilities is a plus, we do not require high accuracy in the actual values. In fact, in our design it is often the relative ordering of the probabilities that matters, and not necessarily the exact values. In practice, one can produce a relatively stable and representative ordering of types of features based on their popularity. Even without precise probability values, one can still obtain significant gains.

In future work, we plan to investigate more advanced stochastic models that capture correlations between cells in an alert zone, as well as cases when the alert zone evolution over time can be estimated by a spread model (e.g., a chemical gas leak). Significant performance gains can be achieved in such scenarios. One possibility is to model the space and time based on a Markov model. For a grid with n cells, the model would consist of 2^n states, each representing a unique subset of grid cells. Next, one can determine a stationary distribution of probabilities over cells, and derive the values required to reach equilibrium.

Finally, while our work focuses on location data, our design can be extended to benefit other types of data as well. Our assumed semantics for ciphertext processing is that of range queries, and numerous other data types can benefit from secure range queries. However, one has to devise specific encodings and optimizations for each type of data, as straightforward application of HVE to generic data types may lead to high performance overhead, as illustrated in our earlier work [14].

ABSTRACT

This paper proposes a system, entitled Concealer that allows sharing time-varying spatial data (*e.g.*, as produced by sensors) in encrypted form to an untrusted third-party service provider to provide location-based applications (involving aggregation queries over selected regions over time windows) to users. Concealer exploits carefully selected encryption techniques to use indexes supported by database systems and combines ways to add fake tuples in order to realize an efficient system that protects against leakage based on output-size. Thus, the design of Concealer overcomes two limitations of existing symmetric searchable encryption (SSE) techniques: (*i*) it avoids the need of specialized data structures that limit usability/practicality of SSE in large scale deployments, and (*ii*) it avoids information leakages based on the output-size, which may leak data distributions. Experimental results validate the efficiency of the proposed algorithms over a spatial time-series dataset (collected from a smart space) and TPC-H datasets, each of 136 Million rows, the size of which prior approaches have not scaled to.

1 INTRODUCTION

We consider the problem wherein trusted data producers ($\mathcal{DP}$) share users' spatial time-series data in the encrypted form with untrusted service providers ($\mathcal{SP}$) to empower $\mathcal{SP}$ to build value-added applications for users. Examples include a cellular company sharing data about the cell tower a user's mobile phone is connected to, or an organization/university providing WiFi connectivity data about the access point a user's device is connected to, for applications such as building dynamic occupancy maps [1]. We classify applications supported by $\mathcal{SP}$ using user's data into two classes, as follows:

(1) **Aggregate Applications** that aggregate data of multiple users to build novel applications. Examples include occupancy of different regions, heat maps, and count of distinct visitors to a given region over a period of time. Such applications are already supported by several service providers, *e.g.*, Google Maps supports information about busy-status and wait times at stores such as restaurants and shopping malls.

(2) **Individualized Applications** that allow users to ask queries based on their own past movements, *e.g.*, locations a person spent the most time during a given time interval, finding the number of people came in contact with, and/or other aggregate operations on user's data. Such applications can be useful for several contexts including exposure tracing in the context of infectious diseases [37].

Implementing applications at the (untrusted) $\mathcal{SP}$ requires: (*i*) $\mathcal{DP}$ to appropriately encrypt data prior to sharing with $\mathcal{SP}$, (*ii*) $\mathcal{SP}$ to be able to execute queries on behalf of the user over the encrypted data, and (*iii*) the user to be able to decrypt the encrypted answers returned by *SP*. Realizing such a data-sharing architecture leads to the following three requirements, (of which the first two are relatively straightforward, while the third requires a careful design of a new cryptographic technique that this paper focuses on):

R1: Query formulation by the user. Given that data is encrypted by $\mathcal{DP}$ and is hosted at $\mathcal{SP}$, the user needs to formulate the query to enable $\mathcal{SP}$ to execute it over encrypted data. The users can formulate an appropriate encrypted query, if they know the key used for encryption by $\mathcal{DP}$. However, $\mathcal{DP}$ cannot share the key with users to prevent them from decrypting the entire dataset. A trivial way to overcome this problem is to involve $\mathcal{DP}$ in processing queries. Particularly, a user can submit queries to $\mathcal{DP}$ that converts the query into appropriate trapdoors to be executed on encrypted data at $\mathcal{SP}$, fetches the partial results from $\mathcal{SP}$, and processes the fetched rows, before producing the final answer to users. Such an architecture incurs significant overhead at $\mathcal{DP}$ and requires $\mathcal{DP}$ to mediate each user query, (pushing $\mathcal{DP}$ to act as a surrogate $\mathcal{SP}$). Thus, ***the first requirement is how users can formulate appropriate encrypted queries without involving $\mathcal{DP}$ in query processing.***

We can overcome this requirement *trivially* by using secure hardware (*e.g.*, Intel Software Guard eXtensions[1] (SGX) [9]) at $\mathcal{SP}$ that works as a trusted agent of $\mathcal{DP}$. SGX receives queries encrypted using the public key of SGX (which we assume to known to all) from users, decrypts the query, converts the query into appropriate secure trapdoors, and provides the answer.

R2: Preventing $\mathcal{SP}$ from impersonating a user. Since we do not wish to involve $\mathcal{DP}$ during query processing, all users ask queries directly to $\mathcal{SP}$. Such query representations should not empower $\mathcal{SP}$ to mimic/masquerade as a legitimate user to gain access to the cleartext data from the answers to the query. Thus, ***the second requirement is how will the system prevent $\mathcal{SP}$ to mimic as a user and execute a query.***

We overcome this requirement *trivially* by building a list of *registered users*, who are allowed to execute queries on the encrypted data (after a negotiation between users and $\mathcal{DP}$) at $\mathcal{DP}$ and provides it in encrypted form to $\mathcal{SP}$. The registry contains credential information (*e.g.*, public/private key and authentication information of users) about the users who are interested

[1] Recent Intel CPUs introduced SGX that allows us to create a small trusted execution environment, called *enclave* that is isolated and protected from the rest of the system. SGX protects computations from the operating system (controlled by the third-party) and from numerous applications/system-level attacks. Unfortunately, existing implementations of SGX are prone to side-channel attacks that exploit one of the microarchitectural components of CPUs, *e.g.*, cache-lines, branch execution, page-table access [20, 39, 40], and power attacks. Nevertheless, systems T-SGX [34] and Sanctum [10] have evolved to overcome such attacks, and it is believed that future versions of SGX will be resilient to those attacks.

Techniques	Frequent and fast insertion	Fast query execution	DBMS supported index	Preventing attacks		
				Data distribution	Output-size	Access-patterns
DET (Always Encrypt [3])	1	1	Yes	No	No	No
NDET (Arx [32] or Always Encrypt [3])	2	2 or 3	Yes	Yes	No	No
Indexable-SSE (PB [22]- or IB [23]-Tree)	4	2	No*	No	No	No
Indexable-SSE with ORAM (Blind Seer [30])	4	4	No*	No	No	Yes
Non-indexable-SSE [11, 35]	2	4	No	No	No	No
SGX system (Opaque [42])	2	3	No	No	No	No
MPC or SS (Jana [4])	4	4	No	Yes	No	Yes
Concealer	1	1	Yes	Yes	Yes	Yes (partial)

Table 1: Comparing different techniques vs Concealer. Note: 1: Very fast, 2: Fast, 3: Slow. 4: Very slow. ∗: Indexable SSEs build their own indexes and their index traversal techniques are not in-built in existing commercial DBMS.

in $\mathcal{SP}$ applications. Thus, before generating any trapdoor by SGX, it first authenticates the user and provides the final answers encrypted using the public key of the user.

R3: Selecting the appropriate encryption technique. Spatial time-series data brings in new challenges (as compared to other datasets) in terms of a large-amount of the dataset and dynamically arriving data. Also, spatial time-series data show new opportunities in terms of limited types of queries (*i.e.*, not involving complex operations such as join and nested queries). Particularly, the data encryption and storage must sustain the data generation rate, *i.e.*, the encryption mechanism must support dynamic insertion without the high overhead. Further, cryptographic query execution time should scale to millions of records. Finally, the system must support strong security properties such that the ciphertext representation and query execution do not reveal information about the data to $\mathcal{SP}$. Note that ciphertext representation leaks data distribution only when deterministic encryption (DET) is used. Query execution leaks information about data due to search- and access-patterns leakages, and volume/output-size leakage. In §1.1, we discuss these leakages and argue that none of the existing cryptographic query processing techniques satisfy all the above requirements. Thus, ***the third requirement is how to design a system that has efficient data encryption and query execution techniques, and not prone to such leakages.***

Concealer. We design, develop, and implement a secure spatial time-series database, entitled Concealer. This paper focuses on how Concealer addresses the above-mentioned third requirement, and below, we briefly discuss the proposed solution to the requirement R3. Concealer is carefully designed to support a high rate of data arrival, and large data sets, but it only supports a limited nature of spatial time-series queries required by the domain of interest. To a degree, Concealer can be considered more of a vertical technology compared to general-purpose horizontal solutions, which as will be discussed in §1.1, lack the ability to support application/data that motivates Concealer.

Concealer, for fast data encryption and minimum cryptographic overheads on each tuple, uses a variant of deterministic encryption that produces secure ciphertext (that does not reveal data distribution) and is fast enough to encrypt tuples (≈37,185 tuples/min). Further, Concealer exploits the index supported by MySQL. Note that we do not use any specialized index (*e.g.*, PB-tree [22] and IB-Tree [23]) and do not require to build the entire index for each insertion at the trusted side. Since Concealer users an index supported by DBMS, it supports efficient query execution. For a point query on 136M rows, Concealer needs at most 0.9s. Thus, our implementation of DET and the use of indexes supported by DBMS satisfy the requirements of fast data insertion and fast query execution.

To address the security challenge during query execution, Concealer (*i*) prevents output-size by fixing the unit of data retrieval of the form of bins, formed over the tuples of a given time period; care is taken to ensure that each bin must be of identical size (by implementing a variant of bin-packing algorithm [8]), and (*ii*) hides *partial* access-patterns, due to retrieving a fixed bin having different tuples corresponding to different sensor readings (with different location/time/other values) for any query corresponding to the element of the bin. That means the adversary observes: which fixed tuples are fetched for a set of queries including the real query posed by the user. However, the adversary cannot find which of the fetched tuples satisfy the user query. Since our focus is on practical system implementation, we relax the complete access-pattern hiding requirements. The exact security offered by Concealer will be discussed in §7.

Since we fetch a bin of several tuples, to filter the useless tuples that do not meet the query predicates, SGX at $\mathcal{SP}$ filters them, (while also hides complete access-patterns inside SGX by performing oblivious operations). Further, to verify the integrity of the data before producing the answer, Concealer provides a *non-mandatory* hash-chain-based verification.

Evaluation. We evaluate Concealer on a real WiFi dataset collected from at UCI. To evaluate its scalability, we executed the algorithms on 136M rows, the size that previous existing cryptographic techniques cannot support. We also compare Concealer against SGX-based Opaque [42]. To the best of our knowledge, there is no system that supports identical security properties (hiding output-size and hiding partial access-patterns, while supporting indexes for efficient processing). Our algorithms can be used to deal with non-time-series datasets also; thus, to evaluate algorithms' practicality, we evaluate aggregation queries on 136M rows LineItem table of TPC-H benchmark.

1.1 Comparison & Advantages of Concealer

We discuss common leakages from cryptographic solutions, argue that they do not satisfy the requirements of fast data insertion, fast query execution, and/or security against information leakages (see Table 1 for a comparison).

Leakages. Cryptographic techniques show following leakages:

(1) *Data distribution leakage from the storage [7]*: allows an adversary to learn the frequency-count of each value by just observing ciphertext. DET reveals such information.

(2) *Search- and access-patterns leakages [7, 16]*: occur during query execution. Search-pattern leakages allow an adversary to learn if and when a query is executed, while access-patterns leakage allows learning which tuples are retrieved (by observing the (physical) address/location of encrypted tuples) to answer a query. Practical techniques (*e.g.*, order-preserving encryption (OPE) [2], DET, symmetric searchable encryption (SSE) [22, 23], and secure hardware-based techniques [3, 33, 42]) reveal access-patterns. In contrast, non-efficient techniques (*e.g.*, secret-sharing [4, 6] or oblivious RAM (ORAM) based techniques) hide access-patterns.

(3) *Volume/output-size leakage [7]*: allows an adversary (having some background knowledge) can deduce the data by simply observing the size of outputs (or the number of qualifying tuples). [7, 16, 26] showed that output-size may also leak data distribution. *Access-patterns revealing techniques implicitly disclose the output-size.* Moreover, the seminal work [19] showed that the output-size revealed even due to access-pattern hiding techniques enables the attacker to reconstruct the dataset. A possible solution is adding fake tuples with the real data, thereby each value has

an identical number of tuples and using indexable SSEs. However, [26] showed that it will be even more expensive than simply scanning the entire database in SGX (or download the data at $\mathcal{DP}$ to execute the query locally). Existing output-size preventing solutions, *e.g.*, Kamara et al. [18] or Patel et al. [31], suffer from one major problem: [18] fetches $\alpha \times max$, $\alpha > 2$, rows, while [31] fetches $2 \times max$ rows with additional secure storage of some rows (which is the function of DB size), where max is the maximum number of rows a value can have. Thus, both [18] and [31] fetch more than the desired rows, *i.e.*, max. Moreover, both [18] and [31] cannot deal with dynamic data.

Existing techniques in terms of data insertion, query execution, and leakages. Existing encrypted search techniques differ in their support for dynamic data, efficient query execution, and offered security properties. For instance, DET supports very efficient insertion and query processing, while its ciphertext data leaks data distribution.

Non-indexable techniques/systems (*e.g.*, SSE [11, 35], secret-sharing (SS) [4, 6], secure hardware-based systems [42]) allow fast data insertions by just encrypting the data, but have inefficient query response time, due to unavailability of an index, and hence, reading the entire data. SS hides search- and access-patterns, while others reveal. Moreover, all such techniques are prone to output-size leakage.

In contrast, indexable techniques/systems (*e.g.*, indexable SSEs (such as PB-Tree [22], IB-Tree [23]) and secure hardware-based index [25]) have faster query execution, but show slow data insertion rate, due to building the entire index at the trusted side for each data insertion; *e.g.*, [30] showed that creating a secure index over 100M rows took more than 1 hour. Moreover, these indexable techniques use ***specialized indexes*** that require specialized encryption and tree traversal protocols that are not supported in the existing standard database systems. This, in turn, limits their usability in dealing with large-scale time-series datasets. All such indexable solutions reveal output-size. While indexable solutions mixed with ORAM (*e.g.*, [30]) hide search- and access-patterns, they are not efficient for query processing (due to several rounds of interaction between the data owner and the server to answer a query). In summary, spatial time-series data adds complexity since (*i*) it can be very large, and (*ii*) arrives dynamically (possibly a high velocity). Existing techniques, as discussed above, are not suitable to support secure data processing over such data.

Advantages of Concealer. (*i*) *Frequent data insert.* We deal with frequent bulk data insertions (which is a requirement of spatial time-series datasets). (*ii*) *Deal with large-size data.* We handle large-sized data with several attributes and large-sized domain efficiently, as our experimental results will show in §8. (*iii*) *Output-size prevention.* While Concealer satisfies the standard security notion (supported by existing SSEs), *i.e.*, indistinguishability under chosen keyword attacks (IND-CKA) [11], it also prevents output-size attacks, unlike IND-CKA. (*iv*) *Oblivious processing in SGX.* As we use the current SGX architecture, suffering from side-channel attacks (*e.g.*, cache-line, branch shadow, and page-fault attack [20, 39, 40]) that enable the adversary to deduce information based on access-patterns in SGX. Thus, we incorporate techniques to deal with these attacks.

1.2 Scoping the Problem

There are other aspects, for them either solutions exist or this paper does not deal with them, as: (*i*) *Key management.* We do not focus on building/improving key infrastructure for public/private keys, as well as, key generation and sharing between

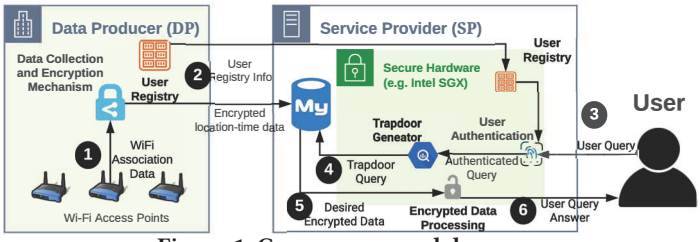

Figure 1: Concealer model.

SGX and $\mathcal{DP}$. Further, changing the keys of encrypted data and re-encrypting the data is out of the scope of this paper, though one may use the recent approach [17] to do so. Also, we do not focus on SGX remote attestation. (*ii*) *Man-in-the-middle (MiM) or replay attacks.* There could be a possibility of MiM and replay attacks on SGX during attestation and query execution. We do not deal with both issues, and techniques [13] can be used to avoid such attacks. (*iii*) *Inference from the number of rows.* Since we send data in epochs, different numbers of tuples in different epochs (*e.g.*, epochs for day vs night time) may reveal information about the user. This can be prevented by sending the same number of rows in each epoch (equals to the maximum rows in any epoch). The current implementation of Concealer does not deal with this issue. (*iv*) *Inference from occupancy count.* Occupancy information mixed with background knowledge reveals the presence/absence of a person at a location (*e.g.*, offices). We do not deal with these inferences, and differential privacy techniques mixed with SGX [41] can be used to deal with such issues.

2 CONCEALER OVERVIEW

This section provides an overview of entities involved in Concealer and its architecture with an overview of algorithms.

2.1 Entities and Assumptions

Concealer consists of the following three entities:

- **Data provider $\mathcal{DP}$:** is a trusted entity that collects user's spatial time-series data as part of its regular operation (*e.g.*, providing cellular service to users). $\mathcal{DP}$ shares such data in encrypted form with service providers $\mathcal{SP}$. $\mathcal{DP}$, also, maintains a *registry*, one per $\mathcal{SP}$, that contains a list of identification information of users, who have registered to use the application provided by the corresponding $\mathcal{SP}$ (*i.e.*, can run queries at that $\mathcal{SP}$). As will be clear, this registry helps to restrict the users to request individualized applications about other users.
- **Service provider $\mathcal{SP}$:** is an untrusted entity that develops location-based applications (as mentioned in §1) over encrypted data. To do so, $\mathcal{SP}$ hosts secure hardware, SGX, that works as a trusted agent of $\mathcal{DP}$.[2] SGX and $\mathcal{DP}$ share a secret key s_k (used for encryption/ decryption of data), and the key s_k is unknown to all other entities.

  An untrusted $\mathcal{SP}$ may try to learn user's data passively by either observing the data retrieved by SGX or exploiting side-channel attacks on SGX during query execution. $\mathcal{SP}$ may, further, learn user's data by actively injecting the fake data into the database and then observing the corresponding ciphertext and query access-patterns. We assume that $\mathcal{SP}$ knows background information, *e.g.*, metadata, the schema of the relation, the number of tuples, and the domain of attributes. However, the adversarial $\mathcal{SP}$ cannot alter anything within the secure hardware and cannot decrypt the data, due to the unavailability of the encryption key. Such assumptions are similar to those considered in the past

[2] The assumption of secure hardware at untrusted third-party machines is consistent with emerging system architectures; *e.g.*, Intel machines are equipped with SGX (see https://newsroom.intel.com/newsroom/wp-content/uploads/sites/11/2017/09/8th-gen-intel-core-product-brief.pdf).

work related to SGX-based computation [33, 42], work on attacks based on background knowledge in [19, 27].

- **User or data consumer $\mathcal{U}$:** that uses the services of $\mathcal{DP}$ (such as cellular or WiFi connectivity) and queries to $\mathcal{SP}$. We assume that $\mathcal{U}$ have their public and private keys, which are used to authenticate $\mathcal{U}$ at $\mathcal{SP}$ (via SGX against registry). As mentioned in §1, $\mathcal{U}$ can request both aggregate and individualized queries. While $\mathcal{U}$ is trusted with the data that corresponds to themselves, they are not trusted with data belonging to other users. Finally, we assume that while $\mathcal{U}$ can execute the aggregation queries, they do not collude with $\mathcal{SP}$, *i.e.*, they do not share cleartext results of any query with $\mathcal{SP}$.

2.2 Architecture

Concealer (Figure 1) consists of the following phases:

Phase 0: *Preliminary step: Announcement of $\mathcal{SP}$ by $\mathcal{DP}$.* As a new $\mathcal{SP}$ is added into the system, $\mathcal{DP}$ announces about the $\mathcal{SP}$ to all their users. Only interested users inform to $\mathcal{DP}$ if they want to use $\mathcal{SP}$'s application. Information of such users, their device-ids, and authentication information is stored by $\mathcal{DP}$ in the registry.

Phase 1: *Data upload by $\mathcal{DP}$.* $\mathcal{DP}$ collects spatial time-series data of the form $\langle l_i, t_i, o_i \rangle$ (❶), where l_i is the location, t_i is the time, and o_i is the observed value at l_i and t_i. For instance, in the case of WiFi data, the location may correspond to the region covered by a specific WiFi access-point, and the observation corresponds to a particular device-id connected to that access-point at a given time. $\mathcal{DP}$ encrypts the data using the mechanism given in §3 and provides the encrypted data to $\mathcal{SP}$ (❷) along with encrypted registry and verifiable tags (to verify the data integrity at $\mathcal{SP}$ by SGX).

Concealer considers the data as a relation R with three attributes: $\mathcal{T}$ (time), $\mathcal{L}$ (location), and $\mathcal{O}$ (observation). Table 2a shows an example of the cleartext spatial time-series data, (which will be used in this paper to explain Concealer). In Table 2a, we have added a row-id r_i ($1 \leq i \leq 6$) to refer to individual rows of Table 2a. Table 2c shows an example of the encrypted spatial time-series data as the output of Concealer.

Phase 2: *Query generation at $\mathcal{U}$.* A query $Q = \langle qa, att \rangle$, where qa is an aggregation (count, maximum, minimum, top-k, and average) or selection operation for a given condition, and att is a set of attributes with predicates on which query will be executed, is submitted to $\mathcal{SP}$ (❸). qa is always encrypted to prevent $\mathcal{SP}$ to know the query values.

Phase 3: *Query processing at $\mathcal{SP}$.* $\mathcal{SP}$ holds encrypted spatial time-series dataset and the user query (submitted to the secure hardware SGX). SGX, first, authenticate the user, and then, translates the query into a set of appropriate secured query trapdoors to fetch the tuples from the databases (❹). Note that since the individualized application is executed for the user itself, trapdoors are only generated if the authentication process succeeds to find that the user is wishing to know his past behavior.

The trapdoors are generated by using the methods of §4 for point queries or of §5 for range queries. On receiving encrypted tuples from the database (❺), the secure hardware, first, *optionally* checks their integrity using verifiable tags, and if find they have not tampered, decrypts them (if necessary), obliviously processes them, and produces the final answer to users (❻).

Phase 4: *Answer decryption at $\mathcal{U}$.* On receiving the answer, $\mathcal{U}$ decrypts them.

2.3 Algorithm Overview

Before going into details of Concealer's data encryption and query execution algorithms, we, first, provide their overview.

Data encryption method at $\mathcal{DP}$: partitions the time into slots, called *epochs*, and for each epoch, it executes the encryption method that consists of the following three stages:

Stage 1: *Setup.* Assume that we want to deal with two attributes (A and B), (*e.g.*, location and time). This stage: (*i*) creates a grid of size, say $x \times y$, (*ii*) sub-partitions the time into y subintervals, *e.g.*, for an epoch of 9-10am, creates y subintervals as: 9:00-9:10, 9:11-9:20, and so on, and (*iii*) using a hash function, say $\mathbb{H}$, allocates x values of A attributes over x columns, allocates y values (or y subintervals) of B attribute to y rows, and allocates some ***cell-ids*** $< x \times y$ (each with their ***counters*** initialized to zero) over the grid cells. (Such grid-creation steps can be used for more than two columns trivially and extended for non-time-series dataset.)

Stage 2: *Encryption:* In this stage, each sensor reading is encrypted and a *verifiable tag* is produced for integrity verification, as: (*i*) a tuple t_i is allocated to a grid cell corresponding to its desired column (*e.g.*, location and time) values using a *hash function*, the counter value of the cell-id is increased by one and attached with the tuples, and the tuples is encrypted to produce secure ciphertext with the encrypted counter value as a new attribute value, (*ii*) a hash-chain is created over the encrypted tuple values of the same cell-id for integrity verification (and verify false data injection or data deletion by $\mathcal{SP}$, and (*iii*) encrypted fake tuples are added (to prevent output-size leakage at $\mathcal{SP}$).

Stage 3: *Sharing:* This stage sends encrypted real and fake tuples with encrypted verifiable tags and encrypted cell-id, counter information to $\mathcal{SP}$.

Example. Table 2a shows six cleartext rows of an epoch. A 2×2 grid with three cell-ids cid_1, cid_2, and cid_3 is shown in Table 2b. Six cleartext rows are distributed over different cells of the grid. Table 2c shows the output of the encryption algorithm with fake tuples to prevent the output-size attack at $\mathcal{SP}$ and an index column created over the cell-ids. Encrypted Table 2c with counters and cell-ids (written below Table 2b) in encrypted form is given to $\mathcal{SP}$. ***Details of the encryption method and example will be given in §3.***■

Data insertion into DBMS at $\mathcal{SP}$: On receiving encrypted data from $\mathcal{DP}$, $\mathcal{SP}$ inserts the data into DBMS that creates/modifies the *index based on the counters* associated with each tuple.

Query execution at $\mathcal{SP}$: As a pre-processing phase, the enclave at $\mathcal{SP}$, first, authenticates the user, as mentioned in Phase 3 of §2.3, and then, executes the query, as follows:

Point queries. Consider a query on a location l and time t. For answering this, the enclave at $\mathcal{SP}$ executes the following steps:

(i) first execute the hash function $\mathbb{H}$ on query predicate l and t to know the cell-id, say cid_z, that was allocated by $\mathcal{DP}$ to l and t, (ii) using the information of cell-id and counter information, which was sent by $\mathcal{DP}$, create *static bins of a fixed size* (to prevent output-size leakage), (iii) among the created bins, find a bin, say B_i that has the cell-id cid_z that was obtained in the first step above, and (iv) fetch data from DBMS corresponding to the bin B_i, and (v) verify the integrity of data (if needed), *obliviously* process the data against query predicate in the enclave, and decrypt only the desired data.

Range queries. A range query, of course, can be executed by using the above point query method by converting the range query into several point queries, but will incur the overhead. To avoid the overhead of several point queries, we create static bins of fixed size over the fixed-sized groups of subintervals and fetch such bins to answer the query by following point queries' step (v). Following ***§3,§4,§5 will describe these algorithms in details***, and then §8 will compare these algorithms on different datasets and against different systems.

Example. Underlying DBMS at $\mathcal{SP}$ creates an index over Index column of Table 2c. SGX creates two bins over cell-ids's as $B_1 : \langle cid_1 \rangle$, $B_2 : \langle cid_2, f||1, f||2 \rangle$. Note that both bins corresponds to four rows—B_1 will fetch r_1, r_2, r_4, r_6, and B_2 will fetch $r_3, r_5, f||1, f||2$ rows. Thus, the output size will be the same. Now, consider a query $Q = \langle \text{count}, (l_2, t_5) \rangle$ over Table 2c. Here, SGX will know that it needs to fetch rows corresponding to the bin having cid_2, by generating four trapdoors: $\mathcal{E}_k(cid_2||1)$, $\mathcal{E}_k(cid_3||1)$, $\mathcal{E}_k(f||1)$, and $\mathcal{E}_k(f||2)$. Finally, based on the retrieve rows, SGX produces the final answer.■

3 DATA ENCRYPTION AT DATA PROVIDER

Concealer stores data in discredited time slots, called *epochs* or *rounds*. Epoch duration is selected based upon the latency requirements of $\mathcal{SP}$. Executing queries over multiple epochs could lead to inference attacks, and for dealing with it, we will present a method in §6. This section describes Algorithm 1, which is executed at $\mathcal{DP}$, for encrypting time-series data (assuming with three attributes location $\mathcal{L}$, time $\mathcal{T}$, and object O) belonging to one epoch. (In our experiments §8, we will consider different datasets with multiple columns.) Algorithm 1 uses deterministic encryption (DET) to support fast query execution. Since DET produces the same ciphertext for more than one occurrence of the same location and object, to ensure ciphertext indistinguishability, we concatenate each occurrence of the location and observation values with the corresponding timestamp.

In Concealer, queries retrieve a subset of tuples based on predicates specified over attributes, such as $\mathcal{L}$, O, or both. Queries, further, are always associated with ranges over time (see Table 4). Thus, to support the efficient execution of such queries, Concealer creates a cell-based index over query attributes (*e.g.*, $\mathcal{L}$ and/or O) along with time. For simplicity, Algorithm 1 illustrates how a cell-based index is created for location and time attributes, Index($\mathcal{L}, \mathcal{T}$). Similar indexes can also be created for other attributes, such as Index($O, \mathcal{T}$) and Index($\mathcal{L}, O, \mathcal{T}$). Details of Algorithm 1 is given below:

Key generation (Lines 2). Since using a single key over multiple epochs results in the identical ciphertext of a value, Concealer produces a key for encryption for each epoch, as: $k \leftarrow s_k||eid$, where s_k is the secret key shared between SGX and $\mathcal{DP}$, eid is the epoch-id (which is the starting timestamp of the epoch), and $||$ denotes concatenation. Thus, encrypting a value v using k in two different epochs will produce different ciphertexts. (Only the first eid and epoch duration is provided to SGX to generate other eids to decrypt the data during query execution.)

Algorithm 1: Data encryption algorithm.

```
Inputs: R: a relation. ℍ: a hash function. ℰ(): an encryption function. s_k: secret key.
Outputs: E(R): the encrypted relation.
1  Variables: ∀c_t ← 0, where 1 ≤ t ≤ r. x ← #ℍ(Domain(ℒ)),
     y ← #ℍ(Domain(𝒯)), cell_id[x, y] ← 0, c_tuple[u] ← 0.
2  Function key_gen(s_k) begin
3      k ← (s_k||eid)
4  Function encrypt_data(R) begin
5      for j ∈ (0, n − 1) do
6          Eo_j ← ℰ_k(o_j||t_j), El_j ← ℰ_k(l_j||t_j), Er_j ← ℰ_k(v_j||l_j||t_j)
7          Function Cell-Formation(j^th tuple) begin
8              p ← ℍ(l_j), q ← ℍ(t_j), cid_z^{p,q} ← cell_id[p, q]
9              c_t ← c_tuple[cid_z^{p,q}] ← c_tuple[cid_z^{p,q}] + 1
10             Ec_j ← E_k(cid_z^{p,q} ||c_t)
11         return E(R) ← ⟨Eo_j, El_j, Er_j, Ec_j⟩
12 Function add_fake_tuples() begin
13     for j ∈ (0, n − 1) do
14         Generate fake Eo_j, El_j, and Er_j, and Ec_j ← ℰ_k(f||j)
15         Append the j^th fake tuple to the relation E(R)
16 Function HashChain(c_tuple[u], ⟨Eo, El, Er⟩) begin
17     for j ∈ c_tuple[ ], ∀p tuples with same cell-id do
18         h_l^j ← H(El_p)||(H(El_{p−1})||(...||(H(El_2)||H(El_1))) ...)))
19         h_o^j ← H(Eo_p)||(H(Eo_{p−1})||(...||(H(Eo_2)||H(Eo_1))) ...)))
20         h_r^j ← H(Er_p)||(H(Er_{p−1})||(...||(H(Er_2)||H(Er_1))) ...)))
21         Ehl^j ← E(h_l^j), Eho^j ← E(o_l^j), Ehr^j ← E(h_r^j)
22 Function Transmit(E(R), cell_id[x, y], c_tuple[u]) begin
23     Ecell_id[x, y] ← ℰ_nd(cell_id[x, y]), Ec_tuple[u] ← ℰ_nd(c_tuple[u])
24     Permute all the tuples of the encrypted relation E(R)
25     Send E(R), Ecell_id[x, y], Ec_tuple[u], Ehl^j, Eho^j, Ehr^j
```

Tuple encryption (Lines 4-11). As the tuple arrives, it got appropriately encrypted (Line 6) using DET. Note that by encryption over the concatenated time with location and object values, results in a unique value in the entire relation. Now, in order to allocate the cell value to be used as the index, we proceed as follows: Let $|\mathcal{L}|$ be the number of locations and $|\mathcal{T}|$ be the duration of the epoch. Concealer maps the set of location $|\mathcal{L}|$ into a range of values from 1 to $x \leq |\mathcal{L}|$ using a simple hash function. It, furthermore, partitions $|\mathcal{T}|$ into $y > 1$ subintervals of duration, $|\mathcal{T}|/y$, which are then mapped using a hash function into $y > 1$ values. Thus, all tuples of the epoch are distributed randomly over the grid of $x \times y$ (see Example 3 below). Then, u cell-ids ($u < x \times y$) are allocated to grid cells. To refer to the cell-id of a cell, we use the notation $cid_z^{\{p,q\}}$ that shows that the cell $\{p, q\}$ is assigned a cell-id cid_z. In Step 3 of query execution §4.2, it will be clear that we will fetch tuples to answer any query based on cell-ids, instead of directly using query predicates.

Here, we keep two vectors: (i) *cell_id* of length $x \times y$ to keep the cell-id allocated to each cell of the grid, and (ii) *c_tuple* of length u to store the number of tuples that have been allocated the same cell-id. During processing a j^{th} tuple, we increment the current counter value of the number of tuples that have the same cell-id by one using *c_tuple*, and encrypts it. This value will be allocated to Index($\mathcal{L}, \mathcal{T}$)$\rangle$ attribute of the j^{th} (Lines 9-10).

Allocating fake tuples (Lines 12 -15). Since $\mathcal{SP}$ will read the data from DBMS into the enclave, different numbers of rows according to different queries may reveal information about the encrypted data. Thus, to fetch an equal number of rows for any query, $\mathcal{DP}$ needs to share some fake rows. There are two methods for adding the fake rows:

(i) *Equal number of real and fake rows*: This is the simplest method for adding the fake rows. Here, $\mathcal{DP}$ adds ciphertext secure fake tuples. The reason of adding the same number of real and fake rows is dependent on the property of the bin-packing algorithm,

which we will explain in §4.2 (Theorem 4.1).[3] In Index attribute, a j^{th} fake tuple contains an encrypted identifier with the tuple-id j, denoted by $\mathcal{E}_k(f||j)$, where f is an identifier (known to only $\mathcal{DP}$) to distinguish real and fake tuples.

(*ii*) *By simulating the bin-creation method*: To reduce the number of fake rows to be sent, we use this method in which $\mathcal{DP}$ simulates the bin-packing algorithm (as will be explained in §4.2) and finds the total number of fake rows required in all bins such that their sizes must be identical. Then, $\mathcal{DP}$ share such ciphertext secure fake tuples with their Index values, as in the previous method. As will be clear soon by Theorem 4.1 in §4.1, in the worst case, both the fake tuple generation methods send the same number of fake tuples, *i.e.*, an equal number of real and fake tuples.

Hash-chain creations (an optional step) Line 16-21. $\mathcal{DP}$ creates hash chains over encrypted tuples allocated the same cell-id, as follows: let p be the numbers of tuples with the same cell-ids and p encrypted location ciphertext as: $E(l_1), E(l_2), \ldots, E(l_p)$. Now, $\mathcal{DP}$ executes a hash function as follows:

$$h_{l1} \leftarrow H(E(l_1))$$
$$h_{l2} \leftarrow H(E(l_2)||h_{l1})$$
$$\ldots$$
$$h_l \leftarrow H(E(l_p)||h_{l(p-1)})$$

In the same way, hash digests for other columns are computed, and the final hash digest (*i.e.*, h_l) is encrypted that works as a verifiable tag at $\mathcal{SP}$.

Sending data (Line 22-25). Finally, $\mathcal{DP}$ permutes all encrypted tuples of the epoch to mix fake and real tuples in the relation and sends them with the two encrypted vectors *Ecell_id*[] and *Ec_tuple*[] and encrypted hash digests.[4]

Example 3. Now, we explain with the help of an example how encryption algorithm works. Consider six rows of Table 2a as the rows of an epoch, and we wish to encrypt those tuples with index on attributes $\mathcal{L}$ and $\mathcal{T}$. Assume that Algorithm 1 creates a 2×2 grid (see Table 2b) with three cell-ids: cid_1, cid_2, and cid_3. Table 2b shows two vectors *cell_id*[] and *c_tuple*[] corresponding to $\mathcal{L}$ and $\mathcal{T}$ attributes. Values in *c_tuple*[] show that the number of tuples has been allocated the same cell-id. For instance, $c\_tuple[1] = 4$ shows that four tuples are allocated the same cell-id (*i.e.*, cid_1). In Table 2b, for explanation purposes, we show which rows of Table 2a correspond to which cell; however, this information is not stored, only information of vectors *cell_id*[] and *c_tuple*[] is stored.

The complete output of Algorithm 1 is shown in Table 2c for cleartext data shown in Table 2a, where Index($\mathcal{L}, \mathcal{T}$) is the column on which DBMS creates an index. In Table 2c, $\mathcal{E}$ refers to DET, $\mathcal{E}_{nd}$ refers to a non-deterministic encryption function, and k be the key used to encrypt the data of the epoch. In addition, we create three hash chains, one hash chain per cell-id. Also, note that this example needs only 2 fake tuples to prevent output-size leakage at $\mathcal{SP}$.■

4 POINT QUERY EXECUTION

This section develops a bin-packing-based (BPB) method for executing point queries. Later, §5 will develop a method for range queries. The objectives of BPB method are twofold: first, create identical-size bins to prevent leakages due to output-size, (*i.e.*, when reading some parts of the data from disk to the enclave), and second, show that the addition of *at most n* fake tuples is enough in the worst case to prevent output-size leakage, where n is the number of real tuples. BPB method partitions the values of *c_tuple*[] into almost equal-sized bins, using which a query can be executed. Note that bins are created only once, prior to the first query execution. This section, first, presents the bin-creation method, and then, BPB query execution method.

4.1 Bin Creation

Bins are created inside the enclave using a bin-packing algorithm, after decrypting vector *Ec_tuple*[].

Bin-packing algorithms. A bin-packing algorithm places the given inputs having different sizes to bins of size at least as big as the size of the largest input, without partitioning an input, while tries to use the minimum number of bins. First-Fit Decreasing (FFD) and Best-Fit Decreasing (BFD) [8] are the most notable bin-packing algorithms and *ensure that all the bins (except only one bin) are at least half-full.*

In our context, u cell-ids ($cid_1, cid_2, \ldots, cid_u$) are inputs to a bin-packing algorithm, and the number of tuples having the same cell-id is considered as a weight of the input. Let *max* be the maximum number of tuples having the same cell-id cid_i. Thus, we create bins of size at least $|b| = max$ and execute FFD or BFD over u different cell-ids, resulting in $|Bin|$ bins as an output of the bin-packing algorithm.

The minimum number of bins. Let n be the number of real tuples sent by $\mathcal{DP}$, *i.e.*, $n = \sum_{i=1}^{i=u} c\_tuple[i]$. Let $|b|$ be the size of each bin. Thus, it is required to divide n inputs into at least $\lceil n/|b| \rceil$ bins.

Theorem 4.1. (Upper bounds on the number of bins and fake tuples) *The above bin-packing method using a bin size $|b|$ achieves the following upper bounds: the number of bins and the number of fake tuples sent by $\mathcal{DP}$ are at most $\frac{2n}{|b|}$ and at most $n + \frac{|b|}{2}$, respectively, where $n \gg |b|$ is the number of real tuples sent by $\mathcal{DP}$.*

In the full version (https://arxiv.org/abs/2102.05238), we will provide the proof of this theorem.

Equi-sized bins. The bins produced by FFD/BFD may have different numbers of tuples. Thus, we pad each bin with fake tuples, thereby all bins have $|b|$ tuples. Let $tuple_{b_i} < |b|$ be the number of tuples assigned to an i^{th} bin (denoted by b_i). Here, the ids (*i.e.*, the value of Index column) of fake tuples allocated to the bin b_i will be $|b| - tuple_{b_i}$, and all these fake tuple ids cannot be used for padding in any other bin. Thus, for padding, we create disjoint sets of fake tuple ids (see the example below to understand the reason).

Example 4.1. Assume five cell-ids $cid_1, cid_2, \ldots, cid_5$ having the following number of tuples $c\_tuple[5] = \{79, 2, 73, 7, 7\}$. Here, cid_1 has the maximum number of tuples; hence, the bin-size is at least 79. After executing FFD bin-packing algorithm, we obtain three bins, each of size 79: b_1: $\langle cid_1 \rangle$, b_2: $\langle cid_3, cid_2 \rangle$, and b_3: $\langle cid_5, cid_4 \rangle$. Here, bins b_2 and b_3 needs 4 and 65 fake tuples, respectively. One can think of sending only 65 fake tuples to access bins b_2 and b_3 to have size 79. However, in the absence of access-pattern hiding techniques, the adversary will observe that any 4 tuples out of 65 fake tuples are accessed in both bins. It will reveal that these four tuples are surely fake, and thus, the adversary may deduce that the bin size of b_2 is 75. Thus, $\mathcal{DP}$ needs to send 69 fake tuples in this example.■

4.2 Bin-Packing-based Query Execution

We develop bin-packing-based (BPB) method (see pseudocode in Algorithm 2) based on the created bins (over location and time

[3] For n real tuples, we add a little bit more than n fake tuples in the worst case (Theorem 4.1).
[4] The size of both vectors is significantly smaller (see experimental section §8.1).

Algorithm 2: Bin-packing-based query execution method.

Inputs: $\langle qa, (\mathcal{L} = l, \mathcal{T} = t)\rangle$: a query qa involving predicates over $\mathcal{L}$ and $\mathcal{T}$ attributes. $cell\_id[x, y]$, $c\_tuple[u]$, $\mathbb{H}$: A hash function, $\mathcal{E}_k()$: An encryption function using a key k.
$|Bin|$: the number of bins. $b[i][j]$: i^{th} bin having j cell-ids, where $j > 0$.
Outputs: A set of ciphertext queries.

1 **Function** *Query_Execution*$(\langle qa, (\mathcal{L} = l, \mathcal{T} = t)\rangle)$ **begin**
2 **Function** *Find_cell*(l, t) **begin**
3 $p \leftarrow \mathbb{H}(l)$, $q \leftarrow \mathbb{H}(t)$, $cid_z \leftarrow cell\_id[p, q]$
4 **return** cid_z; **break**
5 **Function** *Find_bin*$(cid_z, |Bin|, b[*][*])$ **begin**
6 **for** $desired \in (0, |Bin| - 1)$ **do**
7 **if** $cid_z \in b[desired][*]$ **then**
8 **return** $b[desired][*]$; **break**
9 **Function** *Formulate_queries*$(b[desired][*])$ **begin**
10 **for** $\forall j \in (b[desired][j])$ **do**
11 $cell\_id \leftarrow b[desired][j]$, $counter \leftarrow c\_tuple[cell\_id]$
12 $\forall counter$, generate ciphertexts $E_k(cell\_id||counter)$

attributes). A similar method can be extended for other attributes. BPB method contains the following four steps:

Step 0: Bin-creation. By following FFD or BFD as described above, this step creates bins over cell-ids ($c\_tuple[]$), if bins do not exist.

Step 1: Cell identification (Lines 2-4). The objective of this step is to find a cell of the grid corresponding to the requested location and time. A query $Q_e = \langle qa, (\mathcal{L} = l, \mathcal{T} = t)\rangle$ is submitted to the enclave that, on the query predicates l and t, applies the hash function $\mathbb{H}$, which was also used by $\mathcal{DP}$ (in *Cell-Formation* function, Line 8 of Algorithm 1). Thus, the enclave knows the cell, say $\{p, q\}$, corresponds to l and t. Based on the cell $\{p, q\}$ and using the vector $cell\_id[]$, it knows the cell-id, say cid_z, allocated to the cell $\{p, q\}$.

Step 2: Bin identification (Lines 5-8). Based on the output of Step 1, *i.e.*, the cell-id cid_z, this step finds a bin b_i that contains cid_z. Bin b_i may contain several other cell-ids along with identities of the first and the last fake tuples required for b_i.

Step 3: Query formulation (Lines 9-12). After knowing all cell-ids that are required to be fetched for bin b_i, the enclave formulates appropriate ciphertexts that are used as queries. Let the set of cell-ids in b_i be $C_1, C_2, \ldots, C_\alpha$, containing $\#_1, \#_2, \ldots, \#_\alpha$ records, respectively. Let the fake tuple range for b_i be f_l and f_h (let $\#_f = f_h - f_l$ be the number of fake tuples that have to be retrieved for b_i). The enclave generates $\#_i$ number of queries, as: $\mathcal{E}_k(C_p||j)$, where $1 \leq j \leq \#_i$ for each cell C_p corresponding to b_i and k is the key obtained by concatenating s_k and epoch-id (as mentioned in Line 2 of Algorithm 1). Also, it generates $\#_f$ fake queries, one for each of the fake tuples associated with b_i.

Advantage of cell-ids. Now, observe that a bin may contain several locations and time values (or any desired attribute value). Fetching data using cell-id does not need to maintain fine-grain information about the number of tuples per location per time.

Step 4: Integrity verification and final answers filtering. We may optionally verify the integrity of the retrieved tuples. To do so, the enclave, first, creates a hash chain over the real encrypted tuples having the same cell-id, by following the same steps as $\mathcal{DP}$ (Lines 16 of Algorithm 1). Then, compares the final hash digest with the decrypted verifiable tag, provided by $\mathcal{DP}$.

Now, to answer the query, the enclave, first, filters those tuples that do not qualify the query predicate, since all tuples of a bin may not correspond to the answer. Thus, decrypting each tuple to check against the query $Q_e = \langle qa, (\mathcal{L} = l, \mathcal{T} = t)\rangle$ may increase the computation cost. To do so, after implementing the above-mentioned Step 3, the enclave generates appropriate filter values ($\mathcal{E}_k(l_i||t_i)$ or $\mathcal{E}_k(o_i||t_i)$, which are identical to the created by $\mathcal{DP}$ using Algorithm 1); while, at the same time, DBMS executes queries on the encrypted data. On receiving encrypted tuples

```
max(int x,int y){
bool getX = ogreator(x, y),
return omove(getX, x, y)
}
```

(a) Oblivious maximum.

```
mov rcx, x
mov rdx, y
cmp rcx, rdx
setg al
retn
```

(b) Oblivious compare: `ogreator`.

```
mov rcx, cond
mov rdx, x
mov rax, y
test rcx, rcx
cmovz rax, rdx
retn
```

(c) Oblivious move: `omove`.

Figure 2: Register-oblivious operators [28].

from DBMS, the enclave performs string-matching operations using filters and decrypts only the desired tuples, if necessary.

Example 4.2. Consider the cells created in Example 3.1, *i.e.*, $cell\_id[] = cid_1, cid_2, cid_1, cid_4$ and $c\_tuple[] = \{4, 1, 1\}$. Now, assume that there are two bins, namely b_1: $\langle cid_1\rangle$ and b_2: $\langle cid_2, cid_3\rangle$. Consider a query $Q = \langle$count, $(l_2, t_5)\rangle$, *i.e.*, find the number of people at location l_2 at time t_5 on the data shown in Table 2c. Here, after implementing Step 1 and Step 2 of BPB method, the enclave knows that cell-id cid_2 satisfies the query, and hence, the tuples corresponding to bin b_2 are required to be fetched. Thus, in Step 3, the enclave generates the following four queries: $\mathcal{E}_k(cid_2||1)$, $\mathcal{E}_k(cid_3||1)$, $\mathcal{E}_k(f||1)$, and $\mathcal{E}_k(f||2)$. Finally, in Step 4, the filtering via string matching is executed over the retrieved four tuples against $\mathcal{E}_k(l_2||t_5)$. Since all the four retrieved tuples have a filter on location and time values, here is no need to decrypt the tuple that does not match the filter $\mathcal{E}_k(l_2||t_5)$.■

4.3 Oblivious Trapdoor Creation & Filtering

Steps for generating trapdoor (Step 3) and answer filtering (Step 4), in §4.2, were not oblivious due to side-channel attacks (*i.e.*, access-patterns revealed via cache-lines and branching operations) on the enclave. Thus, we describe how can the enclave produce queries and process final answers obliviously for preventing side-channel attacks.

Step 3. Let $\#_{Cmax}$ be the maximum cells required to form a bin. Let $\#_{max}$ be the maximum tuples with a cell-id. Let $\#_i$ be the number of tuples with a cell-id C_i. For a bin b_i, the enclave generates $\#_{Cmax} \times \#_{max}$ numbers of queries: $\mathcal{E}_k(C_i||j, v)$, where $1 \leq j \leq \#_{max}$, $C_i \leq \#_{Cmax}$, and $v = 1$ if $j \leq \#_i$ and C_i is required for b_i; otherwise, $v = 0$. Note that *this step produces the same number of queries for each cell and each bin.*

Let $\#_{fmax}$ be the maximum fake tuples required for a bin. Let $\#_{fb_i}$ be the maximum fake tuples required for b_i. The enclave generates $\#_{fmax}$ number of fake queries: $\mathcal{E}_k(f||j, v)$, where $1 \leq j \leq \#_{fmax}$ and $v = 1$ if $j \leq \#_{fb_i}$; otherwise, 0. This step *produces the same number of fake queries for any bin.* Finally, the enclave sorts all real and fake queries based on value v using a data-independent sorting algorithm (*e.g.*, bitonic sort [5]), such that all queries with $v = 1$ precede other queries, and sends only queries with $v = 1$ to the DBMS.

Step 4. The enclave reads all retrieved tuples and appends $v = 1$ to each tuple if they satisfy the query/filter; otherwise, $v = 0$. Particularly, an i^{th} tuple is checked against each filter, and once it matches one of the filters, $v = 1$ remains unchanged; while the value of $v = 1$ is overwritten for remaining filters checking on the i^{th} tuple. It hides that which filter has matched against a tuple. Then, based on v-value, it sorts all tuples using a data-independent algorithm.[5] (After this all tuples with $v = 1$ are decrypted and checked against the query by following the same procedure, if needed.)

Branch-oblivious computation. Note that after either generating an equal number of queries for any bin or filtering the retrieved tuples using a data-oblivious sort, the entire computation is still

[5] If all tuples can reside in the enclave, then bitonic sort is enough. Otherwise, to obliviously sort the tuples, we use column sort [21] instead of the standard external merge sort.

T_4	$cid_1^{\{1,1\}} = 40$	$cid_6^{\{1,2\}} = 30$	$cid_7^{\{1,2\}} = 2$	$cid_{11}^{\{1,4\}} = 9$
T_3	$cid_2^{\{2,1\}} = 50$	$cid_7^{\{2,2\}} = 50$	$cid_6^{\{2,3\}} = 21$	$cid_9^{\{2,4\}} = 60$
T_2	$cid_3^{\{3,1\}} = 60$	$cid_{11}^{\{3,2\}} = 40$	$cid_4^{\{3,3\}} = 45$	$cid_8^{\{3,4\}} = 48$
T_1	$cid_3^{\{4,1\}} = 40$	$cid_{10}^{\{4,2\}} = 50$	$cid_{10}^{\{4,3\}} = 10$	$cid_5^{\{4,4\}} = 50$
	l_1	l_2	l_3	l_4

Table 3: A 4×4 grid.

vulnerable to an adversary that can observe conditional branches, *i.e.*, an if-else statement used in the comparison. To overcome such an attack, we use the idea proposed by [28] that suggested that any computation on registers cannot be observed by an adversary since register contents are not accessible to any code outside of the enclave; thus, register-to-register computation is oblivious. For this, [28] provided two operators: `omove` and `ogreater`, see Figure 2. For any comparison in the enclave, we use these two operators; readers may find additional details in [28].

5 RANGE QUERY EXECUTION

This section develops an algorithm for executing range queries, by modifying BPB method, given in §4.2. For simplicity, we consider a range condition on time attribute. For illustration purposes, this section uses a 4×4 grid (see Table 3, which was created by $\mathcal{DP}$ using Algorithm 1, §3) corresponding to location and time attributes of a relation. In this grid, 11 cell-ids are used, and a number in a cell shows the number of tuples allocated to the cell. The notation T_i shows an i^{th} sub-time interval (after creating a grid using Algorithm 1 §3).

5.1 Enhanced Bin-Packing-Based (eBPB) Method

eBPB method requires $\mathcal{DP}$ to send the number of tuples in each cell of the grid with the vector *cell_id*[]. Thus, it avoids sending the vector *c_tuple*[]. For example, for the grid shown in Table 3, *cell_id*$[4,4] = \{(1,40),(6,30),(7,2),(11,9),(2,50),(7,50),(6,21),(9,60),(3,60),(11,40),(4,45),(8,48),(3,40),(10,50),(10,10),(5,50)\}$. This information helps us in creating bins more efficiently for a range query, as follows:

Step 1: Preliminary step. The enclave decrypts the encrypted vector *Ecell_id*[].

Step 2: Finding top-ℓ cell-ids. Find top-ℓ cells having the maximum number of tuples in one of the locations, where ℓ is the number of cells required to answer the range query. Say, location l_i has top-ℓ cells that have the maximum number of tuples, denoted by *bsize* tuples.

Step 3: Create bins. Execute this step either if ℓ cells required for the current query are more than the cells required for any previously executed query or it is the first query. Fix the bin size to *bsize* and execute FFD that takes $cid_z^{\{p,q\}}$ as inputs and the number of tuples having $cid_z^{\{p,q\}}$ as the weight of the input. If the bin does not have *bsize* number of tuples, add fake tuples to the bin. It results in $|Bin|$ number of bins and then, use all such bins for answering any range covered by ℓ cells.

Step 4: Query formulation and final answers filtering. Find the desired bin satisfying the range query and formulate appropriate queries, as we formed in Step 3 of BPB method §4.2. The DBMS executes all queries and provides the desired tuples to the enclave. The enclave executes the final processing of the query, likewise Step 4 of BPB method §4.2. *Note that for oblivious query formulation and result filtering, we use the same method as described in §4.3.*

Example 5.1.1. Consider a query to count the number of tuples at the location l_1 during a given time interval that is covered by T_2 to T_4. This query spans over three cells; see Table 3. Here, the maximum number of tuples in any three cells at locations l_1, l_2, l_3, and l_4 are $60+50+40 = 150$, $50+50+40 = 140$, $45+21+5 = 71$, and $60+50+48 = 158$, respectively. Thus, the bin of size 158 can satisfy any query that spans over any three cells (arranged in a column) of the grid. ■

Example 5.1.2: *attack on eBPB.* Consider the following queries on data shown in Table 3: (Q_1) retrieve the number of tuples having location l_1 during a given time interval that is covered by T_1 and T_2, and (Q_2) retrieve the number of tuples having location l_1 during a given time interval that is covered by T_2 and T_3. Answering Q_1 and Q_2 may reveal the number of tuples having T_1, T_2, and T_3, as: in answering Q_2 we do not retrieve 40 tuples (corresponding to $\{4,1\}$ cell) that were sent in answering Q_1 and retrieve 50 new tuples (corresponding to $\{2,1\}$ cell). It, also, reveals that 60 tuples (corresponding to $\{3,1\}$ cell) belong to T_2. Note that all such information was not revealed, prior to query execution, due to the ciphertext indistinguishable dataset.■

5.2 Highly Secured Range Query: winSecRange Method

We, briefly, explain a method to prevent the above-mentioned attacks on a range query. Particularly, we fix the length of a range, say $\lambda > 1$, and discretize n domain values, say $v_1, v_2, \ldots, v_n$, into $\lceil \frac{n}{\lambda} \rceil$ intervals (denoted by $\mathcal{I}_i$, $1 \leq i \leq \lceil \frac{n}{\lambda} \rceil$), as: $\mathcal{I}_1 = \{v_1, v_2, \ldots, v_\lambda\}$, …, $\mathcal{I}_{\lceil \frac{n}{\lambda} \rceil} = \{v_{n-\lambda}, \ldots, v_{n-1}, v_n\}$. Here, the bin size equals to the maximum number of tuples belonging to an interval, and bins are created for each interval *only once*. For example, consider 12 domain values: $v_1, v_2, \ldots v_{12}$, and $\lambda = 3$. Thus, we obtain intervals: $\mathcal{I}_1 = \{v_1, v_2, v_3\}$, $\mathcal{I}_2 = \{v_4, v_5, v_6\}$, $\mathcal{I}_3 = \{v_7, v_8, v_9\}$, and $\mathcal{I}_4 = \{v_{10}, v_{11}, v_{12}\}$. Here, four bins are created, each of size equals to the maximum number of tuples in any of the intervals. Now, we can answer a range query of length β by using one of the following methods:

(*i*) $\beta \leq \lambda$ and $\beta \in \mathcal{I}_i$: Here, the entire range exists in $\mathcal{I}_i$; hence, we retrieve only a single entire bin satisfying the range. E.g., if a range is $[v_1, v_2]$, then we need to retrieve the bin corresponding to $\mathcal{I}_1$. (*ii*) $\beta \leq \lambda$ and $\beta \in \{\mathcal{I}_i, \mathcal{I}_j\}$: It may be possible that $\beta \leq \lambda$ but the range β lies in $\mathcal{I}_i$ and $\mathcal{I}_j$, $i \neq j$. Thus, we need to retrieve two bins that cover $\mathcal{I}_i$ and $\mathcal{I}_j$, and hence, we also prevent the attack due to sliding the time window (see Example 5.1.2). E.g., if a range is $[v_2, v_4]$, then we need to retrieve the bins corresponding to $\mathcal{I}_1$ and $\mathcal{I}_2$. (*iii*) $\beta = z \times \lambda$: Here, a range may belong to at most $z+2$ intervals. Thus, we may fetch at most $z+1$ bins satisfying the query. E.g., if a range is $[v_3, v_8]$, then this range is satisfied by intervals $\mathcal{I}_1$, $\mathcal{I}_2$, and $\mathcal{I}_3$; thus, we fetch bins corresponding to $\mathcal{I}_1$, $\mathcal{I}_2$, and $\mathcal{I}_3$.

6 SUPPORTING DYNAMIC INSERTION

Dynamic insertion in Concealer is supported by batching updates into rounds/epochs, similar to [12]. Tuples inserted in an i^{th} period are said to belong to the round rd_i or epoch eid_i. The insertion algorithm is straightforward. Concealer applies Algorithm 1 on tuples of epochs prior to sending them to $\mathcal{SP}$. Note that since Algorithm 1 for distinct rounds is executed independently, the tuples corresponding to the given attribute value (*e.g.*, location-id) may be associated with different bins in different rounds. Retrieving tuples of a given attribute value across different rounds needs to be done carefully, since it might result in leakage, as shown next.

Example 6.1. Consider that the bin size is three, and we have the following four bins for each round of data insertion, where a bin b_i stores tuples of a location l_j:

Queries	Execution (filtering, decryption, and final processing) by the secure hardware
Location and time attributes	
Q1: # observations at l_i during time t_1 to t_x	SM using the filters $El_1 \leftarrow E_k(l_i \| t_1), El_2 \leftarrow \mathcal{E}_k(l_i \| t_2), \ldots, El_k \leftarrow \mathcal{E}_k(l_i \| t_x)$. No decryption needed.
Q2: Locations that have top-k observations during t_1 to t_x	SM using the filters $El_m \leftarrow \mathcal{E}_k(l_i \| t_j)$ where $i \in Domain(\mathcal{L})$ and $j \in \{t_1, t_x\}$, and then, decrypt $\mathcal{E}_k(l \| t \| o)$
Q3: Locations that have at least 10 observations during t_1 to t_x	of qualified tuples only for final processing.
Observation and time attributes	
Q4: Which locations have an observation o_i during t_1 to t_x	SM using $Eo_j \leftarrow \mathcal{E}_k(o_i \| t_j)$, $j \in \{t_1, t_x\}$, and then, decrypt $\mathcal{E}_k(l \| o \| t)$ of qualified tuples to know locations.
Observation, location, and time attributes	
Q5: # an observation o_i has happened at l_i during t_1 to t_x	SM using $Eo_j \leftarrow \mathcal{E}_k(o_i \| t_j \| l_i)$, where $j \in \{t_1, t_x\}$. No decryption needed.

Table 4: Sample queries. *Notation*: SM: String matching.

rd_1 : $b_1 : \langle l_1, l_2, l_3 \rangle$ $b_2 : \langle l_4, l_4, l_4 \rangle$ $b_3 : \langle l_5, l_5, l_5 \rangle$ $b_4 : \langle l_6, l_6, l_6 \rangle$
rd_2 : $b'_1 : \langle l_1, l_1, l_1 \rangle$ $b'_2 : \langle l_2, l_2, l_2 \rangle$ $b'_3 : \langle l_3, l_3, l_3 \rangle$ $b'_4 : \langle l_4, l_5, l_6 \rangle$

Now, answering a query for l_1 fetches bins b_1 and b'_1; a query for l_2 fetches b_1 and b'_2; and a query for l_3 fetches b_1 and b'_3. Here, b_1 is retrieved with three new bins (b'_1, b'_2, b'_3); it reveals that b_1 has three distinct locations. Similarly, b'_4 will be retrieved with three older bins (b_2, b_3, and b_4). Thus, the query execution on older and newer data reveals additional information.■

To prevent such attacks, we need to appropriately modify our query execution methods. In our technique, we will assume that bins across all rounds are of a fixed size, $|b|$,[6] and the number of tuples for a given attribute value (*i.e.*, location) fits within a bin (*i.e.*, $\leq |b|$). Our idea is inspired by Path-ORAM [36], while we overcome the limitation of Path-ORAM that achieves indistinguishability for query execution by keeping a meta-index structure at the trust entity. Note that Path-ORAM builds a binary tree index on the records. To retrieve a single record, Path-ORAM fetches $O(\log n)$ records and rewrites them under a different encryption. Since Path-ORAM uses an external data structure, it cannot be used for our purpose as argued in §1. Below, we provide our modified query execution strategy.

Executing queries. Let rd_i, rd_j, rd_k, and rd_l be four consecutive rounds of data insertion. Let q be a query that spans over rd_j, rd_k, and rd_l rounds; however, only rounds rd_j and rd_l have bins that satisfy query q. For answering q, the modified query execution method takes the following three steps: (*i*) The enclave fetches the desired bin from rd_j and rd_l rounds by following methods given in §4.2 and §5, with randomly selected $\log |Bin| - 1$ additional bins from each rd_j and rd_l round, where $|Bin|$ are created for each round using Algorithm 2. (*ii*) The enclave fetches $\log |Bin|$ bins from round rd_k, to hide the fact that rd_k does not satisfy the query. (*iii*) For round rd_x, $x \in \{j, k, l\}$, the enclave, first, permutes the retrieved data of rd_x and encrypts with a new key.[7] The newly encrypted data replaces the older data of rd_x.

Aside. We rewrite tuples of fetched bins, when asking a query for another value belonging to the previously fetched bin (*e.g.*, query for l_2 in Example 6.1). The adversary cannot link bins of different rounds of data insertion based on attribute values in bins.

7 SECURITY PROPERTIES

This section presents the desired security requirements, discusses which requirements are satisfied by Concealer, and information leakages from the algorithms. To develop applications on top of spatial time-series dataset at an untrusted $\mathcal{SP}$, a system needs to satisfy the following security properties:

Ciphertext indistinguishability: property requires that any two or more occurrences of a cleartext value look different in the ciphertext. Thus, by observing the ciphertext, an adversary cannot learn anything about encrypted data. Concealer satisfies this property by producing unique ciphertext for each tuple using Algorithm 1 (Line 7).

Data integrity: property requires that if the adversary injects any false data into the real dataset, it must be detected by a trusted entity. Concealer ensures integrity property by maintaining hash chains over the encrypted tuples and sharing encrypted verifiable tags, which helps SGX to detect any inconsistency between the actual data shared by $\mathcal{DP}$ and the data SGX accesses from the disk at $\mathcal{SP}$.

Query execution security: requires satisfying output-size prevention, indistinguishability under chosen keyword attacks (IND-CKA), and forward privacy.

Output-size prevention: property requires that the number of tuples corresponding to a value, *e.g.*, $\mathcal{L}$, (or a value corresponding to a combination of attributes, *e.g.*, $\mathcal{L}$ and $\mathcal{T}$) *i.e.*, the volume of the value, is not revealed, and only the maximum output-size/volume of the value is revealed. Concealer ensures this property by retrieving a fixed-size bin from DBMS into SGX, regardless of the query predicates.

IND-CKA. IND-CKA [11] prevents leakages other than what an adversary can gain through information about (*i*) *metadata*, *i.e.*, size of database/index, known as *setup leakage* $\mathfrak{L}_s$ in [11], and (*ii*) *query execution* that results in *query leakage* $\mathfrak{L}_q$ in [11] and includes search-patterns and access-patterns. Again, note that by revealing the access-patterns, IND-CKA is prone to attacks based on the output-size.

While Concealer leaks $\mathfrak{L}_s$ by the size of database/index and $\mathfrak{L}_q$ by fetching data in the form of a bin, it does not reveal information based on the output-size, except a constant output-size for all query predicates. (Also, since by fetching a bin, it does not reveal which rows of the bin satisfy the answer, it hides partial access-patterns.) Thus, Concealer improves the security guarantees of IND-CKA.

Forward privacy: property requires that newly inserted tuples cannot be linked to previous search queries, *i.e.*, the adversary that have collected trapdoors for previous queries, cannot use them to match newly added tuples. Concealer ensures forward privacy by, first, producing a different ciphertext of an identical value over two different epochs using two different keys (as mentioned in §3), and then, re-encrypting the tuples of different epochs using different keys during query execution spanning over multiple epochs (as mentioned in §6).

Now, we discuss information leakages from different the above-mentioned query execution methods.

BPB information leakage discussion. BPB method prevents the attacks based on output-size by fetching an identical number of tuples for answering any query. It reveals the dataset and index sizes stored in DBMS (as $\mathfrak{L}_s$ condition of IND-CKA [11]). BPB method, also, reveals *partial* access- and search-patterns, which means that for a group of queries it reveals a fixed bin of tuples, and thus, hides which of the tuples of bin satisfy a particular query ($\mathfrak{L}_q$ conditions of IND-CKA). Recall that an index, *e.g.*, B-tree index, on the desired attribute is created by the underlying DBMS. To show that the index will not lead to additional leakages other than $\mathfrak{L}_s$ and $\mathfrak{L}_q$, we follow the identical strategy to prove a technique is IND-CKA secure or not. In short, we need to show that a simulator not having the original data can also produce the

[6] We are not interested in hiding different numbers of tuples in different rounds, but using fake tuples it can be prevented, if desired.

[7] The key k for re-encryption is generated as: $k \leftarrow s_k \| eid \| counter$, where SGX maintains a counter for each round, and increments it by one whenever the data of a round is read in SGX and rewritten.

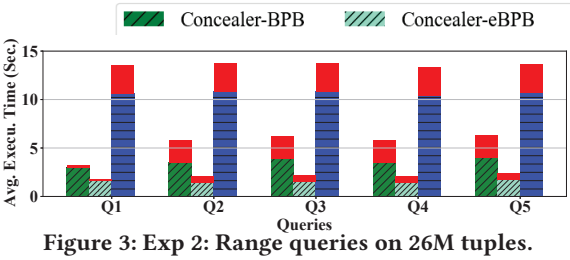

Figure 3: Exp 2: Range queries on 26M tuples.

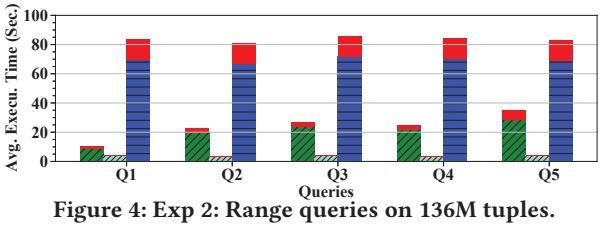

Figure 4: Exp 2: Range queries on 136M tuples.

index attribute based on $\mathfrak{L} = \{\mathfrak{L}_s, \mathfrak{L}_q\}$, *i.e.*, BPB method is secure if a "fake" attribute can mimic the real index attribute, (and hence, mimic the real index). Note that like SSEs, the simulator having only $\mathfrak{L}$ can generate a fake dataset, and hence, the index attribute can mimic the real index attribute; thus, the adversary cannot deduce additional information based on $\mathfrak{L}$.

Also, note that in oblivious Step 3, the enclave generates the same number of real/fake queries regardless of a bin and sorts them using a data-independent algorithm, which hides access-patterns in SGX. Also, it processes all retrieved tuples against the query and does oblivious sorting in Step 4. Thus, it also does not reveal access-patterns (by missing any tuple to process).

eBPB and winSecRange information leakage discussion. eBPB method incurs leakages $\mathfrak{L}_s$ and $\mathfrak{L}_q$. Based on $\mathfrak{L}_q$, we may reveal that a range query is spanning over at most ℓ cells. Hence, *it may also reveal the exact data distribution*, by fetching the same real tuple multiple times for multiple range queries, which we illustrated in Example 5.1.2. To overcome such information leakage, winSecRange fetches a fixed size interval, regardless of the query range. Thus, while winSecRange reveals $\mathfrak{L}_s$ and $\mathfrak{L}_q$, it does not reveal any information based on the output-size.

Insert operation information leakage discussion. Our insert operation satisfies forward privacy property. Since for encrypting tuples of an epoch, we generate a key that is unique among all keys generated for any epoch. Thus, based on the previous query trapdoors, the adversary cannot use them to link new tuples. Furthermore, our insert operation hides the distribution leakage due to executing queries over multiple epochs, since we fetch additional tuples from each epoch that lies in the query range and re-write all tuples.

8 EXPERIMENTAL EVALUATION

This section shows the experimental results of Concealer under various settings and compares them against prior cryptographic approaches.

8.1 Datasets, Queries, and Setup

Dataset 1: Spatial time-series data generation. To get a real spatial time-series dataset, we took our organization WiFi user connectivity dataset over 202 days having 136M(illion) rows. The IT department manages more than 2000 WiFi access-points (AP) by which they collect tuples of the form $\langle l_i, t_i, o_i \rangle$ on which they implemented Algorithm 1 prior to sending WiFi data to us. In this data, each of 2000+ APs is considered as a location. We created two types of WiFi datasets: (*i*) a small dataset of 26M WiFi connectivity rows collected over 44 days, and (*ii*) a large dataset of 136M rows (of 14GB) collected over 202 days. For Concealer Algorithm 1, which produces encrypted data as shown in Table 2c, we fixed a grid of $490 \times 16,000$ and allocated 87,000 cell-ids that resulted in two vectors *cell_id*[] and *c_tuple*[] of size 31MB. Data was encrypted using AES-256. This dataset has also skewed over the number of tuples at locations in a given time. For example, the minimum number of rows at all locations in an hour was ≈6,000, while the maximum number of rows at all locations in an hour was ≈50,000.

Dataset 2: TPC-H dataset. Since WiFi dataset has only three columns, to evaluate Concealer's practicality in other types of data with more columns, we used 136M rows of LineItem table of TPC-H benchmark. We selected nine columns (Orderkey (OK), Partkey (PK), Suppkey(SK), Linenumber (LN), Quantity, Extendedprice, Discount, Tax, Returnflag). This dataset contains large domain values, also; *e.g.*, in OK column, the domain value varies for 1 to 34M. We created (*i*) two indexes on attributes ⟨OK, LN⟩ and ⟨OK, PK, SK, LN⟩, (*ii*) two filters on concatenated values of ⟨OK, LN⟩ and ⟨OK, PK, SK, LN⟩, and (*iii*) one value that is the encryption of the concatenated values of all remaining five attributes. We used a $112,000 \times 7$ grid for index ⟨OK, LN⟩ and a $1500 \times 100 \times 10 \times 7$ grid for index ⟨OK, PK, SK, LN⟩. Each grid was allocated 87,000 cell-ids. The size of *cell_id*[] and *c_tuple*[] vectors for both grids was 54MB. Data is encrypted using Algorithm 1 and AES-256.

Queries. Table 4 lists sample queries supported by Concealer on spatial time-series data. These queries as mentioned in §2.1 provide aggregate (Q1-Q3) and individualized (Q4-Q5) applications. On TPH-C data, we executed count, sum, min/max queries.

Setup. The IT department (worked as $\mathcal{DP}$) had a machine of 16GB RAM. Our side (worked as $\mathcal{SP}$) had a 16GB RAM Intel Xeon E3 machine with Intel SGX. At $\mathcal{SP}$, MySQL is used to store data, and ≈8,000 lines of code in C is written for query execution.

We evaluate both versions of Concealer depending on the security of SGX: (*i*) one that assumes SGX to be completely secure against side-channel attacks, denoted byConcealer, and (*ii*) another that assumes SGX is not secure against side-channel attack (cache-line, branch shadow, page-fault attacks) and hence performs the oblivious computation in SGX (given in §4.3). denoted by Concealer+. In all our experiments, we show the overhead of preventing the side-channel attacks using red color.

8.2 Concealer Evaluation

This section evaluates Concealer on different aspects such as scalability, dynamic data insertion, the impact of the range length, and the number of cell-ids.

Exp 1: Throughput. Since Concealer is designed to deal with data collected during an epoch arriving continuously over time, we measured the throughput (rows/minute) that Concealer can sustain to evaluate its overhead at the ingestion time. Algorithm 1 can encrypt ≈37,185 WiFi connectivity tuple per minute. Also, it sustains our organization-level workload on the relatively weaker machine used for hosting Concealer.

Exp 2: Scalability of Concealer. To evaluate the scalability of Concealer, we compare the five queries as specified in Table 4 on the two WiFi datasets.

Point query. For point query, we executed a variant of Q1 when the time is fixed to be a point (instead of a range). Table 5 shows the average time taken by 5 randomly selected point queries (each executed 10 times). Note that, in Concealer, since the time taken by point queries is dependent upon the number of tuples allocated to the same cell-id (*i.e.*, the bin size) that was 2,378 rows

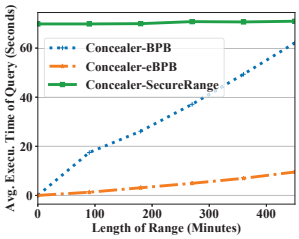

Figure 5: Exp 3: Range length impact.

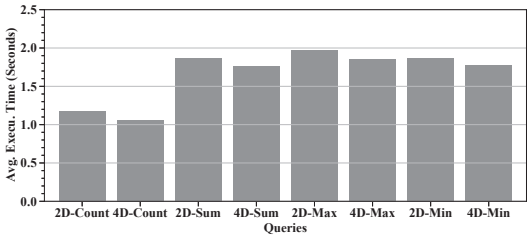

Figure 6: Exp 5: Query performance on TPC-H data.

from small and 6,095 rows from large datasets. Table 5 shows that Concealer with secure SGX using BPB method took 0.23s on small and 0.90s on large datasets, while Concealer+ with the current non-secure SGX using BPB method took 0.37s on small and 1.38s on large datasets. ***Time in Concealer+ increases compared to Concealer***, since we need to obliviously form the queries and obliviously filter the tuples in Concealer+, (and that implements a data-independent sorting algorithm; see §4.3). Here, executing the same query on cleartext data took 0.03s on small and 0.05s on large datasets.

	Small dataset (26M)	Large dataset (136M)
Cleartext processing	0.03s	0.05s
Concealer (secure SGX)	0.23s	0.90s
Concealer+ (non-secure SGX)	0.37s	1.38s

Table 5: Exp 2: Scalability of point query.

Range queries. To evaluate range queries, we set the default time range for queries Q1-Q5 specified in Table 4 to 20min (Exp 4 will study the impact of different range lengths). Figures 3 and 4 show the results as an average over 5 queries (each executed 10 times). We compare BPB, eBPB (§5.1), and winSecRange (§5.2) with both Concealer and Concealer+.

Recall that BPB method answers a range query by converting it into many point queries and fetches bins corresponding to each point query; while eBPB method fetches rows corresponding to top-ℓ cells, which cover the given range. In Concealer, a cell covers ≈18min. Thus, for a range of 20min, BPB and eBPB methods fetch at most 3 bins and at most 3 cells, respectively, for query Q1. Thus, for answering Q1, BPB fetches ≈6K rows from small and ≈18K rows from large datasets, and eBPB fetches ≈1.5K rows from small and ≈3K rows from the large dataset. Since eBPB retrieves few numbers of rows compared to BPB, in sGX, eBPB performs better than BPB (see Figures 3 and 4). Concealer+ again takes more time compared to Concealer for both eBPB and BPB, due to oblivious operations. Note that in queries Q2-Q5, we use more locations; thus, the number of rows retrieved changes accordingly, and hence, the processing time also changes, as shown in Figures 3 and 4.

For winSecRange, we set the range length on the time attribute to 8 hours in case of small and ≈1-day in case of large datasets. Thus, by fetching data for 1-day in the case of the large dataset, the enclave can execute any range query that is of a smaller time length. As expected, winSecRange took more time to execute range queries on both datasets, since it fetches and processes more rows (≈70K rows from small and ≈400K from large datsets). While it takes more time compared to BPB and eBPB, it prevents the attack by sliding the time window (as shown in Example 5.1.2), thereby, prevents revealing output-size attacks due to the sliding time window. Further, winSecRange under Concealer+ took more time compared to winSecRange under Concealer, due to oblivious operations. Recall that under Concealer, SGX architecture is vulnerable to side-channel attacks.

Exp 3. Impact of range length. Figure 5 shows the impact of the length in a range query on Concealer, by executing Q1 (see Table 4) with different time lengths over the large dataset and compares three approaches BPB, eBPB, and winSecRange. In Concealer, a cell covers ≈18min. Thus, for instance, for a range of 100min, BPB and eBPB methods fetch at most 7 bins and at most 7 cells, respectively. As expected, as the length of range increases, the number of rows to be fetched from the DBMS also increases, thereby, the processing time at secure hardware increases. As mentioned in Exp 2, for the large dataset, the range length is set to ≈1-day for winSecRange method; hence, fetching/processing more tuples takes more time and remains almost constant for the given length of queries.

Exp 4. Impact of dynamic insertion. We also investigated how does Concealer support dynamic insertion of WiFi dataset. We initiated Algorithm 1 for an hour of WiFi data at the peak hour, which included ≈50K tuples. For each insertion round, the grid size was $20 \times 1,250$ with 400 allocated cell-ids, and vectors $cell\_id[]$ and $c\_tuple[]$ of size ≈100KB were generated. In non-peak hours, we received at least ≈6K real rows. Recall that we are not interested in hiding peak vs non-peak hour data. Thus, all rows of each hour were sent using Algorithm 1. The query execution performance on dynamically inserted data depends on the number of rounds over which a query spans. For each round, we need to load the two vectors and fetch $\log |Bin|$ bins, as described in §6. For peak hour data, we obtained 146 bins storing ≈400 tuples, in each, using BPB method (§4.2) that resulted in ≈3K row retrieval. On this data, it took at most ≈4s to execute a query, re-encrypting tuples, and writing them, for Concealer.

Exp 5. Concealer on TPC-H data. To evaluate Concealer's practicality in other types of queries, we executed two-dimensional (2D) and four-dimensional (4D) count, sum, maximum, and minimum queries on LineItem table using Concealer. 2D (and 4D) queries involved OK and LN (and OK, PK, SK and LN) attributes. Similar to the point query execution on WiFi dataset, 2D and 4D queries on TPC-H data require to fetch tuples allocated the same cell-id (in the same bin) according to Algorithm 2. Thus, the query execution performance is dependent on the bin size, which was 400 rows for 2D grid and 6,258 for 4D grid. The query execution results are shown in Figure 6.

Figure 6 shows that Concealer using BPB method took ≈1s to 2s on TPC-H dataset. Also, observe that the performance of count queries is ≈36%–40% better than the others queries, since count queries do not need to decrypt retrieved rows and it executed string matching on the filter column to produce the answer. In contrast, other queries that require exact values of the attributes decrypt retrieved rows, and hence, incur the overhead.

8.3 Other Cryptographic Techniques

Since in our setting $\mathcal{SP}$ uses secure hardware, we need to compare Concealer against a system that supports database operations using SGX. Thus, we selected an open-source SGX-based system: Opaque [42].

Comparison between Opaque and Concealer. Opaque supports mechanisms to execute databases queries on encrypted data by first reading the entire data in the enclave, decrypting them, and then providing the answer. Note that both Opaque

System	Q1	Q2	Q3	Q4	Q5
Opaque	>10 m	>10 m	>10 m	>10 m	>10 m
Concealer eBPB	3.6 s	2.8 s	3.4 s	3 s	4s
Concealer winSecRange	70 s	67.2 s	71.9 s	70.2 s	68.9 s

Table 6: Exp 7: Range queries: Opaque vs Concealer.

and Concealer assume that SGX is secure against side-channel attacks, and hence, both reveal access-patterns. Thus, this is a fair comparison of the two systems, while Concealer avoids reading the entire dataset due to using the index and pushing down the selection predicate. Under this comparison, we execute point and range queries using Opaque and Concealer.

Further, note that since Concealer+ completely hides access-patterns inside SGX and partially hides access-patterns when fetching data in the form of fixed-size bins from the disk, we do not directly compare Concealer+ and Opaque due to different level of security offered by two systems.

Exp 6: Point queries on WiFi data. Opaque took more than 10min on both WiFi datasets for executing a variant of Q1 when the time is fixed to be a point, since *Opaque requires reading the entire dataset*. For the same query, Concealer took at most 0.23s on 26M and 0.9s on 136M rows.

Further, to execute the same query, Concealer+ took ≈1.4s. Thus, it shows that Concealer+, which hides access-patterns inside the enclave and prevents the output-size attack, is significantly better than Opaque.

Exp 7: Range queries on WiFi data. In all range queries Q1-Q5 on WiFi data, Concealer's eBPB and winSecRange algorithms take at most 4s and 71.9s over the large dataset compared to Opaque that took at least 10min in any query; see Table 6.

Further, to execute the same queries, Concealer+ takes at most 90s over the large dataset, which shows better performance of Concealer+ than Opaque in the case of range queries also.

Note. Except for Opaque, we did not experimentally compare Concealer against cryptographic techniques, since such techniques either offer different security levels [12, 22, 23], or do not scale to large data (*e.g.*, [4, 15]) for which we have designed Concealer, or are not publicly available. Thus, we decide to compare Concealer results with the reported result in different papers. Previous works on secure OLAP queries either support limited operations, reveal data due to DET or OPE, or scale to a smaller dataset. For example, Monomi [38], Seabed [29], [14], and [24] reveal data due to DET or OPE. Nevertheless, Seabed supports a huge dataset (≈1.75B rows). Novel SSEs, *e.g.*, [12, 22, 23], are very efficient, as given in their experiments; however, over 5M rows and susceptible to output-size attacks. We also checked access-pattern-hiding cryptographic work (*e.g.*, DSSE [15] and Jana [4]) that are prone to output-size attacks; however, as expected, these systems are slow due to using highly secure cryptographic techniques that incur overheads and/or do not support a large dataset. E.g., an industrial MPC-based system Jana took 9 hours to insert 1M LineItem rows, while executing a simple query took 532s.

9 CONCLUSION

This paper proposed Concealer that blends a carefully chosen encryption method with mechanisms to add fake tuples and exploits secure hardware to efficiently answer OLAP-style queries. We applied Concealer to real spatial time-series datasets, as well as, synthetic TPC-H data, and demonstrated scalability to large-sized data. Since Concealer allows indexing, its performance is similar to SSEs.Concealer offers two key advantages over existing SSEs: first, it does not require new data structures to incorporate into databases and leverages existing index structures of modern databases. Second (and perhaps more importantly), Concealer offers a higher level of security, in addition to being IND-CKA, which existing SSEs are, by preventing leakage of data distributions via output-size. *Due to space restrictions, we omit the query workload handling method, proof of Theorem 4.1, and experiments related to the overhead of verification, impact of the number of cells, and impact of different bin-sizes from this paper, and will be given in the full version (https://arxiv.org/abs/2102.05238).*

ABSTRACT

Privacy-preserving record linkage aims at integrating person-related data from different sources while protecting the privacy of individuals by securely encoding and matching quasi-identifying attributes, like names. For this purpose Bloom-filter-based encodings have been frequently used in both research and practical applications. Simultaneously, however, weaknesses and attack scenarios were identified emphasizing that Bloom filters are in principal susceptible to cryptanalysis. To counteract such attacks, various encoding variants and tweaks, also known as hardening techniques, have been proposed. Usually, these techniques bear a trade-off between privacy (security) and the linkage quality outcome. Currently, a comprehensive evaluation of the suggested hardening methods is not available. In this work, we will therefore review and categorize available Bloom-filter-based encoding schemes and hardening techniques. We also comprehensively evaluate the approaches in terms of privacy (security) and linkage quality to assess their practicability and their effectiveness in counteracting attacks.

1 INTRODUCTION

Linking records from different independent sources is an essential task in research, administration and business to facilitate advanced data analysis [6]. In many applications, these records are about individuals and thus contain sensitive information, e. g., personal, health, criminal or financial information. Due to several laws and regulations, data holders have to protect the privacy of individuals [33]. As a consequence, data holders have to ensure that no sensitive or confidential information is revealed during a linkage process.

Privacy-preserving record linkage (PPRL) addresses this problem by providing techniques for linking records referring to the same real-world entity while protecting the privacy of these entities. In contrast to traditional record linkage [6], PPRL encodes sensitive identifying attributes, also known as quasi-identifiers, for instance, names, date of birth or addresses, and then conduct the linkage on the encoded attribute values.

Over the last years, numerous PPRL approaches have been published [33]. However, many approaches are not suited for real-world applications as they either are not able to sufficiently handle dirty data, i. e., erroneous, outdated or missing values, or do not scale to larger datasets. More recent work mainly focuses on encoding techniques utilizing Bloom filters [2] as error-tolerant and privacy-preserving method to encode records containing sensitive information. While Bloom-filter-based encodings have become the quasi-standard in PPRL approaches, several studies analyzed weaknesses and implemented successful attacks on Bloom filters [7, 8, 18, 20, 21, 24]. In general, it was observed that Bloom filters carry a non-negligible re-identification risk because they are vulnerable to frequency-based cryptanalysis. In order to prevent such attacks, various Bloom filter hardening techniques were proposed [7, 25]. Such techniques aim at reducing patterns and frequency information that can be obtained by analyzing the frequency of individual Bloom filters or (co-occurring) 1-bits.

Previous studies on Bloom filter hardening techniques only consider individual methods and do not analyze the effects of combining different approaches. Moreover, many of the proposed hardening techniques have received only limited evaluation on small synthetic datasets making it hard to assess the possible effects on the linkage quality.

The aim of this work is to review hardening techniques proposed in the literature and to evaluate their effectiveness in terms of achieving high privacy (security) and linkage quality.

In particular, we make the following contributions:

- We survey Bloom filter variants and hardening techniques that have been proposed for use in PPRL scenarios to allow secure encoding and matching of sensitive person-related data.
- We categorize existing hardening techniques to generalize the Bloom filter encoding process and thus highlight the different possibilities for building tailored Bloom filter encodings that meet the privacy requirements of individual application scenarios.
- We explore additional variants of hardening techniques, in particular salting utilizing blocking approaches and attribute-specific salting on groups of attributes.
- We propose and analyze measures that allow us to quantify the privacy properties of different Bloom filter variants.
- We comprehensively evaluate different Bloom filter variants and hardening techniques in terms of privacy (security) and linkage quality using two real-world datasets containing typical errors and inconsistencies.

2 BLOOM FILTER

The use of Bloom filters [2] for PPRL has been proposed by Schnell and colleagues [26] and has become the quasi-standard for recent PPRL approaches in both research and real applications [33].

2.1 Basics

A Bloom filter (BF) is a space-efficient probabilistic data structure for representing a set $E = \{e_1, \ldots, e_n\}$ of n elements or features and testing set membership. Therefore, a bit vector of fixed size m is allocated and initially all bits are set to zero. A set of $\mathbf{k}$ hash functions is selected where each function $H_1, \ldots, H_k$ outputs a value in $[0, m-1]$. To represent the set E in the BF, each element is (hash) mapped to the BF by using each of the k hash functions and setting the bits at the resulting positions to one.

To check the membership of an element, the same hash functions are calculated and the bits at the resulting positions are checked. If all bits are set to one, the element probably is in the set. Due to collision, i. e., two or more elements may set the same bit position for the same or different hash functions, BFs have a false-positive probability that is $\text{fpr} = (1 - e^{\frac{k \cdot n}{m}})^k$ [3]. On the other hand, if at least one bit is zero, the element is definitively not in the set.

Union and intersection of BFs with the same size and set of hash functions can be implemented with bit-wise OR and AND operations respectively. While the union operation is lossless, i. e., the resulting BF will be equal to a BF that was build using the union of the two sets, the intersection operation produces a BF that may have a larger false-positive probability [3].

By using BF union and intersection, set-based similarity measures can be used to calculate the similarity of two BFs. Here the **Jaccard coefficient** is frequently used as a similarity measure. Given two BFs x, y the Jaccard coefficient is defined as

$$J(x, y) = \frac{|x \cap y|}{|x \cup y|} = \frac{|x \text{ AND } y|}{|x \text{ OR } y|}$$

For instance, given the BFs $x = [\mathbf{1}0011001]$ and $y = [\mathbf{0}0011001]$ the Jaccard coefficient is $3/4$. The BF similarity is an approximation of the similarity of the underlying (represented) sets.

2.2 Utilization in PPRL

The main idea for utilizing BFs in PPRL scenarios is to use a BF to represent the records attribute values, i. e., all quasi-identifying attributes of a person that are relevant for linkage, e. g., first name, last name and date of birth. The BFs hash functions need to be cryptographic (one-way) hash functions that are keyed (seeded) with a secret key $\mathcal{S}$, i. e., keyed-hash message authentication codes (HMACs) like MD5 or SHA-1 [23]. For approximate matching, the granularity of the record attributes is increased by segmentation into features. A widely used approach is to split the attribute values into small substrings of length q, called **q-grams**, typically setting $1 \leq q \leq 4$. Consequently, in PPRL a BF represents a set of attribute value segments, that we term record (attribute) features. Thus, the number of common 1-bits of two BFs approximates the number of common (overlapping) features between two records.

2.2.1 Types. There are two ways of encoding records into BFs: either one BF is built for each record attribute, which is known as field- or **attribute-level BF**, or a single BF is built for all relevant attributes, which is known as **record-level BF**. For constructing record-level BFs there are two approaches: The first approach [27] builds a single BF in which all record attributes are hashed. The second approach [9] first constructs field-level BFs and then selects bits from these individual BFs according to the weight of the respective attribute. In this work, we will focus on the first approach since it is heavily used in literature and practice [33]. We illustrate the basic BF building process in Fig. 1. By using

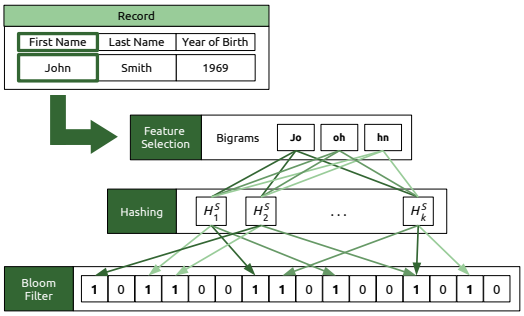

Figure 1: Basic Bloom filter building process.

the first name attribute the figure shows how an attribute value (*'John'*) is segmented into q-gram segments (here $q = 2$), which are then mapped to the bit vector using the k hash functions. Other attributes are mapped in the same way, although a different segmentation strategy can be used. The advantage of using field-level BFs is that individual BFs are produced allowing the use of sophisticated matching techniques known from traditional record linkage, e. g., classification based on attribute weights and attribute error rates, as well as approaches for handling composite fields, for instance, name attributes with compounds (multiple given names). However, as we discuss in the next section, field-level BFs fulfill much weaker privacy properties compared to record-level BFs.

2.2.2 Privacy Properties. The privacy-preserving property of BFs rely on the following aspects:

(1) An adversary has no information on how the record features are obtained, e. g., selected attributes or length of substrings (q-grams).
(2) The selected hash functions, the secret key $\mathcal{S}$ and thus the hash mapping of record features to bit positions is unknown to an adversary. In particular, the use of keyed hash functions is essential to prevent dictionary attacks.
(3) Due to collisions multiple record features will map to a single bit position in general. Keeping the BF size m fixed, the more hash functions are used and the more features are mapped to the BF, the higher will be the number of collisions and thus the confusion.
(4) There is no coherence or positional information: Since a BF encodes a *set* of record features, it is not obvious from where features were obtained, i. e., within an attribute and for record-level BF even from which attribute.

However, BFs are susceptible to frequency attacks as the frequencies of set bit positions correspond to the frequencies of record features. Thus, frequently (co-)occurring record features will lead to frequently set bit positions or even to frequent BFs in the case of field-level BFs. By using publicly available datasets containing person-related data, e. g., telephone books, voter registration databases, social media profiles or databases about persons of interests like authors, actors or politicians, an adversary can estimate the frequencies of record features and then try to align those frequencies to the BFs bit frequencies.

A successful re-identification of attribute values encoded in BF is a real threat as shown by several attacks proposed in the literature. Earlier attacks, namely [18, 20, 21, 24], often exploit the hashing method used in [27], the double-hashing scheme, that combines two hash functions to implement the k BF hash

Table 1: Overview of surveyed Bloom filter hardening techniques.

Subject of modification	Technique	Reference	Description
Bloom filter input	Avoidance of padding	[24, 25]	No use of padded q-grams as BF input due to their higher frequency.
	Standardization of attribute lengths	[24, 25]	The length of attribute values is unified to avoid exceptionally short or long values.
Hashing mechanism	Increasing the number of hash functions (k)	[26, 27]	Using more hash functions (k) while keeping the Bloom filter size (m) fixed will lead to more collisions and thus a higher number of features that are mapped to each position.
	Random hashing	[24]	Replacement for the double-hashing scheme [26] which can be exploited in attacks [24].
	Attribute weighting	[9, 32]	Record features are hashed with a different number of hash functions (k) depending on the weight of the attribute from which they were obtained.
	Salting	[24, 27]	Record features are hashed together with an additional attribute specific and/or record specific value.
Output Bloom filter	Balancing	[28]	Each Bloom filter is concatenated with a negative copy of itself and then the underlying bits are permuted.
	XOR-folding	[29]	Each Bloom filter is split into halves which are then combined using the bit-wise XOR-operation.
	Re-hashing	[25]	Sliding window approach where the Bloom filter bits in each window are used to generate a new set of bits.
	Rule90	[30]	Each Bloom filter bit is replaced by the result of XOR-ing its two neighbouring bits.
	Random noise	[1, 24–26, 28]	Bloom filter bits are changed randomly.
	Fake injections	[16]	Addition of artificial records and thus Bloom filters.

functions. This hashing method can easily be replaced by using independent hash functions or other techniques as discussed in Sec. 3.2.1. Furthermore, these attacks rely on many unrealistic assumptions, for instance, that the encoded records are a random sample of a resource known to the adversary [20, 24] or that all parameters of the BF process, including used secret keys for the hash functions, are known to the adversary [21]. However, recent frequency-based cryptanalysis attacks, namely [7] and in particular [8], are able to correctly re-identify attribute values without relying on such assumptions. These attacks are the more successful, the fewer attributes are encoded in a BF and the larger the number of encoded records. Overall, the attacks show the risk of re-identification when using BFs, especially field-level BFs. In this work, we will focus only on record-level BFs.

3 BLOOM FILTER VARIANTS AND HARDENING METHODS

In the following, we review different variations within the BF encoding process. In general, these variations will affect both the BFs privacy and similarity-preserving (matching) properties. Approaches that try to achieve a more uniform frequency distribution of individual BFs or set bit positions are also known as hardening techniques as they are intended to make BF encodings more robust against cryptanalysis. An overview of these techniques is given in Tab. 1. We divide the approaches into three categories: (A) approaches that alter the way of selecting features from the records attributes values, (B) approaches that modify the BFs hashing process and (C) approaches that modify already existing BFs by changing or aggregating bits. In the following subsections, we will describe the approaches of each category.

3.1 Record Feature Selection

We will first focus on how features are selected from the record's attributes. In the encoding process, at first, all attribute values are pre-processed to bring them into the same format and to reduce data quality issues. After that, all linkage-relevant attributes, i. e., the quasi-identifiers of a person, are transformed into their respective feature set. Such features are pieces of information that are usually obtained by segmenting the attribute values into chunks or tokens. This is necessary because instead of a binary decision for equality (true/false), approximate linkage is desired resulting in similarity scores ranging from zero (completely different) to one (equal).

3.1.1 Standardization of Attribute Lengths. Quasi-identifiers, such as names and addresses, show high variation and skewness leading to significant differences in the length of attribute values [11]. For instance, multiple given names, middle names or compound surnames (e. g., *'Hans-Wilhelm Müller-Wohlfahrt'*) will lead to exceptionally long attribute values and consequently a comparatively large amount of 1-bits in the resulting BF. The same applies for very short names (e. g., *'Ed Lee'*) resulting in very few 1-bits in the BF. By analyzing the number of 1-bits in a set of BFs, an adversary can gain information on the length of encoded attribute values. To address this problem, the length of the quasi-identifiers should be standardized by sampling, deletion or stretching of the attribute values [25]. Stretching can be implemented by concatenating short attribute values with (rarely occurring) character sequences.

3.1.2 Segmentation Strategy. The standard segmentation strategy adopted from traditional record linkage is to transform all quasi-identifiers into their respective **q-gram** set. A q-gram set is a set of all consecutive character sequences of length q that can be built from the attribute's string value by using a sliding window approach. For instance, setting $q = 3$ the value *'Smith'* will produce the q-gram set {*Smi*, *mit*, *ith*}. The idea behind building these q-gram sets is that they allow approximate string comparisons by calculating the number of q-grams two sets have in common. To directly obtain a similarity value, any set-based similarity measure, e. g., Jaccard coefficient, can be used.

The choice of q is important since it can affect the linkage quality. Usually, q is selected in the range [1..4] while most approaches setting $q = 2$. In general, larger values for q are more sensitive to single character differences, e. g., the values *'Smith'* and *'Smyth'* will have two bigrams ($q = 2$), i. e., *'Sm'* and *'th'*, but zero trigrams ($q = 3$) in common. However, choosing a larger q also increases to number of possible q-grams, e. g., for $q = 2$ at maximum $26^2 = 676$ while for $q = 3$ at maximum $26^3 = 17\,576$ are possible. Overall, larger values for q tend to be less error-tolerant and thus possibly lead to missing matches. On the other hand, larger q's are more distinctive and thus tend to reduce false-positives.

As can be seen from the example above, for $q > 1$ each character will contribute to multiple q-grams except the first and last character. Thus, a common extension is to construct **padded q-grams** by surrounding each attribute value with $q - 1$ special characters at the beginning and the end. For our example the

padded q-gram set will be {*++S*, *+Sm*, *Smi*, *mit*, *ith*, *th-*, *h--*}. By using padded q-grams strings with the same beginning and end but variations in the middle will reach larger similarity values, while strings with different beginning and end will produce lower similarity values compared to standard q-grams [6]. It is important to note, that padded q-grams are among the most frequent q-grams and thus can ease any frequency alignment attacks.

There are several other extensions for generating q-grams, two of which have been used in traditional record linkage, but so far not for PPRL: **positional q-grams** and **skip-grams** [6]. Positional q-grams add the information from which position the q-gram was obtained. For our running example, the positional q-gram set for $q = 3$ is $\{(Smi, 0), (mit, 1), (ith, 2)\}$. When determining the overlap between two positional q-gram sets, only the q-grams at the same position or within a specific range are considered. Positional q-grams will be more distinctive and thus tend to reduce false-positives and even the frequency distribution. The idea of skip-grams is to not only consider consecutive characters but to skip one or multiple characters. Depending on the defined skip length multiple skip-gram sets can be created and used in addition to the regular q-gram set.

So far, only a few alternatives to q-grams have been investigated. In [17] and [31] the authors explore methods for handling numerical attribute values. Besides, arbitrary substrings of individual length or phonetic codes, such as Soundex [6], are possible approaches that can be used for feature extraction.

3.2 Modification of the Hashing Mechanism

After transforming all quasi-identifiers in their respective feature set, the features of each set are hashed into one record-level BF. As discussed in Sec. 2.2.2, we do not further consider field-level BFs due to their vulnerabilities. For PPRL several modifications of the standard hashing process of BFs have been proposed which we will discuss below.

3.2.1 Hash Functions. As described in Sec. 2.2, by default k independent (cryptographic) hash functions are used in conjunction with a private key $\mathcal{S}$ to prevent dictionary attacks. However, the authors of [27] proposed the usage of the so-called double-hashing scheme. This scheme only uses two independent hash functions G_1, G_2 to implement the BFs k hash functions. Each hash function is then defined as $H_i(x) = (G_1(x) + (i-1) \cdot G_2(x)) \mod m, \forall i \in \{1, \ldots, k\}$. The attacks described in [18, 24] showed that this specific scheme can be successfully exploited. As a consequence, an alternative method, called **random hashing**, was proposed [24] that utilizes a pseudo-random number generator to calculate the hash values. Therefore, the random number generator is seeded with the private key $\mathcal{S}$ and the actual input of the hash function, i. e., a certain record feature. No attacks against this method are known at present.

3.2.2 Salting. Salting is a well-known technique in cryptography that is often used to safeguard passwords in databases [22]. The idea is to use an additional input, called salt, for the hash functions to flatten the frequency distribution. Already in [27] it is mentioned that a different cryptographic secret key $\mathcal{S}_a$ can be used for each record *attribute a*. We term such kind of key as **attribute salt**. By using this approach, the same feature will be mapped to different positions if it originates from different attributes. For instance, given the first name *'thomas'* and the last name *'smith'* the bigram *'th'* will produce different positions. This approach will smoothen the overall frequency distribution and also reduce false-negatives since features from different attributes will not produce common 1-bits (except due to collision). However, the BF's ability to match exchanged attributes, e. g., transposed first and middle name, is lost. If such errors occur repeatedly this will lead to missing matches. As a compromise, we propose to define groups of attributes, where transpositions are expectable. Then, the same key is used for each attribute from the same group. For instance, all name-related attributes (first name, middle name, last name) could form a group.

Another salting variant is proposed in [24], where *for each record* a specific salt is selected and then used as key for the BFs k hash functions. Therefore, we term such keys as **record salt**, since they depend on a specific record. Record salts can also be combined with the aforementioned attribute salts. Only if the record salt is identical for two records, the same feature (q-gram) will set the same bit positions in the corresponding BFs. However, if the record salts are different, then the probability that the same bit positions are set in the corresponding BFs is very low. Thus, if the attributes (from which the record salts is extracted) contain errors, this will lead to many false-negatives. For this reason only commonly available, stable and small segments of quasi-identifiers, such as year of birth, are suitable as salting key. Consequently, this technique is only an option in PPRL scenarios where the attributes used for salting are guaranteed to be of very high quality which might be rarely the case in practice.

To reduce the aforementioned problem of salting with record-specific keys, we propose to generate the salt by utilizing blocking approaches. Blocking [6] is an essential technique in (privacy-preserving) record linkage to overcome the quadratic complexity of the linkage process since in general each record must be compared to each record of another source. The idea of blocking is to partition records into small blocks and then to compare only records within the same block to reduce the number of record pair comparisons. For this purpose, one or more blocking keys are defined, where each blocking key represents a specific, potentially complex criterion that records must meet to be considered as potential matches. For example, the combination of the first letter of the first and last name and the year of birth might be used as a blocking key. If the attributes used for blocking contain errors, then also the blocking key will be affected leading to many false-negatives, in particular if the blocking key is very restrictive. Hence, often multiple blocking keys are used to increase the probability for records to share at least one blocking key. However, this will lead to duplicate candidates since very similar records will share most blocking keys. The challenge of both, salting and blocking, is to select a key that is as specific as possible (to increase privacy, or to reduce the number of record pair comparisons respectively) and at the same time not prone to errors. For record-dependent salting, only the use of attribute segments was suggested. In contrast, for blocking more sophisticated approaches have been considered, in particular using phonetic codes, e. g., Soundex, or locality-sensitive hashing schemes, e. g., MinHash [4].

3.2.3 Dependency-based Hashing. In traditional record linkage, sophisticated classification models are used to decide whether a record pair represents a match or a non-match. Often these models deploy an attribute-wise or rule-based classification considering the discriminatory power and expected error rate of the attributes [6]. In contrast, PPRL approaches based on record-level BFs only apply classification based on a single similarity threshold since all attributes values are aggregated (encoded) in

a single BF. However, as discussed in Sec. 2.2.1, the record-level BF variant proposed in [9] also considers the weight of attributes by selecting more bits from the field-level BFs of attributes with higher weights. In [32] the authors proposed an extension to the approach of [27] to allow attribute weighting. While also only a single BF is constructed, a different number of hash functions is selected for different attributes according to their weights. Consequently, the higher the weight of an attribute, the more hash functions will be used and thus the more bits the attribute will set in the BF. The idea of varying the number of hash functions can be generalized to dependency-based hashing. For instance, not only the weights of attributes can be considered but instead also the frequency of input features or their position within the attribute value (positional q-grams).

3.3 Bloom Filter Modifications

While the methods described so far modify the way BFs are created, the following approaches are applied directly on the obtained BFs (bit vectors).

3.3.1 Balanced Bloom Filters. Balanced BFs were proposed in [28] for achieving a constant Hamming weight over all BFs. A constant Hamming weight should make the elimination of infrequent patterns more difficult. Balanced BFs are constructed by concatenating a BF with a negative copy of itself and then permuting the underlying bits. For instance, the BF [10011001] will give [10011001] · [01100110] = [1001100101100110] before applying the permutation. Since the size of the BFs is doubled, balanced BFs will increase computing time and required memory for BF comparisons.

3.3.2 XOR-Folding. XOR-folding of bit vectors is a method originating from chemo-informatics to speed up databases queries. In [29] the authors adopted this idea for Bloom-filter-based PPRL for preventing bit pattern attacks. To apply the XOR-folding a BF is split into halves and then the two halves are combined by the XOR-operation. For instance, the BF [11000101] will give [1100] ⊕ [0101] = [1001]. The folding process may be repeated several times. Since the size of the BFs is halved, XOR-folding will decrease computing time and required memory for BF comparisons. The initial evaluation in [29] using unrealistic datasets with full overlap and low error-rates shows that one-time folding does not significantly affect linkage quality. However, n-time folding drastically increases the number of false-positives.

3.3.3 Rule90. In [30] the use of the so-called *Rule90* was suggested to increase the resistance of BFs against bit-pattern-based attacks. The Rule90 is also based on the XOR-operation which is applied on the two neighboring values of each BF bit. Consequently, there are 8 possible combinations (patterns), which are listed in Tab. 2. So each bit b_i ($0 \leq i \leq m-1$) is replaced by the result of XOR-ing the two adjacent bits at positions $(i-1) \bmod m$ and $(i+1) \bmod m$. By using the modulo function the first and the last bit are treated as if they were adjacent. For example, applying Rule90 to the BF [11000101] will lead to the following patterns 1**1**1, 1**1**0, 1**0**0, 0**0**0, 0**0**1, 0**1**0, 1**0**1, 0**1**1 where the middle bit corresponds to the bit at position $i \in \{0, m-1\}$ of the BF. After applying the transformation rules (Tab. 2) we obtain [01101001].

Table 2: Transformation rules for Rule90.

Pattern	111	110	101	100	011	010	001	000
New Bit Value	0	1	0	1	1	0	1	0

3.3.4 Re-hashing. The idea of re-hashing [25] is to use consecutive bits of a BF to generate a new bit vector. Therefore, a window of width w bits is moved over the BF where in each step the window slides forward s positions (step size). At first, a new bit vector v of size m' is allocated. Then, the w bits, which are currently covered by the window, are represented as an integer value. The integer value is then used in combination with a secret key as input for a random number generator (RNG). With that, r new integer values are generated with replacement, each in the range $[0, m'-1]$. Finally, the bits at these r positions are set to one in the bit vector v. For example, given the BF [11000101] and setting $w = 4, s = 2$ will lead to three windows, namely $w_1 = [1100], w_2 = [0001], w_3 = [0101]$. By transforming the bits in each window into an integer value we obtain the seeds 12, 1 and 5. Setting $r = 2$ the RNG might generate the positions $(4, 2), (2, 5), (8, 6)$ for the respective seeds which finally results in the bit vector [001011101]. The evaluation in [28] uses very unrealistic datasets (full overlap, no errors) and shows no clear trend. However, this technique is highly dependent on the choice of the parameters m', w, s and r as well as on the original BFs, in particular the average fill factor (amount of 1-bits).

3.3.5 Random Noise. In order to make the frequency distribution of BFs more uniform, random noise can be added to the BFs [25, 28]. Trivial options are to randomly set bits to one/zero or to flip bits (complement). Additionally, the amount of random noise can depend on the frequency of mapped record features. For instance, for BFs containing frequent q-grams more noise can be added. In [1] a ϵ-differential private BF variant, called BLoom-and-flIP (BLIP), based on permanent randomized response is proposed. Each bit position $b_i, \forall i \in \{0, \ldots, m-1\}$ is assigned a new value b'_i based on the probability f such that

$$b'_i = \begin{cases} 1 & \text{with probability } \frac{1}{2}f \\ 0 & \text{with probability } \frac{1}{2}f \\ b_i & \text{with probability } 1-f. \end{cases}$$

3.3.6 Fake Injections. Another option to modify the frequency distribution of BFs is to add artificial records or attribute values [16]. By inserting random strings containing rarely occurring q-grams the overall frequency distribution will become more uniform making any frequency alignment less accurate. The drawback of fake records is that they produce computational overhead in the matching process. Moreover, it is possible that a fake record will match with another record by chance. Thus, after the linkage, fake records need to be winnowed.

4 BLOOM FILTER PRIVACY MEASURES

Several attacks on BFs have been described in the literature (see Sec. 2.2.2), which show that BFs carry the risk of re-identification of attribute values and even complete records. Currently, the privacy of BF-based encoding schemes is mainly evaluated by simulating attacks and inspecting their results, i. e., the more attribute values and records can be correctly re-identified by an attack, the lower is the assumed degree of privacy of the encoding scheme. However, this way of measuring privacy strongly depends on the used attacks, their assumptions and the used reference dataset. Besides, only a few studies investigated evaluation measures for privacy [33]. These measures are either calculating the probability of suspicion [32] or are based on entropy and information gain between masked and unmasked data [28]. The disadvantage of these measures is that they strongly depend on

the reference data set used. In the following, we therefore propose privacy measures that solely depend on a BF dataset.

To evaluate the disclosure risk of BF-based encoding schemes we propose to analyze the frequency distribution of the BF 1-bits. As described in Sec. 2.2.2, attacks on BFs mostly try to align the frequency of frequent (co-occuring) bit patterns to frequent (co-occuring) record features (q-grams). Thus, the more uniform the frequency distribution of 1-bits is, the less likely an attack will be successful. To measure the uniformity of the bit frequency distribution of a BF dataset $\mathfrak{B}$, we calculate for each BF bit position (column) $0 \leq i < m-1$ the number of 1-bits, given as $\mathbf{c}_i = \sum_{\text{Bf} \in \mathfrak{B}} \text{Bf}(i)$, where $\text{Bf}(i)$ returns the BFs bit value at position i. The total number of 1-bits is then $\mathbf{b} = \sum_{i=0}^{m-1} c_i = \sum_{\text{Bf} \in \mathfrak{B}} |\text{Bf}|$ where $|\text{Bf}|$ denotes the cardinality of a BF (number of 1-bits). We can then calculate for each column its share of the total number of 1-bits, i. e., $\mathbf{p}_i = c_i / b$. Ideally, for a perfect uniform bit distribution, p_i will be close to b/m for all $i \in \{0, m-1\}$.

In mathematics and economics there are several measures that allow to assess the (non-) uniformity of a certain distribution. Consequently, we are adapting the most promising of these measures to our problem. At first, we consider the **Shannon entropy** $\mathcal{H}(\mathfrak{B}) = -\sum_{i=0}^{m-1} p_i \cdot \log_2(p_i)$ since uniform probability will yield maximum entropy. The maximum entropy is given as $\mathcal{H}_{max}(\mathfrak{B}) = \log_2(m)$. We define the normalized Shannon entropy ranging from 0 (high entropy - close to uniform) to 1 (low entropy) as

$$\widetilde{\mathcal{H}}(\mathfrak{B}) = 1 - \frac{H(\mathfrak{B})}{H_{max}(\mathfrak{B})} \tag{1}$$

Next, we consider the **Gini coefficient** [5, 15], which is well-known in economics as a measure of income inequality. The Gini coefficient can range from 0 (perfect equality – all values are the same) to 1 (maximal inequality – one column has all 1-bits and all others have only 0-bits) and is defined as

$$\mathbf{G}(\mathfrak{B}) = \frac{\sum_{i=0}^{m-1} \sum_{j=0}^{m-1} |c_i - c_j|}{2m \cdot b} \tag{2}$$

Moreover, we calculate the **Jensen-Shannon divergence** (JSD) [14] which is a measure of similarity between two probability distributions. The JSD is based on the Kullback-Leibler divergence (KLD) [19], but has better properties for our application: In contrast to the KLD, the JSD is a symmetric measure and the square root of the JSD is a metric known as **Jensen-Shannon distance** (D_{JS}) [10]. For discrete probability distributions P and Q defined on the same probability space, the JSD is defined as

$$\text{JSD}(P \,||\, Q) = \frac{1}{2} \text{KLD}(P \,||\, M) + \frac{1}{2} \text{KLD}(Q \,||\, M) \quad \text{where}$$

$$\text{KLD}(P \,||\, Q) = \sum_{s \in \mathcal{S}} P(s) \cdot \log_2 \left(\frac{P(s)}{Q(s)} \right) \quad \text{and} \quad M = \frac{1}{2}(P + Q).$$

The JSD also provides scores between 0 (identical) to 1 (maximal different). Since we want to measure the uniformity of the bit frequency distribution of a BF dataset $\mathfrak{B}$, we calculate the Jensen-Shannon distance given as

$$\mathbf{D}_{\text{JS}}(\mathfrak{B}) = \sqrt{\text{JSD}(\mathfrak{B})} \tag{3}$$

where

$$\text{JSD}(\mathfrak{B}) = \frac{1}{2} \left(\sum_{i=0}^{m-1} \frac{1}{m} \cdot \log_2 \left(\frac{\frac{1}{m}}{\frac{1}{2} \cdot (p_i + \frac{1}{m})} \right) \right) + \frac{1}{2} \left(\sum_{i=0}^{m-1} p_i \cdot \log_2 \left(\frac{p_i}{\frac{1}{2} \cdot (p_i + \frac{1}{m})} \right) \right)$$

Finally, we measure how many different record features (q-grams) are mapped to each bit position, which we denote as **feature ratio** (fr). The more features are mapped to each position, the harder becomes a one-to-one assignment between bit positions and record features which will limit the accuracy of an attack.

5 EVALUATION SETUP

Before presenting the evaluation results we describe our experimental setup as well as the datasets and metrics we use.

5.1 PPRL Setup

We implement the PPRL process as a three-party protocol assuming a trusted linkage unit [31]. Furthermore, we set the BF length $m = 1024$. To overcome the quadratic complexity of linkage, we use LSH-based blocking based on the Hamming distance [13]. We empirically determined the necessary parameters leading to high efficiency and effectiveness. As a result, we set $\Psi = 16$ (LSH key length) and $\Lambda = 30$ (number of LSH keys) as default. Finally, we calculate the Jaccard coefficient to determine the similarity of candidate record pairs. We classify every record pair with a similarity equal or greater than t as a match. Finally, we apply a one-to-one matching constraint, i. e., a record of one source can match to at maximum one record of another source, utilizing a symmetric best match approach [12].

5.2 Datasets

For evaluation, we use two real datasets that are obtained from the North Carolina voter registration database (NCVR) (https://www.ncsbe.gov/) and the Ohio voter files (OHVF) (https://www.ohiosos.gov/). For both datasets, we select subsets of two snapshots at different points in time. Due to the time difference records contain errors and inconsistencies, e. g., due to marriages/divorces or moves. Please note that we do not insert artificial errors or otherwise modify the records. We only determine how many attributes of a record have changed and use this information to construct subsets with a specific amount of records containing errors. An overview of all relevant dataset characteristics is given in Tab. 3. Each dataset consists of two subsets, S_A and S_B, to be linked with each other. The two subsets are associated with two data owners (or sources) A and B respectively.

Table 3: Dataset characteristics

Characteristic	Dataset	
	N	O
Type	Real (NCVR)	Real (OHVF)
$\lvert S_A \rvert$	50 000	120 000
$\lvert S_B \rvert$	50 000	80 000
$\lvert S_A \cap S_B \rvert$	10 000	40 000
Attributes	{First, middle, last} name, year of birth (YOB), city	{First, middle, last} name, date of birth (BD), city
|Errors|/record	0 (40 %), 1 (30 %), 2 (20 %), 3 (10 %)	0 (37.5 %), 1 (55 %), 2 (6.875 %), 3 (0.625 %)

5.3 Metrics

To assess the linkage quality we determine **recall**, **precision** and **F-measure** (F1-score). Recall measures the proportion of true-matches that have been correctly classified as matches after the linkage process. Precision is defined as the fraction of classified matches that are true-matches. F-measure is the harmonic mean of recall and precision. To assess the privacy (security) of the

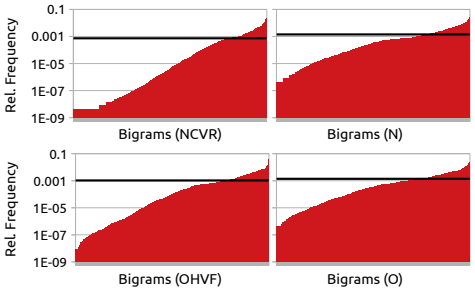

Figure 2: Relative bigram frequencies for used datasets.

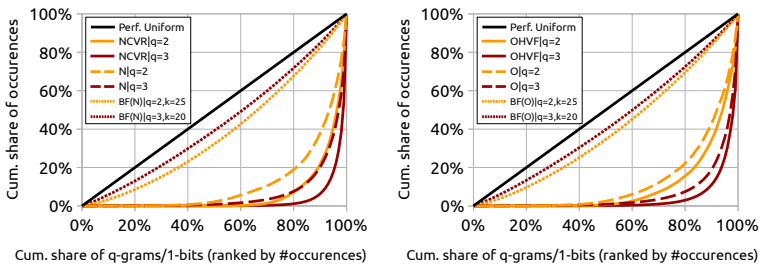

(a) NCVR **(b) OHVF**

Figure 3: Comparison of Lorenz curves for plaintext and Bloom filters.

different Bloom-filter-based encoding schemes, we analyze the frequency distribution of the BF's 1-bits in order to determine the **normalized Shannon entropy**, the **Gini coefficient** and the **Jensen-Shannon distance** (see Sec. 4). Furthermore, we calculate the **feature ratio** (fr) that determines how many record features are mapped on average to each bit position.

5.4 Q-Gram Frequencies

Before we begin our evaluation on BFs, we analyze the plaintext frequencies of our datasets N and O as well as the complete NCVR and OHVF datasets. At first, we measure the relative bigram frequencies as shown in Fig. 2. What can be seen in this figure is the high dispersion of bigrams. For the complete NCVR and OHVF the non-uniformity is a bit higher than in our datasets which is mainly due to the larger number of infrequent bigrams. Since our datasets are only subsets from the respective voter registrations (NCVR/OHVF), some of these rare bigrams do simply not occur in our dataset subsets. In Fig. 3 we plot the Lorenz curves [15] for the plaintext datasets as well as BFs (see Sec. 6). These diagrams again illustrate the high dispersion for the plaintext values. Comparing bigrams and trigrams, it can be seen that the non-uniformity for trigrams is even higher than for bigrams. Our observations are confirmed by our uniformity (privacy) measures (see Sec. 4) which we calculate for the datasets as listed in Tab. 4. We use these values as a baseline for the BF privacy analysis. The closer the values for a set of BFs are to these values, the more likely a frequency alignment will be successful. On the other hand, the larger the difference between the values for plaintext and BFs, the better the BFs can hide the plaintext frequencies and thus the less likely a successful frequency alignment becomes. Comparing our three measures, it can be seen that the values for the normalized Shannon entropy ($\widetilde{\mathcal{H}}$) are much lower than the values for the Gini coefficient (G) and the Jensen-Shannon distance (D_{JS}). However, all measures clearly indicate the differences in the frequency distribution of bigrams and trigrams. Comparing both datasets, it can be seen that the non-uniformity of bi- and trigrams is slightly higher for the NCVR than for the OHVF dataset.

Table 4: Analysis of q-gram frequency distribution.

Measure	Datasets							
	Bigrams				Trigrams			
	N	NCVR	O	OHVF	N	NCVR	O	OHVF

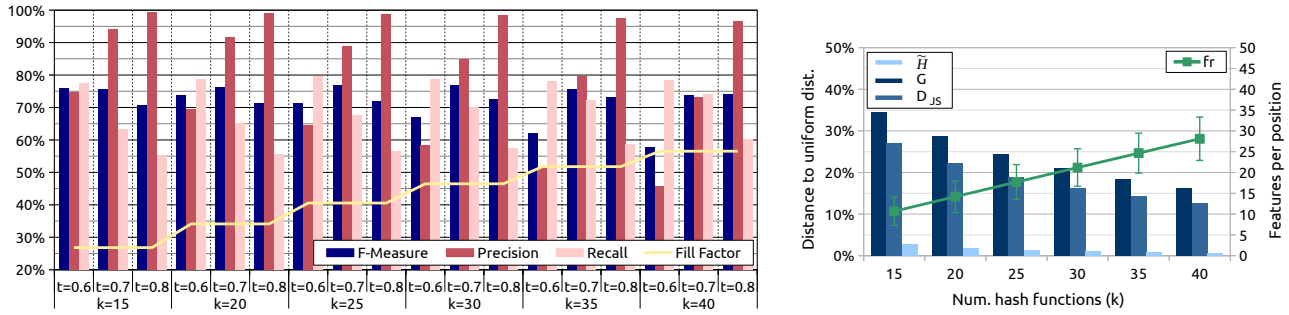
6 RESULTS AND DISCUSSION

In this section, we evaluate various BF variants and hardening techniques in terms of linkage quality and privacy (security).

6.1 Hash Functions and Fill Factor

In the following, we evaluate the linkage quality outcome and the privacy properties of basic BFs by inspecting the frequency distribution of the BF 1-bits compared to the q-gram frequencies. At first, we vary the number of hash functions (k), selecting $k \in \{15, 20, \ldots, 40\}$ and bigrams ($q = 2$), to adjust the fill factor (amount of 1-bits) of the BFs. The results for dataset N are depicted in Fig. 4. The results show, that for the high similarity thresholds of $t = 0.8$, all configurations achieve high precision $\geq 96.58\,\%$, but low recall $\leq 60.19\,\%$, leading to a max. F-measure of 74.16 %. For lower similarity thresholds ($t = \{0.7, 0.6\}$), precision is reduced drastically the more hash functions are used. For instance, setting $t = 0.6$ and $k = 15$, the highest precision of 75.93 % is achieved, while for $k = 40$ the precision is only 45.74 %. In contrast, the higher the number of hash functions, the higher the recall. For instance, setting $t = 0.6$ and $k = 15$, the recall is 73.28 %, while for $k = 40$ it increases to 78.51 %. However, the impact on precision is much higher (difference of around 34 %) than on recall (difference of around 5 %). Overall, the configuration with $t = 0.7$ and $k = 25$ achieves the best F-measure of 76.89 %. However, the other configuration except those with a fill factor over 50 % ($k \in \{35, 40\}$) achieve only slightly less F-measure. When averaging precision and recall for each k over all thresholds, the configurations with $k \leq 25$ achieve a mean F-measure of over 75 %, while for larger k it declines from around 74 % for $k = 30$ to around 71 % for $k = 40$.

Next, we analyze our privacy measures, which are depicted in Fig. 4(b). The figure shows that the more hash functions are used (and thus the higher the fill factor of the BFs) the higher is the avg. number of features that are mapped to each bit position. Even for the lowest number of hash functions, on average around 10 different bigrams are mapped to each individual bit position. Compared to the plaintext frequencies (see Tab. 4), we see that basic BFs have a significantly more uniform frequency distribution than the original plaintext dataset. For instance, using $k = 25$ hash functions, we obtain a Gini coefficient of 0.2443 and a Jensen-Shannon distance of 0.1891 compared to 0.7709 and 0.6315 for the unencoded dataset. Although for the Shannon entropy also a difference is visible, i. e., from 0.1848 for plaintext to 0.0137 for BFs setting $k = 25$, the values are in general much



(a) Quality **(b) Privacy**

Figure 4: Evaluation of standard Bloom filters using bigrams without padding for varying number of hash functions (k) on dataset N.

closer to zero and thus less intuitive to compare. As a consequence, in the following, we will focus on the other two privacy measures. Finally, the privacy measures indicate, that the more hash functions are used, the more closer the 1-bit distribution will get to uniform. However, the effect is not linear, such that the privacy gain is continuously getting lower, in particular for $k \geq 30$.

6.2 Choice of q and the Impact of Padding

In Tab. 5 we compare the linkage quality of BFs using different configurations for $q \in \{2, 3\}$ and padding for dataset N. Without the use of padding the best configuration for bigrams, i. e., $k = 25$ and $t = 0.7$, achieves a slightly less F-measure of 76.89 % than the best configuration for trigrams, i. e., $k = 20$ and $t = 0.6$, of 77.45 %. However, considering the mean over all configurations, using bigrams achieves a slightly higher F-measure of 75.07 % compared to 74.69 % for trigrams. Surprisingly, using trigrams results in an overall higher recall but lower precision if we average the results over all configurations. Moreover, the use of padding leads to a higher linkage quality, i. e., the best configurations for bigrams achieves a F-measure of 82.75 % while for trigrams even 85.10 % is attained. Averaged over all configurations, by using padding recall is increased about 5 % for bigrams and around 2.8 % for trigrams. Interestingly, also precision is increased by around 2.11 % for bigrams and around 4.02 % for trigrams. Thus, for both bigrams and trigrams, the mean F-measure can be increased by padding by more than 3 %. We repeat the experiments on dataset O and report the best configurations in Tab. 6. The results

Table 6: Comparison of Bloom filter encodings using bi- and trigrams with and without padding for dataset O.

q	Padding	k	t	Recall [%]	Precision [%]	F-Meas. [%]
2	No	25	0.7	68.17	88.32	76.95
	Yes	10	0.6	93.99	83.17	88.25
3	No	15	0.6	72.68	82.76	77.39
	Yes	10	0.6	95.49	90.14	92.74

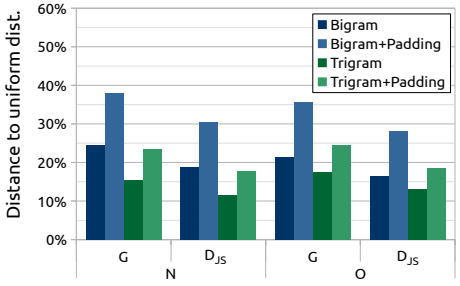

Figure 5: Comparison of Bloom filter privacy for bigrams and trigrams with and without using padding for datasets N and O.

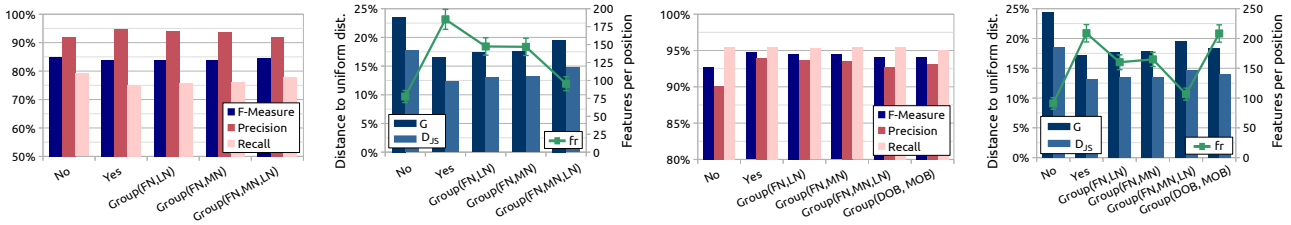


(a) Quality - N dataset **(b) Privacy - N dataset** **(c) Quality - O dataset** **(d) Privacy - O dataset**

Figure 6: Impact of attribute salting.

confirm our previous observation that trigrams with padding lead to the highest linkage quality. Here, the best configuration using trigrams and padding outperforms that with bigrams and padding even slightly more than for dataset N, i. e., F-measure increases 2.35 % for N and 4.49 % for O.

Fig. 5 shows our privacy measures for the best configuration in each group. In general, the use of bigrams leads to a less uniform distribution of 1-bits and thus lower privacy. Also, the use of padding leads to a higher dispersion of the BFs 1-bits. However, even the worst configuration, namely bigrams using padding, leads to a significantly less Gini coefficient as for the plaintext datasets. For N, for instance, the Gini coefficient is reduced from 0.7709 to 0.3801 (see Tab. 4 and Fig. 3). Also the Jensen-Shannon distance reduces drastically, e. g., for dataset N from 0.6315 for the plaintext dataset to 0.3045 for the BF dataset using bigrams with padding. In contrast, the use of trigrams leads to a more even distribution of 1-bits, so that despite using padding, a slightly more uniform frequency distribution is achieved than with bigrams and without using padding.

To summarize, the highest linkage quality is achieved by using padding which indeed leads to less uniform 1-bit distribution making frequency-based cryptanalysis more likely to be successful. However, this can be compensated by using trigrams leading even to a slightly better linkage quality than for bigrams. Consequently, for our following evaluation, we select the best configuration using trigrams and padding with $k = 10$ as a baseline for our experiments.

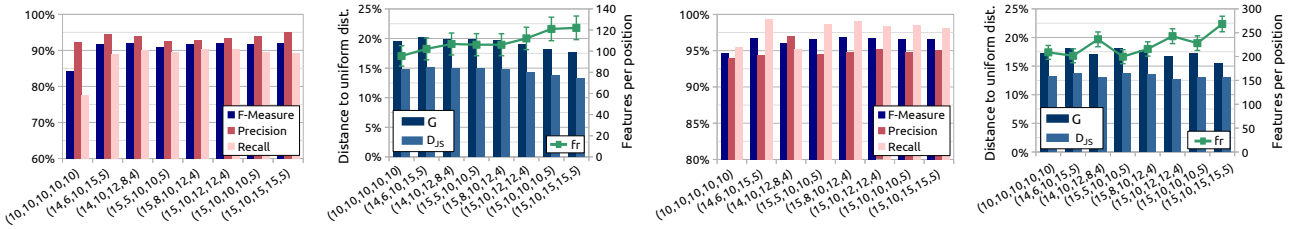
6.3 Salting and Weighting

In this section, we evaluate the impact of methods that alter the BFs hashing process by varying the number of hash functions and using salting keys to modify the hash mapping.

6.3.1 Attribute Salts. Fig. 6 depicts the results for BFs where the used hash functions are keyed (seeded) with a salt depending on the attribute a feature belongs to. For dataset N we observe that using an individual salt for each attribute increases precision from 91.99 % to 94.69 % but also decreases recall from 79.17 % to 75.26 % leading to a F-measure loss of around 1.2 %. Surprisingly, for dataset O precision increases from 90.14 % to 93.93 % while recall remains stable. Simultaneously, the average number of features that are mapped to each bit position increases by more than a factor of two for both datasets (Fig. 6 (b)/(d)). Furthermore, also the Gini coefficient and the Jensen-Shannon distance are significantly decreased and thus indicating an additional smoothing of the 1-bit distribution.

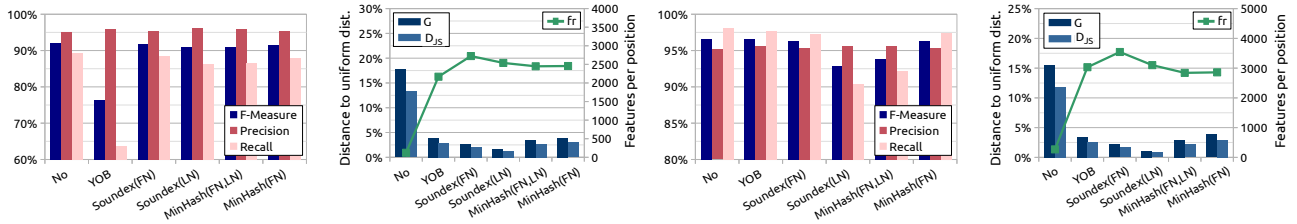
To be tolerant of swapped attributes, we build groups containing name-related attributes, i. e., one group for first name (FN) and last name (LN), one for first name and middle name (MN) and one for all three name components. Additionally, for dataset O, we build a group containing day and month of birth (DOB, MOB). For all attributes within one group, the same attribute salt is used. For dataset N we observe that all groups can slightly increase F-measure, while the group `(FN,MN,LN)` performs best and can increase F-measure to 84.48 %. Compared to the variant without using attribute salts, F-measure is therefore only decreased by 0.6 %. On dataset O, all groups achieve similar results, whereby precision and thus F-measure is always slightly lower than without using groups. Accordingly, swapped attributes seem to occur only rarely in dataset O. Using attribute salt groups also reduce the feature ratio and are also less effective in flattening the 1-bit distribution. Overall, however, the use of attribute salts can significantly reduce the dispersion of 1-bits while maintaining a high linkage quality. Building attribute salt groups can be beneficial for linkage quality, namely for applications where attribute transpositions are likely to occur. In the following, we include attribute salting as a baseline for our experiments, where for dataset N the group `(FN,MN,LN)` is used.

6.3.2 Impact of Attribute Weighting. In the following, we evaluate the impact of attribute weighting. Therefore, the number of hash functions is varied for each attribute depending on attribute weight. We tested several configurations and report the results in Fig. 7. The number of hash functions for each attribute is denoted



(a) Quality - N dataset **(b) Privacy - N dataset** **(c) Quality - O dataset** **(d) Privacy - O dataset**

Figure 7: Evaluation of varying number of hash functions based on attribute weights.



(a) Quality - N dataset **(b) Privacy - N dataset** **(c) Quality - O dataset** **(d) Privacy - O dataset**

Figure 8: Impact of record salting.

in the order (FN,LN,MN,YOB/BD,City). We observe that using attribute weighting strongly affects the linkage quality. All configurations that use a lower number of hash functions to map the attribute *city* can significantly increase both recall and precision. As a consequence, F-measure is improved by more than 6 % to over 91 % for dataset N and by around 2 % to over 96 % for dataset O. Analyzing the privacy results depicted in Fig. 7 (b)/(d), we observe that most weighting configurations can slightly increase the feature ratio and also slightly decrease the non-uniformity of 1-bits. By comparatively analyzing linkage quality and privacy, we select the configuration (15,10,15,15,5) as new baseline since it achieves the highest privacy while F-measure is only minimal less than for (14,10,12,8,4) (dataset N) and (15,10,12,12,4) (dataset O).

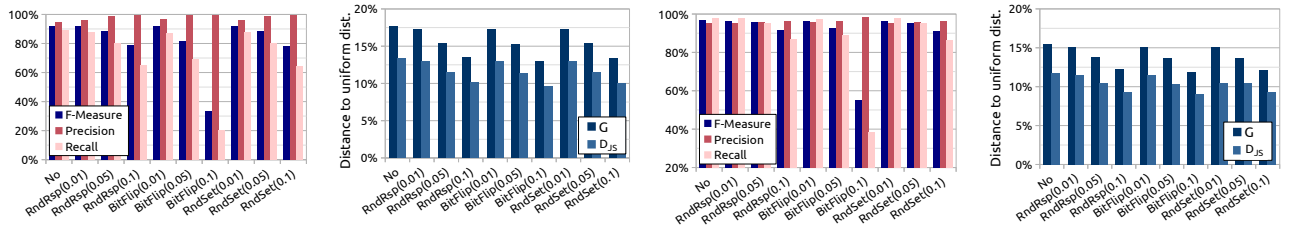
6.3.3 Record Salts. We now evaluate the approach of using a hash function salt that is individually selected for *each record*. The record salt is used in addition to the attribute salt we selected in the previous experiment. We tested several configurations using different attributes (year of birth, first name, last name). As Fig. 8(a)/(c) illustrate, record salts highly affect the linkage quality outcome. If we use the person's year of birth (YOB) as record-specific salt for the BFs hash function, recall drops drastically from 89.20 % (baseline) to only 63.58 % for dataset N. Apparently, in this dataset, this attribute is often erroneous and thus not suitable as record salt. In contrast, applying this configuration on dataset O, recall is only slightly reduced while precision is slightly increased, resulting in nearly the same F-measure. In order to compensate erroneous attributes, we test two techniques that are often utilized as blocking approaches, namely Soundex and MinHashing that we apply on the first and/or last name attribute. All tested approaches can slightly increase precision as they make the hash-mapping of the record features more unique. However, the Soundex and MinHash-based approaches also decrease recall, depending on the attribute(s) used. For instance, using Soundex on last name leads to relatively low recall in both datasets indicating many errors, e. g., due to marriages or divorces. Nevertheless, with the approaches using the first name, a similar high F-measure (loss ≤ 1 %) can be achieved as with the baseline.

Inspecting the privacy results depicted in Fig. 8 (b)/(d), we observe that the number of features that are mapped to each individual bit position is greatly increased by at least a factor of 10. At the same time, using record salts leads to a much more uniform 1-bit distribution. For instance, the Gini coefficient can be reduced from 0.1772 (baseline dataset N) and 0.1549 (baseline dataset O) to less than 0.04 for all tested approaches. The most uniform 1-bit distribution is achieved by using Soundex applied on last name, which leads to a Gini coefficient of less than 0.02. This implies that the 1-bit distribution is almost perfectly uniform which will make any frequency-based attack very unlikely to be successful. By analyzing privacy in relation to quality, we conclude that for both datasets Soundex applied to the first name performs the best and is able to achieve high linkage quality while effectively flattening the 1-bit distribution.

6.4 Modifications

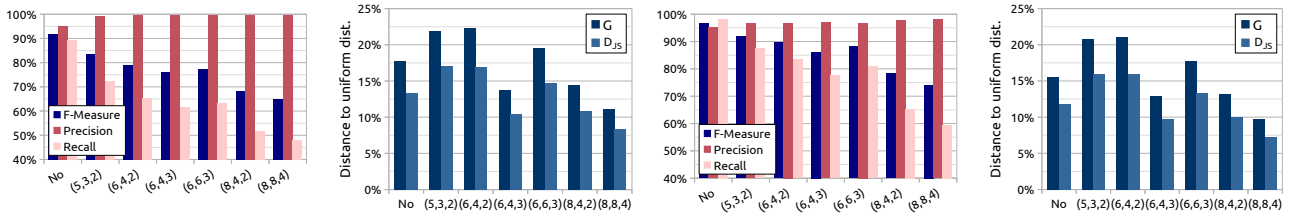
In the following, we evaluate hardening techniques that are applied directly on BFs (bit vectors).

6.4.1 Adding Random Noise. There are several ways of adding random noise to a BF (see Sec. 3.3.5). We compare the randomized response technique (RndRsp), random bit flipping (BitFlip) and randomly setting bits to one (RndSet) with each other. We vary the probability for changing an individual bit by setting $\rho = \{0.01, 0.05, 0.1\}$. The results are depicted in Fig. 9. As expected, recall and F-measure decrease with increasing ρ. While for $\rho = 0.01$ the loss is relatively small, it becomes significantly large for $\rho = 0.1$, in particular for the bit flip approach where recall drastically drops below 20 % for N and below 40 % for O. Interestingly, precision can be raised for all approaches and configurations up to 4.7 % (for $\rho = 0.1$). Overall, the bit flipping approach leads to the highest loss in linkage quality.



(a) Quality - N dataset **(b) Privacy - N dataset** **(c) Quality - O dataset** **(d) Privacy - O dataset**

Figure 9: Evaluation of random noise approaches.



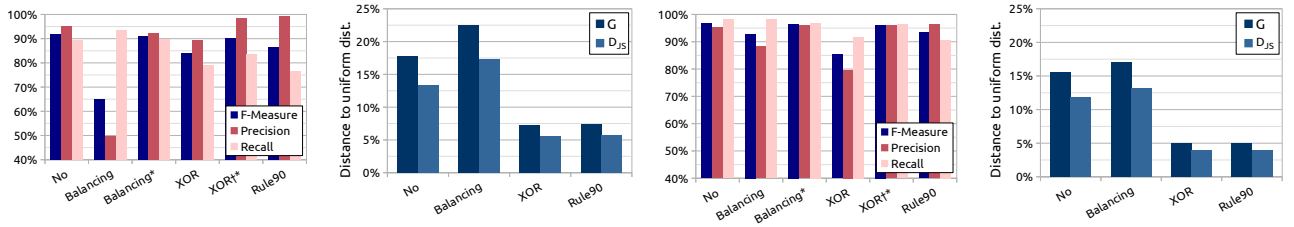
(a) Quality - N dataset **(b) Privacy - N dataset** **(c) Quality - O dataset** **(d) Privacy - O dataset**

Figure 10: Evaluation of re-hashing.

By analyzing the privacy results shown in Fig. 9 (b)/(d), it is evident that all random noise approaches can reduce the frequency information only a little. Only at a high ρ-value of 0.1 the Gini coefficient can be reduced by up to 4.81 % and the Jensen-Shannon distance up to 3.65 %. Analyzing the trade-off between linkage quality and privacy, we observe that a high value for ρ leads to an unacceptable loss in linkage quality. For lower ρ-values both techniques, randomized response and randomly setting bits to one, lead to relatively small losses in linkage quality. However, they are not able to significantly flatten the 1-bit distribution. Nevertheless, hardening techniques based on random noise may impede deterministic attacks by increasing the number of unique bit patterns.

6.4.2 Re-Hashing. To evaluate re-hashing, we tested several configurations regarding window size w, step size s and the number of re-hashed values r. In Fig. 10 we report the best configurations which are denoted in the order `(w,s,r)` setting $m' = m$. The results regarding linkage quality show that re-hashing increases precision but in contrast drastically decreases recall. In general, the larger the window size w the lower the recall that can be achieved. This effect is due to the fact that with larger windows there is a higher probability that a bit in the window is different for two similar BFs. This will result in another integer value (seed) on which the re-hashed 1-bit positions are selected. Even for the configuration with the smallest window size $w = 5$, recall decreases by more than 16 % for both datasets. We could not further decrease the window size, as with $w = 4$ only 16 different bit patterns are possible, so the re-hashed values will be often the same. This observation is confirmed by inspecting the privacy measures illustrated in Fig. 10 (b)/(d). Surprisingly, several configurations, namely `(5,3,2)`, `(6,4,2)` and `(6,6,3)`, will increase the non-uniformity of 1-bits. This is because the re-hashed values will be mapped only to a small range and thus increase the frequencies of these bits. In contrast, the configuration `(6,4,3)` and those with $w = 8$ can flatten the similarity distribution moderately. At the same time, however, these configurations will lead to an unacceptable low recall, e. g., for dataset N to only 61.66 % for `(6,4,3)` or even less then 50 % for `(8,8,4)`. As illustrated by the two configurations `(8,8,4)` and `(8,4,4)`, a reduction of the step size can increase recall since configurations with $s < w$ will lead to overlapping windows and thus a higher chance of finding overlapping bit patterns between two BFs. However, this again increases the unequal distribution of 1-bits. To summarize, we observe that re-hashing will decrease linkage quality while being not effective in increasing the uniformity of 1-bits. Therefore, we can not recommend this method for practical applications.

6.4.3 Balanced Bloom Filter, XOR-folding and Rule90. Finally, we evaluate balanced BFs, XOR-folding and applying Rule90 in terms of linkage quality and privacy. The results are depicted in Fig. 11. The results indicate that balancing reduces precision. While for dataset O precision decreases moderately by 6.93 %, for dataset N it drops drastically by 45.19 %. In contrast, recall remains stable for dataset O whereas it is slightly increased for dataset O. We found that changing our basic similarity threshold from 0.6 to 0.7 can significantly improve linkage quality for balancing. This might be due to the fact that balancing doubles the size of the BFs. Thus, we included the starred version of balancing indicating that a different threshold was used. With this configuration, balancing reduces F-measure only slightly for both datasets. For dataset N this is due to a little less precision and a little higher recall than for the baseline. For dataset O, however, it is the other way around, i. e., less recall and higher precision. XOR-folding also causes a reduction in linkage quality for both datasets. Since XOR-folding halves the size of the BFs, LSH-based blocking is affected in such a way that the amount of bits selected for the LSH keys is comparatively large. We therefore reduced the LSH key length from $\Psi = 16$ to $\Psi = 10$ and indicate this configuration with a dagger (†). By using this configuration and setting $t = 0.7$, for both datasets XOR-folding results in a minor loss of F-measure of less than 1 % compared to the baseline. Primarily accountable for the high F-measure is the high precision, which is slightly increased. Furthermore, we observe that



(a) Quality - N dataset **(b) Privacy - N dataset** **(c) Quality - O dataset** **(d) Privacy - O dataset**

Figure 11: Evaluation of balanced Bloom filters, XOR-folding and Rule90.

applying Rule90 also leads to a relatively high loss of recall of around 12.5 % for datast N and 7.6 % for dataset O. Again, Rule90 increases precision slightly thus leading to a moderate loss of F-measure of around 5.5 % for dataset N and 3.2 % for dataset O.

Examining Fig. 11 (b)/(d), we can see that balancing interestingly increases the dispersion of 1-bits. For dataset N, for instance, the Gini coefficient is increased by around 4.8 % and the Jensen-Shannon distance by around 4 %. In contrast, XOR-folding and Rule90 lead to a more uniform distribution of 1-bits. Both approaches reduce the Gini coefficient by about 10 % and the Jensen-Shannon distance by more than 7.5 %. Considering both, linkage quality and privacy, we conclude that XOR-folding performs the best by maintaining high linkage quality while effectively flattening the 1-bit distribution.

7 CONCLUSION

Bloom filters are frequently used in both research and practice for PPRL applications. In this paper, we reviewed and classified various BF variants and hardening techniques that aim at making Bloom filters more robust against cryptanalysis. Currently, no privacy measure exists that allows comparison of different encoding schemes in terms of privacy (security) and is independent of any reference dataset. We therefore proposed three privacy measures that allow assessing the privacy properties of Bloom filter encodings. These measures are based solely on a set of Bloom filters and do not need any reference dataset or other information. Moreover, we comprehensively evaluated the Bloom filter variants and hardening techniques in terms of both linkage quality and privacy. The evaluation showed that multiple hardening techniques drastically reduce linkage quality and are thus not applicable in real-world scenarios. However, in particular two techniques, namely salting and XOR-folding, drastically reduce any frequency information while maintaining high linkage quality. Carefully selected Bloom filter parameters in combination with these techniques will make any frequency-based cryptanalysis very unlikely to be successful.

For future work, we aim to evaluate these approaches against modern Bloom filter attacks described in the literature to further verify our findings.

Proof-of-Execution: Reaching Consensus through Fault-Tolerant Speculation

ABSTRACT

Multi-party data management and blockchain systems require data sharing among participants. To provide resilient and consistent data sharing, transactions engines rely on Byzantine Fault-Tolerant consensus (BFT), which enables operations during failures and malicious behavior. Unfortunately, existing BFT protocols are unsuitable for high-throughput applications due to their high computational costs, high communication costs, high client latencies, and/or reliance on twin-paths and non-faulty clients.

In this paper, we present the *Proof-of-Execution consensus protocol* (PoE) that alleviates these challenges. At the core of PoE are *out-of-order* processing and *speculative execution*, which allow PoE to execute transactions before consensus is reached among the replicas. With these techniques, PoE manages to reduce the costs of BFT in normal cases, while guaranteeing reliable consensus for clients in all cases. We envision the use of PoE in high-throughput multi-party data-management and blockchain systems. To validate this vision, we implement PoE in our efficient ResilientDB fabric and extensively evaluate PoE against several state-of-the-art BFT protocols. Our evaluation showcases that PoE achieves up-to-80% higher throughputs than existing BFT protocols in the presence of failures.

1 INTRODUCTION

In *federate data management* a single common database is managed by many independent stakeholders (e.g., an industry consortium). In doing so, federated data management can ease data sharing and improve data quality [17, 32, 48]. At the core of federated data management is *reaching agreement* on any updates on the common database in an efficient manner, this to enable fast query processing, data retrieval, and data modifications.

One can achieve federated data management by *replicating* the common database among all participant, this by replicating the sequence of transactions that affect the database to all stakeholders. One can do so using commit protocols designed for distributed databases such as two-phase [22] and three-phase commit [49], or by using crash-resilient replication protocols such as Paxos [39] and Raft [45].

These solutions are error-prone in a federated *decentralized* environment in which each stakeholder manages its own replicas and replicas of each stakeholder can fail (e.g., due to software, hardware, or network failure) or act malicious: commit protocols and replication protocols can only deal with crashes. Consequently, recent federated designs propose the usage of Byzantine Fault-Tolerant (BFT) consensus protocols. BFT consensus aims at *ordering client requests among a set of replicas, some of which could be Byzantine, such that all non-faulty replicas reach agreement on a common order for these requests* [9, 21, 29, 38, 51]. Furthermore, BFT consensus comes with the added benefit of *democracy*, as BFT consensus gives all replicas an equal vote in all agreement decisions, while the resilience of BFT can aid in dealing with the billions of dollars losses associated with prevalent attacks on data management systems [44].

Akin to commit protocols, the majority of BFT consensus protocols use a *primary-backup model* in which one replica is designated *the primary* that coordinates agreement, while the remaining replicas act as backups and follow the protocol [46]. This primary-backup BFT consensus was first popularized by the influential PBFT consensus protocol of Castro and Liskov [9]. The design of PBFT requires at least $3\mathbf{f}+1$ replicas to deal with up-to-$\mathbf{f}$ malicious replicas and operates in *three communication phases*, two of which necessitate quadratic communication complexity. As such, PBFT is considered costly when compared to commit or replication protocols, which has negatively impacted the usage of BFT consensus in large-scale data management systems [8].
