The recent interest in blockchain technology has revived interest in BFT consensus, has led to several new resilient data management systems (e.g., [3, 18, 29, 43]), and has led to the development of new BFT consensus protocols that promise efficiency at the cost of flexibility (e.g., [21, 28, 38, 51]). Despite the existence of these modern BFT consensus protocols, the majority of BFT-fueled systems [3, 18, 29, 43] still employ the classical time-tested, flexible, and safe design of PBFT, however.

In this paper, we explore different design principles that can enable implementing a scalable and reliable agreement protocol that shields against malicious attacks. We use these design principles to introduce Proof-of-Execution (PoE), a novel BFT protocol that achieves resilient agreement in just three linear phases. To concoct PoE's scalable and resilient design, we start with PBFT and successively add *four* design elements:

(I1) **Non-Divergent Speculative Execution.** In PBFT, when the primary replica receives a client request, it forwards that request to the backups. Each backup on receiving a request from the primary agrees to support by broadcasting a PREPARE message. When a replica receives PREPARE message from the majority of other replicas, it marks itself as *prepared* and broadcasts a COMMIT message. Each replica that has prepared, and receives COMMIT messages from a majority of other replicas, executes the request.

Evidently, PBFT requires two phases of *all-to-all* communication. Our first ingredient towards faster consensus is speculative execution. In PBFT terminology, PoE replicas execute requests after they get *prepared*, that is, they do not broadcast COMMIT messages. This speculative execution is non-divergent as each replica has a partial guarantee–it has prepared–prior to execution.

(I2) **Safe Rollbacks and Robustness under Failures.** Due to speculative execution, a malicious primary in PoE can ensure that only a subset of replicas prepare and execute a request. Hence, a client may or may not receive a sufficient number of matching responses. PoE ensures that if a client receives a *full proof-of-execution*, consisting of responses from a majority of the non-faulty replicas, then such a request persists in time. Otherwise, PoE permits replicas to *rollback* their state if necessary. This proof-of-execution is the cornerstone of the correctness of PoE.

(I3) **Agnostic Signatures and Linear Communication.** BFT protocols are run among distrusting parties. To provide security, these protocols employ cryptographic primitives for signing the messages and generating message digests. Prior works have shown that the choice of cryptographic signature scheme can impact the performance of the underlying system [9, 30]. Hence, we allow replicas to either employ *message authentication codes* (MACs) or *threshold signatures* (TSs) for signing [36]. When few replicas are participating in consensus (up to 16), then a single phase of all-to-all communication is inexpensive and using MACs for such setups can make computations cheap. For larger setups, we employ TSs to achieve linear communication complexity. TSs permit us to split a phase of all-to-all communication into *two linear phases* [21, 51].

(I4) **Avoid Response Aggregation.** SBFT [21], a recently-proposed BFT protocol, suggests the use of a single replica (designated as the *executor*) to act as a response aggregator. In specific, all replicas execute each client request and send their response to the executor. It is the duty of the executor to reply to the client and *send a proof* that a majority of the replicas not only executed this request, but also outputted the same result. In PoE, we avoid this additional communication between the replicas by allowing each replica to respond directly to the client.

In specific, we make the following contributions:

(1) We introduce PoE, a novel Byzantine fault-tolerant consensus protocol that uses *speculative execution* to reach agreement among replicas.
(2) To guarantee failure recovery in the presence of speculative execution and Byzantine behavior, we introduce a novel view-change protocol that can rollback requests.
(3) PoE supports batching, out-of-order processing, and is signature-scheme agnostic and can be made to employ either MACs or threshold signatures.
(4) PoE does not rely on non-faulty replicas, clients, or trusted hardware to achieve safe and efficient consensus.
(5) To validate our vision of using PoE in resilient federated data management systems, we implement PoE and four other BFT protocols (Zyzzyva, Pbft, SBFT, and HotStuff) in our efficient ResilientDB[1] fabric [23–25, 27, 29, 30, 47].
(6) We extensively evaluate PoE against these protocols on a Google Cloud deployment consisting of 91 replicas and 320 k clients under (i) no failure, (ii) backup failure, (iii) primary failure, (iv) batching of requests, (v) zero payload, and (vi) scaling the number of replicas. Further, to prove the correctness of our results, we also stress test PoE and other protocols in a simulated environment. Our results show that PoE can achieve up to 80% more throughput than existing BFT protocols in the presence of failures.

To the best of our knowledge, PoE is the first protocol that achieves consensus in *only two phases* while being able to deal with Byzantine failures and without relying on trusted clients (e.g., Zyzzyva [38]) or on trusted hardware (e.g., MinBFT [50]). Hence, PoE can serve as a drop-in replacement of Pbft to improve scalability and performance in permissioned blockchain fabrics such as our ResilientDB fabric [27–31], MultiChain [20], and Hyperledger Fabric [4]; in multi-primary meta-protocols such as RCC [26, 28]; and in sharding protocols such as AHL [15].

2 ANALYSIS OF DESIGN PRINCIPLES

To arrive at an optimal design for PoE, we studied practices followed by state-of-the-art distributed data management systems and applied their principles to the design of PoE where possible. In Figure 1, we present a comparison of PoE against *four* well-known resilient consensus protocols.

Protocol	Phases	Messages	Resilience	Requirements
Zyzzyva	1	$O(\mathbf{n})$	0	Reliable clients and unsafe
PoE (our paper)	3	$O(3\mathbf{n})$	$\mathbf{f}$	Sign. agnostic
Pbft	3	$O(\mathbf{n} + 2\mathbf{n}^2)$	$\mathbf{f}$	
HotStuff	8	$O(8\mathbf{n})$	$\mathbf{f}$	Sequential Consensus
SBFT	5	$O(5\mathbf{n})$	0	Optimistic path

Figure 1: Comparison of BFT consensus protocols in a system with n replicas of which f are faulty. The costs given are for the normal-case behavior.

To illustrate the merits of PoE's design, we first briefly look at Pbft. The last phase of Pbft ensures that non-faulty replicas only execute requests and inform clients when there is a guarantee that such a transaction will be recovered after any failures. Hence, clients need to wait for only $\mathbf{f} + 1$ identical responses, of which at-least one is from a non-faulty replica, to ensure *guaranteed execution*. By eliminating this last phase, replicas speculatively execute requests before obtaining recovery guarantees. This impacts Pbft-style consensus in two ways:

(1) First, clients need a way to determine *proof-of-execution* after which they have a guarantee that their requests are executed and maintained by the system. We shall show that such a proof-of-execution can be obtained using $\mathbf{nf} \geq 2\mathbf{f} + 1$ identical responses (instead of $\mathbf{f} + 1$ responses).
(2) Second, as requests are executed before they are guaranteed, replicas need to be able to rollback requests that are dropped during periods of recovery.

PoE's speculative execution guarantees that requests with a proof-of-execution will never rollback and that only a single request can obtain a proof-of-execution per round. Hence, speculative execution provides the same strong consistency (safety) of Pbft in all cases, this at much lower cost under normal operations. Furthermore, we show that speculative execution is fully compatible with other scalable design principles applied to Pbft, e.g., batching and out-of-order processing to maximize throughput, even with high message delays.

Out-of-order execution. Typical BFT systems follow the *order-execute* model: first replicas agree on a unique order of the client request, and only then they execute the requests in order [9, 21, 29, 38, 51]. Unfortunately, this prevents these systems from providing any support for concurrent execution. A few BFT systems suggest executing prior to ordering, but even such systems need to re-verify their results prior to committing changes [4, 35]. Our PoE protocol lies between these two extremes: the replicas speculatively execute using only partial ordering guarantees. By doing so, PoE can eliminate communication costs and minimize latencies of typical BFT systems, this without needing to re-verify results in the normal case.

Out-of-order processing. Although BFT consensus typically executes requests in-order, this does not imply they need to process proposals to order requests sequentially. To maximize throughput, Pbft and other primary-backup protocols support *out-of-order processing* in which all available bandwidth of the primary is used to continuously propose requests (even when previous proposals are still being processed by the system). By doing so, out-of-order processing can eliminate the impact of high message delays. To provide out-of-order processing, all replicas will process any request proposed as the k-th request whenever k is within some *active window* bounded by a *low-watermark* and *high-watermark* [9]. These watermarks are increased as the

[1] ResilientDB is open-sourced at https://github.com/resilientdb.

system progresses. The size of this active window is—in practice—only limited by the memory resources available to replicas. As out-of-order processing is an essential technique to deliver high throughputs in environments with high message delays, we have included out-of-order processing in the design of PoE.

Twin-path consensus. Speculative execution employed by PoE is different that the *twin-path model* utilized by Zyzzyva [38] and SBFT [21]. These twin-path protocols have an optimistic *fast* path that works only if none of the replicas are *faulty* and require aid to determine whether these optimistic condition hold.

In the fast path of Zyzzyva, primaries propose requests, and backups directly execute such proposals and inform the client (without further coordination). The client waits for responses from all $\mathbf{n}$ replicas before marking the request executed. When the client does not receive $\mathbf{n}$ responses, it *timeouts* and sends a message to all replicas, after which the replicas perform an expensive client-dependent *slow-path* recovery process (which is prone to errors when communication is unreliable [2]).

The fast path of SBFT can deal with up to $\mathbf{c}$ crash-failures using $3\mathbf{f} + 2\mathbf{c} + 1$ replicas and uses threshold signatures to make communication linear. The fast path of SBFT requires a reliable collector and executor to aggregate messages and to send only *a single* (instead of at-least-$\mathbf{f} + 1$) response to the client. Due to aggregating execution, the fast path of SBFT still performs four rounds of communication before the client gets a response, whereas PoE only uses two rounds of communication (or three when PoE uses threshold signatures). If the fast path *timeouts* (e.g., the collector or executor fails), then SBFT falls back to a threshold-version of Pbft that takes an additional round before the client gets a response. Twin-path consensus is in sharp contrast with the design of PoE, which does not need outside aid (reliable clients, collectors, or executors), and can operate optimally even while dealing with replica failures.

Primary rotation. To minimize the influence of any single replica on bft consensus, HotStuff opts to replace the primary after every consensus decision. To efficiently do so, HotStuff uses an extra communication phase (as compared to Pbft), which minimizes the cost of primary replacement. Furthermore, HotStuff uses threshold signatures to make its communication linear (resulting in eight communication phases before a client gets responses). The event-based version of HotStuff can overlap phases of consecutive rounds, thereby assuring that consensus of a client request starts in every one-to-all-to-one communication phase. Unfortunately, the primary replacements require that all consensus rounds are performed in a strictly *sequential* manner, eliminating any possibility of *out-of-order processing*.

3 PROOF-OF-EXECUTION

In our *Proof-of-Execution consensus protocol* (PoE), the primary replica is responsible for proposing transactions requested by clients to all backup replicas. Each backup replica *speculatively* executes these transactions with the belief that the primary is behaving correctly. Speculative execution expedites processing of transactions in all cases. Finally, when malicious behavior is detected, replicas can recover by *rolling back transactions*, which ensures correctness without depending on any twin-path model.

3.1 System model and notations

Before providing a full description of our PoE protocol, we present the system model we use and the relevant notations.

A system is a set $\mathfrak{R}$ of *replicas* that process client requests. We assign each replica $\mathrm{R} \in \mathfrak{R}$ a unique identifier $\mathrm{id}(\mathrm{R})$ with $0 \leq \mathrm{id}(\mathrm{R}) < |\mathfrak{R}|$. We write $\mathcal{F} \subseteq \mathfrak{R}$ to denote the set of *Byzantine replicas* that can behave in arbitrary, possibly coordinated and malicious, manners. We assume that non-faulty replicas (those in $\mathfrak{R} \setminus \mathcal{F}$) behave in accordance to the protocol and are deterministic: on identical inputs, all non-faulty replicas must produce identical outputs. We do not make any assumptions on clients: all client can be malicious without affecting PoE. We write $\mathbf{n} = |\mathfrak{R}|$, $\mathbf{f} = |\mathcal{F}|$, and $\mathbf{nf} = |\mathfrak{R} \setminus \mathcal{F}|$ to denote the number of replicas, faulty replicas, and non-faulty replicas, respectively. We assume that $\mathbf{n} > 3\mathbf{f}$ ($\mathbf{nf} > 2\mathbf{f}$).

We assume *authenticated communication*: Byzantine replicas are able to impersonate each other, but replicas cannot impersonate non-faulty replicas. Authenticated communication is a minimal requirement to deal with Byzantine behavior. Depending on the type of message, we use message authentication codes (MACs) or threshold signatures (TSs) to achieve authenticated communication [36]. MACs are based on symmetric cryptography in which every pair of communicating nodes has a *secret key*. We expect non-faulty replicas to keep their *secret keys* hidden. TSs are based on asymmetric cryptography. In specific, each replica holds a distinct *private key*, which it can use to create a signature share. Next, one can produce a valid threshold signature given at least $\mathbf{nf}$ such signature shares (from distinct replicas). We write $s\langle v \rangle_i$ to denote the signature share of the i-th replica for signing value v. Anyone that receives a set $T = \{s\langle v \rangle_j \mid j \in T'\}$ of signature shares for v from $|T'| = \mathbf{nf}$ distinct replicas, can aggregate T into a single signature $\langle v \rangle$. This digital signature can then be verified using a public key.

We also employ a *collision-resistant cryptographic hash function* $\mathrm{D}(\cdot)$ that can map an arbitrary value v to a constant-sized digest $\mathrm{D}(v)$ [36]. We assume that it is practically impossible to find another value v', $v \neq v'$, such that $\mathrm{D}(v) = \mathrm{D}(v')$. We use notation $v||w$ to denotes the *concatenation* of two values v and w.

Next, we define the consensus provided by PoE.

Definition 3.1. A single run of any *consensus protocol* should satisfy the following requirements:

Termination. Each non-faulty replica executes a transaction.

Non-divergence. All non-faulty replicas execute the same transaction.

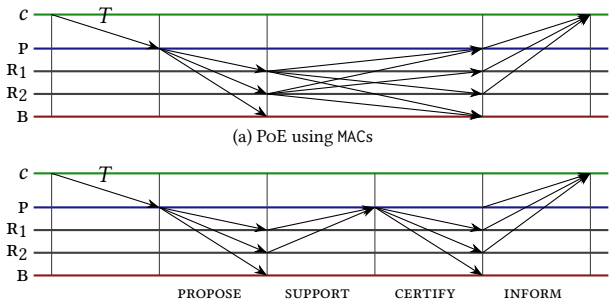
Termination is typically referred to as *liveness*, whereas non-divergence is typically referred to as *safety*. In PoE, execution is speculative: replicas can execute and rollback transactions. To provide safety, PoE provides speculative non-divergence instead of non-divergence:

Speculative non-divergence. If $\mathbf{nf} - \mathbf{f} \geq \mathbf{f} + 1$ non-faulty replicas accept and execute the same transaction T, then all non-faulty replicas will eventually accept and execute T (after rolling back any other executed transactions).

To provide *safety*, we do not need any other assumptions on communication or on clients. Due to well-known impossibility results for asynchronous consensus [19], we can only provide *liveness* in periods of *reliable bounded-delay communication* during which all messages sent by non-faulty replicas will arrive at their destination within some maximum delay.

3.2 The Normal-Case Algorithm of PoE

PoE operates in *views* $v = 0, 1, \ldots$. In view v, replica R with $\mathrm{id}(\mathrm{R}) = v \bmod \mathbf{n}$ is elected as the primary. The design of PoE relies on authenticated communication, which can be provided using MACs or TSs. In Figure 2, we sketch the normal-case working of PoE for both cases. For the sake of brevity, we will describe PoE built on top of TSs, which results in a protocol with low—*linear*—message complexity in the normal case. The full pseudo-code for



(a) PoE using MACs

(b) PoE using TSs.

Figure 2: Normal-case algorithm of PoE: Client c sends its request containing transaction T to the primary P, which proposes this request to all replicas. Although replica B is Byzantine, it fails to affect PoE.

this algorithm can be found in Figure 3. In Section 3.6, we detail the minimal changes to PoE necessary when switching to MACs.

Consider a view v with primary P. To request execution of transaction T, a client c signs transaction T and sends the signed transaction $\langle T \rangle_c$ to P. The usage of signatures assures that malicious primaries cannot forge transactions. To initiate replication and execution of T as the k-th transaction, the primary proposes T to all replicas via a PROPOSE message.

After the i-th replica R receives a PROPOSE message m from P, it checks whether at least **nf** other replicas received the same proposal m from primary P. This check assures R that at least $\mathbf{nf} - \mathbf{f}$ non-faulty replicas received the same proposal, which will play a central role in achieving speculative non-divergence. To perform this check, each replica *supports* the first proposal m it receives from the primary by computing a *signature share* $s\langle m \rangle_i$ and sending a SUPPORT message containing this share to the primary.

The primary P waits for SUPPORT messages with valid signature shares from **nf** distinct replicas, which can then be aggregated into a single signature $\langle m \rangle$. After generating such a signature, the primary broadcasts this signature to all replicas via a CERTIFY message.

After a replica R receives a valid CERTIFY message, it *view-commits* to T as the k-th transaction in view v. The replica logs this view-commit decision as $\texttt{VCommit}_R(\langle T \rangle_c, v, k)$. After R view-commits to T, R schedules T for speculative execution as the k-th transaction of view v. Consequently, T will be executed by R after all preceding transactions are executed. We write $\texttt{Execute}_R(\langle T \rangle_c, v, k)$ to log this execution.

After execution, R informs the client of the order of execution and of execution result r (if any) via a message INFORM. In turn, client c will wait for a *proof-of-execution* for the transaction T it requested, which consists of identical INFORM messages from **nf** distinct replicas. This proof-of-execution guarantees that at least $\mathbf{nf} - \mathbf{f} \geq \mathbf{f} + 1$ non-faulty replicas executed T as the k-th transaction and in Section 3.3, we will see that such transactions are always preserved by PoE when recovering from failures.

If client c does not know the current primary or does not get any timely response for its requests, then it can broadcast its request $\langle T \rangle_c$ to all replicas. The non-faulty replicas will then forward this request to the current primary (if T is not yet executed) and ensure that the primary initiates successful proposal of this request in a timely manner.

To prove correctness of PoE in all cases, we will need the following technical safety-related property of view-commits.

Client-role (used by client c to request transaction T) :

1: Send $\langle T \rangle_c$ to the primary P.
2: Await receipt of messages INFORM$(\langle T \rangle_c, v, k, r)$ from **nf** replicas.
3: Considers T executed, with result r, as the k-th transaction.

Primary-role (running at the primary P of view v, $\text{id}(\text{P}) = v \bmod \mathbf{n}$) :

4: Let view v start after execution of the k-th transaction.
5: **event** P awaits receipt of message $\langle T \rangle_c$ from client c **do**
6: Broadcast PROPOSE$(\langle T \rangle_c, v, k)$ to all replicas.
7: $k := k + 1$.
8: **end event**
9: **event** P receives **nf** message SUPPORT$(s\langle h \rangle_i, v, k)$ such that:
(1) each message was sent by a distinct replica, $i \in \{1, \ldots, n\}$; and
(2) All $s\langle h \rangle_i$ in this set can be combined to generate signature $\langle h \rangle$.
do
10: Broadcast CERTIFY$(\langle h \rangle, v, k)$ to all replicas.
11: **end event**

Backup-role (running at every i-th replica R.) :

12: **event** R receives message $m :=$ PROPOSE$(\langle T \rangle_c, v, k)$ such that:
(1) v is the current view;
(2) m is sent by the primary of v; and
(3) R did not accept a k-th proposal in v
do
13: Compute $h := \text{D}(\langle T \rangle_c || v || k)$.
14: Compute signature share $s\langle h \rangle_i$.
15: Transmit SUPPORT$(s\langle h \rangle_i, v, k)$ to P.
16: **end event**
17: **event** R receives messages CERTIFY$(\langle h \rangle, v, k)$ from P such that:
(1) R transmitted SUPPORT$(s\langle h \rangle_i, v, k)$ to P; and
(2) $\langle h \rangle$ is a valid threshold signature
do
18: View-commit T, the k-th transaction of v ($\texttt{VCommit}_R(\langle T \rangle_c, v, k)$).
19: **end event**
20: **event** R logged $\texttt{VCommit}_R(\langle T \rangle_c, v, k)$ and
has logged $\texttt{Execute}_R(t', v', k')$ for all $0 \leq k' < k$ **do**
21: Execute T as the k-th transaction of v ($\texttt{Execute}_R(\langle T \rangle_c, v, k)$).
22: Let r be the result of execution of T (if there is any result).
23: Send INFORM$(\text{D}(\langle T \rangle_c), v, k, r)$ to c.
24: **end event**

Figure 3: The normal-case algorithm of PoE.

PROPOSITION 3.2. *Let* R_i, $i \in \{1, 2\}$, *be two non-faulty replicas that view-committed to* $\langle T_i \rangle_{c_i}$ *as the* k*-th transaction of view* v ($\texttt{VCommit}_R(\langle T \rangle_c, v, k)$). *If* $\mathbf{n} > 3\mathbf{f}$, *then* $\langle T_1 \rangle_{c_1} = \langle T_2 \rangle_{c_2}$.

PROOF. Replica R_i only view-committed to $\langle T_i \rangle_{c_i}$ after R_i received CERTIFY$(\langle h \rangle, v, k)$ from the primary P (Line 17 of Figure 3). This message includes a threshold signature $\langle h \rangle$, whose construction requires signature shares from a set S_i of **nf** distinct replicas. Let $X_i = S_i \setminus \mathcal{F}$ be the non-faulty replicas in S_i. As $|S_i| = \mathbf{nf}$ and $|\mathcal{F}| = \mathbf{f}$, we have $|X_i| \geq \mathbf{nf} - \mathbf{f}$. The non-faulty replicas in X_i will only send a single SUPPORT message for the k-th transaction in view v (Line 12 of Figure 3). Hence, if $\langle T_1 \rangle_{c_1} \neq \langle T_2 \rangle_{c_2}$, then X_1 and X_2 must not overlap and $\mathbf{nf} \geq |X_1 \cup X_2| \geq 2(\mathbf{nf} - \mathbf{f})$ must hold. As $\mathbf{n} = \mathbf{nf} + \mathbf{f}$, this simplifies to $3\mathbf{f} \geq \mathbf{n}$, which contradicts $\mathbf{n} > 3\mathbf{f}$. Hence, we conclude $\langle T_1 \rangle_{c_1} = \langle T_2 \rangle_{c_2}$. □

We will later use Proposition 3.2 to show that PoE provides speculative non-divergence. Next, we look at typical cases in which the normal-case of PoE is interrupted:

Example 3.3. A malicious primary can try to affect PoE by not conforming to the normal-case algorithm in the following ways:

(1) By sending proposals for different transactions to different non-faulty replicas. In this case, Proposition 3.2 guarantees that at most a single such proposed transaction will get view-committed by any non-faulty replica.
(2) By keeping some non-faulty replicas in the dark by not sending proposals to them. In this case, the remaining non-faulty replicas can still end up view-committing the transactions as long as at least $\mathbf{nf} - \mathbf{f}$ non-faulty replicas receive proposals: the faulty replicas in $\mathcal{F}$ can take over the

role of up to **f** non-faulty replicas left in the dark (giving the false illusion that the non-faulty replicas in the dark are malicious).

(3) By preventing execution by not proposing a k-th transaction, even though transactions following the k-th transaction are being proposed.

When the network is unreliable and messages do not get delivered (or not on time), then the behavior of a non-faulty primary can match that of the malicious primary in the above example. Indeed, failure of the normal-case of PoE has only two possible causes: primary failure and unreliable communication. If communication is unreliable, then there is no way to guarantee continuous service [19]. Hence, replicas simply assume failure of the current primary if the normal-case behavior of PoE is interrupted, while the design of PoE guarantees that unreliable communication does not affect the correctness of PoE.

To deal with primary failure, each replica maintains a timer for each request. If this timer expires (*timeout*) and it has not been able to execute the request, it assumes that the primary is malicious. To deal with such a failure, replicas will replace the primary. Next, we present the *view-change algorithm* that performs primary replacement.

3.3 The View-Change Algorithm

If PoE observes failure of the primary P of view v, then PoE will elect a new primary and move to the next view, view $v+1$, via the *view-change algorithm*. The goals of the view-change are

(1) to assure that each request that *is considered executed* by any client is preserved under all circumstances; and

(2) to assure that the replicas are able to agree on a new view whenever communication is reliable.

As described in the previous section, a client will consider its request executed if it receives a *proof-of-execution* consisting of identical INFORM responses from at-least **nf** distinct replicas. Of these **nf** responses, at-most **f** can come from faulty replicas. Hence, a client can only consider its request executed whenever the requested transaction was executed (and view-committed) by at-least $\mathbf{nf} - \mathbf{f} \geq \mathbf{f} + 1$ non-faulty replicas in the system. We note the similarity with the view-change algorithm of PBFT, which will preserve any request that is *prepared* by at-least $\mathbf{nf} - \mathbf{f} \geq \mathbf{f} + 1$ non-faulty replicas.

The view-change algorithm of PoE consists of three steps. First, failure of the current primary P needs to be detected by all non-faulty replicas. Second, all replicas exchange information to establish which transactions were included in view v and which were not. Third, the new primary P′ proposes a new view. This new view proposal contains a list of the transactions executed in the previous views (based on the information exchanged earlier). Finally, if the new view proposal is valid, then replicas switch to this view; otherwise, replicas detect failure of P′ and initiate a view-change for the next view ($v+2$). The communication of the view-change algorithm of PoE is sketched in Figure 4 and the full pseudo-code of the algorithm can be found in Figure 5. Next, we discuss each step in detail.

3.3.1 Failure Detection and View-Change Requests. If a replica R detects failure of the primary of view v, then it halts the normal-case algorithm of PoE for view v and informs all other replicas of this failure by requesting a view-change. The replica R does so by broadcasting a message VC-REQUEST(v, E), in which E is a summary of all transactions executed by R (Figure 5, Line 1). Each replica R can detect the failure of primary in two ways:

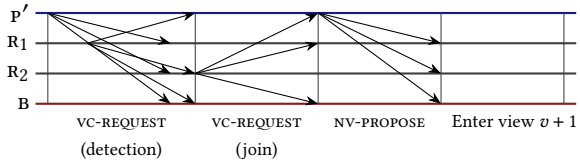


Figure 4: The current primary B of view v is faulty and needs to be replaced. The next primary, P′, and the replica R_1 detected this failure first and request view-change via VC-REQUEST messages. The replica R_2 joins these requests.

vc-request (used by replica R to request view-change) **:**

1: **event** R detects failure of the primary **do**
2: R halts the normal-case algorithm of Figure 3 for view v.
3: $E := \{(\text{CERTIFY}(\langle h \rangle, w, k), \langle T \rangle_c) \mid w \leq v$ and $\text{Execute}_R(\langle T \rangle_c, w, k)$ and $h = \text{D}(\langle T \rangle_c || w || k)\}$.
4: Broadcast VC-REQUEST(v, E) to all replicas.
5: **end event**
6: **event** R receives **f** + 1 messages VC-REQUEST(v_i, E_i) such that
(1) each message was sent by a distinct replica; and
(2) v_i, $1 \leq i \leq \mathbf{f}+1$, is the current view
do
7: R detects failure of the primary (join).
8: **end event**

On receiving nv-propose (use by replica R) **:**

9: **event** R receives $m =$ NV-PROPOSE$(v+1, m_1, m_2, ..., m_{\mathbf{nf}})$ **do**
10: **if** m is a valid new-view proposal (similar to creating NV-PROPOSE) **then**
11: Derive the transactions N for the new-view from $m_1, m_2, \ldots, m_{\mathbf{nf}}$.
12: Rollback any executed transactions not included in N.
13: Execute the transactions in N not yet executed.
14: Move into view $v+1$ (see Section 3.3.3 for details).
15: **end if**
16: **end event**

nv-propose (used by replica P′ that will act as the new primary) **:**

17: **event** P′ receives **nf** messages $m_i =$ VC-REQUEST(v_i, E_i) such that
(1) these messages are sent by a set S, $|S| = \mathbf{nf}$, of distinct replicas;
(2) for each m_i, $1 \leq i \leq \mathbf{nf}$, sent by replica $Q_i \in S$, E_i consists of a consecutive sequence of entries (CERTIFY$(\langle h \rangle, v, k)$, $\langle T \rangle_c$);
(3) v_i, $1 \leq i \leq \mathbf{nf}$, is the current view v; and
(4) P′ is the next primary (id(P′) $= (v+1) \bmod \mathbf{n}$)
do
18: Broadcast NV-PROPOSE$(v+1, m_1, m_2, ..., m_{\mathbf{nf}})$ to all replicas.
19: **end event**

Figure 5: The view-change algorithm of PoE.

(1) R *timeouts* while expecting normal-case operations toward executing a client request. E.g., when R forwards a client request to the current primary, and the current primary fails to propose this request on time.

(2) R receives VC-REQUEST messages, indicating that the primary of view v failed, from **f** + 1 distinct replicas. As at most **f** of these messages can come from faulty replicas, at least one non-faulty replica must have detected a failure. In this case, R joins the view-change (Figure 5, Line 6).

3.3.2 Proposing the New View. To start view $v+1$, the new primary P′ (with id(P′) $= (v+1) \bmod \mathbf{n}$) needs to propose a new view by determining a valid list of requests that need to be preserved. To do so, P′ waits until it receives sufficient information. In specific, P′ waits until it received *valid* VC-REQUEST messages from a set $S \subseteq \mathfrak{R}$ of $|S| = \mathbf{nf}$ distinct replicas.

An i-th view-change request m_i is considered valid if it includes a *consecutive sequence* of pairs $(c, \langle T \rangle_c)$, where c is a valid CERTIFY message for request $\langle T \rangle_c$. Such a set S is guaranteed to exist when communication is reliable, as all non-faulty replicas will participate in the view-change algorithm. The new primary

collects the set S of $|S| = \mathbf{nf}$ valid VC-REQUEST and proposes them in a new view message NV-PROPOSE to all replicas.

3.3.3 Move to the New View. After a replica R receives a NV-PROPOSE message containing a new-view proposal from the new primary P′, R validates the content of this message. From the set of VC-REQUEST messages in the new-view proposal, R chooses, for each k, the pair $(\text{CERTIFY}(\langle h \rangle, w, k), \langle T \rangle_c)$ proposed in the most-recent view w. Furthermore, R determines the total number of such requests $k_{\max}$. Then, R view-commits and executes all $k_{\max}$ chosen requests that happened before view $v + 1$. Notice that replica R can skip execution of any transaction it already executed. If R executed transactions not included in the new-view proposal, then R needs to *rollback* these transactions before it can proceed executing requests in view $v + 1$. After these steps, R can switch to the new view $v + 1$. In the new view, the new primary P′ starts by proposing the $k_{\max} + 1$-th transaction.

When moving into the new view, we see the cost of speculative execution: some replicas can be forced to *rollback execution* of transactions:

Example 3.4. Consider a system with non-faulty replica R. When deciding the k-th request, communication became unreliable, due to which only R received a CERTIFY message for request $\langle T \rangle_c$. Consequently, R speculatively executes T and informs the client c. During the view-change, all other replicas—none of which have a CERTIFY message for $\langle T \rangle_c$—provide their local state to the new primary, which proposes a new view that does not include any k-th request. Hence, the new primary will start its view by proposing client request $\langle T' \rangle_{c'}$ as the k-th request, which gets accepted. Consequently, R needs to rollback execution of T. Luckily, this is not an issue: the client c only got at-most $\mathbf{f}+1 < \mathbf{nf}$ responses for request, does not yet have a proof-of-execution, and, consequently, does not consider T executed.

In practice, rollbacks can be supported by, e.g., undoing the operations of transaction in reverse order, or by reverting to an old state. For the correct working of PoE, the exact working of rollbacks is not important as long as the execution layer provides support for rollbacks.

3.4 Correctness of PoE

First, we show that the normal-case algorithm of PoE provides non-divergent speculative consensus when the primary is non-faulty and communication is reliable.

THEOREM 3.5. *Consider a system in view v, in which the first $k-1$ transactions have been executed by all non-faulty replicas, in which the primary is non-faulty, and communication is reliable. If the primary received $\langle T \rangle_c$, then the primary can use the algorithm in Figure 3 to ensure that*

(1) there is non-divergent execution of T;
(2) c considers T executed as the k-th transaction; and
(3) c learns the result of executing T (if any),

this independent of any malicious behavior by faulty replicas.

PROOF. Each non-faulty primary would follow the algorithm of PoE described in Figure 3 and send $\text{PROPOSE}(\langle T \rangle_c, v, k)$ to all replicas (Line 6). In response, all **nf** non-faulty replicas will compute a signature share and send a SUPPORT message to the primary (Line 15). Consequently, the primary will receive signature shares from **nf** replicas and will combine them to generate a threshold signature $\langle h \rangle$. The primary will include this signature $\langle h \rangle$ in a CERTIFY message and broadcast it to all replicas. Each replica will successfully verify $\langle h \rangle$ and will view-commit to T (Line 17). As the first $k-1$ transactions have already been executed, every non-faulty replica will execute T. As all non-faulty replicas behave deterministically, execution will yield the same result r (if any) across all non-faulty replicas. Hence, when the non-faulty replicas inform c, they do so by all sending identical messages $\text{INFORM}(\text{D}(\langle T \rangle_c), v, k, r)$ to c (Line 20–Line 23). As all **nf** non-faulty replicas executed T, we have non-divergent execution. Finally, as there are at most **f** faulty replicas, the faulty replicas can only forge up to **f** invalid INFORM messages. Consequently, the client c will only receive the message $\text{INFORM}(\text{D}(\langle T \rangle_c), v, k, r)$ from at least **nf** distinct replicas, and will conclude that T is executed yielding result r (Line 3). □

At the core of the correctness of PoE, under all conditions, is that no replica will rollback requests $\langle T \rangle_c$ for which client c already received a proof-of-execution. We prove this next:

PROPOSITION 3.6. *Let $\langle T \rangle_c$ be a request for which client c already received a proof-of-execution showing that T was executed as the k-th transaction of view v. If $\mathbf{n} > 3\mathbf{f}$, then every non-faulty replica that switches to a view $v' > v$ will preserve T as the k-th transaction of view v.*

PROOF. Client c considers $\langle T \rangle_c$ executed as the k-th transaction of view v when it received identical INFORM-messages for T from a set A of $|A| = \mathbf{nf}$ distinct replicas (Figure 3, Line 3). Let $B = A \setminus \mathcal{F}$ be the set of non-faulty replicas in A.

Now consider a non-faulty replica R that switches to view $v' > v$. Before doing so, R must have received a valid proposal $m = \text{NV-PROPOSE}(v', m_1, ..., m_{\mathbf{nf}})$ from the primary of view v'. Let C be the set of **nf** distinct replicas that provided messages $m_1, \ldots, m_{\mathbf{nf}}$ and let $D = C \setminus \mathcal{F}$ be the set of non-faulty replicas in C. We have $|B| \geq \mathbf{nf} - \mathbf{f}$ and $|D| \geq \mathbf{nf} - \mathbf{f}$. Hence, using a contradiction argument similar to the one in the proof of Proposition 3.2, we conclude that there must exists a non-faulty replica $\text{Q} \in (B \cap D)$ that executed $\langle T \rangle_c$, informed c, and requested a view-change.

To complete the proof, we need to show that $\langle T \rangle_c$ was proposed and executed in the last view that proposed and view-committed a k-th transaction and, hence, that Q will include $\langle T \rangle_c$ in its VC-REQUEST message for view v'. We do so by induction on the difference $v' - v$. As the base case, we have $v' - v = 1$, in which case no view after v exists yet and, hence, $\langle T \rangle_c$ must be the newest k-th transaction available to Q. As the induction hypothesis, we assume that all non-faulty replicas will preserve T when entering a new view w, $v < w \leq w'$. Hence, non-faulty replicas participating in view w will not support any k-th transactions proposed in view w. Consequently, no CERTIFY messages can be constructed for any k-th transaction in view w. Hence, the new-view proposal for $w' + 1$ will include $\langle T \rangle_c$, completing the proof. □

As a direct consequence of the above, we have

COROLLARY 3.7 (SAFETY OF POE). *PoE provides speculative non-divergence if $\mathbf{n} > 3\mathbf{f}$.*

We notice that the view-change algorithm does not deal with minor malicious behavior (e.g., a single replica left in the dark). Furthermore, the presented view-change algorithm will recover all transactions since the start of the system, which will result in unreasonable large messages when many transactions have already been proposed. In practice, both these issues can be resolved by regularly making *checkpoints* (e.g., after every 100 requests) and only including requests since the last checkpoint in each VC-REQUEST message. To do so, PoE uses a standard fully-decentralized PBFT-style checkpoint algorithm that enables the independent checkpointing and recovery of any request that is

executed by at least $\mathbf{f}+1$ non-faulty replicas whenever communication is reliable [9]. Finally, utilizing the view-change algorithm and checkpoints, we prove

Theorem 3.8 (Liveness of PoE). *PoE provides termination in periods of reliable bounded-delay communication if* $\mathbf{n} > 3\mathbf{f}$.

Proof. When the primary is non-faulty, Theorem 3.5 guarantees termination as replicas continuously accept and execute requests. If the primary is Byzantine and fails to guarantee termination for at most $\mathbf{f}$ non-faulty replicas, then the checkpoint algorithm will assure termination of these non-faulty replicas. Finally, if the primary is Byzantine and fails to guarantee termination for at least $\mathbf{f}+1$ non-faulty replicas, then it will be replaced using the view-change algorithm. For the view-change process, each replica will start with a timeout δ after it receives $\mathbf{nf}$ matching vc-requests and double this timeout after each view-change (exponential backoff). When communication becomes reliable, this mechanism guarantees that all replicas will eventually view-change to the same view at the same time. After this point, a non-faulty replica will become primary in at most $\mathbf{f}$ view-changes, after which Theorem 3.5 guarantees termination. □

3.5 Fine-Tuning and Optimizations

To keep presentation simple, we did not include the following optimizations in the protocol description:

(1) To reach $\mathbf{nf}$ signature shares, the primary can generate one itself. Hence, it only needs $\mathbf{nf}-1$ shares of other replicas.
(2) The propose, support, inform, and nv-propose messages are not forwarded and only need MACs to provide message authentication. The certify messages need not be signed, as tampering them would invalidate the threshold signature. The vc-request messages need to be signed, as they need to be forwarded without tampering.

Finally, the design of PoE is fully compatible with *out-of-order processing* as a replica only supports proposals for a k-th transaction if it had not previously supported another k-th proposal (Figure 3, Line 12) and only executes a k-th transaction if it has already executed all the preceding transactions (Figure 3, Line 20). As the size of the active out-of-order processing window determines how many client requests are being processed at the same time (without receiving a proof-of-execution), the size of the active window determines the number of transactions that can be rolled back during view-changes.

3.6 Designing PoE using MACs

The design of PoE can be adapted to only use message authentication codes (MACs) to authenticate communication. This will sharply reduce the computational complexity of PoE and eliminate one round of communication, this at the cost of higher *quadratic* overall communication costs (see Figure 2).

The usage of only MACs makes it impossible to obtain threshold signatures or reliably forward messages (as forwarding replicas can tamper with the content of unsigned messages). Hence, using MACs requires changes to how client requests are included in proposals (as client requests are forwarded), to the normal-case algorithm of PoE (which uses threshold signatures), and to the view-change algorithm of PoE (which forwards vc-request messages). The changes to the proposal of client requests and to the view-change algorithm can be derived from the strategies used by Pbft to support MACs [9]. Hence, next we only review the changes to the normal-case algorithm of PoE.

Consider a replica r that receives a propose message from the primary p. Next, r needs to determine whether at least $\mathbf{nf}$ other replicas received the same proposal, which is required to achieve speculative non-divergence (see Proposition 3.2). When using MACs, r can do so by replacing the all-to-one support and one-to-all certify phases by a single all-to-all *support phase*. In the support phase, each replica agrees to *support* the first proposal $\text{propose}(\langle T \rangle_c, v, k)$ it receives from the primary by broadcasting a message $\text{support}(\text{D}(\langle T \rangle_c), v, k)$ to all replicas. After this broadcast, each replica waits until it receives support messages, identical to the message it sent, from $\mathbf{nf}$ distinct replicas. If r receives these messages, it *view-commits* to T as the k-th transaction in view v and schedules T for execution. We have sketched this algorithm in Figure 2.

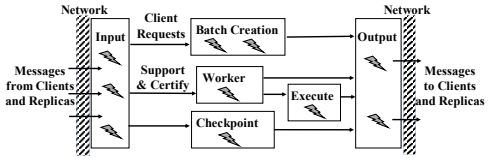

Figure 6: Multi-threaded Pipelines at different replicas.

4 RESILIENTDB FABRIC

To test our design principles in practical settings, we implement our PoE protocol in our ResilientDB fabric [27–31]. ResilientDB provides its users access to a state-of-the-art replicated transactional engine and fulfills the need of a high-throughput permissioned blockchain fabric. ResilientDB helps us to realize the following goals: (i) implement and test different consensus protocols; (ii) balance the tasks done by a replica through a *parallel pipelined architecture*; (iii) minimize the cost of communication through *batching* client transactions; and (iv) enable use of a secure and efficient ledger. Next, we present a brief overview of our ResilientDB fabric.

ResilientDB lays down a *client-server* architecture where clients send their transactions to servers for processing. We use Figure 6 to illustrate the multi-threaded pipelined architecture associated with each replica. At each replica, we spawn multiple *input* and *output* threads for communicating with the network.

Batching. During our formal description of PoE, we assumed that the propose message from the primary includes a single client request. An effective way to reduce the overall cost of consensus is by aggregating several client requests in a single batch and use one consensus step to reach agreement on all these requests [9, 21, 38]. To maximize performance, ResilientDB facilitates batching requests at both replicas and clients.

At the primary replica, we spawn multiple *batch-threads* that aggregate clients requests into a batch. The input-threads at the primary receive client requests, assign them a sequence number and enqueue these requests in the *batch-queue*. In ResilientDB, all batch-threads share a common *lock-free queue*. When a client request is available, a batch-thread dequeues the request and continues adding it to an existing batch until the batch has reached a pre-defined size. Each batching-thread also hashes the requests in a batch to create a unique digest.

All other messages received at a replica are enqueued by the input-thread in the *work-queue* to be processed by the single *worker-thread*. Once a replica receive a certify message from the primary, it forwards the request to the *execute-thread* for execution. Once the execution is complete, the execution-thread creates an inform message, which is transmitted to the client.

Ledger Management. We now explain how we efficiently maintain a blockchain ledger across different replicas. A blockchain is an immutable ledger, where blocks are chained as a linked-list. An i-th block can be represented as $B_i := \{k, d, v,$

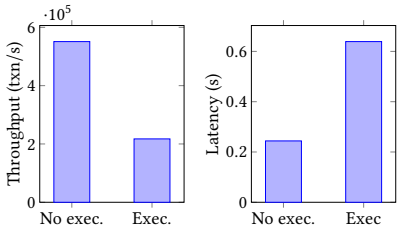

Figure 7: Upper bound on performance when primary only replies to clients (*No exec.*) and when primary executes a request and replies to clients (*Exec.*).

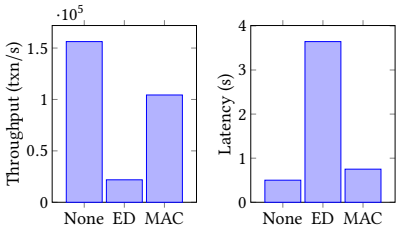

Figure 8: System performance using three different signature schemes. In all cases, n = 16 replicas participate in consensus.

$H(B_{i-1})\}$, in which k is the sequence number of the client request, d the digest of the request, v the view number, and $H(B_{i-1})$ the hash of the previous block. In ResilientDB, prior to any consensus, we require the *first* primary replica to create a *genesis block* [31]. This genesis block acts as the first block in the blockchain and contains some basic data. We use the hash of the identity of the initial primary, as this information is available to each participating replicas (eliminating the need for any extra communication to exchange this block).

After the genesis block, each replica can independently create the next block in the blockchain. As stated above, each block corresponds to some batch of transactions. A block is only created by the execute-thread once it completes executing a batch of transactions. To create a block, the execute-thread hashes the previous block in the blockchain and creates a *new block*. To prove the validity of individual blocks, ResilientDB stores the *proof-of-accepting the k-th request* in the k-th block. In PoE, such a proof includes the threshold signature sent by the primary as part of the certify message.

5 EVALUATION

We now analyze our design principles in practice. To do so, we evaluate our PoE protocol against four state-of-the-art bft protocols. There are many bft protocols we could compare with. Hence, we pick a representative sample: (1) Zyzzyva—as it has the absolute minimal cost in the fault-free case, (2) Pbft—as it is a common baseline (the used design is based on BFTSmart [7]), (3) SBFT—as it is a safer variation of Zyzzyva, and (3) HotStuff—as it is a linear-communication protocol that adopts the notion of rotating leaders. Through our experiments, we want to answer the following questions:

(Q1) How does PoE fare in comparison with the other protocols under failures?
(Q2) Does PoE benefits from batching client requests?
(Q3) How does PoE perform under zero payload?
(Q4) How scalable is PoE on increasing the number of replicas participating in the consensus, in the normal-case?

Setup. We run our experiments on the Google Cloud, and deploy each replicas on a *c2* machine having a 16-core Intel Xeon Cascade Lake CPU running at 3.8 GHz with 32 GB memory. We deploy up to 320 k clients on 16 machines. To collect results after reaching a steady-state, we run each experiment for 180 s: the first 60 s are warmup, and measurement results are collected over the next 120 s. We average our results over three runs.

Configuration and Benchmarking. For evaluating the protocols, we employed YCSB [13] from Blockbench's macro benchmarks [16]. Each client request queries a YCSB table that holds half a million active records. We require 90% of the requests to be write queries as the majority of typical blockchain transactions are updates to existing records. Prior to the experiments, each replica is initialized with an identical copy of the YCSB table. The client requests generated by YCSB follow a Zipfian distribution and are heavily skewed (skew factor 0.9).

Unless *explicitly* stated, we use the following configuration for all experiments. We perform scaling experiments by varying replicas from 4 to 91. We divide our experiments in two dimensions: (1) *Zero Payload* or *Standard Payload*, and (2) *Failures* or *Non-Failures*. We employ batching with a batch size of 100 as the percentage increase in throughput on larger batch sizes is small.

Under Zero Payload conditions, all replicas execute 100 dummy instructions per batch, while the primary sends an empty proposal (and not a batch of 100 requests). Under Standard Payload, with a batch size of 100, the size of Propose message is 5400 B, of Response message is 1748 B, and of other messages is around 250 B. For experiments with failures, we force one backup replica to crash. Additionally, we present an experiment that illustrates the effect of primary failure. We measure *throughput* as transactions executed per second. We measure *latency* as the time from when the client sends a request to the time when the client receives a response.

Other protocols: We also implement Pbft, Zyzzyva, SBFT and HotStuff in our ResilientDB fabric. We refer to Section 2 for further details on the working of Zyzzyva, SBFT, and HotStuff. Our implementation of Pbft is based on the BFTSmart [7] framework with the added benefits of out-of-order processing, pipelining, and multi-threading. In both Pbft and Zyzzyva, digital signatures are used for authenticating messages sent by the clients, while MACs are used for other messages. Both SBFT and HotStuff require threshold signatures for their communication.

5.1 System Characterization

We first determine the upper bounds on the performance of ResilientDB. In Figure 7, we present the maximum throughput and latency of ResilientDB when there is *no communication* among the replicas. We use the term *No Execution* to refer to the case where all clients send their request to the primary replica and primary simply responds back to the client. We count every query responded back in the system throughput. We use the term *Execution* to refer to the case where the primary replica executes each query before responding back to the client.

The architecture of ResilientDB (see Section 4) states the use of one worker thread. In these experiments, we maximize system performance by allowing up to two threads to work independently at the primary replica without ordering any queries. Our results indicate that the system can attain high throughputs (up to 500 ktxn/s) and can reach low latencies (up to 0.25 s). Notice that if we employ additional worker-threads, our ResilientDB fabric can easily attain higher throughput.

5.2 Effect of Cryptographic Signatures.

ResilientDB enables a flexible design where replicas and clients can employ both digital signatures (threshold signatures) and

message authentication codes. This helps us to implement PoE and other consensus protocols in ResilientDB.

To achieve authenticated communication using symmetric cryptography, we employ a combination of CMAC and AES [36]. Further, we employ ED25519-based digital signatures to enable asymmetric cryptographic signing. For generating efficient threshold signature scheme, we use Boneh–Lynn–Shacham (BLS) signatures [36]. To create message digests and for hashing purposes, we use the SHA256 algorithm.

Next, we determine the cost of different cryptographic signing schemes. For this purpose, we run three different experiments in which (i) no signature scheme is used (*None*); (ii) everyone uses digital signatures based on ED25519 (*ED*); and (iii) all replicas use CMAC+AES for signing, while clients sign their message using ED25519 (*MAC*). In these three experiments, we run Pbft consensus among 16 replicas. In Figure 8, we illustrate the throughput attained and latency incurred by ResilientDB for the experiments. Clearly, the system attains its highest throughput when no signatures are employed. However, such a system cannot handle malicious attacks. Further, using just digital signatures for signing messages can prove to be expensive. An optimal configuration can require clients to sign their messages using digital signatures, while replicas can communicate using MACs.

5.3 Scaling Replicas under Standard Payload

In this section, we evaluate scalability of PoE both under backup failure and no failures.

(1) ***Single Backup Failure.*** We use Figures 9(a) and 9(b) to illustrate the throughput and latency attained by the system on running different consensus protocols under a backup failure. These graphs affirm our claim that PoE attains higher throughput and incurs lower latency than all other protocols.

In case of Pbft, each replica participates in two phases of quadratic communication, which limits its throughput. For the twin-path protocols such as Zyzzyva and SBFT, a single failure is sufficient to cause massive reductions in their system throughputs. Notice that the collector in SBFT and the clients in Zyzzyva have to wait for messages from all **n** replicas, respectively. As predicting an optimal value for timeouts is hard [11, 12], we chose a very small value for the timeout (3 s) for replicas and clients. We justify these values, as the experiments we show later in this section show that the average latency can be as large as 6 s. We note that high timeouts affect Zyzzyva more than SBFT. In Zyzzyva, clients are waiting for timeouts during which they stop sending requests, which empties the pipeline at the primary, starving it from new request to propose. To alleviate such issues in real-world deployments of Zyzzyva, clients need to be able to precisely predict the latency to minimize the time the clients needs to wait between requests. Unfortunately, this is hard and runs the risk of ending up in the expensive slow path of Zyzzyva whenever the predicted latency is slightly off. In SBFT, the collector may timeout waiting for threshold shares for the k-th round while the primary can continues propose requests for future round l, $l > k$. Hence, in SBFT replicas have more opportunity to occupy themselves with useful work.

HotStuff attains significantly low throughput due to its sequential primary-rotation model in which each of its primaries has to wait for the previous primary before proposing the next request, which leads to a huge reduction in its throughput. Interestingly, HotStuff incurs the least average latency among all protocols. This is a result of intensive load on the system when running other protocols. As these protocols process several requests concurrently (see the multi-threaded architecture in Section 4), these requests spend on average more time in the queue before being processed by a replica. Notice that all out-of-order consensus protocols employ this trade off: a small sacrifice on latency yields higher gains on system throughput.

In case of PoE, its high throughputs under failures is a result of its three-phase linear protocol that does not rely on any twin-path model. To summarize, PoE attains up to 43%, 72%, 24× and 62× more throughputs than Pbft, SBFT, HotStuff and Zyzzyva.

(2) ***No Replica Failure.*** We use Figures 9(c) and 9(d) to illustrate the throughput and latency attained by the system on running different consensus protocols in fault-free conditions. These plots help us to bound the maximum throughput that can be attained by different consensus protocols in our system.

First, as expected, in comparison to the Figures 9(a) and 9(b), the throughputs for PoE and Pbft are slightly higher. Second, PoE continues to outperform both Pbft and HotStuff, for the reasons described earlier. Third, both Zyzzyva and SBFT are now attaining higher throughputs as their clients and collector no longer timeout, respectively. The key reason SBFT's gains are limited is because SBFT requires five phases and becomes computation bounded. Although Pbft is quadratic, it employs MAC, which are cheaper to sign and verify.

Notice that the differences in throughputs of PoE and Zyzzyva are small. PoE has 20% (on 91 replicas) to 13% (on 4 replicas) less throughputs than Zyzzyva. An interesting observation is that on 91 replicas, Zyzzyva incurs almost the same latency as PoE, even though it has higher throughput. This happens as clients in PoE have to wait for only the fastest $\mathbf{nf} = 61$ replies, whereas a client for Zyzzyva has to wait for replies from all replicas (even the slowest ones). To conclude, PoE attains up to 35%, 27% and 21× more throughput than Pbft, SBFT and HotStuff, respectively.

5.4 Scaling Replicas under Zero Payload

We now measure the performance of different protocols under zero payload. In any bft protocol, the primary starts consensus by sending a Propose message that includes all transactions. As a result, this message has the largest size and is responsible for consuming the majority of the bandwidth. A zero payload experiment ensures that each replica executes dummy instructions. Hence, the primary is no longer a bottleneck.

We again run these experiments for both ***Single Failure*** and ***Failure-Free*** cases, and use Figures 9(e) to 9(h) to illustrate our observations. It is evident from these figures that zero payload experiments have helped in increasing PoE's gains. PoE attains up to 85%, 62% and 27× more throughputs than Pbft, SBFT and HotStuff, respectively. In fact, under failure-free conditions, the throughput attained by PoE is comparable to Zyzzyva. This is easily explained. First, both PoE and Zyzzyva are linear protocols. Second, although in failure-free cases Zyzzyva attains consensus in one phase, its clients need to wait for response from all **n** replicas, which gives PoE an opportunity to cover the gap. However, SBFT being a linear protocol does not perform as good as its other linear counterparts. Its throughput is impacted by the delay of five phases.

5.5 Impact of Batching under Failures

Next, we study the effect of batching client requests on bft protocols [9, 51]. To answer this question, we measure performance as function of the number of requests in a batch (*the batch-size*), which we vary between 10 and 400. For this experiment, we use a system with 32 available replicas, of which one replica has failed.

We use Figures 9(i) and 9(j) to illustrate, for each consensus protocol, the throughput and average latency attained by the system. For each protocol, increasing the batch-size also increases

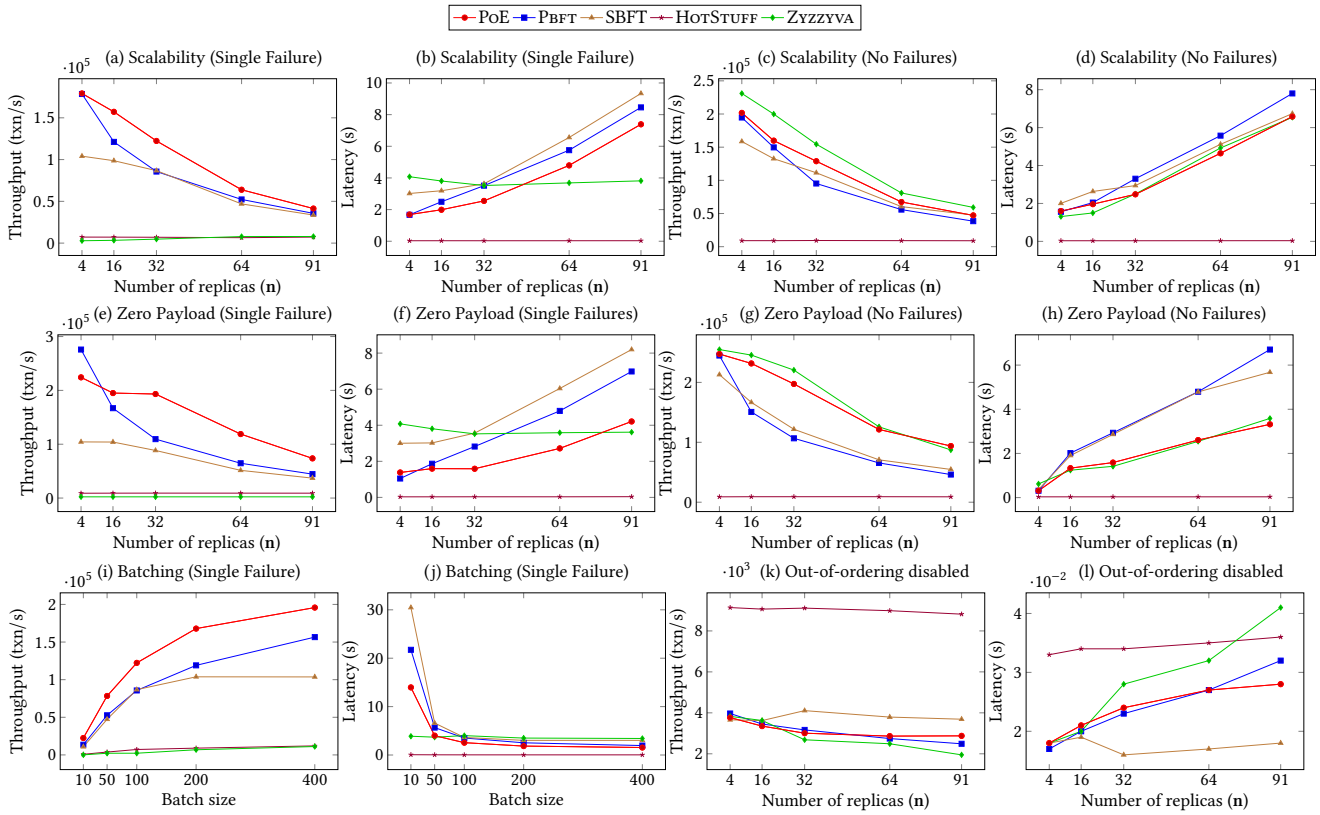

Figure 9: Evaluating system throughput and average latency incurred by PoE and other BFT protocols.

throughput, while decreasing the latency. This happens as larger batch-sizes require fewer consensus rounds to complete the exact same set of requests, reducing the cost of ordering and executing the transactions. This not only improves throughput, but also reduces client latencies as clients receive faster responses for their requests. Although increasing the batch-size reduces the number of consensus rounds, the large message size causes a proportional decrease in throughput (or increase in latency). This is evident from the experiments at higher batch-sizes: increasing the batch-size beyond 100 gradually curves the throughput plots towards a limit for PoE, Pbft and SBFT. For example, on increasing the batch size from 100 to 400, PoE and Pbft see an increase in throughput by 60% and 80%, respectively, while the gap in throughput reduces from 43% to 25%. As in the previous experiments, Zyzzyva yields a significantly lower throughput as it cannot handle failures. In case of HotStuff, an increase in batch size does increases its throughput but due to high scaling of the graph this change seems insignificant.

5.6 Disabling Out-of-Ordering

Until now, we allowed protocols like Pbft, PoE, SBFT and Zyzzyva to process requests *out-of-order*. As a result, these protocols achieve much higher throughputs than HotStuff, which is restricted by its sequential primary-rotation model. In Figures 9(k) and 9(l), we evaluate the performance of the protocols when there are no opportunities for out-of-ordering.

In this setting, we require each client to only send its request when it has accepted a response for its previous query. As HotStuff pipelines its phases of consensus into a *four*-phase pipeline, so we allow it to access four client requests (each on a distinct subsequent replica) at any time. As expected, HotStuff performs better than all other protocols at the expense of a higher latency as it rotates primaries at the end of each consensus, which allows

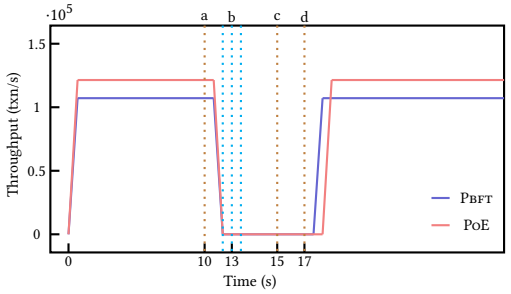

Figure 10: System throughput under instance failures (n = 32). (a) replicas detect failure of primary and broadcast VC-REQUEST; (b) replicas receives VC-REQUEST from others; (c) replicas receives NV-PROPOSE from new primary; (d) state recovery;

it to pipeline four requests. However, notice that once out-of-ordering is disabled, throughput drops from 200 ktransactions/s to just under a few *thousand* transactions/s. Hence, from a practical standpoint, out-of-ordering is simply crucial. Further, the difference in latency of different protocols is quite small, and the visible variation is a result of graph scaling while the actual numbers are in the range of 20 ms–40 ms.

5.7 Primary Failure–View Change

In Figure 10, we study the impact of of a benign primary failure on PoE and Pbft. To recover from a primary failure, backup replicas run the view-change protocol. We skip illustrating view-change plots for Zyzzyva and SBFT as they already face severe reduction in throughput for a single backup failure. Further, Zyzzyva has an *unsafe* view-change algorithm and SBFT's view-change algorithm is no less expensive than Pbft. For HotStuff, we do not

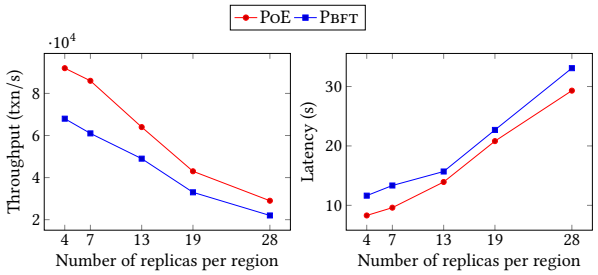

Figure 11: System throughput and average latency incurred by PoE and Pbft in a WAN deployment of five regions under a single failure. In the largest deployment, we have 140 replicas spread equally over these regions.

show results as it changes primary at the end of every consensus. Although single primary protocols face a momentary loss in throughput during view-change, these protocols easily cover this gap through their ability to process messages out-of-order.

For our experiments, we let the primary replica complete consensus for 10 s (or around a million transactions) and then fail. This causes clients to timeout while waiting for responses for their pending transactions. Hence, these clients forward their requests to backup replicas.

When a backup replica receives a client request, it forwards that request to the primary and waits on a timer. Once a replicas timeouts, it detects a primary failure and broadcasts a VC-REQUEST message to all other replicas—initiate view-change protocol (a). Next, each replica waits for a new view message from the next primary. In the meantime, a replica may receive VC-REQUEST messages from other replicas (b). Once a replica receives NV-PROPOSE message from the new primary (c), it moves to the next view.

5.8 WAN Scalability

In this section, we use Figure 11 to illustrate the throughputs and latencies for different PoE and Pbft deployments on a wide-area network in the presence of a single failure. In specific, we deploy clients and replicas across *five* locations across the globe: Oregon, Iowa, Montreal, the Netherlands, and Taiwan. Next, we vary the number of replicas from 20 to 140 by equally distributing these replicas across each region.

These plots affirm our existing observations that PoE outperforms existing state-of-the-art protocols and scales well in wide-area deployments. In specific, PoE achieves up to 1.41× higher throughput and incurs 28.67% less latency than Pbft. We skip presenting plots for SBFT, HotStuff and Zyzzyva due to their low throughputs under failures.

5.9 Simulating bft Protocols

To further underline that the *message delay* and not *bandwidth requirements* becomes a determining factor in the throughput of protocols in which the primary does not propose requests out-of-order, we performed a separate simulation of the maximum performance of PoE, Pbft, and HotStuff. The simulation makes 500 consensus decisions and processes all message send and receive steps, but delays the arrival of messages by a predetermined message delay. The simulation skips any expensive computations and, hence, the simulated performance is entirely determined by the cost of message exchanges. We ran the simulation with $\mathbf{n} \in \{4, 16, 128\}$ replicas, for which the results can be found in Figure 12, first three plots. As one can see, if bandwidth is not a limiting factor, then the performance of protocols that do not propose requests out-of-order will be determined by the number of communication rounds and the message delay. As both Pbft and PoE have one communication round more than the two rounds of HotStuff, their performance is roughly two-thirds that of HotStuff, this independent of the number of replicas or the message delay. Furthermore, doubling message delay will roughly half performance. Finally, we also measured the maximum performance of protocols that do allow out-of-order processing of up to 250 consensus decisions. These results can be found in Figure 12, last plot. As these results show, out-of-order processing increases performance by a factor of roughly 200, even with 128 replicas.

6 RELATED WORK

Consensus is an age-old problem that received much theoretical and practical attention (see, e.g., [34, 39, 45]). Further, the use of rollbacks is common in distributed systems. E.g., the crash-resilient replication protocol Raft [45] allows primaries to rewrite the log of any replica. In a Byzantine environment, such an approach would delegate too much power to the primary, as they can maliciously overwrite transactions that need to be preserved.

The interest in practical bft consensus protocols took off with the introduction of Pbft [9]. Apart from the protocols that we already discussed, there are some interesting protocols that achieve efficient consensus by requiring $5\mathbf{f} + 1$ replicas [1, 14]. However, these protocols have been shown to work only in the cases where transactions are non-conflicting [38]. Some other bft protocols [10, 50] suggest the use of *trusted components* to reduce the cost of bft consensus. These works require only $2\mathbf{f}+1$ replicas as the trusted component helps to guarantee a correct ordering. The safety of these protocols relies on the security of trusted component. In comparison, PoE does (i) not require extra replicas, (ii) not depend on clients, (iii) not require trusted components, and (iv) not need the two phases of quadratic communication required by Pbft.

As a promising future direction, Castro [9] also suggested exploring speculative optimizations for Pbft, which he referred to as tentative execution. However, this lacked: (i) formal description, (ii) non-divergence safety property, (iii) specification of rollback under attacks, (iv) re-examination of the view change protocol, and (v) any actual evaluation.

Consensus for Blockchains: Since the introduction of Bitcoin [42], the well-known cryptocurrency that led to the coining of the term blockchain, several new bft consensus protocols that cater to cryptocurrencies have been designed [33, 37]. Bitcoin [42] employs the *Proof-of-Work* [33] consensus protocol (PoW), which is computationally intensive, achieves low throughput, and can cause forks (divergence) in the blockchain: separate chains can exist on non-faulty replicas, which in turn can cause *double-spending attacks* [31]. Due to these limitations, several other similar algorithms have been proposed. E.g., *Proof-of-Stake* (PoS) [37], which is design such that any replica owning $n\%$ of the total resources gets the opportunity to create $n\%$ of the new blocks. As PoS is resource driven, it can face attacks where replicas are incentivized to work simultaneously on several forks of the blokchain, without ever trying to eliminate these forks.

There are also a set of interesting alternative designs such as ConFlux [40], Caper [3] and MeshCash [6] that suggest the use of directed acyclic graphs (DAGs) to store a blockchain to improve the performance of Bitcoin. However, these protocols either rely on PoW or Pbft for consensus.

Meta-protocols such as RCC [28] and RBFT [5] run multiple Pbft consensuses in parallel. These protocols also aim at removing dependence on the consensus led by a single primary. A recent protocol, PoV [41], provides fast bft consensus in a

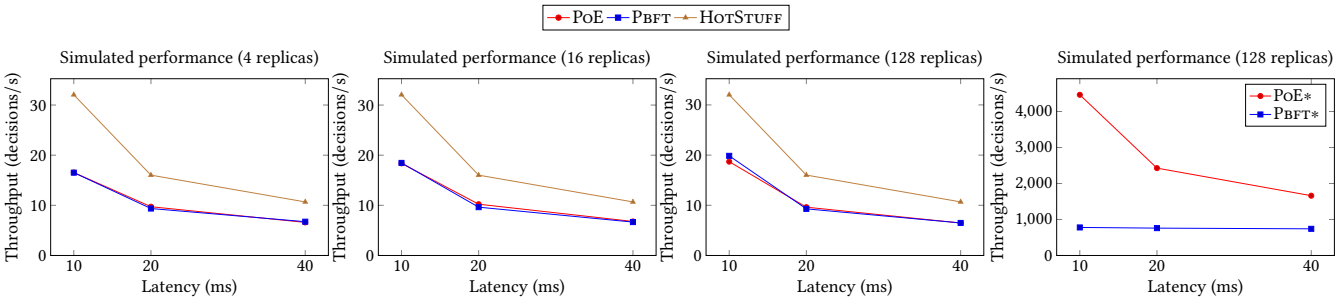

Figure 12: The simulated number of consensus decisions PoE, Pbft, and HotStuff can make as a function of the latency. Only the protocols in the right-most plot and marked with $*$ process requests out-of-order processing.

consortium architecture. PoV does this by restricting the ability to propose blocks among a subset of trusted replicas.

PoE does not face the limitations faced by PoW [33] and PoS [37]. The use of DAGs [3, 6, 40], and sharding [15, 52] is orthogonal to the design of PoE. Hence, their use with PoE can reap further benefits. Further, PoE can be employed by meta-protocols and does not restrict consensus to any subset of replicas.

7 CONCLUSIONS

We present Proof-of-Execution (PoE), a novel Byzantine fault-tolerant consensus protocol that guarantees safety and liveness and does so in only three linear phases. PoE decouples ordering from execution by allowing replicas to process messages out-of-order and execute client-transactions speculatively. Despite these properties, PoE ensures that all the replicas reach a single unique order for all the transactions. Further, PoE guarantees that if a client observes identical results of execution from a majority of the replicas, then it can reliably mark its transaction committed. Due to speculative execution, PoE may require replicas to revert executed transactions, however. To evaluate PoE's design, we implement it in our ResilientDB fabric. Our evaluation shows that PoE achieves up-to-80% higher throughputs than existing bft protocols in the presence of failures.

Scalable Linear Algebra Programming for Big Data Analysis

Leonidas Fegaras
University of Texas at Arlington
Arlington, Texas
fegaras@cse.uta.edu

ABSTRACT

Arrays are very important data structures for many data-centric and scientific applications. One of the most effective representations of large dense arrays in a distributed setting is a block array, such as a tiled matrix, which is a distributed collection of non-overlapping dense array blocks. Although there are many linear algebra libraries for machine learning that support distributed block arrays and provide an optimal implementation for many array operations, these libraries do not support ad-hoc array programming and customized storage structures. Imperative programs with loops and array indexing, on the other hand, are more powerful as they allow arbitrary array computations but are hard to parallelize and convert to distributed programs.

Our goal is to provide an SQL-like abstraction for data-parallel distributed array computations that is expressive enough to capture a large class of array computations and can be compiled to efficient data-parallel distributed code. Our abstraction is a monolithic array construction in the form of an array comprehension that is as expressive as SQL by supporting a group-by syntax that allows us to capture many array computations in declarative form. We present rules for translating array comprehensions on block arrays to data-parallel distributed code that can run on Apache Spark. We describe a comprehensive set of effective optimizations that can produce very efficient translations, such as the optimal block matrix multiplication algorithm, even though they are oblivious to linear algebra operations. Finally, we justify our claims by evaluating the performance of our generated code on Apache Spark relative to Spark MLlib.

1 INTRODUCTION

Much of the data used in data-centric applications come in the form of arrays, such as vectors, matrices, and tensors. In the early days of numerical computing, most of the array programming was done in an imperative loop-based language, such as Fortran or C, using array indexing to access and update array elements incrementally, one at a time. Although loop-based programs are efficient when they run on a single processor, they are hard to parallelize and reason about. Currently, most array programming is done using vectorization languages, such as MATLAB, R, and NumPy, that allow programmers to write high-level array code that closely resembles mathematical formulas. These languages provide highly tuned array operations that are applied to whole arrays instead of individual elements, thus making loops inessential. Moreover, they hide the implementation details and optimize performance by choosing an implementation (a kernel) for an array operation from a variety of build-in array storages and algorithms. Internally, these languages rely on numerical libraries, such as BLAS [9], for efficient linear algebra computations. These libraries, which are also an integral part of many machine learning (ML) sytems, such as TensorFlow [1], PyTorch, and MLlib [5], implement basic array operations efficiently using multicore parallelism and GPU acceleration. Many array operations provided by the vectorization languages are overloaded to work on a variety of array storage structures, thus offering an implementation-independent view to the programmer. Given that there are numerous storage structures for arrays, such as dense, tiled, and compressed sparse matrices, each library operation must have numerous implementations, especially those operations that operate on multiple arrays, such as matrix multiplication. As a result, this code specialization based on array implementation is hard to extend with user-defined storage structures and algorithms. This is particularly true for distributed arrays, which have to be partitioned into blocks and distributed across compute nodes. In that case, not only there are numerous ways to implement these blocks as arrays, but there are also numerous ways to partition the arrays into blocks. A better solution would have been to express array computations in a high-level declarative language for array computations that is expressive enough to capture most array programs and is supported by a translation scheme that separates the specification from the implementation and generates high-quality code.

This problem of sacrificing expressiveness and extensibility for efficiency incurred from the library approach is exacerbated by the need to process large arrays that do not fit in memory. Given that the accuracy of the data analysis and ML models depends on the data size, current data-centric applications must analyze enormous amounts of array data using complex mathematical data processing methods. In recent years, new frameworks in distributed Big Data analytics have become essential tools for large-scale machine learning and scientific discoveries. These systems, which are also known as Data-Intensive Scalable Computing (DISC) systems, have revolutionized our ability to analyze Big Data. Unlike High-Performance Computing (HPC) systems, which are mainly designed for shared-memory architectures, DISC systems are distributed data-parallel systems on clusters of shared-nothing computers connected through a high-speed network. Compared to low-level distributed-memory communication paradigms, such as MPI, DISC systems automate many aspects of distributed computing, such as fault tolerance, which is important for long-running Big Data analysis on thousands of computers, scalability, data partitioning and distribution, and task scheduling and management. One of the earliest DISC systems is Map-Reduce [8], which was introduced by Google and later became popular as an open-source software with Apache Hadoop. Recent systems, such as Apache Spark [4] and Apache Flink [3], go beyond Map-Reduce by maintaining dataset partitions in the memory of the compute nodes. All these systems use data shuffling to exchange data among compute nodes, which takes place implicitly between the map and reduce stages in Map-Reduce and during group-bys and joins in Spark and Flink. Essentially, all data exchanges across compute nodes are done in a controlled way using special operations, which implement data shuffling by

distributing data based on some key, so that data associated with the same key are processed together by the same compute node.

The goal of this paper is to provide a well-formed abstraction for data-parallel distributed array computations "without regret", that is, an abstraction that is declarative so that we can reason about it, is expressive enough to capture a large class of array computations, and can be compiled to efficient data-parallel distributed code. Our main construct is the *array comprehension*, which is a monolithic array construction in the form of a list comprehension. List comprehensions are found in many modern programming languages, such as Python, Scala, and Haskell. Unlike regular list comprehensions though, our array comprehensions are as expressive as SQL queries by supporting a group-by syntax that allows us to capture many array computations in declarative form without using array indexing which is hard to reason about. An array comprehension can access and correlate multiple arrays by traversing their elements one-by-one and can construct a new array in one shot by mapping array indices to values, which are derived from the elements of the input arrays. Array comprehensions can capture many linear algebra operations, including inner and outer products of vectors, matrix addition and multiplication, matrix rotation and transpose, array slicing and concatenation. More complex array operations, such as matrix inverse and LU decomposition, can be coded using array comprehensions inside loops.

1.1 Highlights of our Approach

This paper presents a generic and customizable system that translates abstract array programs to high-performance distributed code that can run on current DISC platforms. When designing storage structures for arrays in a distributed setting, there are many choices to consider, each exhibiting different performance characteristics for various array computations. One example of such a storage method is organizing contiguous array elements into dense non-overlapping blocks of fixed capacity. Our framework uses a two-layer approach where array programs are expressed in a powerful high-level syntax on abstract arrays, while these abstract arrays are mapped to customized storage structures based on user-defined type mappings, thus separating specification from implementation.

An abstract array with dimensionality i in our framework has type array$i$[T], for an arbitrary type T. The most common abstract arrays are vector[T], equal to array1[T], and matrix[T], equal to array2[T]. An abstract array is represented as an association list of key-value pairs in which the key contains the array indices. This array representation is also known as a sparse representation or a coordinate format. For example, a matrix M of type matrix[Double] is represented as an association list of type List[((Int,Int),Double)] so that an element M_{ij} is represented by the key-value pair $((i,j),M_{ij})$, which associates the indices i and j with the value M_{ij}. This association list can be sparse (i.e., some elements may be missing) if the array is sparse. A concrete implementation of an array (i.e., its storage structure) is specified by two customized functions: the *sparsifier*, which converts the storage structure to an association list, and the *builder*, which constructs the storage structure from the association list. These two functions, which are inverse of each other, are used by our translator to transform any operation $f(x_1,\ldots,x_n)$ on abstract arrays x_i to an operation on their concrete storage structures c_i by up-coercing the storages c_i using the sparsifiers s_i and down-coercing the abstract result using the builder b, that is,

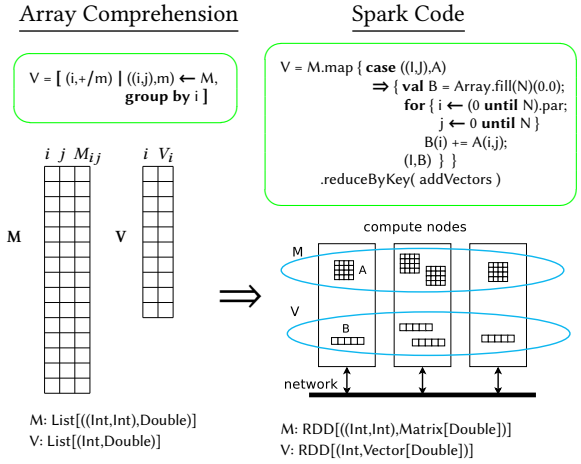

Figure 1: Code generation for $V_i = \sum_j M_{ij}$

$b(f(s_1(c_1),\ldots,s_n(c_n)))$. This layered approach introduces levels of indirection and generates superfluous intermediate structures (the abstract arrays x_i) that need to be removed. In our framework, this is accomplished by fusing these functions into one function that represents the concrete code so that the resulting program builds the output structures directly and works on the storage structures c_i without creating the association lists x_i.

Our language for expressing abstract array programs uses a monolithic array construction in the form of an array comprehension that is as expressive as SQL by supporting a group-by syntax that allows us to capture many array computations in declarative form. Comprehensions with a group-by syntax were first introduced by Wadler and Peyton Jones [24] and have been used as the formal calculus for the DISC query languages MRQL [10] and DIQL [12]. For example, the following comprehension returns the number of employees in each department:

```
[ (d.name,count(e)) | e ← Employees, d ← Departments,
                      e.dno == d.dnumber, group by d.name ].
```

The formal semantics of comprehensions, the translation of comprehensions to an algebra, and a query optimization framework are described in our earlier work [10, 12]. Array comprehensions are actually list comprehensions in which the array storages used in a comprehension are implicitly converted to association lists by array sparsifiers and the list returned by the comprehension is converted to an array storage by an array builder.

Consider for example the following array comprehension that constructs a vector V of size n from a matrix M of size $n \times m$ such that $V_i = \sum_j M_{ij}$, where both the matrix M and the resulting vector V are stored in memory:

```
V = vector(n)[ ( i, +/m ) | ((i,j),m) ← M, group by i ],        (1)
```

which constructs the entire array V in one shot. The matrix M of type matrix[Double] is implicitly converted to an association list of type List[((Int,Int),Double)]. The generator ((i,j),m) ← M traverses M one element at a time and each time the traversed element is pattern-matched with the pattern ((i,j),m), which binds the pattern variables i, j, and m to the the corresponding components of this element. A group-by operation in a comprehension lifts each pattern variable defined before the group-by (except the group-by keys) from some type t to a bag of t, indicating that each such variable must now contain all the values associated with the same group-by key value. Consequently, after we group

by i, the pattern variables that are not used in the group-by key, j and m, are now lifted to lists that contain all their values associated with a certain group-by key i. The term +/m adds up all the bindings of the variable m associated with the key i. That is, it calculates $\sum_j M_{ij}$. Finally, the array builder, vector(n)(L), converts the association list L of type List[(Int,Double)] to a vector of type vector[Double] of size n.

In Query (1), both matrix M and the query result V are stored in memory. However, in our framework, the storage of these arrays can be customized by using a different sparsifier for M and a different builder for the result. More specifically, we want to translate array comprehensions to efficient distributed programs over block arrays, which are distributed bags of dense array chunks. In Spark [4], we can implement a tiled matrix as a distributed collection (an RDD) of fix-sized square tiles of type RDD[((Int,Int),Array[Double])], where each tile ((i,j),A) has coordinates i and j and values stored in the dense matrix A, which has a fixed size N*N, for some constant N. Similarly, we can implement the query result V as a block vector of type RDD[(Int,Array[Double])], where each block (i,B) has a coordinate i and values stored in the vector B of size N. Then, Query (1) can be rewritten as:

V = tiled[(i, +/m) | ((i,j),m) ← M, **group by** i]. (2)

For this query, the implicit sparsifier that converts a tiled matrix M of type RDD[((Int,Int),Array[Double])] to an association list of type List[((Int,Int),Double)] is:

```
[ ( ( ii*N+i, jj*N+j ), A(i,j) )
| ((ii,jj),A) ← M, i ← 0 until N, j ← 0 until N ],
```

where the index variable i in 'i ← 0 **until** N' iterates from 0 to N−1. Here, ii and jj are tile coordinates, and i and j are indices within a tile. That is, for each tile A with coordinates ii and jj read from the tiled matrix M, this list comprehension constructs $N * N$ elements from the data stored in A, so that each element has row coordinate ii*N+i, column coordinate jj*N+j, and value A(i,j). On the other hand, the builder tiled(L), which constructs a block array of type RDD[(Int,Array[Double])] from the list L of type List[(Int,Double)], is:

```
rdd[ ( i/N, vector(N)(w) )
   | (i,v) ← L, let w = ( i%N, v ), group by i/N ],
```

where the builder rdd builds an RDD from a list. That is, this comprehension groups the elements (i,v) of L by i/N (the tile coordinate) so that all N pairs (i,v) with the same i/N go into the same tile. After the group-by, the value of w is lifted to a list that contains all the values (i%N,v) that belong to the same tile at location i/N. The builder vector(N)(w), used in Query (1), converts the list w to a vector, which is an array block of size N.

Like array queries, sparsifiers and builders are expressed as comprehensions, but unlike array queries, they use efficient array indexing. This implicit coercion from stored arrays to lists and the building of stored arrays from the results of a comprehension introduce levels of indirection and generate superfluous intermediate structures that need to be removed. This is done by unnesting nested comprehensions into flat comprehensions. As we will show in this paper, after some simple transformations, Query (2) is optimized to the Spark code shown on the right of Figure 1. That is, from every tile A in M with tile coordinates I and J, a new vector block B with a coordinate I is constructed. The tile processing, which takes place at each compute node, is parallelized using the the Scala's par method [20]. Finally, vector blocks with the same coordinate are reduced pairwise using vector addition, addVectors.

In this paper, we present a small set of generic rules for translating array comprehensions to efficient Spark RDD programs that operate on block arrays. These rules are not based on specific array operations but can apply to many array processing programs that can be expressed as array comprehensions. Matrix multiplication, for example, is translated to an optimal block matrix multiplication algorithm by one generic rule that recognizes a certain class of group-by-joins (joins between two datasets followed by a group-by and an aggregation), and translates them to a special block group-by-join algorithm. Our system, called *SAC* (Scalable Array Comprehensions), has been implemented using Scala's compile-time reflection and macros. It translates array comprehensions to Scala code that calls Spark RDD operations whose functional arguments use the Scala's Parallel Collections library for multicore parallelism [20].

In an earlier work [13], we have presented a framework, called DIABLO (a Data-Intensive Array-Based Loop Optimizer), for translating array-based loops to array comprehensions, which in turn are translated to Spark programs expressed in the Spark Core API. The DIABLO input language resembles the syntax of some loop-based imperative languages, such as C and Java. DIABLO can translate any array-based loop expressed in this loop-based language to an equivalent Spark program as long as this loop satisfies some simple syntactic restrictions, which are more permissive than the recurrence restrictions imposed by many current systems. Unlike SAC, DIABLO generates Spark programs that operate on arrays in the coordinate format. In a distributed setting, arrays stored in the coordinate format are known to be less efficient than block arrays because 1) they occupy more space and therefore require more data shuffling to evaluate complex array operations, and 2) they are less amenable to multicore parallelism at each compute node since they store the array elements in random order. Furthermore, the focus of DIABLO is in the translation of imperative programs to array comprehensions, while the focus of SAC is in the translation of array comprehensions to efficient code on customizable array storages, with an emphasis on block arrays. That is, SAC supplements DIABLO and can be used as a drop-in back-end replacement for DIABLO to make it able to work on block arrays. Finally, the work reported in this paper generalizes our earlier work on extending MRQL with array-based computations [11]. It extends the MRQL query optimizer with a GroupByJoin physical operator that generalizes the SUMMA parallel algorithm for matrix multiplication [14], an idea also used in Section 5.4 in the context of block arrays. However, unlike our current framework, this system too is based on arrays stored in the coordinate format.

The contributions of this paper are summarized as follows:

- We introduce a novel comprehension syntax for array computations that can capture many array computations in declarative form and is independent of array storage.
- We describe a translation scheme that translates array comprehensions to efficient imperative programs with memory effects (Sections 2 and 3).
- We extend this translation scheme to generate efficient Spark code from array comprehensions (Section 4).
- We introduce special type transformations to translate comprehensions on block arrays to efficient Spark code that reduces the amount of data shuffling (Section 5).

Expression:

e	::=	$[\, e \mid \overline{q}\,]$	comprehension
	|	$\oplus/e$	reduction using $\oplus$
	|	$v[e_1, \ldots, e_n]$	array indexing $n \geq 1$
	|	$\ldots$	other expression

Qualifiers:

$\overline{q}$	::=	$q_1, \ldots, q_n$	$n \geq 0$

Qualifier:

q	::=	$p \leftarrow e$	generator
	|	**let** $p = e$	local declaration
	|	e	filtering
	|	**group by** $p\,[: e\,]$	group-by

Pattern:

p	::=	v	pattern variable
	|	$(p_1, \ldots, p_n)$	tuple $n \geq 0$

Figure 2: Language syntax

$$[\, e_1 \mid p \leftarrow e_2, \overline{q}\,] = e_2.\text{flatMap}(\lambda p.\, [\, e_1 \mid \overline{q}\,]) \quad (4)$$

$$[\, e_1 \mid \textbf{let}\, p = e_2, \overline{q}\,] = \textbf{let}\, p = e_2\, \textbf{in}\, [\, e_1 \mid \overline{q}\,] \quad (5)$$

$$[\, e_1 \mid e_2, \overline{q}\,] = \textbf{if}\, (e_2)\, \textbf{then}\, [\, e_1 \mid \overline{q}\,]\, \textbf{else}\, \text{Nil} \quad (6)$$

$$[\, e \mid\,] = [\, e\,] \quad (7)$$

Figure 3: Desugaring rules

- We evaluate the performance of our system relative to Spark's MLlib.linalg library (Section 6). Based on these results, SAC is up to 6 times faster than MLlib for matrix multiplication and up to 3 times faster than MLlib for matrix factorization.

2 SYNTAX AND SEMANTICS OF ARRAY COMPREHENSIONS

Figure 2 describes the syntax of our language and Figure 3 gives the desugaring rules, which are based on standard methods for translating list comprehensions [23]. The meaning, desugaring rules, and code generation for the group-by syntax are given in Section 3.

Flattening nested comprehensions that do not have a group-by qualifier is done using the following rule:

$$[\, e_1 \mid \overline{q_1},\, p \leftarrow [\, e_2 \mid \overline{q_3}\,],\, \overline{q_2}\,] = [\, e_1 \mid \overline{q_1},\, \overline{q_3},\, \textbf{let}\, p = e_2,\, \overline{q_2}\,] \quad (3)$$

for any sequence of qualifiers $\overline{q_1}$, $\overline{q_2}$, and $\overline{q_3}$. It may require renaming the variables in $[\, e_2 \mid \overline{q_3}\,]$ before we apply this rule to prevent variable capture.

As explained in Section 1.1, abstract arrays in our framework are represented as association lists that uniquely map array indices to values. These abstract representations are mapped to concrete storage structures with the help of a pair of customized functions, a sparsifier and a builder. Then, array comprehensions on abstract arrays are translated to efficient concrete programs on storage structures based on these type mappings. In this and the following section, we describe this program translation in more detail using one specific type mapping that stores a matrix in a flat vector in row-major order. Although this storage structure is not a distributed tiled array, which is the focus of this paper, this example is important for two reasons: First, it illustrates our program translation process in detail using a simpler storage. Second, it is useful for translating comprehensions on block arrays to Spark code (described in Sections 4 and 5) because it shows how the code for tile operations is generated, given that a tile is a matrix.

Consider a matrix M of type Matrix[T] stored in row-major order as a triple (n,m,V) of type (Int,Int,Array[T]), where n and m are the matrix dimensions and V is the vector that contains the matrix elements in row-major order. The following sparsifier converts the storage S of type (Int,Int,Array[T]) to the abstract representation of the matrix M, which is of type List[((Int,Int),T)]:

```
def sparsify[T] ( S: (Int,Int,Array[T]) ): List[((Int,Int),T)]
= [ ((i,j),A(i*n+j)) | let (n,m,A) = S, i ← 0 until n, j ← 0 until m ],
```

where A(i) is array indexing in Scala. The builder matrix(n,m) L takes two groups of parameters. The n and m parameters specify the matrix dimensions, while L is the association list to be converted to a flat vector that contains the matrix values in row-major order:

```
def matrix[T] ( n: Int, m: Int )
              ( L: List[((Int,Int),T)] ): (Int,Int,Array[T])
= { val V = Array.ofDim[T](n*m);
    [ V(i*n+j) = v | ((i,j),v) ← L, i≥0, i<n, j≥0, j<m ];
    (n,m,V) },
```

where Array.ofDim[T](n) creates a new array of size n and V(i) = a is an assignment that updates V(i). The sparsifier function is always named 'sparsify' because, as we will see next, it is implicitly embedded in the code by the compiler by looking at the code type, while the builder must have a unique name or type signature since all builders transform association lists. Nevertheless, the builder too can be inferred by the compiler in certain assignments, such as in the following example. In the following declaration:

```
var M: matrix[Double]
  = matrix(n,m)[ ((i,j),random()) | i ← 0 until n, j ← 0 until m ];
```

the builder matrix(n,m) is required because the M declaration specifies the abstract type, matrix[Double], but not the storage. However, in the following assignment:

```
M = [ ((j,i),m+1) | ((i,j),m) ← M, m > 10 ];
```

the builder can be inferred to be matrix(n,m), since the compiler can infer the storage type of M.

As a running example to illustrate code generation, consider the addition of two matrices M and N of size $n \times m$, expressed as follows using array comprehensions:

```
matrix(n,m)[ ((i,j),a+b) | ((i,j),a) ← M, ((ii,jj),b) ← N,
                           ii == i, jj == j ].                    (8)
```

This query can also be expressed as:

```
matrix(n,m)[ ((i,j),a+N[i,j]) | ((i,j),a) ← M ],
```

which is translated to Query (8). Basically, an array indexing $V[e_1, \ldots, e_n]$ in a comprehension is transformed by adding the qualifiers $((k_1, \ldots, k_n), k_0) \leftarrow V, k_1 == e_1, \ldots, k_n == e_n$ to the comprehension, where $k_0, k_1, \ldots, k_n$ are fresh variables, and by replacing $V[e_1, \ldots, e_n]$ with k_0. Without such translation, array indexing would not be able to map to operations on the underlying array storage.

Given a generator $p \leftarrow e$ in a comprehension, the compiler will infer the type of e using standard type inference. Then, it will

search all defined sparsifiers to find one, if exists, that applies to the type of e, and will embed this sparsifier by replacing e with sparsify(e). For Query (8), the compiler will infer the storage type of M and N to be (Int,Int,Array[Float]) and then will embed the right sparsifiers to convert them to association lists, which for these matrices is the sparsify function defined earlier. Then, it will inline the code of the sparsifiers and builder and will optimize the resulting program. This can be done effectively when these functions are expressed as comprehensions. By expressing these functions as comprehensions, the optimizer can fuse them with the array comprehension of the query, resulting to a comprehension that traverses the array storage directly, without creating the intermediate lists. Furthermore, unlike array comprehensions, these functions can and must use array indexing so that the fused comprehension results to efficient array operations.

In addition to flattening nested comprehensions using Rule (3), the only optimizations needed are those related to index traversals. More specifically, if two index generators i ← 0 **until** n and j ← 0 **until** m are related with i==j, then they are fused to one generator and a let-binding: i ← 0 **until** min(n,m), **let** j = i.

For Query (8), if for simplicity, the inequalities in the matrix(n,m) builder are ignored, we have:

```
matrix(n,m)[ ((i,j),a+b) | ((i,j),a) ← sparsify(M),
                           ((ii,jj),b) ← sparsify(N),
                           ii == i, jj == j ]
    (if we inline the array builder without the inequalities)
= { val V = Array.ofDim[T](n*m);
    [ V(i*n+j) = v
    | ((i,j),v) ← [ ((i,j),a+b) | ((i,j),a) ← sparsify(M),
                                  ((ii,jj),b) ← sparsify(N),
                                  ii == i, jj == j ];
    (n,m,V) }
    (if we unnest the comprehension using Rule (3))
= { val V = Array.ofDim[T](n*m);
    [ V(i*n+j) = v
    | ((i,j),a+b) | ((i,j),a) ← sparsify(M),
                  ((ii,jj),b) ← sparsify(N),
                  ii == i, jj == j ];
    (n,m,V) }
    (if we inline the sparsifiers and rename their variables)
= { val V = Array.ofDim[T](n*m);
    [ V(i*n+j) = v
    | ((i,j),a+b) | ((i,j),a) ← [ ((i1,j1),A(i1*n1+j1))
                                | let (n1,m1,A) = M,
                                  i1 ← 0 until n1,
                                  j1 ← 0 until m1 ],
                  ((ii,jj),b) ← [ ((i2,j2),B(i2*n2+j2))
                                | let (n2,m2,B) = N,
                                  i2 ← 0 until n2,
                                  j2 ← 0 until m2 ],
                  ii == i, jj == j ];
    (n,m,V) }
    (if we unnest the comprehension using Rule (3))
= { val V = Array.ofDim[T](n*m);
    [ V(i*n+j) = v
    | let (n1,m1,A) = M,
      i1 ← 0 until n1, j1 ← 0 until m1,
      let (n2,m2,B) = N,
      i2 ← 0 until n2, j2 ← 0 until m2,
      i2 == i1, j2 == j1,
      let ((i,j),v) = ((i1,j1),A(i1*n1+j1)+B(i2*n2+j2)) ];
    (n,m,V) }
    (if we merge the array index bounds)
= { val V = Array.ofDim[T](n*m);
    [ V(i*n+j) = A(i1*n1+j1)+B(i1*n2+j1))
    | let (n1,m1,A) = M, let (n2,m2,B) = N,
      i1 ← 0 until min(n1,n2), j1 ← 0 until min(m1,m2) ];
    (n,m,V) }
```

Given that comprehensions over arrays are translated to array index traversals of type scala.collection.immutable.Range in Scala, to parallelize the code, the only transformation needed is to convert the outer index traversal to a parallel traversal of type scala.collection.parallel.immutable.ParRange. This is done by applying par, such as i1 ← (0 **until** min(n1,n2)).par in our example.

Comprehensions can also be used along with total aggregations, such as for checking whether a vector V is sorted:

```
&&/[ v <= w | (i,v) ← V, (j,w) ← V, j == i+1 ],
```

which checks if all consecutive elements of V (i.e., V_i and V_{i+1}) are ordered. The builder of $\oplus/e$ is:

```
{ var b = 1⊕; [ b = (b ⊕ v) | v ← e ]; b },
```

where $\mathbf{1}_\oplus$ is the zero value of the monoid $\oplus$. Similar to the matrix sparsifier, the vector sparsifier is:

```
def sparsify[T] ( V: Array[T] ): List[(Int,T)]
  = [ (i,V(i)) | i ← 0 until V.length ].
```

If we embed the sparsifiers, unfold the builder code, and unnest the list comprehensions, the array comprehension becomes:

```
{ var b = true;
  [ b = (b && (V(i) <= V(j))) | i ← 0 until V.length,
                                j ← 0 until V.length, j == i+1 ];
  b },
```

which is further optimized to:

```
{ var b = true;
  [ b = (b && (V(i) <= V(i+1))) | i ← 0 until V.length−1 ];
  b },
```

given that min(V.length,V.length−1) = V.length−1.

3 COMPREHENSIONS WITH A GROUP-BY

Consider the product of two matrices M and N with dimensions $n \times l$ and $l \times m$, respectively, which is equal to a matrix C so that $C_{ij} = \sum_k M_{ik} * N_{kj}$. Using our array comprehensions enhanced with a group-by syntax, matrix multiplication can be expressed as follows:

```
matrix(n,m)[ ((i,j),+/v) | ((i,k),a) ← M, ((kk,j),b) ← N,
                           kk == k, let v = a*b,
                           group by (i,j) ].                    (9)
```

This comprehension retrieves the values M_{ik} and N_{kj} and sets $v = M_{ik} * N_{kj}$. After we group the values by the matrix indices i and j, the variable v is lifted to a bag of numerical values $M_{ik} * N_{kj}$, for all k. Hence, the aggregation $+/v$ sums up all the values in the bag v, deriving $\sum_k M_{ik} * N_{kj}$ for the ij element of the resulting matrix.

Another example of a group-by comprehension is matrix smoothing for a matrix M, which is a matrix C such that $C_{ij} =$

$\frac{1}{9}\sum_{i-1\le I\le i+1}\sum_{j-1\le J\le j+1} M_{IJ}$. That is, C_{ij} is the average value in the neighborhood of M_{ij}:

```
matrix(n,m)[ ((ii,jj),(+/a)/a.length)
           | ((i,j),a) ← M,
             ii ← (i−1) to (i+1), jj ← (j−1) to (j+1),
             ii >= 0, ii < n, jj >= 0, jj < m,
             group by (ii,jj) ],
```

which also takes care of the boundary cases.

Given a pattern p that consists of bound pattern variables, the qualifier **group by** p in $[\, e \mid \overline{q_1},$ **group by** $p,\ \overline{q_2}\,]$ groups every pattern variable in $\overline{q_1}$ (except the variables in p) by the group-by key p into a list that contains all the values of this variable associated with this group-by key. Furthermore, the qualifier **group by** $p : e$ is syntactic sugar for the qualifiers **let** $p = e,$ **group by** p. Group-by qualifiers may appear in multiple places in a comprehension. For all these cases, only the pattern variables that precede the group-by qualifier in the same comprehension must be lifted to lists, and if multiple group-by qualifiers exist, these variables will have to be lifted multiple times to nested lists.

Group-by qualifiers are translated to groupBy operations before a comprehension is translated by the rules in Figure 2. Given a list s of type List$[(K,V)]$, the operation groupBy(s) groups the elements of s by their first component (the group-by key) and returns an association list of type Map$[K,$ List$[V]]$, which is implemented as a hash table:

```
def groupBy[K,V] ( s: List[(K,V)] ): Map[K,List[V]]
 = { val m = Map[K,List[V]]();
     [ m(k) = if (m.contains(k)) m(k):+v else List(v)          (10)
     | (k,v) ← s ];
     m }.
```

Let $\overline{v} = (v_1,\ldots,v_n)$ be the pattern variables in the sequence of qualifiers $\overline{q_1}$ that are used in the rest of the comprehension $[\, e \mid \overline{q_2}\,]$ but do not appear in the group-by pattern p. Then, the group-by syntax is translated as follows:

$$[\, e \mid \overline{q_1},\ \textbf{group by}\ p,\ \overline{q_2}\,] = [\, e \mid (p,s) \leftarrow \text{groupBy}([\, (p,\overline{v}) \mid \overline{q_1}\,]),\ \textbf{let}\ \overline{v} = \text{unzip}(s),\ \overline{q_2}\,], \quad (11)$$

where unzip$(s) = ([\, v_1 \mid \overline{v} \leftarrow s\,],\ldots,[\, v_n \mid \overline{v} \leftarrow s\,])$. That is, each pattern variable v_i in $\overline{v}$ is lifted to a list that contains all the values of v_i in the current group.

For example, the matrix multiplication in Query (9) has the following meaning:

```
matrix(n,m)[ ((i,j),(+/v)) | ((i,j),s) ← groupBy(S), let v = s ],
```

where S is:

```
[ ((i,j),v) | ((i,k),a) ← M, ((kk,j),b) ← N, kk == k, let v = a*b ]
```

since the only variable lifted is v with v = [v | v ← s], which is equal to s.

Array comprehensions with a group-by syntax allow more array operations to be expressed declaratively without having to use array indexing and loops. They also make comprehensions equivalent to basic SQL queries. As we will show, although it has pure semantics, the group-by syntax makes it easier to recognize certain code patterns in a comprehension and translate them to efficient code. For example, we will see next that the matrix multiplication in Query (9) is translated to the following code, which is as efficient as a program hand-coded in an imperative language:

```
{ val V = Array.ofDim[T](n*m)(0.0);
  [ V(i*n+j) += A(i*n+k)*B(k*l+j)
  | let (n,l,A) = M, let (ll,m,B) = N,
    i ← 0 until n, k ← 0 until l, j ← 0 until m ];
  (n,m,V) },
```

which is equivalent to a triple loop with body $V_{ij} \mathrel{+}= A_{ik} \times B_{kj}$.

Consider the general comprehension $[\, e \mid \overline{q_1},$ **group by** $p,\ \overline{q_2}\,]$. To simplify our translation rules, we rewrite this term to $[\, z \mid \overline{q_1},$ **group by** $p,\ z \leftarrow [\, e \mid \overline{q_2}\,]\,]$. Let $\mathcal{V} = \{v_1,\ldots,v_n\}$ be the set of variables that are lifted by the group-by but are not lifted or redefined in $\overline{q_2}$ and let $\overline{v} = (v_1,\ldots,v_n)$. Recall that these variables are lifted to lists that contain all the values of these variables associated with the group-by key p. A lifted variable may occur any number of times in the rest of the comprehension, $[\, e \mid \overline{q_2}\,]$. Let $w_1,\ldots,w_m$ be the occurrences of the lifted variables in $[\, e \mid \overline{q_2}\,]$. A lifted variable $w_i \in \mathcal{V}$ may occur in $[\, e \mid \overline{q_2}\,]$ as a term that takes one of the following forms:

- $\oplus_i/w_i$, for some monoid $\oplus_i$, or
- $\oplus_i/w_i.\text{map}(g_i)$, for some monoid $\oplus_i$ and a function g_i, or otherwise
- w_i, which is equal to $+\!\!+/w_i.\text{map}(x \Rightarrow \mathit{List}(x))$,

where the last case is used when the first two do not match. All these cases can be generalized to $\oplus_i/w_i.\text{map}(g_i)$, for some monoid $\oplus_i$ and function g_i. Hence, we can represent the term after group-by as follows:

$$\begin{aligned}[\, e \mid \overline{q_2}\,] &= f(\oplus_1/w_1.\text{map}(g_1),\ldots,\oplus_n/w_m.\text{map}(g_m)) \\ &= f(\otimes/\text{zip}(\overline{w}).\text{map}(g)),\end{aligned}$$

for some term function f, where $\overline{w} = (w_1,\ldots,w_m)$, $g = g_1 \times \cdots \times g_m$, and $\otimes = \oplus_1 \times \cdots \times \oplus_m$ (a product of monoids[1]). Then, based on the Rule (11) and the implementation of groupBy in definition (10), we have:

```
[ e | q̄1, group by p, q̄2 ]
= [ z | q̄1, group by p, z ← f(⊗/zip(w̄).map(g)) ]
= { val M = Map();                                            (12)
    [ M(p) = if (M.contains(p)) M(p) ⊗ g(w̄) else g(w̄) | q̄1 ];
    [ z | p ← M.keys, z ← f(M(p)) ] }
```

Consider now an array comprehension of the form:

$$\text{matrix}(n,m)[\, ((i,j),e) \mid \overline{q_1},\ \textbf{group by}\ (i,j),\ \overline{q_2}\,],$$

Notice that, here, the matrix index (i,j) in the comprehension head is the group-by key. In the implementation (12) of an array comprehension with group-by, we can now use arrays of size n*m, one array for each aggregation, instead of a Map:

```
matrix(n,m)[ ((i,j),e) | q̄1, group by (i,j), q̄2 ]
= matrix(n,m)[ z | q̄1, group by (i,j),
                 z ← f(⊕1/w1.map(g1),...,⊕n/wn.map(gn)) ]
= { val V1 = Array.fill(n*m)(1⊕1);
    ...
    val Vn = Array.fill(n*m)(1⊕n);
    [ { V1(i*n+j) = V1(i*n+j) ⊕1 g1(v1);
        ...
        Vn(i*n+j) = Vn(i*n+j) ⊕n gn(vn) } | q̄1 ];
    matrix(n,m)[ z | ((i,j),_) ← V1,
```

[1] That is, the monoid $\otimes$ with identity $\mathbf{1}_\otimes = (\mathbf{1}_{\oplus_1},\ldots,\mathbf{1}_{\oplus_m})$ and $(x_1,\ldots,x_m) \otimes (y_1,\ldots,y_m) = (x_1 \oplus_1 y_1,\ldots,x_m \oplus_m y_m)$.

$$z \leftarrow f(V_1(i*n+j),\ldots,V_n(i*n+j))\ ]\ \}.$$

Notice that, the final result is a matrix constructed using the matrix(n,m) builder, and is made out of the arrays that hold the aggregation results. This matrix though does not have a group-by and can be translated using the methods given in Section 2.

For example, the matrix multiplication in Query (9) is translated as follows:

```
matrix(n,m)[ ((i,j),+/v)
             | ((i,k),a) ← sparsify(M), ((kk,j),a) ← sparsify(N),
               kk == k, let v = a*b, group by (i,j) ],
    (after unfolding the sparsifiers for M and N)
= matrix(n,m)[ ((i,j),+/v)
             | let (n,l,A) = M, i ← 0 until n, k ← 0 until l,
               let (ll,m,B) = N, kk ← 0 until ll, j ← 0 until m,
               kk == k, let v = A(i*n+k)*B(kk*ll+j), group by (i,j) ]
    (after merging the array index kk with k)
= matrix(n,m)[ ((i,j),+/v)
             | let (n,l,A) = M, i ← 0 until n, k ← 0 until l,
               let (ll,m,B) = N, j ← 0 until m,
               let v = A(i*n+k)*B(k*ll+j), group by (i,j) ]
    (by translating the group-by qualifier)
= { val V = Array.fill(n,m)(0.0);
    [ V(i*n+j) = V(i*n+j) + A(i*n+k)*B(k*ll+j)
    | let (n,l,A) = M, i ← 0 until n, k ← 0 until l,
      let (ll,m,B) = N, j ← 0 until m ];
    matrix(n,m)[ v | ((i,j),_) ← V, v ← [ ((i,j),V(i*n+j)) |] ] }
= { val V = Array.fill(n,m)(0.0);
    [ V(i*n+j) = V(i*n+j) + A(i*n+k)*B(k*ll+j)
    | let (n,l,A) = M, i ← 0 until n, k ← 0 until l,
      let (ll,m,B) = N, j ← 0 until m ];
    matrix(n,m)[ ((i,j),V(i*n+j)) | ((i,j),_) ← V ] }
    (since the last term is equal to (n,m,V))
= { val V = Array.fill(n,m)(0.0);
    [ V(i*n+j) = V(i*n+j) + A(i*n+k)*B(k*ll+j)
    | let (n,l,A) = M, i ← 0 until n, k ← 0 until l,
      let (ll,m,B) = N, j ← 0 until m ];
    (n,m,V) }
```

which is equivalent to the desired efficient loop-based program.

4 TRANSLATING QUERIES ON SPARK

In this section, we translate array comprehensions to distributed programs that can run on Apache Spark [27]. Distributed datasets in Spark are represented as Resilient Distributed Datasets (RDDs), which support a functional API that is very similar to that for Scala collections. Most RDD operations are second-order, in which the functional argument is evaluated sequentially while the operation itself is evaluated in parallel, in a distributed mode. Unlike Scala collections, Spark does not allow nested RDDs and will raise a run-time error if the functional parameter of an RDD operation accesses another RDD. That is, Spark does not support nested parallelism because it is hard to implement efficiently in a distributed setting. However, instead of using nested RDD operations, one may use joins, cogroups, and cross products to correlate RDDs. Consequently, RDD comprehensions require special translation rules to derive joins, instead of nested flatMaps.

The RDD builder, rdd, that converts a List[T] to an RDD[T] can be implemented by applying the Spark method 'parallelize' on this list. However, RDD comprehensions must be translated to RDD operations in a special way to avoid generating nested operations. A group-by qualifier can be translated to the Spark groupByKey operation of type RDD[(K,V)]⇒RDD[(K,List[V])] using Equation (11). However, groupByKey is an expensive operation because it collects the grouped values into a list, shuffles these lists to the reducers, and finally reduces them by some aggregation. Instead, we want to generate calls to the more efficient reduceByKey(⊗), for some monoid ⊕, that reduces the values of type V using the monoid ⊗, instead of placing them into a list. That way, grouped values are partially reduced before they are shuffled. To generate these reduceByKey calls, we consider the group-by qualifier in combination with the aggregations in the comprehension. Recall that, based on the discussion in Section 3 and on Equation (12), any comprehension with a group-by can be put into the following form:

$$\begin{aligned}&\text{rdd}[\ e \mid \overline{q_1},\ \textbf{group by}\ p,\ \overline{q_2}\ ]\\ &\quad=\text{rdd}[\ z \mid \overline{q_1},\ \textbf{group by}\ p,\ z \leftarrow [\ e \mid \overline{q_2}\ ]\ ]\\ &\quad=\text{rdd}[\ z \mid \overline{q_1},\ \textbf{group by}\ p,\\ &\qquad z \leftarrow f(\oplus_1/w_1.\text{map}(g_1),\ldots,\oplus_m/w_m.\text{map}(g_m))\ ],\end{aligned}$$

for some variables w_i lifted by group-by, some monoids $\oplus_i$, and some functions g_i and f. Then, the group-by comprehension can be translated to a reduceByKey operation:

$$\begin{aligned}&\text{rdd}[\ e \mid \overline{q_1},\ \textbf{group by}\ p,\ \overline{q_2}\ ]\\ &\quad=\text{rdd}[\ (p,(g_1(w_1),\ldots,g_m(w_m))) \mid \overline{q_1}\ ]\\ &\qquad.\text{reduceByKey}(\otimes)\\ &\qquad.\text{map}\{\ \textbf{case}\ (p,(a_1,\ldots,a_m))\ \Rightarrow\ f(a_1,\ldots,a_m)\ \},\end{aligned}\tag{13}$$

where $\otimes = \oplus_1 \times \cdots \times \oplus_m$.

The following rule identifies and generates joins between the RDDs X and Y, instead of nested flatMaps, when $\text{vars}(e_1) \subseteq \text{vars}(p_1)$ and $\text{vars}(e_2) \subseteq \text{vars}(p_2)$, where function 'vars' returns the free variables in a pattern or expression:

$$\begin{aligned}&\text{rdd}[\ e \mid \overline{q_1},\ p_1 \leftarrow X,\ \overline{q_2},\ p_2 \leftarrow Y,\ \overline{q_3},\ e_1 == e_2,\ \overline{q_4}\ ]\\ &\quad=\text{rdd}[\ e \mid \overline{q_1},\ (\_,(p_1,p_2)) \leftarrow Z, \overline{q_2},\ \overline{q_3},\ \overline{q_4}\ ],\end{aligned}\tag{14}$$

where $Z = X.\text{map}(\lambda p_1.\,(e_1,p_1)).\text{join}(Y.\text{map}(\lambda p_2.\,(e_2,p_2)))$.

One way to represent arrays in a distributed setting is to store them as coordinate arrays, similar to the array representation used in Section 2. For instance, a matrix can be defined in Spark as an RDD of type RDD[((Long,Long),Double)], while matrix multiplication of two RDD matrices A and B, which was defined in (9), will be translated to the following program using Rules (14) and (13):

```
A.map{ case ((i,k),a) ⇒ (k,((i,k),a)) }
  .join( B.map{ case ((kk,j),b) ⇒ (kk,((kk,j),b)) } )
  .map{ case (_,(((i,k),a),((kk,j),b))) ⇒ ((i,j),a*b) }
  .reduceByKey(_+_).
```

Although correct, this Spark program has a high cost: it shuffles the matrices A and B across the compute nodes to perform the join, and then it shuffles all the products $A_{ik} * B_{kj}$ to perform the reduceByKey. Since data shuffling is the main cost factor for a distributed program, instead of fully sparse matrices in the coordinate format, we want to use a more compact representation for matrices by partitioning a matrix into tiles, which are unboxed arrays of type Array[Double] in which indices are calculated, not stored. The sparse matrix representation, on the other hand, is preferable when both dimensions of the matrix are large and the matrix is very sparse.

5 TRANSLATING BLOCK ARRAY QUERIES

A more effective way of representing an array in a distributed setting is to encode it as a distributed bag of non-overlapping blocks, where each block is a fix-sized chunk of the distributed array. A block is the unit of data distribution. Our goal in this section is to translate RDD comprehensions over block arrays to Spark's distributed data-parallel programs whose functional parameters will process the blocks very efficiently using multicore parallelism and array indexing. Given that data partitioning is necessary for data-parallel distributed processing, blocks are a natural way to partition large arrays and at the same time to minimize space overhead, compared to fully sparse arrays in coordinate format, in which the indices are stored along with a matrix element. This small space footprint translates to less data to shuffle across nodes and faster time to process each partition. Spark actually uses thread-level parallelism at each compute node to process the elements of each RDD partition in parallel using multicore parallelism, but the unit of parallelism for a block array is the entire block, which is likely to be one block for each compute node. Consequently, in addition to generating distributed operations from array comprehensions on block arrays, our goal is to process the data inside blocks using multicore parallelism.

In this paper, we focus on tiled matrices but our work can be easily extended to handle other block arrays too. We represent a tiled matrix using the following Scala class:

```
case class Tiled[T] ( rows: Long, cols: Long,
                      tiles: RDD[((Long,Long),Array[T])] ),
```

where rows is the number of rows, cols is the number of columns, and tiles is an RDD of fix-sized square tiles, where each tile ((i,j),A) has coordinates i and j and values stored in the array A. The array A has a fixed size N*N, for some constant N which is the same for all tiles. The coordinates i and j of a tile are unique, that is, tiles is an association list. A matrix element with indices ij is stored in the tile that has coordinates $(i/N, j/N)$ at the location $(i\%N) * N + (j\%N)$ inside the tile. The tile sparsifier is as follows:

```
def sparsify[T] ( S: Tiled[T] ): List[((Long,Long),T)]
  = [ ( ( ii*N+i, jj*N+j ), a(i*N+j) )
    | ((ii,jj),a) ← S.tiles,
      i ← 0 until N, j ← 0 until N ],
```

where ii and jj are the tile coordinates, and i and j are indices within a tile. The tiled builder uses the rdd and the array builders:

```
def tiled[T] ( n: Long, m: Long )
             ( L: List[((Long,Long),T)] ): Tiled[T]
  = Tiled( n, m, rdd[ ( (ii, jj), array(N*N)(w) )
                    | ((i,j),v) ← L, let ii = i/N, let jj = j/N,
                      let w = ( (i%N)*N+(j%N), v ),
                      group by (ii,jj) ] ),
```

where the group-by collects all tile elements into an array. The group-by comprehension is in an RDD comprehension, which means that it will be translated to a groupByKey operation in Spark, which requires data shuffling across the compute nodes. However, in some cases, this group-by qualifier can be eliminated, as in the case of a map over a matrix. Such an optimization is actually a general optimization over comprehensions with a group-by. A group-by qualifier in a comprehension can be eliminated if the group-by key is unique, that is, when the group-by function is injective. Although it is in general undecidable to prove whether a group-by key is unique, it is easy to do so for special cases, such as when the group-by key consists of array indices that are bound through an array traversal. For an array or map A, and the pattern variables v_i in $\overline{q_1}$ or $\overline{q_2}$, we have:

$$[\, e \mid \overline{q_1},\ (k,v) \leftarrow A,\ \overline{q_2},\ \textbf{group by}\ k\,] \\ = [\, e \mid \overline{q_1},\ (k,v) \leftarrow A,\ \textbf{let}\ \overline{v} = \text{unzip}([\,\overline{v} \mid \overline{q_2}\,])\,], \tag{15}$$

since the generator $(k,v) \leftarrow A$ for an array or map A indicates that k is unique. That is, this group-by is removed and every pattern variable v_i in $\overline{q_1}$ or $\overline{q_2}$ is lifted to a bag that contains all its values in the group. A similar rule exists for a generator $k \leftarrow e_1$ **until** e_2, since every value of k is unique.

Although correct, unfolding and normalizing tiled array comprehensions based on the tiled sparsifier and builder do not always result to optimal translations. In the rest of this section, we present special rules to translate tiled array comprehensions to efficient Spark programs.

5.1 Queries that Preserve Tiling

Consider the block comprehension without a group-by:

$$\text{tiled}(\overline{d})[\,(key, e) \mid \overline{q}\,] \tag{16}$$

where $\overline{d}$ is the tile dimensions (e.g., (m,n) for a matrix), key is the tile indices (e.g., (i,j) for a matrix) and e is the associated value. Let $(\overline{k_i}, v_i) \leftarrow X_i$ be a generator over a tiled array X_i in $\overline{q}$, where $\overline{k_i}$ is a tuple of index variables, such as $((i,j),v) \leftarrow X$ for a tiled matrix X. We say that this tiled comprehension *preserves tiling* if key is a tuple $\overline{w}$ that consists of variables that are defined in the tuples $\overline{k_i}$. The rest of the variables in the tuples $\overline{k_i}$ (not in $\overline{w}$) must be related to the variables in $\overline{w}$ with equality predicates in $\overline{q}$, so that the index of the constructed array is unique. For example, matrix addition and matrix diagonal preserve tiling:

```
tiled(n,m)[ ((i,j),a+b) | ((i,j),a) ← A, ((ii,jj),b) ← B,
                          ii == i, jj == j ],
tiled(n)[ (i,a) | ((i,j),a) ← A, i == j ].
```

A comprehension that preserves tiling is translated to an RDD comprehension that does not need a group-by to shuffle tiles. More specifically, the comprehension (16) is translated to:

$$\text{Tiled}(\overline{d}, \text{rdd}[\,(\overline{w}, \text{array}(N*N)[\,(\overline{w}, e) \mid \overline{q_2}\,]) \mid \overline{q_1}\,]), \tag{17}$$

where the qualifiers in $\overline{q_1}$ are those from $\overline{q}$ that do not refer to the tile values and each tiled generator $(\overline{k_i}, v_i) \leftarrow X_i$ has been modified to be $(\overline{k_i}, \_v_i) \leftarrow X_i$.tiles (given the pattern variable v_i bound to an array value, $\_v_i$ is bound to the entire tile in $\overline{q_1}$). The qualifier list $\overline{q_2}$ is equal to $\overline{q}$ but each tiled generator $(\overline{k_i}, v_i) \leftarrow X_i$ in $\overline{q}$ has been modified to be $(\overline{k_i}, v_i) \leftarrow \_v_i$. For example, matrix addition:

```
tiled(n,m)[ ((i,j),a+b) | ((i,j),a) ← A, ((ii,jj),b) ← B,
                          ii == i, jj == j ]
```

is translated to:

```
Tiled( n, m, rdd[ ( (i,j), V(_a,_b) )
                | ((i,j),_a) ← A.tiles, ((ii,jj),_b) ← B.tiles,
                  ii == i, jj == j ] ),
```

where V(_a,_b) is:

```
array(N*N)[ ((i,j),a+b) | ((i,j),a) ← _a, ((ii,jj),b) ← _b,
                          ii == i, jj == j ],
```

which is a regular array comprehension in which the tiles _a and _b will be lifted using the following array sparsifier for a tile A:

```
[ ((i,j),A(i*N+j)) | i ← 0 until N, j ← 0 until N ].
```

Based on the translation of RDD and array comprehensions, matrix addition is translated to the following Spark code:

```
Tiled( n, m, A.tiles.join(B.tiles)
         .map{ case ((ii,jj),(_a,_b)) ⇒ ((ii,jj),V(_a,_b)) } ).
```

After optimizations similar to those for matrix addition for regular matrices, we get the following code for V(_a,_b):

```
{ val V = Array.ofDim[Double](N*N);
  [ V((i%N)*N+(j%N)) = _a( (i%N)*N+(j%N) )
                     + _b( (i%N)*N+(j%N) )
  | i ← (0 until N).par, /* multicore parallelism */
    j ← 0 until N ];
  V }.
```

5.2 Queries that do not Preserve Tiling

For those array comprehensions that do not have a group-by and do not preserve tiling, we need to shuffle only the relevant tiles to the appropriate reducers. The array indices $\overline{w}$ in the result of the tiled comprehension

$$\text{tiled}(\overline{d})[\,(\overline{w}, e) \mid \overline{q}\,] \tag{18}$$

may now be arbitrary expressions that depend on the indices of the tiled generators in $\overline{q}$.

Let $f(\overline{k})$ be a term that depends on the array indices $\overline{k} = k_1, \ldots, k_m$ from the tiled generators in $\overline{q}$. The tiles accessed from the tiled generators $\overline{q}$ will have tile coordinates $\overline{K}$, where $K_i = k_i/N$. Given the tile coordinates $\overline{K}$ of the input tiles, the tile coordinate returned by $f(\overline{k})$ would be equal to $f(K_1 * N + j_1, \ldots, K_m * N + j_m)/N$, for $j_i \in [0, N)$ (the tile dimensions). We define, $\mathcal{I}_f(\overline{K})$ to be the set of all such tile coordinates:

$$\text{set}[\, f(K_1 * N + j_1, \ldots, K_m * N + j_m)/N \mid j_1 \leftarrow 0 \,\textbf{until}\, N, \ \ldots, \ j_m \leftarrow 0 \,\textbf{until}\, N\,],$$

where set(s) returns the distinct values of s. For example, if $f(k) = k+1$, then $\mathcal{I}_f(K) = \text{set}[\, f(K*N+j)/N \mid j \leftarrow 0 \,\textbf{until}\, N\,]$, which is equal to the set $\{K, K+1\}$ since $f(K * N + j)/N = (K*N+j+1)/N = K+(j+1)/N$. On the other hand, if $f(k) = k$, then $\mathcal{I}_f(K) = \{K\}$.

Based on this definition, comprehension (18) can be transformed to:

$$\text{Tiled}(\overline{d}, \text{rdd}[\,(\overline{K}, V) \mid \overline{q_1}, K_1 \leftarrow \mathcal{I}_{w_1}(\overline{k}), \ \ldots, \ K_m \leftarrow \mathcal{I}_{w_m}(\overline{k}), \ \textbf{group by}\, \overline{K}\,]), \tag{19}$$

where V is:

$$\text{array}[\,(\overline{w}, e) \mid \overline{q_2}, \ \textstyle\bigwedge_i \overline{K_i} == w_i(\overline{\_k} * N + \overline{k})/N\,].$$

The qualifiers in $\overline{q_1}$ are those from $\overline{q}$ that do not refer to the tile values and each tiled generator $(\overline{k_i}, v_i) \leftarrow X_i$ has been transformed to the two qualifiers $(\overline{k_i}, \_v_i) \leftarrow X_i$.tiles and **let** $\_\_v_i = (\overline{k_i}, \_v_i)$ (given the pattern variable v_i bound to an array value, $\_v_i$ is bound to the entire tile in $\overline{q_1}$, while $\_\_v_i$ is bound to the index-tile pair). The group-by operation shuffles all the required tiles to the reducers to compute the resulting tiles. The qualifier list $\overline{q_2}$ in V is equal to $\overline{q}$ but each tiled generator $(\overline{k_i}, v_i) \leftarrow X_i$ in $\overline{q}$ has been transformed to the two qualifiers $(\overline{\_k_i}, \_v_i) \leftarrow \_\_v_i$ and $(\overline{k_i}, v_i) \leftarrow \_v_i$. The guards $\overline{K_i} == w_i(\overline{\_k} * N + \overline{k})/N$ selects only the proper tiles from all those shuffled by group-by.

For example, the following comprehension rotates the rows so that the first row is moved to the second, the second to third, etc, and the last to the first:

```
tiled(n,m)[ ( ( (i+1)%m, j ), v ) | ((i,j),v) ← X ].
```

The shuffled tiles for a tile in X with coordinates (i,j) have row coordinates from set[(i*N+_i+1)%m/N | _i ← 0 **until** N], which will be evaluated to List(i,i+1) for i < n/N and to List(i,0) for i = n/N, and column coordinates from List(j). That is, for each tile with coordinates (i,j) such that i < n/N, we require two tiles: the tile itself and its row successor with coordinates (i+1,j). Hence, the row rotation is translated to:

```
Tiled(n,m,rdd[ ( (K1,K2), V )
             | ((i,j),_a) ← X.tiles, let __a = ((i,j),_a),
               K1 ← set[ (i*N+_i+1)%m/N | _i ← 0 until N ],
               K2 ← List(j),
               group by (K1,K2) ] ),
```

which is translated to a Spark groupByKey operation. V is:

```
array(N*N)[ (((i+1)%m,j),a) | ((_i,_j),_a) ← __a, ((i,j),a) ← _a,
            K1 == (_i*N+i+1)%m/N, K2 == (_j*N+j)/N ] ),
```

which is translated to an efficient array-based program over the list of tiles __a.

5.3 Queries with a Group-By

Tile comprehensions with a group-by do not preserve tiling. They can be translated in a way similar to that for comprehension (18), but we can do better by using the RDD operation reduceByKey instead of the RDD operation groupByKey, because a group-by in a group-by comprehension is often followed by aggregation. A reduceByKey($\oplus$) operation, for some monoid $\oplus$, is equivalent to a groupByKey followed by reduction of each group using $\oplus$. Although functionally equivalent, reduceByKey is far more efficient than groupByKey in a distributed setting because it partially reduces the groups locally before they are shuffled to the reducers for the final reduction, resulting to less data shuffling.

Before we describe the general translation scheme, we explain the key idea using the example of matrix multiplication of the tiled matrices A and B:

```
tiled(n,m)[ ((i,j),+/v)) | ((i,k),a) ← A, ((kk,j),a) ← B,
                           kk == k, let v = a*b,
                           group by (i,j) ].
```

We want to translate it to the reduceByKey operation:

```
Tiled( n, m, rdd[ ((i,j),V(_a,_b))
                | ((i,k),_a) ← A.tiles, ((kk,j),_a) ← B.tiles,
                  kk == k ].reduceByKey(⊕) ),
```

where the tile V(_a,_b) is the tile _a multiplied by _b:

```
array(N*N)[ ((i,j),+/v)) | ((i,k),a) ← _a, ((kk,j),a) ← _b,
                           kk == k, let v = a*b,
                           group by (i,j) ]
```

and the monoid $\oplus$ over the tiles _x and _y adds the tiles pairwise:

```
_x⊕_y = array(N*N)[ ((i,j),x+y) | ((i,j),x) ← _x, ((ii,jj),y) ← _y,
                                  ii == i, jj == j ].
```

That is, the rdd comprehension calculates the partial sum of products of all matching tiles and the reduceByKey calculates the final sums by adding the tiles pairwise. Then, after translating the rdd and array comprehensions, we will get:

```
Tiled(n,m,A.tiles.map{ case ((i,k),_a) ⇒ (k,((i,k),_a)) }
     .join( B.tiles.map{ case ((kk,j),_a) ⇒ (kk,((kk,j),_a)) } )
     .map{ case (_,(((i,k),_a),((kk,j),_a))) ⇒ ((i,j),V(_a,_b)) }
     .reduceByKey(⊕))
```

where V(_a,_b) is translated to efficient code that multiplies the tiles _a and _b:

```
{ val V = Array.ofDim[Double](N*N);
  for { i ← 0 until N; j ← 0 until N; k ← 0 until N }
    V(i*N+j) += _a(i*N+k)*_b(k*N+j);
  V },
```

and _x⊕_y is pairwise addition:

```
{ val V = Array.ofDim[Double](N*N);
  for { i ← 0 until N; j ← 0 until N }
    V(i*N+j) = _x(i*N+j)+_y(i*N+j);
  V }.
```

To generate these reduceByKey calls, we consider the group-by qualifier in combination with the aggregations in the comprehension. Recall that, based on the discussion in Section 3 and on Equation (12), any tiled comprehension with a group-by can be put into the following form:

$$\begin{aligned}&\text{tiled}(n,m)[\,(p,e) \mid \overline{q},\ \textbf{group by}\ p,\ \overline{q'}\,]\\ &\quad= \text{tiled}(n,m)[\,(p,z) \mid \overline{q},\ \textbf{group by}\ p,\ z \leftarrow [\,e \mid \overline{q'}\,]\,]\\ &\quad= \text{tiled}(n,m)[\,(p,z) \mid \overline{q},\ \textbf{group by}\ p,\\ &\qquad z \leftarrow f(\oplus_1/w_1.\text{map}(g_1),\ldots,\oplus_m/w_m.\text{map}(g_m))\,],\end{aligned}$$

for some variables w_i lifted by group-by, some monoids $\oplus_i$, and some functions g_i and f. That is, we abstract all reductions $\oplus_i/w_i.\text{map}(g_i)$ from the term $[\,e \mid \overline{q'}\,]$. Notice that, here, the key of the tiled comprehension is equal to the group-by key, p. Then, the group-by comprehension can be translated to the following reduceByKey operation:

$$\begin{aligned}&\text{Tiled}(n,m,\text{rdd}[\,(p,(\text{array}(N*N)[\,g_1(w_1) \mid \overline{q_2}\,],\ldots,\\ &\qquad\qquad \text{array}(N*N)[\,g_m(w_m) \mid \overline{q_2}\,]))\\ &\qquad\qquad \mid \overline{q_1}\,]\\ &\qquad .\text{reduceByKey}(\otimes').\text{mapValues}(f'))\end{aligned}$$

Like in (17), the qualifiers in $\overline{q_1}$ are those from $\overline{q}$ that do not refer to the tile values and each tiled generator $(\overline{k_i},v_i) \leftarrow X_i$ has been modified to be $(\overline{k_i},\_v_i) \leftarrow X_i$.tiles. The qualifier list $\overline{q_2}$ is equal to $\overline{q}$ but each tiled generator $(\overline{k_i},v_i) \leftarrow X_i$ in $\overline{q}$ has been modified to be $(\overline{k_i},v_i) \leftarrow \_v_i$. The monoid $\otimes'$ is:

$$(x_1,\ldots,x_m) \otimes' (y_1,\ldots,y_m) \;=\; (x_1 \oplus'_1 y_1,\ldots,x_m \oplus'_m y_m)$$

where $x_k \oplus'_k y_k$ applies $\oplus_k$ to the tile elements pairwise:

$$\begin{aligned}&\text{array}(N*N)[\,a \oplus_k b \mid ((i,j),a) \leftarrow x_k,\ ((ii,jj),b) \leftarrow y_k,\\ &\qquad\qquad ii == i,\ jj == j\,]\end{aligned}$$

Finally, $f'(x_1,\ldots,x_m)$ is:

$$\begin{aligned}&\text{array}(N*N)[\,f(a_1,\ldots,a_m)\\ &\qquad\qquad \mid ((i_1,j_1),a_1) \leftarrow x_1,\ldots,\ ((i_m,j_m),a_m) \leftarrow x_m,\\ &\qquad\qquad i_1 == \cdots == i_m,\ j_1 == \cdots == j_m\,]\end{aligned}$$

For the matrix multiplication example, there is only one reduction with $\oplus_1 = +$ and f is identity, which means that mapValues(f') is identity too.

5.4 Using a Group-By-Join

There is a special class of tiled comprehensions with a group-by that can be translated to more efficient code. Consider the following comprehension:

```
tiled(n,m)[ (k,⊕/c) | ((i,j),a) ← A, ((ii,jj),b) ← B,
                      kx(i,j) == ky(ii,jj),  let c = h(a,b),
                      group by k: ( gx(i,j), gy(ii,jj) ) ],
```

for some arbitrary term functions kx, ky, gx, gy, and h, and some aggregation ⊕. Notice that the key k of the output matrix is the group-by key, which must be a pair where one component depends on i,j and the other on ii,jj only. This is called a group-by-join because it is a join between A and B, followed by a group-by with aggregation. Matrix multiplication, defined in (9), is an example of a group-by-join. Many group-by comprehensions can be put in the group-by-join form by combining generators in pairs forming joins until we are left with two generators and a group-by. A group-by-join can be evaluated very efficiently by joining each row of tiles from A with each column of tiles from B, which requires that we replicate every tile from A and B. When applied to the matrix multiplication, this algorithm is equivalent to the block matrix multiplication implemented using the SUMMA algorithm [14]. The group-by-join is translated to the following Spark RDD code:

```
Tiled( n, m, rdd[ (k,V) | (k,(__a,__b)) ← As.cogroup(Bs) ] ),
```

where As, Bs, and V are

```
As = A.tiles.flatMap{ case ((i,j),a)
     ⇒ (0 until B.cols/N).map(k ⇒ ((gx(i,j),k),(kx(i,j),a))) }
Bs = B.tiles.flatMap{ case ((ii,jj),b)
     ⇒ (0 until A.rows/N).map(k ⇒ ((k,gy(ii,jj)),(ky(ii,jj),b))) }
V = array(N*N)[ (k,⊕/c)
          | (k1,_a) ← __a, (k2,_b) ← __b, k2 == k1,
            ((i,j),a) ←_ a, ((ii,jj),b) ← _b, kx(i,j) == ky(ii,jj),
            let c = h(a,b), group by k: (gx(i,j),gy(ii,jj)) ].
```

That is, the tiles in A are replicated B.cols/N times and the tiles in B are replicated A.rows/N times.

6 PERFORMANCE EVALUATION

Our system, SAC, has been implemented using Scala's compile-time reflection and macros. Our code generator uses the Scala typechecker to infer the types of the generator domains to select the appropriate sparsifiers based on these types. It translates array comprehensions to Scala code that calls Spark RDD operations whose functional arguments use the Scala's Parallel Collections library [20] for multicore parallelism. The produced Scala code is embedded in the rest of the Scala code generated at compile-time. The source code of our system is available on GitHub at https://github.com/fegaras/array.

We have evaluated the performance of our system relative to the Spark MLlib.linalg library [5]. MLlib uses the linear algebra package Breeze, but in our experiments, instead of using a native Breeze library implementation, such as OpenBLAS, we used the pure JVM implementation of this library. Although there are many linear algebra libraries that support distributed tiled arrays, MLlib is the closest to our work since it is built on top of Spark and has a Scala API.

The platform used for these evaluations was a small cluster of 4 nodes, where each node has one Xeon E5-2680v3 at 2.5GHz, with 24 cores, 128GB RAM, and 320GB SSD. For our experiments,

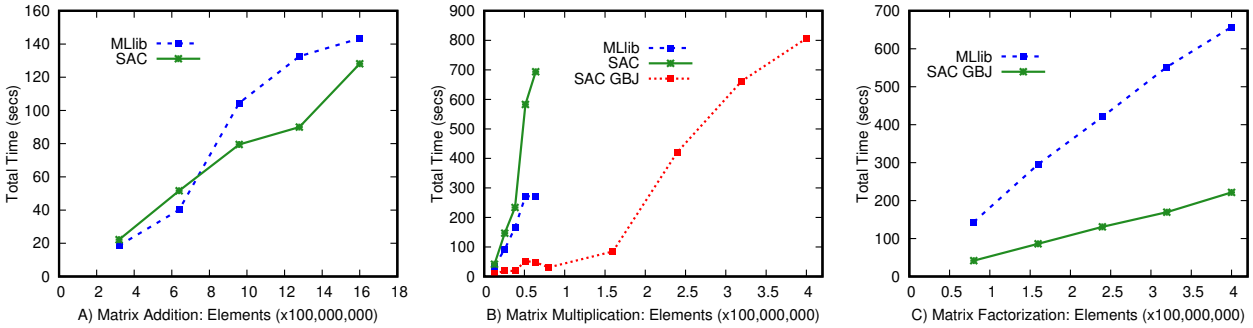

Figure 4: Performance evaluation of matrix addition, multiplication, and factorization of tiled matrices on Apache Spark

we used Apache Spark 3.0.0 running on Apache Hadoop 2.7.0. Each Spark executor was configured to have 11 cores and 60GB RAM. Consequently, there were 2 executors per node, giving a total of 8 executors. Each program was evaluated over 5 datasets and each evaluation was repeated 4 times, so each data point in the plots in Figure 4 represents the mean value of these 4 evaluations.

The matrices used in our experiments were tiled matrices where each tile had size 1000*1000. We implemented these distributed tiled matrices in MLlib.linalg as instances of BlockMatrix, where each tile was an instance of DenseMatrix. The matrices used for addition and multiplication were pairs of square matrices of the same size filled with random values between 0.0 and 10.0. The largest matrices used in matrix addition had 40000×40000 elements and size 12GB each, while those used in matrix multiplication had 20000×20000 elements and size 3GB each. Matrix multiplication was translated in two different ways in SAC: as a join followed by a group-by, and using a special group-by join (see Section 5.4 for a discussion). The results are shown in Figure 4.A and B. We can see that, for matrix addition, SAC performs a bit faster than MLlib. For matrix multiplication though, SAC (that uses a join followed by a group-by) is up to 3 times slower than MLlib, while MLib is up to 6 times slower than SAC GBJ (that uses the special group-by join).

The third program to evaluate was one iteration of matrix factorization using gradient descent [16]. The goal of this computation is to split a matrix R of dimension $n \times m$ into two low-rank matrices P and Q of dimensions $n \times k$ and $m \times k$, for small k, such that the error between the predicted and the original rating matrix $R - P \times Q^T$ is below some threshold, where $P \times Q^T$ is the matrix multiplication of P with the transpose of Q and '$-$' is cell-wise matrix subtraction. Matrix factorization can be implemented by repeatedly applying the following operations:

$$\begin{aligned} E &\leftarrow R - P \times Q^T \\ P &\leftarrow P + \gamma(2E \times Q - \lambda P) \\ Q &\leftarrow Q + \gamma(2E^T \times P - \lambda Q) \end{aligned}$$

where γ is the learning rate and λ is the normalization factor used in avoiding overfitting. For our experiments, we used $\gamma = 0.002$ and $\lambda = 0.02$. The matrix to be factorized, R, was a square sparse matrix $n*n$ with random integer values between 0 and 5, in which only the 10% of the elements were non-zero. The dimension k was set to 1000. The derived matrices P and Q had dimension $n * 1000$ and were initialized with random values between 0.0 and 1.0. The largest matrix R used had 20000×20000 elements and size 3GB. The results are shown in Figure 4.C. We can see that SAC (using GBJ) is up to three times faster than MLlib.

7 RELATED WORK

Many array-processing systems use special storage techniques, such as regular tiling, to achieve better performance on certain array computations. TileDB [19] is an array data storage management system that performs complex analytics on scientific data. It organizes array elements into ordered collections called fragments, where each fragment is dense or sparse, and groups contiguous array elements into data tiles of fixed capacity. Unlike our work, the focus of TileDB is on the I/O optimization of array operations by using small block updates to update the array stores. SciDB [22] is a large-scale data management system for scientific analysis based on an array data model with implicit ordering. The SciDB storage manager decomposes arrays into a number of equal sized and potentially overlapping chunks, in a way that allows parallel and pipeline processing of array data. Like SciDB, ArrayStore [21] stores arrays into chunks, which are typically the size of a storage block. One of their most effective storage method is a two-level chunking strategy with regular chunks and regular tiles. SciHadoop [7] is a Hadoop plugin that allows scientists to specify logical queries over arrays stored in the NetCDF file format. Their chunking strategy, which is called the Baseline partitioning strategy, subdivides the logical input into a set of partitions (sub-arrays), one for each physical block of the input file. SciHive [15] is a scalable array-based query system that enables scientists to process raw array datasets in parallel with a SQL-like query language. SciHive maps array datasets in NetCDF files to Hive tables and executes queries via Map-Reduce. Based on the mapping of array variables to Hive tables, SQL-like queries on arrays are translated to HiveQL queries on tables and then optimized by the Hive query optimizer. SciMATE [25] extends the Map-Reduce API to support the processing of the NetCDF and HDF5 scientific formats, in addition to flat-files. SciMATE supports various optimizations specific to scientific applications by selecting a small number of attributes used by an application and perform data partition based on these attributes. TensorFlow [1] is a dataflow language for machine learning that supports data parallelism on multi-core machines and GPUs but has limited support for distributed computing. Linalg [26] (now part of Spark's MLlib library) is a distributed linear algebra and optimization library that runs on Spark. It consists of fast and scalable implementations of standard matrix computations for common linear algebra operations, such as matrix multiplication and factorization. One of its distributed matrix representations, BlockMatrix, treats the matrix as dense blocks of data, where each block is small enough to fit in memory on a single machine. Linalg allows matrix computations to be pushed from the JVM

down to hardware via the Basic Linear Algebra Subprograms (BLAS) interface. SystemML [6] is a machine learning (ML) library built on top of Spark. It supports a high-level specification of ML algorithms that simplifies the development and deployment of ML algorithms by separating algorithm semantics from underlying data representations and runtime execution plans. Distributed matrices in SystemML are partitioned into fixed size blocks, called Binary Block Matrices. Although many of these systems support block matrices, their runtime systems are based on a library of build-in, hand-optimized linear algebra operations, which is hard to extend with new storage structures and algorithms. Furthermore, many of these systems lack a comprehensive framework for automatic inter-operator optimization, such as finding the best way to form the product of several matrices. Like these systems, our framework separates specification from implementation, but, unlike these systems, our system supports ad-hoc operations on array collections, rather than a library of build-in array operations, is extensible with customized storage structures, and uses relational-style optimizations to optimize array programs with multiple operations.

There has also been some recent work on combining linear algebra with relational algebra to let programmers implement ML algorithms on relational database systems [2, 17, 18]. The work by Luo *et al.* [18] adds a new attribute type to relational schemas to capture arrays that can fit in memory and extends SQL with array operators. Although their system evaluates SQL queries in Map-Reduce, the arrays are not fully distributed. Instead, large matrices must be split into multiple rows as indexed tiles while the programmer is expected to write SQL code to implement matrix operations by correlating these tiles using array operators in SQL. That is, SQL queries on distributed arrays are customizable but the array operators used in correlating tiles are build-in from a library. However, even if these tile operations were customizable, this system would differ from ours since it does not separate specification from implementation, thus making hard to change the array storage, and requires programmers to write explicit code to correlate tiles.

8 CONCLUSION AND FUTURE WORK

Our performance results show that SAC can be as efficient as a highly optimized array library when applied to certain distributed operations on tiled arrays. The same layered approach can also be used for translating comprehensions on other types of array storage, such as on tiled arrays where each tile is stored in the compressed sparse column format. As future work, we plan to look at operations that are hard to express using comprehensions, such as inverting a matrix, which requires a special LU decomposition algorithm. We believe that such operations should be coded as black-box library functions in a high-performance array library, such as BLAS or LAPACK. Such operations would require special optimizations to fuse them with general array comprehensions and with each other. Furthermore, our framework cannot directly generate calls to a high-performance array library, such as BLAS or LAPACK, or to GPU libraries, such as CUDA or OpenGL, but it can be improved to recognize certain patterns in a comprehension that are translatable to such calls. Finally, we would like to investigate general methods to optimize storage, such as unboxing arrays where vectors of tuples are mapped to tuples of vectors, and to parallelize irregular structures using nested parallelism.

Acknowledgments: Our evaluations were performed at the XSEDE Comet cloud computing infrastructure at SDSC, www.xsede.org, supported by NSF.

Short Paper

Automated Machine Learning for Entity Matching Tasks

University of Modena and Reggio Emilia
Modena, Italy

ABSTRACT

The paper studies the application of automated machine learning approaches (AutoML) for addressing the problem of Entity Matching (EM). This would make the existing, highly effective, Machine Learning (ML) and Deep Learning based approaches for EM usable also by non-expert users, who do not have the expertise to train and tune such complex systems. Our experiments show that the direct application of AutoML systems to this scenario does not provide high quality results. To address this issue, we introduce a new component, the *EM adapter*, to be pipelined with standard AutoML systems, that preprocesses the EM datasets to make them usable by automated approaches. The experimental evaluation shows that our proposal obtains the same effectiveness as the state-of-the-art EM systems, but it does not require any skill on ML to tune it.

1 INTRODUCTION

Machine Learning (ML) has significantly advanced over the past ten years [1]. On one side, the research on Big Data let emerge new challenges and made available scenarios and datasets where to experiment and improve ML techniques. On the other side, the increase of computer processing power, thanks in particular to the use of graphic processing units, enabled ML approaches running in commodity hardware. This led to the development of new ML algorithms and their implementations through frameworks and libraries is extensive and growing [17]. Thus the ML technology moved from an R&D phase, for the exclusive use of specialized laboratories, to a mature phase where it can be adopted in business applications.

Mature technologies have to be easy to use for both non-experts and professionals. One of the main bottlenecks towards a large use of the ML technology is related to the configuration of the systems, where experts are typically needed to set the large number of hyper-parameters. Furthermore, the selection of the algorithm that best performs in a given ML task is based on an experimental evaluation in which the performances of competing approaches are compared. This requires a time-consuming and expensive iterative process in which multiple alternative solutions are tested until an optimal result is achieved.

To address these issues, automated machine learning (AutoML) tools have been proposed. These are user-friendly and easy-to-use systems that provide a unified interface for the automatic selection of the most appropriate ML model/algorithm for a given task and its automatic configuration. Some examples are Auto-WEKA [12], AutoSklearn [9], AutoGluon [8], Auto-Keras [11], H20 AutoML [10], and many other.

This paper analyzes the application of AutoML systems to Entity Matching (EM), i.e. the task of identifying which records in a dataset refer to the same real-world entity [5]. Applications addressing EM tasks are becoming mature technologies and AutoML can promote this maturation for three main reasons. First of all, the state of the art EM systems are based on complex and advanced neural architectures [2, 7, 13, 16, 25] which require a non-trivial configuration process performed by expert users. Therefore, AutoML can make the application of EM techniques possible also to less experienced users. Secondly, the implementation of an EM system based on ML is expensive since it is performed through a time-consuming process that requires the active involvement of domain experts for evaluating the model. Introducing a form of automation would reduce the cost and time for the model deployment. Finally, in business scenarios where annotating data for the training process is costly and the performance evaluation is a critical task, the results obtained with an AutoML system represent a low-cost baseline.

Our experiments showed that the direct application of AutoML systems to the EM task was not effective. One of the main reasons is that such systems have been designed to solve generic ML tasks. Therefore, they are ineffective in dealing with the peculiarities of EM, characterized by an "unusual" data format, where each record is a description of pairs of entities, and there is a high imbalance between the “match" and “non-match" classes to predict.

For this reason, we introduce in this paper a software component, the *EM adapter*, encoding the datasets used in the EM task into a numerical form that make them to be effectively processed by AutoML systems. The *EM adapters* rely on the most recent transformer architectures, such as BERT and variants [6, 14, 19, 24], whose out of the box application to the EM problem has proved to be particularly effective [2]. We show in our experiments that *EM adapters* pipelined with AutoML systems are able to ensure quality performance comparable with the one of EM approaches parametrized by ML experts, thus making possible the use of complex ML techniques to non-expert users.

Summarizing, the main contributions of our paper are:

- An analysis about the application of AutoML systems to the EM task;
- The design of *EM adapters*, components based on pre-trained transformer architectures, to be pipelined with AutoML systems for making them able to effectively perform the EM task;
- An extensive experimentation (including a comparison with other state of the art EM tools) to evaluate the effectiveness of our proposal in different scenarios (reduced training times and different types of data).

The rest of the paper is organized as follows. Section 2 introduces the state-of-the-art techniques developed in the AutoML and EM fields. Section 3 describes the main features of the *EM adapters*, the components we developed for making AutoML systems addressing EM tasks, and Section 4 presents the implementation we developed. Our approach has been experimented as described in Section 5. Finally, in Section 6 we sketched out some conclusions and future work.

2 RELATED WORK

Entity Matching. Despite the effort put by the research community for more than thirty years, EM is still an open challenge. Several techniques have been proposed: they range from rules-based approaches [18, 20, 22] to ML models, that conceive EM as a binary classification problem [4] applied on datasets whose records describe pairs of entities. Recently, Deep Learning (DL) approaches (DeepER [7] and DeepMatcher [16] are the first proposals) have proved to be very effective. They suffer from two main problems: 1) the need for a significant amount of labeled data for their training and 2) a non-trivial configuration. To address the first problem, approaches based on transfer learning and fine-tuning techniques relying on architectures pre-trained on large generalist corpus have been proposed [2, 13, 25]. [25] presents a transfer learning approach to EM leveraging on pre-trained models from large-scale, production knowledge bases. [13] applies a fine-tuning process based on a pre-trained Bert architecture [6] using a limited number of labeled data, whose performance is further improved through the exploitation of data augmentation techniques. An analogous approach is described in [2], in which a larger collection of transformer architectures (Bert, XLNet [24], DistilBERT [19] and RoBERTa [14]) are applied to the EM problem.

Although these systems address the problem of the need for a significant number of labeled data, they require specific skills in modifying, training, and configuring complex neural architectures. In this work, we aim to make an EM architecture accessible also to non-expert users and to generate low-cost baselines for EM tasks.

AutoML AutoML is a recent research topic and consists in the automatic identification of the most effective algorithms to make ML inference requiring minimal human intervention and exploiting a limited computational budget (e.g. in terms of use of CPU and RAM).

The first definition of this problem is given in [12], where AutoML is formalized as a *Combined Algorithm Selection and Hyperparameter optimization (CASH)* problem. The solution proposed in this work is Auto-WEKA: a system designed to automatically select and configure, using methods based on Bayesian optimization, the classification models available within the WEKA[1] ML library. Starting with this pioneering work, numerous AutoML systems have been developed. Among them, AutoSklearn [9] combines a meta-learning technique, to boost a Bayesian optimization, with an ensemble method applied to the models selected in the previous step. AutoGluon [8] uses ensembling and multi-layer stacking techniques to combine multiple models (such as LightGBM boosted trees, CatBoost boosted trees, Random Forests, Extremely Randomized Trees, and k-Nearest Neighbors). In the context of neural networks, the main exponent is Auto-Keras [11], which applies Bayesian optimization in the search for the most efficient neural architecture (the so-called *Neural Architecture Search - NAS*). Another promising AutoML system is H2OAutoML [10], which, in place of Bayesian optimization, uses a combination of fast random search with ensemble staking techniques. Finally, a comparison of state-of-the-art approaches is provided in [21].

To the best of our knowledge, no study has been proposed for the application of AutoML systems to the EM task.

3 DESIGNING AUTOML FOR EM TASKS

AutoML systems could largely support the application of ML and DL approaches to EM tasks by selecting the best classification models for given datasets and providing the tuning of the parameters. Nevertheless, our experiments (partially reported in Section 5) showed that AutoML systems are not effective in this scenario.

To investigate the reasons for such behavior, we considered AutoML systems as black-box tools and we analyzed if there are peculiarities that make EM, conceived as ML task, a hard issue for these approaches. Firstly, we observed that the datasets used for representing EM tasks describe pairs of entities. The insight that an ML model can learn from them is mainly obtained by comparing the values assumed by pairs of attributes describing the same feature in different entities. Since an entity is described through several features, and pairs of attributes describing the same features have value distributions clearly close, selecting and tuning an ML model can be a complex task. Secondly, the classification problem is highly imbalanced, due to the very large number of unmatching entities with respect to the matching ones.

In this paper, we address the first issue by developing and experimenting with a component, the *EM adapter*, which provides an encoding of EM datasets that effectively supports the training of AutoML systems. We consider the second issue as future work that we intend to address designing data augmentation techniques for building a more balanced dataset to train the AutoML system.

The existing AutoML systems provide limited pre-processing and feature extraction capabilities. Our approach represents a first attempt towards the development of a new generation of AutoML systems able to operate in specific scenarios thanks to data transformation capabilities. The design of the *EM adapter* was based on a preliminary analysis of the main features implemented in the existing approaches. This allowed us to get insights into the design choices to adopt in the creation of the component.

The existing state-of-the-art approaches for solving EM tasks are typically based on neural architectures, and in particular on recurrent neural networks (RNNs), as DeepER and DeepMatcher. The RNN (e.g., a bi–directional recurring network made up of LSTM cells in DeepER) is trained to encode the pairs of entities, input of the network, into multi-dimensional vectors. The application of some similarity function to these vectors makes them a training dataset for a binary classifier. The systems based on these architectures are highly effective thus demonstrating their ability in managing the particular schemas adopted by datasets describing EM tasks.

Insight#1: RNNs are an effective means to represent in a single multi-dimensional vector the values of the attributes describing the same feature of pairs of entities.

Training models based on RNN requires large datasets, thus preventing their use in several business scenarios. To address this issue, approaches have been experimented RNNs trained on large “external" knowledge bases and applied to in-production systems via transfer learning techniques. Transfer learning has been successfully applied to several ML applications, and to tasks

related to the EM as in [25] where the problem was recognizing categories where entity features belong to.

Insight#2: External knowledge-bases can be effectively exploited in ML architectures addressing EM tasks to reduce the need for annotated data.

Transformers [23] have recently gained large popularity in the NLP field. They are deep neural networks that, once trained on a large corpus, are able to learn the semantics of words better than conventional word embedding techniques (e.g., Word2vec [15]). They have also been proved effective in EM tasks [2, 13]. In [13], for example, a fine-tuning process is applied to a pre-trained Bert transformer architecture. The dataset is completely denormalized and, in the resulting text fields, meta-tokens are inserted not to lose the semantics of the schema. In this way, the knowledge through which an ML algorithm learns to discriminate between pairs of matching/non-matching entities is no longer obtained by comparing the values assumed by pairs of attributes, but emerges from the analysis of the record as a whole. A broad experimentation of transformers approaches in the field of EM performed in [2] let emerge two main findings: 1) the transformers can be used for EM out of the box, without the need for a task-specific architecture, and 2) fine-tuning a transformer on an EM task takes relatively little time and requires no particularly capable hardware.

Insight#3: Transformers serialize in numerical vectors the fields of EM datasets describing pairs of entities by exploiting a highly-contextualized analysis of EM data. Their use in EM tasks is a good compromise between simplicity and performance, and their fine-tuning does not require high training times and expensive hardware.

4 IMPLEMENTING AUTOML FOR EM TASKS

The *EM adapter* is the component in charge of computing an encoding of a dataset representing EM to be effectively exploited by an AutoML system. Its functional architecture is based on the insights defined in Section 3 and consists of three main components: the *Tokenizer* which tokenizes the dataset records into one or more token sequences; the *Embedder* which transforms the token sequences into embeddings; and the *Combiner* which generates a single multi-dimensional vector from all embeddings associated the same dataset entry.

Tokenizer. This component transforms an entity pair $(e1, e2)$, described in the records of the EM dataset as a series of attributes $a_{11}, ..., a_{1M}, a_{21}, ..., a_{2M}$, where a_{ij} is the attribute j of the entity e_i, into one or more token sequences. The component defines how to combine the values of the records to obtain tokens that enable the automatic learning of deep relations between attributes describing the same features of different entities. There are three alternative ways for performing this operation: the unstructured, attribute-based, and hybrid tokenization mode. In the unstructured mode, all fields describing the entities are concatenated into a unique sentence and any reference to the dataset schema is lost. In the attribute-based mode, the dataset entry is tokenized at the attribute level and the values of the same attribute for the considered pair of entities are coupled. Through this kind of tokenization, the records in the EM datasets describing pairs of entities are broken down into multiple sub-pairs, one for each attribute. Finally, in the hybrid mode, partial and / or incremental concatenations of the attribute values are performed. A hybrid strategy can for example apply an attribute-level tokenization and then incrementally combine the sub-pairs so that the $i-th$ pair contains the values of the first i attributes, and the last one compares the entire original matching pair. The aforementioned hybrid technique and the attribute-based technique have been experimented in the paper.

Dataset	Type	Datasets	Size	% Match

Table 1: Magellan Benchmark

Regardless of the specific implementation, the result of this step consists of one or more token sequences for each entry of the original EM dataset.

Embedder. The goal of the *Embedder* is to encode a token sequence into a multi-dimensional vector, i.e., an embedding. The approach usually adopted in the literature starts from a pre-trained word embedding deep learning architecture which is experimented with some token sequences. The embeddings are generally then extracted from these architectures by averaging the last hidden layer for each token, but other techniques have been experimented (the concatenations of the last 4 hidden layers for each token in [6]). In the paper, we experimented five embedders: Bert, DistilBert (DBert), Albert, Roberta and XLNET.

The *Embedder* outputs an embedding for each input token sequence. Recall that, according to the tokenization strategy adopted, an entry in the dataset can generate from one to many embeddings.

Combiner. The embeddings generated from each entry in the EM dataset are summarized in a single multi-dimensional vector by the *Combiner*. The standard approach, experimented in the paper, for performing this task is to calculate an average embedding.

5 EXPERIMENTAL EVALUATION

This section aims to provide an experimental answer to three main questions: 1) How effective are standard AutoML systems in solving EM tasks (Section 5.1); 2) To which extent the performance of AutoML systems applied to the EM task benefit from data preprocessing techniques (Section 5.2); and 3) How much AutoML systems pipelined with the *EM adapters* outperform the current state-of-the-art EM models (Section 5.3).

Datasets. The experiments have been performed against the datasets provided by the Magellan library[2] which are considered as a standard benchmark for the evaluation of EM tasks. In Table 1 we summarize with some statistic measures the 12 datasets analyzed, reporting for each of them the total number of records representing matching entities (fourth column) and the percentage of records associated with a matching label (last column). Each dataset is divided into training, validation, and test sets which were created with 60-20-20 proportions. The code used in the experiments is available at *https://github.com/softlab-unimore/automl-for-em*.

Table 2: Effectiveness of AutoML systems in EM tasks.

5.1 AutoML systems solving EM tasks

The experiment shows the application of standards AutoML systems in solving EM tasks. We selected three well-known approaches, AutoSklearn, AutoGluon, and H2OAutoML. We evaluated their performance as binary classifiers against the chosen datasets. The AutoML systems have been experimented with their default configuration, no parameter tuning has been performed. Only the AutoSklearn system required the application of a data pre-processing step to transform categorical features (which are not managed by this system) into numerical values. We performed this operation via a standard Word2Vec embedding, where the average Word2Vec embedding for each token of non-numeric attributes has been computed and concatenated. The results of this experiment are shown in Table 2, reporting the F1 score and the training time of each AutoML system for each dataset. The last column in the Table shows the scores achieved by DeepMatcher, in the *Hybrid* configuration, which we consider as a baseline[3].

Discussion. The AutoML systems are not effective in solving EM tasks as DeepMatcher. They perform close to DeepMatcher (and with an average F1 score greater than 75%) in two datasets only (S-DA and S-FZ). Even if there are small variations among the performance achieved, there is no AutoML system that clearly outperforms the others: the average F1 scores along all the datasets are close, ranging from 48.66% for AutoGluon, to 51.4% for H2OAutoML, and 52.33% for AutoSklearn. Nevertheless, the time required for training the models was largely varying. H2OAutoML took 1 hour maximum to finalize the training in all the datasets; AutoSklearn limits the training time to one hour by default; the time required for training AutoGluon was larger, more than four hours for the S-DG and D-DG datasets. We performed a further experiment, limiting the training time of AutoGluon to 1 hour. The quality of the results largely decreased and the average F1 score across all datasets dropped to 42.4%.

Lesson Learned. AutoML systems are not competitive when addressing binary classification problems associated with EM tasks.

5.2 AutoML systems pipelined with EM adapters

In this section, we evaluate the effectiveness of AutoML systems coupled with an *EM adapter*. For this reason, we experimented several adapters, obtained by combining possible implementations for their constituting modules, the tokenizer, the embedder and the combiner, introduced in Section 4. In the following, we report the effectiveness measured in adapters implementing attribute-based and hybrid tokenizers, where the best results are obtained. For each kind of tokenizer, five standard transformer architectures, namely Bert, DistilBert (DBert), Albert, RoBERTa and XLNET have been evaluated[4]. For sake of simplicity, we only consider combiners generating the embeddings from the last hidden layer for each token and averaging it with the layers referring to the other tokens. Tables 3 shows the results of this evaluation for AutoSklearn, AutoGluon and H2OAutoML respectively. The scores of the *EM adapters* were grouped according to the tokenization technique (attribute-based vs hybrid). The F1 scores in bold represent the best result per dataset obtained for the category of tokenizer considered. The values in bold and underlined represent the results of the most effective *EM adapter* for the considered dataset.

Discussion. We observe that (1) the *EM adapters* implementing hybrid tokenizers typically obtain the best performance (only in 3/12 datasets, i.e. S-DA, S-WA and S-FZ, the results are worse); (2) the Albert embedder achieves the best results (i.e., *EM adapter* implementing an Albert embedder is the best solution for 7/12 datasets considering the AutoSklearn system and 8/12 considering AutoGluon and H2OAutoML). Finally, Table 4 reports an overall evaluation of the impact of an *EM adapter* as a preprocessing component for an AutoML system in solving EM tasks. For each dataset and AutoML system, the F1 scores obtained in the absence and presence of an *EM adapter* are reported. The "No EM-Adapter" column is the reference column showing the F1 scores obtained by AutoML systems with no *EM adapter*. The remaining columns show the average F1 score (through the 5 transformer architectures considered) obtained by the adapters implementing attribute-based and hybrid tokenizers. Finally, for each AutoML system, the delta column shows the difference between the F1 score obtained with no *EM adapter* and the average of the two versions including the *EM adapters*. The experiments show that adapters significantly improve the effectiveness of AutoML systems in solving EM tasks in almost all datasets (the datasets S-FZ for AutoSklearn and S-DA for AutoGluon show an anomaly result). The average F1 score increases of 24.96%, 28.02% and 23.6% for AutoSklearn, AutoGluon and H2OAutoML respectively.

Lesson Learned. *EM adapters* largely improve the effectiveness of AutoML systems in addressing EM tasks. The experiments were not able to show a clear winner among the approaches tested. This is a positive result since it means that the AutoML technology can benefit from the application of *EM adapters*.

5.3 EM adapters pipelined with AutoML systems vs ad hoc solutions

The aim of this experiment is to evaluate if an AutoML system pipelined with an *EM adapter* can obtain competitive results with respect to other state-of-the-art EM models. For this evaluation, we consider an AutoML system with an *EM adapter* consisting of a hybrid tokenizer and an Albert embedder, whose combination provided the best performances in the previous experiments.

[3]We used the implementation available at https://github.com/anhaidgroup/deepmatcher

[4]No fine-tuning technique was applied in the experiments.

Table 4: Impact of EM-Adapter on AutoML performance. Bold values indicate the best configuration for a specific AutoML system; underlined values the best results for the considered dataset.

This system was then compared with the *Hybrid* variant of DeepMatcher. Table 5 reports the results of this comparison. We performed two experiments, in the first we limited the training time of the AutoML systems to 1 hour. In the second experiment, we set that time to 6 hours. The offset between the average effectiveness of AutoML systems and DeepMatcher is shown for each configuration.

Discussion. AutoML systems limited to 1 hour of training show better effectiveness than DeepMatcher in 5/12 datasets (i.e. S-BR, S-IA, T-AB , D-IA and D-WA, with an average increase of F1 equal to 9%). In the remaining cases, they generate slightly lower results, with an average F1 difference of 3.2%. However, we notice that AutoSklearn used the entire training time budget, but AutoGluon and H2OAutoML took on average a training time of 0.61 h and 0.76 h respectively. Furthermore, DeepMatcher has been trained for less than 1 hour in only 4/12 datasets. If we consider a tolerance threshold of 2%, the EM-adapted AutoML systems are comparable or outperform DeepMatcher in 9/12 datasets. This trend is further confirmed when we limit the training time to 6 hours. The average F1 score increases of 12% in the 5 datasets where the AutoML systems obtain the best results. Assuming as before a 2% tolerance threshold in F1 scores, EM-adapted AutoML systems are comparable or outperform DeepMatcher in 11/12 datasets. Also in this case, only AutoSklearn used the entire time budget for training, while AutoGluon and H2OAutoML took an average of 3.68 hours and 3.24 hours respectively (compared to 2.92 hours of DeepMatcher).

Lesson Learned. AutoML systems pipelined with *EM adapters* perform as or greater than state-of-the-art EM tools.

	DeepMatcher (Hybrid)		EM-Adapted AutoMLs (1h time budget)				EM-Adapted AutoMLs (6h time budget)			
	F1	Time (h)	AutoSklearn	AutoGluon	H2OAutoML	Δ	AutoSklearn	AutoGluon	H2OAutoML	Δ

Table 5: Effectiveness of EM-Adapter with AutoML systems compared to DeepMatcher. Values in bold indicate the best configuration for a training time budget configuration.

6 CONCLUSION

The adoption of AutoML systems would make machine learning and deep learning based approaches for addressing EM tasks usable also for non-expert people. The direct application of AutoML systems to the EM problem is not possible. The reason is mainly due to the schema adopted by the datasets representing EM tasks whose records encode pairs of entities, and to the classification problem which is highly imbalanced. In this paper, we address the first problem, by introducing the *EM adapter* component which transforms the records of datasets representing entity pairs into a form which is effectively processable by AutoML systems. Our experiments show that this approach achieves a performance similar to the one of EM-task specific systems (but it does not require expert users to tune it). The future work will try to improve the performance (1) by introducing data augmentation techniques for creating more balanced training datasets for the AutoML systems; (2) by experimenting techniques for improving the embeddings (via "local embeddings" [3], generated taking into account the current dataset, and/or performing a fine-tune of the existing techniques).

ABSTRACT

Calculating correlation coefficients is one of the most used measures in data science. Although linear correlations are fast and easy to calculate, they lack robustness and effectiveness in the existence of non-linear associations. Rank-based coefficients such as Spearman's are more suitable. However, rank-based measures first require to sort the values and obtain the ranks, making their calculation super-linear. One of the use-cases that is affected by this is data enrichment for Machine Learning (ML) through feature extraction from large databases. Finding the most promising features from millions of candidates to increase the ML accuracy requires billions of correlation calculations. In this paper, we introduce an index structure that ensures rank-based correlation calculation in a linear time. Our solution accelerates the correlation calculation up to 500 times in the data enrichment setting.

1 INTRODUCTION

The correlation coefficient is one of the extensively used statistical measures in data science. Data scientists use the correlation coefficient to find dependencies in the data and identify possible causal relationships. In machine learning (ML) tasks, correlations can be used to evaluate the relevance of features. Correlating features expose redundancy. Thus, one can remove redundant features to avoid the curse of dimensionality. Also, a correlation between a feature and a target value can serve as a heuristic for the importance of a feature. This is exactly what filter-based feature selections are aiming for [4]: They leverage correlation to find informative and drop redundant features to achieve high accuracy in the following ML task.

Various correlation coefficients can be used to identify correlations between features in datasets. The most prominent one is the Pearson Correlation Coefficient (Pcc). Although calculating the Pcc is fairly simple and linear in the size of the compared datasets, there are several situations where a non-linear coefficient, such as the Spearman's correlation coefficient (Scc) is preferred.

Robustness. Linear correlations such as Pcc are very sensitive to outliers. As an example, Table 1 compares robustness of Pcc and Scc. Although there is no clear correlation between the two columns, the calculated Pcc identifies them as correlated, because of one outlier point (shown in red). A correlation of 1.0 is clearly misleading. Scc shows a more fitting correlation of only 0.1. This robustness makes Scc to be a better fit for noisy and dirty data such as webtables that are likely to contain outliers [7, 14].

Effectiveness. Linear correlations are not effective in capturing more complex dependencies. They are only able to find linear associations between two features. This can be useful in the case of feature selection for linear models such as linear regression. However, for complex ML models such as Random Forest or Neural Network that can train non-linear patterns, linear correlation-based feature selections can miss features with non-linear dependencies harming the achievable accuracy [23].

Table 1: Correlation in the existence of outlier.

Area (Million sq. miles)	*Calling Code*
0.29	56
0.3	90
3.8	1
0.5	51
600	9800
Pearson = 1.0	**Spearman's = 0.1**

The disadvantage of non-linear approaches, such as Scc and Kendall tau [13] is that they are rank-based and as such require a sortation of values, which poses a higher time complexity, i.e. $O(m \cdot \log(m))$ where m is the size of the variable, for calculation than their linear counterparts. The time complexity increases when we want to calculate non-linear correlation for categorical columns. The Rank-biserial correlation coefficient Rbc can be applied on one-hot encoded columns, so Rbc has a time complexity of $O(m^2)$ [7, 14]. This computation overhead negatively impacts the analysis pipeline when a large number of features have to be analyzed. For instance, to detect the redundant features, the correlation computation between each possible pair is required, which inherently leads to $O(N^2)$ correlation computations for N different features [23]. For datasets with several hundreds of potential features, the runtime overhead impedes live analysis and fast model building. For example in data enrichment [2, 17, 22, 24, 26], one aims to detect features that correlate to the given target feature from millions of extracted candidates. At this scale, runtime overhead for rank-based correlations becomes evidently a hurdle.

In this paper, we introduce a light-weight indexing structure to compute the non-linear correlation coefficient in a linear time for large-scale data enrichment tasks. It avoids the $O(m \cdot \log(m))$ sorting operation for numerical columns, benefiting the Scc calculation, and avoiding the $O(m^2)$ complexity of dealing with the one-hot encoding of categorical columns for Rbc. Our light-weight index also enables Cocoa (our system) to scale to the massive number of external tables. Furthermore, the nature of the correlation calculation also enables Cocoa to perform light-weight joins instead of full materialization of joins with candidate columns. In summary, we make three major contributions:

(1) We introduce a new index structure that enables us to compute the non-linear correlation coefficient in linear time and generalizes also for enrichment through partial joins where ranks are missing and have to be adapted.
(2) We propose algorithms that leverage our index structure to detect correlations between numerical and categorical columns to a target column in linear time.
(3) We introduce a correlation-based data enrichment solution that increases the accuracy of the ML model for a user-defined task compared to other enrichment solutions.

2 PROBLEM STATEMENT

Given an input dataset D with m rows, two explicitly selected columns q and t from D, so-called query and target columns respectively, and a corpus of external tables $T = \{T_1, ..., T_n\}$, the goal is to enrich D with the top-k_c columns from any table $T_i \in T$ that correlate with t. As we focus on regression tasks, t is a numerical column while features can be either numerical or categorical. The query column q is used to find the related tables, i.e., tables that are joinable with D on q. Ideally, q is an identity exposing column, such as name or ID. Without loss of generality, we thus assume q is selected explicitly by the user.

Depending on whether an extracted feature is numerical or categorical, one has to use Scc or Rbc, respectively. Equation 1 shows the formula of Scc where x_i and y_i are the i^{th} values in the first and second column respectively. Both columns are of size m. $R(x_i)$ represents the rank of value x_i. For instance, $R(8) = 2$ in list $[8, 11, 4, 9]$ because the value 8 is second in the sorted list $[4, 8, 9, 11]$. $\overline{R(x)}$ and $\overline{R(y)}$ represent the average of ranks in the first and the second column respectively.

$$\text{Scc} = \frac{\sum_{i=1}^{m}(R(x_i) - \overline{R(x)})(R(y_i) - \overline{R(y)})}{\sqrt{\sum_{i=1}^{m}(R(x_i) - \overline{R(x)})^2 (R(y_i) - \overline{R(y)})^2}} \quad (1)$$

The Scc calculation for numerical columns is in $O(m \cdot \log m)$ because one has to obtain the ranks through sortation.

To compute the correlation between categorical columns and t, the Rbc calculates the Scc between each one-hot feature of the categorical column and t [3, 9, 18]:

$$\text{Rbc} = \frac{M_1 - M_0}{std} \sqrt{\frac{n_1 n_0}{m^2}} \quad (2)$$

M_1 and M_0 represent the average target rank for 1s and 0s in a one-hot feature, n_0, n_1 are the number of ones and zeros in the one-hot feature, and std and m define the standard deviation of target ranks and the number of values in columns, respectively. In our case, m is the number of rows in the input dataset. The overall correlation is then the maximum Rbc between each one-hot feature and t Based on Equation 2, we can calculate the Rbc in $O(m)$ time complexity per one-hot feature. As a column can have up to m unique values, thus the overall complexity is $O(m^2)$.

If the join operation is implemented as a hash-based join, the join task has a time complexity of $O(m)$ per table. The follow-up correlation calculation per column has either a complexity of $O(m \cdot \log m)$ or $O(m^2)$ depending on whether the feature is numerical or categorical. In retrieval tasks with large databases, we can observe the runtime is dominated by the correlation calculation.

Problem We are thus looking for an index structure that allows us to calculate both Scc and Rbc in linear time. To be able to index data repositories in the scale of web tables, our index structure should be simple and light-weight.

3 COCOA SYSTEM

Figure 1 depicts the abstract view of the components designed in our system Cocoa. The main components are *Table Finder*, *Join Mapper*, and *Data Augmenter*. A user provides Cocoa with a dataset D and specifies its query column q and ML target column t. At last, it returns the top-k_c most correlating columns as the output of the system. Now, we describe each of these components.

Table Finder. This component uses q and the inverted index of the DataXformer system [1] to obtain top-k_t joinable tables.

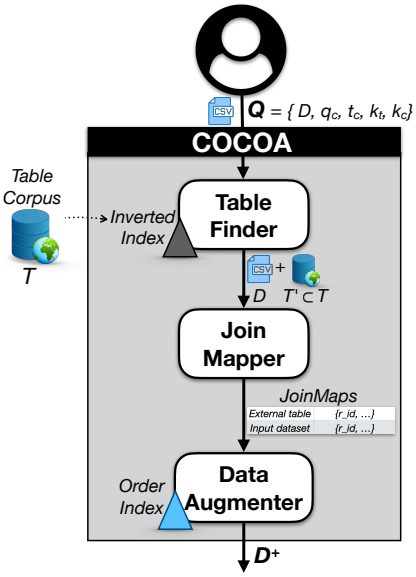

Figure 1: The overall architecture of Cocoa

A table is joinable if it contains at least one column that overlaps values with q. For each value v_i in external tables, the inverted index lists the coordinates of its containing tables: $v_i \mapsto \{(T_{i1}, C_{i1}, P_{i1}), (T_{i2}, C_{i2}, P_{i2}), ...\}$, where T_{ij}, C_{ij}, and P_{ij} are identifiers of tables, columns, and rows in the table corpus, respectively. We store the inverted indices inside a column store and generate a SQL query to find joinable external tables in parallel and using database-level optimizations. This approach allows to push the process of finding the joinable tables down to the database itself. The SQL query calculates the overlap between each external column and q and then selects the top-k_t tables by sorting them based on the overlap score.

Running example Figure 2(a) depicts a user-provided dataset D for the task of predicting the population of a country. The column with the country names will serve as the query column q and the population as the ML target column t. Figure 2(b) depicts an external table (T_1) that contains three columns: *Country*, *Area*, and *Calling Code*. In our example, the index entry for the values "Germany" in *Country* would be: $Germany \mapsto \{(T_1, Country, 5)\}$.

Join Mapper. The *Join Mapper* receives a set of joinable tables T' as input and *virtually* joins them with the input dataset D. To enrich the input dataset with external tables, we have to apply a LEFT JOIN because we need to keep information in D and add only overlapping information from the external tables [6]. Instead of a complete materialized LEFT JOIN, our *Join Mapper* generates a lightweight JoinMap, which is inspired by P.Valduriez's "Join Indices" [19]. Using our *Order index*, we can use the light-weight join to also calculate the correlations before materializing the join. Thus we limit the join materialization for relevant columns with high correlation and further speed up the process.

Figure 3 depicts the JoinMap for the example in Figure 2. *Country* column in T_1 is overlapping with q in D. The corresponding map shows which row in *Country* has the same respective value in q. As it is shown, the value "Switzerland" in row 2 of *Country* appears in row 3 of q. In the case of duplicates in q, respective cells in the JoinMap will contain more than one value.

Data Augmenter. This component receives the JoinMaps as input and uses a novel structure, called *Order index*, to efficiently compute the Scc and Rbc. It evaluates the external columns based on their correlation with t and enriches the input dataset D with the top-k_c correlating columns to generate the final dataset D^+.

Figure 3: An example of JoinMap

4 CORRELATION CALCULATION

The main goal of the *Data Augmenter* is to calculate the Scc and Rbc between each provided external column and the target column t in $O(m)$. Thus, we want to refrain from sorting the values of every potential numerical column and the generation of one-hot encodings for every categorical column during the extraction time. One might think of a simple solution that calculates the ranks and one-hot encodings offline and maintains them as part of the inverted index. However, maintaining the ranks will lead to calculation errors of the Scc when related tables are only partially joinable. Columns *Area (Rank)* and *Calling Code (Rank)* in Figure 2(c) show this error in obtaining the ranks after the partial join. Non-consecutive ranks lead to incorrect Scc. For instance, the correct Scc between *Calling Code* and t is -0.1, but using the incomplete ranks returns the Scc of $+0.117$. Furthermore, storing the one-hot encoding of all columns would unnecessarily blow up the index size. Therefore, we propose algorithms based on a new *Order index* that keeps track of the order of each value in the numerical columns and efficiently generates one-hot encodings for categorical columns.

4.1 Order Index Structure

We now introduce the simple, yet effective, *Order index* structure. Instead of the actual ranks, it stores the relative order of column values enabling the system to compute Scc and Rbc in a linear time. Keeping track of the order of values enables us to calculate the correct ranks on-demand despite partial joins. Also, keeping relative orders enables us to walk through all non-zero values in one-hot features in the right order to calculate the Rbc for categorical columns. To maintain the order information in a concise way, the *Order index* maps each pair of a table identifier T_{id} and a column identifier C_{id} to the column values as follows:

$$T_{id}, C_{id} \mapsto \{s,\ (o_1,\ ...,\ o_r),\ (b_1,\ ...,\ b_r)\} \tag{3}$$

$$s \leftarrow \alpha, \quad where \quad R(v_\alpha) = 1 \tag{4}$$

$$b_i = \begin{cases} False, & R(v_i) = R(v_{o_i}) \\ True, & R(v_i) \neq R(v_{o_i}) \end{cases} \tag{5}$$

Each entry in the *Order index* consists of the starting point s, which represents the row id of the minimum value in the column (α in Equation 4). v_i is the value located in the i^{th} row. The rank of the minimum value is always 1. In categorical columns, the minimum is the first value in the alphabetically sorted list. The second item (order list), contains a list of values where o_i is the row id of the next greater value than v_i. In case of having repetitive values, o_i is the row id of the next equal value. If v_i is the last value in the sorted list, $o_i = -1$. The item b_i denotes whether v_{o_i} is greater than its predecessor v_i or not (Equation 5). We use the same index for both numerical and categorical columns. To distinguish the numerical and categorical columns during the correlation calculation, we use a simple heuristic: a column is considered as categorical if it contains at least one non-numeric value. We store it as an additional bit per column. The *Order index* of the column *Area* in our running example in Figure 2(b) would be:

$\{2,\ (9,\ 5,\ 4,\ 6,\ 8,\ 7,\ -1,\ 1,\ 3), (T,\ T,\ T,\ T,\ T,\ T,\ \emptyset,\ T,\ T)\}$

In column *Area*, the minimum is located in row 2 (0.01), so, $s = 2$. The second element of the index represents a list of pointers to the next greater (or equal) values. The first item in this list o_1 points to row id 9 and it means that the next greater value "0.3" after the first value "0.29" is stored in the 9^{th} row. Likewise, the 9^{th} pointer o_9 in the order list is 3, which means that the next greater value "0.5" is located in row 3. Notice that as there are no repetitive values in column *Area*, all of the binary values in the third index element, except for the maximum value pointer, are *True*.

Figure 4 shows the visualized representation of the *Order index* for the column *Area* in T_1. Each square represents one value in the external column. The blue square represents the minimum value and the red one shows the maximum. Each edge that connects one square to another depicts the relative order o_i. Small numbers in the circles are the row ids of the values in the column *Area*. Each value has an outgoing edge except the maximum value. Labels on each edge represent the index values stored for the source value. For example, the outgoing edge from the 4^{th} item in the list, is $[6, T]$, which translates to $o_4 = 6$ and $b_4 = T$.

The *Order index* is the most basic index structure that supports correlation calculation in $O(m)$. A more complex B+ tree adaptation can be used if frequent corpus updates are expected. Here, we exclude the tree benefits for a more space-efficient index.

4.2 SCC for Numerical Columns

We use an example to describe how we leverage the underlying *Order index* to calculate the Scc between numerical columns of an external table and t. Figure 4 shows the *Order index* of the *Area* column and the JoinMap of the table T_1 from our running example. Assume that `p` is a pointer and in the beginning, `p` references the minimum value in the column. In each iteration, `p` traverses through the available links until it reaches the red square which means that the ranking process is finished.

Starting from the minimum value "0.01", the algorithm checks the `JoinMap` for any mapping from the value in *Area* to a value in q. There is a mapping from "0.01" to the value in the 3^{rd} row of

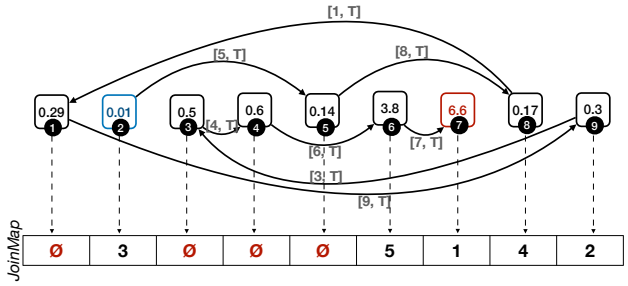

Figure 4: Visual representation of the Order index for the column *Area* from the running example in Figure 2.

q. Therefore, initial rank, which is 1, is assigned to the 3^{rd} value of *Area* (see *Area (Correct Rank)* in Figure 2(c)). Then, p will be updated to the next greater value. Here, "0.01" is linked to the 5^{th} value, which is "0.14". However, there is no map from "0.14" to any value in q. Thus, p will be updated based on the outgoing link from "0.14" to the next greater value located in the 8^{th} square with the value of "0.17". There is a mapping from the value "0.17" to the row with id 4, so the next rank, which currently is 2, will be assigned to the 4^{th} value in *Area*. This process continues until the pointer p reaches the 7^{th} and the maximum value. Since there are no outgoing links, the iteration is finished. The ranks for both *Area* and *Calling Code* columns are shown in the Figure 2(c) as *Area (Correct Rank)* and *Calling Code (Correct Rank)*, respectively.

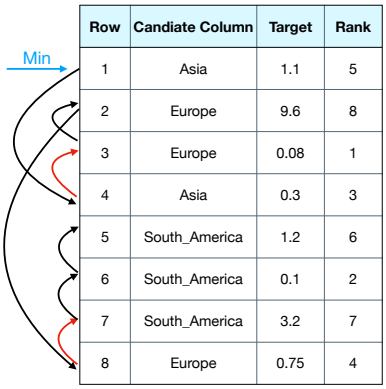
According to Equation 1, we can indeed compute the Scc in $O(m)$ by having correct ranks. Obtaining the ranks is now also possible in $O(m)$. The algorithm iterates over the values in the ordered list only once. Therefore, if the time complexity of the operations per value is constant and the path from the minimum to the maximum value is cycle-free, we conclude that the Scc calculation is done in $O(m)$. First, all operations of reading the *JoinMap*, assigning/updating current rank, and updating p to the next value are done in a constant time because the *JoinMap* and the *Order index* items are implemented using array structure and accessing the array cells is performed in a constant time using the available cell index. We also know that each o_i value, which is represented by an edge, refers to a unique row id even in the existence of repetitive values. Thus, the path from the minimum to the maximum value is cycle-free. The path length is r, i.e., the average number of rows in the external columns. External tables are often smaller than the input datasets ($r << m$), e.g., the average external table size is 10 for DWTC and 1540 for open data [26]. Thus, the complexity is typically bound by m.

4.3 RBC for Categorical Columns

To calculate the dependency between external categorical columns and t, we have to generate the one-hot features of the column and calculate the Rbc between each generated feature and the target rank column. Using our index we can avoid this and simulate the calculation in linear time. The *Order index* allows us to walk through the non-zero values in the one-hot features, one feature at a time. By iterating non-zero values of each one-hot feature consecutively we can compute the Rbc for all possible feature in one pass of reading the categorical column using the following derived Equation 6, which is obtained by replacing M_0 and n_0 in Equation 2 with $\frac{S-M_1 n_1}{n_0}$ and $m - m_1$ respectively:

$$\text{Rbc} = \frac{m \cdot s_1 - n_1 \cdot S}{std \cdot m \cdot \sqrt{n_1(m - n_1)}} \tag{6}$$

In Equation 6, S is the sum of all the ranks in the target column and s_1 the sum of the ranks where the corresponding one-hot value is one. Using Equation 6, variables m, S, and std are calculated once. To compute the Rbc between each one-hot feature and t, it is enough to compute s_1 and n_1 for each one-hot feature.



Row	Candiate Column	Target	Rank
1	Asia	1.1	5
2	Europe	9.6	8
3	Europe	0.08	1
4	Asia	0.3	3
5	South_America	1.2	6
6	South_America	0.1	2
7	South_America	3.2	7
8	Europe	0.75	4

Figure 5: Categorical candidate column example.

Cocoa uses the *Order index* to iterate over the sorted list of categorical values. It is able to compute s_1 and n_1 per one-hot feature without generating the features because the *Order index* allows to read the repetitions of the values consecutively. Once the iteration reaches a different value, b_i announces the end of the current one-hot feature. At this point, the Rbc is calculated based on Equation 6. In the end, the maximum Rbc will be reported.

Figure 5 shows an example for Rbc calculation. It depicts a categorical column "Candidate Column" and the target column "Target". We would like to compute the Rbc of all one-hot features in one pass of reading the values. The ranks of the target values are shown in the "Rank" column. The location of the minimum value is represented in blue and each link depicts the location of the next value. The red-colored links show that the next value is greater, i.e., different, than the current value. Obtaining the standard deviation of the "Rank" column and m, we only need to calculate s_1 and n_1 for each unique value.

Starting with the minimum value, as long as the followed arrow is not red, we continue reading rank values and adding them to s_1, increasing n_1 by 1 in each iteration. After reading the value in row number 1, s_1 and n_1 are equal to 5 and 1 respectively. Following the links gets us to the 4^{th} row. Reading the rank value, s_1 is increased to 5+3 = 8 and n_1 to 1+1 = 2. The next arrow is red and it means that the following value is different from the current one. Therefore, we calculate the correlation using Equation 6. Repeating this process, another correlation is calculated in row number 7. Reaching the last row, we compute the final correlation and report the maximum Rbc. Rbc calculation is done in $O(m)$ as the algorithm iterates over the ordered list only once.

5 EXPERIMENTS

We carried out a series of experiments to evaluate Cocoa with the following questions in mind: (i) What is the performance gain through *Order index* for calculating feature correlations on large corpora? (ii) How efficient is the light-weight virtual join? (iii) How scalable is Cocoa? Before we delve into the detail, we first describe the setup of our experimental evaluation.

5.1 Data and Experimental Setup

We tested our approach on top of several open databases. The Dresden webtable corpus (DWTC)[1] contains more than 145M tables and 870M unique columns. The Canada, US, and Uk Open Data corpus used in prior work [26] contains more than 745,000 columns and 14,000 tables. It is noteworthy that the Open Data

corpus only contains numerical data. We ran our experiments on a server with 28 CPU cores and 250GBs of main memory. We implemented our solution in *Python 3.7* and used Vertica *v9.1.1-0* [16] as the storage. Implementations and datasets are available in our GitHub repository[2]. All compared approaches use the same table retrieval module. They only differ with regard to the join, filtering, and correlation calculation steps.

Table 2 shows the datasets that we chose from different domains as query datasets. For the Open Data corpus, we use the benchmark query columns provided in the *Josie* paper [26].

Baselines. For these experiments, we compare Cocoa with three baselines and two combined versions of Cocoa:

(1) Sort-based enrichment (Sbe). Sbe calculates the Scc and Rbc without using the provided order index. It has to sort online and create one-hot encoding of categorical columns. The comparison with this baseline allows us to evaluate the efficiency of the *Order index* in the enrichment pipeline.

(2) TR. It is a rule-based method that skips joins with non-informative tables before any further calculation [15].

(3) TR+Cocoa. TR is a complementary approach to Cocoa. TR drops the non-informative tables before joining. Then, Cocoa extracts the correlating columns from the tables.

(4) RF. Here, we apply the random forest feature selection (RF) on top of the overlap-based enrichment method [26]. In this method, we join k_t related tables and RF picks the most informative features with respect to the ML task.

(5) Cocoa+RF. Here, Cocoa enriches the input data with the top 100 correlated columns and delivers to RF.

5.2 Results

We start with the DWTC experiments. Figure 6(a) shows the average runtime of Cocoa, Sbe, and TR applied on all query datasets. The average runtime is shown for varied k_t values. In this experiment, we drop the break-down based on k_c because it has only a negligible improvement on the runtime of Cocoa and no impact on the other approaches. The depicted runtime includes the time for joining tables and calculating the Scc/Rbc. In the case of TR, runtime represents joining and rule validation time. Note that the runtime is depicted in logarithmic scale.

Cocoa outperforms Sbe on all datasets and for all different k_t values and ultimately, we see better performance on average. Cocoa can be up to 520X faster than Sbe using the introduced *Order index*. Cocoa, on average, is slower than *TR*. *TR* applies a rule-based table filter before joining the tables. It computes the cardinality of the tables and decides whether the join is safe to skip or not. Rules in TR - unlike Cocoa- are applied per external table and not per columns. Therefore, the rule verification in TR is computationally less expensive. The coarse-granular filtering comes at the cost of effectiveness [6]. According to Figure 6(a), the runtime of all approaches increases with k_t because more external tables have to be processed for the Scc calculation.

[2]https://github.com/BigDaMa/COCOA

Figure 6(b) shows the runtime experiment on Open Data. Here, k_t has a lower impact compared to the DWTC corpus, because of the small number of tables. So, we consider all tables that have overlap with q as candidate join tables. As expected, similar to the DWTC, Cocoa is faster than Sbe due to the fast correlation calculation through our introduced index structure. However, TR is surprisingly slower than the other two systems. The reason is that in comparison to DWTC, the tables in the Open Data benchmark, are not sparse and yield higher overlap between queries and the tables. Therefore, the TR rule is passed and most of the tables are joint. In this case not only does TR not provide any additional runtime benefits but also it introduces cardinality calculation overhead with almost zero pruned external table.

Figure 6(c) compares Cocoa to three hybrid system on DTWC with $k_t = 1000$. We build these hybrid systems to evaluate the impact of the feature pre-filtering on the runtime of the systems and determine the fastest system combination that considers feature-target association for the ML task. The combination *TR*+Cocoa results in better performance than every other strategy. TR drops the non-informative tables and reduces the search space for Cocoa to find the correlating features in a faster way. This experiment shows that although *TR* does not perform well with regard to effectiveness [6], it can be a complementary heuristic for Cocoa to reduce the search space and enrich the input dataset much faster than any other solutions at hand.

RF is the slowest approach on all datasets except the *University* dataset. This is due to the tremendous number of features that are delivered to *RF*. Note that experiments that are not finished within 8 hours are underestimated with 8 hours in the runtime. RF fails to terminate for 4 datasets: *Cities*, *IMDB*, *Food*, and *NYC Airbnb*. Pruning the search space using Cocoa improves runtime for RF. Cocoa +RF only fails to finish on the *Food* dataset.

We notice that *TR*+Cocoa performs even better than TR on larger datasets, such as *Food*. The reason is that TR materializes all joins but Cocoa uses the light-weight virtual joins that are much faster because only the top-k_c columns are materialized.

Scalability. To better evaluate the scalability of Sbe- and Cocoa-based solutions with regard to the dataset size, we measure the average runtime for a single correlation calculation in both approaches. Figure 7 shows this experiment on the *City* dataset scaling the number of rows. The average calculation time increases much faster for Sbe than for Cocoa. On a dataset with $1M$ rows, the runtime difference between the two approaches for one correlation calculation is about 118 seconds. This difference is crucial in the scale of thousands of external tables. In our experiments, for the *City* dataset the number of correlation calculations easily exceeds 52, 000 calculations to enrich the dataset, thus this scalability issue will lead to serious runtime problems. In this case, Sbe would need 71 days to complete the task while Cocoa would require only 9.5 minutes. Notably, the variances in the graph are negligible and at most 0.0001 milliseconds.

Index Size. We only store the row ids and bits instead of actual values, therefore, indexing the DWTC corpus requires less than 12GB disk storage compared to almost 300GB database size.

6 RELATED WORK

Data enrichment It is referred to the line of research that expands an input dataset using external sources such as webtables [11, 22, 24], Open data [17, 26], or knowledge bases [5].

Most pieces of work from the database community focus on finding joinable tables. For this purpose, some heuristics, such as

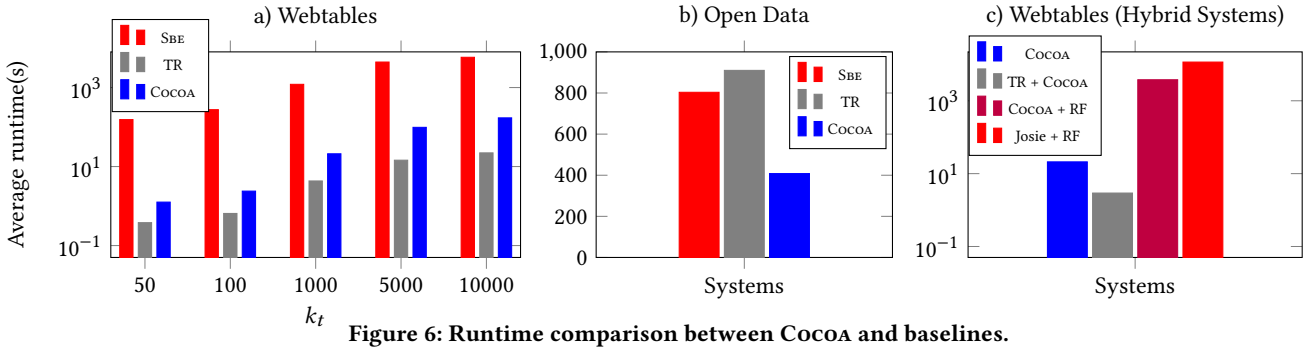

Figure 6: Runtime comparison between COCOA and baselines.

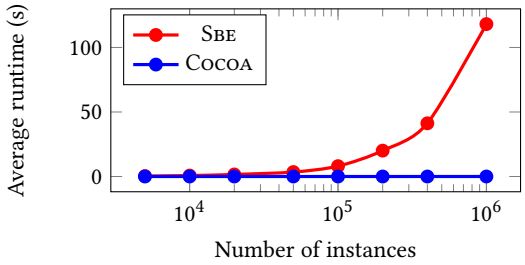

Figure 7: Scaling SCC and RBC on the *City* dataset.

overlap similarity [21, 25, 26] or a combination of the coverage and value consistency [8, 11] is used to find candidate tables for enrichment. These works do not consider the downstream ML task for the retrieval process and only rely on the joinability of the extracted tables. Furthermore, they assume that the external tables can fit in the main memory. Kumar et al. address the problem of data enrichment by defining a set of decision rules to prevent the joins that will not contribute to higher accuracy in the downstream ML models [15]. Their approach skips the joins to achieve the minimum information loss. Therefore, the dropping rate is quite low and in the scale of a large corpus of tables, the final enriched dataset will still contain a large number of columns, that have to be handled in the time-consuming feature selection process [23]. In COCOA, we propose an ML-aware data enrichment solution. It leverages the SCC/RBC to find the most promising columns for the downstream ML task. ARDA [6] is an enrichment system that leverages sampling techniques to find the informative joins and then uses an ensemble feature selection method to select the best features. Its feature selection algorithm RF focuses on accuracy and is not efficient when it comes to a large number of external tables.

Feature Selection Feature selection algorithms [6, 10, 12, 20] are designed to find the best feature set for a specific ML task after the enrichment process. In this paper, we aim to blend the feature selection with the extraction phase that can speed up the traditional *Extract-Then-Select* pipeline. We also discussed a combination of COCOA with the most promising feature selection method [6] in our experiments.

7 CONCLUSION

We presented COCOA, a new data enrichment system. It enables the efficient calculation of non-linear correlation coefficients to select the most correlating features for a user-defined ML task. In particular, we introduced an index structure that allows to calculate non-linear correlation coefficients in linear time complexity. COCOA is designed to be general and hence it can be complemented with other table-based filters or used for any analytic task that depends on value rankings and rank-based scores.

ABSTRACT

Clustering is a fundamental primitive for exploratory data analyses. Yet, finding valuable clustering results for previously unseen datasets is a pivotal challenge. Analysts as well as automated exploration methods often perform an exploratory clustering analysis, i.e., they repeatedly execute a clustering algorithm with varying parameters until valuable results can be found. k-center clustering algorithms, such as k-Means, are commonly used in such exploratory processes. However, in the worst case, each single execution of k-Means requires a super-polynomial runtime, making the overall exploratory process on voluminous datasets infeasible in a reasonable time frame. We propose a novel and efficient approach for approximating results of k-center clustering algorithms, thus supporting analysts in an ad-hoc exploratory process for valuable clustering results. Our evaluation on an Apache Spark cluster unveils that our approach significantly outperforms the regular execution of a k-center clustering algorithm by several orders of magnitude in runtime with a predefinable qualitative demand. Hence, our approach is a strong fit for clustering voluminous datasets in exploratory settings.

1 INTRODUCTION

Clustering is a fundamental primitive for exploratory tasks. Jain identified three main general purposes of clustering, which emphasize the exploratory power of clustering analyses [15]: (1) Assessing the structure of the data. Here, the goal is to exploit clustering to gain a better understanding of data, to generate hypotheses or to detect anomalies. (2) Grouping entities. Clustering aims to group similar entities into the same cluster. Thus, previously unseen entities can be assigned to a specific cluster. (3) Compressing data, i.e., to use clusters and their information as summary for further steps.

Due to their runtime behavior, k-center clustering algorithms, such as k-Means [16], k-Medians [6] or k-Mode [14] are commonly used [18], especially on voluminous data. However, the expected number of clusters k has to be provided prior to their execution. Particularly for previously unknown datasets, choosing this parameter is a tremendous pitfall and requires particular caution: Wrong values lead to bad results regarding the above-mentioned purposes, i.e., imprecise structurings, groupings or compressions are performed, thus making the clustering results unusable in the worst case.

In order to achieve valuable clustering results, k-center clustering algorithms are typically executed with varying values for k. This can be performed manually by analysts or in an automated manner by exploration methods, which perform an automated exploratory process in order to find valuable clustering results [9]. However, as these approaches require several complete runs of a clustering algorithm, they tend to be very time-consuming, in particular when the clustering algorithm is repeatedly executed on voluminous datasets [11].

Regarding k-Means as instantiation of a k-center clustering algorithm, the runtime for a single execution is $O(knd\omega)$ [13], where k is the number of clusters, n is the number of entities in a dataset, d is the number of dimensions, and ω is the number of clustering iterations performed. In the worst case, i.e., when performing k-Means until convergence, ω is super-polynomial regarding n [3], i.e., a single execution of the clustering algorithm on large datasets is already very time-consuming. However, for exploratory clustering analyses, where clustering results of several parameter values are of interest, analysts typically require fast, yet adequately accurate approaches that can be used to gain a fundamental understanding of the results. As we show in this paper, efficient exploratory clustering analyses are possible by controlling the number of clustering iterations in the exploration process for promising parameter values.

Many implementations, such as sklearn[1] or Spark's MLlib[2], allow to reduce the runtime of clustering algorithms by setting a fixed threshold for the number of clustering iterations. However, it is not clear how to set this threshold such that a valuable clustering result can be achieved, since this choice highly depends on dataset characteristics and the initialization of a clustering algorithm. Hence, too few clustering iterations lead to an imprecise clustering result, whereas too many clustering iterations lead to an unacceptable runtime. In this work, we introduce a novel approach to efficiently terminate k-center clustering algorithms as soon as a predefined qualitative demand is met, thus reducing the number of clustering iterations and therefore also the runtime.

Our contributions include the following:

- We propose our novel approach to terminate k-center clustering algorithms based on a predefined qualitative demand, which is typically defined by analysts.
- We show, that our approach (i) provides negligible runtime overhead for its calculations, and (ii) can be seamlessly integrated into exploratory clustering analyses.
- The results of our comprehensive evaluation on a distributed Spark cluster unveil that our approach outperforms a regular execution of a k-center clustering algorithm with speedups of several orders of magnitude, while the given qualitative demand is met in most cases.

The remainder of this paper is structured as follows: We present related work in Section 2. In Section 3, we analyze advantages and pitfalls of a closely related approach to reduce the number of clustering iterations. Subsequently, we present our novel generic qualitative approximation approach for k-center clustering algorithms in Section 4. In Section 5, we summarize the results of a comprehensive evaluation unveiling the benefits of our method. Finally, we conclude this work in Section 6.

2 RELATED WORK

All k-center clustering algorithms proceed in an iterative manner, i.e., the same sequence of steps is repeated until a given convergence criterion is met. Each clustering iteration comprises the following three steps: (1) initialize or change the position of the centroids, which are centers of gravity for a specific cluster, (2) improve the clustering by (re-)assigning entities to the closest centroid, and (3) check for convergence. Eventually, many clustering algorithms terminate when no entities change their membership anymore. As mentioned above, k-Means as concrete instantiation of such an algorithm has the runtime complexity of $O(knd\omega)$ [13]. Since clustering results for several values for k are at the core of exploratory processes, we focus on related work, which addresses the remaining influencing factors.

In order to reduce the number of entities n in a dataset, sampling or coresets [4] can be used to ultimately reduce the runtime of a clustering algorithm. Similar observations apply to (i) dimensionality reduction techniques, e.g., PCA or SVD, (ii) embeddings, or (iii) sketches, which all together aim to reduce the number of dimensions d of the dataset [1].

Regarding the number of clustering iterations ω, there are three categories of related work, which address the internals of a clustering iteration: (a) It has been shown that the initialization of k-center clustering algorithms is crucial to reduce the number of clustering iterations [5, 10]. The initial centroids of state-of-the-art initialization techniques are close to their optimum position, therefore requiring less clustering iterations until convergence. (b) Several works address how a single clustering iteration can be accelerated, i.e., by making distance calculations faster [7] or by caching previously calculated distances [12]. (c) Undoubtedly, reducing ω is crucial since it subsumes approaches from (a) and (b). Therefore, the "check for convergence" step is of paramount interest when reducing ω and thereby reducing the runtime of the clustering algorithm.

As each iteration comprises costly distance calculations, it is practically not feasible to perform a clustering algorithm on large datasets until convergence due to the excessive runtime. Hence, the question arises when to terminate the algorithm earlier than convergence. An easy approach to reduce the runtime of the clustering algorithm is to allow a fixed number of clustering iterations. However, it is challenging to choose a promising value for this threshold: Too few iterations lead to an imprecise result, whereas too many iterations lead to a high runtime. A generic threshold for all datasets is not feasible, because of too many influencing factors, such as the feature space or data distribution.

3 META-LEARNING TERMINATION (MTL)

In a previous work [8], we proposed a generic meta-learning approach to terminate k-center clustering algorithms early based on an arbitrary definable qualitative demand $q \in [0; 1]$. This approach relies on a correlation between the quality of intermediate clustering results throughout several clustering iterations and corresponding clustering validity measures (CVMs). To this end, the meta-learning procedure requires an offline phase, which gathers the necessary meta-knowledge, and an online phase, which applies the meta-knowledge on previously unseen datasets.

In the offline phase, a clustering algorithm is executed with varying parameter values on datasets with different characteristics. Throughout these executions, values of selected CVMs are recorded for each clustering iteration. The resulting values of these CVMs are often not normalized, i.e., the value ranges can be unbounded. In order to make these values tangible for analysts, we introduced the notion of quality $q \in [0; 1]$. That is, q indicates the quality of the intermediate clustering result after a certain clustering iteration in contrast to the quality of the last clustering iteration, which only becomes available after convergence. Hence, the clustering quality for each clustering iteration can only be investigated in retrospective after convergence. We proposed to create a correlation between the quality q and the CVMs, e.g., with a regression function that is trained during the offline phase based on several executions.

In the online phase, the analyst defines the expected qualitative demand q for the clustering result of a previously unseen dataset. Subsequently, the above-mentioned correlation is exploited to terminate the clustering algorithm earlier than convergence, while aiming to achieve the desired qualitative demand.

We showed that considerable runtime savings are possible, while regularly meeting the qualitative demand for several CVMs. However, we face two pitfalls regarding this method: (1) In order to exploit the correlation, it is first necessary to perform the offline phase. Since the offline phase comprises several executions of a k-center clustering algorithm, the high runtimes are solely moved from the online phase to the mandatory offline phase. (2) Creating a sound correlation between the quality and the corresponding CVM is an optimization problem. Influencing factors are for example datasets and their characteristics, the selected CVM, or chosen parameter values in the offline phase. Furthermore, formalizing the correlation itself, i.e., choosing a promising correlation method, poses another optimization problem.

To the best of our knowledge, this proposed approach is nonetheless currently the only one to limit the number of clustering iterations ω based on an arbitrarily predefinable qualitative demand. In the next section, we propose a novel method to reduce the number of clustering iterations based on a qualitative demand, which avoids the two mentioned pitfalls, yet still provides a tangible notion of quality for analysts.

4 GENERIC QUALITATIVE APPROXIMATION TERMINATION (GQA)

Before detailing on our new approach, we briefly summarize the basics of k-center clustering algorithms. Let $\mathcal{X}$ be a dataset with n entities and d dimensions, i.e., $\mathcal{X} \subset \mathbb{R}^d$. The goal of k-center clustering algorithms is to group $\mathcal{X}$ into k disjoint clusters, such that each entity is assigned to the closest centroid $c \in C$. As this problem is NP-hard [2], several heuristics exist, which aim to approximate the solution. One of these heuristics is the k-Means algorithm [16]. The goal of k-Means is to find the set C of k centroids which minimizes the objective function in Equation 1.

$$\phi_{\mathcal{X}}(C) = \sum_{x \in \mathcal{X}} \min_{c \in C} \|x - c\|^2 \tag{1}$$

Here, the Euclidean distance from an entity $x \in \mathcal{X}$ to the closest centroid $c \in C$ is calculated. $\phi_{\mathcal{X}}(C)$ denotes the sum of these distances over all entities in $\mathcal{X}$ and is also called sum of squared errors (SSE) for k-Means or variance for all k-center clustering algorithms. k-center algorithms minimize their notion of variance by moving these k centroids to a better position in each clustering iteration until a certain convergence criterion is met.

4.1 Intuition of our Approach

The goal of our approach is to exploit a tangible qualitative demand q in order to terminate the clustering algorithm as soon

as q is met. In contrast to MTL [8], we explicitly aim for no preparations, e.g., no prior meta-learning step.

Our novel approach GQA draws on two properties, which are valid independent of datasets and eventualities of k-center clustering algorithms, thus preserving generality.

Property 1: Monotonically decreasing variance. According to the objective function in Equation 1, the variance ϕ decreases throughout each clustering iteration, which is applicable for all k-center clustering algorithms. Manning et al. discuss this property for k-Means in detail [17], which can be transferred to other k-center clustering algorithms analogously.

Since ϕ is monotonically decreasing, we derive that the quality of the clustering is becoming better in each iteration (cf. Equation 1). Hence, we can formulate the gain in quality as changes of the variance between two subsequent iterations. To this end, we focus on the quotient σ_i of the variance between two subsequent clustering iterations $i-1$ and i, i.e., $\sigma_i = (\phi_{i-1}/\phi_i)$. Finally, k-center clustering algorithms converge as soon as $\phi_{i-1} = \phi_i$, hence $\sigma_i = 1$, i.e., the variance cannot be reduced any further. As σ_i typically becomes smaller per iteration and since we do not make any further assumptions on the dataset $\mathcal{X}$ and its variance in order to preserve generality, we can conclude that $\sigma_i \in [1; \infty]$.

Property 2: Notion of quality. Similarly to MTL, we also draw on a qualitative demand $q \in [0; 1]$ of the approximated clustering result, yet in a different way. That is, q can be specified by an analyst, where the choice of q has impact on the clustering result: If a very accurate clustering result is of interest, q should be set larger than for exploratory purposes, where already potentially moderate results may lead to valuable insights.

Yet, the question remains how to combine the qualitative demand $q \in [0; 1]$ of the approximated clustering result with $\sigma_i \in [1; \infty]$, while avoiding time-consuming preparations. Putting both above-mentioned properties together, we can formalize our approach as follows: During each clustering iteration, σ_i (and therefore ϕ_i) has to be calculated. Subsequently, terminate the k-center clustering algorithm as soon as Inequality 2 is satisfied.

$$1 - q \geq \sigma_i - 1 \tag{2}$$

Inequality 2 denotes that further clustering iterations would typically reduce $\sigma_i - 1$ less than $1 - q$. Note, that our approach preserves generality, since both properties are generally valid regarding dataset characteristics or k-center clustering algorithms.

4.2 Algorithm

Algorithm 1 outlines how GQA can be incorporated in the generic procedure of k-center clustering algorithms. The algorithm proceeds in four steps: (1) The centroids are initialized in line 1 according to a specific initialization, e.g., random, or k-Means‖ [5]. (2) The clustering is improved, i.e., the entities are assigned to the closest centroid (cf. lines 4-6). (3) The centroids are moved to the center of the cluster. To this end, the new position of the centroids $c \in C$ and the corresponding variance for each cluster are determined according to an objective function (cf. line 9). (4) Finally, the algorithm converges in line 16.

Changes in contrast to the regular procedure of k-center clustering algorithms are depicted underlined. As the variance for each single cluster is calculated in line 9, the overall variance for the current iteration ϕ_i is the sum of these individual values. Subsequently, σ_i is calculated in line 13, if a previous iteration was already performed. It is necessary to check this state, since our approach draws on the change of ϕ between two subsequent

Algorithm 1: k-center clustering algorithms with GQA.

Input: $\mathcal{X}$ - dataset, k - number of clusters, q - qualitative demand
Output: $\mathcal{K}$ - a combination ($\circ$) between $\mathcal{X}$ and the assigned centroid for each entity

```
/* initialize centroids                                          */
```
1 $C \leftarrow$ initialize a set of k centroids;
2 $i \leftarrow 0$;
3 **repeat**
```
    /* improve clustering                                        */
```
4 **for** $\forall x \in \mathcal{X}$ **do**
5 $\mathcal{K} \leftarrow \{x \circ c\}$, where c denotes the closest centroid to x according to an objective function;
6 **end**
7 $\phi_i(C) \leftarrow 0$;
```
    /* change centroids                                          */
```
8 **for** $\forall c \in C$ **do**
9 $c, \phi(c) \leftarrow$ new c and its corresponding variance according to an objective function, where $\{x \circ c\} \in \mathcal{K}$;
10 $\phi_i(C) \leftarrow \phi_i(C) + \phi(c)$;
11 **end**
12 **if** $i > 0$ **then**
13 $\sigma_i \leftarrow \phi_{i-1}(C)/\phi_i(C)$;
14 $\phi_{i-1}(C) \leftarrow \phi_i(C)$;
15 $i \leftarrow i + 1$;
16 **until** $i > 1$ *and* $1 - q \geq \sigma_i - 1$; `// check for convergence`
17 **return** $\mathcal{K}$;

iterations. After σ_i is calculated, ϕ is adjusted properly for the next iteration, i.e., ϕ of the previous iteration is set as ϕ of the current iteration. Finally, the convergence criterion is set according to Inequality 2 in line 16. Note however, that this convergence criterion can only be met after at least 2 clustering iterations are performed, since σ_i draws on the variance ϕ of two subsequent iterations. Hence, we introduce the additional check for $i > 1$ in the convergence criterion in line 16.

4.3 Analysis and Discussion

The goal of our approach is to keep additional calculations as cheap as possible. As already mentioned, the computations required by our approach are underlined in Algorithm 1. The computations rely on (a) allocations of variables (lines 7, 10, 13 and 14), (b) comparisons (lines 12 and 16), as well as (c) arithmetic operations (lines 10, 13, 16). Allocations and comparisons can be performed in $O(1)$. For the arithmetic operations, we reuse byproducts of the k-center clustering algorithm, such as ϕ_i. These values are used throughout several iterations with simple additions (line 10) or divisions (line 13). Therefore, the runtime complexity for the arithmetic operations is $O(1)$. Concluding, the overall runtime complexity of our approach is $O(1)$, thus preserving the runtime complexity of a k-center clustering algorithm without a significant runtime overhead.

In contrast to MTL, our novel approach GQA (i) can be used for ad-hoc exploratory clustering analyses, since it does not rely on a time-consuming meta-learning step, (ii) preserves generality regarding dataset characteristics, which may not be the case for MTL, since it obeys an optimization problem (cf. Section 3), and (iii) directly addresses the objective function of k-center clustering algorithms instead of additional CVMs as MTL does. As discussed above, addressing the objective function can be

Dataset	n	d	c

x	Heterogeneity activity recognition	33,741,500	5	6

Table 2: 10 real-world datasets as used in the work of MTL [8], where c denotes #classes, if available.

done very efficiently, whereas using an additional CVM in each clustering iteration may require noticeable runtime overhead [8].

Furthermore, it should be emphasized that GQA can be easily used by analysts and automated exploration methods due to its striking resemblance to the regular procedure of k-center clustering algorithms. Because solely q should be defined, the additional complexity of our novel approach is clearly manageable.

5 EVALUATION

In our evaluation, we investigate the benefits of our proposed approach for exploratory clustering analyses. To this end, we will compare our novel approach GQA with its closest competitor MTL [8] and a regular execution of a k-center clustering algorithm. We present the setup for our evaluation, before presenting the runtime and quality results.

5.1 Experimental Setup

Hardware and Software. We conducted all of our experiments on a distributed Apache Spark cluster. This cluster consists of one master node and six worker nodes. The master node has a 12-core CPU with 2.10 GHz each and 192 GB RAM. Each worker has a 12-core CPU with 2.10 GHz each and 160 GB RAM. Each node in this cluster operates on Ubuntu 18.04. We installed OpenJDK 8u191, Scala 2.11.12, Hadoop 3.2.0 as well as Spark 2.4.0.

Synthetic Datasets. We implemented a synthetic dataset generator in order to perform a systematic evaluation with controlled dataset characteristics. This tool generates datasets based on the following input parameters: The number of entities in the dataset (n), the number of dimensions (d) and the number of clusters in a dataset (c), where each cluster contains n/c entities. Our tool generates datasets with values that lie within the range $[-10; 10]$ for each dimension. Each cluster has a Gaussian distribution with the mean at the center and a standard deviation of 0.5. The c centers are randomly chosen and the clusters are non-overlapping. Table 1 depicts the characteristics of the 27 synthetic datasets.

Real-World Datasets. We use the same datasets as in our prior work for MTL [8], which are publicly available[3]. Table 2 summarizes the characteristics of these 10 datasets. Note, that not all of them have class labels, i.e., the number of classes is unknown for some datasets (indicated by "-" in Table 2).

Implementation. We base our implementation on Apache Spark. We focus on k-Means as instantiation of a k-center clustering algorithm due to its overwhelming popularity [18]. To this end, we implemented several methods to terminate k-Means.

[3] https://archive.ics.uci.edu/ml/datasets.php

The baseline (BASE) for this experiment is Spark's MLlib implementation of k-Means. This implementation uses k-Means‖ [5] for the initialization step and terminates after 20 clustering iterations at most. We explicitly remove the threshold for the number of clustering iterations, since we want to highlight the differences in quality when performing k-Means until convergence.

For MTL, it should be noted that this obeys an optimization problem regarding (i) the used datasets and their characteristics, and (ii) the choice of the used correlation technique. However, for synthetic datasets, we have closely followed the approach described in our previous work [8]. For the offline phase, we used datasets from Table 1 where $d = 50$. We clustered these datasets with k in 11 equidistant values in $[2; 2c]$ and let each clustering run until Spark's convergence criterion is met. We performed three runs per value of k. For each clustering iteration, we measured the SSE as well as the separation (SEP) between the centroids, since we achieved the best results with the SEP metric in our previous work [8]. Subsequently, we trained a second-degree polynomial regression between the change rate of SEP in contrast to the relative error of the SSE regarding the current clustering iteration and the final clustering iteration. The whole process took 11.17 hours and is thus not feasible for ad-hoc exploratory clustering analyses. Regarding the real-world datasets, we use the same ones as in [8], i.e., we also use the same regression function. The meta-learning process on those real-world datasets required several days, which emphasizes the impractical runtime for the offline phase of MTL. Furthermore, we implemented our novel GQA approach as described in Section 4.

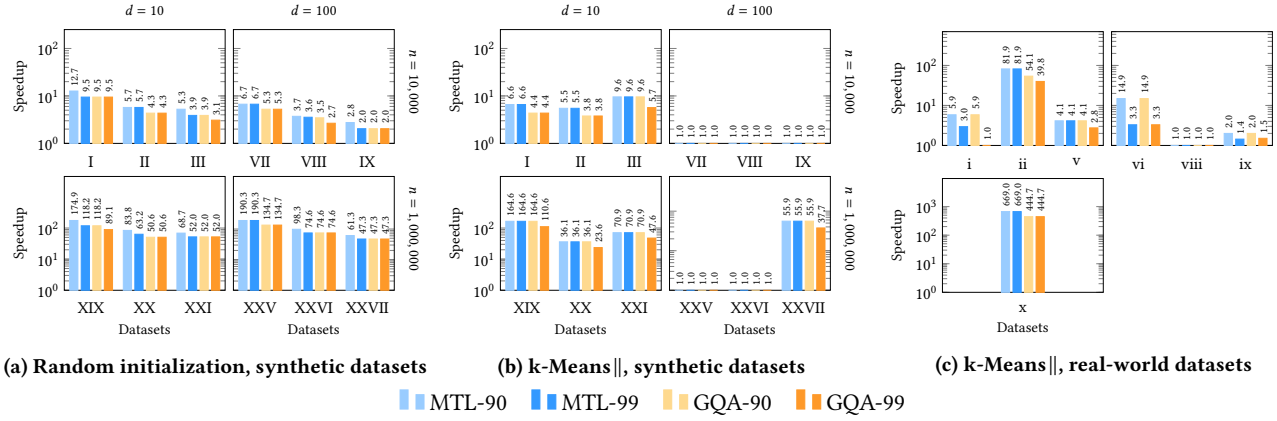
For MTL and GQA, we set the respective qualitative demands to 90 % and 99 % in order to achieve valuable results. Hence, we compare Spark's implementation (BASE) to MTL-90, MTL-99, GQA-90 and GQA-99 on synthetic and real-world datasets.

Furthermore, we use different initialization techniques in order to investigate the differences in the results. We run k-Means with $k = c$ for each dataset, where c is known. For each method, we performed three runs and present median values.

5.2 Runtime Results

Figure 1 summarizes the results regarding the speedups in contrast to the baseline, where Figure 1a focuses on the results with random initialization and Figure 1b addresses the results with the initialization via k-Means‖. While both of them show the results on synthetic datasets, Figure 1c unveils the results with k-Means‖ initialization on real-world datasets.

It can be seen that for random initialization, speedups can be achieved for all datasets in contrast to the initialization via k-Means‖. Since k-Means‖ initializes centroids closer to their optimum, less clustering iterations are necessary than for random



(a) Random initialization, synthetic datasets **(b) k-Means‖, synthetic datasets** **(c) k-Means‖, real-world datasets**

Figure 1: Speedup of MTL and GQA in contrast to BASE for all synthetic and real-world datasets where $k = c$.

initialization. Hence, MTL and GQA lead to remarkable speedups for random initialization of up to 190.3 (MTL) and 134.7 (GQA).

On the other hand, k-Means‖ provides an $O(log\ k)$-approximation to the final clustering result [5]. Therefore, some speedups of 1 are observed, i.e., BASE terminates k-Means as early as MTL and GQA. However, as shown in Figure 1b, MTL and GQA still provide strong speedups in many cases, such as for datasets XIX and XXVII. We observe speedups of roughly up to 164.6. When comparing dataset IX with dataset XXVII, it is evident that the latter has 100× more entities, where the remaining dataset characteristics, such as d and c, remain unchanged. As k-Means‖ does not select promising initial centroids for dataset XXVII, several clustering iterations are necessary for BASE. Yet, MTL and GQA terminate k-Means earlier than convergence, thus achieving significant speedups. More generally speaking, k-Means‖ can only select promising initial centroids, if the underlying dataset characteristics and number of clusters are a strong fit for its procedure.

Regarding the results of the real-world data (cf. Figure 1c), we make very similar observations. Here, even more significant speedups of up to 669.0 (MTL) and 444.7 (GQA) can be observed for the largest real-world dataset x.

In general, MTL and GQA achieve similar speedups, however MTL is faster in some cases. Note, that MTL addresses the SEP, whereas GQA addresses the variance (= SSE for k-Means) in order to approximate clustering results. Since the SEP typically changes more significantly in the first few iterations than the SSE, we argue that GQA requires a few additional clustering iterations.

Regarding the different qualitative demands, we observe only small deviations in the resulting speedups. These differences mostly occurred on real-world datasets (cf. Figure 1c). Here, the higher qualitative demand of 99 % requires more iterations and therefore leads to lower speedups.

We conclude that both approaches are well-suited for rather voluminous datasets, since k-center clustering algorithms require more clustering iterations on these datasets until convergence, which is explicitly addressed by MTL and GQA.

5.3 Quality Results

Since MTL and GQA are able to speedup the execution of a clustering algorithm significantly, the question remains how these approximations affect the clustering quality.

As clustering aims to provide compact and well-separated clusters, we focus on the compactness and the separation (SEP) of the centroids. We use the sum of squared errors (SSE) as instantiation of the compactness, since the smaller the SSE for k-Means, the less variance in the clusters, i.e., the more compact are the clusters. For a better comparison, we focus on the relative error δ of SSE and SEP of the clustering results of MTL and GQA in contrast to the baseline, i.e., the smaller the better.

Figure 2 summarizes the results for MTL and GQA. Note the different y-axes throughout the figures. The results unveil that the qualitative demands of 90 % and 99 % are mostly met in average for MTL and GQA. It should be noted, that the qualitative demand of GQA addresses the SSE (left), whereas the qualitative demand of MTL addresses the SEP (right). A more detailed investigation of the results unveiled that for all synthetic datasets, the respective qualitative demands are always met. Regarding the real-world datasets, MTL and GQA rarely terminated the clustering algorithm too early, thus omitting better clustering results. This happened for both approaches only once for a qualitative demand of 90 % and twice for a qualitative demand of 99 %. This observation supports the practical feasibility of our novel approach GQA, i.e., addressing the decreasing trend of σ_i leads to satisfying clustering results in practice.

The quality of the clustering results achieved by MTL and GQA differ only marginally from the baseline, i.e., the regular execution of k-Means. Furthermore, the initialization via k-Means‖ leads to more compact and better separated clustering results than initializing at random, since the values for δSSE and δSEP are mostly smaller (cf. Figure 2a and b). Hence, this initialization is better suited for exploratory clustering analysis, since it allows more correct insights into clustering results.

Moreover, the results achieved by GQA are always better than the corresponding pendant of MTL in terms of δSSE and δSEP. The reason can be found in the additional clustering iterations that GQA performed in contrast to MTL (cf. Section 5.2).

Concluding, MTL and GQA perform similar in terms of runtime, yet GQA does not rely on a previously conducted offline phase for meta-learning. Remember, that MTL required several executions of a k-center clustering algorithm on several datasets, which required more than 11 hours for synthetic datasets and several days for real-world datasets in our scenario. In addition, MTL and GQA lead to compact and well-separated clustering results. However, GQA achieves better clustering results, because

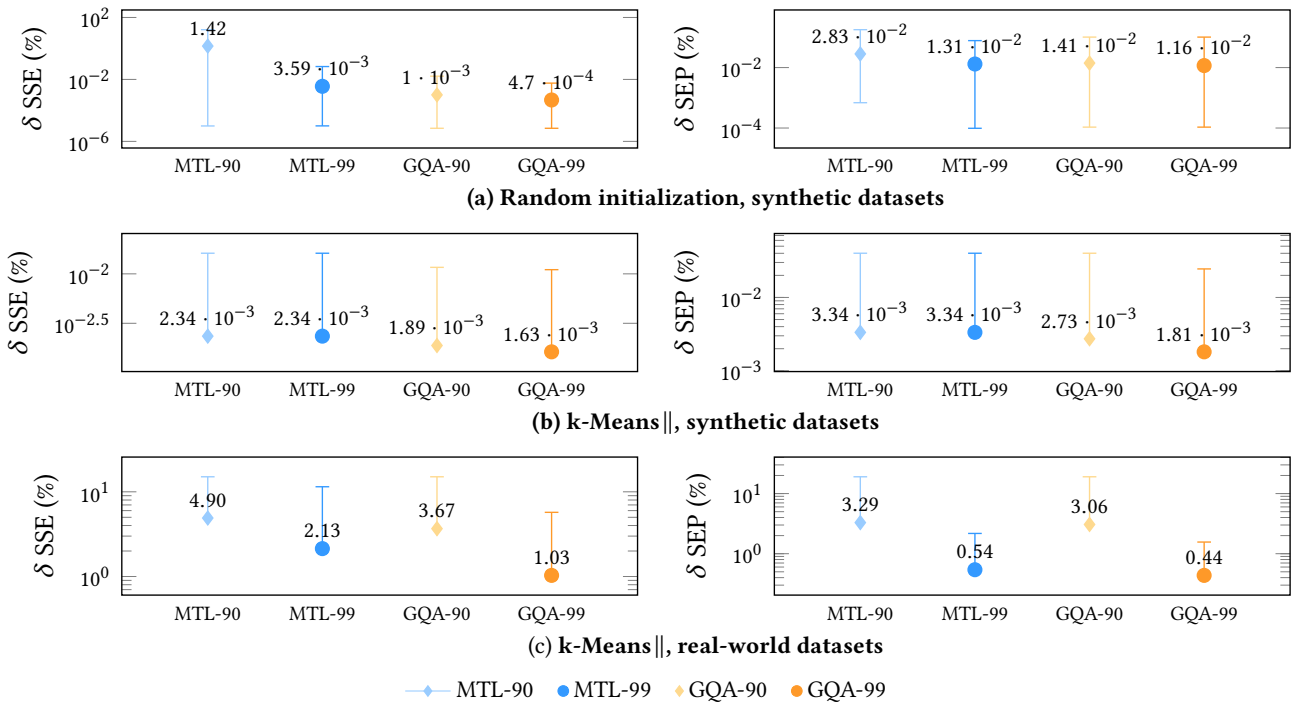


Figure 2: Relative error δ of SSE and SEP compared to the baseline. Average values are depicted per error bar. Smaller values indicate more similar clustering results w.r.t. the baseline, i.e., they show better clustering results.

it typically requires a few more clustering iterations than MTL. Therefore, our novel approach GQA is well-suited for ad-hoc exploratory clustering analyses, especially on voluminous datasets, since it provides very accurate results in a short time period.

6 CONCLUSION

In this work, we proposed a novel approach to terminate k-center clustering algorithms as soon as a predefined qualitative demand of the clustering results is met. Our approach aims to trade off quality of clustering results, while achieving them in a short time frame. We showed that our approach is generic, i.e., it can be used with several k-center clustering algorithms and initialization strategies. In our comprehensive evaluation, we unveiled that our approach significantly outperforms state-of-the-art executions of k-center clustering algorithms in terms of runtime, yet achieves very similar clustering results. Therefore, it is of particular interest for exploratory clustering analyses. Future work will address to what extent automated exploration methods benefit from our novel approach.

ABSTRACT

Data analysis is a highly iterative process. In order to achieve valuable analysis results, analysts typically execute many configurations, i.e., algorithms and their hyperparameter settings, based on their domain knowledge. While experienced analysts may be able to define small search spaces for promising configurations, especially novice analysts define large search spaces due to their lack of domain knowledge. In the worst case, they perform an exhaustive search throughout the whole search space, resulting in infeasible runtimes. Recent advances in the research area of AutoML address this challenge by supporting novice analysts in the combined algorithm selection and hyperparameter optimization (CASH) problem for supervised learning tasks. However, no such systems exist for unsupervised learning tasks, such as the prevalent task of clustering analysis. In this work, we present our novel AutoML4Clust approach, which efficiently supports novice analysts regarding CASH for clustering analyses. To the best of our knowledge, this is the first thoroughly elaborated approach in this area. Our comprehensive evaluation unveils that AutoML4Clust significantly outperforms several existing approaches, as it achieves considerable speedups for the CASH problem, while still achieving very valuable clustering results.

1 INTRODUCTION

Data analysis is a crucial discipline to extract knowledge and insights from data. Therefore, analysts apply data mining techniques, typically machine learning algorithms, to extract patterns from data and to gain insights about data. A fundamental primitive in data mining is clustering analysis, which is an unsupervised machine learning task being used in various application domains, e.g., computer vision, document clustering, for business purposes, or to study genome data in biology [11].

Throughout these manifold fields of application domains, analysts typically struggle with the selection of a promising clustering configuration, i.e., a clustering algorithm and its corresponding hyperparameter settings, that achieves valuable clustering results. Hence, analysts typically define a configuration space, i.e., a search space of clustering algorithms and their hyperparameter settings, in which they expect promising configurations. Yet, novice analysts lack in-depth domain knowledge and hence define very large configuration spaces. In the worst case, novice analysts cannot limit configuration spaces at all and perform an exhaustive search throughout all possible configurations. Since this exhaustive search is very time-consuming, novice analysts often explore only a few configurations, e.g., randomly selected, from the configuration space, which often leads to solely moderate results. Hence, novice analysts require support to achieve valuable clustering results in a reasonable amount of time.

For supervised learning tasks, recent advances in the research area of AutoML are able to support novice analysts in the combined algorithm selection and hyperparameter optimization (CASH) problem in an automated and efficient manner [5, 18]. These approaches greedily explore large configuration spaces by trading off exploration and exploitation strategies, thus avoiding a time-consuming or even infeasible exhaustive search.

In this work, we propose AutoML4Clust, an efficient AutoML approach to support novice analysts in the CASH problem for clustering analyses. To the best of our knowledge, this is the first thoroughly elaborated AutoML approach for efficient clustering analyses, capable of automatically selecting promising clustering algorithms and their hyperparameters in combination.

Our contributions include the following:

- We introduce AutoML4Clust, our novel approach to efficiently support novice analysts in the prevalent CASH problem for clustering analyses.
- We reveal that AutoML4Clust is generic, i.e., it can be instantiated with different AutoML concepts, clustering algorithms and clustering metrics.
- In our evaluation, we unveil that AutoML4Clust significantly outperforms several existing approaches, as it achieves speedups of up to 437x for the CASH problem, while still achieving valuable clustering results. Hence, AutoML4Clust efficiently supports novice analysts in the CASH problem for clustering analyses.

The remainder of this paper is structured as follows: We present related work in this area in Section 2. In Section 3, we present AutoML4Clust, our novel AutoML approach for clustering analyses. In Section 4, we unveil the results of our evaluation. Finally, we conclude this work in Section 5.

2 RELATED WORK

Based on the generally accepted separation of machine learning tasks, we separate related work into support for the CASH problem regarding supervised and unsupervised learning tasks. We distinguish two important groups of related work to support analysts regarding the CASH problem: (1) AutoML systems for supervised learning, and (2) methods for unsupervised clustering analyses that either explore the algorithm selection or the hyperparameter optimization.

We define a configuration c as the combination of an algorithm $a \in \mathcal{A}$ and its hyperparameters $h \in \mathcal{H}$. Hence, we define the configuration space as $\mathcal{CS} = \mathcal{A} \times \mathcal{H}$. In the following, we investigate related work based on the machine learning task and its ability to explore $\mathcal{CS}$.

2.1 AutoML Systems for Supervised Learning

AutoML systems arose in the area of supervised machine learning to support novice analysts in the combined algorithm selection and hyperparameter optimization problem [5, 18]. As class labels are already available in the datasets, $\mathcal{CS} = \mathcal{A} \times \mathcal{H}$ can be explored automatically. The common underlying procedure of existing

AutoML systems is as follows: Given a budget, training data and an optimization metric, they execute and evaluate different configurations from $\mathcal{CS}$, i.e., they execute classification algorithms with the specified hyperparameter settings, and return the configuration that yields the best value for the optimization metric. In order to steer the exploration towards valuable results, several hyperparameter optimization techniques are proposed, such as Bayes [1], Hyperband [13], or BOHB [3]. These optimization techniques proceed in a greedy manner, since they define a specific trade-off between exploration, i.e., exploring new regions in the $\mathcal{CS}$, and exploitation, i.e., exploiting regions in the $\mathcal{CS}$, where already executed configurations performed well.

2.2 Algorithm Selection and Hyperparameter Optimization for Clustering Analyses

Related work that supports novice analysts regarding CASH for clustering analyses can be divided into methods that consider algorithm selection and methods that consider hyperparameter optimization.

Algorithm Selection. For unsupervised learning tasks, several approaches were developed to support novice analysts with the selection of a promising clustering algorithm, i.e., $\mathcal{CS} = \mathcal{A}$ for certain problems [4, 16]. These methods are based on meta-learning, i.e., they learn from past experiences in order to select the most promising algorithm on a previously unseen dataset.

Existing approaches differ in the used (a) implementation of the meta-learning steps, (b) clustering algorithms, and (c) metrics for evaluating the clustering results. However, these approaches solely focus on the clustering algorithm, yet completely ignore the corresponding hyperparameters $\mathcal{H}$.

Hyperparameter Optimization. Regarding the hyperparameter optimization, i.e., $\mathcal{CS} = \mathcal{H}$ of clustering algorithms, two types of approaches exist [7]: While exhaustive methods execute all configurations from $\mathcal{CS}$, non-exhaustive methods only execute some configurations. However, non-exhaustive methods are designed to optimize the hyperparameters of specific algorithms, e.g., k-Means. Exhaustive methods could also be applied for $\mathcal{CS} = \mathcal{A} \times \mathcal{H}$, though this results in tremendous runtime as the whole configuration space has to be explored.

Summary. Summarizing related work, existing AutoML systems only focus on supervised learning algorithms, yet can explore valuable results, where $\mathcal{CS} = \mathcal{A} \times \mathcal{H}$. For clustering analyses, there are approaches that either conduct an exploration for valuable clustering algorithms ($\mathcal{CS} = \mathcal{A}$) or their hyperparameters ($\mathcal{CS} = \mathcal{H}$). However, they do not address the combination of both, i.e., the CASH problem for clustering analyses, where $\mathcal{CS} = \mathcal{A} \times \mathcal{H}$, which is a crucial problem for novice analysts. We identified only some experimental implementations[1] [2] that address this problem, however they use (a) one specific optimization technique, or (b) one specific clustering metric, without explaining, evaluating or justifying their choice regarding (a) and (b). In addition, they miss a clear scientific elaboration and a systematic evaluation in comparison to existing approaches in this area.

3 AUTOML4CLUST

In this section, we introduce our generic AutoML4Clust approach to support novice analysts regarding the CASH problem for clustering analyses, where we apply concepts from existing supervised AutoML systems on clustering. Existing AutoML systems solely focus on supervised learning tasks, whereas we focus on clustering analysis, which is an unsupervised learning task. The key difference between supervised and unsupervised learning tasks is that the input datasets for unsupervised learning tasks do not contain ground-truth labels. Therefore, it is not possible to evaluate the result based on an external metric. Consequently, existing AutoML systems and their components cannot be applied per se for clustering analyses.

Figure 1 presents the procedure of our AutoML4Clust approach. Similar to supervised AutoML systems, it draws on a configuration space $\mathcal{CS}$, which defines the set of configurations that can be selected, executed and evaluated during the optimizer loop, which is at the core of existing hyperparameter optimization techniques. To this end, we rely on the configuration space $\mathcal{CS} = \mathcal{A} \times \mathcal{H}$. When considering different families of clustering algorithms, e.g., k-center and density-based ones, $\mathcal{CS}$ has to be defined in a hierarchical way, i.e., by defining the algorithm as conditional root-level hyperparameter [18]. Our AutoML4Clust procedure is structured into three parts (cf. Figure 1): The inputs, the optimizer loop, and return best configuration. In the following, we present these three parts in detail and subsequently discuss the benefits of AutoML4Clust.

3.1 Inputs

AutoML4Clust requires three inputs prior to execution. These are a dataset $\mathcal{D}$, an internal metric $\mathcal{M}$, and a budget l. Here, $\mathcal{D}$ does not contain any additional information, e.g., class labels. Hence, $\mathcal{M}$ is an internal metric that evaluates the internal structure of a clustering result. In the literature, many different internal metrics with different objectives are proposed [11, 14]. Most of them measure the compactness and the separation of clusters in different variations. Subsequently, they consider a quotient of both. The budget l defines the resources that can be used by the system. A common choice for the budget is a time constraint to limit the runtime or the number of configurations to execute. In this work, we use the number of optimizer loops that are performed as budget. However, we note that choosing an appropriate kind of budget and also an appropriate value for the budget is a difficult task. A too large value may lead to a long runtime, whereas a too small one can lead to solely moderate results.

3.2 Optimizer Loop

In the optimizer loop, an optimizer such as Random [1], Bayes [18], Hyperband [13], or BOHB [3] is used to find well-performing configurations efficiently. Here, the optimizer performs l loops, where each loop consists of three steps:

i) *Selection:* $c \in \mathcal{CS}$, where the optimizer selects a configuration c from the configuration space $\mathcal{CS}$. The different aforementioned optimizers mostly differ in their greedy procedure, i.e., trading off exploration and exploitation, in order to select a configuration $c \in CS$ in each optimizer loop l_i. Yet, all optimizers require the definition of a black-box function $f : \mathcal{CS} \rightarrow \mathbb{R}$, which is subject to optimization. This function f assigns each configuration $c \in \mathcal{CS}$ a metric value and is implemented with the following steps ii) and iii).

ii) *Execution:* $\mathcal{R} \leftarrow c(\mathcal{D})$. Here, the previously selected configuration c is executed on $\mathcal{D}$. The result of the execution is $\mathcal{R}$, which can be any kind of clustering result, e.g., the resulting labels or the final centroids.

[1] https://git.io/JUNKu [2] https://git.io/JUNKz

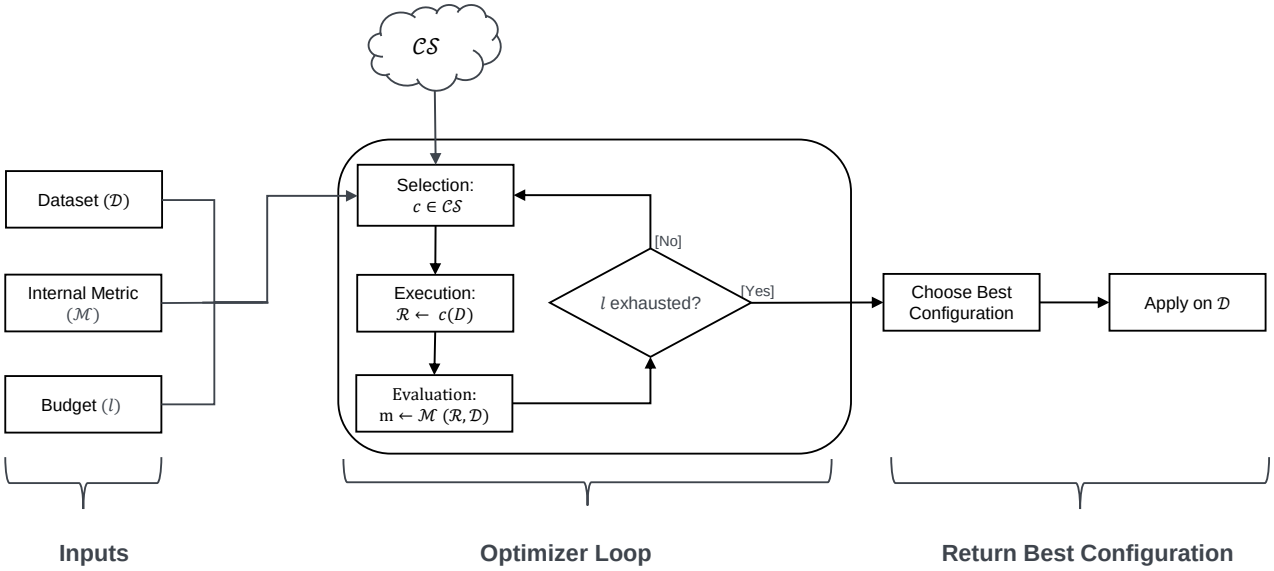

Figure 1: Procedure of AutoML4Clust.

iii) *Evaluation:* $m \leftarrow \mathcal{M}(\mathcal{R}, \mathcal{D})$, where the clustering result is evaluated. This means that the metric $\mathcal{M}$ is calculated based on the clustering result $\mathcal{R}$ and on the dataset $\mathcal{D}$.

3.3 Return Best Configuration

In the third step, the best configuration from all considered configurations is chosen. This is the configuration that achieves the best metric value regarding $\mathcal{M}$ from all configurations that are selected, executed and evaluated during each optimizer loop. This configuration is applied on the dataset $\mathcal{D}$ to finally obtain the best clustering result that is found by AutoML4Clust.

3.4 Discussion

Existing AutoML systems solely focus on supervised learning tasks in order to achieve valuable results, where $\mathcal{CS} = \mathcal{A} \times \mathcal{H}$, i.e., $\mathcal{CS}$ is typically very large. In contrast, AutoML4Clust addresses this problem for the prevalent unsupervised task of clustering analyses, where ground-truth labels are missing. Therefore, especially novice analysts are supported, which can neither limit $\mathcal{A}$ nor $\mathcal{H}$ to a manageable size and thus perform in the worst case an exhaustive exploration throughout $\mathcal{CS}$. Our proposed procedure draws on the latest fundamental concepts of existing AutoML systems, yet remains generic regarding the used clustering algorithms, metrics, and optimizers.

Regarding possible clustering algorithms, AutoML4Clust can use any kind of clustering algorithm by defining $\mathcal{CS}$ in a hierarchical way, similar to existing AutoML systems for supervised learning tasks. Regarding the metrics, AutoML4Clust draws on an internal metrics to asses the internal structure of a clustering result. Furthermore, several optimizers can be used, which follow the three steps (1) select a configuration, (2) execute the configuration, and (3) evaluate the result of the configuration.

Especially the combination of an internal metric and the used optimizer is of paramount importance: Since optimizers proceed in a greedy manner by defining a trade-off between exploration and exploitation throughout $\mathcal{CS}$, it is per se not clear which internal metric supports their behavior best. Yet, as prior work in the area of supervised learning has shown, these optimizers are able to efficiently explore large configuration spaces, while still achieving valuable results [3, 5, 18]. Therefore, we assume that AutoML4Clust similarly benefits from these optimizers. That is, we argue that AutoML4Clust is able to efficiently achieve valuable results within a predefined budget l. However, it is a very challenging task for novice analysts to specify such a suitable budget, since a too small budget leads to imprecise results, whereas a too large budget leads to long runtimes. Furthermore, it is not clear at all, if the used metric supports the greedy behavior of the optimizers within a reasonable budget.

4 EVALUATION

Since analysts are interested in fast and valuable results, the question remains how well different instantiations of our approach, i.e., combinations of optimizers and metrics, perform in order to achieve this goal. To this end, we compare in our evaluation how our novel AutoML4Clust approach performs (i) with different instantiations of optimizers and metrics for clustering analyses, and (ii) in contrast to existing approaches in this area. We first discuss the setup of our evaluation, before we investigate the accuracy of the results of different instantiations of AutoML4Clust in contrast to existing approaches. Subsequently, we analyze the runtime of AutoML4Clust in contrast to existing approaches. Finally, we show the practical feasibility of AutoML4Clust on real-world datasets regarding accuracy and runtime.

4.1 Setup

In the following, we describe the setup of our experiments. We focus on (i) the used hard- and software, (ii) the synthetic and real-world datasets that we use, (iii) the implementation details, and (iv) the performed experiment with its baselines.

Dataset	n	d	k_{act}
Statlog (Landsat Satellite)	6,435	35	7
ISOLET	7,797	617	26
Motion Capture Hand Postures	7,805	34	5
Avila	10,430	10	12
Pen-Based Recognition of Handwritten Digits	10,992	16	10

Table 1: Real-world datasets with their corresponding dataset characteristics n, d and k_{act}.

4.1.1 Hard- and Software. The experiments are performed on a virtual machine, which operates on Ubuntu 18.04. It has a 6-core CPU with 2.5 GHz and 32 GB RAM. Our implementation is based on Python 3.6 and on scikit-learn[3].

4.1.2 Datasets. We draw our evaluation on synthetically generated and real-world datasets. Regarding the synthetic datasets, we use the dataset generation tool from [7–9]. This tool generates datasets based on these four input characteristics:

1) n, which describes the number of entities, 2) d, which denotes the number of dimensions, where the values in each dimension lie in the interval $[-10, 10]$, 3) k_{act}, which is the actual number of clusters, where each cluster contains $\frac{n}{k_{act}}$ entities and 4) r, which is the ratio of noise, i.e., $\frac{r}{100} \cdot n$ additional entities are added uniformly at random to the dataset.

We generate datasets with $n \in [2{,}500; 7{,}500]$, $d \in [20; 40]$, $k_{act} \in [25; 75]$, and $r \in [0; 17; 50]$. We generate these datasets as a cross product of the above-mentioned characteristics, i.e., 24 synthetic datasets are used within our evaluation.

For the real-world datasets, we use 5 classification datasets from the UCI machine learning repository[4] with different dataset characteristics regarding n, d and k_{act}. Here, k_{act} describes the number of classes in the dataset. We removed the class labels from these datasets when applying instantiations of our AutoML4Clust approach and solely used them to evaluate the accuracy of our approach. In order to use these datasets for clustering, we removed any non-numeric and symbolic values, IDs, timestamps, class labels and empty values. Table 1 summarizes the datasets' characteristics. Note, that these datasets exhibit similar or even larger characteristics as the synthetic datasets regarding n and d.

4.1.3 Implementation. We evaluate AutoML4Clust with overall 12 instantiations, i.e., four optimizers and three internal metrics to unveil the best-performing combinations thereof. We provide our prototypical implementation of all AutoML4Clust instantiations in Python[5] with all versions of the used libraries[6].

Optimizers: We use the following four frequently used optimizers from the area of hyperparameter optimization (cf. Section 2.1): Random Search (RS) [1], Bayesian Optimization (BO) [1], Hyperband (HB) [13], and the combination of Bayesian Optimization and Hyperband (BOHB) [3]. We define the budget as number of optimizer loops that each optimizer performs.

Clustering algorithms: We focus on k-center clustering algorithms, due to their appealing runtime behavior and their popularity across researchers and practitioners [20]. We note that other kind of clustering algorithms, e.g., density-based ones like DBSCAN, have a runtime complexity of $O(n^2)$ or even higher, which makes them infeasible in practice for large datasets [10]. Therefore, we use k-Means [15], MiniBatch k-Means [17], k-Medoids [12], and GMM [2] as concrete instantiations of k-center clustering algorithms. We set the maximum number of clustering iterations for each algorithm to ten since Fritz et al. showed that even a few iterations already lead to valuable results [6].

Internal metrics: For the evaluation of the clustering result in each optimizer loop, we use three commonly used internal metrics that are implemented in scikit-learn: Calinski-Harabasz (CH), the Davies-Bouldin Index (DBI), and the Silhouettte (SIL).

4.1.4 CASH Experiment and Baselines. Based on $\mathcal{CS} = \mathcal{A} \times \mathcal{H}$, we define the CASH experiment analogue to related work in the area of AutoML [18]. We set $\mathcal{A}$ as described in Section 4.1.3. We set the search space $\mathcal{H}$ for the hyperparameter k of k-center clustering algorithms to $\mathcal{H} = \{2, \ldots, \frac{n}{10}\}$, i.e., the maximum k value is set in relation to the number of entities in the dataset. Since analysts perform in the worst-case an exhaustive search throughout $\mathcal{CS}$ due to the lack of more efficient approaches, we compare AutoML4Clust to an exhaustive search.

4.2 Accuracy Evaluation

In this section, we investigate the accuracy obtained by different instantiations of AutoML4Clust in contrast to the baselines. Therefore, we explain how we (i) examine a suitable budget to achieve valuable clustering results, (ii) compare the accuracy with the baselines, and (iii) discuss the effect of noisy data.

Since the actual labels of the datasets are known in our experiments, we use an external clustering metric to asses the accuracy of the achieved clustering result, similar to the accuracy from classification tasks. Therefore, we use the adjusted mutual information (AMI) [19], which is limited to $[0; 1]$, while values closer to one indicate a better matching of the predicted labeling with the actual labeling of the dataset.

4.2.1 Time to Accuracy. Figure 2 summarizes the accuracy results of the AutoML4Clust instantiations, i.e., the four optimizers and the three internal metrics at each optimizer loop l_i.

Budget: After about 60 optimizer loops, i.e., $l_i = 60$ (which is marked by the vertical line), the accuracy of AutoML4Clust does not further improve significantly for all instantiations. Hence, we argue that $l = 60$ is a suitable budget for AutoML4Clust to support novice analyst in achieving valuable results efficiently.

AutoML4Clust accuracy: AutoML4Clust achieves with every optimizer very accurate results, i.e., AMI values over 90%. Furthermore, we observe that more optimizer loops increase the accuracy.

AutoML4Clust instantiations: The AutoML4Clust instantiations with the CH metric achieve the highest accuracy. The reason for this is that the CH metric focuses on the intra- and inter-cluster compactness. Therefore, in contrast to DBI, it is less sensitive to sub-clusters, i.e., two or more clusters in a dataset that are very close to each other [14]. The most inaccurate results are obtained by instantiations with the SIL metric. This can be explained by the calculation of the SIL, as it can be highly influenced by the position of single entities. Due to its imprecise results, we do not present results for the SIL metric in the remaining experiments.

4.2.2 Accuracy Comparison. Figure 3 unveils the accuracy of AutoML4Clust in comparison to the respective baselines. We present the results of the AutoML4Clust instantiations with the four optimizers, the budget of $l = 60$, and the CH and DBI metrics.

[3] scikit-learn.org [4] https://archive.ics.uci.edu/ml/datasets.php
[5] https://git.io/JTeix [6] https://git.io/JTeXG

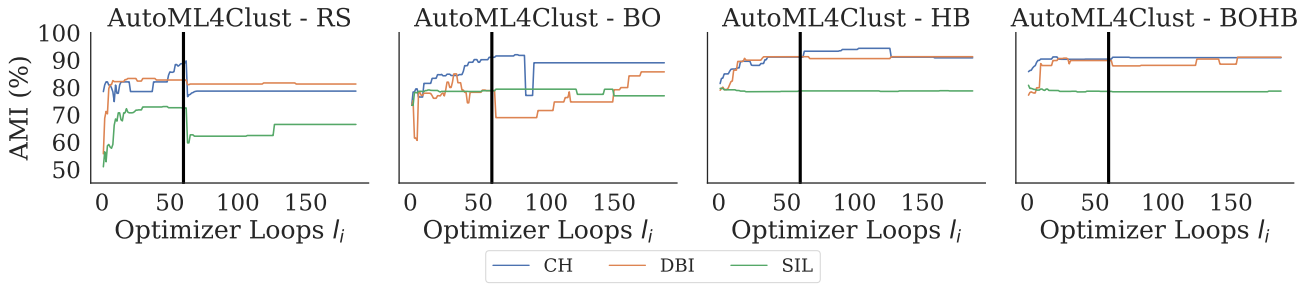

Figure 2: Accuracy of the AutoML4Clust instantiations over all synthetic datasets at each optimizer loop l_i for the CASH experiment. The vertical line at $l_i = 60$ marks where the accuracy does not further improve significantly.

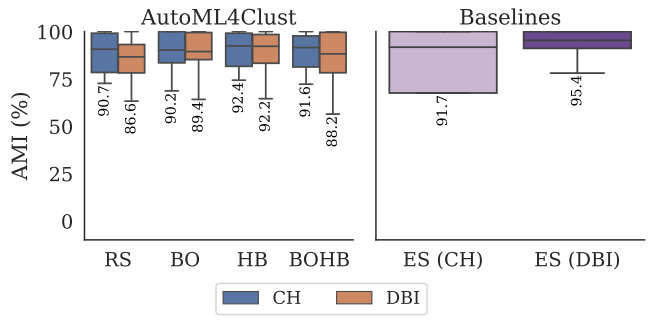

Figure 3: Accuracy of AutoML4Clust over synthetic datasets in contrast to exhaustive search (ES) with CH and DBI. Median values are shown at each box plot.

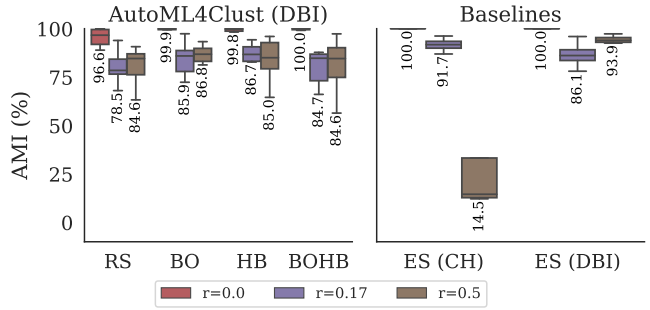

Figure 4: Comparison of the impact of noise (r) for AutoML4Clust and the baselines regarding the AMI results. Median values are shown at each box plot.

AutoML4Clust achieves similarly accurate results as the exhaustive search (ES), i.e., HB with CH achieve higher accuracy than ES (CH) and only deviates 3% from ES (DBI). Hence, the best result of AutoML4Clust deviates only 3% from the best result of ES. Therefore, AutoML4Clust supports novice analysts nearly as good as an exhaustive search, while being more efficient since it does not execute all configurations in $\mathcal{CS}$. Furthermore, we emphasize that AutoML4Clust achieves higher accuracy when using the CH metric. Regarding optimizers, we observe that AutoML4Clust achieves in most cases the best results with the HB optimizer and the CH metric. One possible reason is that BO and BOHB are more effective in higher dimensional configuration spaces. Yet, it achieves higher accuracy than RS since it discards poorly performing configurations early on [3].

4.2.3 Effect of Noisy Data. Throughout our experiments, we observed that noisy data have a significant impact on the baselines. However, noisy data are prevalent in real-world scenarios and should therefore be considered specifically. Figure 4 unveils the results for three different noise ratios $r \in [0; 0.17; 0.5]$. It can be seen that AutoML4Clust is robust against noise, i.e., it achieves AMI values typically over 85% even for $r = 0.5$ and can therefore almost compete with a time-consuming exhaustive search, which achieves an AMI value of 93.9% for DBI. The ES (CH) achieves accurate results for $r = 0$ and $r = 0.17$, while it performs poorly for $r = 0.5$. Hence, it is most affected by noise for $r = 0.5$. We observe a similar behaviour for the AutoML4Clust instantiations with the CH metric. The reason for the bad performance is that the calculation of the CH metric is essentially based on the compactness. Therefore, it is less robust against noise than the DBI metric [14]. However, we note that the results of AutoML4Clust with the CH metric (cf. Section 4.2.2) are still very accurate for $r \in [0; 0.17]$ and are only imprecise for $r = 0.5$, i.e., for highly noisy datasets.

4.3 Runtime Evaluation

Besides an accurate clustering result, the runtime is also crucial for analysts. Figure 5 summarizes the runtime results for all investigated AutoML4Clust instantiations for $l = 60$ and the corresponding baselines.

AutoML4Clust exhibits the highest runtimes with the SIL metric, since this metric has a runtime complexity of $O(n^2)$ [14]. The runtimes of the CH and DBI metrics differ only marginally, while the CH metric has the lower runtime in most cases. Regarding the optimizers, AutoML4Clust achieves faster results with the HB and BOHB optimizers than with the RS and BO optimizers. The reason is that HB and BOHB execute optimizer loops in parallel, while RS and BO execute them sequentially [3].

The results clearly show that AutoML4Clust is orders of magnitude faster than the time-consuming ES. It achieves the fastest results in 57 seconds, while the fastest results for the ES require roughly 6 hours. In comparison to ES (DBI), we even observe speedups of more than 437×. Hence, AutoML4Clust provides an efficient support for novice analysts regarding the CASH problem for clustering analyses.

4.4 Results on Real-World Datasets

In order to assess the practical feasibility of AutoML4Clust, we perform the same experiments as for the synthetic datasets, yet use real-world datasets. We focus on the CH and the DBI metric for these experiments, since the results on the synthetic datasets clearly showed that the SIL metric does not achieve valuable

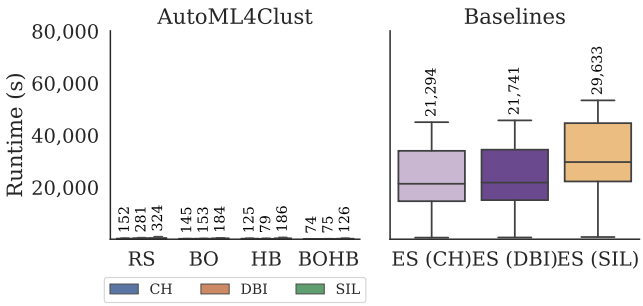

Figure 5: Runtime results of AutoML4Clust with all instantiations in contrast to the respective baselines. Median values are shown at each box plot.

Approach	Optimizer	Metric	AMI (%)	Runtime (s)
AutoML4Clust	RS	CH	**45.4**	781
		DBI	28.5	791
	BO	CH	22.5	879
		DBI	33.6	1,305
	HB	CH	**38.5**	**420**
		DBI	**33.9**	604
	BOHB	CH	22.0	**276**
		DBI	33.7	**598**
Baseline	ES	CH	13.8	76,211
	ES	DBI	33.5	77,196

Table 2: Median results on real-world datasets regarding AMI and the runtimes. We indicate the top-3 results for AMI and runtime in bold.

results and furthermore exhibits high runtimes. Table 2 summarizes the results on the real-world datasets, which are mostly very similar to the results on the synthetic datasets. We indicate the top three results for AMI and runtime in bold.

AutoML4Clust achieves higher accuracy than an exhaustive search, while also significantly outperforming it regarding runtime. The fastest results of AutoML4Clust requires less than 5 minutes, while the ES required with both metrics roughly 21 hours, i.e., AutoML4Clust achieves speedups of up to 276×. Furthermore, AutoML4Clust achieves with HB and CH up to 5% higher AMI values than the ES. The reason that AutoML4Clust can be more accurate than ES is that both optimize the internal metric value of CH or DBI and do not directly address the external metric AMI. Therefore, both approaches return the configuration with the best metric value, but not necessarily with the best accuracy, i.e., AMI value. We argue that HB and CH is a well-performing instantiation of AutoML4Clust, since it is the only instantiation that achieves one of the top-3 results with both, AMI and runtime.

Combining these observations with the results from synthetic datasets, we can state that the instantiation of the HB optimizer and the CH metric achieves in most cases the best results regarding accuracy and runtime.

5 CONCLUSION

In this work, we propose AutoML4Clust, an AutoML approach to support novice analysts efficiently with the combined algorithm selection and hyperparameter optimization (CASH) problem for clustering analyses. To the best of our knowledge, this is the first thoroughly elaborated AutoML approach for clustering analyses. AutoML4Clust remains generic, i.e., it can be instantiated with different optimizers and internal metrics. However, the concrete instantiation is crucial for an efficient exploration of large configuration spaces. Our evaluation reveals that specific instantiations of AutoML4Clust achieve similar or even more accurate results, while tremendously outperforming existing approaches regarding runtime on synthetic and real-world datasets.

Future work will address how clustering ensembles can be exploited to achieve even more valuable clustering results.

ABSTRACT

The problem of clustering time series has several applications in real-life contexts, especially in data science and data analytics pipelines. Existing time series clustering algorithms are ineffective for feature-rich real-world time series since they only compute the similarity of time series based on raw data or use a fixed set of features. In this paper, we develop a feature-based semi-supervised clustering framework addressing the above issues for variable-length and heterogeneous time series. Specifically, we rely on a graph encoding of the time series that is obtained by considering a high number of significant extracted features. We then employ community detection and leverage a co-occurrence matrix in order to group together all the best clustering results. Our extensive experimental assessment shows the scalability and robustness of our approach along with its superiority against state of the art clustering algorithms on both real-world healthcare data and UCR benchmark data.

1 INTRODUCTION

The goal of clustering is to organize unlabeled data objects into homogeneous groups while minimizing intra-cluster dissimilarity and maximizing inter-cluster dissimilarity [9]. In this paper, we present FeatTS, a Semi-Supervised Clustering method that leverages features extracted from the raw time series to create clusters that reflect, as much as possible, the original time series. The FeatTS algorithm leverages the concepts of Constrained Clustering, more specifically Clustering by Seeding. The most prominent approach in this category is Seeded kMeans [3], which relies on a small amount of labels of the original dataset in order to create two kinds of links, i.e. Must Link and Cannot Link. Must links are connections between two data points that represent a "constraint of belonging". This means that the data points (or time series at large) should be clustered together. Cannot links do the opposite thus leading to separate data points. Leveraging these two kinds of links, Seeded kMeans allows to discover clusters that respect them.

Our approach differs from existing methods in the literature since it employs the features of the time series, whereas existing methods focus on the similarity of the time series themselves [20]. The novelty of FeatTS consists in automatically selecting the most appropriate statistical features based on the dataset provided as input, the latter characteristic being relevant for data science and data analytics pipelines. In fact, not all the features have the same quality and choosing a subset of high-quality features for each dataset is beneficial for the clustering step. Moreover, the features of time series are interpretable by humans, thus leading to a more transparent and human-centric clustering process. To the best of our knowledge, FeatTS is the first feature-based semi-supervised clustering framework with these characteristics.

In designing our approach, we were inspired by the peculiarities of real-life time series, in particular those found in the time series of patients suffering from end-stage kidney diseases. These time series describe the change over time of the Glomerular Filtration Rate(GFR) signal, estimating how much blood passes through the glomeruli each minute. How GFR changes is crucial for the patient's survival, since rapidly descending values of GFR over time indicate a dangerous condition that might lead to kidney failure and even death. A more stable evolution of GFR over time is less worrisome for the concerned patient, thus guiding an appropriate treatment. The key question to tackle is how to select the subset of features that help medical doctors to discriminate the patients based on the label while performing clustering.

Once the features are selected, FeatTS computes the global relationships between the time series based on their statistical features. We use graph networks to obtain such an encoding. Indeed, FeatTS converts each time series into nodes and creates weighted edges. Each edge represents the distance between the connected nodes of the edge, i.e. the difference between the values of two different time series using the selected feature. FeatTS prunes the graphs based on a threshold and applies a Community Detection algorithm in order to obtain the global relationship among time series. As a final step, FeatTS will holistically merge the results of the communities into a Co-Occurrence matrix, on which clustering (K-Medoid) is applied. Figure 1 depicts at a high level the various steps of our proposed algorithm, while a detailed explanation is provided in the rest of the paper.

As already observed, in the supervised feature selection step, FeatTS allows to select the most appropriate statistical features based on the labels of the time series. The selected features are then used to cluster the entire dataset, including the time series that may have unknown labels. Using Figure 2(a) as a running example on GFR data, our algorithm allows us to obtain the resulted clusters for the four time series reported in Figure 2 (d) even with missing labels for TS_2 and TS_4.

An observant reader may question how this clustering task is different from classification, in which features are selected to build classifiers separating the time series based on the class labels. The key advantage of the clustering task we perform here is that the number of clusters to be formed can be arbitrarily different from the number of classes. For instance, in our kidney failure example, medical researchers may want more clusters to be formed than the two classes of kidney failures or not. Notice that the same separation cannot be achieved with classification [2] as a classifier cannot "sub-divide" the "kidney failure" label. We summarize our main contributions as follows:

(1) We introduce a novel semi-supervised clustering method leveraging the most discriminating features extracted from the time series. We treat the time series similar to each other as communities and we encode the different communities into a co-occurrence matrix, allowing to obtain a unified similarity value for the time series.

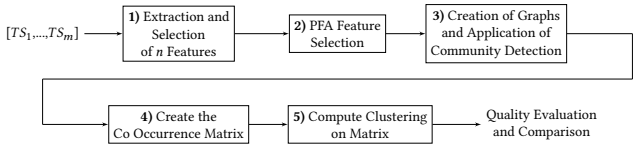

Figure 1: The algorithmic pipeline of FeatTS.

(2) Contrarily to previous work, our method allows to treat at par all the features of a given dataset instead of preselecting a fixed number of them for all datasets or just leveraging the similarity of raw data.
(3) Our method achieves more high-quality results compared with the latest baselines (among which Seeded kMeans [3] and k-Shape [17]) on the literature datasets. In addition, it obtains excellent results in terms of scalability.

The paper is organized as follows. Section 2 discusses the related work. In Sections 3, we describe in detail the steps of our clustering framework. In Section 4, we describe our experimental setup on real-life and on benchmarking data. Section 5 presents the various results of our experimental assessment. Finally, Section 6 concludes our work and discusses future directions.

2 RELATED WORK

Semi-supervised learning is a combination of supervised and unsupervised learning. It uses a small amount of labeled data and a large amount of unlabeled data in order to train a model. As such, it avoids the problem of finding a large amount of labeled data. A subcategory of semi-supervised clustering is Constrained Clustering, that enables the creation of Must Link and Cannot Link, as already explained in Section 1. There exist various methods to create these constraints; among which active learning [19] by relying on the user to provide such constraints. Another method would exploit the labelled data provided on input, as done by Seeded KMeans[3]. The latter uses the labels provided as input to find the constraints among the data and the centroids and then applies the kMeans algorithm to find the clusters.

In the literature, approaches similar to ours exist that perform time series clustering. However, other feature-based approaches [15, 21] only consider a predefined set of features that are limited with real-life time series exhibiting a richer number of features.

Among the unsupervised clustering algorithms [1], kShape[17] can be considered as the state of the art algorithm. It computes the most representative time series in a given cluster and inserts each new time series into one of these clusters based on distance. The problem with this approach is that it can often lead to assigning spurious time series to clusters. As shown in the literature [7], the usage of raw time series can spur high noise levels.

3 A FULL-FLEDGED PIPELINE

The pipeline of FeatTS as illustrated in Figure 1 is a combination of steps that contribute to the quality of the clustering results. We describe these steps in detail in the following.

3.1 Feature Extraction and Selection

The first step of the pipeline is the *feature extraction* step from the time series corresponding to step 1) in Figure 1. We consider feature extraction methods available in the literature and in readily predefined libraries [5]. Formally, given a vector of features $[f_1, f_2, \ldots, f_n]$ extracted, we construct a table containing the value of each feature, thus having as columns the features and having the time series $[TS_1, TS_2, \ldots, TS_m]$ as rows. As a simple example, in Figure 2(a), we show an instance of the table for 4 time series and 6 features. Moreover, each time series is displayed with its corresponding label.

The features shown in Figure 2(a) represent only a tiny subset of the set of features that can be extrapolated from the time series. Indeed, the tsfresh[5] library allows us to extract a significantly higher number of features. Therefore, *feature selection* becomes pivotal in our setting, since not all the features have the same relevance for the subsequent clustering steps. In particular, we compute the relevance of the extracted features by solely using the feature values corresponding to the class label of the time series (e.g. in Figure 2(a) the class 'Kidney Failure' or ' No Kidney Failure').

The Benjamini-Yekutieli is a supervised procedure [4] that allows us to identify the relevance of the features, based on the label associated with the time series. It computes the p-value of each feature provided as input based on their relevance. The p-value is an important metric that allows us to quantify the significance of each feature. The output of Benjamini-Yekutieli procedure is a list of features ranked by their p-values. Among these features, usually only a subset of them have an acceptable relevance. From our empirical study, it has been evinced that the top-20 features in order of relevance are sufficient to obtain high-quality clustering.

Usually, one of the main problems when computing the p-value is that the redundancy of the obtained features. It is desirable to find a duplicate-free combination of the features that is still quality preserving and small in number. Therefore, once we select the 20 features from the list produced by Benjamini-Yekutieli, we need an algorithm that allows us to find a minimum number of features that is representative of the other features not included in the analysis.

To do so, we apply a technique called Principal Feature Analysis (PFA) [12]. PFA is a variation of Principal Component Analysis (PCA). The key difference is that PFA preserves the original values of the features and thus the distance between them. Thus, we can leverage the concept of explained variance, representing the ratio between the variance of one single feature and the sum of variances of all individual features. We fix a value t of the explained variance, which is in our experiments equal to 0.9. That is, out of the 20 features selected in the Benjamini-Yekutieli procedure, we choose the minimum number of features for which the sum of their variance covers the 90% of the information produced by the rest of the features. This value is the best result produced empirically with various values of the threshold t. In our example, among all the features presented in Figure 2(a), we have selected only *quantile*, *trend_stderr* and *trend_rvalue*, as shown in Figure 2(b).

3.2 Graph Rendering and Community Detection

We convert the time series and their relationships into edge-weighted graphs. The encoding of time series into edge-weighted graphs allows us to represent our clustering problem in another dimension space without loss of information. This operation is crucial in order to be able to capture the global relationships among the raw time series samples.

Suppose we have a feature F_i (as selected by PFA in the previous step) and a set of n time series $\{TS_1, .., TS_n\}$. Let TS_i be a node v_i in the set of vertices V of a graph G. Let E be the set of

edges of graph G, where each edge e_i connects two nodes in G representing two distinct time series. Let $w : E \rightarrow \mathbb{R}$ be an edge-based weight function. Each edge e_i is thus assigned a weight $w(e_i)$ representing the distance between the connected nodes of the edge, i.e. the difference between the values of two different time series using the feature F_i. In order to capture similarity, we only retain in G the edges whose weight is less than a given threshold distance th.

Example 3.1. As an example, let us consider the four time series as in Figure 2(a), each of which has the values of quantile; we will compute all the distances between these values. Figure 3a shows the graph encoding of these time series where the weights on the edges represent the distance between the time series, based on quantile.

One immediate question is the choice of the threshold th. Given n nodes in G corresponding to the n time series, there are $\frac{N*(N-1)}{2}$ distances between all pairs of nodes. To capture similarity, we use a simple heuristic of a percentage x that represents the proportion of the smallest distances to be kept. The threshold th is thus selected based on this x percentage.

Example 3.2. For instance, for the graph in Figure 3a, the array in Figure 3b contains the distances between the vertices in ascending order. Suppose that the user specifies as percentage 50% of the vector. This implies that the distance boundary will be 28 and the distances higher than 28 will be discarded (i.e. the corresponding edges in the graph will be ignored). Once we have chosen the boundary distance, we can create the corresponding graph as depicted in Figure 3b.

Notice that a higher threshold would consider lower significance edges and thus weaker similarities between the times series. On the other hand a lower threshold may cut important edges. In our empirical evaluation, we used a threshold determined by a user-specified percentage of 80%, which works well in practical scenarios as we will see in the remainder of the paper. The chosen threshold will be used for all features selected by PFA and thus for all graphs created.

Note that each graph is created based on one selected feature from PFA in the previous step. Thus, if PFA selects k features, there will be k graphs, each corresponding to one notion of similarity between a pair of time series. The intention is to combine these different notions of similarity in time series clustering, by leveraging the structures of connectivity in the various graphs.

To this purpose, we apply a community detection (CD) algorithm in order to search for groups of densely connected vertices forming communities. Among the different tested algorithms, we have opted for the Greedy Modularity Algorithm [16] in the NetworkX library [8]. This algorithm turns out to strike a balance between speed and robustness and does not require any additional input parameter other than the graphs.

In Figure 4, we show an example of clustering obtained by applying this algorithm to a family of graphs. We can notice that the clustering varies from one graph to another graph. A natural question is how we can unify the different clusters in order to obtain understandable results.

3.3 Creation of the Co-Occurrence Matrix

The underlying intuition is that if two time series are similar, they will be similar for the majority of their discriminating features.

We employ a *co-occurrence matrix* [14] to put this in practice. The matrix consists of recording for each pair of time series how many times they are grouped within the same community. Intuitively, the more times they are placed within the same community, the more similar the time series are.

Co-Occurrence Matrices without weights. Assuming we have M time series and L features, we know that, once applied the CD algorithm on the L graphs, we will obtain the following result:

$$\begin{gathered} Feature_1 = \{(TS_1, TS_3, ..., TS_s), ..., (TS_2, TS_4, ..., TS_p)\} \\ Feature_2 = \{(TS_2, TS_3, ..., TS_t), ..., (TS_1, TS_4, ..., TS_i)\} \\ ... \\ Feature_n = \{(TS_2, TS_1, ..., TS_m), ..., (TS_3, TS_4, ..., TS_q)\} \end{gathered}$$

where for each feature $Feature_i$ selected by the PFA, we obtain different communities $(TS_1, ..., TS_i)$ composed by the time series. We can now create a matrix in which the rows and columns contain all the time series of the dataset. Each cell x_{ij} in the matrix corresponds to the similarity between time series TS_i (in row i of the matrix) and TS_j (in column j of the matrix).

Next we convert the counts in the Co-Occurrence matrix into a similarity metric for the eventual clustering. We consider the number of times that a pair of time series is present in all possible communities where at least one of the two time series belongs. That is, given the time series TS_i, TS_j, the communities C and the set of all the time series M, the similarity between TS_i and TS_j will be as follows.

$$\forall\, TS_i, TS_j \ \in M,\ \forall c \in C\ x_{ij} = \frac{\left|\{\, c \in C \mid TS_i \in c \quad \& \quad TS_j \in c \,\}\right|}{|\{c \in C |\ TS_i \in c\}|} \tag{1}$$

That is, the number of times that the two time series TS_i and TS_j fall within the same community divided by the number of times that TS_i is found within any community.

Notice that (1) is completely symmetrical. Indeed, the communities found for each feature are considered as hard clustered, i.e. a time series TS_i cannot be part of two communities of the same feature and must necessarily belong to one community. Thus, if TS_i and TS_j are within the same community of a specific feature, neither of them can be part of other communities of the same feature. Therefore, the value x_{ij}, given by the number of times TS_i and TS_j are in the same community, will be equal to x_{ji}, because TS_j and TS_i must also be in the same community.

Co-Occurrence Matrices with Weights. The application of the CD algorithm and its processing with co-occurrence matrices without weights might incur the problem of community fragmentation. More precisely, the CD algorithm might lead to the formation of a high number of communities each of which contains a few time series. This is due to the fact that some features are often not discriminatory enough for that dataset.

To overcome this problem, we assign an approximate weight to each feature, based on the number of communities that the CD algorithm derives from the graph. Again, to correctly determine the weights, we require the input of the user on the expected number of clusters.

Let w_i be a weighting function defined on each feature F_i as follows:

$$\begin{cases} w_i = \frac{C}{O_i},\ if\ O_i > C \\ w_i = \frac{O_i}{C},\ if\ C > O_i \\ w_i = 1,\ otherwise \end{cases} \tag{2}$$

Dataset	TS_1	TS_2	TS_3	TS_4
TS_1	0	0.64	1.36	1.36
TS_2	0.64	0	1.36	1.36
TS_3	1.36	1.36	0	0
TS_4	1.36	1.36	0	0

Table 1: Co-Occurrence Matrix with weights.

where C is the number of clusters expected by the user and O_i is the number of communities extracted by means of the CD algorithm. Hence, the weights will be higher if the number of obtained communities O is equal or sufficiently close to C and lower otherwise.

The weights will be propagated to the similarity matrix, which will now reflect the importance of each feature from a user viewpoint. Not surprisingly, instead of simply counting the number of times that the time series TS_i and TS_j co-occur in the same community, we now sum their weights and divide by the sum of the weights of all time series, as also shown in the following.

Example 3.3. As shown in Figure 2(b), the PFA feature selection has chosen three features, namely [$trend\_stderr$, $quantile$, $trend\_rvalue$] *. After applying the CD algorithm, we obtained the following communities (per feature) among the* 4 *Time Series in Figure 2(a):*

$$\begin{gathered} quantile = \{(TS_1, TS_2), (TS_3, TS_4)\} \\ trend\_stderr = \{(TS_1), (TS_2), (TS_3, TS_4)\} \\ trend\_rvalue = \{(TS_1, TS_2, TS_3, TS_4)\} \end{gathered}$$

Assume now that the user specified an expected number of clusters equal to 2. $Trend\_stderr$ *and* $trend\_rvalue$ *do not satisfy the number of clusters expected by the user. Therefore,* $trend\_stderr$ *will have a weight of* $\frac{2}{3}$ *(*0.66*), while* $trend\_rvalue$ *will have a weight of* $\frac{1}{2}$ *(*0.5*), and* $quantile$ *we will have* 1 *as weight. We report the intermediate computation of the co-occurrence matrix with weights for this example in the Table in Figure 2(c) and the final result in the Table in Figure 2(d).*

3.4 Clustering the Co-Occurrence Matrix

The co-occurrence matrix obtained in the previous step allows us to quantify the similarity between two time series. In order to be prepared for the creation of the time series clusters, we need one more intermediate step, i.e. to compute the distances between the rows of the Co-Occurrence Matrix. We employ a standard Euclidean distance to perform the row comparison.

As an example, applying the Euclidean distance between the rows of the table in Figure 2(d), we obtain Table 1. For instance, the value of the cell $C_{3,4}$ of the Table 1 is 0 because the row 3 and 4 of the Table in Figure2(d) are equal. As a consequence, the time series 3 and 4 are always together in each cluster discovered by the CD algorithm.

Finally, we apply the standard K-Medoid algorithm [10] on the distances computed above. K-Medoid allows us to extract the time series that have the smallest distance among them.

To complete our running example, applying the K-Medoid algorithm to Table 1 requiring 2 clusters as the input parameter, we obtain two clusters $Cl_1 = \{TS_1, TS_2\}$ and $Cl_2 = \{TS_3, TS_4\}$, as shown in the Table in Figure 2(d).

The time complexity of the FeatTS is summarized in Lemma 3.4. The proof of the Lemma is available in the online repository[1].

Lemma 3.4. *Let D a dataset composed by m time series and let L the number of features chosen by PFA among the N features*

[1] https://github.com/DonaTProject/FeatTS

extracted and k the number of requested clusters. A dataset D is evaluated by FeatTS in time $O(L(m^2) + m^2 + k(m-k)^2 + n \cdot t_f)$ *and in space* $O(n + L(m + E) + m^2)$.

4 EXPERIMENTAL SETUP AND A CLINICAL CASE STUDY

We use real-life time series courtesy of the Personalized Medicine Department at the European Hospital George Pompidou in Paris. These time series contain signals from patients suffering from kidney diseases. As a background, the human kidney has a lot of functions including maintenance of acid-base balance. Proper function of the kidney requires that it receives and adequately filters blood. This is performed at the microscopic level by many hundreds of thousands of filtration units called renal corpuscles, each of which is composed of a glomerulus. A global assessment of renal function is often ascertained by estimating the rate of filtration, called the glomerular filtration rate (GFR). GFR estimates how much blood passes through the glomeruli each minute. Kidney failure occurs when GFR is under $90mL/min/1.73m^2$, whereas when it drops to $15mL/min/1.73m^2$, it means that the patient needs dialysis or a transplant. Thus, it is very important to understand when a patient needs medical treatment before the GFR reaches its lowest possible value. Moreover, since dialysis is an invasive operation, it is important to understand if a sudden drop in the GFR occurs. In this case, medical doctors might recommend urgent surgery or to resort to dialysis depending on the GFR values over time.

We ran experiments on two variants of this dataset. The first variant named $Kidney3Yr$ contains 222 patients (one time series per patient) and spans 1 to 3 years with a variable length between 90 and 230 data points in the time series. The second variant called $Kidney5Yr$ is composed of 278 patients spanning 5 years with time series having roughly 100 data points. In both cases, we ran our experiments using only the 20% of the labeled time series in order to compute the set of features necessary to run the clustering algorithm and to emulate the real-world scenario where not all the labels of the data points are available. The features thus being ordered based on their relevance have been employed to cluster the entire unlabeled dataset into those with GFR signals concerning high-risk patients and those containing GFR for patients with lower risk.

UCR datasets. We also used 64 benchmark datasets belonging to the UCR collection[6], including both real-life and synthetic datasets. The entire list of datasets used for benchmark is available online [2]. For consistency, we also used only 20% of the labeled time series during feature extraction during the clustering step in all experiments.

Implementation and reproducibility. Our code base is available online [2] with more details about the reproducibility.

5 EXPERIMENTAL RESULTS

For each dataset, we consider 20 as the upper bound of the number of features we consider in the analysis. A higher number of features are supported by our method but not indispensable to obtain better accuracy. Moreover, a higher number of features deteriorates the performance. Furthermore, we chose 80% as the threshold value of the percentage of features selected by the user. We used the AMI [18] metric, which is a well-established measurement of the quality of clustering. We adopt the same metric for our comparisons as well.

Table 2: Results showing the values of AMI for UCR datasets

We consider two main baselines, the first being the state-of-the-art algorithm for time series clustering, i.e. KShape[17], and the second being the state-of-the-art algorithm for Semi Supervised time series clustering i.e. Seeded kMeans [3], sharing the same category of our approach (as detailed in Section 2). KShape[17] could not be used on the real-world GFR time series as it cannot process variable-length time series. Hence, we limit the comparison with KShape to the UCR datasets.

Other baselines of semi-supervised clustering algorithms such as SSSL[20] (Self Labeling Algorithm) and SUCCESS[13] (Cluster then Label Algorithm) could not be used in our study due to the lack of available source code.

All experiments have been executed on a Server running Linux with 64GB of RAM, Intel Xeon CPU Skylake,IBRS @ 2.6GHz.

5.1 UCR Dataset

The results in Table 2 are an excerpt of the entire results obtained by our algorithm and its baselines for various UCR datasets. It can be observed that FeatTS obtains the best results among all.

Indeed, out of 64 datasets used for the comparison, FeatTS performed better on 37 datasets. In addition, kShape performed well only on 15 datasets (out of 64) and Seeded kMeans outperformed the others in only 12 datasets (out of 64).

5.2 Kidney Case Study

As shown in Table 3, the results obtained by FeatTS are significantly more accurate than Seeded kMeans on the clinical case study. For the patients under medical supervision for 5 years, as shown in Table 3, we have obtained results following a similar trend.

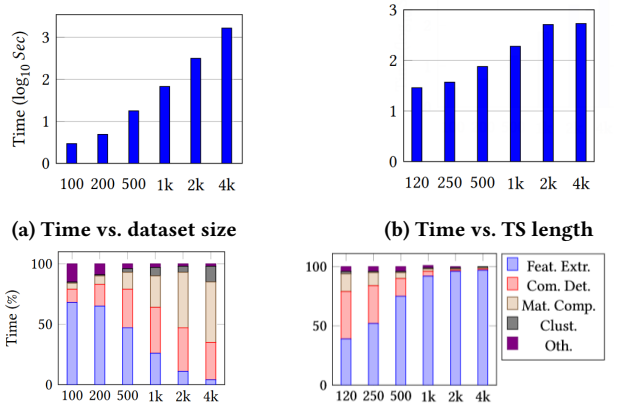
Dataset	FeatTS	SeededKMeans
Kidney3Yr	**0.56**	0.44
Kidney5Yr	**0.58**	0.48

Table 3: Results on Kidney 3Yr and 5Yr Datasets

5.3 Scalability

We have assessed the scalability of our method by increasing both the number and length of time series in a dataset. In this experiment, we have used synthetic time series generated with GRATIS [11]. This tool allows a controlled generation of time series by using diverse characteristics as spectral entropy, trend, seasonality, stability, etc.

In our case, in the synthetic generation we have opted for spectral entropy and trend as the underlying characteristics since they reflect the real-life time series we have used in the rest of our experimental assessment. The spectral entropy allows to



(a) Time vs. dataset size **(b) Time vs. TS length**

(c) % Time of each component vs. dataset size. **(d) % Time of each component vs TS length.**

Figure 5: Scalability Results.

measure the "forecastability" of a time series. It has a range of values between 0 to 1 and a low value of entropy indicates a high signal-to-noise ratio, while large values occur when a time series is difficult to forecast. For this characteristic, we have fixed a value of spectral entropy equal to 0.6. Conversely, the trend allows to represent the occurrence of low-frequency variations in the time series and as such it is opposite to seasonality. It has a range of values between 0 to 1 and we have chosen a value of 0.9 for this experiment.

In the first experiment, we increase the number of time series for each tested dataset while the the length of the time series is fixed and equal to 60. Figure 5a shows the results obtained on datasets consisting of 100, 200, 500, 1000, 2000, 4000 time series, respectively. The results show the scalability of the method in terms of time performance, while an important increase can be observed when shifting to more than 2000 time series. The times in Figure 5a are in logarithmic scale for clarity of exposition.

In order to better understand the results, we have studied the percentage of time due to each component of our pipeline as shown in Figure 5c. Upon increasing the size of the dataset, the component that is computationally more demanding is the creation of the co-occurrence matrix. Obviously, since the Co-Occurrence Matrix depends on the number of time series, the time required for its creation increases as the size increases.

In the second experiment, we have increased the length of the time series while fixing to 500 the number of time series belonging to each dataset. Figure 5b shows the results obtained increasing the length of the time series between 120 and 4000. The figure shows the scalability of the approach for time series under 2000 and a sudden increase of the time beyond this value. Also in this case, the times in Figure 5b are in logarithmic scale for better clarity. The time breakdown in Figure 5d shows that the more expensive step of the pipeline for this experiment is the feature extraction step.

6 CONCLUSION AND FUTURE WORK

Our work on clustering of time series shows that there is no one-size-fits-all solution regarding the set of features to use. In fact, we leveraged the features drawn from the data itself rather than taking a predefined set of features for all the datasets. Our flexible graph encoding allows us to process the most significant features in parallel and the further steps of our method allow us to combine the results.

This work could be improved by rendering the entire pipeline unsupervised instead of the current semi-supervised approach. This requires non-trivial extensions in order to be able to cluster the time series without loss of performance. Another improvement would be to dynamically choose the threshold for graph creation based on the processed features. Finally, the weights of the community detection algorithm could be combined with relevance degrees of the features.

ABSTRACT

Main Memory Database Systems (MMDBSs) may significantly increment IOPS (Input/Output Operations per Second) rates by avoiding access to secondary memory. This occurs because they maintain the database in Random Access Memory (RAM). Similar to traditional Disk-Based Database Systems (DBSs), MMDBSs are expected to trigger recovery activities after system failures to restore the database to its last consistent state before the failure. Nonetheless, MMDBSs executes the recovery process in an offline way, thus the database becomes available for new transactions only after the full recovery process has been performed. Systems can keep database replicas for high availability. However, replication is not immune to some failure sources that can cause multiple and shared malfunctions. Therefore, software techniques are required to prevent failures and repair crashed systems as soon as possible. This work proposes a novel MMDBS instant recovery process which makes MMDBS able to schedule new transactions simultaneously with the recovery activities. In order to validate this new approach, simulations with a prototype implemented on Redis have been conducted over Memtier benchmark. The achieved results evidence the suitability of the proposed recovery mechanism.

1 INTRODUCTION

Main Memory Databases (MMDBs), or In-Memory Databases (IMDBs), can provide very high throughput rates given that the primary data are located in memory. In that manner, MMDB reduces secondary memory I/O bottleneck, and can consequently speed up data access. Moreover, the development of new memory technologies has provided a larger storage capacity with lower costs. The fact that the database resides in volatile storage influences the design approaches adopted by MMDBs, such as query processing, concurrency control, recovery after crashes, data storage, and indexing. For this reason, these systems are designed to optimize access to main memory instead of secondary memory, as with traditional disk-resident systems [7, 21, 24].

MMDBs provide very high IOPS given that the primary database is handled in volatile storage. However, the database residing in a volatile memory makes these systems much more sensitive to system failures than conventional disk-resident database systems. The recovery mechanism is responsible for restoring the database to the most recent consistent state before a system failure has occurred. In this way, after a system crash, the recovery manager loads the last valid checkpoint (a prior database backup copy) and then starts to execute all actions recorded in the log file forward from the checkpoint record [10, 12, 13].

Accordingly, the recovery process for most MMDBs is performed offline, meaning that the database and its applications only become available for new transactions after the full recovery process is completed. One may claim that systems can keep database replicas for high availability. In fact, with the advent of high-availability infrastructure, recovery speed has become secondary in importance to runtime performance for most MMDBs [7, 12, 22]. Nevertheless, replication is not immune to human errors and unpredictable defects in software and firmware that are a source of failures and can cause multiple and shared problems [18, 21].

In this sense, this paper proposes an instant recovery approach for OLTP MMDBs. Said approach allows MMDBs to schedule new transactions immediately after the failure during the recovery process, giving the impression that the system was instantly restored. The main idea of instant recovery is to organize the log file in a way that enables efficient on-demand and incremental recovery of individual database tuples.

It is important to note that the existing MMDBs recovery strategy has two deficiencies that make instant recovery impossible. First, the recovery process uses a sequential log file. The recovery in the sequential log is not incremental and requires full recovery before any tuple can be accessed. This scenario does not allow the system to execute an on-demand transaction during recovery, which means that new transactions can only start executing after the recovery process has finished. The second problem is the random access pattern in the sequential log for restoring tuples individually. The sequential log has efficient record writes, but it has inefficient reads for individual log records. A full log scan must be done to restore a given tuple individually [12, 18].

The instant recovery technique presented in this work builds the log file as an index structure. This log organization enables an efficient restoration of a tuple. A single fetch on the indexed log can restore one tuple. Thus, the system can use the indexed log to recover a database by restoring tuple by tuple incrementally. This technique naturally supports database availability because a new transaction can access a tuple immediately after the tuple is restored, i.e., transactions do not have to wait for a full recovery to access restored tuples. We have empirically evaluated the proposed instant recovery approach in order to show its efficiency

and suitability to be implemented in MMDBs. The workload used for the experiments belongs to Memetier benchmark.

The remainder of this paper is organized as follows. Session 2 provides an overview of MMDB recovery. Section 3 discusses related work. Section 4 presents the proposed approach for database instant recovery. Section 5 discusses the results of empirical experiments. Finally, Section 6 concludes this paper.

2 BACKGROUND

Most main memory database systems implement logical logging technique which records higher-level database operations, such as inserting a record in a table. MMDBSs do not record Before images of modified tuples, i.e., they produce only Redo log records to reduce the amount of data written to secondary storage. The commit processing uses group commit, i.e., it tries to group multiple log records into one large I/O. SSD is the log device of choice for almost all systems in order to increase the I/O performance [12, 22, 26].

The recovery component of most MMDBs asynchronously produces a consistent checkpoint, commonly called snapshot. Snapshot is equivalent to a materialized database state in an instant of time by means of a Copy-on-Update method (COU, for short) [4, 6]. At the checkpoint beginning, MMDBS enters into a COU mode. Thereafter, the recovery component starts to scan all tuples in database tables at system run-time. Three bits are used to identify if a row was inserted, deleted, or updated after the checkpoint generation has begun. Inserted tuples are disregarded. Before an update or delete, the original content of a tuple is copied to a shadow table. The shadow version is removed after it is scanned. A background process serializes the snapshot to secondary memory until the checkpoint ends [2, 12].

Whenever a system crash occurs in an MMDB, the primary copy of the database is lost. In this case, MMDBs recover the database by loading the last valid checkpoint. Thereafter, the recovery component starts to execute the actions recorded in the log file forward from the checkpoint record. The recovery component activities are briefly illustrated in Figure 1. All actions of committed transactions are flushed to the log file on secondary memory by the Logger component. Periodically, the Checkpoint component produces a snapshot on secondary storage. After a failure, the Restorer component loads the snapshot into memory and then replay the log file. After the recovery process has finished, the database is available for new transactions [7, 22].

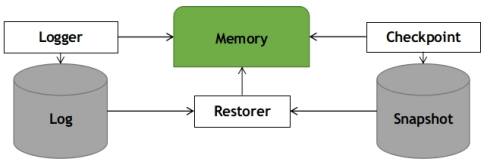

Figure 1: MMDBS recovery component architecture.

3 RELATED WORK

Hekaton [5], VoltDB [20], HyPer [9], SAP HANA [8] and SiloR [26] are examples of modern MMDBSs that perform the recovery activities discussed in Section 2. Nevertheless, those systems do not execute new transactions until the full recovery is completed.

PACMAN [22] and Adaptive Logging [23] utilize a dependency graph between transactions performed to identify opportunities for database recovery in parallel. After a failure, they use a dependency graph to generate a scheduled execution to replay the log records. The schedule allows transactions to be executed in parallel, following the constraints of the dependency graph. Those systems must wait for the full database recovery to service new transactions.

The Log-Structured Merge tree (LSM-tree) [15] provides low-cost indexing for a file that has a high rate of record insertions and deletions. However, the LSM-tree access method uses a buffer to avoid multiple I/Os in secondary memory for frequently referenced pages. This approach is not suitable for writing log records since they require immediate and atomic persistence during commit processing.

FineLine [17–19] presents an instant database restoration technique. This technique uses a partitioned index in the log to write records efficiently. The partition index may search for multiple partitions to retrieve a page. After a crash, the recovery process loads pages incrementally from a backup device. While a set of pages is loaded, the records in the log file that are related to that set are probed. This approach also can recover pages on-demand for transactions. New transactions can perform as soon as necessary pages are restored.

4 A NOVEL INSTANT RECOVERY MECHANISM

In this section, firstly the architecture of the proposed instant recovery mechanism is described. Thereafter, the proposed log data structure is discussed. Finally, the recovery algorithm based on the proposed indexed log structure is detailed.

4.1 The Architecture

Figure 2 proposes an architecture to implement our MMDB instant recovery approach, which uses an indexed log structure. This section provides an overview of the main components that comprise the architecture and their interactions.

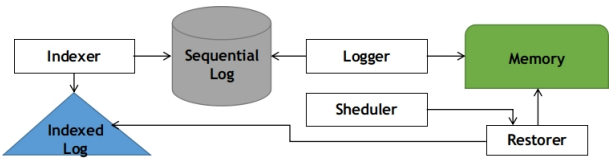

Figure 2: Architecture for in-memory database instant recovery using an indexed log.

Below, we present a brief description of the main components of the architecture discussed in the following subsections.

- **Logger**: writes transaction update actions in a log file on secondary memory. The records are flushed sequentially in an append-only file whose writes must be synchronized to transaction commit.
- **Indexer**: indexes records from sequential log to indexed log. The records are indexed in a B-tree asynchronously to transaction commit.
- **Restorer**: restores tuples from a failed database by replaying records from indexed log. Tuples can be restored incrementally and on-demand.
- **Scheduler**: during the recovery process, requests the Restorer component for tuples (that have not yet been restored into memory) requested by new transactions.

4.2 The Logging Strategy

The proposed approach for MMDB instant recovery uses two logs: a sequential log (Figure 3 (a)), and an indexed log (Figure 3 (b)). Each record in the sequential log represents an update performed on a tuple by a transaction. During transaction processing, transaction update records are appended to the sequential log file by the Logger component. Each transaction generates Redo records that are kept in a thread-local. During the commitment, all log records generated by a transaction are appended atomically on the sequential log. This scheme ensures log consistency to recover the database.

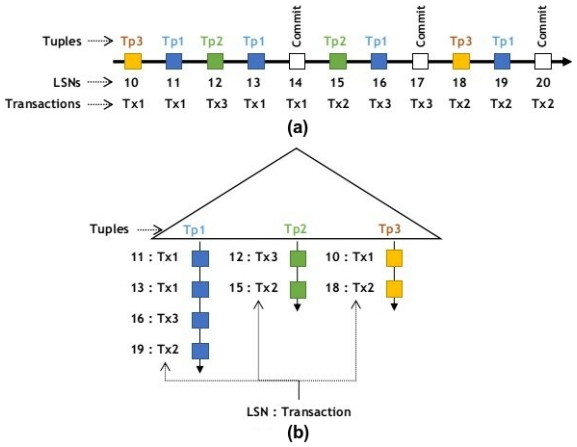

Figure 3: Sequential log (a), and indexed log (b).

The proposed recovery scheme requires efficient log reading to fetch the records to redo a given tuple during recovery. For this reason, the logging strategy implements an indexed log. The index structure is a B-tree in which each node contains a tuple ID and the update records generated by transaction updates in the tuple. Only one probe on B-tree can retrieve all the necessary records to restore a single tuple. The Indexer component is responsible for indexing records from the sequential log to the indexed log. The indexing is asynchronous to transaction commit, i.e., a transaction does not need to wait for the log indexing to confirm its writing in the data. Records can be removed from the sequential log after they are indexed in the B-tree. However, the sequential log is maintained to ensure consistent database recovery in the event of index corruption. In this case, the system must build a new indexed log from the sequential log. This process will delay the start of recovery.

The primary purpose of instant recovery is to restore the database efficiently, without degrading the transaction throughout provided by the system. The indexed log requires random writes, while a sequential log has a sequential write pattern. Writing records to a sequential log file is potentially faster than doing so to an indexed log file. For this reason, in our approach, log records are written to the sequential file and, periodically, flushed to the indexed log file. The indexing process occurs asynchronously to the transaction commit operation so as not to degrade the transaction processing. It is important to highlight that restoring an individual tuple by indexed log requires only one fetch on B-Tree, while restoring a single tuple by sequential log requires a full scan of the log file. Therefore, our recovery technique only uses the indexed log to recover the database after a failure.

FineLine [17–19] uses an instant recovery technique that allows efficient write of log records by a partitioned index. However, probes on log require inspecting multiple partitions to restore a page. This approach can delay recovery. The number of partitions can be reduced by intermediate merges. However, this process can interfere with the transaction processing performance. Our log organization is simpler and writes/reads records efficiently. Transactions must wait only for writes on the sequential log to commit. The log indexing does not interfere with transaction processing since records are indexed asynchronously to transaction commit. During recovery, only one fetch on B-tree can restore a tuple individually.

As it was exemplified in Figure 3, transactions Tx1, Tx2, and Tx3 generated log records for updates performed in tuples Tp1, Tp2, and Tp3. Sequential log (Figure 3 (a)) stores the records flushed by the three transactions. The log records with LSN 11, 13, 16, and 19 represent the last update performed in tuple Tp1, for example. A fetch on the indexed log can retrieve the records of LSN 11, 13, 16, and 19 to redo the tuple Tp1. The absence of an index implies the necessity of a full scan on the sequential log to restore Tp1.

4.3 The Recovery Algorithm

After a system failure, the system should initiate the database recovery by restoring tuples through the indexed log. However, the record indexing process is asynchronous to the transaction commit. As a result, some records on the sequential log may not have been indexed before a failure. Therefore, immediately before starting recovery, the system must verify if any records have not yet been indexed. Indexer component must index those records to ensure the recovery consistency. When this process ends, recovery can begin and new transactions can be performed. Thus, the Restorer component begins redoing tuples by traversing the indexed log B-Tree. Each visit to a B-Tree node can retrieve the update records to redo a tuple. After visiting all B-Tree nodes, all database tuples are restored, and the recovery process is completed.

The indexed log recovery scheme can naturally support availability since new transactions can be executed immediately after restoring their required tuples. Furthermore, this recovery scheme can service new transactions whose necessary tuples have not yet been loaded into memory during recovery. When a transaction requires tuples, the system checks if the tuples are stored in memory. If they are not in memory, the Scheduler component must request the Restorer for these tuples on-demand. Then, the recovery manager should pause the incremental recovery (the traversing in B-tree) and begin fetching the necessary tuples for the transaction from the indexed log. After the transaction's tuples are restored, they are marked as restored, the transaction can run, and the system can continue the incremental recovery.

4.4 The Evaluation Prototype

The instant recovery approach proposed in this paper was implemented in Redis 5.0.7 [16] to evaluate the feasibility of indexing for log replay. The evaluation prototype can be downloaded[1]. Redis is an open-source in-memory data structure store used as an in-memory key-value database. Redis is written in ANSI C.

Persistence in Redis can be achieved through snapshotting and logging. In snapshotting, the database is asynchronously transferred from memory to secondary storage at regular intervals as a binary dump using the Redis RDB Dump File Format.

[1]https://drive.google.com/drive/folders/1LTbtY36O0kWIpxZBM-hc1BPvIjICuy2F

In logging, a record of each operation that modifies the database is added to an append-only file (AOF). Redis can automatically rewrite the AOF in the background when it gets too big [16]. Our prototype uses only the AOF, i.e., the RDB was disabled. Moreover, the system does not rewrite the log.

During transaction performing, each update operation generates a log record that contains basically its command, key, and value. For example, the operation *SET(K1, V1)* stores the value *V1* with the key *K1* and generates the log record fields *SET*, *K1*, and *V1*. Each record is written in the AOF atomically only at a committed time and at the same order each in which the command was performed. Our prototype uses the AOF from Redis, i.e., we did not need to implement a sequential log.

The records must be copied from the sequential log to the indexed log periodically. The indexed log is a B-tree implemented in Berkeley DB 4.8 [14]. Berkeley Database (Berkeley DB or BDB) is a software library intended to provide a high-performance embedded database for key/value data.

5 EVALUATION

We have empirically evaluated the instant recovery approach proposed in this research. We used the Memtier Benchmark to perform the tests in Redis. All experiments shown in this paper were executed with 4 worker threads on Intel Core i7-9700k CPU 3.60GHz x 8. The system has 64GB of RAM and 400GB of SSD Kingston SA400S37 as a persistent storage device. The operating system was Ubuntu Linux 18.04.2 LTS.

5.1 Mentier Benchmark

Memtier is a high-throughput benchmarking tool for Redis developed by Redis Labs. This tool has a command-line interface that provides a set of customization and reporting features to generate various workload patterns. It can launch multiple worker threads, with each thread driving a configurable number of clients. The tool can control the ratio between read and write operations. Moreover, it offers control over the pattern of keys used by the operations (e.g., random and sequential patterns). Memtier provides options to set the number of total requests per client or the number of seconds to run a test. The tool offers other options for configuring custom workloads [1, 11]. Memtier has already been used in several scientific works, such as in [25] and [3].

5.2 Recovery Experiments

The first group of experiments was focused on measuring the time to fully recover a database, availability to process transactions after a system failure, time to run a workload entirely, and logging overhead. These experiments were performed on a database containing 99, 507 kyes that generated an 11.8GB sequential log file containing 160 million records. Additionally, an indexed log was generated along with this sequential log using the recovery technique proposed in this work. For each experiment, the system was shut down to simulate a failure. At the database restart, as soon as the recovery process was been triggered, a workload would be submitted. Thus, one could measure transaction throughput and recovery time from system restart.

The key goal was to compare the proposed instant recovery approach to the traditional main memory database recovery. However, we also tested our instant recovery scheme in different scenarios to confirm the following expectations about our technique: (1) an indexed log must be employed to incrementally and on-demand recover the database, and (2) asynchronous indexing of log records must be used to avoid transaction processing overhead. Thus, the experiments have been conducted in the three following scenarios: *(i)* Sequential Log Recovery - SLR; *(ii)* Asynchronous Indexed Log Instant Recovery - AILIR; *(iii)* Synchronous Indexed Log Instant Recovery - SILIR.

The SLR scenario (traditional recovery) uses only a sequential log. In this scenario, transaction update records are written to a sequential log file during transaction processing. The recovery process recovers the database by scanning the entire log file. Transactions can be performed only after the recovery is complete. The AILIR scenario (our approach) uses a sequential log + indexed log. In AILIR, transaction update records are written in a sequential log during transaction processing and stored asynchronously to transaction commit in an indexed log. The SILIR scenario (scenario derived from AILIR) uses only an indexed log. In SILIR, transaction update records are written directly to an indexed log synchronously to the transaction commit. After a failure, for both scenarios ii (AILIR) and iii (SILIR), the recovery manager must traverse the B-tree to recover the database, and transactions can perform during recovery. The SILIR scenario was created to measure the log indexing overhead during transaction processing and instant recovery processing.

For each scenario mentioned above, three experiments were performed by different types of workload: *(i)* read-only workload that contains only read operations, *(ii)* read-write workload that has read and write operations in the 5:5 ratio, and *(iii)* write-only workload that has only write operations. These three workloads were simulated using Memtier benchmark that used 4 worker threads, with each thread driving 50 clients. Each client made 170,000 requests in a random pattern.

Figure 4 shows the results of recovery experiments for the three scenarios (SLR, AILIR, and SILIR) performing the read-only workload, denoted Scenarios Read-Only. The vertical dashed lines in the figure indicate the final recovery time of the respective color approach. AILIR and SILIR recovered the database at the same time interval (85 seconds) since both techniques use the same algorithm to recover the database. They recovered before SLR which took 91 seconds to recover. In addition, they were available for new transactions since the database restart and before SLR which can execute transactions only after full recovery. Those two approaches had a quite similar throughput during the workload performing. Moreover, after the recovery, the three scenarios had a similar throughput. This was because there were no records to flush to the log file. AILIR and SILIR had a slightly lower throughput during recovery due to access to the indexed log. AILIR and SILIR performed the entire workload before SLR, as they can process new transactions during recovery.

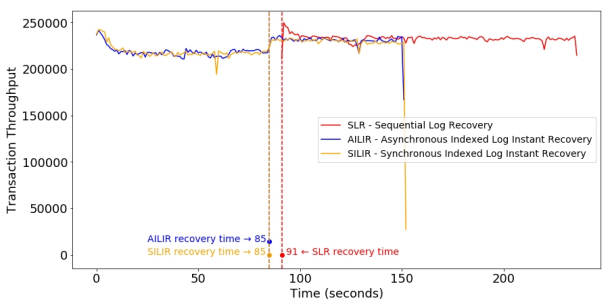

Figure 4: Recovery experiments - Scenarios Read-Only.

The results of recovery experiments for the three scenarios mentioned in this paper performing the read-write workload (denoted Scenarios Read-Write) are in Figure 5. The vertical dashed lines in the figure indicate the final recovery time of the respective color approach. The AILIR approach did not overload the throughput of transactions since its throughput was similar to that of the default approach (SLR). This result was already expected because AILIR and SLR flush log records to secondary memory in a similar manner, except that AILIR additionally indexes the log records. However, the indexing did not interfere with the transaction throughput because it is performed asynchronously to transaction commit. SILIR had the worst performance due to its synchronous log indexing, i.e., a transaction must wait for indexing to confirm its writes. Although SLR recovered the database before AILIR, AILIR was the fastest approach to finish the workload execution. This result was achieved because AILIR has asynchronous indexing and can process transactions while the system is recovering. In addition, the client application did not notice the AILIR recovery, giving the impression that the recovery was instantaneous.

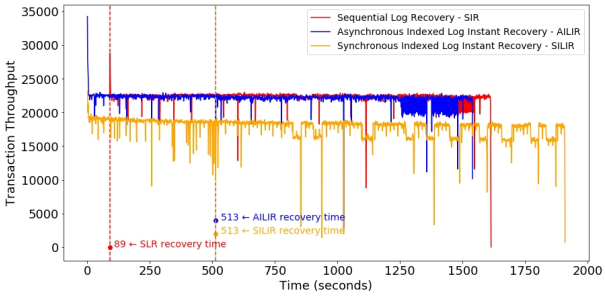

Figure 5: Recovery experiments - Scenarios Read-Write.

Figure 6 presents the results of recovery experiments for the three scenarios performing the write-only workload (denoted Scenarios Write-Only). These results are similar to those in Figure 5. Except for the fact that SILIR recovered the database faster than AILIR. However, this fact did not influence AILIR's performance. The AILIR approach had better performance since it was the fastest approach to finish the workload execution without overloading the transaction throughput. It had a very similar throughput to default recovery.

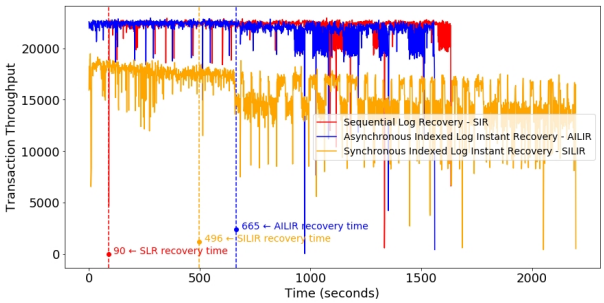

Figure 6: Recovery experiments - Scenarios Write-Only.

5.3 Scalability Experiments

We ran further experiments in which the proposed recovery strategy deals with different log file sizes. The goal is to observe the behavior and performance of the recovery strategy when the log file increases in size. These experiments were performed on the following four databases:

(1) DB1: containing 49, 866 kyes that generated a 5.9GB sequential log file containing 80 million records.
(2) DB2: containing 99, 507 kyes that generated an 11.8GB sequential log file containing 160 million records.
(3) DB3: containing 198, 067 kyes that generated a 23.6GB sequential log file containing 320 million records.
(4) DB4: containing 392, 041 kyes that generated a 47.3GB sequential log file containing 640 million records.

These four databases mentioned above have a ratio of approximately 1:1600 between keys and log records. Each sequential log was generated along with an indexed log using the recovery technique proposed in this work. The experiments used the same scenarios handled in the previous section (Section 5.2): *(i)* Sequential Log Recovery - SLR; *(ii)* Asynchronous Indexed Log Instant Recovery - AILIR; *(iii)* Synchronous Indexed Log Instant Recovery - SILIR. An experiment was performed for each of the four databases (DB1, DB2, DB3, and DB4) in each scenario (SLR, AILIR, and SILIR). For each experiment, the system was shut down to simulate a failure. At the database restart, as soon as the recovery process was been triggered, a workload would be submitted. The workload was simulated using Memtier benchmark that used 4 worker threads, with each thread driving 50 clients. Each client made 300,000 requests. The workload had 5:5 read and write operations in a random pattern. From the system restart, we measured the average transaction throughput during the execution of the workload, the recovery time, and the total workload execution time.

Figure 7 presents the recovery time obtained in each test. As expected, these results show that the number of database keys and log records can delay the recovery process in all approaches, as the recovery time increases with the size of the database. The instant recovery approaches (AILIR and SILIR) had a similar recovery time because they use the same recovery technique. However, AILIR was slightly faster than SILIR in all tests. This is because the weight of synchronous indexing by SILIR influences the overall performance of the system. SLR recovered the database faster than AILIR and SILIR.

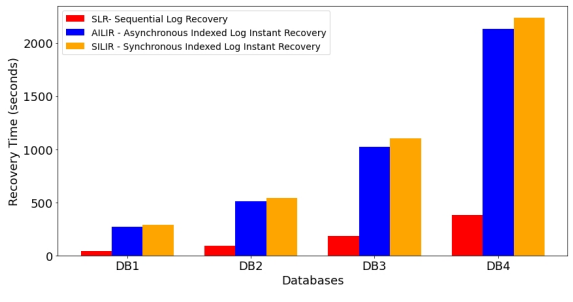

Figure 7: Scalability experiments - Recovery time.

Figure 8 shows that AILIR interferes very little in the throughput of transactions. This is evidenced by the fact that the AILIR average throughput, for the execution of a given workload, remained similar to that of the standard approach (SLR) in all experiments. On the other hand, SILIR's average transaction throughput was much lower than that of AILIR, proving that asynchronous indexing is essential for a better performance of

the instant recovery technique. The throughput difference between AILIR and SLR may occur because the Indexer component blocks the sequential log to read it. In the meantime, transactions must wait for the lock to be released before writing records to the log. Nevertheless, the approach proposed in this paper has the advantage of high availability. It can perform new transactions since the system restart, while the standard approach must wait for full database recovery to perform new transactions.

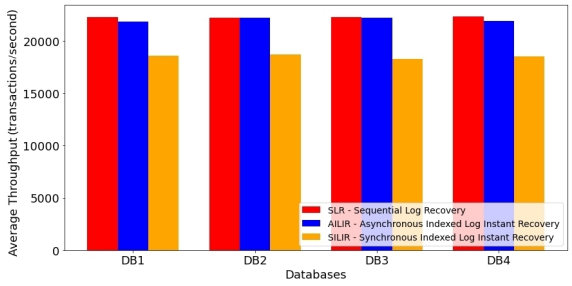

Figure 8: Scalability experiments - Average throughput.

The results of the experiments in Figure 9 show that the execution time of AILIR's workload is slightly longer than that of SLR. Although the experiments in Figures 4, 5, and 6 have shown that AILIR performed the workload faster than SLR, the experiments in Figure 9 show that this behavior changes with higher workloads. The workload of the experiments in Figure 9 (300,000 operations) is 1.7x greater than the workload of the experiments in Figures 4, 5, and 6 (170,000 operations). This is because SLR's transaction throughput is slightly higher than that of AILIR, as shown in Figure 8.

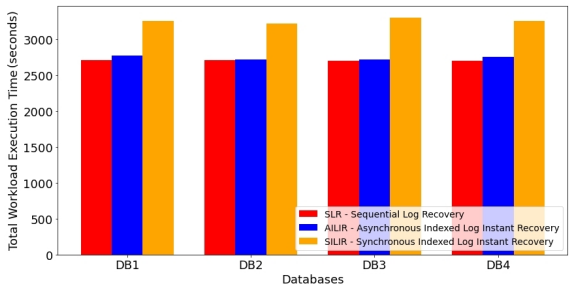

Figure 9: Scalability experiments - Total workload execution time.

6 CONCLUSION

This paper proposed an instant recovery approach for main memory database systems. The proposed approach allows new transactions to run concurrently to the recovery process. Our approach implements an indexed log to fetch tuples directly on the log to restore data incrementally. Consequently, new transactions are scheduled as soon as required tuples are restored into the main memory database. Furthermore, the proposed recovery mechanism restores data on-demand since it restores tuples for new transactions whose data has not yet been restored.

The results show that instant recovery reduces the perceived time to repair the database since transactions can be performed since the system is restarted. In other words, it can effectively deliver tuples that new transactions need during the recovery process. The experiments also analyzed the impact of using a log indexed structure on transaction throughput rates in an OLTP workload benchmark.

ABSTRACT

The rising popularity of data science has resulted in a challenging interplay between traditional declarative queries and numerical computations on the data. In this paper, we present and evaluate the advanced analytical system HorsePower that is able to combine and optimize both programming styles in a holistic manner. It can execute traditional SQL-based database queries, programs written in the statistical language MATLAB, as well as a mix of both by supporting user-defined functions within database queries. HorsePower exploits HorseIR, an array-based intermediate representation (IR), to which source programs are translated, allowing to combine query optimization and compiler optimization techniques at an intermediate level of abstraction.

1 INTRODUCTION

Complex data analytics has become the cornerstone of our data-driven society. Although the amount of data stored in traditional relational database systems (DBS) has been growing rapidly, the by far most common current approach is to take the data first out of the DBS and load it into stand-alone analytical tools, which are based on languages such as Python, or the statistical languages MATLAB [1], and R [3]. However, as the size of the data increases, the expensive data movement between DBS and analytics tools can become a severe bottleneck.

Integrating analytical capabilities into the DBS avoids such expensive data exchange. A common approach is to use user-defined functions (UDFs) that are embedded in SQL queries [13]. For example, MonetDB supports UDFs written in Python, that are executed by a Python language interpreter that is embedded inside the DBS engine.

While no data transfer is needed with this approach, there are still two separate execution environments, one being the SQL execution engine, the other the programming language execution environment. This can lead to costly data format conversion. Furthermore, the SQL and the UDF components of the query are each individually optimized by their respective execution environments, without the consideration of any holistic optimization across the entire task.

To address these issues, we propose `HorsePower`, an advanced analytical SQL system, which provides a holistic solution to integrate UDFs in SQL queries. The system is based on HorseIR [5], an array-based intermediate representation (IR) language which was developed to explore the usage of compiler optimizations for query execution. Chen et al. [5] translated the execution plans of standard SQL queries into HorseIR and compiled the generated HorseIR code using various compiler optimization strategies developed for array-based languages. Using arrays to represent database columns, HorseIR follows conceptually the data model of column-based DBS, which has been proven to be effective for data analytics tasks.

HorsePower extends the idea to a full-fledged execution environment for data analytics. Additionally to supporting plain SQL queries, HorsePower also supports functions written in MATLAB, a popular high-level array language widely used in the field of statistics and engineering. HorsePower can take stand-alone functions written in MATLAB and translate them to HorseIR, of have these functions be embedded in SQL queries and then translate all into a single HorseIR program, before optimizing and compiling the code in a holistic manner.

As such HorsePower avoids the overhead of inter-system data movements as it has a single execution environment, and eliminates the barriers between SQL queries and analytical functions allowing optimizations across both the declarative and functional parts of the query.

The contributions of this paper are thus as follows:

- We present HorsePower, an advanced analytical system, that extends the approach proposed in [5] to not only offer a compiler-based execution environment for SQL queries, but also for programs written in the array-based language MATLAB and for SQL queries with embedded UDFs.
- HorsePower uses a holistic approach of exploiting array-based compiler optimization techniques for both SQL and MATLAB taking advantage of the conceptual similarities of columns and arrays.
- The performance of HorsePower is shown through an extensive set of experiments on programs written in MATLAB, and SQL queries with embedded UDFs.

2 BACKGROUND

2.1 HorseIR: an Array-based IR for SQL

Recent years have seen the development of modern query compilers that translate an SQL query into an intermediate representation (IR) before target code is generated from the IR, making it possible to leverage any existing code optimizations available within the IR platform.

In this context, HorseIR [5] was developed as a high-level IR specifically for database applications [7]. Being an array-based IR, it is relatively straightforward to generate basic HorseIR code following the execution plans developed by column-based DBS, as the operators executing on entire columns can be translated to functions executing on vectors in HorseIR. In fact, Chen et al. [5] took the execution plans generated by the column-based database system HyPer [11], that incorporate a wide range of traditional DBS optimizations, as the input for generating HorseIR programs.

In this regard, HorseIR provides a rich set of array-based built-in functions to which one can map the standard database operations. Moreover, the HorseIR compiler provides vital optimizations over these array-based operations. For example, *loop fusion* merges multiple loops into one loop, allowing for an intuitive merge of chained operations and

```
SELECT SUM(l_price * l_discount) AS RevenueChange
FROM lineitem WHERE l_discount >= 0.05;
```

```
module ExampleQuery{
 def main(): table{
  ...
  // assume t1, t2 are references to l_price/l_discount columns
  t3:bool = @geq(t2, 0.05);
  t4:f64  = @compress(t3, t1);
  t5:f64  = @compress(t3, t2);
  t6:f64  = @mul(t4, t5);
  t7:f64  = @sum(t6);
  ...}}
```

Figure 1: Example query and its HorseIR program

thus, avoiding intermediate results. Thus, optimizations developed for array-based programming languages can be exploited to improve query performance.

Example The top of Figure 1 shows a simplified version of Query 6 of the TPC-H benchmark [16] computing the change in total revenue given prices and discounts from the table `lineitem`. A basic translation into a HorseIR program prior to performing any optimizations is shown at the bottom of Figure 1, outlining only the part of the code that performs the actual relational operators. We assume that arrays `t1` and `t2` represent the price and discount columns. The program computes the WHERE condition (`@geq`), which returns a boolean vector of the same length as `t2` with `true` values in all rows that fulfill the condition. The function `@compress` then extracts from both `t1` and `t2` the rows for which the boolean vector has a `true` value. The output are "compressed" vectors with relevant rows, over which then the aggregation is performed in two steps.

HorseIR Optimizations As can be seen, such an approach can generate a fair amount of intermediate results (arrays `t3` to `t6` in the example). If lines 5 to 9 are translated to lower-level code independently, each of them generates its own `for` loop over the corresponding arrays. However, array-based optimization techniques, including loop fusion, and some pattern-based optimizations developed specifically for the operator sequences found in SQL statements, allow the HorseIR compiler to fuse these loops to just one loop to avoid materializing these intermediate vectors. To do such fusion, HorseIR first builds a data dependence graph across all the statements. Statements which can be fused or follow a pattern, are then identified by a well-defined data flow analysis, and compiled together to efficient C code. For our example, the resulting sequential C code would look similar to

```
...
revenue = 0;
for(i = 0; i < numRows; i++)
{ if(t2[i] >= 0.05) revenue += t1[i] * t2[i]; }
...
```

Although the example C code does not convey it explicitly, behind the scenes, HorseIR uses OpenMP to compile the program into a parallel implementation, as outlined in [5].

2.2 Traditional Database UDFs

A UDF is a high-level language function embedded within an SQL statement, and is used to offload partial computation into are more concise language than SQL, or provide additional functionality. To support UDFs, the database system integrates the language runtime environment into the DBS (such as the Python interpreter in MonetDB [13]). We will focus only on *Scalar UDFs* and *Table UDFs*, as

```
FUNCTION RevChangeSclr(price,discount)
  RETURN price * discount;
END
```

```
SELECT SUM(RevChangeSclr(l_price,l_discount)) AS RevChange
FROM lineitem WHERE l_discount >= 0.05;
```

Figure 2: Rewriting the example query with a scalar UDF

these are the most commonly employed types of UDFs and also the ones supported presently in HorsePower.

A *scalar UDF* returns a single value per row (which could be a vector) and can be therefore essentially used wherever a regular table column is used, such as the `SELECT` or the `WHERE` clause of SQL queries. Figure 2 shows a scalar UDF which performs the multiplication that was originally part of the `SELECT` clause in Figure 1. In a column-based database system, the execution of such a query first evaluates the `WHERE` clause on `l_discount`, returning a boolean vector. Then, the database applies the corresponding boolean selection on columns `l_discount` and `l_extendedprice`, returning compressed vectors containing the rows where the boolean vector was true. These columns are then given to the UDF as arrays, and the UDF performs an element-wise multiplication on them and produces a result array. This is then the input to the `SUM` operator. Thus, the UDF is only called a single time and works on entire arrays.

A *table UDF* returns a table-like data structure, and thus, is typically called within the `FROM` clause of an SQL statement, similar to regular database tables. For an example of a table UDF, we refer to a technical report [6].

Introducing UDFs into queries can bring performance issues. If the data types used by the two execution environments are different, this can introduce a conversion overhead when exchanging data. Further, as UDF languages are typically black-boxes to the database engine, cross optimization attempts are minimal, resulting in sub-optimal execution plans.

3 HORSEPOWER

In this section we present HorsePower, a system designed for the code generation and optimization of HorseIR generated from (1) SQL queries, (2) MATLAB programs, and (3) SQL queries with analytical functions written in MATLAB.

3.1 SQL to HorseIR

While prior work used HyPer's execution plans [11] to translate SQL to HorseIR, HorsePower uses MonetDB's execution plans, as MonetDB supports UDFs and the execution plans contain the relevant UDF information. Our implementation first translates the tree-based plans to JSON objects that are then translated to HorseIR[1].

Furthermore, HorsePower supports a wider range of SQL queries than [5], which did not properly support multi-join queries. This includes all queries of the TPC-H benchmark [16].

3.2 MATLAB to HorseIR

MATLAB is a sophisticated dynamic language which provides numerous flexible language features. In order to transform MATLAB code to HorseIR, as an intermediate step,

[1]HorsePower could generate it own execution plans. However, as the traditional query optimization techniques are not the focus of our research, we preferred to integrate the already optimized execution plans generated by existing DBS.

HorsePower calls upon the McLab framework [2] which translates MATLAB programs to its own internal IR, called TameIR, handling MATLAB's many dynamic features and lack of strict typing. Type and shape information for all variables in the program are automatically derived. Furthermore, class program analysis steps, such as constant propagation, are performed to produce optimized TameIR code [9]. TameIR can represent MATLAB's matrix and high-dimension arrays, and currently supports an essential subset of MATLAB array operations.

HorsePower then translates TameIR code to HorseIR. So far, this translator supports a core subset of MATLAB features and built-in functions. It preserves MATLAB pass-by-value semantics but automatically switches to pass-by-reference when it determines that the input parameters are not modified, avoiding data copies. It supports the common control structures `if-else` and `while` with a restriction on the condition which must be a single boolean element. While explicit loop iteration is not supported, MATLAB's array-based built-in functions (which have implicit loop execution) are translated in a straightforward way as similar functions exist in HorseIR. All types supported by TameIR are also supported by HorseIR, however, due to type rule mismatches, input types for some operators are restricted (e.g. because *integer + double* returns integer in MATLAB, but double in HorseIR). Finally, the translator requires MATLAB arrays to have the data layout of `1-by-N` instead of `N-by-1`, as the former one is more cache-friendly in MATLAB.

3.3 SQL and UDF to HorseIR

HorsePower supports SQL queries with embedded UDFs written in MATLAB. As described in Section 3.1, HorsePower uses execution plans generated by MonetDB, which contain hooks into UDFs with their names, and input and output parameters, but otherwise treat the UDFs as a black-box. HorsePower translates such a plan to HorseIR, where the invocation of the UDF is translated to a method invocation in HorseIR. Next, we generate a separate piece of HorseIR code by translating the UDF written in MATLAB using the MATLAB-to-HorseIR translator introduced in Section 3.2. Finally, the two segments of code for SQL and UDFs are integrated into a single HorseIR program.

HorsePower supports both scalar and table UDFs. In order to make the MATLAB functions conform to the semantic form expected of these types of UDFs, we enforce some restrictions on the MATLAB functions. For instance, we require a function to have one return statement with either a single vector (for scalar UDFs) or a table-like data structure (for table UDFs).

Figure 3 shows the HorseIR program for the example query in Figure 2 with a scalar UDF. The HorseIR code consists of a module with two methods: the SQL component is translated to the main method, and the UDF is translated to the method `RevChangeSclr` which takes two arrays of type float as input and returns the resulting product. This method is called by the main method, which otherwise is the same as we have already seen in Figure 1.

3.4 Holistic HorsePower Optimizations

HorsePower performs compiler-based optimizations when translating a HorseIR program to target C code. We have discussed in Sec. 2.1, how *automatic loop-fusion* and *pattern-based*, as introduced in [7] lead to efficient parallel C code.

```
1  module ExampleQuery{
2    def RevChangeSclr(price:f64, discount:f64): f64{
3       x0:f64 = @mul(price, discount); // S5
4       return x0;
5    }
6    def main(): table{
7       ...
8       // compute revenue change
9       t3:bool= @geq(t2, 0.05:f64);     // S0
10      t4:f64 = @compress(t3, t1);      // S1
11      t5:f64 = @compress(t3, t2);      // S2
12      t6:f64 = @RevChangeSclr(t4,t5); // S3
13      t7:f64 = @sum(t6);               // S4
14      ...
15 }}
```

Figure 3: HorseIR code for the Query in Figure 2

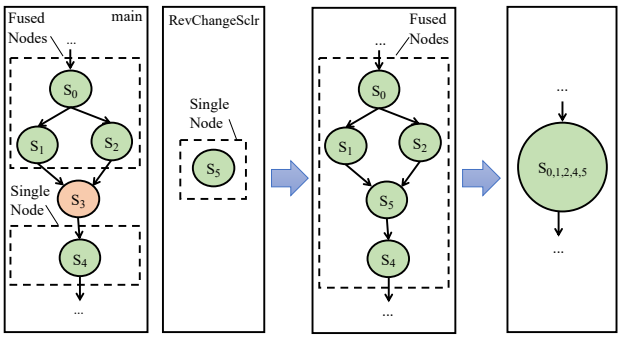

Figure 4: Dependence graphs for the example in Figure 3

However, such optimizations require all statements to be in one method. But when SQL statements have embedded UDFs, the HorseIR code has at least two methods, with a main method calling the method representing the UDF as shown in our example in Figure 3.

If we were to optimize both parts independently using loop fusion and pattern-based fusion, the overall result would be sub-optimal. In fact, if we look at the dependence graph for this program on the left side of Figure 4 (with S_0 to S_4 depicting the statements in the code), we can see that the optimization opportunities are now separated into three snippets: before, after, and in the method being called in the statement S_3. The snippets have to be optimized individually because the content of the statement S_3 is invisible to the rest of the code. Thus, statements S_1 and S_2 of the main method need to be evaluated and intermediate results `t4` and `t5` cannot be eliminated as the method `RevChangeSclr` requires their actual values to be passed as parameters. Furthermore, the return value of the method needs to be materialized to be assigned to `t6` which is then the input of the statement S_4. This means the potential scope for fusion is significantly reduced leading to more intermediate results.

In order to enable a more holistic cross-optimization, we use the concept of *inlining*. This involves replacing the method calls within the main method with the corresponding code segments that constitute the method that is being called. For our example program in Figure 3 this means the code of `RevChangeSclr` can be inlined into the main method with the generated HorseIR being almost the same as the one in Figure 1 except for possibly different variable names. As a result, a dependence graph can be built across the main method, as illustrated on the right side of Figure 4, allowing for loop fusion across all statements and generating a single loop of all tasks as outlined in Section 2.1, and avoiding the

materialization of any intermediate results introduced by UDF invocations.

In some scenarios method inlining offers additional optimization opportunities, such as the elimination of unused computations. For example, consider a scenario where a table UDF computes and returns two columns as part of its invocation, but the enclosing SQL query itself uses only one of those two columns. HorsePower will employ the *backward slicing* technique [15] to avoid the computation of the unused column in the table UDF.

While performing inlining, to respect the pass-by-value convention for parameter passing, a copy of the object used as the parameter will be generated if the parameter is found to be modified inside the original callee method. This ensures that inlining does not result in any unintended data modifications to the objects inside the method that was making the call. Further, if inlining results in any variable name conflicts, they are resolved by assigning new but unique variable names. Finally, an inlined method is removed if it can be inlined in all the code locations where it is called.

4 EVALUATION

In this section we present the evaluation result of our framework for pure MATLAB programs, and for SQL queries with analytical UDFs written in MATLAB. For the latter, we compare it with MonetDB.

The experiments are conducted on a server equipped with 4 Intel Xeon E7-4850 2.00GHz (total 40 cores with 80 threads, and 24 MB of shared L3 CPU cache) and 128 GB RAM running Ubuntu 18.04.4 LTS. We use GCC v8.1.0 to compile HorseIR source code with optimization options `-O3` and `-march=native`; MonetDB version v11.35.9 (Nov2019-SP1) and NumPy v1.13.3 along with Python v2.7.17 interpreter for embedded Python support in MonetDB; and MATLAB version R2019a.

The response time is measured only for the core computation, and excludes the overhead for parsing SQL, plan generation, compilation, and serialization for sending the results to the client. We only consider execution time once data resides in the main memory. We run each test 15 times but only measure the average execution time over the last 10 times. Scripts and data used in our experiments can be found in our GitHub repository[2].

4.1 MATLAB Benchmarks

We first evaluate MATLAB programs in order to understand the performance of using HorsePower for executing non-SQL based data analytics, and use the following benchmarks: the `Black-Scholes` algorithm from the PARSEC benchmark suite v3.0 [4] having two UDFs *BlackScholes* and *CNDF*, and the `Morgan` algorithm [8] from a finance application having a main function *morgan* and another function *msum*. Both contain several element-wise functions and are fully vectorizable.

In our experiments, we compare the following:

- We execute the original MATLAB program using the MATLAB interpreter with default settings.
- We compile the HorseIR program generated from the MATLAB code into C code without any of the optimizations that we mentioned in Section 3.4. We refer to this version as HorsePower-Naive. As such, it is likely to produce a similar amount of intermediate results as the MATLAB interpreter.

[2] https://github.com/Sable/edbt21-analysis

Table 1: Speedup of HorsePower over MATLAB in execution time using Black-Scholes (in milliseconds)

Size	MATLAB	HorsePower			
		Naive	Speedup	Opt.	Speedup
1M	61	66	0.92x	7	9.34x
2M	145	137	1.06x	14	10.17x
4M	491	463	1.06x	49	10.12x
8M	1009	1384	0.73x	117	8.60x

- We compile the HorseIR code into C code with all optimizations enabled, referred to as HorsePower-Opt.

Table 1 shows the execution times for MATLAB and for the two HorsePower versions with different sizes of the Black-Scholes tables. We also indicate the speedup of HorsePower over MATLAB in execution time. Note that the MATLAB interpreter uses all physical threads. For HorsePower, we used 40 threads.

The execution times for MATLAB and HorsePower-Naive are similar, with slightly better performance for MATLAB, probably due to MATLAB having more efficient library functions. When comparing with HorsePower-Opt, MATLAB is significantly slower. The reason is that HorsePower-Opt optimizations, in particular loop fusion, are able to avoid many intermediate results. We also observe that the size of the data set plays a minor role.

For Morgan (no table shown due to space limitations) we run experiments up to 8 million rows as well. HorsePower-Naive also provides similar performance to MATLAB with smaller data sizes, but already has a speedup of 2 with 8 million rows. We believe the reason is our efficient parallel implementation of built-in functions, such as the cumulative sum. Again, the optimized version is significantly faster, with a speedup of 7 with 8 million rows.

In summary, HorsePower can execute data analytics tasks in an efficient manner due to its data-centric IR and compiler optimization techniques.

4.2 SQL and UDF Benchmarks: TPC-H

This is the first of two sections to evaluate the performance of HorsePower in executing SQL statements with embedded UDFs, and comparing it with MonetDB.

Froid [14] proposed a whole range of queries derived from the TPC-H benchmark in which part of the SELECT or WHERE clauses, e.g., to check certain conditions, are outsourced into a UDF. In all cases, these are scalar UDFs. For instance, they propose a variation of the q6 of the TPC-H benchmark, which is very similar to our example query of Figure 1, simply containing more conditions.

For MonetDB, we rewrote the queries to use Python-based UDFs, for HorsePower, the UDFs are written in MATLAB. The structure of the programs is very similar for both languages. Some of the proposed UDFs have embedded SQL statements which are currently not supported by the McLab framework that we use. Thus, we excluded those unsupported queries and present results only for queries q1, q6, q12, q14, and q19.

Table 2 shows the execution times of these queries with a different number of threads using HorsePower and MonetDB. When first looking only at MonetDB we can see that execution times are relatively low for some queries and improve with an increasing number of threads considerably (q1 and q14), but are high for others with little benefit of parallelization (q6, q12, q19). The reason is that in these queries, the UDF is in the WHERE clause and MonetDB

Table 2: Speedup (SP) of HorsePower over MonetDB in execution time using the modified TPC-H benchmarks with UDFs

Thread	MonetDB (ms)					HorsePower (ms)									
	q1	q6	q12	q14	q19	q1	SP	q6	SP	q12	SP	q14	SP	q19	SP
T1	16853	48832	137195	1040	69045	3799	4.44x	392	125x	900	152x	904	1.15x	858	80.5x
T8	5724	47775	143714	773	72124	3316	1.73x	56	853x	300	479x	396	1.95x	364	198x
T32	2502	44636	140438	750	64267	1883	1.33x	45	1000x	170	826x	216	3.48x	209	307x

has to perform costly data conversion when sending the entire database columns as arrays to the Python interpreter in order to execute the UDF. MonetDB is able to use zero-copy transfer for data types where the database system uses the same main-memory representation as Python. But for strings, it needs to convert the data to a different format as the database internal and the Python formats are incompatible. This data conversion seems to not be parallelized to multiple threads, making it the predominant factor of the execution. In q1 and q14, the UDFs are in the SELECT clause (where data sizes are smaller as they got reduced due to the selection that was already executed), and do not require any string conversions.

HorsePower has overall much better performance for all queries, being under 1 second for all queries except q1, and can always improve execution times by increasing the number of threads. As no data conversion is necessary it is orders of magnitude faster than MonetDB for queries q6, q12, and q19. We observe the advantage of having a unified execution environment that has translated both the UDF part and the SQL part to a single HorseIR program with its own data structures. But we also observe significant improvements for q1 and q14. These are due to the unified optimization across the HorseIR code generated from SQL and UDF.

4.3 SQL and UDF Benchmarks: MATLAB

In this second experiment, we embed the Black-Scholes algorithm in form of UDFs into SQL queries.

We again have a HorsePower version, with the Black-Scholes UDF implemented in MATLAB, and a MonetDB version, with the UDF implemented in Python UDF using the NumPy library and the same array programming style as the MATLAB UDF.

In order to understand the implication of having the UDFs written in different programming languages, we first compared the execution time of Black-Scholes written in Python and using HorseIR (both naive and optimized). Execution is in one thread because NumPy does not support multi-threading. Similar to what we have seen with our analysis with MATLAB, a naive usage of HorseIR provides similar execution time as Python (around 500 ms); performing optimizations achieves a speedup of 2.

In order to look at the impact of embedding this UDF into SQL statements, we created both scalar and table UDF variations as well as designed several enclosing SQL statements that offer different potential for optimizations. In particular, we created a *scalar UDF* that returns just the computed `optionPrice` to the calling SQL.

```
CREATE SCALAR UDF bScholesUDF(spotPrice, ..., optionType)
{
  import blackScholesAlgorithm as bsa
  return bsa.calcOptionPrice(spotPrice, ..., optionType)
};
```

Furthermore, we implemented the solution as a *Table UDF*, which returns in table form the computed `optionPrice` along with the associated `spotPrice` and `optionType` which are columns from the original input table.

In order to have a broad set of tests and comparisons, we first integrated these two UDF versions into a straightforward base query. From there we created three significant variations of this base query that had different columns in the `SELECT` and `WHERE` clauses. Furthermore, the selectivity of WHERE clause can be high (returning few records) or low (having many qualifying records).

Table 3 shows the result of all the variations for MonetDB and HorsePower for 1 thread (T1) and 64 threads (T64).

Base query. The base query `bs0_base` selects all the data from the database table and passes it to the UDF and returns all the data produced by the UDF.

```
-- Base query, bs0_base, Scalar UDF
SELECT spotPrice, optionType,
  bScholesUDF(spotPrice,...,optionType) AS optionPrice
FROM blackScholesData;

-- Base query, bs0_base, Table UDF
SELECT spotPrice, optionType, optionPrice
FROM bScholesTblUDF ((SELECT * FROM blackScholesData));
```

We first observe that for MonetDB multi-threading has little impact on its performance while HorsePower benefits a lot. As Python is not multi-threaded, the Black-Scholes UDF in MonetDB runs always in a single thread even if 64 threads are enabled, while HorsePower creates optimized parallel also for the Black-Scholes part. But HorsePower is already significantly better with a single thread. We then find that HorsePower has even significant benefits with a single thread. In fact, HorsePower's execution time for the entire query is nearly the same as executing the Black-Scholes algorithm alone, while MonetDB takes nearly double the time (> 900 ms) to execute the entire query than the time used by the Python interpreter to execute Black-Scholes (around 500 ms). The reason for this performance penalty in MonetDB must be the communication between its SQL engine and the Python UDF interpreter.

Variation 1. The first variation `bs1_*` applies a predicate condition on `spotPrice`, a column which is actually part of the input database table. The objective of this test case is to analyze if the systems can intelligently avoid performing the UDF computation on records that will not be in the result set. As can be seen, for one thread, HorsePower's speedup over MonetDB is at least 3.5x for both scalar and table UDFs, and for 64 threads at least 50x. MonetDB follows the traditional database optimization technique of applying high selectivity operations first, discarding the records that do not qualify before processing the UDFs. As HorsePower relies on MonetDB for database execution plans, it is similarly impacted by the plans generated by MonetDB for table UDF based queries. This results in HorsePower's own table UDF based queries costing more than its scalar versions. However, unlike MonetDB, HorsePower benefits from being able to avoid data copies and conversions as well as from generating parallelized code for UDFs, thus expanding this performance gap when the number of threads increases.

Variation 2. In the next variation, `bs2_*`, the SQL does not include the computed column `optionPrice` in the final

Table 3: Performance comparison between HorsePower (HP) and MonetDB (MDB) for variations in Black-Scholes.

UDF	Selectivity	Table UDF (ms)						Scalar UDF (ms)					
		T1			T64			T1			T64		
		MDB	HP	Speedup	MDB	HP	Speedup	MDB	HP	Speedup	MDB	HP	Speedup
bs0_base	100.0%	927.5	249.8	3.71x	774.0	7.09	109x	670.0	249.5	2.69x	696.5	7.06	98.6x
bs1_high	0.2%	926.4	256.2	3.62x	818.0	7.62	107x	6.10	0.32	19.1x	6.55	0.13	50.4x
bs1_low	99.8%	929.7	266.4	3.49x	832.9	14.6	57.0x	725.4	169.6	4.28x	645.4	4.90	132x
bs2_high	0.2%	895.6	4.67	192x	791.5	0.70	1131x	4.29	4.59	0.93x	3.52	0.63	5.59x
bs2_low	99.8%	916.4	11.0	83.7x	820.4	6.64	124x	15.9	10.95	1.45x	5.11	5.95	0.86x
bs3_high	10.0%	911.8	259.0	3.52x	824.4	10.1	81.6x	673.8	179.3	3.76x	623.2	7.69	81.0x
bs3_low	90.0%	879.1	262.5	3.35x	793.6	13.7	57.8x	685.4	182.6	3.75x	641.7	12.8	50.1x

result. A smart system should be able to analyze the semantics of the request and avoid processing the UDF both together. MonetDB is able to do the optimization when the SQL query is using the scalar UDF, avoiding the computation of the `optionPrice` column that is not included in the final result. Similarly, HorsePower, being an integrated system, can avoid the computation of `optionPrice` by using a backward slice. As both avoid executing the UDF, HorsePower has only moderate speedup over MonetDB due to other optimizations. However, with a table UDF, MonetDB is unable to avoid this computation as there is no way for it to pass this optimization information to the UDF interpreter. On the other hand, HorsePower uses method inlining and backward slicing to remove this computation, offering a huge advantage.

Variation 3. The last variation, `bs3_*` applies a predicate condition on `optionPrice`. As this is a column computed by the UDFs, both the systems have to process the UDFs across all input records before discarding records that do not qualify, providing limited opportunities for optimization. As can be seen, HorsePower has speedups of around 3.5x for both scalar and table UDFs with one thread and between around 50x and 80x for 64 threads. HorsePower has better performance than MonetDB simply because HorsePower can avoid the data movement between the UDF. With more threads, HorsePower's speedup is even better as the data movement in MonetDB is not parallelized and takes most of the time in the whole execution pipeline.

In summary, HorsePower avoids the problems of a black-box integration of programming language execution environments as used in current DBS. As such, it avoids expensive data conversions, can optimize in a holistic manner and provides full support for parallelization, leading to significant speedups.

5 RELATED WORK AND CONCLUSIONS

Intermediate representations and compiler techniques have been applied by others to improve the performance of database queries. However, there is little research in these systems extending to support UDFs within the database queries.

Froid [14] shows a holistic optimization solution by transforming simple UDF to relational code. Thus, the existing query optimizer can be utilized for the optimizations of the execution plan. However, this approach is limited as not all UDFs are translatable to a relational operator.

Weld [12] presents its IR (WeldIR) to support the code generation from various source languages. WeldIR is able to handle database queries and call UDFs written in C code. However, in contrast to HorsePower that automatically optimizes across different source languages, such capabilities have not been implemented by Weld.

Lara [10] is a domain-specific language tailored for relational algebra and UDFs. Its code is first compiled to an IR which is able to inspect UDFs by collecting necessary information from UDFs. Thus, Lara can optimize such transparent UDFs together with its IR code. This is different from our HorsePower which compiles database queries and UDFs to its common IR with holistic optimizations enabled.

In conclusion, `HorsePower` differs from previous work in that it is a compiler-based approach exploiting array-based optimizations to support database queries, MATLAB programs and database queries with analytical UDFs in a holistic framework. Given the very promising evaluation results, future work will integrate different programming languages, and enhance our relational operators.

Short Paper

Robust and Memory-Efficient Database Fragment Allocation for Large and Uncertain Database Workloads

Rainer Schlosser*

ABSTRACT

Database replication and query load-balancing are mechanisms to scale query throughput. The analysis of workloads allows load-balancing queries to replica nodes according to their accessed data. As a result, replica nodes must only store and synchronize subsets of the data. However, balancing the load of large-scale workloads evenly while minimizing the memory footprint is complex and challenging. State-of-the-art allocation approaches are either time consuming or the resulting allocations are not memory-efficient. Further, partial replication approaches usually optimize only against a single fixed workload. If the actual workload deviates from this expected one, load-balancing can be highly skewed, resulting in severe performance degradation.

This paper proposes a novel approach to compute memory-efficient fragment allocations that enable balancing multiple potential future workloads. Applied on the TPS-DS benchmark and a large-size enterprise workload, we show that, compared to state-of-the-art allocations, our solutions are (i) more flexible, (ii) require up to 50% less data, (iii) have competitive runtimes, and (iv) are more robust against uncertain out-of-sample workloads.

1 INTRODUCTION

Increasing demand for database processing capabilities can be managed by scale-out approaches, using additional servers. Analyses of enterprise workloads have shown that both OLTP and OLAP are read-dominant [9]. Database replication is an approach to scale-out read-only queries, which can be executed on snapshots of a primary server without violating consistency [4].

Given that most queries require only a limited set of tuples and attributes, partial replication is an efficient approach: Instead of duplicating all data to all replica nodes, partial replicas store only a subset of the data while being able to process a large workload share. Thereby, splitting the overall workload evenly among the replica nodes is essential to scale the query throughput linearly with the number of nodes. Partial replication consists of two steps, which are typically separated from each other to better deal with the problem complexity [11]. First, the data set is partitioned horizontally and/or vertically into disjoint data partitions/fragments. Second, the individual fragments are allocated to one or multiple nodes.

This paper addresses the second step, i.e., a fragment allocation problem (given a fixed data partitioning). Calculating efficient fragment allocations that minimize the replicas' memory consumption while evenly balancing the query load is challenging, because the data allocation and the workload distribution are mutually dependent. As the calculation of optimal allocations is an NP-hard problem, heuristic approaches have to be used for large problem sizes. Rabl and Jacobsen propose a greedy allocation approach with short computation times [12]. We have previously proposed a decomposition approach [5] based on linear programming (LP), which calculates allocations with up to 23% lower memory consumption for the TPC-H benchmark.

Allocations for larger workloads are harder to solve, but typically offer greater potential for sophisticated approaches compared to simple heuristics. However, when using the LP-based decomposition approach for larger problems, computation times increase, and problems may finally become practically intractable, e.g., for an application in dynamic settings, in which model inputs change and quick recalculations are required. Considering multiple potential workloads to increase an allocation's robustness increases the problem complexity even further. However, such robustness is necessary in practice, when workloads fluctuate, and query costs or frequencies cannot be predicted precisely.

The goal of this paper is to overcome the limitations of existing allocation approaches. Applied to TPC-DS and a real-world accounting workload, we show that the greedy rule-based heuristic [12] is not memory-efficient, while the solver-based solution [5] provides low robustness against diversified workloads and has unacceptable runtimes to be used in practice. To fill this gap, we propose a heuristic LP-based clustering approach to *flexibly combine robustness, memory-efficiency, and a short calculation time* for large-scale problems. Our *contributions* are the following:

First, we derive robust and memory-efficient fragment allocations, which enable an even load balancing against multiple potential future workloads. Second, exploiting the skewness of workloads, we use partial clustering techniques to compute solutions for large-scale workloads quickly. Third, for the TPC-DS and a large real-world workload, we show that, with our techniques, the trade-off between memory-efficiency, robustness, and a short calculation time can be smoothly balanced in a targeted way. Fourth, we verify the robustness of our allocations by confronting them with unseen out-of-sample workloads.

2 FRAGMENT ALLOCATION PROBLEM AND LIMITS OF EXISTING APPROACHES

2.1 Problem Description and Difficulty

The scale-out of workloads to partially replicated databases leads to a coupled data assignment and workload distribution problem. We consider a horizontally and/or vertically partitioned database consisting of N disjoint fragments.

The workload input can be described as follows. We consider the case where data (fragments) can be stored on K nodes to distribute a given workload. The size of a fragment i is a_i, $i = 1, ..., N$. Further, we consider a set of Q queries j, characterized by fragments accessed, i.e., $q_j \subseteq \{1, ..., N\}$, $j = 1, ..., Q$. We assume that the costs of queries j are independent of the executing node k, $k = 1, ..., K$, and determined by c_j, $j = 1, ..., Q$. Query costs are numerical and can, e.g., be modeled as average processing times. We assume that the queries j occur with a given frequency f_j, $j = 1, ..., Q$. The total workload costs C are $C := \sum_{j=1,...,Q} f_j \cdot c_j$.

*Both authors contributed equally to this research.

The allocation problem can be described as follows. The goal is to decide (i) on which node to put which fragments and (ii) which query is executed at which node to which extent (workload share). Our objective is to *minimize* the total amount of data at all nodes such that the workload can be evenly distributed between them. Further: (i) A query j can only be executed at node k if all relevant fragments are stored on node k. (ii) For each of the Q queries, the workload shares, assigned to the different nodes, have to sum up to one. (iii) At each of the K nodes, the workload share has to be $1/K$ such that the overall query throughput can be scaled. (iv) Further, as high calculation times may limit the applicability in practice, we want to compute optimized allocations quickly. (v) The allocation should work for multiple given workload scenarios and should be robust against new unseen ones.

2.2 Existing Fragment Allocation Approaches

2.2.1 Optimal Solution via Linear Programming. For a single given workload, the described fragment allocation problem can be formulated as a linear mixed integer problem, cf. [5, 12]. However, the complexity of the linear program quickly increases with the number of queries (Q), fragments (N), and nodes (K). For this reason, the optimal solution can only be derived as long as the size of the problem is sufficiently *small*.

2.2.2 Greedy Heuristic. Rabl and Jacobsen [12] start to assign queries with the largest workload share and accessing the most data. Queries are ordered by the product of the workload share and the total size of accessed fragments. A query is assigned to the node with the largest overlap of already allocated fragments and those accessed by the query. Nodes with no assigned queries are thereby treated as if they have a complete overlap. If a query's workload share exceeds the assigned node's load capacity, the node is filled up to its limit. The query with its remaining workload is merged back into the list of queries and assigned later.

2.2.3 LP-Based Decomposition. We proposed to iteratively *split* the workload into smaller workload packages (chunks) such that the data redundancy is minimized in each step [5]. In a split with B subnodes, each subnode b represents n_b final nodes, $b = 1, ..., B$, and takes the workload share $w_b := n_b/K$. The special case $B = K$ corresponds to the optimal solution, cf. Section 2.2.1. The workload splits are obtained using small-sized LP *subproblems* similar to the LP structure of optimal solutions. In the LP, the following variables are used: The binary variables $x_{i,k} \in \{0, 1\}$, $i = 1, ..., N$, $k = 1, ..., K$, indicate whether fragment i is allocated to node k (1) or not (0). The binary variables $y_{j,k} \in \{0, 1\}$, $j = 1, ..., Q$, $k = 1, ..., K$, indicate whether query j can run on node k (1) or not (0). The continuous variables $z_{j,k} \in [0, 1]$, $j = 1, ..., Q$, $k = 1, ..., K$, represent the workload share of query j executed at node k. The sum of shares has to sum up to one for all queries. Further, by W/V, the *replication factor* is denoted, where the total amount of data used

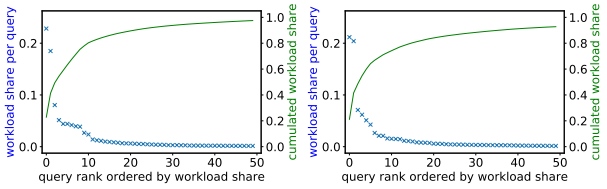
$$W := \sum_{i=1,..,N,k=1,...,K} x_{i,k} \cdot a_i \tag{1}$$

is normalized by the amount of overall accessed data

$$V := \sum_{i \in \bigcup_{j=1,...,Q: f_j > 0} \{q_j\}} a_i. \tag{2}$$

2.3 Large and Skewed Workloads

The results of [5] and [12] were shown for the TPC-H benchmark, which consists of $Q = 22$ queries and $N = 61$ fragments/columns. We use the more complex TPC-DS benchmark ($Q = 99$, $N = 425$) and a real-world enterprise workload ($Q = 4\,461$, $N = 344$).



(a) TPC-DS **(b) Accounting workload**

Figure 1: Distribution of top 50 query workload shares in decreasing order, cf. (a) Section 2.3.1 and (b) Section 2.3.2.

2.3.1 TPC-DS Workload. To obtain model inputs, we loaded the tables with scale factor 1 into a PostgreSQL 12.2 database system. We use vertical partitioning with each column as an individual fragment. We deployed single column indices on all primary key columns. Fragment sizes a_i, $i = 1, ..., 425$, are modeled by using the function `pg_column_size()` to calculate the pure value sizes, abstracting from the PostgreSQL page layout with meta-information and padding. In case the column is part of a primary key, the index size increases the associated fragment size. We use the command `pg_table_size(index_name)` to calculate index sizes. We derived query costs c_j as average execution time for query template j with varying parameters. For TPC-DS queries 1, 4, 6, 11, and 74, the set timeout of 120 s was exceeded. Thus, we omitted them in our experiments, resulting in $Q = 94$ queries.

2.3.2 Real-World Accounting Workload. We got access to metadata of an enterprise's central accounting table and a summary of a workload trace against this table in the form of query templates and statistics. The metadata enabled us to derive all required model inputs for calculating fragment allocations using vertical partitioning. The anonymized workload metadata and source code to reproduce the allocations are publicly available online [1]. The analyzed table stores accounting information and has N=344 columns. The summary of the workload trace consists of Q=4 461 SQL templates with aggregated execution properties of individual queries. Thereby, the most important properties for our research are query frequencies f_j (occurrences) and costs c_j, i.e., the average execution time per query (template).

2.3.3 Workload Skewness. Figure 1 shows the distribution of and cumulative query workload shares $f_j \cdot c_j$, $j = 1, ..., Q$. For both workloads, the distribution is *highly skewed*: The queries with the 50 highest workload shares account for more than 97% of the TPC-DS and more than 92% of the real-world workload.

2.4 Limitations of Existing Approaches

To study the suitability of existing approaches, we calculated allocations for TPC-DS and a real-world workload, cf. Section 2.3. For different numbers K, Table 1 summarizes memory consumption and runtime of existing allocations approaches. We used $f_j := 1$, for all $j = 1, ..., Q$. The LP-results of [5] were achieved using the Gurobi solver (version 9.0.0) (single-threaded). For the comparison with [12]'s approach, we implemented their algorithms in Python 3, and declare the runtime as an upper limit (<).

The upper part of both subtables shows the memory consumption (W/V) and required runtime for the optimal solution, cf. W^D without chunking, for up to $K = 6$ (TPC-DS) and $K = 5$ (accounting workload) nodes compared to the greedy heuristic, cf. W^G. We could not compute optimal allocations for larger numbers of nodes K within 8 hours. The optimal replication factors provide a useful reference to verify the quality of heuristic approaches. In this context, we observe that the greedy heuristic requires up to 100% more data than the optimal solution.

Table 1: Advantages and disadvantages of existing approaches: the greedy heuristic [12] (W^G), cf. Sec. 2.2.2, vs. the decomposition heuristic [5] (W^D), cf. Sec. 2.2.3, including optimal solutions, cf. Sec. 2.2.1, (*no decomposition).

(a) TPC-DS; $K = 2, ..., 12$, $N = 425$, $Q = 94$.

K	chunks	$\frac{W^D}{V}$	solve time$_{W^D}$	$\frac{W^G}{W^D}$	solve time$_{W^G}$
2	2	1.126*	1 s	+1%	<0.1 s
3	3	1.205*	9 s	+53%	<0.1 s
4	4	1.298*	43 s	+94%	<0.1 s
5	5	1.393*	407 s	+88%	<0.1 s
6	6	1.457*	1074 s	+100%	<0.1 s

The lower part of the subtables shows the results of the decomposition heuristic compared to the greedy heuristic. The decomposition and greedy approach make it possible to solve the problem for larger K heuristically. We observe that the decomposition approach (W^D) yields better replication factors than the greedy approach (W^G), which requires up to 93% and 87% more data for TPC-DS and the accounting workload, respectively. Further, the decomposition approach performs close to optimal compared to the optimal solution results (for $K \leq 6$, see Table 1a and for $K \leq 5$, see Table 1b). However, the decomposition approach requires high computation times if the problem becomes large, e.g., in the case of the accounting workload. In contrast, the greedy approach is fast and requires only seconds.

2.5 Uncertain Future Workloads

In general, future workloads are not entirely predictable. Thus, a further weakness of existing approaches is that they are only optimized for a single workload and can perform poorly if actual workloads differ. Hence, it is crucial to take potential workload scenarios into account to obtain a robust performance. Potential future workload scenarios can be determined, e.g., based on previously observed (seasonal) workloads or forecasts. In this context, fragment allocations should be such that the workload can be successfully balanced in any scenario. We assume that a workload scenario is characterized by a set of queries with given frequencies and costs within a certain time span.

In [12], Rabl and Jacobsen also describe an extension of their approach to cope with multiple workload scenarios. They propose to calculate a separate allocation for each scenario independently. Individual allocations are merged pairwise, mapping each node of the first allocation to a node of the second allocation. A merged allocation enables an even load balancing for both input allocations. The Hungarian method allows calculating an optimal mapping, which minimizes the memory consumption of the merged allocation (in polynomial time). However, because entire nodes are merged, optimization potential is given away.

Overall, we observe that existing approaches have different strengths and weaknesses (runtime vs. memory-efficiency). Further, from a practical perspective, solutions are required that can provide a *reasonable combination* of (i) memory-efficiency, (ii) robustness against different workloads, and (iii) short runtimes. Our goal is to design a heuristic approach that is of that kind.

3 ROBUST FRAGMENT ALLOCATION FOR MULTIPLE POTENTIAL WORKLOADS

3.1 LP-Based Robust Solution Approach

In the following, we consider S potential workload scenarios. Each scenario s, $s = 1, ..., S$, is characterized by query frequencies $f_{j,s}$ and associated workload costs $C_s := \sum_{j=1,...,Q} f_{j,s} \cdot c_j$, cp. Section 2.1. Note, in this framework, also uncertain query costs c_j can be expressed similarly by using potential scenario-based costs $c_{j,s}$ without increasing the model's complexity.

The core idea is finding a single allocation that enables an even load balancing for all S potential workloads scenarios. Further, by enabling an even load balance for specific diversified scenarios, such enriched allocations also allow improved load balancing for *unseen* scenarios, which may be similar to mixtures of input scenarios. Thereby, an allocation's robustness can be increased by choosing a larger number of diverse scenarios.

Our robust multi-scenario model is an extension of the LP-based decomposition approach, cf. Section 2.2.3, which considers one deterministic workload, cf. $S = 1$. Compared to [5], we use extended variables (cf. z), to model workload shares for each scenario s, $s = 1, ..., S$. Based on the decomposition concept of [5], we propose the following extended LP model to allocate data fragments and to distribute workload shares to multiple nodes in the presence of multiple potential workloads:

$$\begin{aligned} &\textit{minimize} \\ &x_{i,b}, y_{j,b} \in \{0,1\}, z_{j,b,s} \in [0,1], 0 \leq L \leq 1, (\text{given } \bar{x}_i, \bar{y}_j, \bar{z}_{j,s}) \\ &i = 1, ..., N,\ j = 1, ..., Q,\ b = 1, ..., B,\ s = 1, ..., S \end{aligned}$$

$$\frac{1}{V} \cdot \sum_{i=1,..,N, b=1,...,B:\bar{x}_i=1} x_{i,b} \cdot a_i + \alpha \cdot L \tag{3}$$

$$s.t. \quad y_{j,b} \cdot |q_j| \leq \sum_{i \in q_j} x_{i,b}, \qquad \begin{matrix} j = 1, ..., Q : \bar{y}_j = 1 \\ b = 1, ..., B \end{matrix} \tag{4}$$

$$z_{j,b,s} \leq y_{j,b}, \qquad \begin{matrix} j = 1, ..., Q : \bar{y}_j = 1 \\ b = 1, ..., B, \quad s = 1, ..., S \end{matrix} \tag{5}$$

$$\sum_{j=1,...,Q:\bar{y}_j=1} f_{j,s} \cdot c_j / C_s / w_b \cdot z_{j,b,s} \leq L, \qquad \begin{matrix} b = 1, ..., B \\ s = 1, ..., S \end{matrix} \tag{6}$$

$$\sum_{b=1,...,B} z_{j,b,s} = \bar{z}_{j,s}, \qquad \begin{matrix} j = 1, ..., Q : \bar{y}_j = 1 \\ s = 1, ..., S \end{matrix} \tag{7}$$

The overall idea is that the model allocates the fragments such that the workload can be distributed evenly for all workload scenarios s, $s = 1, ..., S$. Note, scenario probabilities are not used and thus do not have to be quantified in advance.

The objective (3) minimizes the replication factor W/V, cp. (1) - (2). Constraint (4) guarantees that a query j can only be executed on node b if all relevant fragments are available, see Section 2.1. The cardinality term $|q_j|$ expresses the number of fragments used in query j. Constraint (5) ensures that a query j can only have a positive workload share on node b in scenario s if it can be executed on node b. Constraint (6) guarantees that,

in all scenarios s, all nodes b do not exceed the workload limit L. Here the workload is normalized by the total workload cost C_s of scenario s and the workload share $w_b := n_b/K$, cf. Sec. 2.2.3. Finally, (7) ensures that a query's workload shares on nodes k sum up to the shares assigned to the chunk, cf. $\bar{z}$. To minimize the worst-case workload share over all nodes and scenarios, in (6) we use a continuous variable L and add a penalty term $\alpha \cdot L$ in the objective (3). Hence, to achieve an even load balance, the parameter α has to be sufficiently large compared to K (e.g., $\alpha = 1\,000$); note, the factor W/V is bounded by K, cf. full replication.

The recursive decomposition principle of the LP (3) - (7) works as follows. Let x^*, y^*, and z^* denote the optimal solution of the LP (3) - (7) for a certain split. Then, for each subnode b, the input for its associated subproblem on the next level is characterized by the selected fragments (i.e., where $\bar{x}_{\bar{i}} := x^*_{i,b}$ is 1), the executable queries (i.e., where $\bar{y}_{\bar{j}} := y^*_{j,b}$ is 1), and the assigned workload shares (i.e., where $\bar{z}_{\bar{j},s} := z^*_{j,b,s}$ is positive). In this context, the top node represents the total workload, initially characterized by $\bar{x}_i := 1$, $\bar{y}_j := 1$, $\bar{z}_j := 1$, for all $i = 1, ..., N$ and $j = 1, ..., Q$. On the next decomposition level, the LP (3) - (7) is applied again for the new input. Recall, that for $B = K$ and $w_b = 1/K$, i.e., without using chunks, the LP guarantees an *optimal* allocation.

3.2 Heuristic Relaxation: Partial Clustering

The complexity of the LP (3) - (7) grows with the number of queries Q, fragments N, nodes K, and considered scenarios S. As a result, runtimes can get too large when considering huge workloads with thousands of queries and dozens of scenarios. While the decomposition heuristic allows dealing with larger numbers K, this does not solve the issue. As S can be chosen in a targeted way, the main limitation of our LP-based concept are large Q and N as they appear in real-world workloads (cf. $Q = 4\,461$, Section 2.3.2). Particularly Q is critical for the LP's complexity as the variables y and z as well as constraints (4), (5), and (7) are involved; instead, N is only relevant for x and does not affect the number of constraints. To still allow for short runtimes, we seek to address this problem by heuristically relaxing our LP.

The analysis of real-world workloads reveals, cf. Section 2.3, that the workload distribution of queries and accessed fragments is highly skewed (see Figure 1). Exploiting this property, we cluster queries and, in turn, simplify the complexity of the allocation problem as follows: (i) The majority of queries that represent only a small share of the workload are clustered within a set denoted by Q^F and assigned to the same node. (ii) The set of remaining (costly) queries denoted by, cf. (i),

$$Q^R := \{1, ..., Q\} \setminus Q^F \tag{8}$$

are used as (a smaller) input for the fragment allocation problem with K nodes, including the replica used for step (i). Following this concept, we propose the following approach.

Partial Clustering Approach: *Order the queries according to their expected loads over all scenarios $s = 1, ..., S$, cf. $E(f_{j,s}) \cdot c_j$ (if no distribution for s is given, we use uniform probabilities).* Then, assign the F queries with the smallest (expected) workload share, i.e., $Q^F := \{1, ..., F\}$, to one (e.g., the first) of the K nodes. Note, the number F has to be sufficiently small such that the workload share of the queries assigned to Q^F is (significantly) smaller than $1/K$. *The remaining workload $Q^R := \{F + 1, ..., Q\}$, cf. (8), has to be allocated to the other $K - 1$ nodes and the residual resources of the first cluster node ($k = 1$). The approach can be directly included in our LP model (3) - (7) via the additional constraints*

$$z_{j,1} = 1 \quad \forall j \in Q^F. \tag{9}$$

Note, the constraints (9) imply $y_{j,1} = 1$ for all $j \in Q^F$, cf. (5), as well as the allocation of all required fragments to the cluster node 1, cf. (4). If chunks are used, (9) is only active for the parent chunk $b = 1$ that is associated to the leaf node $k = 1$. Leaving some space on the cluster node allows the LP to assign other data-intensive queries to that node. Naturally, the LP's complexity decreases in F as we have fewer flexible queries ($Q - F$).

4 NUMERICAL EVALUATION

4.1 Results for a Single Fixed Workload

In this section, we compare the memory consumption and runtime of our partial clustering heuristic, cf. (3) - (9), against existing allocation approaches (see Section 2.2) for a single fixed workload scenario ($S = 1$) with $f_{j,1} := 1$, $j = 1, ..., Q$, for all queries.

4.1.1 TPC-DS Workload. For different numbers of nodes K, Table 2a summarizes the replication factor $\frac{W}{V}$ and runtime of our partial clustering heuristic (3) - (9). We used the penalty factor $\alpha := 1\,000$ and the Gurobi solver (version 9.0.0) (single-threaded).

The partial clustering approach allows reducing runtimes (by F via $|Q^F| = F$ and $|Q^R| = Q - F$) and is compatible with the decomposition approach. The results (Table 2a) show that our approach exploits both heuristics in a mutually supportive way. For instance, while for K=6 (TPC-DS), the optimal solution yields $W/V = 1.457$ in 1074 s, cp. Table 1a, our heuristic solution obtains $W/V = 1.584$ in 6 s. Compared to [12] (W^G) and [5] (W^D) we observe that via F we obtain a convenient mix of memory-efficiency and runtime, which has not been possible before.

4.1.2 Real-World Accounting Workload. We also applied our partial clustering approach for the real-world workload, cf. Section 2.3.2. For the example of $F = 4\,361$ fixed and $Q - F = 100$ flexibly assignable queries (being responsible for about 95% of the workload), Table 2b presents the results of our approach compared to the heuristics [5] and [12]. Compared to Table 1b, our partial clustering heuristic yields a competitive memory-efficiency (cf. $W/W^D < +7\%$) and runtimes below 10 s. Overall, we find that our approach can address both the performance limitations of [12] and the runtime limitations of [5].

Table 2: Best of both worlds: Memory-efficiency vs. runtime results achieved by partial clustering ($S = 1$): Our solution (W) with F fixed queries vs. [5] (W^D) and [12] (W^G).

(a) TPC-DS; $K = 4, ..., 12$, $N = 425$, $Q = 94$

K	F	chunks	$\frac{W}{V}$	solve time$_W$	$\frac{W}{W^D}$	$\frac{W}{W^G}$
4	36	4	1.314	1.3 s	+1.2%	-47.9%
5	47	5	1.501	2.0 s	+7.8%	-42.7%
6	4	3+3	1.584	5.5 s	+4.3%	-45.7%
8	15	4+4	1.957	2.6 s	+4.4%	-36.9%
10	47	5+5	2.330	5.0 s	+12.2%	-30.4%
12	15	4+4+4	2.416	7.0 s	+9.8%	-31.2%

(b) Real-world workload; $K = 4, ..., 12$, $N = 344$, $Q = 4\,461$, cf. source [1]

K	F	chunks	$\frac{W}{V}$	solve time$_W$	$\frac{W}{W^D}$	$\frac{W}{W^G}$
4	4 361	4	2.124	3.8 s	+ 0.9%	-41.9%
5	4 361	5	2.492	8.9 s	+ 0.8%	-35.8%
6	4 361	3+3	2.942	0.9 s	+ 3.0%	-35.1%
8	4 361	4+4	3.534	2.1 s	+ 1.0%	-45.9%
10	4 361	5+5	4.638	4.0 s	+ 3.9%	-40.2%
12	4 361	6+6	5.226	25.2 s	+ 1.2%	-44.5%
12	4 361	4+4+4	5.489	3.3 s	+ 6.3%	-41.7%

With decreasing F, the memory W decreases (improves), because the allocation gets more flexible. However, the runtime increases due to the larger remaining problem size. We observe that if the number of flexibly assigned queries $|Q^R|$ is large, the performance increase due to additional flexible queries is *diminishing* and does not justify the higher runtimes anymore.

Remark 1 *The partial clustering heuristic, cf. (3) - (9), is effective and flexible as it combines: (i) the reduction of problem complexity with workload knowledge and (ii) the possibility to exploit decomposition techniques (cf. Section 2.2.3). Combining these techniques allows balancing the solution quality and computation time in a targeted way such that memory-efficient solutions can be computed within short and plannable response times. Compared to the greedy heuristic (W^G), we find that the combined LP-based approach (W) requires (up to 48%) less data (within a similar computation time). Compared to the decomposition approach (W^G), we obtain solutions orders of magnitude (up to ×10 000) faster (using only slightly more memory).*

4.2 Multiple Workloads and Robustness

In this section, we compare fragment allocations for multiple scenarios, cf. $S > 1$. For workload scenario $s = 1$, we again let $f_{j,1} := 1$ for all queries j. For all other scenarios, we consider randomly generated query frequencies $f_{j,s}$ via $f_{j,s} :=$ if $U(0,1) < p$ then $1/p \cdot U(0,2)$ else 0, i.e., each query occurs only with probability p (cf. workloads with different queries, ad-hoc queries, etc.) and, on average, we have $E(f_{j,s}) = 1$, $j = 1, ..., Q$, $s = 2, ..., S$. In our examples, we use $p = 0.75$. Out-of-sample workloads, cf. $\tilde{s} = 1, ..., \tilde{S}$, for verification purposes are generated in the same way. Scenario-specific input details are available online [1].

4.2.1 TPC-DS Workload. Table 3a shows the results of our combined approach (3) - (9), cf. $W(S)$, for different numbers $F = 0, 15, 47, 62$ of fixed queries and different numbers of seen scenarios S (up to 100). While our approach without fixed queries ($F = 0$) is time-consuming, the partial clustering approach is again effective and allows deriving allocations for dozens of scenarios S quickly. We find that the required amount of data $\frac{W}{V}$ is overall (concave) increasing in S. Our replication factor is still significantly below K (cf. full replication) and (for the same S) far better than those of [12]'s merge approach, cf. $W^G(S)$, Section 2.5.

Moreover, we compared the *robustness* of our approach to the merge approach of [12] by analyzing the allocations' performance for *unseen* workloads. To calculate the worst (highest) workload share over all nodes (denoted by $\tilde{L}$) for a given scenario $\tilde{s}$, we can directly use the LP (3) - (7) without chunking ($B = K$) to evaluate a given fragment allocation $\vec{x}_{fix}$ by fixing the variables $\vec{x} := \vec{x}_{fix}$; (this also determines y, cf. (4)). When solving the LP for a *new* (randomly generated) workload scenario $\tilde{s}$, $\tilde{s} = 1, ..., \tilde{S}$, the remaining variables z and L are then chosen such that L is as small as possible and coincides with $\tilde{L}$. The *average* worst-case workload share over all $\tilde{S}$ unseen scenarios is denoted by $E(\tilde{L})$.

Table 3a shows the results for $\tilde{S} = 100$ unseen randomly generated workload scenarios. If more scenarios are taken into account, cf. S, the robustness improves, while the required amount of data and runtime increase. We observe that the average difference of $E(\tilde{L})$ and $1/K$ over all unseen (out-of-sample) scenarios is (concave) decreasing in the number of seen scenarios S. In our example, considering $S = 10$ (randomly chosen) scenarios were, on average, enough to obtain a fragment allocation that is robust against various unseen workloads by achieving an optimality gap for a node's highest workload share of $E^{(S)}(\tilde{L}) - 1/K \leq 0.0089$,

Table 3: Adding Robustness: Performance comparison with $\tilde{S} = 100$ random unseen workloads for different numbers seen workloads S. Memory vs. average out-of-sample workload limits $\tilde{L}$ of our partial clustering ($W(S)$) compared to the greedy merge approach [12] ($W^G(S)$).

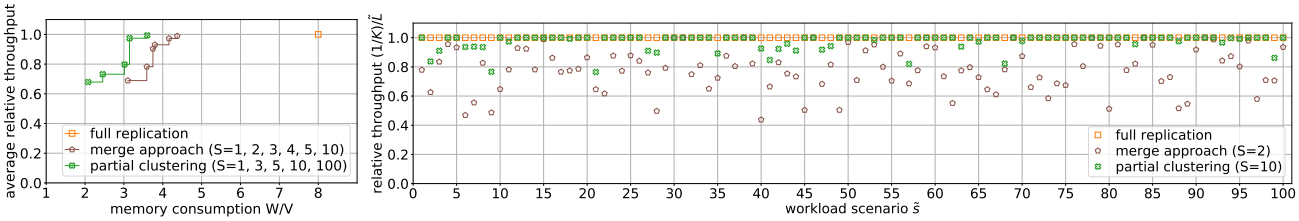
$W^G(S)$	1	/	6.536	<3 s	0.0040	0.971
$W^G(S)$	3	/	6.792	<10 s	0.0013	0.991
$W^G(S)$	5	/	6.913	<16 s	0.0013	0.991
$W^G(S)$	10	/	7.040	<34 s	0.0000	1.000

which is by far better than the standard $S = 1$ solution (cf. $E^{(S)}(\tilde{L}) - 1/K = 0.0641$ for $F = 0$) that optimizes only against the expected load. Naturally, the higher robustness with $S = 10$ is achieved by using more data, i.e., a higher replication factor of 2.721 (in 562 s, $F = 0$) and 3.145 (in 20 s, $F = 47$), instead of 1.874 ($F = 0$) and 2.079 ($F = 47$) when using only one scenario ($S = 1$). Note, compared to achieving robustness via full replication (with $W/V = K = 8$), this is a remarkable result.

Further, we evaluated the robustness of the merge approach, cf. $W^G(S)$, for the same ($\tilde{S}$) unseen workloads. For $S = 5$, we obtained the average worst-case workload limit $E^{(G)}(\tilde{L}) - 1/K = 0.0041$ and replication factor $W^G(S)/V = 4.162$. Compared to that, our $S = 10$ solution with $F = 47$ fixed queries obtains a *better robustness* (cf. $E^{(S)}(\tilde{L}) - 1/K = 0.0037$) and requires *clearly less memory* $W^G(S)/V = 3.145$. The better combinations of memory (W/V) and robustness can be observed over the full range of S. Figure 2a visualizes this result: For selected S, the figure shows the expected throughput (average over $\tilde{S} = 100$ unseen workloads)



(a) Memory consumption vs. average relative throughput over 100 unseen scenarios.

(b) Relative throughput for all 100 unseen scenarios.

Figure 2: Performance of allocation approaches for $\tilde{S} = 100$ unseen workload scenarios based on TPC-DS; $K = 8$.

per memory consumption for full replication, the merge approach, and our partial clustering. For merged allocations with $S = 2$ and our partial clustering with $S = 10$ input scenarios, Figure 2b shows the expected throughput $(1/K)/\tilde{L}$ for all $\tilde{S} = 100$ individual unseen scenarios.

Naturally, the specific results depend on underlying random numbers. However, using repeated simulations, we verified that the overall properties remain.

4.2.2 Real-World Accounting Workload. The results for the real-world workload (see Table 3b) show that our solution also remains applicable for larger workloads. The number of fixed queries F can be chosen such that for up to 20 scenarios, the runtime is below 10 s. A good trade-off (depending on the targets in practice) between robustness, runtime, and memory is achieved for 5 to 20 in-sample scenarios, cf. S.

Compared to the merge approach, cf. $W^G(S)$, we again obtain that our approach clearly outperforms their combinations of memory and throughput robustness against uncertain workloads. Moreover, our approach provides the flexibility to *tune* results by adjusting S and F according to a decision-maker's preferences.

Compared to TPC-DS, we find that, for all S, the optimality gap $E^{(S)}(\tilde{L}) - 1/K$ is on average lower, while replication factors are higher. This difference indicates that, in such cases, a *smaller* number of scenarios might be necessary to obtain a certain robustness. It can be explained by the fact that the workload is distributed over a higher number of queries Q, making the impact of single query frequencies, on average, less important.

Remark 2 *We find that optimizing the memory for an expected workload only is not robust against unseen workloads. Less memory-efficient approaches as [12] and particularly its merge extension are (indirectly) more robust against out-of-sample workloads as they systematically allocate more data. However, our approach to directly minimize required memory for multiple seen workloads, yields a better robustness using the same or even less data. The memory-efficiency of our LP-based approach allows including more scenarios within a certain memory budget than the merge approach [12]. Being able to deal with more representative workload scenarios, in turn, allows to better deal with altered unseen ones.*

5 RELATED WORK

Database replication is a means to improve availability and increase processing capabilities, and is supported in many systems, e.g., in HANA [10], Postgres-R [8], and as replication middleware [3]. Thereby, most systems implement full replication.

To calculate partial allocations, Rabl and Jacobsen propose a greedy algorithm (Section 2.2.2). For the same problem, we propose an LP-based decomposition approach [5] (Section 2.2.3). In both papers, the authors only consider a comparably small benchmark workload (TPC-H) and do neither (i) derive results for large-size workloads, (ii) study techniques to reduce the computation time for allocations, nor (iii) evaluate robustness against uncertain workloads. In [6], we visualize calculated allocations and investigate the intermediate steps taken by different algorithms. In [7], we visualize the load balancing behavior of allocations.

Özsu and Valduriez present a general overview of allocation problems in the field of distributed database systems [11]. They point out that allocation problems differ in constraints and optimization goals, such as performance, costs, and dependability.

Archer et al. [2] address an allocation problem, which is similar to ours. They evenly load-balance queries for web search containing multiple terms, which correspond to the fragments in our model. They cluster queries with a distributed balanced graph partitioning tool.

6 CONCLUSIONS

To overcome the limitations of existing allocation approaches [5, 12], we proposed a novel heuristic that combines different concepts. First, to achieve *memory-efficiency*, instead of rule-based heuristics, we leverage the power of LP techniques. Second, for *short calculation times*, we exploit that (real-world) workloads are skewed and reduce the problem complexity by a partial clustering approach that assigns a majority of queries with comparably small workload shares to a fixed node. Third, to add *robustness*, we force the allocation to be prepared against multiple diversified workloads. Moreover, we are able to balance the three target dimensions of the problem *flexibly*. Using TPC-DS and a large real-world workload, we verified the applicability and effectiveness of our approach, which clearly outperformed existing approaches regarding the mix of the three key dimensions.

ABSTRACT

This paper introduces an effective algorithm, called **TD-AC**, for the truth discovery problem in scenarios where data attributes are *correlated* by distinct levels of reliability of the sources. **TD-AC** is built on an abstract representation of the truth in the data to automatically find an optimal partitioning of the input data using the k-means clustering technique and the silhouette measure. Such a data partitioning strategy ensures to maximize the accuracy of any *base* truth discovery process when executed on each partition. The intensive experiments conducted on synthetic and real datasets show that **TD-AC** outperforms baseline approaches with a more reasonable running time. It improves on synthetic datasets the accuracy of standard truth discovery algorithms by 1% at least and by 14% at most and also significantly when the data coverage rate is high for the other types of datasets.

Truth discovery, attribute, data partitioning, clustering, attribute truth vector, k-means, silhouette index, performance evaluation

1 INTRODUCTION

Dealing with contradictory claims about the same facts is a real concern in many real-world applications such as Web data integration systems [3], online crowdsourcing platforms, online news Websites, social media, etc. Truth discovery resolves such a issue by predicting which of the values provided by conflicting sources is true with no prior knowledge about the level of reliability of the sources. Many approaches [1, 2, 5, 7, 12] for truth discovery have been proposed based on an estimation of the reliability of sources by corroborating their claims under various settings. As in [2], we investigate in this work the truth discovery with attribute partitioning problem that may occur in cases where the attributes over data are structurally correlated so that sources exhibit different levels of reliability on distinct groups of data attributes, as in the setting given in Table 1. Table 1 shows conflicting claims about facts (or data attributes) on two distinct topics (Table 1b) from three sources as depicted in Table 1a. Given the correct answers inside red ellipses, we note that the sources present different levels of reliability according to distinct subsets of facts. For instance, Source 1 is good on Q1 and Q3 while being bad on Q2. Meanwhile Source 2 is good on Q2 and bad on Q1 and Q3. We say that Q1 and Q3 are about data attributes that are *correlated* according to the sources' reliability levels ; *capturing these unknown groups of correlated attributes may help to avoid having a biased truth discovery process.*

The approach in [2] finds the set of correlated data attributes for truth discovery as an optimal partitiioning of the set of input data attributes using various weighting functions over sources' reliability levels themselves estimated by the truth discovery

algorithm. However, the different exploration strategies introduced in [2] are *time-consuming* and *error-prone*. In addition, its different weighting functions do not give any guarantees about the correctness of the returned optimal partition.

This paper revisits [2] and proposes a new more effective and efficient approach to the problem of truth discovery with attribute partitioning. The presented approach, called **TD-AC**, is based on an abstract representation of the truth in the data using the new concept of *attribute truth vector*. Given the set of attribute truth vectors, we rely on *k-means clustering* technique from machine learning domain to find the optimal partitioning of the data attributes. To determine the optimal number of clusters, we assess the homogeneity of the individuals in a clustering result with the help of the silhouette measure. This methodology guarantees to find an optimal partition or a near-optimal one maximizing the accuracy of any base truth discovery process, without an exploration of all the possible partitions. The results of our intensive experiments on synthetic, semi-synthetic and real datasets show that **TD-AC** outperforms approaches in [2], with a more reasonable time cost. On synthetic data, it improves the accuracy of standard algorithms at least by 1% and at most

by 14% and also significantly when the data coverage is high for the other types of datasets.

The remainning of this paper is organized as follow. First, we give some preliminaries and define the studied problem in Section 2. Then, we detail our proposed approach by providing its different building blocks in Section 3. In order to validate our approach, we present in Section 4 the results of our intensive experiments conducted on various types of datasets and a thorough analysis of the obtained results. We briefly review the state-of-the-art truth discovery algorithms in Section 5 before concluding in Section 6 with some research perspectives.

2 CONCEPTS AND STUDIED PROBLEM

This section resumes the key concepts of the truth discovery problem and informally introduces the studied problem.

2.1 DEFINITION OF CONCEPTS

A typical truth discovery process usually assumes a *structured world* where input data consist of a set O of objects corresponding to real world entities. Each object is characterized by a set A of attributes (or properties) with values in V coming from a collection S of data sources. In a *one-truth setting*, every attribute for each object has one true value and several possible false values. Thus, the notion of value confidence C_v is used to assess the level of veracity of every value v. Meanwhile, the level of reliability T_s of a source s (or source accuracy) models its ability to provide true values for given real-world object attributes. In real applications, the confidence scores over provided values and the reliability levels of sources are both often unknown and initialized to default values depending on the setting before being updated during the execution of the truth discovery algorithm. *This work considers groups of attributes over data to be structurally correlated if every source has the same reliability level on these latter.*

2.2 PROBLEM STATEMENT

Given the triplet (S, A, O) in a one-truth setting in which a given source may not cover all the objects or attributes, the truth discovery problem is commonly defined as follows.

Problem 1. *Find, for each object o in O, the true value of every attribute a in A_o amongst its set V_{o-a} of possible values by corroborating claims from sources in S_o where A_o and S_o are the set of attributes of o and the set of sources providinng values for o.*

We informally introduce the truth discovery with attribute partitioning problem as follows.

Problem 2. *Find an optimal partitioning P of A that maximizes the accuracy of any solution for Problem 1 where each partition in P contains correlated data attributes according to sources' reliability levels.*

In next, we propose an efficient clustering based approach to solve Problem 2 when data attributes are structurally correlated.

3 TRUTH DISCOVERY WITH CLUSTERING

This section presents our proposed algorithm, called **TD-AC**, that discovers the truth by data partitioning. **TD-AC**, that stands for *Truth Discovery with Attribute Clustering*, applies *k-means* to find optimal clusters of structurally correlated data attributes based on sources' reliability level by relying on *attribute truth vectors* and the *silhouette index*, as we detail it below.

3.1 DATA ATTRIBUTE TRUTH VECTORS

We define and use the concept of *data attribute truth vectors* as an abstract representation of the precision (or quality) of a given truth discovery algorithm using attributes as dimensions. To build such vectors, we firstly apply a *base truth discovery algorithm* (e.g. majority voting) on input data to obtain a *reference truth*. Then, for each attribute of an object and every source we verify whether or not the value given by the source is true regarding the reference truth; we set the value for each rank of any attribute truth vector according to Equation 1.

$$\forall a \in A, \forall o \in O, \forall s \in S; x(a,o,s) = \begin{cases} 1 & if\, \rho\ is\ true \\ 0 & otherwise \end{cases} \quad (1)$$

where $\rho = (v(a,o,s)\ \text{exists}\ \wedge\ v(a,o,s) = v_F(a,o))$ with $v(a,o,s)$ representing the value given by s about a of o, $v_F(a,o)$ is the true value of a of o predicted by the base algorithm and $x(a,o,s)$ is a binary value of our truth vector. Table 2 sketches the matrix of attribute truth vectors obtained on our running example in Table 1 by applying the procedure described above and Equation 1.

Q3	1	0	0	0	1	1

Table 2: Matrix of attribute truth vectors with data in Table 1 using TruthFinder as base algorithm

3.2 GROUPING CORRELATED ATTRIBUTES

We find and group correlated data attributes by assessing the similarity distance of their corresponding truth vectors. Given two distinct attributes a_1, a_2 and their truth vectors $(a_1^1, a_1^2, \ldots, a_1^l)$ and $(a_2^1, a_2^2, \ldots, a_2^l)$, we define the similarity between a_1 and a_2 using the Hamming distance as : $d(a_1, a_2) = \sum_{i=1}^{l} |a_1^i - a_2^i|$ (2).

To automatically devise the *threshold value* for grouping the attributes based on our similarity measure, we rely on *k-means* and its optimization strategy in order to provide a domain-independent clustering process in practical cases. The k-means clustering approach [8] uses a similarity distance metric between data points to group them in k clusters. Given a set of observations $(a_1, a_2, ..., a_n)$, where every observation is an attribute truth vector having l dimensions, we define the partitioning of these attributes using k-means algorithm as the clustering of the n observations in k ($k \leq n$) disjoint sets (or clusters) $C = \{g_1, g_2, ..., g_k\}$ in such a way that the sum of the squares (i.e. the Inertia) within each cluster is minimized. Formally, the goal is to find:
$argmin_C \sum_i^k \sum_{a \in g_i} ||a - \mu_i||^2 = argmin_C \sum_i^k |g_i| Inertia(g_i)$ (3)
where μ_i is the centroid of the points in g_i. This corresponds to minimize the squared deviations of the points in the same cluster: $argmin_C \sum_i^k \sum_{a_1 \in g_i} \frac{1}{2|g_i|} \sum_{a_1, a_2 \in g_i} ||a_1 - a_2||^2$ (4). K-means requires to specify the value of k in input. We find the optimal k using the *silhouette index* as described next.

3.3 ESTIMATION OF k WITH SILHOUETTE

The silhouette index [11] evaluates the quality of a clustering result with the help of the separation criteria β and the cohesion criteria α. Consider two attributes a_1 and a_2 that belong to clusters $g(1)$ and $g(2)$, respectively. Formally, the silhouette coefficient $CS(a_1)$ of the attribute a_1 is defined as: $CS(a_1) = \frac{\beta(a_1) - \alpha(a_1)}{\max(\alpha(a_1), \beta(a_1))}$ with $\alpha(a_1) = \frac{1}{|g(1)|-1} \sum_{a_j \in g(1); a_j \neq a_1} d(a_1, a_j)$ and $\beta(a_1) = \min_{a_1 \neq a_2} \frac{1}{|g(2)|} \sum_{a_k \in g(2)} d(a_1, a_k)$ (5). If $CS(a_1) <$

0, a_1 is *badly classified*. Conversely, if $CS(a_1) > 0$ a_1 is *well classified*. Finally, if $CS(a_1) = 0$ then a_1 is between two clusters. The silhouette coefficient $CS(g)$ of a cluster g is thus given by: $CS(g) = \frac{1}{|g|} \sum_{a \in g} CS(a)$ (6).

The silhouette value of a partition P is the average of the silhouette coefficients of all its clusters: $CS(P) = \frac{1}{|P|} \sum_{g \in P} CS(g)$ (7).

The optimal k is the one associated to the partition having the highest silhouette coefficient amongst all the possible partitions.

3.4 TD-AC TRUTH DISCOVERY APPROACH

As depicted by Algorithm 1, our proposed algorithm **TD-AC** runs as follows: (i) considers a *base truth discovery algorithm* and input data (A, O, S); (ii) computes the matrix of attribute truth vectors from input data using the base algorithm and Equation 1; (iii) efficiently clusters the data attributes by applying k-means combined with the silhouette index ; and (iv) executes the input base truth discovery algorithm on each data partition, and then aggregates the partial results to generate the entire result.

Algorithm 1 TD-AC(F, A, O, S) – Truth discovery with Attribute clustering using k-means and silhouette coefficient

23: Add *partial_result* in *results*
24: **end for**

4 EXPERIMENTS AND RESULTS

In this section, we demonstrate the efficiency of our approach on various datasets, proving that it outperforms approaches proposed in [2] and standard truth discovery algorithms in the literature in the presence of structurally correlated data attributes. We also show that its execution time is similar to that of standard algorithms unlike partitioning strategies in [2]. We start by presenting the experiment setting up and performed tests.

4.1 EXPERIMENTATION SETTING UP

For the comparison purposes, we have implemented the different analyzed algorithms using *Python* programming language. The following standard truth discovery algorithms have been implemented: **MajorityVote**,**TruthFinder** [14], **DEPEN**, **Accu** and **AccuSim** [4]. We have compared ourselves to these algorithms because they are amongst the best in terms of efficiency and effectiveness for solving the truth discovery problem in various settings. In addition we have also implemented **AccuGenPartition** in [2] along with the different weighting functions to compute the optimal partition. The source codes of the tested algorithms are all available at **https://github.com/osiastossou/ProjetTD-AC.git**.

	DS1	DS2	DS3

m_2	0.0	0.0	0.2
m_3	1.0	0.8	0.8

Table 3: Average accuracy values for the various configurations of the synthetic datasets

We have conducted all our experiments on a Intel Core i5 2.6GHz laptop computer with 8GB of RAM, 250GB of hard disk space, and 1.5GB of graphics memory. The implemented algorithms here require all hyper-parameters in input whose values have been fixed for the various tests according to [12]. At last, we have relied on usual metrics such as *precision*, *recall*, *F1-measure*, *accuracy*, and *execution time* to evaluate and compare the performance of our tested algorithms.

4.2 EXPERIMENTS ON SYNTHETIC DATA

We detail here the results of our experiments on synthetic data which simulate conditions where data attributes are structurally correlated.

We have used and re-implemented in Python the synthetic data generator in [2] to produce our synthetic data sets; we defer to [2] for the details. For the evaluation process, we have then generated three synthetic datasets (DS1, DS2 and DS3) of 6 attributes, 1000 objects, 10 sources and 60, 000 observations with three different configurations as depicted in Table 3; DS1 meets the seeting of this work while DS3 relaxes the assumptions to test the robustness of our approach. The partition selected for each configuration is given in Table 5.

Tables 4a, 4b and 4c respectively present the performances of each algorithm on DS1, DS2 and DS3. For the tests, we used **Accu** as our base algorithm similarly to the approaches in [2]. We observe that the attribute partitioning truth discovery algorithms perform better than the standard ones on all three synthetic datasets, proving the importance of partitioning when data attributes are structurally correlated. Specifically, **TD-AC** is the only partitionning strategy with a precision comparable to the real world (i.e. an *Oracle*) without a blowup of the running time. Table 5 reports the partitions returned by the different partitioning approaches.

4.3 TESTS ON SEMI-SYNTHETIC DATA

The semi-synthetic datasets have been generated from a real dataset called **Exam**. This real dataset comes from [2] and has been used in that paper to validate the proposed approaches. The **Exam** dataset has been obtained by aggregating the anonymous results of admission examinations. Unfortunately, it cannot be redistributed for privacy reasons. We had access to answers from 248 students (*sources*) to 124 questions (*attributes*) in total, from 9 different domains: **Math 1A, Chemistry 1, Math 1B, Physics, Electrical Engineering, Computer Science, Chemistry 2, Science of life,** and **Math 2**. We also know the correct answer to each question. Math 1A and Physics were only mandatory with the choice of an additional domain between Chemistry 1 and Math 1B. The five remaining domains were completely optional and wrong answers were penalized. As a result, all the attributes were not covered (missing data). For each unanswered

Table 5: Partitions chosen by the generator and returned by the different partitioning algorithms

question we have synthetically chosen a false answer, randomly in a range of false values of size equal to 25, 50, 100 or 1000.

Tables 6 and 7 respectively present the different results of these tests on the semi-synthetic data of 62 and 124 attributes, each with configurations on ranges of false values of size 25, 50, 100, and 1000. The tests compare the performances of **Accu** and **TD-AC+Accu** on the one hand and on the other hand **TruthFinder** and **TD-AC+TruthFinder**. In general, we note that combining a base algorithm with **TD-AC** does not highly deteriorate the performance of the standard algorithm whatever the configuration considered, and even improves it in some cases, for example for the dataset with 124 attributes (see Figures 2 and 3).

4.4 EXPERIMENTS ON REAL DATA

To end our performance evaluation, we present in this section the results of the experimentation of our approach and the existing algorithms on real data. The evaluation on real data sets enables to validates our approach against practical applications. For this purpose, we have considered and used the real datasets **Exam** [2], **Stocks** and **Flights** [9]. Real data contain missing values that

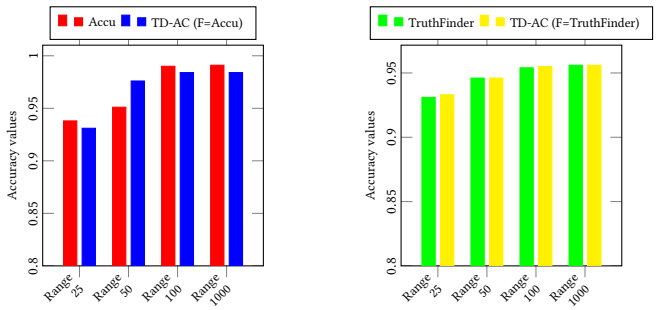

Figure 2: Study of the impact of TD-AC on Accu and TruthFinder by pairwise comparison of the accuracy values on semi-synthetic datasets with 62 attributes

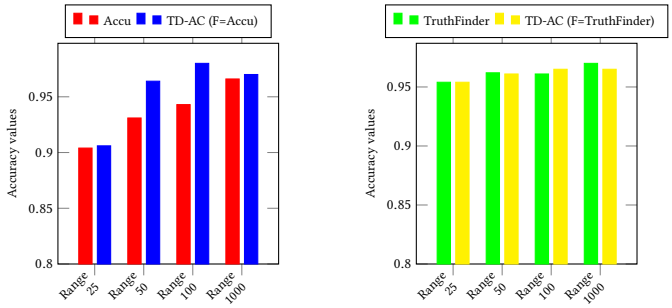

Figure 3: Study of the impact of TD-AC on Accu and TruthFinder by pairwise comparison of the accuracy values on semi-synthetic datasets with 124 attributes

may impact the performance of truth discovery algorithms. We assess the *Data Coverage Rate* (DCR) of each dataset with: $DCR = \left(1 - \frac{\sum_{o \in O}(|S_o| \times |A_o| - \sum_{s \in S_o} |A_{o-s}|)}{\sum_{o \in O}(|S_o| \times |A_o|)}\right) \times 100$ (7). Table 8 presents the details of the three real data sets after pre-processing; for Exam we have considered three configurations.

	Stocks	Exam 32	Exam 62	Exam 124	Flights
Number of sources	55	248	248	248	38
Number of objects	100	1	1	1	100
Number of attributes	15	32	62	124	6
Number of observations	56992	6451	8585	11305	8644
Data Coverage Rate (%)	75	81	55	36	66

Table 8: Statistics about the different real datasets

Table 9 presents the performance measures of **Accu**, **TD-AC+Accu**, **TruthFinder**, and **TD-AC+TruthFinder**. We have also reported in Figures 4 and 5 the comparative study of the accuracy values of **Accu** and **TD-AC+Accu** on the one hand and **TruthFinder** and **TD-AC+TruthFinder** on the other hand on real datasets with data coverage greater than 66% and less than 55% respectively. We observe that **Accu** and **TruthFinder** outperform when used with our **TD-AC** approach, especially when the data coverage rate is greater than 66%. We also remark that the execution time of **TD-AC** is very close to that of standard algorithms on real data, unlike **AccuGenPartition**.

4.5 Analysis of the results and discussion

The analysis of the presented intensive performance evaluation carried out on several datasets yields to three main observations.

Dataset	Algorithm	Precision	Recall	Accuracy	F1-measure	Time(s)	#Iteration
Exam 32	**Accu**	0.607	0.837	0.658	0.704	4059	11
	TD-AC (F=Accu)	0.614	0.912	0.679	0.734	4075	1
	TruthFinder	0.540	0.772	0.570	0.636	6.66	5

	TruthFinder	0.859	0.900	0.857	0.879	22.3	3
	TD-AC (F=TruthFinder)	0.848	0.885	0.842	0.866	33	1

(e) Flights

Table 9: Performance of Accu, TruthFinder, TD-AC+Accu, and TD-AC+TruthFinder on real datasets

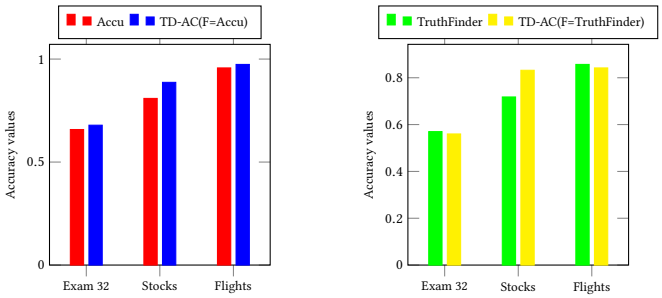

Figure 4: Study of the impact of TD-AC on Accu and TruthFinder by pairwise comparison of the accuracy values on real datasets Exam with 32 attributes, Stocks and Flights (DCR $\geq$ 66)

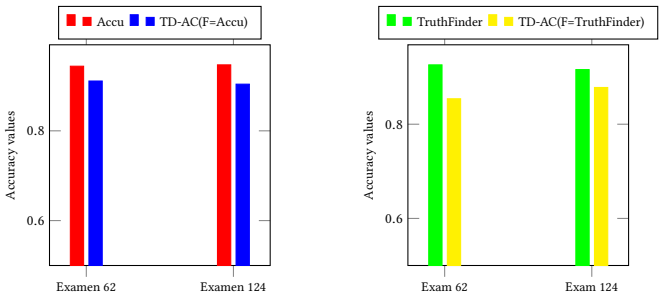

Figure 5: Study of the impact of TD-AC on Accu and TruthFinder by pairwise comparison of the accuracy values on the real datasets Exam with 62 and 124 attributes (DCR $\leq$ 55)

TD-AC outperforms baseline partitioning approaches. TD-AC highly improves the accuracy of **AccuGenPartition** by 1% at least and by 14% at most (see Figure 1) with a time complexity

around 200 less significant (see Tables 4a, 4b and 4c). **AccuGenPartition** is our baseline *brute force* approach proposed in [2] for the truth discovery with attribute partitioning problem with two weighting functions: **Max** and **Avg**. To discover the optimal partition, *k-means* combined with the*silhouette index* has been shown in Table 5 to be better than **Max** and **Avg** because: (i) k-means is a robust partitioning technique with a well-defined optimization strategy; and (ii) silhouette returns the most structurally homogeneous existing clusters. This explains the effectiveness of **TD-AC**. The drastic reduction of the running time with **TD-AC** is because it only requires one iteration to last without exploring all the possible partitions.

TD-AC improves the accuracy of base algorithms. When data attributes are structurally correlated, **TD-AC** significantly enhances the accuracy (from 5 to 35%) of standard algorithms (see Tables 4a, 4b, 4c, 9 and Figure 3). Standard algorithms alone do not capture the structural correlations between attributes leading to biased results. In the cases where the conditions do not match our working setting, **TD-AC** does not degrade the performances of the standard algorithms (see Tables 6 and 7). The impact of **TD-AC** is more important for **Accu** than **TruthFinder** because the former captures better the different levels of reliability of the sources. Such a impact introduces, however, a surplus in terms of execution time which is fortunately reasonable.

Correlation between coverage and TD-AC accuracy. The main observation is that **TD-AC** is more efficient when the data coverage is very high, i.e. DCR $\geq$ 66% (see Figure 4) because more one has in terms of information the better is the clustering with k-means. Lot of missing values, i.e. very sparse truth vectors affect both the quality of the clustering and the truth discovery process (see Figure 5).

5 RELATED WORK

A significant effort has been made in truth discovery area over the past years which has led to several approaches [12, 15]. The simplest approach is the majority vote which considers the truth said by the majority of sources. More elaborated approaches try to model the different levels of reliability of the sources and domain-specific aspects of the truth. For instance, **TruthFinder**[14], one of the first proposed standard algorithms, is a probabilistic model based on Bayesian analysis with similar values supporting each others in vote counts. Methods such as **DEPEN**, **Accu** and **AccuSim**[4] take into consideration copy relationships that may exist between sources by penalizing the vote of a source if it is detected as a copy of another source. **DART** (Domain-AwaRe Truth Discovery) [10] is both a probabilistic and a bayesian model which integrates the domain expertise level. Very recent methods such as [6, 15] capture the correlations between objects in the domain of **Mobile Crowd Sensing**.

The research works that are connexe to our studied problem are [2] and [13]. The proposal in [2] is a brute force approach that explores all the possible partitions of a given set of attributes in order to discover the one maximizing the precision of a standard truth discovery algorithm. The goodness of a partition in this case is based on a weighting function over sources' reliability levels. The work in [13] focuses on object partitioning based on domain knowledge and some additional constraints.

6 CONCLUSION AND PERSPECTIVES

In this work, we have studied the truth discovery problem in a setting where the attributes of the data are structurally correlated. As a solution, we have proposed a new approach, called **TD-AC**, built on an abstract representation of the truth in the data, the k-means clustering technique and the silhouette measure to automatically find an optimal partitioning of the input data (or a near-optimal) maximizing the accuracy of any base truth discovery process. Through an intensive experimental evaluation over various types of datasets, we have then shown the effectiveness and efficiency of **TD-AC** compared to existing partitioning strategies and its positive impact to the accuracy of any standard truth discovery process.

Despites of that, we have noticed that when the dataset contains lot of missing values, the impact of our approach is less significant. This can be explained by the use of sparse truth vectors in the clustering step, making the finding of the optimal partition hard. Moreover, even if the running time of our approach and standard algorithms is reasonable in the presence of small size datasets, it become important when the number of attributes, objects and sources is very large. As research perspectives, we plan to (i) improve our approach to better account for data with lot of missing values on the one hand; and (ii) on the other hand, to propose an optimization of the running time of our approach, in particular the optimal partition computation, by using parallel computation. We also plan to compare ourselves to a larger set of standard truth discovery algorithms and the partitioning approach in [13].

ABSTRACT

Currently, deep learning models have been widely used in different application domains due to their notable performance. Explaining the decisions made by deep learning models is important for end-users to enable them to comprehend and diagnose the trustworthiness of the model. Most of the current interpretability techniques provide explanations in the form of importance score for the input pixels or features. However, summarizing such importance scores for input features to provide human-interpretable explanations is challenging. To this end, we propose *Automated Concept-based Decision Tree Explanations* (ACDTE), a novel local explanation framework that provides human-understandable and concept-based explanations for classification networks. Our framework provides end users with the flexibility of customizing the explanations by allowing users to provide the dataset in which visual human-understandable concepts are automatically extracted. Then, such concepts are interpreted through a shallow decision tree that includes concepts that are deemed important to the model in predicting the decision of specific instance. In addition, ACDTE generates counterfactual explanations, suggesting the the minimum changes in the instance's concept-based explanation that lead to a different prediction. Our experiments demonstrate that such a shallow decision tree is faithful to the original neural network at low tree depth. The human interpretability of the explanations provided from our framework is evaluated through humans experiments, showing that our framework generates faithful and interpretable explanations.

1 INTRODUCTION

Since deep learning (DL) models have been achieving remarkable success over the last years in different application domains [1, 3], gaining insights into such models' predictions has received great attention over the last few years and in some cases, there is also a legal requirement to do so [7]. Among the various DL models, convolution neural networks (CNN) achieve remarkable performance in different computer vision tasks including self-driving cars and medical diagnoses. A main drawback for DL models, that prevents their wide adoption in critical domains, is their inscrutable nature of their prediction process that makes them black-boxes. Explaining the behaviour of DL models enables humans to understand the model behaviour, and hence, can increase their trust in the model if the decisions made by the model appear reasonable to humans.

There is no agreement among researchers about what would constitute a satisfactory explanation [13]. However, recent studies over 250 papers have concluded that explanations are counterfactual [12, 13]. Techniques for explaining DL models can be broadly partitioned into two main approaches. The first approach is to identify the evidence that the network uses to make a specific prediction by creating a heatmap that identifies the main parts of the image, which are salient to the prediction [16, 19, 21]. The second approach focuses on providing explanations in the form of human-understandable concepts [5, 6, 20]. Instead of assigning an importance score for each pixel or input feature, the explanation comes in the form of important human-understandable concepts that contribute toward the prediction. Understanding how concepts affect a particular model prediction may reveal potential unwanted bias learned by the model.

In this paper, we describe a framework called Automated Concept-based Decision Tree Explanations (ACDTE) to automatically identify high-level human-understandable concepts which are important for the machine learning model for predicting the decision of a specific instance by aggregating related local image segments (concepts) across diverse data and then decompose the evidence for a prediction for image classification into such concepts through an interpretable shallow decision tree. The explanation provided by the ACDTE framework is expressive and provides not only succinct evidence why a particular image has been assigned to a particular class, but also counterfactuals suggesting what is the least number of concepts needed to be changed are, in an instance's explanation, to change the predicted outcome. We summarize our contributions as follows: 1) A novel local explanation framework to provide automatically extracted concept-based explanations for CNNs in the form of important concepts for the prediction of specific instance presented as a shallow interpretable decision tree that is faithful to the black-box model, 2) A counterfactual explanation, suggesting the changes in the important concepts for the prediction of a specific image that lead to a different outcome, 3) Evaluation of the faithfulness of the explanations provided by ACDTE to the black-box model and the quality of the provided explanations. For ensuring repeatability as one of the main targets of this work, we provide access to the source codes and the detailed results for the experiments of our study[1].

The remainder of this paper is organized as follows. In Section 2, we present our proposed technique, ACDTE. We present a detailed experimental evaluation for our proposed techniques in Section 3 before we finally conclude the paper in Section 4

2 METHODS

In the following, we present ACDTE which is a local explanation technique that explains the prediction of a particular image. ACDTE takes a trained classifier, an image to be explained, and a set of images from user-specified dataset as input. It then extracts concepts presented in these images and interpret these concepts through a shallow decision tree that identifies the main concepts

[1] https://github.com/DataSystemsGroupUT/ACDTE

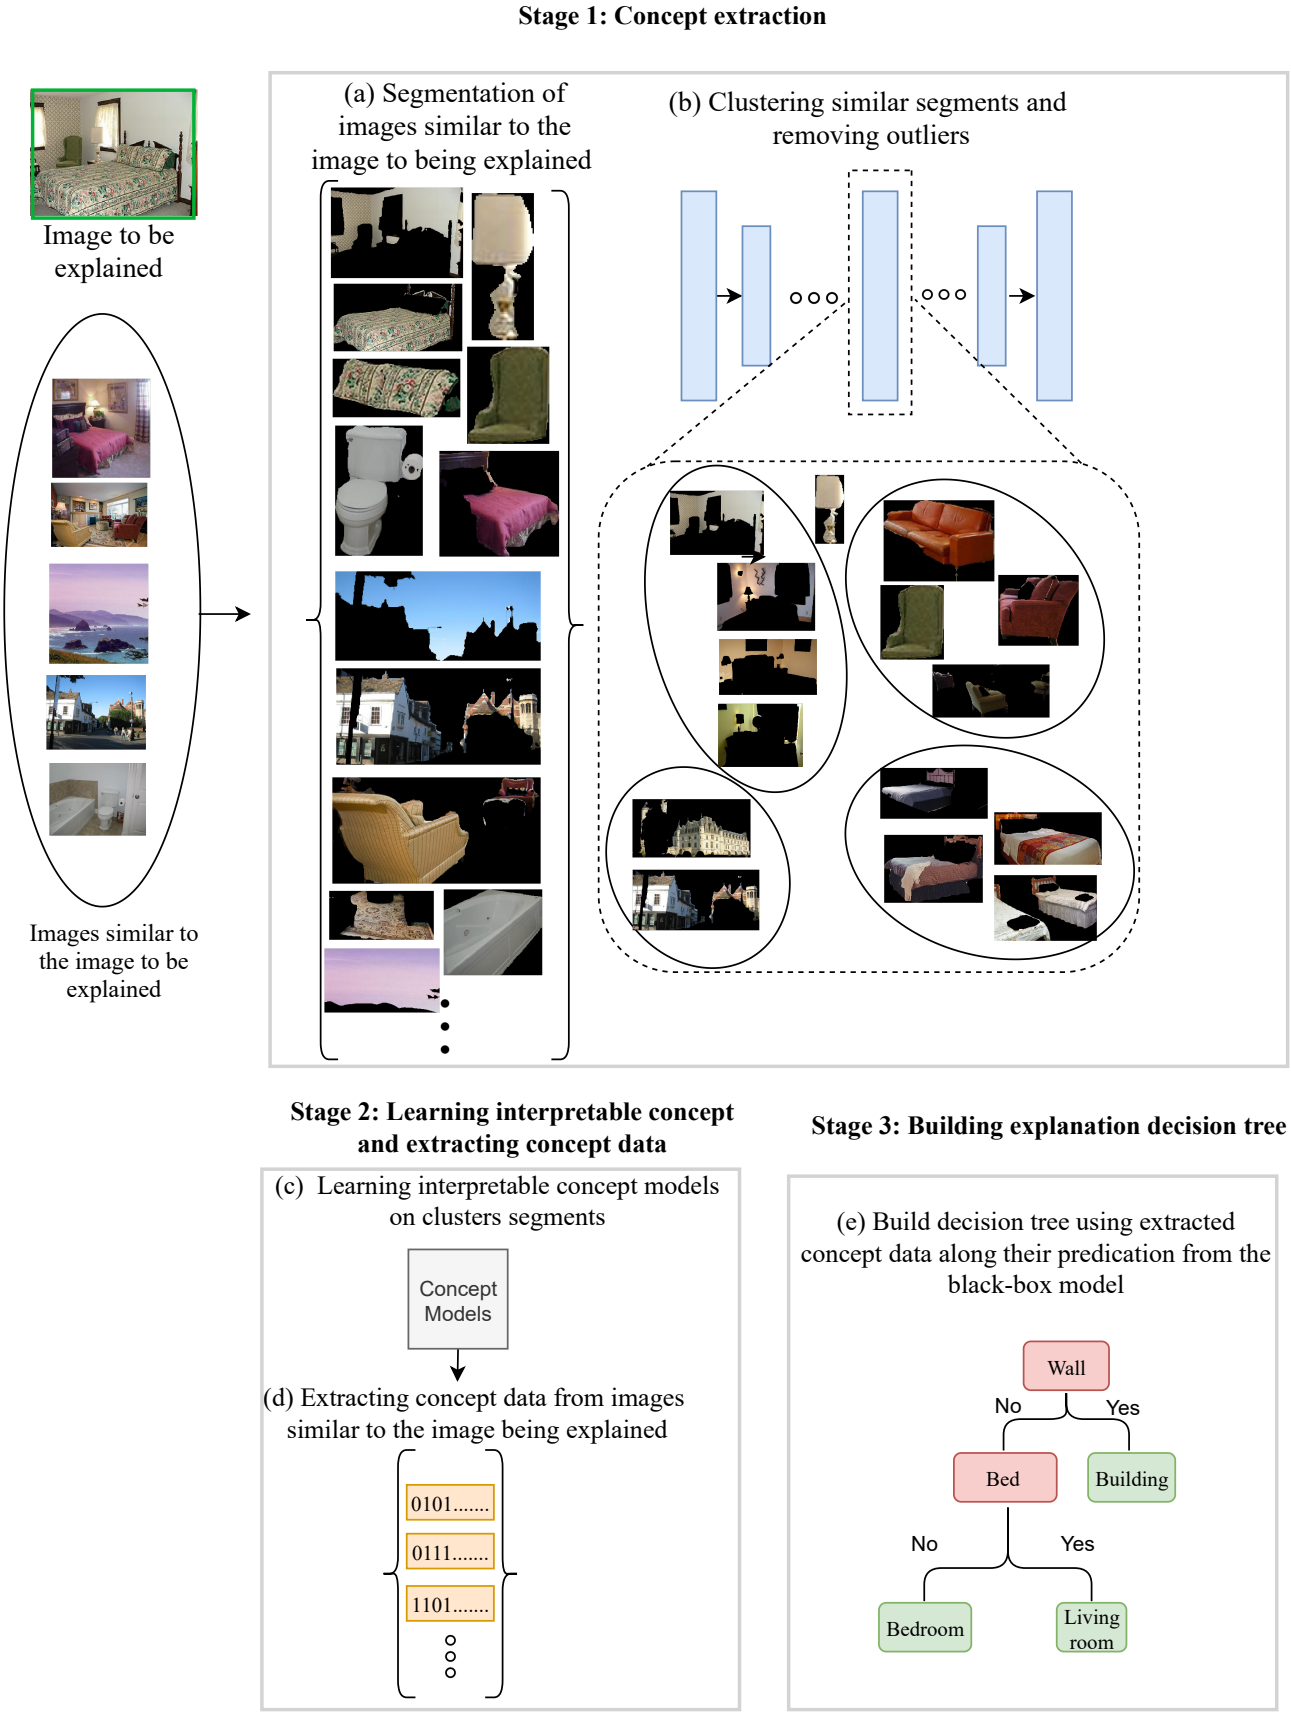

Figure 1: ACDTE pipeline (a) Extract a set of similar images to the image to be explained either from the main task dataset or related dataset. Each image in the selected images is segmented. (b) Segments are clustered in the activation space and outliers are removed to form coherent clusters that represent concepts. (c) Training a linear model for each concept to act as a concept detector. (d) For each image in the activation space, use concepts detectors to form a binary feature vector. (e) Feature vectors along with the prediction of the target network are used to train a shallow decision tree. The decision tree provides a natural explanation for the contributing concepts for the prediction, in addition to counterfactual explanation.

that have deemed important for the prediction of the image being explained, in addition to the minimum number of concepts that need to be changed to alter the prediction of the image to be explained. Figure 1 summarizes the general pipeline for the proposed framework consists of three main phases concept extraction, learning interpretable concept models and extracting concept data, and building explanation decision tree in which explanation based on both decision and counterfactuals, is extracted.

2.1 Phase 1: Concept Extraction

Given a pretrained image classification model m, and the image to be explained I, our framework provides end users with the flexibility of extracting concepts either from the dataset used in the classification task or from a related dataset to the main task dataset. To extract concepts, we choose the top k images similar to I, denoted S. Similarity between I and the set of provided images is defined to be the Euclidian distance between their corresponding activation maps obtained from an intermediate layer from m. In this paper, we use a constant value for $K = 100$, leaving the exploration of different values to future work. To extract concept data, each of the images in S is segmented using semantic image segmentation technique, see Figure 1(a). In order to automate the process of concept extraction, a significant number of studies in literature focused on semantic segmentation algorithms that aim to assign a meaningful class to each pixel [9, 11, 14, 18]. ACDTE uses DeepLabv3+ [2] segmentation technique which has been widely used due to its superior performance on dense datasets (after examining several segmentation techniques). To ensure meaningfulness of the extracted concepts, we cluster segments into a number of clusters such that segments of the same cluster represent a particular concept. In order to automate the process of clustering segments, we define the similarity between segments to be the euclidian distance between their corresponding activation maps obtained from the intermediate layer of model m. Each segment was resized to the original size of m. All segments were then passed through m to obtain their layer presentations. All segments are then clustered using K-means clustering algorithm [10], see Figure 1(b). To ensure meaningfulness of the extracted concepts, we exclude the following two types of clusters: 1) Clusters that have segments that only coming from a single image or a very few number of images. 2) Clusters with segments less than N segments. In this work, we use a constant value for N equals $0.4\sqrt{n_c}$, where n_c is the number of segments in cluster c, leaving the exploration of different values for N to future work. The main problem with clusters of few segments is that the concepts they present are uncommon in the neighborhood of the image being explained. For example, bed segments are present in almost every bedroom image and therefore, are expected to form a coherent cluster while lamp segments are presented in very few bedroom images and hence lamp cluster should be removed. The output of this phase is the final set of clusters representing the learnt concepts denoted $C = \{c_1, ...c_n\}$, where n is the number of clusters after the exclusion criteria.

2.2 Phase 2: Learning Interpretable Concept Models and Extracting Concept Data

For each segment $x \in c$, the hidden layer activations $a = m_l(x)$ at layer l are extracted and stored along its corresponding concept label. For each candidate concept $c \in C$, we train a logistic binary classifier h_c to detect the presence of concept c, see Figure 1(c). Training each concept c is done on dataset D_c, which is mix of segments balancing the presence and absence of concept c. We define $D_c = D_c^+ \cup D_c^-$, where $D_c^+ = \{(m_l(x^1), y_c^1), ..., (m_l(x^{|c|}), y_c^{|c|})|_{y_c=1}\}$ and $D_c^- = \{(m_l(x^1), y_c^1), ..., (m_l(x^{|c|}), y_c^{|c|})|_{y_c=0}\}$, where $y \in \{0, 1\}$ indicates the absence or the presence of concept c in a segment. Negative examples D_c^- for each concept c are selected randomly from other cluster concepts such that the number of examples in D_c^+ and D_c^- are equal. We use these concept classifiers for each image $s \in S$ to create a binary vector $v = (r_1, r_2, ..., r_n)$ representing the presence or absence of each concept $c \in C$ in s, where $r_i = h_{c_i}(s)$, $r_i \in \{0, 1\}$. For each image $s \in S$, we store its class prediction from model m along with its binary concept vector v for training a decision tree, see Figure 1(d).

2.3 Phase 3: Building Concept Decision Tree

Concept vector v predicted for each image $s \in S$ along with the corresponding prediction $m(s)$ are used to train a decision tree T which is intended to mimic the behavior of m locally in the S neighborhood, see Figure 1(e). We use the default implementation of decision tree from *scikit-learn* [15]. The ACDTE approach considers decision tree classifier due to its interpretable nature that allows concept rules to be derived from a root-leaf path in the decision tree, in addition to counterfactuals that can be extracted by symbolic reasoning over a decision tree. Increasing the depth of a decision tree increases the prediction accuracy which leads to less interpretable results as the number of nodes increases exponentially with depth. Thus, a shallow decision is favourable as it is more comprehensible by humans. In this work, we use a fixed depth leaving the exploration of dynamic depth to future work. In order to guarantee fast and easy search for counterfactuals, we consider all possible paths in the decision tree leading to a decision that is not equal to the decision of I. Among all these paths, we only consider the one with the minimum number of spilt conditions that are not satisfied by instance I. As an example, consider the decision tree in Figure 2 explaining the prediction from ResNet50 pretrained on places dataset [22] of an image as a coast. The concepts used in building the decision tree is based on selecting the top 100 images from a random selection of 1000 images from the ADE20k dataset [23]. The left branch of the tree indicates the presence of a concept while the right branch indicates the absence of that concept. The tree gives insights into the main human-understandable concepts from ADE20K dataset that appear important for ResNet50 in predicting the coast image. The decision tree provides a natural explanation for each path. It is clear from the explanation tree that the image has been predicted as a coast because of the existence of the concepts 'mountain' and 'sea'. As a further output, ACDTE computes a counterfactual; we have two counterfactual paths in the decision tree shown in Figure 2. The first one is the presence of 'mountain', absence of 'sea', presence of 'tree' that leads to the prediction of class 'snowy mountain', while the second is the presence of 'mountain', absence of 'sea', absence of 'tree' that leads to the prediction of class 'highway', as shown in Figure 2. Figure 3 shows sample segments of concepts along the explanation path of the coast image shown in Figure 2.

3 EXPERIMENTS AND RESULTS

In this section, we evaluate the meaningfulness of the explanations provided by our framework. In addition, we evaluate the faithfulness of the proposed framework to the black-box model.

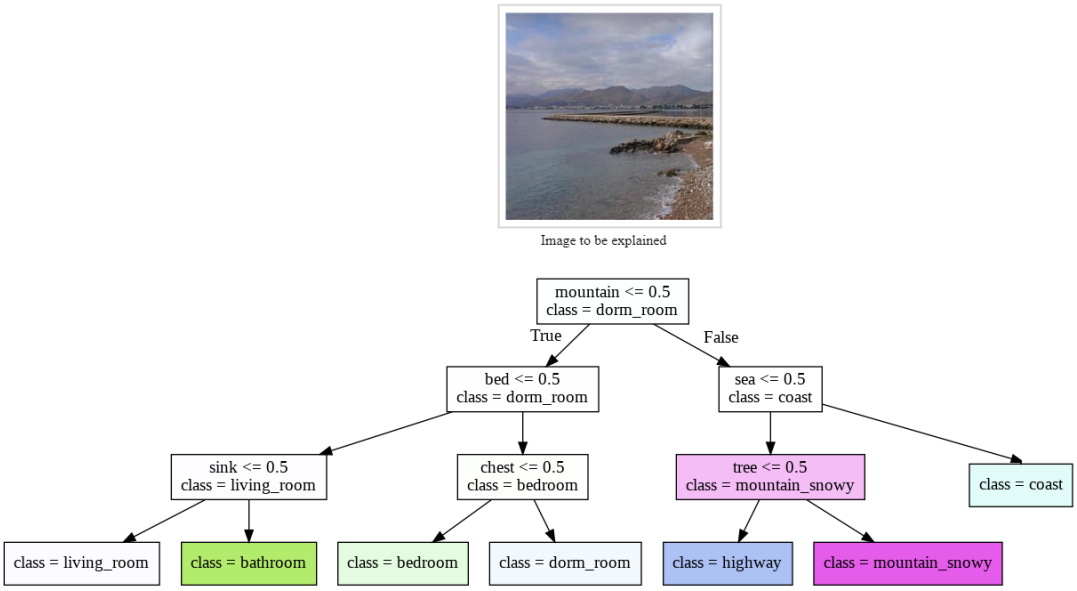

Figure 2: Shallow concept-based explanation decision tree of depth 4 explaining the prediction of coast image.

Figure 3: Sample segments of concepts along the explanation path of the coast image shown in Figure 2. Text below each group of images describes its original class of the extracted concepts.

3.1 Experiment Setup

As an experimental example, we use ACDTE to explain the predictions of the widely-used Resnet50 that has been pre-trained on the places dataset. We select a subset of 30 classes out of the 365 classes from places dataset. We experimented extracting the concepts from ADE20K dataset. More specifically, to explain the prediction of an instance from places dataset, we randomly select 1000 images from ADE20K dataset and extract concepts from the nearest 100 images. To evaluate the performance of the ACDTE, we randomly select 1000 images, denoted X, from the 30 selected classes of the places dataset.

3.2 Are ACDTE Explanations Faithful to the Black-box Model?

We consider the following metrics in evaluating how well the decision tree inferred by ACDTE and the explanations returned mimic the black-box model.

- **fidelity** $\in [0, 1]$: It compares the prediction of the decision tree T and the black-box model m on the set of images S used to train the decision tree [4].
- **hit** $\in \{0, 1\}$: It compares the prediction of the decision tree c and the black-box model m on the instance to be explained I [8]. It returns 1 if $m(I) = T(I)$, and 0 otherwise.

We measure the fidelity by F1-measure [17] and report the aggregated values of the F1 measure across all instances in X at tree depth of 5, 10, 15 and 20, see Figure 4(a). We report hit by averaging its values across the instances in X at tree depth of 5, 10, 15 and 20, see Figure 4(b). The results show that fidelity and hit increases as the tree depth increases, however tree depth of 10 is able to achieve reasonable fidelity of 0.87 and hit of 0.91.

3.3 Examining the Significance of the Extracted Concepts from ACDTE

To confirm the importance of the formed concepts of ACDTE, we run ACDTE on each of the images in X and return the set of clusters obtained from the concept extraction phase. We rank the returned clusters for each image in X according to their compactness that is captured by calculating the average distance between cluster center and each point in the same cluster. The smaller the average distance indicates that the cluster is tightly formed and shows a motion coherent view. The intuition behind that ranking is that compact clusters most likely represent a concept that is frequently present in the neighbourhood of the image to be explained, and hence, have a significant role in forming the decision boundary between classes. For each image in X, we build different decision trees based on excluding the top k concepts obtained from the concept extraction phase, where k=0, 2, 5, 8 and 10. Figure 5 shows the prediction accuracies on the set of images used to train the decision tree when removing the most important k concepts aggregated across all the instances in X. The results show that accuracy decreases significantly from 92.4% to 75.3% when removing the 10 most important concepts which reflects the variable significance of the automatically extracted concepts.

3.4 Concept Classifier Prediction Performance

Concept models performance vary across the different layers of the main task model (ResNet50). In order to identify the best

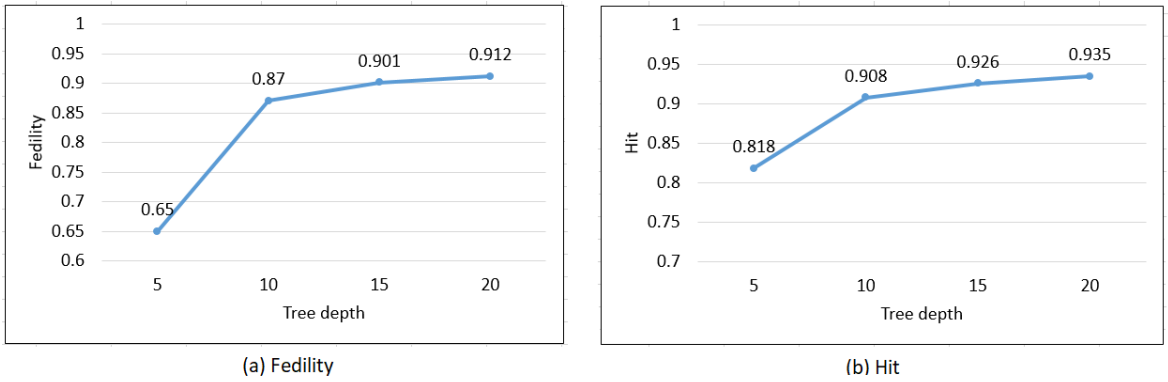

Figure 4: Fidelity and hit at different tree depth

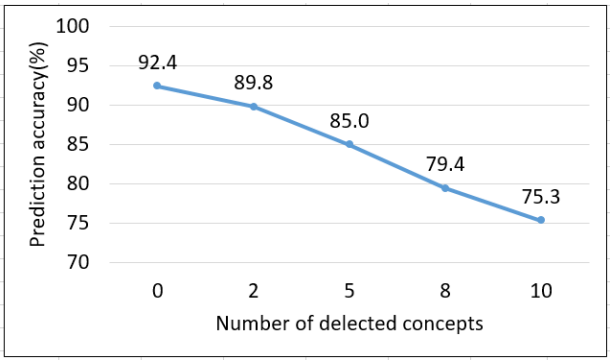

Figure 5: Prediction accuracy of decision tree as removing the top k important concepts aggregated across all the instances in X.

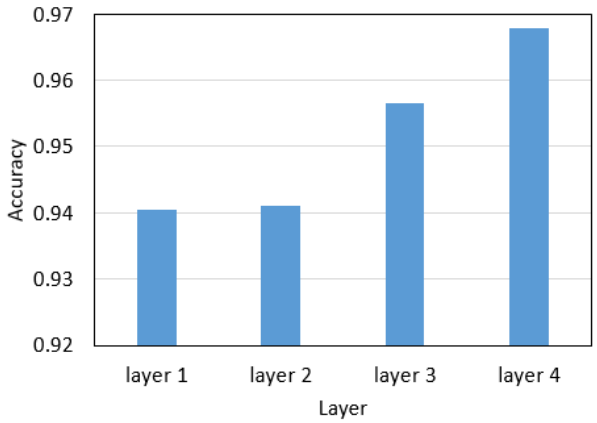

Figure 6: Average accuracy of all concept classifiers trained for the main layers of ResNet50

layer to extract feature vectors used to train concept classifiers, we compare the average accuracy of the concept models built on vectors extracted from the major layers of Resnet50 and report this average accuracy averaged over all instances in X. Major layers refer to the conv2 x (layer1), conv3 x (layer 2), conv4 x (layer 3), and conv5 x (layer 4) blocksections of sublayers of Resnet50. Figure 6 shows that all layers have high average accuracy and the deeper the extraction layer, the higher the accuracy. Figure 6 shows that the average classifiers accuracy was the highest at the fourth layer, achieving an accuracy of 0.97.

3.5 Decision Tree Performance

Figure 7 shows how the accuracy of the decision tree obtained from ACDTE responds to the changes in the maximum tree depth and the layer from which deep features are extracted, to train the concept models. We incrementally increase the depth of the decision tree obtained from ACDTE for each instance in X and change the layer in which features from ResNet are extracted to train the concept models. Then, we measure the prediction accuracy of the instances used to train the decision tree and report this accuracy averaged over all instances in X. Result show that the accuracy improves significantly as more concepts are added and then slightly flatten out as depth increases beyond 15. The results also demonstrates that layer 4 of ResNet50 achieves the best performance in terms of the decision tree prediction accuracy.

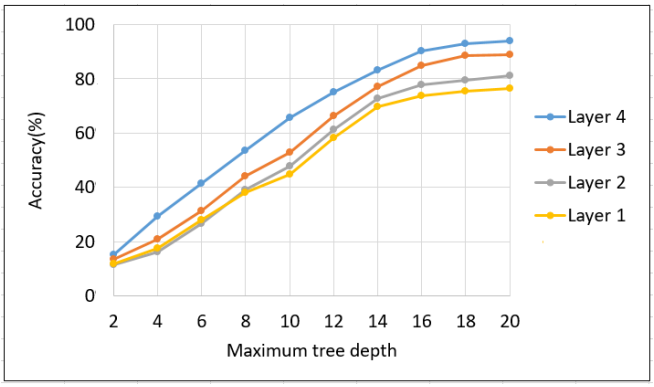

Figure 7: Decision tree accuracy vs. decision tree depth

3.6 Human Evaluation of the Visual Explanations

To measure the meaningfulness of the extracted concepts, we randomly select 50 instances from X and get the concepts used in their explanations. We ask 30 human participants to identify that segments belong to a concept versus a random set of segments. The evaluation interface is shown in Figure 8. Results show that 87% of participants choose the concept segments. To measure the significance of the important concepts extracted from the ACDTE,

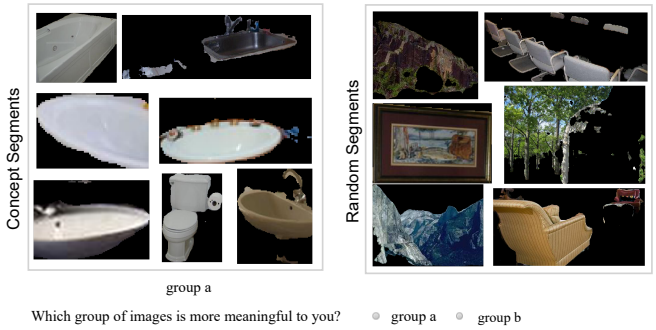

Figure 8: Human evaluation interface for identifying meaningful concepts

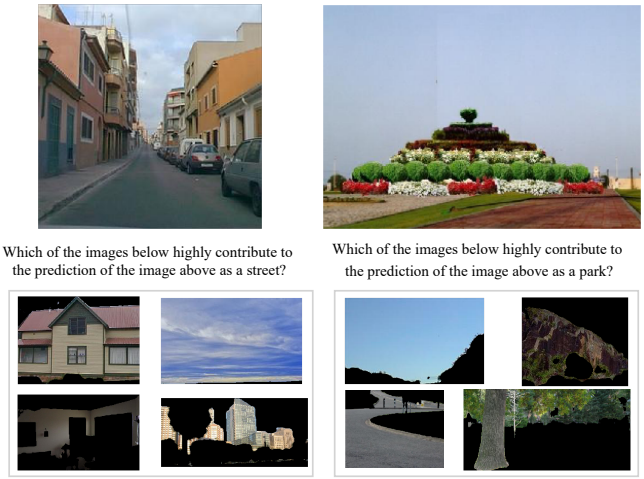

Figure 9: Sample examples of human experiments for choosing the most contributing concept to their predictions

we ask the 30 participants to select the most meaningful concept that contributes to a particular prediction made by ResNet50 for 30 different images. In each task, participants are shown the image to be explained along with its prediction and four concepts in which one of them represents the top concept identified by ACDET for explaining this image and the other three concepts are randomly chosen. Participants are asked to select the most meaningful concept that contribute to the prediction. Figure 9 shows two sample images along with four different concepts in which participants are asked to choose the most contributing concept for the prediction of these images. On average, 85% of the participants chose the concept obtained by ACDTE as the most important concept.

4 CONCLUSION

We introduced ACDTE, a post-training local explanation technique that automatically extract groups of input features from images similar to the images to be explained and group these features into high-level human-understandable concepts. We verified the meaningfulness and coherence of these concepts through human experiments and further validated that these concepts carry some signals indicating to the correct prediction class for the instance to be explained. Representing these concepts in a shallow decision tree allows users to infer which concepts are significant in the prediction of the image to be explained. A future direction of automated concept-based explanation is to consider other types of data such as texts.

Short Paper

Efficient Maintenance of Distance Labelling for Incremental Updates in Large Dynamic Graphs

ABSTRACT

Finding the shortest path distance between an arbitrary pair of vertices is a fundamental problem in graph theory. A tremendous amount of research has been successfully attempted on this problem, most of which is limited to static graphs. Due to the dynamic nature of real-world networks, there is a pressing need to address this problem for dynamic networks undergoing changes. In this paper, we propose an *online incremental* method to efficiently answer distance queries over very large dynamic graphs. Our proposed method incorporates incremental update operations, i.e. edge and vertex additions, into a highly scalable framework of answering distance queries. We theoretically prove the correctness of our method and the preservation of labelling minimality. We have also conducted extensive experiments on 12 large real-world networks to empirically verify the efficiency, scalability, and robustness of our method.

1 INTRODUCTION

Given a very large graph with billions of vertices and edges, how efficiently can we find the shortest path distance between any two vertices? If such a graph is dynamically changing over time (e.g. inserting edges or vertices), how can we not only efficiently but also accurately find the shortest path distance between any two vertices? These questions are intimately related to distance queries on dynamic graphs. As one of the most fundamental operations on graphs, distance queries have a wide range of real-world applications that operate on increasingly large dynamic graphs, such as context-aware search in web graphs [19], social network analysis in social networks [5, 20], management of resources in computer networks [6], and so on. Many of these applications use distance queries as a building block to realise more complicated tasks, and require distance queries to be answered instantly, e.g. in the order of milliseconds.

Previous studies have primarily focused on distance queries on static graphs [1–3, 10, 11, 13, 22], with little attention being paid to dynamics on graphs. To speed up query response time, a key technique is to precompute a data structure called *distance labelling* that satisfies certain properties such as 2-hop cover [8], and then use this data structure to answer distance queries efficiently. However, when a graph dynamically changes, its distance labelling needs to be changed accordingly; otherwise, distance queries may yield overestimated distances. Although it is possible to recompute a distance labelling from scratch, this leads to inefficiency. As shown in Figure 1, the percentage of affected vertices by a single change often ranges from 10^{-5}% to 10% in various real-world networks, recomputing distance labelling from scratch for each single change not only wastes computing resources, but also may generate inaccurate query results during recomputing process. The question arising is thus how to efficiently and accurately change distance labelling on dynamic graphs in order to support distance queries?

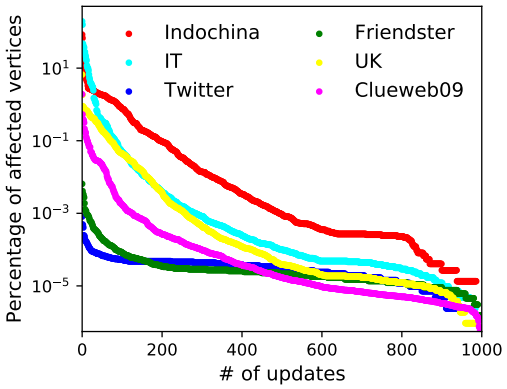

Figure 1: Distribution of affected vertices by a single graph change in various networks, where the results for 1000 graph changes are sorted in the descending order.

In this paper, we aim to develop an *online incremental* method that can dynamically maintain distance labelling on graphs being changed by edge and vertex insertions. Typically, real-world dynamic networks are more vulnerable to insertions than removals and a plethora of such real-world networks are large and frequently updated, primarily accommodating insertions [15, 21]. Thus, an online incremental method for dynamic graphs should possess the following desirable characteristics: (1) *time efficiency* - It can answer distance queries and update distance labelling efficiently (in the order of milliseconds); 2) *space efficiency* - It guarantees the minimum size of distance labelling to reduce storage costs; (3) *scalability* - It can scale to very large networks with billions of vertices and edges.

Challenges. Designing online incremental methods for distance queries on dynamic graphs is known to be challenging [4]. When an edge or a vertex is inserted into a graph, outdated and redundant entries of distance labelling may occur. It was reported that removing such entries is a complicated task [4] because affected vertices need to be precisely identified so as to update their labels without violating the original properties of a distance labelling such as minimality. Further, although query time and update time are both critical for answering distance queries on dynamic graphs, it is not easy (if not impossible) to design a solution that is efficient in both. This requires us to find new insights into dynamic properties of a distance labelling, as well as a good trade-off between query time and update time. Last but not least, scaling distance queries to dynamic graphs with billions of nodes and edges is hard. Previous work [4, 12] mostly considered 2-hop labelling, which has very high space requirements and index construction time; as a result, their query and update performance

are dramatically degraded on large-scale dynamic graphs. Ideally, the labelling size of a graph should be much smaller than its original size. However, the state-of-the-art distance labelling technique, i.e. pruned landmark labeling method (PLL) [4], still yields a distance labelling whose size is 20-30 times larger than the original size of a dataset.

Contributions. Our contributions are summarised as follows:

- Our method overcomes the challenge of eliminating outdated and redundant distance entries. None of the previous studies have addressed this challenge because detecting those entries is too costly [4, 9]. When an edge or a vertex is inserted, previous studies only add new distance entries or modify existing distance entries. This would however lead to an ever increasing size of labelling, particularly when a graph is frequently updated by newly added edges or vertices. Accordingly, both query performance and space efficiency would deteriorate over time.
- We prove the correctness of our proposed method and show that it preserves the desirable property of minimality on our distance labelling. Due to a property called highway cover [10], the minimal size of a distance labelling in this work is much smaller than the size of a 2-hop labelling in previous work [4, 12]. Preserving minimality on a distance labelling thus improves space efficiency and query performance, as well as update performance. We also provide a complexity analysis of our proposed method.
- We conducted experiments using 12 real-world large networks across different domains to show the efficiency, scalability and robustness of our method. Particularly, our method can perform updates under one second, on average, even on billion-scale networks, while still answering queries efficiently in the order of milliseconds and guaranteeing the labelling size of a graph to be much smaller.

2 RELATED WORK

Answering shortest-path distance queries in graphs has been an active research topic for many years. Traditionally, a distance query can be answered using Dijkstra's algorithm [18] on positively weighted graphs or Breadth-First Search (BFS) algorithm on unweighted graphs. However, these traditional algorithms fail to achieve desired response time for distance queries on large graphs. Later, labelling-based methods have emerged as an attractive way of accelerating response time to distance queries [1–3, 8, 10, 11, 13], among which Akiba et al. [3] proposed a pruned landmark labeling (PLL) to precompute a 2-hop cover distance labelling [8]. This method serves as the state-of-the-art for labelling-based distance queries and can handle graphs with hundreds of millions of edges.

So far, only a few attempts have been made to study distance queries over dynamic graphs [4, 12], which are all based on the idea of 2-hop distance labelling or its variants. Akiba et al. [4] studied the problem of updating a pruned landmark labelling for incremental updates (i.e. vertex additions and edge additions). This work however does not remove redundant entries in distance labels because the authors considered that detecting such outdated entries is too costly. This inevitably breaks the minimality of pruned landmark labelling, leading to an ever increase of labelling size and deteriorated query performance over time. To accelerate shortest-path distance queries on large networks, another line of research is to combine a partial distance labelling with online shortest-path searches. Hayashi et al. [12] proposed a fully dynamic approach that selects a small set of landmarks R and precompute a shortest-path tree (SPT) rooted at each $r \in R$. Then, an online search is conducted on a sparsified graph under an upper distance bound being computed via the SPTs. Nevertheless, this method still fails to construct labelling on networks with billions of vertices. Following the same line, a recent work by Farhan et al. [10] introduced a highway-cover labelling method (HL), which can provide fast response time (milliseconds) for distance queries even on billion-scale graphs. However, this approach only works for static graphs.

3 PROBLEM FORMULATION

Let $G = (V, E)$ be an undirected graph where V is a set of vertices and E is a set of edges. We denote by $N(v)$ the set of neighbors of a vertex $v \in V$, i.e. $N(v) = \{u \in V | (u, v) \in E\}$. Given two vertices u and v in G, the *distance* between u and v, denoted as $d_G(u, v)$, is the length of the shortest path from u to v. If there does not exist a path from u to v, then $d_G(u, v) = \infty$. We use $P_G(u, v)$ to denote the set of all shortest paths between u and v in G. Given a graph $G = (V, E)$, an *edge insertion* is to add an edge (a, b) into G where $\{a, b\} \subseteq V$ and $(a, b) \notin E$. Accordingly, a *node insertion* is to add a new node into G together with a set of edge insertions that connect v to existing vertices in G. The following fact is critical for designing algorithms for an edge insertion.

Fact 3.1. *Let $G' = (V, E \cup \{(u, v)\})$ be the graph after inserting an edge (u, v) into $G = (V, E)$. Then for any two vertices $s, t \in V$, $d_G(s, t) \geq d_{G'}(s, t)$.*

That is, the distance between any two vertices never increases after inserting edges or vertices in a graph.

Highway cover labelling. Unlike the previous work [4, 9, 12] that uses 2-hop cover labelling [8], we develop our method using a highly scalable labelling approach, called *highway cover labelling* [10]. Let $R \subseteq V$ be a small set of *landmarks* in a graph $G = (V, E)$. For each vertex $v \in V$, the *label* of v is a set of *distance entries* $L(v) = \{(r_1, \delta_L(r_1, v)), \ldots, (r_n, \delta_L(r_n, v))\}$, where $r_i \in R$ and $\delta_L(r_i, v) = d_G(r_i, v)$. We call $L = \{L(v)\}_{v \in V}$ a *distance labelling* over G whose *size* is defined as: $size(L) = \sum_{v \in V} |L(v)|$. A *highway* $H = (R, \delta_H)$ consists of a set R of landmarks and a distance decoding function $\delta_H : R \times R \rightarrow \mathbb{N}^+$ such that, for any two landmarks $r_1, r_2 \in R$, $\delta_H(r_1, r_2) = d_G(r_1, r_2)$ holds.

Definition 3.2. A *highway cover labelling* is a pair $\Gamma = (H, L)$ where H is a highway and L is a distance labelling s.t. for any vertex $v \in V \backslash R$ and $r \in R$, we have:

$$d_G(r, v) = \min\{\delta_L(r_i, v) + \delta_H(r, r_i) | (r_i, \delta_L(r_i, v)) \in L(v)\}. \quad (1)$$

Highway cover labelling enjoys several nice theoretical properties, such as minimality and order independence. A minimal highway cover labelling can be efficiently constructed, independently of the order of applying landmarks [10].

Given a highway cover labeling $\Gamma = (H, L)$, an upper bound on the distance between any two vertices $u, v \in V \backslash R$ is computed:

$$d^{\top}_{uv} = \min\{\delta_L(r_i, u) + \delta_H(r_i, r_j) + \delta_L(r_j, v) | (r_i, \delta_L(r_i, u)) \in L(u), (r_j, \delta_L(r_j, v)) \in L(v)\} \quad (2)$$

An exact distance query $Q(u, v, \Gamma)$ can be answered by conducting a distance-bounded shortest-path search over a sparsified graph $G[V \backslash R]$ (i.e., removing all landmarks in R from G) under the upper bound $d^{\top}_{uv}$ such that:

$$Q(u, v, \Gamma) = \begin{cases} d_{G[V \backslash R]}(u, v) & \text{if } d_{G[V \backslash R]}(u, v) \leq d^{\top}_{uv}, \\ d^{\top}_{uv} & \text{otherwise.} \end{cases}$$

Problem definition. In this work, we study the problem of answering distance queries over a graph that is dynamically changed by edge and vertex insertions over time. Since a vertex insertion can be treated as a set of edge insertions, without loss of generality, below we define the problem based on edge insertions.

Definition 3.3. Let $G \hookrightarrow G'$ denote that a graph G is changed to a graph G' by an edge insertion. The *dynamic distance querying* problem is, given any two vertices u and v in the changed graph G', to efficiently compute the distance $d_{G'}(u, v)$.

4 ONLINE INCREMENTAL ALGORITHM

In this section, we propose an algorithm IncHL$^+$ to incrementally update labelling to reflect graph changes. Algorithm 1 describes the main steps of IncHL$^+$. Below, we discuss them in detail.

4.1 Finding Affected Vertices

When an update operation occurs on a graph $G = (V, E)$, there exists a subset of "affected" vertices in V whose labels need to be updated as a consequence of this update operation on the graph.

Definition 4.1. A vertex $v \in V$ is *affected* by $G \hookrightarrow G'$ iff $P_G(v, r) \neq P_{G'}(v, r)$ for at least one $r \in R$; *unaffected* otherwise.

We use Λ_r to denote the set of all affected vertices w.r.t. a landmark r and $\Lambda = \bigcup_{r \in R} \Lambda_r$ the set of all affected vertices.

Example 4.2. Consider Figure 2(a) in which 0 and 10 are two landmarks. After inserting an edge $(2, 5)$, $\Lambda_0 = \{5, 8, 9, 10, 13, 14\}$ in Figure 2(b) and $\Lambda_{10} = \{0, 1, 2\}$ in Figure 2(d).

The following lemma states how affected vertices relate to an edge being inserted.

Lemma 4.3. *When $G \hookrightarrow G'$ for an edge insertion (a, b), a vertex $v \in \Lambda_r$ iff there exists a shortest path between v and r in G' passing through (a, b).*

Following Lemma 4.3, we can reduce the search space of affected vertices by eliminating landmarks r with $d_G(r, a) = d_G(r, b)$ since $\Lambda_r = \emptyset$ in such a case. Thus, we assume that $d_G(r, b) > d_G(r, a)$ w.r.t. a landmark r in the rest of this section w.l.o.g. Further, by the lemma below, we can also reduce the search space by "jumping" from the root of a BFS to vertex b.

Lemma 4.4. *When $G \hookrightarrow G'$ with an inserted edge (a, b), we have $d_G(v, r) \geq d_G(a, r) + 1$ for any affected vertex $v \in \Lambda_r$.*

Proof. By Lemma 4.3, there exists a shortest path from any affected vertex v to r going through the edge (a, b) and thus through a. Since a is unaffected and the distance from a to v is equal to or greater than 1, $d_G(v, r) \geq d_G(a, r) + 1$ thus holds. □

Algorithm 2 describes our algorithm for finding affected vertices. Given a graph G with an inserted edge (a, b) and a highway cover labelling $\Gamma = (H, L)$ over G, we conduct a *jumped* BFS w.r.t. a landmark r starting from the vertex b with its new depth $\pi = Q(r, a, \Gamma) + 1$ (Lines 3-4). For every $(v, \pi) \in Q$, we enqueue all the neighbors of v that are affected into Q with new distances $\pi + 1$ (Lines 7-8) and add v to Λ_r as affected vertex (Line 9). This process continues until Q is empty.

Example 4.5. Figure 2 illustrates how our algorithm finds affected vertices as a result of inserting an edge $(2, 5)$. The BFS rooted at landmark 0 is depicted in Figure 2(b), which jumps to vertex 5 and finds six affected vertices $\{5, 8, 9, 10, 13, 14\}$. Similarly, the BFS rooted at landmark 10 is depicted in Figure 2(d), which jumps to vertex 2 and finds three affected vertices $\{0, 1, 2\}$.

Algorithm 1: Incremental algorithm (IncHL$^+$).

```
Input: G, G', (a, b), Γ = (H, L)
Output: Γ' = (H', L')
1 foreach r ∈ R do
2     Λ_r ← FindAffected(G, (a, b), r, Γ)
3     RepairAffected(G', (a, b), Λ_r, r, Γ)
```

Algorithm 2: Finding affected vertices.

```
1  Function FindAffected(G, (a, b), r, Γ)
2      Q ← ∅, Λ_r ← ∅
3      π ← Q(r, a, Γ) + 1
4      Enqueue (b, π) to Q
5      while Q is not empty do
6          Dequeue (v, π) from Q
7          foreach w ∈ N(v) s.t. Q(r, w, Γ) ≥ π + 1 do
8              Enqueue (w, π + 1) to Q
9          Λ_r = Λ_r ∪ {v}
10     return Λ_r
```

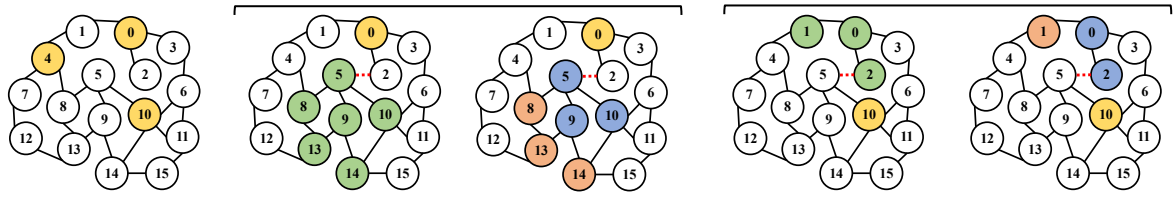
4.2 Repairing Affected Vertices

Now we propose a repair strategy to efficiently update the labels of affected vertices in order to reflect graph changes. The key idea is that, instead of conducting a full BFS on all vertices, we conduct a partial BFS from b only on affected vertices. Further, to avoid unnecessary computations, we distinguish two kinds of affected vertices: (1) affected vertices that are *covered* by other landmarks and can thus be easily repaired by removing an entry from their labels; (2) affected vertices whose labels need to be repaired with accurately calculated distances on a changed graph. The following lemma characterizes the first kind according to the definition of highway cover labelling.

Lemma 4.6. *An affected vertex $v \in \Lambda_r$ is* covered *by a landmark $r' \in R \backslash \{r\}$ iff r' exists in $P_{G'}(v, r)$. If an affected vertex $v \in \Lambda_r$ is covered by r', then any affected vertex $v' \in \Lambda_r$ satisfying $d_{G'}(r, v') = d_{G'}(r, v) + d_{G'}(v, v')$ must also be covered by r'.*

By Lemma 4.6, we can efficiently repair affected vertices $v \in \Lambda_r$ as follows. If v is covered by a landmark $r' \in R \backslash \{r\}$ (i.e., one of the unaffected parents of v does not contain r in its label) and is also a landmark, we only update the highway; otherwise, we remove the entry of r from $L(v)$. If v is not covered by any $r' \in R \backslash \{r\}$, we add/modify the entry of r in $L(v)$. If v is a descendant of covered vertices, we simply remove the entry of r from $L(v)$ (if exists).

Algorithm 3 describes our algorithm for repairing affected vertices. Given a graph G with an inserted edge (a, b) and a set of affected vertices Λ_r, we conduct a BFS w.r.t. a landmark r starting from the vertex b with its new distance $\pi = d_G(r, a) + 1$ (Lines 3-4). We use two queues $Q_{uncovered}$ and $Q_{covered}$ to process uncovered and covered vertices, respectively. If b is covered, we enqueue (b, π) to $Q_{covered}$ and remove the entry of r from the labels of affected vertices (Line 25). Otherwise, we enqueue (b, π) to $Q_{uncovered}$ and start processing vertices in $Q_{uncovered}$ (Line 5). For each vertex $v \in Q_{uncovered}$ at depth π, we examine its affected neighbors w at depth $\pi + 1$. If w is covered, then if w is a landmark, we update the highway (Line 10); otherwise we remove the entry of r from $L(w)$ (Line 12) because there must exist another landmark in the shortest path from w to r and add



(a) (b) (c) (d) (e)

Figure 2: An illustration of our online incremental algorithm IncHL$^+$: (a) a graph with three landmarks 0, 4 and 10 (colored in yellow); (b) and (d) the BFSs for finding affected vertices (colored in green) w.r.t. landmarks 0 and 10, respectively; (c) and (e) the BFSs for repairing affected vertices w.r.t. landmarks 0 and 10, respectively, where vertices with added/modified entries are colored in blue, and vertices with removed entries are colored in red.

Algorithm 3: Repairing affected vertices.

```
1  Function RepairAffected(G', (a, b), Λ_r, r, Γ)
2      Q_uncovered ← ∅, Q_covered ← ∅
3      π ← d_G(r, a) + 1
4      Enqueue (b, π) to Q_covered if covered; otherwise to
         Q_uncovered
5      while Q_uncovered is not empty do
6          while (v, π) ∈ Q_uncovered at depth π do
7              forall w ∈ N(v) s.t. w ∈ Λ_r at depth π + 1 do
8                  if covered(w, π + 1) then
9                      if w is a landmark then
10                         δ_H(r, w) ← π + 1
11                     else
12                         Remove r from L(w)
13                     Enqueue (w, π + 1) to Q_covered
14                 else
15                     Add/Modify {(r, π + 1)} in L(w)
16                     Enqueue (w, π + 1) to Q_uncovered
17                 Remove w from Λ_r
18             Dequeue (v, π) from Q_uncovered
19         while (v, π) ∈ Q_covered at depth π do
20             forall w ∈ N(v) s.t. w ∈ Λ_r at depth π + 1 do
21                 Remove r from L(w)
22                 Remove w from Λ_r
23                 Enqueue (w, π + 1) to Q_covered
24             Dequeue (v, π) from Q_covered
25     Remove entry r from remaining vertices in Q_covered
```

$(w, \pi+1)$ to $Q_{covered}$ (Line 13). Otherwise, we add/modify the entry of r with the new distance $\pi+1$ in $L(w)$ and enqueue w to $Q_{uncovered}$ (Lines 15-16). After that, we remove w from Λ_r (line 17). Then, for each $(v, \pi) \in Q_{covered}$, we remove r from the labels of affected neighbors of v, remove these affected vertices from Λ_r and enqueue them to $Q_{covered}$ (Lines 19-24). We process these two queues, one after the other, until $Q_{uncovered}$ is empty. Finally, we remove the entry of r from the labels of the remaining vertices in $Q_{covered}$ (Line 25).

Example 4.7. Figure 2 illustrates how our algorithm repairs labels as a result of inserting an edge $(2, 5)$. The BFS for landmark 0 is depicted in Figure 2(c), which jumps to vertex 5 and repairs three affected vertices $\{5, 9, 10\}$. The vertices $\{8, 13, 14\}$ are covered by landmarks 4 and 10. Similarly, the BFS for landmark 10 is depicted in Figure 2(e), in which vertices $\{0, 2\}$ are repaired and vertex 1 is covered by landmarks 0 and 4.

5 THEORETICAL RESULTS

Proof of correctness. For $G \hookrightarrow G'$ where our method IncHL$^+$ updates a highway cover labelling Γ over G into a highway cover labelling Γ' over G', we consider IncHL$^+$ to be *correct* iff, whenever $Q(u, v, \Gamma) = d_G(u, v)$ holds for any two vertices u and v in G, then $Q(u', v', \Gamma') = d_{G'}(u', v')$ also holds for any two vertices u' and v' in G'. We prove the theorem below for IncHL$^+$.

Theorem 5.1. *IncHL$^+$ is correct.*

Proof. First, we prove that `FindAffected` returns the set of all affected vertices Λ_r as a result of an edge insertion. IncHL$^+$ (Lines 7-8 of Algorithm 2) guarantees that any vertex being added to Q has one shortest path to a landmark r which goes through the inserted edge (a, b). By Lemma 4.3, such vertices are affected vertices, and thus a vertex v is added to Q in Algorithm 2 iff $v \in \Lambda_r$. Then, we prove that `RepairAffected` repairs $\Gamma = (H, L)$ s.t. (1) $(r, d_{G'}(r, v)) \in L(v)$ for $v \in \Lambda_r$, iff $P_{G'}(r, v)$ contains only one landmark r; (2) $\delta_H(r, r') = d_{G'}(r, r')$ for any $r' \in R \backslash \{r\}$. Starting from b with new distance π, the distances of affected vertices in Λ_r are iteratively inferred on G' and reflected into their labels via $Q_{uncovered}$ if these affected vertices are not covered (Lines 15-16 of Algorithm 3). If an affected vertex v is covered, it is kept in $Q_{covered}$; if v is also a landmark, $\delta_H(r, v)$ in H is updated (Lines 9-10). Thus, the distance entry of r is removed from the labels of affected vertices appearing in $Q_{covered}$, whereas any vertex v appearing in $Q_{uncovered}$ must have $(r, d_{G'}(r, v)) \in L(v)$. □

Preservation of minimality. It has been reported in [10] that, given a graph G, a minimal highway cover labelling $\Gamma = (H, L)$ of G can be constructed using an algorithm proposed in their work, i.e., $size(L') \geq size(L)$ holds for any $\Gamma' = (H, L')$ of G. For $G \hookrightarrow G'$ where IncHL$^+$ updates Γ over G into Γ' over G', we prove that IncHL$^+$ preserves the minimality of labelling.

Theorem 5.2. *If Γ is minimal on G, then Γ' is minimal on G'.*

Proof. By Lemma 4.6, $(r, d_{G'}(r, v)) \in L(v)$ for $v \in \Lambda_r$ iff $P_{G'}(r, v)$ does not contain any other landmark $R \backslash \{r\}$; otherwise we remove the entry of r from the label of v (Line 12, 21 and 25 of Algorithm 3). Thus, the labels of all affected vertices must be minimal after applying IncHL$^+$. For unaffected vertices, their labels should remain unchanged. Hence, Γ' must be minimal. □

Complexity analysis. Let m be the total number of affected vertices, l be the average size of labels (i.e. $l = size(L)/|V|$), and d be the average degree of vertices. For a landmark, Algorithm 2 takes $O(mdl)$ time to find all affected vertices and Algorithm 3 takes $O(md)$ to repair the labels of all affected vertices. We omit l from $O(md)$ for Algorithm 3 because distances for all unaffected neighbors of affected vertices are stored in Algorithm 2. Therefore, IncHL$^+$ has time complexity $O(|R| \times mdl)$. In our

experiments, we notice that m is usually orders of magnitudes smaller than $|V|$ and l is also significantly smaller than $|R|$.

Directed and weighted graphs. For directed graphs, we can store sets of forward and backward labels, namely $L_f(v)$ and $L_b(v)$, for each vertex v which contain pairs $(r_i, \delta_{r_i v})$ from forward and backward BFSs w.r.t. each landmark. Accordingly, we can store forward and backward highways H_f and H_b. Then, we conduct two BFSs to update these labels and highways: one in the forward direction and the other in the backward direction. Our method can also be easily extended to handling weighted graphs by using Dijkstra's algorithm instead of BFSs.

6 EXPERIMENTS

We have evaluated our method to answer the following questions: (Q1) How efficiently can our method perform against state-of-the-art methods? (Q2) How does the number of landmarks affect the performance of our method? (Q3) How does our method scale to perform updates occurring rapidly in large dynamic networks?

Datasets. We used 12 large real-world networks as detailed in Table 2. These networks are accessible at Stanford Network Analysis Project [16], Laboratory for web Algorithmics [7], Koblenz Network Collection [14], and Network Repository [17]. We treated these networks as undirected and unweighted graphs.

Updates and queries. For each network, we randomly sampled 1,000 pairs of vertices as edge insertions, denoted as E_I, where $E_I \cap E = \emptyset$ to evaluate the average update time. Further, we evaluate the average query time with 100,000 randomly sampled pairs of vertices from each network and report the labelling size after reflecting all the updates.

Baseline methods. We compared our method (IncHL$^+$) with the state-of-the-art methods: (1) IncPLL: an online incremental algorithm proposed in [4] which is based on the 2-hop cover labelling to answer distance queries; (2) IncFD: an online incremental algorithm proposed in [12] which combines a 2-hop cover labelling with a graph traversal algorithm to answer distance queries. The codes of these methods were provided by their authors and implemented in C++. We used the same parameter settings for these methods as suggested by their authors unless otherwise stated. For a fair comparison, following [12] we set $|R| = 20$ for IncFD and our methods, except for Clueweb09 which has $|R| = 150$ due to its billion-scale vertices. Our methods were implemented in C++11 and compiled using gcc 5.5.0 with the -O3 option. We performed all the experiments using a single thread on Linux server (Intel Xeon W-2175 with 2.50GHz and 512GB of main memory).

6.1 Performance Comparison

6.1.1 Update Time. Table 1 shows that the average update time of our method IncHL$^+$ outperforms the state-of-the-art methods IncFD and IncPLL on all datasets. This is due to a novel repair strategy utilized by IncHL$^+$. Further, only IncHL$^+$ can scale to very large networks with billions of vertices and edges. IncFD fails to scale to Clueweb09, and IncPLL fails for 7 out of 12 datasets due to very high preprocessing time and memory requirements.

6.1.2 Labelling Size. From Table 1, we see that IncHL$^+$ has significantly smaller labelling sizes than IncFD and IncPLL. When updates occur on a graph, the labelling sizes of IncFD and IncHL$^+$ remain stable because their average label sizes are bounded by the size of landmarks set (i.e. $|R|$). Moreover, IncFD stores complete shortest path trees w.r.t. landmarks; while IncHL$^+$ stores pruned shortest-path trees which lead to labelling of much smaller sizes than IncFD. For IncPLL, the labelling sizes may increase because IncPLL does not remove outdated and redundant entries.

6.1.3 Query Time. In Table 1 the query times of IncHL$^+$ are comparable with IncFD and IncPLL. It has been shown in [9] that query time depends on labelling size. As discussed in Section 6.1.2, the update operations do not considerably affect the labelling sizes of IncFD and IncHL$^+$, and thus their query times remain stable. However, the query times for IncPLL may increase over time because of the presence of outdated and redundant entries, which result in labelling of increasing size.

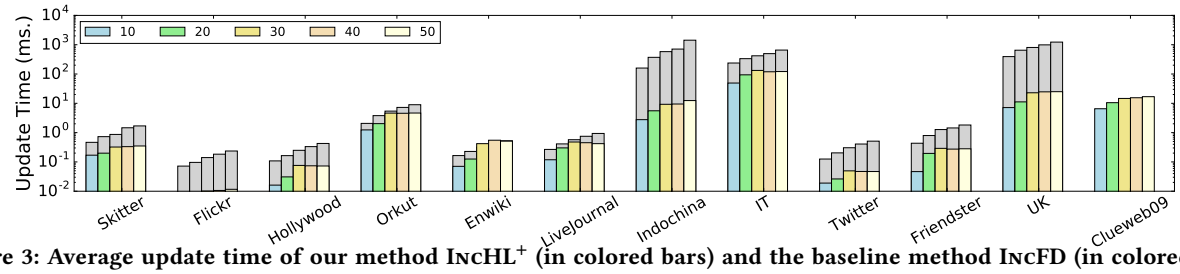

Figure 3: Average update time of our method IncHL$^+$ (in colored bars) and the baseline method IncFD (in colored plus grey bars) under 10-50 landmarks. There are no results of IncFD for Clueweb09 due to the scalability issue.

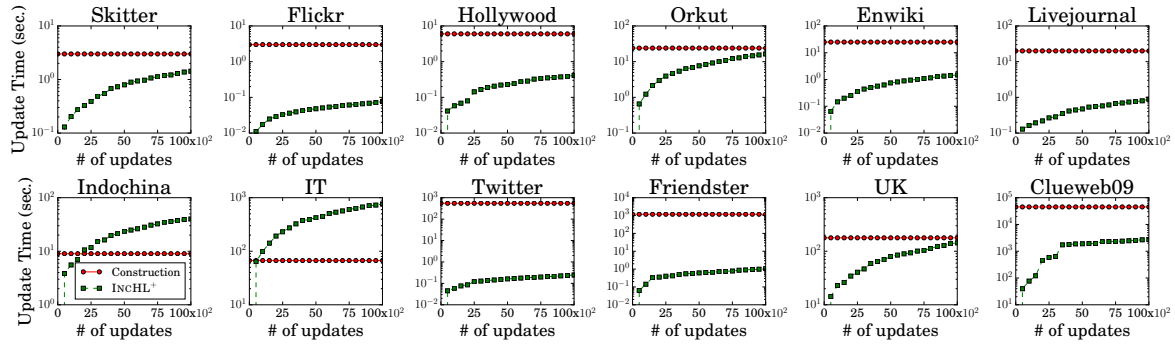

Figure 4: Update time of IncHL$^+$ for performing up to 10,000 updates against construction time of labelling from scratch.

6.2 Performance with Varying Landmarks

Figure 3 shows the average update time of our method IncHL$^+$ against the baseline method IncFD under varying landmarks, i.e., $|R| \in [10, 20, 30, 40, 50]$. As we can see, IncHL$^+$ outperforms IncFD on all the datasets against almost every selection of landmarks. We can also see the performance gap remains stable for most of the datasets when increasing the number of landmarks. This empirically verifies the efficiency of our repair strategy.

6.3 Scalability Test

We conducted a scalability test on the update time of our method IncHL$^+$, by starting with 500 updates and then iteratively adding 500 updates each time until 10,000 updates. Figure 4 shows the results. We observe that the update time of IncHL$^+$ on almost all the datasets is considerably below the construction time of labelling. On Indochina and IT, IncHL$^+$ performs relatively worse because these networks have large average distances as depicted in Table 2, which lead to high percentages of affected vertices as shown in Figure 1. In contrast, IncHL$^+$ performs well on graphs with small average distances such as Twitter. Overall, IncHL$^+$ can scale to perform a large number of updates efficiently.

7 CONCLUSION

This paper has studied the problem of answering distance queries on large dynamic networks. Our proposed algorithm exploits properties of a recent labelling technique called highway cover labelling [10] to efficiently process incremental graph updates, and can preserve the minimality property of labelling after each update operation. We have empirically evaluated the efficiency and scalability of the proposed algorithm. The results show that our proposed algorithm outperforms the state-of-the-art methods. In future, we plan to further investigate the effects of decremental updates on graphs since they are also commonly used in practice.

ABSTRACT

In high-dimensional datasets some dimensions or attributes can be more important than others. Whereas most algorithms neglect one or more dimensions for all points of a dataset or at least for all points of a certain cluster together, our method KISS (***k***NN-based **I**mportance **S**core of **S**ubspaces) detects the most important dimensions for each point individually. It is fully unsupervised and does not depend on distorted multidimensional distance measures. Instead, the k nearest neighbors (kNN) in one-dimensional projections of the data points are used to calculate the score for every dimension's importance. Experiments across a variety of settings show that those scores reflect well the structure of the data. KISS can be used for subspace clustering. What sets it apart from other methods for this task is its runtime, which is linear in the number of dimensions and $O(n \log(n))$ in the number of points, as opposed to quadratic or even exponential runtimes for previous algorithms.

1 INTRODUCTION

As sensors in fields like biology and chemistry become more and more sophisticated, websites collect more and more data about their users, and IoT and manufacturing devices get equipped with sensors that allow for predictive maintenance, the amount, granularity and dimensionality of data increases. In order to still be able to analyze the data in a meaningful way and in a reasonable time, one often needs to reduce at least one of the three; this paper will focus on the dimensionality. The more dimensions there are, the more of them are not important and distort further data mining tasks. The more dimensions, the longer it takes to process them all: the running time of many algorithms increases exponentially with the number of dimensions, especially of those designed for fewer dimensions. But not only that: many distance measures become more and more useless with an increasing number of dimensions [4]. Thus, instead of dragging along all dimensions of a point, many methods focus on working on only a small subset of the dimensions. The dimensions that a point is reduced to should, of course, be the ones that capture the most relevant information that this point contains. But to learn those important dimensions proves difficult: users do not want to waste time studying the data and its features thoroughly before applying a data mining algorithm. However, most algorithms still require user input that needs expert knowledge, or even require the user to label data by hand. In addition, the number of possibly important subspaces is exponential, making it a complex and time-consuming task to find the most important one. As datasets grow in size and contain data from different sources, one part of a dataset might differ a lot from a different part. Nonetheless, methods for dimensionality reduction typically try to find a common subspace for all data points, which can potentially be completely unsuited for heterogeneous data. Often, every single point has its own properties and thus the importance of a subspace may vary for each point, as shown in Fig. 1: for objects 1,4,7 in the first column the texture may be relevant, whereas it does not seem to be important for the other objects, since every other texture only occurs once. Also, for objects 1,2,3 in the first row and the quadrangles 4 and 5 in the second row the number of corners may be important. The color could be the best attribute to distinguish objects 1,5, and 9 in the diagonal from the others. Thus, for object 1 all three considered dimensions — number of corners, color, and texture — may be relevant, while there are other objects in the same dataset for which not all of those dimensions are important, e.g., for object 7 only the texture is relevant.

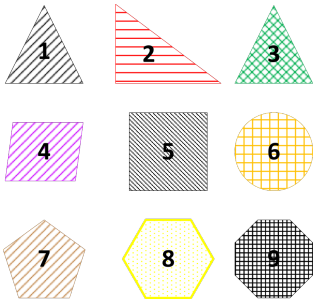

Figure 1: For different objects, different attributes or subspaces can be relevant: texture, number of corners, color, or a subset of those dimensions may be important.

A method to score the importance and expressiveness of each dimension for every point of a dataset individually without requiring any user input that scales to high dimensionalities would solve the problems mentioned above. In this paper, we develop KISS, a ***k***NN-based **I**mportance **S**core of **S**ubspaces, which fulfills all of these requirements. KISS can detect the most important subspace for a point fast and reliably in highly noisy data and data where only few dimensions are important per point.

One of the fundamental considerations that led to KISS is that those dimensions are most expressive for a point whose values lie in a cluster. We use the observation that if a point lies in a cluster in a certain subspace, the kNN of the projections of this point onto each dimension of this subspace intersect heavily. Since kNN in one-dimensional projections of the data can be computed fast, we

can efficiently calculate a score indicating the likelihood of the point lying in a cluster in the considered dimension. Usage of the kNN prevents relying on non-expressive distance measures, and there is no need for the users to know the data beforehand. KISS is deterministic, simple, fully unsupervised, and scalable w.r.t. the number of points as well as to the number of dimensions. It is easy to implement and reliably detects important dimensions for individual points fast. Our main contributions are as follows:

- We develop KISS, an importance scoring for every dimension for each individual point.
- KISS is fast w.r.t. both the number of points as well as the number of dimensions.
- KISS is fully unsupervised
- KISS does not rely on any multidimensional distance measure that gets useless for a high number of dimensions.

2 RELATED WORK

The problem of finding a global important subspace for all points has been addressed in previous work, which we introduce in Section 2.1. We restrict ourselves to algorithms that, like KISS (and contrary to, e.g., PCA or FOSSCLU), work in the standard basis of the vector space, as it simplifies getting insights into the data, which KISS was developed for.

2.1 Subspace Search

There exists some work on scoring of dimensions, where RIS, SURFING, and SCHISM are some of the most common algorithms.

RIS [6] produces a ranked list of all dimensions using a density-based quality criterion ("interestingness") that requires multiple parameters, which are set based on heuristic methods. The rating is only a relative comparison between different dimensions of the same dataset and is the same for all points.

SURFING [3] is a bottom-up approach that also returns the most "interesting" subspaces of a dataset. It is, like KISS, based on kNN, declaring subspaces as interesting in which "the k-nn-distances of the objects differ significantly from each other" [3]. The kNN distances are computed w.r.t. the subspaces, making their expressiveness dependent on the dimensionality of the subspaces. The algorithm has a runtime complexity of $O(mn^2)$, where n is the number of points and m is the number of different subspaces analyzed, which is 2^D in the worst case, making it much less scalable regarding both the number of points as well as the number of dimensions. Additionally, the minimum cluster size k has to be specified by the user.

SCHISM [8] extends the CLIQUE [2] principle and looks at the density of grid cells using an adaptive threshold function τ given by the user and applying the Chernoff-Hoeffding bound. It uses several preprocessing steps and requires three user given parameters u, τ, and ξ. Like RIS, and in contrast to KISS, it calculates a global score for "interesting" subspaces that is not adapted to individual points.

Although the dimension weightings at first glance seem to be suitable for comparing with KISS, such a comparison proves difficult: These dimension scoring methods do not return important subspaces for each point individually, or require at least two parameters set by the user, making it hard to objectively evaluate without overoptimism. But most notably, they are far more complex: The fastest of them, RIS, has runtime at least quadratic in the number of dimensions as well as the number of points. SCHISM is only linear in the number of points, but exponential in the number of dimensions. SURFING is quadratic in the number of points and exponential in the number of dimensions.

2.2 Subspace Clustering

We do not perform any clustering in this paper, but since we define "important dimensions" as dimensions in which a point lies in a cluster, there is a relation to the field of subspace clustering. Even though subspace clustering algorithms also deliver important dimensions in a way, their focus is different from KISS. Whereas those algorithms often need to perform a complete clustering of the dataset, we aim to get the relevant subspaces directly, individually for every point. We do not need to know the precise clusters to find important dimensions. Also, most of those algorithms rely on parameters that are not easy to set. We found that especially our first two goals, being fully unsupervised, and returning individual scores for different points, are to the best of our knowledge not achieved simultaneously by any other algorithm in this field. COSA and DISH are most related to our work, since they both consider subspaces for individual points:

COSA [5] finds important subspaces individually for each point using the kNN. A hierarchical clustering is applied based on a dimension weighting matrix and the relevant dimensions can be calculated based on the dimension weights of the respective cluster members. Despite the similarities to KISS, there are two major differences: First, users need to set a not quite intuitive parameter λ, which gives the "strength of incentive for clustering on more dimensions" [7]. Second, the kNN are calculated in the full-dimensional space, making COSA vulnerable to the loss of expressiveness of distance measures in high dimensions.

DiSH [1] is a density-based algorithm that finds cluster hierarchies and nested clusters. It has two parameters: a smoothing factor μ representing the minimum number of points in a cluster and ε for ε-range queries. Even though DiSH also uses only one-dimensional range queries and delivers subspace preference vectors for every point, the nesting of subspaces makes it impossible to determine the distinctly important subspaces. Also, the vectors are only calculated in an intermediate step, and depend on the parameter choices.

2.3 Possible Competitors

Finding suitable methods to compare KISS to is difficult: there are a number of subspace clustering algorithms, but they perform clustering, and not detection of the most important subspaces. For some algorithms one could extract the important subspaces of a point by looking at the subspace of the cluster the point was assigned to. This assignment, however, can only be obtained after an expensive clustering of the complete dataset. Some algorithms like, e.g., RIS or SURFING rank the subspaces in a similar way as KISS scores them, but they deliver one ranking for the complete dataset, not for each point individually. To the best of our knowledge, there is no algorithm yet that fulfills all of the requirements we impose. In particular, returning individual dimension ratings for each point and being completely unsupervised are very rare properties. Nevertheless, to at least have *some* point of reference, we exemplarily compare against CLIQUE, which is a grid-based bottom-up approach for subspace clustering. It requires two parameters, ξ and τ, which determine the number of intervals every dimension is partitioned into and the density threshold. We try out different parameter settings, showing that the results are very

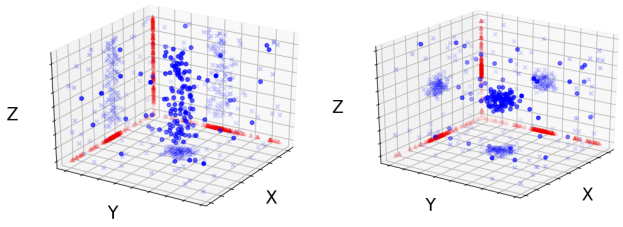

Figure 2: Projections of a 2-dimensional resp. 3-dimensional cluster. Blue crosses are projections onto the 2-dimensional subspace, red triangles projections onto one dimension.

sensitive to the parameter choices, whereas for KISS no parameters need to be tuned. In addition, we use the quality criterion of SURFING to obtain scores for every dimension and compare KISS to them. However, those are global scores for all points and not individual ones like those computed by KISS.

3 KISS

This section presents our newly developed dimension score KISS. We first describe the basic idea to use the k nearest neighbors in one-dimensional projections of the n data points to be able to compute KISS, which gives a scoring for the importance of every dimension for each individual point. Section 3.2 motivates our idea mathematically. In Section 3.3 we develop the exact formula of KISS, and present the complete KISS-based algorithm to obtain the most important subspace of a point. We analyze the complexity of our algorithm in Section 3.4.

3.1 Idea: Using One-dimensional kNN

If a point lies in a cluster in a d-dimensional subspace, most of the kNN of this point in the projection of the dataset onto those d dimensions will be members of that cluster, too. If we look at only one of those d dimensions (cf. the red triangles in Fig. 2), we still see the cluster structure: the cluster on the left lies in dimensions X and Y, and the red triangles on the according axes show a clear cluster structure. Projected onto those axes, most of the one-dimensional kNN of a point will lie in the same (original) d-dimensional cluster as the point itself.

Following this observation, for a given point p, we count for every other point q in how many dimensions it belongs to the one-dimensional kNN of p, giving us a Point Score $PS(p, q)$. A high Point Score means that q is likely to be contained in the same (higher-dimensional) cluster as p, meaning that the dimensions that they share carry more importance for p than the others. Summing up the Point Scores for each dimension individually gives us a measure for the importance of each dimension, where we account for outliers by incorporating the one-dimensional distances to the kNN of a point.

3.2 Mathematical Perspective

In the following we give some theoretical insights which support our idea. We denote cluster indices by superscripts and dimension indices by subscripts, and see clusters as collections of points drawn from a common probability distribution over $\mathbb{R}^D$.

Consider a cluster C^1 with center c^1 in dimensions $\{1, \dots, l\}$ (without loss of generality). We will consider the neighborhood of points in dimension 1. Let C^2 be a different cluster with center c^2 that overlaps with cluster C^1 in dimension 1, and assume that for all points $r^1 \in C^1$ and all $r^2 \in C^2$ we have $\Pr(|r_1^1 - c_1| \leq \varepsilon) \geq \delta$ and $\Pr(|r_1^2 - c_1| \leq \varepsilon) \geq \delta$, respectively, where $\varepsilon > 0$ and δ is a value close to 1. Furthermore, C^1 and C^2 should not overlap and be sufficiently far apart in the dimension that they share: $|c_1^1 - c_1^2| \leq 4\varepsilon + \varepsilon'$ for an arbitrarily small $\varepsilon' > 0$. This is, e.g., the case for all shared dimensions with high probability if c^1 and c^2 are uniform samples from a sufficiently large set in $\mathbb{R}^D$.
Let $p^1, \tilde{p}^1 \in C^1$, and $p^2 \in C^2$. In addition, let q be a point that does not lie in any cluster in dimension 1 and is drawn from a somewhat uniform distribution on a large enough interval. Precisely, we require it to fulfill $\Pr(|q - c_{1,2}| \leq 3\varepsilon) \leq \delta'$, where δ' is close to 0.
We now consider the distance of p^1 to the other three points in dimension 1.
For the point from the same cluster, we get

$$\Pr(|p_1^1 - \tilde{p}_1^1| \leq 2\varepsilon) \geq \Pr(|p_1^1 - c_1^1| + |c_1^1 - \tilde{p}_1^1| \leq 2\varepsilon)$$
$$\geq \Pr(|p_1^1 - c_1^1| \leq \varepsilon) \Pr(|c_1^1 - \tilde{p}_1^1| \leq \varepsilon) \geq \delta^2 \approx 1.$$

The point from the other cluster yields

$$\Pr(|p_1^1 - p_1^2| \leq 2\varepsilon) \leq \Pr(|p_1^1 - c_1^2| > \varepsilon \text{ or } |p_1^2 - c_1^1| > \varepsilon)$$
$$\leq \Pr(|p_1^1 - c_1^2| > \varepsilon) + \Pr(|p_1^2 - c_1^1| > \varepsilon) = 2(1 - \delta) \approx 0,$$

where for the first step we observed that at least one of p_1^1, p_1^2 needs to lie outside of the ε-interval around its cluster's center, and applied a simple union bound to obtain the second inequality. Finally, for the point that does not lie in any cluster in dimension 1, we have, using the same arguments as above,

$$\Pr(|p_1^1 - q_1| \leq 2\varepsilon) \leq \Pr(|p_1^1 - c_1^1| > \varepsilon \text{ or } |q_1 - c_1^1| \leq 3\varepsilon)$$
$$\leq \Pr(|p_1^1 - c_1^1| > \varepsilon) + \Pr(|q_1 - c_1^1| \leq 3\varepsilon) \leq (1 - \delta) + \delta' \approx 0.$$

Thus, if k is chosen smaller than the size of C^1, the kNN of p_1^1 will almost exclusively consist of points from C^1. Thus,

$$\mathbb{E}(|\{i \in \{1, \dots, l\} \mid \tilde{p}_i^1 \text{ is part of the } k\text{-NN of } p_i^1\}|) \approx l\frac{k}{|C^1|} > l\frac{k}{n},$$

where the last quantity corresponds to a uniform distribution of points.

3.3 The Full Algorithm

KISS, the score indicating the importance of a dimension d for a point p in a dataset DB, depends on the k nearest neighbors (kNN) of p in the one-dimensional projection onto d: $kNN_p(d)$. Note that their number can be larger than k in case of ties, since we chose the deterministic variant of kNN.

The more often a point occurs in the sets of one-dimensional nearest neighbors of p, the closer related it is to p, which we capture in the *Point Score* $PS(p, q)$, where $\mathbb{1}$ is the indicator function: $PS(p, q) = \sum_{d=1}^{D} \mathbb{1}\{q \in kNN_p(d)\}$.

Higher values for k lead to more accurate scores, as shown in Fig. 3. However, the runtime of our algorithm depends on k and we would like to keep it $O(n \log(n))$ in the number of points (see our complexity analysis in Section 3.4). For this reason, k is set to $\sqrt{n}$, which is also in line with previous literature [5].

The importance a dimension d has for a point p depends not only on the intersection of the kNN in this dimension with the kNN in the other dimensions, but also on the distance of those kNN. Otherwise, the important dimensions for outliers would be distorted. Thus, the farther away a point in the kNN is, the less influence it should have on the importance of the respective dimension, which is why we divide the Point Score of each

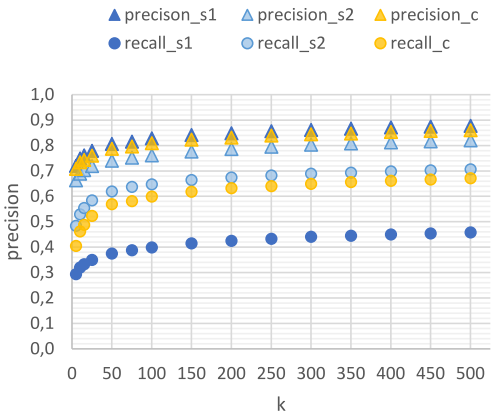

Figure 3: Results for different values of k. _s1, _s2, and _c denote different binarization methods, see Sec. 4.

$q \in kNN_p(d)$ by the distance between the corresponding projections of q and p. Additionally, the computed value is divided by the neighborhood size to account for ties among the nearest neighbors:

$$KISS'(p,d) = \frac{1}{|kNN_p(d)|} \sum_{q \in kNN_p(d)} \frac{1}{dist(p_d, q_d)} PS(p,q) \quad (1)$$

Finally, KISS is normalized for every point by dividing every value by the highest KISS occurring for the respective point:

$$KISS(p,d) = \frac{KISS'(p,d)}{\max_{e \in \{1,\ldots,D\}} KISS'(p,e)}. \quad (2)$$

This gives a value between 0 and 1 and allows for a meaningful comparison between different points of a dataset.

3.4 Complexity

The calculation of the kNN of all points in all dimensions needs $O(D * k * n + D * n * \log(n))$ steps, where D is the number of dimensions in the data set DB of size $|DB| = n$. Computing the kNN in one dimension can be performed efficiently by sorting the points w.r.t. this dimension and going to the left and right of the query point in the sorted list. Given the kNN of every point for every dimension, all Point Scores $PS(p,\cdot)$ w.r.t. a point p can be calculated in $O(D*k)$ by iterating through the k nearest neighbors of p in all D dimensions, keeping track of the scores via a hashmap where they get continuously updated. This has to be done for all n points, resulting in $O(n * D * k)$. For calculating the KISS for a point p and a dimension d, we need to sum up the Point Scores of all of p's kNN in d divided by their (one-dimensional) distance in this dimension, which can be done in $O(1)$. The summation can be performed in $O(k)$. We want to compute the KISS for all points and all dimensions, thus we get $O(n * D * k)$.

The KISS for all dimensions and all points can hence be computed in time $O(D*k*n+D*n*\log(n)+n*D*k+n*D*k) = O(D*n*(k+\log(n))$, which is linear in the dimension D and close to linear in the size of the dataset n. Runtime experiments confirmed this behavior, but were omitted due to space constraints.

4 EXPERIMENTAL EVALUATION

In Section 4.1 we introduce a technical tool that is needed to validate our method against a ground truth. In Section 4.2 we describe our experiments, and summarize the results in Section 4.3.

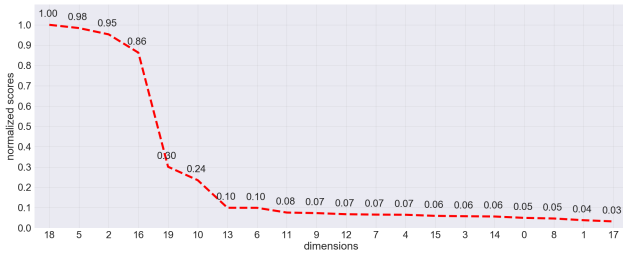

Figure 4: Typically distributed scores for different dimensions for a point p, sorted by descending normalized score.

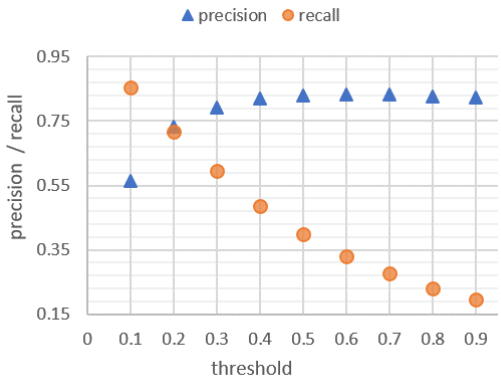

Figure 5: Precision and recall using simple binarization with different thresholds.

4.1 Binarization

To be able to validate our results and because for certain applications a division of the dimensions into important and unimportant ones can be needed, we suggest two possibilities to binarize the values obtained by KISS. Ordered by score value, a typical distribution of the scores for a point is shown in Fig. 4. If a point lies in a cluster, the KISS of the according dimensions clearly differs from the KISS of unimportant dimensions.

The naïve approach "simple binarization" of using a fixed threshold for the normalized score based on which we set the score to either 0 or 1, already delivers good results, as we show in Section 4.2. Fig. 5 shows recall and precision for our base case experiment and different values for the threshold, where 0.2 offers a good trade-off between the two. We performed the other experiments with the thresholds 0.5 and 0.2, denoted by _s1 and _s2, respectively.

Additionally, we developed a more sophisticated approach — "complex binarization" —, which comes with an only negligable increase in runtime, to improve our results even further. Here, we look for the most appropriate cut position in the ranked scores: e.g., for the KISS distribution depicted in Fig. 4 it could be dimension 12 since the scores for all dimensions to the right of it are significantly lower than the ones to the left of it. Our approach for detecting this cut position in the score ranking consists of first setting the importance of each dimension to 1 and then lowering it to 0 if its KISS lies below one of the three thresholds described below.

We set all parameters required for the complex binarization to the same reasonable values we give below for all experiments. Both strategies are introduced mainly to be able to validate our results against a binary ground truth. Note that the parameter values rely on the data being scaled to the D-dimensional unit

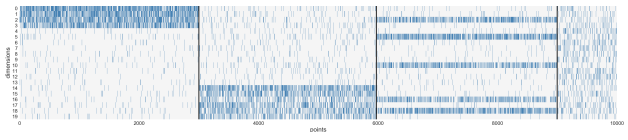

Figure 6: Transpose of the binary matrix for the base case dataset computed using KISS with complex binarization. The subspace boundaries are depicted as black lines.

hypercube. The three thresholds for the complex binarization are:

(1) *normalized threshold* t_n: If $KISS(p,d) < t_v = 0.1$, then $KISS(p,d)$ is set to 0.
(2) *unnormalized threshold* t_u: Because we normalize the KISS of each dimension by dividing by the largest KISS for this point, even a point that is just random noise has at least one dimension with score 1. However, the unnormalized value of dimensions with a high normalized KISS for this noise point will be significantly lower than the unnormalized values of dimensions with a high normlized KISS for a point that lies in a cluster. Thus, in addition to setting a threshold for the normalized KISS, we also set one for the unnormalized KISS' (cf. Equation 1): if $KISS'(p,d) < t_u$, the score for d is set to 0, where t_u equals the difference between mean and minimum of all unnormalized scores.
(3) *descent threshold* t_d: The descent threshold controls the decline between consecutive KISS values. If $\frac{KISS(p,e)-KISS(p,d)}{KISS(p,e)} > t_d = 0.7$, where $KISS(p,e)$ is the next largest KISS value of p, then all KISS values smaller than or equal to $KISS(p,d)$ become 0.

The result of the binarization can be expressed in a binary matrix as in Fig. 6.

Empirically, setting t_n significantly lower than 0.5 and t_d rather high allows for detecting more relevant dimensions and therefore detecting subspaces of higher dimensionality. t_u affects mostly how well outliers are detected. However, setting this parameter too high leads to very restricted binarized scores and can possibly decrease the detection rate of the important dimensions of the cluster points. In general, the parameters allow us to trade precision for recall. KISS is supposed to be used in settings where working with the original data without a significant reduction of the dimensionality is infeasible, either due to limited human capacity when manually analyzing the data or due to non-favorable dependence of a downstream task's performance on the number of dimensions. Hence we can live with a mediocre recall if in return the precision is high, allowing us to get rid of many dimensions, which is why we mainly focus on achieving a high precision.

In real-world settings where one needs a binary division of the dimensions, one typically has a (computational or storage) budget of dimensions one can deal with in the downstream task, and would binarize in a way so that exactly this many dimensions are labeled as important.

4.2 Experiments

We test with both the simple and complex binarization of KISS and denote the corresponding values with the abbreviations _s and _c, respectively. To have ground truth values for the importance of all dimensions, we generated data containing subspace clusters with possibly overlapping subspaces. The clusters are

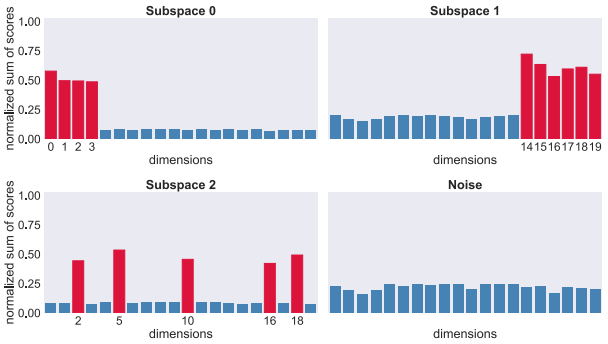

Figure 7: Average KISS for all points, partitioned according to ground-truth based important subspaces. Red bars show dimensions containing clusters.

Gaussians with mean randomly drawn from the uniform distribution on the D-dimensional unit hypercube. The values for the dimensions of a point that do not lie in a cluster are uniformly distributed in the hypercube [1].

Looking at the distribution of KISS per important (according to the ground truth) subspace in Fig. 7, we already see the correlation to the cluster subspaces: the average scores for the important dimensions (red bars) are visibly higher than those for unimportant dimensions (blue bars). Noise points that do not lie in any cluster are shown in the lower right diagram: the average KISS values do not differ much. The precision we achieve for both types of binarization are good, as can be seen in Fig. 8.

To the best of our knowledge there are no alternatives yet to KISS (see Section 2.3). However, with CLIQUE and SURFING we compare KISS to representative algorithms for subspace clustering and for subspace search. The comparison makes the disadvantages of having to set parameters as well as the benefit of individual scores in contrast to a global ranking clear.

Among others, Fig. 8 shows results obtained with CLIQUE for different parameter configurations. Even though CLIQUE was able to obtain high recall values, the precision was even for the best parameter settings much lower than for KISS (for both binarization methods). We also see that the results heavily depend on the choice of CLIQUE's parameters, with precision ranging from 35% to 77% and recall from 53% to 87%. Fig. 8 further includes the results obtained by binarizing the "quality" of each particular dimension as computed by SURFING for different values of k (in the same way as we binarize the KISS values). The classification performance of SURFING is very dependent on the parameter choice as well. With a good choice, it is able to achieve a high recall, but, as expected, the precision values are rather low, since the quality assignments are the same for all points, which does not match the ground truth.

Starting from this base case, we altered one parameter of the data in each of the following subsections to investigate KISS' behaviour w.r.t. this parameter.

4.2.1 Number of points. Changing the number of points n did not affect the precision, recall or accuracy of KISS significantly.

[1] The settings for our base case dataset are as follows: number of points $n = 10000$, dimensionality of point p: $dim(p) = 20$, percentage of noise $noise = 0.1$, set of dimensions in subspace S_i: $S_0 = \{0 \dots 3\}$, $S_1 = \{14 \dots 19\}$, $S_2 = \{2, 5, 10, 16, 18\}$, percentage of points w.r.t. n lying in subspace S_i: $|S_i| = [0.3, 0.3, 0.3]$, dimensionality of S_i: $dim(S_i) = [4, 6, 5]$, number of clusters in subspace S_i: $n_c(S_i) = [1, 2, 1]$, variance of cluster C_i: $var(C_i) = [1.5, 1.0, 1.3]$.

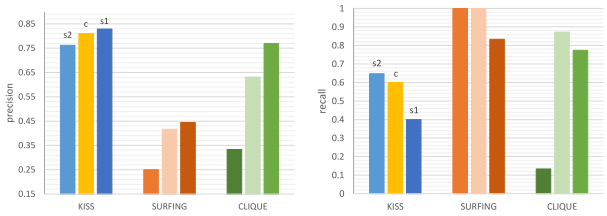

Figure 8: Results for KISS, SURFING, and CLIQUE for the base case dataset and different parameters ξ and τ resp. k. Same color indicates same parameters.

The three values deviated by at most 3% for $n \in \{5\,000, 10\,000, 25\,000, 50\,000, 75\,000, 100\,000\}$.

4.2.2 Number of dimensions. With growing number of dimensions (while keeping the ratio of dimensions lying in important subspaces the same) the recall decreases, but the precision, which we put more emphasis on, stays high.

4.2.3 Noise. Increasing the percentage of pure noise points leads to less points in each cluster, thus precision drops. Nevertheless, the decrease of quality is slow, and up to 50% of data can be pure noise points before precision falls below 75% (for the complex binarization).

4.2.4 Number of subspaces. We examine KISS for up to 10 different subspaces and obtain good results with precisions above 73% in all cases. Additionally, recall as well as accuracy diminish only slightly with increasing number of subspaces.

4.2.5 Subspace size ratio. We tested several size ratios between the three base case subspaces our dataset consists of. In our base case, every subspace contains one third of the non-noise data points. We set the share of instances in the first subspace to values $\{0.4, 0.5, 0.6, 0.7, 0.8\}$, while dividing the remaining points equally among the other two subspaces (and additionally keeping the 10% noise of the base case). The quality of the scores hardly changed: we received precision values for the simple binarization between 83% and 85%, and between 84% and 86% for the complex binarization. Recall values ranged between 39% and 41%, and 47% and 49%, respectively, showing that the size ratio of the subspaces does not constitute a problem for KISS. Thus, even subspaces containing only very few points of the complete dataset can be found as easily as bigger subspaces.

4.2.6 Number of clusters per subspace. With an increasing number of clusters, precision as well as recall decrease, since there are fewer points per cluster that could help identify a point in the cluster.

4.2.7 Density of clusters. We tested several density settings for the clusters. When all subspaces contain similarly dense clusters, the quality decreases with lower density (i.e., higher standard deviation). If each subspace contains differently dense clusters, the results are rather determined by the average density than by the lowest or highest occurring density. Thus, a large difference in cluster density does not influence the results negatively.

[1]When adding more subspaces to the base case dataset, we use the same settings as for the original subspaces: the points are evenly distributed among the subspaces, and the cluster settings of the clusters lying in subspaces S_{0+3i}, S_{1+3i}, S_{2+3i} correspond to the settings of the clusters lying in subspaces S_0, S_1, S_2.

4.3 Summary of Results

Our experiments show that KISS achieves a high precision and reasonable recall across a wide range of settings. With a high number of subspaces or clusters the performance starts to degrade, but KISS is robust to noise and can deal with high numbers of points as well as clusters of different density. We would like to point out that the experiments only show a small part of KISS' capabilities, since the original KISS is a continuous value, which we just binarized here, and likely not even optimally.

5 CONCLUSION AND FUTURE WORK

We developed KISS, a scoring that assigns an importance value to each dimension of each point of a dataset. It is scalable, does not suffer from the curse of dimensionality, since it replaces multi-dimensional distance measures by one-dimensional ones, and does not require significant user involvement to set parameters. Its runtime is linear in the dimensionality and close to linear in the number of points, setting it apart from similar methods.

KISS has numerous applications, both as a tool to get an insight into datasets as well as a foundation for data mining applications, in particular to accelerate downstream tasks or to make them more robust to noise. We are currently working on some of the most immediate extensions: (1) performing clustering using especially the most relevant dimensions for each point; and (2), using KISS for outlier and noise detection, following the observation that points that have a low KISS in every dimension are typically in none of those in a cluster. We encourage the usage of KISS for preprocessing data and gaining knowledge in an early stage of a data anlysis process, since it is simple, fast, delivers good results and does not require parameter tuning.

ABSTRACT

Collaborative filtering has been largely used to advance modern recommender systems to predict user preference. A key component in collaborative filtering is representation learning, which aims to project users and items into a low dimensional space to capture collaborative signals. However, the scene information, which has effectively guided many recommendation tasks, is rarely considered in existing collaborative filtering methods. To bridge this gap, we focus on scene-based collaborative recommendation and propose a novel representation model SceneRec. SceneRec formally defines a *scene* as a set of pre-defined item categories that occur simultaneously in real-life situations and creatively designs an item-category-scene hierarchical structure to build a scene-based graph. In the scene-based graph, we adopt graph neural networks to learn scene-specific representation on each item node, which is further aggregated with latent representation learned from collaborative interactions to make recommendations. We perform extensive experiments on real-world E-commerce datasets and the results demonstrate the effectiveness of the proposed method.

1 INTRODUCTION

Recommender systems have become increasingly important to address the information overload problem and have been widely applied in many different fields, such as social networks [22] and news websites [24]. To predict a user's preference, an extensive amount of collaborative filtering (CF) methods have been proposed to advance recommender systems. The basic idea of CF is that user behavior would always be similar and a user's interest can be predicted from the historical interactive data like clicks or purchases. A key component of CF is to learn the latent representation, which usually projects users and items into a lower dimensional space. A variety of CF models, including matrix factorization [8], deep neural networks [7] and graph convolutional networks [16], are adopted to capture collaborative signals from a user-item matrix or a user-item bipartite graph.

In the meantime, recommender systems that integrate scene information are attracting more and more attention. For example, predictive models are able to recommend substitutable or complementary items [9, 10, 13] that visually match the scene which is represented in an input image. The image data contains rich contextual information like background color, location, landscape, etc., which may be ignored by conventional CF methods. However, the input image could reveal no scene information or even becomes unavailable in many recommendation scenarios. For example, in E-commerce systems, most thumbnail images only contain product pictures which are embedded in the white background. In such circumstances, scene-based recommendation becomes infeasible because the scene definition is not clear.

To address this issue, this work investigates the utility of incorporating scene information into CF recommendation. However, this study brings two challenges. First, a formal definition on scene is essential to this problem. Without image data, how to formally define a scene becomes a problem. Second, how to incorporate scene information into existing CF models should also be taken into account. Keeping these two key points in mind, we propose SceneRec, a novel method for scene-based collaborative filtering. Specifically, we propose a principled item-category-scene hierarchical structure to construct the scene-based graph (Figure 1). In particular, a *scene* is formally defined by a set of fine-grained item categories that could simultaneously occur in real-life situations. For example, the set of item categories {Keyboard, Mouse, Mouse Pad, Battery Charger, Headset} represents the scene "Peripheral Devices". This can be naturally applied to a situation where a user has already bought a PC and many different types of supplementary devices are recommended. Moreover, SceneRec applies graph neural networks on the scene-based graph to learn the item representation based on the scene information, which is further aggregated with the latent representation learned from user-item interactions to make predictions.

To the best of our knowledge, SceneRec is among the first to study scene-based recommendation with a principled scene definition and our main contributions are summarized as follows:
(1) We study the problem of scene-based collaborative filtering for recommender system where a scene is formally defined as a set of item categories that could reflect a real-world situation.
(2)We propose a novel recommendation model SceneRec. It leverages graph neural networks to propagate scene information and learn the scene-specific representation for each item. This representation is further incorporated with a latent representation from user-item collaborative interactions to make predictions.
(3) We conduct extensive experiments to evaluate the performance of SceneRec against 9 other baseline methods. We find that our method SceneRec is effective. Specifically, SceneRec on average improves the two metrics (NDCG@10, HR@10) over the baselines by (14.8%, 12.1%) on 4 real-world datasets.

2 RELATED WORK

Collaborative filtering has been widely applied in modern recommender systems. One class of CF methods try to build explicit models on the user-item interactions. For example, matrix factorization [2, 8, 12, 14] maps the representation of each user and each item into a lower dimensional space and calculates inner product

between vector representations to make predictions. To enhance recommendation, various contextual information has been incorporated into CF, such as user review [21], social connections [22] and item side information [17]. Different from existing works that rely on linear predictive function, many recent efforts apply deep learning techniques [7] to learn non-linearities between user embedding and item embedding.

Another line of CF methods take user-item interactions as a bipartite graph. For example, some early efforts [5] conduct label propagation, which essentially searches neighborhood on the graph, to capture collaborative signals. Inspired by the success of graph neural networks (GNN) [6, 11] that directly conduct convolutional operations on the non-grid network data, a series of GNN-based recommendation methods have been proposed on an item-item graph [23] or a user-item graph [16] to learn a vector embedding for each item or user. The general idea is the representation of one graph node can be aggregated and combined by the representation of its neighbor nodes. NGCF [20] extends GNN to multiple depths to capture high-order connectivities that are included in user-item interactions. KGAT [19] and KGCN [18] investigate the utility of incorporating knowledge graph (KG) into CF by projecting KG entities to item nodes.

Our work is also related to the application of scene information in recommender systems. For example, given the scene in the form of an input image, recommendation methods are capable of providing substitutable [10, 13] or supplementary[9] products that visually match the input scene. However, in these tasks, the scene is represented by image data, which is not readily available in many recommendation scenarios. In such cases, scene-based recommendations become difficult or even impossible because the scene has not been well defined. In this paper, we aim to integrate scene information into CF where each scene is define by a set of fine-grained item categories. By exploiting the scene-specific representation into conventional CF signals, the model can potentially improve predictions on user preference.

3 PROBLEM FORMULATION

Definition 3.1. **Scene**. A *scene* is defined as a set of item categories that occur simultaneously and frequently in a real-life situation, denoted as $s = \{c_1, c_2, \cdots, c_{|s|} | c_i \in C, 1 \leq i \leq |s|\}$, where C is the set of item categories and $|s| \geq 1$. The item category is one of a item's attributes and $s \subset C$.

Definition 3.2. **User-Item Bipartite Graph.** The user-item interactions can be represented as a bipartite graph $\mathcal{G} = \{(u, x_{ui}, i) | u \in \mathcal{U}, i \in \mathcal{I}\}$, where $\mathcal{U}$ and $\mathcal{I}$ are the set of users and items respectively, and the edge x_{ui} indicates the occurrence or frequency with that the user u has interacted with the item i, such as clicking and purchasing.

Definition 3.3. **Scene-based Graph.** The scene-based graph $\mathcal{H}$ is a hierarchical network with three layers: the item layer, the category layer, and the scene layer as shown in Figure 1. The item layer consists of items and is denoted as $\mathcal{L}_{item} = \{(i_p, y_{pq}, i_q) | i_p, i_q \in \mathcal{I}\}$, where the edge y_{pq} represents the similarity between two items i_p and i_q. The category layer is denoted as $\mathcal{L}_{cate} = \{(c_p, z_{pq}, c_q) | c_p, c_q \in C\}$, where the edge z_{pq} represents that the category c_p has relevance to the category c_q. The interaction between the item layer and the category layer is described by $\mathcal{L}_{ic} = \{(i_p, a_{pq}, c_q) | i_p \in \mathcal{I}, c_q \in C\}$, where the edge a_{pq} connects an item i_p to a pre-defined item category c_q. The scene layer is composed of scenes, where a scene s is formally defined as a set of item categories $\{c_1, c_2, \cdots, c_{|s|}\}$.

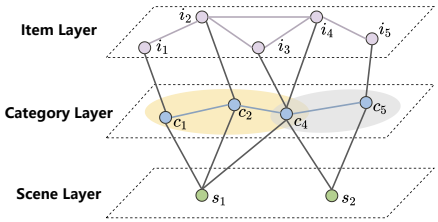

Figure 1: An illustrative example of the scene-based graph that consists of the item layer, the category layer and the scene layer. Each item is associated with a category. In the item layer and the category layer, the set of edges represent the item-item relations and the category-category relations. There are connections between categories and scenes, which indicates that a category belongs to a scene.

The relation between categories and scenes is illustrated by $\mathcal{L}_{cs} = \{(c_p, b_{pq}, s_q) | c_p \in C, s_q \in \mathcal{S}\}$, where the edge b_{pq} indicates that a category c_p belongs to a scene s_q and $\mathcal{S} = \{s_1, s_2, \cdots\}$ is the set of scenes. For simplicity, we set the weights of edges in the scene-based graph $\mathcal{H}$ to be 1; otherwise, 0.

Definition 3.4. **Scene-based Recommendation.** Given a user-item bipartite graph $\mathcal{G}$ recording interaction history, the goal of the scene-based recommendation is to predict the probability $\mathbf{r}_{ui}$ that the user u has potential interest in the item i with the help of scene information from a scene-based graph $\mathcal{H}$.

4 FRAMEWORK

In this section, we will first give an overview about the proposed framework, then introduce each model component in detail.

4.1 Architecture Overview

The architecture of the proposed model is shown in Figure 2. There are three components in the model: user modeling, item modeling, and rating prediction. User modeling aims to learn a latent representation for each user. To achieve this, we take user-item interaction as input and aggregate the latent representation of items that the user has interacted with to generate the user latent factor. Item modeling aims to generate the item latent factor representation. Since each item exists in both user-item bipartite graph and the scene-based graph, SceneRec learns item representations in each graph space, i.e., item modeling in the user-based space and item modeling in the scene-based space. In the user-based space, we take a similar strategy which aggregates the representation of all users that each item has interacted with to generate vector embedding. In the scene-based space, we exploit the hierarchical structure of the scene-based graph where the information is propagated from the scene layer to the category layer and from the category layer to the item layer. Then we concatenate two item latent factors for the general representation. In the last component, we integrate item and user representations to make rating prediction.

4.2 User Modeling

In the user-item graph, a user u_p is connected with a set of items and these items directly capture the user's interests. We thus learn user u_p's embedding $\mathbf{m}_{u_p}$ by aggregating the embeddings of item neighbors, which is formulated as,

$$\mathbf{m}_{u_p} = \sigma(\mathbf{W}_{\mathbf{u}} \cdot \left\{ \sum_{i_q \in UI(u_p)} \mathbf{e}_{i_q} \right\} + \mathbf{b}_{\mathbf{u}}), \tag{1}$$

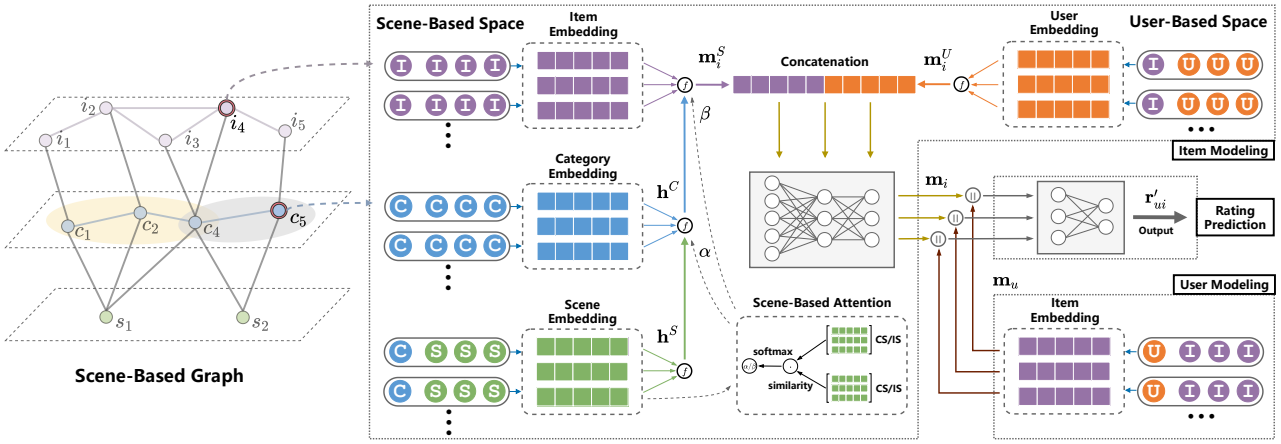

Figure 2: The illustration of SceneRec architecture (the arrowed lines present the bottom-up information flow). The embeddings of users and items are learned by user modeling and item modeling, respectively.

where $UI(u_p)$ denotes the set of items that are connected to user u_p, $\mathbf{e}_{i_q}$ is the embedding vector of item i_q, and σ is the nonlinear activation function. $\mathbf{W_u}$ and $\mathbf{b_u}$ are the weight matrix and the bias vector to be learned.

4.3 Item Modeling

The general representation $\mathbf{m}_{i_p}$ for item i_p can be further split into two parts: the embedding $\mathbf{m}^U_{i_p}$ in the user-based space and the embedding $\mathbf{m}^S_{i_p}$ in the scene-based space.

4.3.1 User-based embedding. In the user-item graph, an item i_p has connections with a set of users. We learn its embedding $\mathbf{m}^U_{i_p}$ by aggregating the embedding of these engaged users:

$$\mathbf{m}^U_{i_p} = \sigma(\mathbf{W_{iu}} \cdot \left\{ \sum_{u_q \in IU(i_p)} \mathbf{e}_{u_q} \right\} + \mathbf{b_{iu}}), \tag{2}$$

where $IU(i_p)$ denotes the set of users that are connected to item i_p, $\mathbf{e}_{u_q}$ is the embedding vector of user u_q, $\mathbf{W_{iu}}$ and $\mathbf{b_{iu}}$ are parameters to be learned. Since $\mathbf{m}^U_{i_p}$ is aggregated from user neighbors, $\mathbf{m}^U_{i_p}$ represents the user-based embedding of item i_p.

4.3.2 Scene-based embedding. In the scene-based graph, each item is connected to both other items and its category. So, the scene-based embedding $\mathbf{m}^S_{i_p}$ for item i_p is composed of representation that is specific to item neighbors and category neighbors.

For the category-specific representation, we should first generate the latent factor of each category. Since one category node can connect to both scene nodes and other related category nodes, the category representation can be further split into two types: the scene-specific and category-specific representation.

Given a category c_p, it may belong to a set of scenes and its scene-specific embedding vector $\mathbf{h}^S_{c_p}$ can be updated as follows:

$$\mathbf{h}^S_{c_p} = \sum_{s_q \in CS(c_p)} \mathbf{e}_{s_q}, \tag{3}$$

where $CS(c_p)$ is the set of scenes that category c_p belongs to and $\mathbf{e}_{s_q}$ is the embedding vector of scene s_q.

Besides the connection between scene nodes and category nodes, our model also captures the interactions between different category nodes. Each category contributes to the category-specific representation but categories do not always affect each other equally. Therefore, we apply the attention mechanism to learn the influence between different item categories. In this way, the category-specific representation $\mathbf{h}^C_{c_p}$ of the category c_p can be aggregated as follows:

$$\mathbf{h}^C_{c_p} = \sum_{c_q \in CC(c_p)} \alpha_{pq} \mathbf{e}_{c_q}, \tag{4}$$

where $CC(c_p)$ is the set of neighbor categories, $\mathbf{e}_{c_q}$ is the embedding vector of c_q, and α_{pq} is the attention weight. For a pair of categories, the more scenes they share, the higher relevance between them. Therefore, we propose a scene-based attention function to compute α_{pq}. Specifically, we calculate the attention score by comparing the sets of scenes that c_p and c_q belong to:

$$\alpha^*_{pq} = f\left(\sum_{s_a \in CS(c_p)} \mathbf{e}_{s_a}, \sum_{s_b \in CS(c_q)} \mathbf{e}_{s_b} \right), \tag{5}$$

where $f(\cdot)$ is an attention function to measure the input similarity. For simplicity, we use cosine similarity as $f(\cdot)$ in this work. α_{pq} is obtained by further normalizing α^*_{pq} via the softmax function:

$$\alpha_{pq} = \frac{\exp\left(\alpha^*_{pq}\right)}{\sum_{\{q|\forall c_q \in CC(c_p)\}} \exp\left(\alpha^*_{pq}\right)}. \tag{6}$$

Finally, we generate the overall representation $\mathbf{m}_{c_p}$ of category c_p by integrating the scene-specific representation and the category-specific representation:

$$\mathbf{m}_{c_p} = \sigma\left(\mathbf{W_{ic}} \cdot [\mathbf{h}^s_{c_p} \| \mathbf{h}^c_{c_p}] + \mathbf{b_{ic}}\right), \tag{7}$$

where $\|$ denotes the concatenation operation, $\mathbf{W_{ic}}$ and $\mathbf{b_{ic}}$ are parameters to be learned.

For item i_p, it is only connected to one pre-defined category and thus its category-specific representation $\mathbf{h}^C_{i_p}$ is denoted as:

$$\mathbf{h}^C_{i_p} = \mathbf{m}_{C(i_p)}, \tag{8}$$

where $C(i_p)$ indicates the category of i_p.

We continue to learn the item-specific representation $\mathbf{h}^I_{i_p}$ since there exist connections between different item nodes. Similar to category-category relations, items do not always affect each other equally and we apply the attention mechanism to learn $\mathbf{h}^I_{i_p}$:

$$\mathbf{h}^I_{i_p} = \sum_{i_q \in II(i_p)} \beta_{pq} \mathbf{e}_{i_q}, \tag{9}$$

Table 1: Statistics of JD datasets. Each relation A-B has three parts: number of A, number of B, and number of A-B.

Relations (A-B)	Baby & Toy	Electronics	Fashion	Food & Drink
User-Item	4,521-51,759 (481,831)	3,842-52,025 (539,066)	3,959-53,005 (541,238)	3,236-47,402 (463,391)
Item-Item	51,759-51,759 (3,002,806)	52,025-52,025 (2,992,333)	53,005-53,005 (2,750,495)	47,402-47,402 (2,606,003)
Item-Category	51,759-103 (51,759)	52,025-78 (52,025)	53,005-91 (53,005)	47,402-105 (47,402)
Category-Category	103-103 (1,791)	78-78 (825)	91-91 (1,058)	105-105 (1,628)
Scene-Category	323-103 (1,370)	54-78 (281)	438-91 (1,646)	136-105 (630)

where β_{pq} denotes the attention weight. Since items that belong to the same category share similarity, we leverage scene information to calculate β_{pq} by comparing their categories via the scene-based attention mechanism:

$$\beta^*_{pq} = f\left(\sum_{s_a \in IS(i_p)} \mathbf{e}_{s_a}, \sum_{s_b \in IS(i_q)} \mathbf{e}_{s_b}\right), \tag{10}$$

$$\beta_{pq} = \frac{\exp\left(\beta^*_{pq}\right)}{\sum_{\{q|\forall i_q \in II(i_p)\}} \exp\left(\beta^*_{pq}\right)}, \tag{11}$$

where $IS(i_p)$ is the set of scenes that contain item i_p's category.

In the end, we concatenate the category-specific representation $\mathbf{h}^C_{i_p}$ and the item-specific representation $\mathbf{h}^I_{i_p}$ to derive the overall representation $\mathbf{m}^S_{i_p}$ of the item i_p in the scene-based space:

$$\mathbf{m}^S_{i_p} = \sigma\left(\mathbf{W_{ii}} \cdot [\mathbf{h}^C_{i_p} \| \mathbf{h}^I_{i_p}] + \mathbf{b_{ii}}\right), \tag{12}$$

where $\mathbf{W_{ii}}$ and $\mathbf{b_{ii}}$ are parameters to be learned.

4.3.3 The general item embedding. The item embedding $\mathbf{m}^U_{i_p}$ in the user-based space learns the collaborative signals from user-item interactions, while the item embedding $\mathbf{m}^S_{i_p}$ in the scene-based space provides additional information from the scene-based graph. These two types of representations could be complementary to each other, and they are combined by a multilayer perceptron (MLP) to generate the general item embedding as follows:

$$\mathbf{m}_{i_p} = \mathbf{F}\left(\mathbf{W_i} \cdot [\mathbf{m}^U_{i_p} \| \mathbf{m}^S_{i_p}] + \mathbf{b_i}\right), \tag{13}$$

where $\mathbf{F}(\cdot)$ is a MLP network, $\mathbf{W_i}$ and $\mathbf{b_i}$ are parameters.

4.4 Model Optimization

Given the representation of user u_p and the general representation of item i_q, the user preference is obtained via a MLP network:

$$\mathbf{r}'_{pq} = \mathbf{F}\left(\mathbf{W_r} \cdot [\mathbf{m}_{u_p} \| \mathbf{m}_{i_q}] + \mathbf{b_r}\right), \tag{14}$$

where $\mathbf{W_r}$ and $\mathbf{b_r}$ are parameters to be learned.

To optimize the model parameters, we apply the pairwise BPR loss [14], which takes into account the relative order between observed and unobserved user-item interactions and assigns higher prediction scores to observed ones. The loss function is as follow:

$$\Omega(\Theta) = \sum_{(p,x,y) \in O} -\ln \sigma\left(\mathbf{r}'_{px} - \mathbf{r}'_{py}\right) + \lambda \|\Theta\|_2^2, \tag{15}$$

where $O = \left\{(p,x,y)|(p,x) \in \mathcal{R}^+, (p,y) \in \mathcal{R}^-\right\}$ denotes the pairwise training data, $\mathcal{R}^+$ and $\mathcal{R}^-$ are the observed and unobserved user-item interactions, respectively. Θ denotes all trainable model parameters and λ controls ℓ_2 regularization to prevent overfitting.

To sum up, we have different entity types, i.e., user, item, category and scene, in the user-item bipartite graph and the scene-based graph. In the learning process, the user representation is learnt from interactions between users and items. The item latent factor is generated from two components: the representation in the user-based space and the representation in the scene-based space. Then the user embedding and the item embedding are integrated to make prediction via pairwise learning.

5 EXPERIMENTS

In this section, we evaluate SceneRec on 4 real-world E-commerce datasets and focus on the following research questions:

RQ1: How does SceneRec perform compared with state-of-the-art recommendation methods?

RQ2: How do different key components of SceneRec affect the model performance?

RQ3: How does the scene information benefit recommendation?

5.1 Datasets

To the best of our knowledge, there are no public datasets that describe scene-based graph for recommender systems. To evaluate the effectiveness of SceneRec, we construct 4 datasets, namely, Baby & Toy, Electronics, Fashion, and Food & Drink, from JD.com, one of the largest B2C E-commerce platform in China. In each dataset, we build the user-item bipartite graph and the scene-based graph from online logs and commodity information. Statistics of the above datasets are shown in Table 1 and more details are discussed next. We have released the codes and datasets (available at https://github.com/e09b47e1/Scene-Based_Recommendation).

We first build the user-item bipartite graph that by randomly sampling a set of users and items from online logs. A user is then connected to an item if she or he clicked the item.

Next we build the scene-based graph where three different nodes, i.e., item, category and scene, are taken as input. We first consider connections between different item nodes. In E-commerce systems, users perform various behaviors such as "view" and "purchase", which can be further used to construct item-item relations. In this work, we choose "view" to build the item-item connections. A view session is a sequence of items that are viewed by a user within a period of time and it is intuitive that two items should be highly relevant if they are frequently co-viewed. In the item layer, two items are linked if they are co-viewed by a user within the same session where the weight is the sum of co-occurrence frequency within 2 months. For each item, we rank all the connected items by the edge weight and at most top 300 connections are preserved. All time period and numbers of connection are empirically set based on the trade-off between the size of datasets and co-view relevance between items.

We then connect each item to its pre-defined category to build the item-category relations. We also consider connections between different category nodes as shown in the second layer of the scene-based graph. For example, in E-commerce systems, the category "Mobile Phone" is strongly related to the category "Phone Case" but has little relevance to the category "Washing Machine", and thus the first two categories are linked. To achieve this, we compute the co-view frequency within six months between each pair of category node, and only top 100 connections of each category is preserved. In the end, each pair is further labeled as 0 or 1 from consensus decision-making by three data labeling engineers to indicate if there exists relevance or not.

The last step of building the scene-based graph is to link category nodes to scene nodes. Each scene consists of a set of selected categories which can be manually coded by human experts (scene mining is our future work). Specifically, this procedure consists

Table 2: Comparisons with baselines and model variants.

SceneRec	**0.4298**	**0.6771**	**0.4926**	**0.7524**	**0.4220**	**0.6763**	**0.4266**	**0.6211**

of two steps. First, an expert team (about 10 operations staff) edits a set of scene candidates based on the corresponding domain knowledge. Then, a data labeling team which consists of 3 engineers refines the generated scenes based on the criteria that whether each scene is reasonable to reflect a real-life situation.

To sum up, there is a user-item bipartite graph and a scene-based graph in the constructed E-commerce datasets where we have different types of nodes, i.e., user, item, category and scene. The scene-based graph presents a 3-layer hierarchical structure. There exist multiple relations among items, categories and scenes that are derived from user behavior data, commodity information and manual labeling. Thus, the datasets have all the characteristics of networks we want to study as described in Section 3.

5.2 Baselines

SceneRec leverages scene information to learn the representation vector of users and items in recommendation. Therefore, we compare SceneRec against various recommendation methods or network representation learning methods.

(1) **BPR-MF** [14] is a benchmark matrix factorization (MF) model which takes the user-item graph as input and BPR loss is adopted.

(2) **NCF** [7] leverages multi-layer perceptron to learn non-linearities between user and item interactions in the traditional MF model.

(3) **CMN** [3] is a state-of-the-art memory-based model to capture both global and local neighborhood structure of latent factors.

(4) **PinSAGE** [23] learns node representations on the large-scale item-item network where the representation of one item can be aggregated by the representation of its neighbor nodes. Here, we directly apply PinSAGE on the input user-item bipartite graph.

(5) **NGCF** [20]: This is a state-of-the-art GNN-based recommendation method, which learns the high-order connectivities based on the network structure.

(6) **KGAT** [19] investigates the utility of KG into GNN-based collaborative filtering where each item is mapped to an entity in KG. In our experiments, we regard each scene as a special type of KG entity and link it to item nodes via the category node connection. In such cases, the scene-based graph is degraded to the one that contains only item-scene connections. The graph contains two types of relations: an item *belongs to* a scene and a scene *includes* an item.

(7) **SceneRec-noitem** is a variant of SceneRec by removing item-item interactions in the scene-based graph.

(8) **SceneRec-nosce** is a variant of SceneRec by removing both category and scene nodes, and thus the scene-based graph only includes relations between items.

(9) **SceneRec-noatt** is another variant of SceneRec by removing the attention mechanism between item-item relations and category-category relations.

5.3 Experimental Settings

We evaluate the model performance using the leave-one-out strategy as in [1, 7]. For each user, we randomly hold out one positive item that the user has clicked and sample 100 unobserved items to build the validation set. Similarly, we randomly choose another positive item along with 100 negative samples to build the test set. The remaining positive items form the training set.

In our experiments, we choose *Hit Ratio* (HR) and *Normalized Discounted Cumulative Gain* [15] (NDCG) as evaluation metrics. HR measures whether positive items are ranked in the top K scores while NDCG focuses more on hit positions by assigning higher scores to top results. For both metrics, a larger value indicates a better performance. We report the average performance over all users with $K = 10$.

The hyper-parameters of SceneRec are fine-tuned using the validation set. We apply RMSProp [4] as the optimizer where the learning rate is determined by a grid search among $\{10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}\}$ and the ℓ_2 normalization coefficient λ is determined by a grid search among $\{0, 10^{-6}, 10^{-4}, 10^{-2}\}$. For fair comparisons, the embedding dimension d is set to 64 for all methods except NCF. For NCF, d is set to 8 due to the poor performance in higher dimensional space. For NGCF and KGAT, the depth L is set to 4 since it shows competitive performance via the high-order connectivity.

5.4 Experimental Results

5.4.1 Performance Comparison (RQ1). Table 2 reports comparative results of SceneRec against all 6 baseline methods, and we have the following observations:

(1) In general, NGCF achieves better results than baseline methods that take the user-item bipartite graph as input. There are two main reasons. First, GNN can effectively capture the non-linearity relations from user-item collaborative behaviors via information propagation on the graph. Second, NGCF learns the high-order connectivities between different types of nodes as shown in [20].

(2) KGAT further adds KG information into recommender systems, but it does not obtain the best result. Note that the KG quality is essential to the model performance. In our work, there are no available KG attributes that match our datasets, so there is no additional information to describe network items. Furthermore, the simple item-scene connection loses rich relations, e.g. category-category interactions and item-item interactions, in the scene-based graph, and may not advance model prediction.

(3) The proposed framework SceneRec obtains best overall performance using different evaluation metrics. Specifically, SceneRec boosts (16.8%, 10.8%, 25.6%, 5.9%) for NDCG@10, and (12.9%, 11.9%, 17.6%, 6.1%) for HR@10 on datasets (Baby & Toy, Electronics, Fashion, and Food & Drink), compared with the best baseline. There are several main reasons. First, SceneRec considers multiple types of entity nodes. To be specific, SceneRec generates

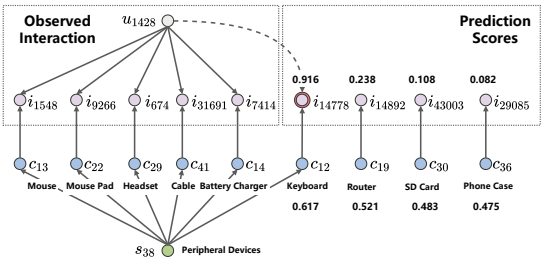

Figure 3: A real example on the Electronics dataset.

embedding representations of users and items from the user-item bipartite graph while it learns complementary representations of items from the scene-based graph, which is not accessible in baseline methods. Second, SceneRec creatively designs a principled hierarchical structure in the scene-based graph where additional scene-guided information is propagated into collaborative filtering. Third, SceneRec leverages GNN which captures local network structure to learn non-linear transformation of different types of graph nodes. Fourth, SceneRec adopts attention mechanism to attentively learn weighting importance among item-item connections and category-category connections.

5.4.2 Key Component Analysis (RQ2). Table 2 also reports comparative results against 3 variants and it is observed that:
(1) SceneRec-noitem obtains better experimental results than other baseline methods, and this indicates that the hierarchical structure of the scene-based graph can effectively propagate information and generate complementary scene-based representations. Moreover, SceneRec outperforms SceneRec-noitem and this verifies the effectiveness of incorporating item-item subnetwork into the scene-based graph.
(2) SceneRec-nosce outperforms all baselines because the item-item connections provide additional knowledge into conventional collaborative filtering. Comparing to SceneRec-nosce, SceneRec achieves better performance on both datasets and this indicates that, by leveraging scene information, SceneRec is capable of learning complementary representations beyond CF interactions.
(3) The prediction result of SceneRec is consistently better than that of SceneRec-noatt, and this verifies that the attention mechanism does benefit the recommendation by learning weights of 1-hop neighbors for each item node or each category node.

5.4.3 Case Study (RQ3). Finally, we use a case study to show the effects of integrating scene-specific representations into collaborative filtering in Figure 3. From the Electronics dataset, we randomly select a user u_{1428}, a set of items that the user has interacted with and a set of candidate items (whose prediction scores are given above item nodes). It is noted that we especially compute the average attention score (below the category node) between the candidate item and each item that the user has interacted with by the scene-based attentive mechanism.

The higher average attention score means more shared scenes between the candidate item and the user's interacted items. Therefore, the candidate item is more likely to occur in the scene derived from user interests, which could boost recommendation prediction. From this case study, we see that the average attention score does relate to the prediction result. For example, the positive sample of item i_{14778} that the user has interacted with has the highest prediction score and the largest average attention weight. Similar results can be also observed from other users. The item i_{14778} is recommended because its category "Keyboard" complements the user-interacted items' categories in the same scene "Peripheral Devices".

6 CONCLUSIONS

In this paper, we investigate the utility of integrating the scene information into recommender systems using graph neural networks, where a scene is formally defined as a set of pre-defined item categories. To integrate the scene information into graph neural networks, we design a principled 3-layer hierarchical structure to construct the scene-based graph and propose a novel method SceneRec. SceneRec learns item representation from the scene-based graph, which is further combined with the conventional latent representation learned from user-item interactions to make predictions. We conduct extensive experiments on four datasets that are collected from a real-world E-commerce platform. The comparative results and a case study demonstrate the rationality and effectiveness of SceneRec.

ABSTRACT

The problem of studying the effective contact between different moving objects (MOs) has received great interest in recent years. However, the uncertain nature of trajectory data poses significant challenges for the researchers. Most of the existing studies focus on range query or similarity join. But they cannot find MOs who may contact each other for a long enough time in the same location. In this paper, we study how to evaluate the effective contact among MOs. More specifically, we provide a purposeful definition for measuring the contact effectiveness, called **Contact Similarity**. Based on this notion, we introduce a novel query called **Contact Similarity Query** (*CSQ*). A necklace-based model is used for representing uncertain trajectories, in which a bead (or an ellipse) indicates the possible locations of an object in-between two successive trajectory observations. To enable efficient query processing, we design a novel data structure called UTM-tree (i.e., Uncertain Trajectory M-tree) for indexing the necklace-based trajectories. Experiments have been conducted on a real-world dataset, and the results demonstrate that our proposed solution significantly outperforms the baseline approaches.

1 INTRODUCTION

With the increasing availability and rapid development of global positioning technologies, moving objects (MOs)' trajectories can be utilized by Location-Based Services (LBS) in many applications, such as vehicle navigation, traffic management, and co-occurrence analysis. However, due to sensor devices' physical and resource limitations or privacy considerations, MOs' trajectories are often captured at low sampling rates, and the time interval between two consecutive observations is quite long. In such uncertain courses, no information can be found about the whereabouts of MOs in-between two successive points. Recently, the problem of querying uncertain trajectory has been studied by many works, e.g., [1, 2, 5, 6, 10, 13]. However, most of them focused on retrieving qualified results regarding either probabilistic range query or similarity join. The existing approaches are not applicable to the problem of modeling the effective contact among individuals, which is a research topic of great importance. As follows, a real-world example is presented to describe a motivational scenario.

Example 1. *Fig. 1 shows the uncertain trajectories of three visitors m_1, m_2, and m_3 in one day. They are equipped with a GPS device in their car, and they periodically reported their real-time locations along their trajectories. But we don't know where they are in-between two consecutive reports. We can see that m_1 and m_3 may have a very high trajectory similarity since the spatial and temporal distance between their observations can be very small. However, m_1 and m_3 may never come in contact with each other. On the other hand, assume that along the trip, m_1 parked the car at location A, disembarked the car, walked into the Park and stayed there for a while. Then m_1 went back to A to board the car and continued with the trip. Perhaps m_2 can take similar action at location B, i.e., m_2 may also stay in the Park for a while during his/her trip. Therefore, even though m_1 and m_2 have very low trajectory similarity, they may have an effective contact either in the Park or in the Shopping District. But such a result can never be captured by the traditional trajectory similarity query. Besides, assume that several days later, m_1 found him/herself as an infected individual of a highly contagious disease (e.g., Covid 19). To help determine other susceptible persons who might be infected, m_1 provided more details about his/her trajectory to an authorized third-party, such as a local public health agency (LPHA). For example, m_1 stayed in the Park from 10:00 am to 10:50 am, and then went to the Shopping District from 11:35 am to 12:30 pm. Next, given this information, LPHA discovered that m_1 and m_2 may have possible contact with each other, and may like to know the effectiveness of their contact (e.g., the chance of their contact and how long they may contact with each other). Moreover, hundreds of people may have visited the neighboring areas on the same day. LPHA wants to find the susceptible individuals from the big group of candidates who may have effective contact with m_1.*

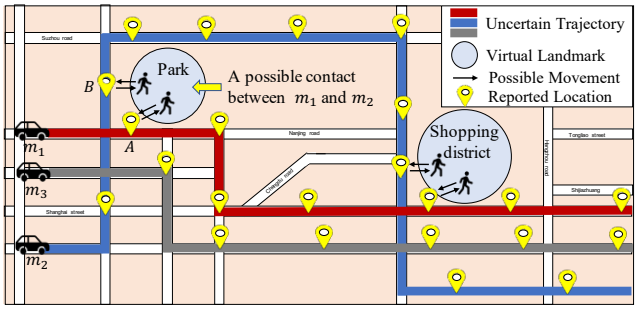

Figure 1: An real-world example of possible contacts between MOs m_1, m_2, and m_3

To address the problem described above, it is important to answer the following questions successively:

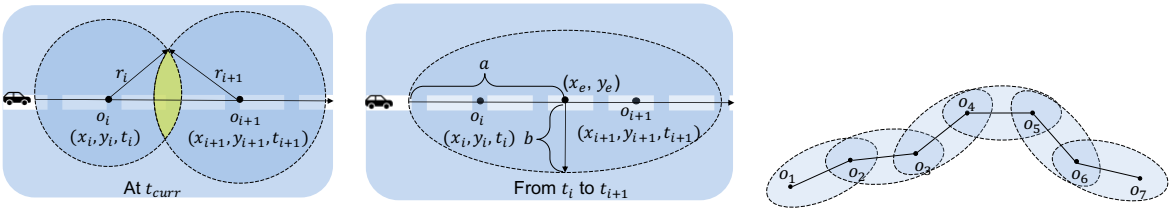
Q1: How to calculate the potential contact area and the possible longest contact time duration between m_1 and m_2?

Q2: How to measure the effective contact between m_1 and m_2?

Q3: How to efficiently retrieve the qualified results from a large number of people who visited the park on the same day as m_1?

To the best of our knowledge, little or no systematic and theoretical study has been conducted to address the abovementioned questions. Aiming to fill this research gap, we propose a study on analyzing the effective contact between MOs over uncertain trajectories. Specifically, the main contributions of this work are three-fold as follows.

• We propose a definition of **Contact Similarity** over uncertain trajectories and a novel query called **Contact Similarity Query** (*CSQ*). With *CSQ*, we can assess the effectiveness of contact between MOs in free space.



(a) The possible locations of the MO at time $t_{curr}(t_i \le t_{curr} \le t_{i+1})$

(b) All the possible locations (the bead B_i) of the MO between t_i and t_{i+1}.

(c) An example of necklace for a given uncertain trajectory with 7 observations.

Figure 2: An example of bead B_i given the information of o_i, o_{i+1}, and v_{max}.

Table 1: The summary of notations

Notation	Definition
Trajectory Notations	
MO	Moving object
$\mathsf{T} = \{o_1, o_2, ..., o_n\}$	An uncertain trajectory
$t_i/(x_i, y_i)$	Timestamp/coordinates of o_i in T
v_{max}	The maximum speed of a MO
T_{neck}	The necklace of T
B_i	A bead in T_{neck}
P	A virtual landmark
t^s/t^e	The arrival/departure time of P
Query Notations	
R_{int}	The intersection area ratio
$\tau(\mathsf{P}, \mathsf{B}_i)$	The possible longest time duration
$Sim_{cont}^{\mathsf{P}\cap\mathsf{B}_i}$	Contact similarity at bead level
D	A MO database
$Sim_{cont}^{\mathsf{P}\cap\mathsf{T}}$	Contact similarity at trajectory level
$\bar{t}^s$	The earliest arrival time
$\bar{t}^e$	The latest departure time

• We design a novel data structure called UTM-tree (Uncertain Trajectory M-tree) for indexing uncertain trajectories, which significantly improves the efficiency for processing *CSQ*.

• We conduct an extensive experimental evaluation of the proposed approaches, demonstrating the effectiveness and efficiency of the methodology proposed in this work.

The rest of this paper is organized as follows. In Section 2, we introduce the preliminaries and problem definition. In Section 3, we propose the novel indexing structure for managing uncertain trajectories. In Section 4, we present the details of our experiments and the evaluation results, followed by the related works in Section 5. Finally, we recap the conclusions in Section 6.

2 PRELIMINARIES

In this section, we briefly introduce the preliminaries of this work. The frequently used notations are listed in Table 1.

2.1 Trajectories, Beads, and Necklaces

We first introduce the definitions of trajectory, beads, and necklaces. A trajectory is defined as follows.

Definition 1. *A **trajectory** T of a MO is defined as finite, time-ordered observations $\mathsf{T} = \{o_1, o_2, ..., o_n\}$, where $o_i = (x_i, y_i, t_i)$ for $i \in [1, n]$, with (x_i, y_i) being a sample point in Euclidean space, and t_i being a timestamp.*

The possible locations of a MO in-between two observations can be defined by a bead (or ellipse) [10] as follows.

Definition 2. *Let v_{max} denote the maximum speed that an object can take between o_i and o_{i+1}. A **bead** $\mathsf{B}_i = \{(x_i, y_i, t_i), (x_{i+1}, y_{i+1}, t_{i+1})\}$ is defined as all points (x, y, t) that satisfy the following constraints:*

$$\begin{cases} t_i \le t \le t_{i+1} \\ (x - x_i)^2 + (y - y_i)^2 \le (t - t_i)^2 \times v_{max}^2 \\ (x - x_{i+1})^2 + (y - y_{i+1})^2 \le (t_{i+1} - t)^2 \times v_{max}^2. \end{cases} \tag{1}$$

From Fig. 2 (a), we can see that from time t_i to t_{curr} ($t_{curr} > t_i$), the MO's possible travel area is a circle with (x_i, y_i) being the center and $r_i = (t_{curr} - t_i) \times v_{max}$ being the radius. Similarly, from time t_{curr} to t_{i+1} ($t_{curr} < t_{i+1}$), the possible locations are included in a circle centered at (x_{i+1}, y_{i+1}) with radius $r_{i+1} = (t_{i+1} - t_{curr}) \times v_{max}$. So, the overlapped area in Fig. 2 (a) of the two circles includes MO's possible locations at current time t_{curr}. Based on [8], all the possible locations from time t_i to t_{i+1} form an ellipse (or bead) with foci at (x_i, y_i) and (x_{i+1}, y_{i+1}) (see in Fig. 2 (b)). According to [10], the equation of the bead B is:

$$(x - x_e)^2/a^2 + (y - y_e)^2/b^2 = 1, \tag{2}$$

where (x_e, y_e) is the center of the ellipse; a and b represents the semi-major axis and semi-minor axis of the ellipse, as follows.

$$x_e = \frac{x_i + x_{i+1}}{2},\ y_e = \frac{y_i + y_{i+1}}{2},\ a = \frac{v_{max} \times (t_{i+1} - t_i)}{2}$$
$$b = \frac{\sqrt{v_{max}^2 \times (t_{i+1} - t_i)^2 - (x_{i+1} - x_i)^2 - (y_{i+1} - y_i)^2}}{2}. \tag{3}$$

Definition 3. *A trajectory $\mathsf{T} = \{o_1, o_2, ..., o_n\}$ can be represented as a sequence of beads, which is called a **necklace** and denoted as $\mathsf{T}_n = \{\mathsf{B}_1, \mathsf{B}_2, ..., \mathsf{B}_{n-1}\}$ (see an example in Fig. 2 (c)), such that o_i and o_{i+1} form the bead B_i for $i \in [1, n-1]$.*

2.2 Contact Similarity

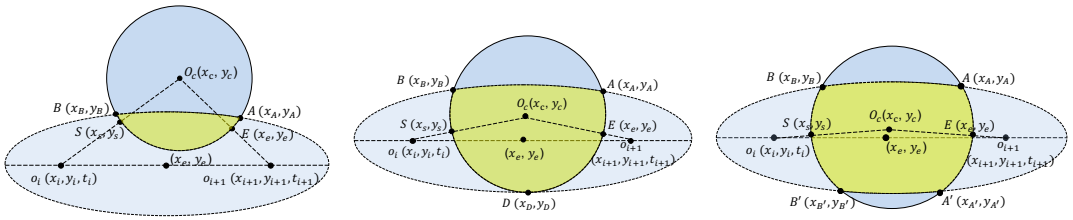
In this section, we introduce the essential definitions for contact similarity.

Definition 4. *A **virtual landmark** P is a place where two MOs can contact with each other. P can be either meaningful locations (e.g., a shopping district or a park) or non-meaningful locations (e.g., a crossroad). For simplicity sake, any P in this work is considered as a circle that is centered at $O_c = (x_c, y_c)$ with a given radius r_c. Hence, the equation of P is $(x - x_c)^2 + (y - y_c)^2 = r_c^2$.*

Definition 5. *For a MO m_1, he/she stayed at P for a certain period time. For another MO m_2, his/her necklace is $\mathsf{T}_n = \{\mathsf{B}_1, \mathsf{B}_2, ..., \mathsf{B}_{n-1}\}$. If P spatially overlaps with one bead B_i for $i \in [1, n-1]$ (denoted as $\mathsf{P} \cap_S \mathsf{B}_i \neq \emptyset$), then the **intersection area ratio** R_{int} is*

$$\mathsf{R}_{int} = \mathsf{Area}_{int}/\mathsf{Area}_P, \tag{4}$$

where Area_{int} is the intersection area between the P and B_i, and Area_P is the area of P.



(a) *Two* intersection points (A, B) (b) *Three* intersection points (A, B, D) (c) *Four* intersection points (A, B, A', B')

Figure 3: Examples of overlap between a virtual landmark and a bead with different intersection points

Fig. 3 shows different scenarios that P (the circle) overlaps with a bead B (the ellipse), with two, three, and four intersection points, respectively. Then, we difine the possible longest contact time duration between MOs as follows.

Definition 6. *For MO m_1, he/she stayed at* P *from time t^s to t^e. For another MO m_2, his/her necklace $\mathsf{T}_n = \{\mathsf{B}_1, \mathsf{B}_2, ..., \mathsf{B}_{n-1}\}$. Moreover, if one of the beads B_i (for $i \in [1, n-1]$) temporally overlaps with* P *(denoted as $\mathsf{P} \cap_T \mathsf{B}_i \neq \emptyset$), then the **possible longest time duration** $\tau(\mathsf{P}, \mathsf{B}_i)$ between m_1 and m_2 can be calculated as*

$$\tau(\mathsf{P}, \mathsf{B}_i) = \min\{t^e, \bar{t}^e\} - \max\{t^s, \bar{t}^s\}, \tag{5}$$

where $\bar{t}^s$ means the possible earliest time for m_2 to arrive at P*, and $\bar{t}^e$ means the possible latest time for m_2 to leave* P*.*

Example 2. *If m_1 stayed at* P *from t^s = 10:00 am and t^e = 10:50 am. For m_2, $\bar{t}^s$ = 10:05 am and $\bar{t}^e$ = 10:35 am, then $\tau(\mathsf{P}, \mathsf{B}_i)$ = min{10:50, 10:35} - max{10:00, 10:05} = 30 min.*

Next, inspired by [7], we formally propose the definition of contact similarity as below.

Definition 7. *For m_1, he/she stayed at* P *from time t^s to t^e. For m_2, his/her necklace is $\mathsf{T}_n = \{\mathsf{B}_1, \mathsf{B}_2, ..., \mathsf{B}_{n-1}\}$. If $\forall \mathsf{B}_i \in \mathsf{T}_n$ for $i \in [i, n-1]$ such that $\mathsf{P} \cap_S \mathsf{B}_i \neq \emptyset$ and $\mathsf{P} \cap_T \mathsf{B}_i \neq \emptyset$, then **the contact similarity at bead level** $Sim_{cont}^{\mathsf{P}\cap\mathsf{B}_i}$ between m_1 and m_2 at* P *in terms of B_i can be calculated as:*

$$Sim_{cont}^{\mathsf{P}\cap\mathsf{B}_i} = 1 - (1 - \mathsf{R}_{int})^{\tau(\mathsf{P}, \mathsf{B}_i)} \tag{6}$$

We assume that the intersection area ratio R_{int} indicates the possible opportunities that m_1 may be in contact with m_2 at P per unit time. Therefore, $(1 - \mathsf{R}_{int})^{\tau(\mathsf{P}, \mathsf{B}_i)}$ denotes the probability that m_1 and m_2 have no effective contact during the time period $\tau(\mathsf{P}, \mathsf{B}_i)$. Consequently, $Sim_{cont}^{\mathsf{P}\cap\mathsf{B}_i}(m_1, m_2) = 1 - (1 - \mathsf{R}_{int})^{\tau(\mathsf{P}, \mathsf{B}_i)}$. A larger value of $Sim_{cont}^{\mathsf{P}\cap\mathsf{B}_i}(m_1, m_2)$ indicates a higher probability that an effecitive contact may happen between m_1 and m_2 at P.

Definition 8. *Let $\mathbb{B}$ denote a set of beads in T_n, such that for $\forall \mathsf{B}_i \in \mathbb{B}$, $\mathsf{P} \cap_S \mathsf{B}_i \neq \emptyset$ and $\mathsf{P} \cap_T \mathsf{B}_i \neq \emptyset$. Then, **the contact similarity at trajectory level** $Sim_{cont}^{\mathsf{P}\cap\mathsf{T}}$ can be calculated as:*

$$Sim_{cont}^{\mathsf{P}\cap\mathsf{T}} = \frac{\sum_{\mathsf{B}_i \in \mathbb{B}} Sim_{cont}^{\mathsf{P}\cap\mathsf{B}_i}}{|\mathbb{B}|}. \tag{7}$$

Here, $|\mathbb{B}|$ denotes the number of beads in $\mathbb{B}$.

2.3 Problem Definition

Definition 9. *For m_1, the **query trajectory** T_q is defined as a sequence of* P*(s) that m_1 visited, i.e., $\mathsf{T}_q = \{\mathsf{P}_1, \mathsf{P}_2, ..., \mathsf{P}_d\}$. $\mathsf{P}_k = (x_k^c, y_k^c, r_k^c, t_k^s, t_k^e)$ for $k \in [1, d]$. Here, m_1 stayed at P_k from t_k^s to t_k^e, (x_k^c, y_k^c) and r_k^c are the center and radius of P_k, respectively.*

Definition 10. *Given a query trajectory $\mathsf{T}_q = \{\mathsf{P}_1, \mathsf{P}_2, ..., \mathsf{P}_d\}$, a MO database D that contains s necklaces (e.g., $D = \{\mathsf{T}_{n1}, \mathsf{T}_{n2}, ..., \mathsf{T}_{ns}\}$), and a predefined threshold α, for each $\mathsf{P}_k \in \mathsf{T}_q$ where $k \in [1, d]$, the **Contact Similarity Query** (CSQ) finds all the necklaces $\mathsf{T}_{nj} \in D$ for $j \in [1, s]$, such that $Sim_{cont}^{\mathsf{P}_k\cap\mathsf{T}_{nj}} \geq \alpha$.*

Example 3. *In Fig. 1, T_q is m_1's query trajectory. For example, m_1 stayed in the park P_1 from 10:00 to 10:50 am, then m_1 went to the shopping district P_2 and stayed there from 11:35 am to 12:30 pm. D is a MO database that contains 1000 people's trajectory necklaces who visited the neighboring areas on the same day, and let $\alpha = 0.8$. For every virtual landmark P_k that m_1 visited, the CSQ finds all the trajectory necklaces $\mathsf{T}_{nj} \in D$ such that $Sim_{cont}^{\mathsf{P}_k\cap\mathsf{T}_{nj}} \geq 0.8$.*

2.4 Calculation of $\mathtt{Area}_{int}$ and $\tau(\mathsf{P}, \mathsf{B}_i)$

In this section, we discuss how to calculate $\mathtt{Area}_{int}$ and $\tau(\mathsf{P}, \mathsf{B}_i)$, followed by the workflow for *CSQ*.

Given the P with equation $(x - x_c)^2 + (y - y_c)^2 = r_c^2$ and the B_i with equation $(x - x_e)^2/a^2 + (y - y_e)^2/b^2 = 1$, it is straightforward to calculate $\mathtt{Area}_{int}$ as follows.

• There are two or three intersection points between the virtual landmark P and the bead B_i (see Fig. 3 (a) and (b)).

$$\mathtt{Area}_{int} = \int_{x_B}^{x_A} \left(\frac{b}{a}\sqrt{a^2 - (x - x_e)^2} + y_e + \sqrt{r_c^2 - (x - x_c)^2} - y_c\right) dx \tag{8}$$

• There are four intersection points between the virtual landmark P and the bead B_i (see Fig. 3 (c)).

$$\begin{aligned}\mathtt{Area}_{int} = &\pi r_c^2 - \int_{x_B}^{x_A} \left(\sqrt{r_c^2 - (x - x_c^2)} + y_c - \frac{b}{a}\sqrt{a^2 - (x - x_e)^2} - y_e\right) dx \\ &- \int_{x_B'}^{x_A'} \left(y_e - \frac{b}{a}\sqrt{a^2 - (x - x_e)^2} + \sqrt{r_c^2 - (x - x_c)^2} - y_c\right) dx\end{aligned} \tag{9}$$

In Fig. 3, we can easily know that S is the earliest point that one MO can arrive at P, and E is the latest point that MO can leave P. Therefore, given the maximum speed v_{max}, we can calculate $\bar{t}^s$ and $\bar{t}^e$ as follows.

$$\bar{t}^s = t_i + \frac{|o_i S|}{v_{max}},\ \bar{t}^e = t_{i+1} - \frac{|o_{i+1} E|}{v_{max}} \tag{10}$$

Based on $\bar{t}^s$ and $\bar{t}^e$, we can calculate $\tau(\mathsf{P}, \mathsf{B}_i)$ by Eq. (5). After calculating R_{int} and $\tau(\mathsf{P}, \mathsf{B}_i)$, given an uncertain trajectory necklace database D and a trajectory query T_q, we can compute $Sim_{cont}^{\mathsf{P}\cap\mathsf{B}_i}$ and $Sim_{cont}^{\mathsf{P}\cap\mathsf{T}}$ by Eq. (6) and (7), respectively. If $Sim_{cont}^{\mathsf{P}\cap\mathsf{T}} \geq \alpha$, the result should be returned. We repeat the above mentioned process untill all the necklaces have been visited.

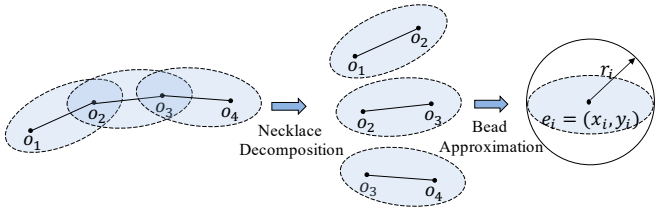


Figure 4: Decomposition of necklaces into circles

3 THE INDEXING STRUCTURE FOR *CSQ*

M-tree [4] is a popular indexing structure for efficient range query and k-nearest neighbor query. But we cannot directly adopt it in this work, because M-tree cannot handle entries like ellipse or beads. Therefore, based on M-tree, we propose a novel indexing structure called Uncertain Trajectory M-tree (UTM-tree), which is discussed next.

3.1 Decomposing the Necklace

First, we decompose the necklaces into beads. After decomposition, we use a circle to approximate each bead, and the circle is centered at the center of the bead (x, y) with radius $r = a/2$ (see in Fig. 4). Each circle is considered an individual entry and is stored independently in the leaf node of the UTM-tree.

Algorithm 1: The Inserion Algorithm: Insert(E_i, N_j)

Input : A new entry $E_i = [e_i, r_i, t_i, t_{i+1}, \texttt{TID}, \texttt{Ptr}(E_p), \texttt{Ptr}(E_n)]$, a tree node $N_j = [E_j, R_j, t_{min}, t_{max}, \texttt{ptr}]$
Output: A UTM-tree with E_i added

```
if N_j is not a leaf node then
    for all the child nodes N_j^sub of N_j do
        Let R_j^sub denote the covering radius of N_j^sub, calculate d(E_i, N_j^sub);
        if ∃ at least one N_j^sub s.t. d(E_i, N_j^sub) + r_i ≤ R_j^sub then
            Insert(E_i, N_j^sub) where d(E_i, N_j^sub) is minimun;
        else
            Insert(E_i, N_j^sub) where d(E_i, N_j^sub) + r_i − R_j^sub is minimum;
else
    if N_j is not full then
        Add E_i into N_j, update t_min and t_max;
        if d(E_i, N_j) + r_i > R_j then R_j = d(E_i, N_j) + r_i ;
    else Split(E_i, N_j) ;
return An updated UTM-tree after inserting E_i into N_j
```

3.2 Building the UTM-tree

Next, we describe how to construct a UTM-tree, including the format of an entry/node, entry insertion, splitting policy, selection of routing objects, and query processing. An illustration of the UTM-tree is shown in Fig. 5.

3.2.1 Format of the entry. Same as the M-tree, in a UTM-tree, all the entries are stored in the leaf nodes. And also, each node in the tree can store at most M entries, which is also called the capacity of the tree. Specifically, we consider each circle as the entry of the UTM-tree, and each entry is in format of E_i. Here, $E_i = [e_i, r_i, t_i, t_{i+1}, \texttt{TID}, \texttt{Ptr}(E_p), \texttt{Ptr}(E_n)]$, where $e_i = (x_i, y_i)$ and r_i are the center and radius of the approximating circle, t_i and t_{i+1} are the observation timestamps from the original trajectory that form the bead, TID is the trajectory identifier which the bead belongs to, and $\texttt{Ptr}(E_p)$ and $\texttt{Ptr}(E_n)$ are doubly linked list pointers for the previous/next entry that corresponding to beads in the original trajectory.

In the UTM-tree, each node selects an entry from the leaf node as its routing object (similar to M-tree). The format of a node is represented as $N_j = [E_j, R_j, t_{min}, t_{max}, \texttt{ptr}(N_j^{sub})]$, where E_j is its routing object, R_j is the covering radius that covers all the entries stored in N_j. t_{min} and t_{max} are the minimum and maximum time for all the entries stored in N_j, and ptr is a pointer pointing to its child node N_j^{sub} if N_j is a non-leaf node.

3.2.2 Insert an Entry. First, we define the distance between an entry E_i and a node N_j as $d(E_i, N_j) = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2}$, where (x_i, y_i) is the center of E_i, and (x_j, y_j) is the center of the rounting object of N_j. The insert algorithm recursively descends the tree to locate the most suitable leaf node for E_i. We first find the leaf node such that after adding E_i, no enlargement of the covering radius is needed, i.e., $d(E_i, N_j) + r_i \le R_j$. If more than one child nodes are found, then the node that is closest to E_i will be chosen. However, if no such node exists, the choice is to minimize the increase of the covering radius, i.e., $d(E_i, N_j) + r_i - R_j$ is minimum. After inserion, if $d(E_i, N_j) + r_i > R_j$, then we update $R_j = d(E_i, N_j) + r_i$. Besides, t_{min} and t_{max} for all the visited nodes should be updated as well. After inserting all the entries into the UTM-tree, we use a doubly linked list to connect those from the same trajectory (see in Fig. 5). The details of the insertion algorithm is shown in Algorithm 1.

Algorithm 2: The Split Algorithm: Split(E_i, N_j)

Input : An entry $E_i = [e_i, r_i, t_i, t_{i+1}, \texttt{TID}, \texttt{Ptr}(E_p), \texttt{Ptr}(E_n)]$, a leaf node $N_j = [E_j, R_j, t_{min}, t_{max}, \texttt{ptr}]$
Output: A UTM-tree that splits N_j into N_j^1 and N_j^2

```
Let N_j be the set of all N_j's entries plus E_i;
Select two routing objects E_j^1 and E_j^2 from N_j based on m_RAD algorithm [4], and then partition N_j into two sets, N_j^1 and N_j^2;
Allocate a new node N_j', store N_j^1 in N_j and N_j^2 in N_j';
Replace N_j's rounting object E_j with E_j^1, update N_j's R_j;
Set E_j^2 as N_j''s rounting object, and update N_j''s R_j';
if N_j is not the root of the tree (N_j^par is N_j's parent) then
    if N_j^par is full then Split(N_j', N_j^par) ;
    else add N_j' into N_j^par;
else Allocate a new root node N_r, set N_r as parent node for N_j and N_j' ;
Update t_min and t_max for all the visited nodes;
return An updated UTM-tree after spliting N_j by E_i
```

3.2.3 Split a Node. E_i cannot be inserted into a leaf node N_j if there are M entries in N_j. we need to split N_j into two nodes. Particularly, let $\mathcal{N}_j$ denote the set of all N_j's entries plus E_i. We find two rounting objects E_j^1 and E_j^2 from $\mathcal{N}_j$ and partition N_j into two nodes N_j^1 and N_j^2 based on the *m_RAD* algorithm [4]. After partitioning, the sum of the covering radius $R_j^1 + R_j^2$ is miminum. The split algorithm is shown in Algorithm 2.

3.2.4 Data Filtering for CSQ Query. In this part, we discuss how to filter qualified candidates for *CSQ* using UTM-tree.

Given a root node N_r and a query trajectory $\mathsf{T}_q = \{\mathsf{P}_1, \mathsf{P}_2, ..., \mathsf{P}_d\}$ where $\mathsf{P}_k = (x_k^c, y_k^c, r_k^c, t_k^s, t_k^e)$ for $k \in [1, d]$, we can first filter all the entries $E_i = [e_i, r_i, t_i, t_{i+1}, \texttt{TID}, \texttt{Ptr}(E_p), \texttt{Ptr}(E_n)]$ such that (1) $d(e_i, (x_k^c, y_k^c)) \le r_i + r_k^c$ and (2) $t_i \le t_k^s$ and $t_{i+1} \ge t_k^c$ for all pairs of (N_r, P_k). Next, based on the filtered entries, we can get a list of trajectory identifiers TID (s). For each trajectory T from this list, we can calculate $Sim_{cont}^{\mathsf{P}_k \cap \mathsf{T}}$, and then check if $Sim_{cont}^{\mathsf{P}_k \cap \mathsf{T}} \ge \alpha$. The UTM-tree indexing structure can significantly reduce the

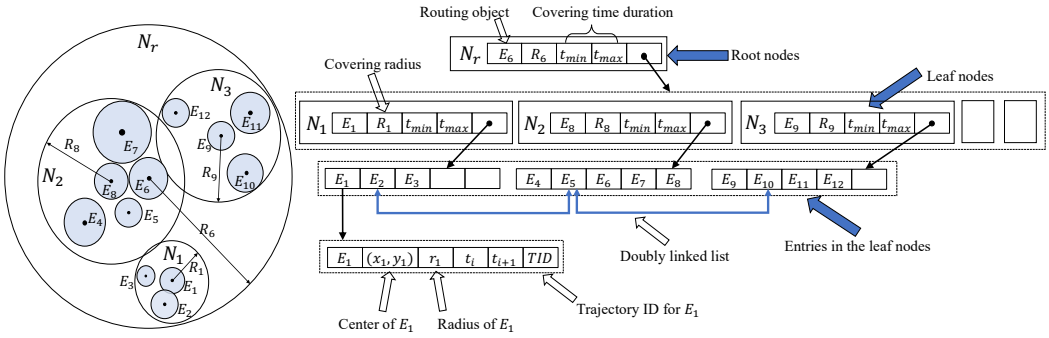

Figure 5: An example of the UTM-tree with capacity of 5

number of trajectories to be visited, thus it can greatly increase the performance of the *CSQ* query. The details of the data filtering algorithm is shown in Algorithm 3.

Algorithm 3: The filtering algorithm: Filter(N_r, P_k)

Input : A root node N_r, and P_k where $\mathsf{P}_k = (x_k^c, y_k^c, r_k^c, t_k^s, t_k^e)$
Output: A list of the trajectories IDs that satisfy the query

if N_r *is not a leaf node* **then**
  for *all the children nodes* N_r^{sub} *in* N_r *where* $N_r^{sub} = [E_r^{sub}, R_r^{sub}, t_{min}^{sub}, t_{max}^{sub}, \mathtt{ptr}(N_r^{sub(sub)})]$ **do**
    if $(t_{min}^{sub}, t_{max}^{sub}) \cap (t_k^s, t_k^e) \neq \emptyset$ **then**
      if $d(E_r^{sub}, (x_k^c, y_k^c)) \leq r_k^c + R_r^{sub}$ **then** Filter(N_r^{sub}, P_k);
      else Prune N_r^{sub};
    else Prune N_r^{sub};
else
  for *every* $E_i = [e_i, r_i, t_i, t_{i+1}, \mathtt{TID}, \mathtt{Ptr}(E_p), \mathtt{Ptr}(E_n)]$ *in* N_r **do**
    if $(t_i, t_{i+1}) \cap (t_k^s, t_k^e) \neq \emptyset$ **then**
      if $d(e_i, (x_k^c, y_k^c)) \leq r_k^c + r_i$ **then** Add TID into an ID list;
      else Prune E_i;
    else Prune E_i;
return *The ID list*

4 EXPERIMENTAL EVALUATION

We implemented the systems with Python on an Intel(R) Core(TM) i7-6700 CPU @3.60GHz running Windows 64-bit OS with 32 GB RAM. The details of experimental settings and the performance evaluation are discussed as follows.

4.1 Settings

In this part, we discuss the datasets, experimental settings, and the basic approaches in this work.

• Beijing Taxi Dataset: This dataset [12] contains the GPS trajectories of 10357 taxis from Feb. 2 to Feb. 8, 2008 in Beijing. The total number of points in this dataset is about 15 million, and the total distance traversed by the trajectories is 9 million kilometers. The average sampling interval is 177 seconds, with an average length of 623 meters.

Table 2: The summary of simulation settings

Parameters	Settings
# of observations in one trajectory ($\mathtt{Num}_o$)	30
# of trajectories ($\mathtt{Num}_\mathsf{T}$)	25K, 50K, 100K, 250K, 500K
Radius of each virtual landmark (r_k^c)	5m, 10m, 15m, 20m, 25m
# of virtual landmark in a query ($\mathtt{Num}_\mathsf{P}$)	20, 25, 30, 35, 40
Query time interval (τ_q)	1h, 2h, 4h, 6h, 8h

• Experimental Settings: There are two metrics for evaluating the performance of the proposed UTM-tree, they are (1) running time and (2) the number of visited trajectories. Table 2 shows all the parameter settings in the experiment. Specifically, for a virtual landmark $\mathsf{P}_k = (x_k^c, y_k^c, r_k^c, t_k^s, t_k^e) \in T_q$, query time interval equals $\tau_q = t_k^e - t_k^s$. Moreover, considering a day with 24 hours, τ_q is randomly selected from 8:00 am to 6:00 pm in the same day. For each P_k, its coordinates (x_k^c, y_k^c) are randomly selected such that $x_k^c \in (116.1650, 116.6201)$ and $y_k^c \in (39.7133, 40, 0070)$. Besides, the maximum speed v_{max} in-between any two continuous observations is set to a random number in $[10\ km/h, 50\ km/h]$.

• Other approaches evaluated: To evaluate the performance of the UTM-tree, we implemented two other approaches for comparison purposes, they are (1) baseline method and (2) temporal-first matching (TF-matching). In the baseline method, we do not index the trajectories at all. More specifically, we evaluate every pair of $(\mathsf{B}_i, \mathsf{P}_k)$ for the *CSQ* query. In the TF-matching method, we follow the steps in [9] to build a temporal filtering tree. Specifically, we split a day into 12 time slots by considering every two hours as a time slot. And then, we store each trajectory into the corresponding nodes. In the TF-matching method, all the trajectories are processed by the temporal filtering tree.

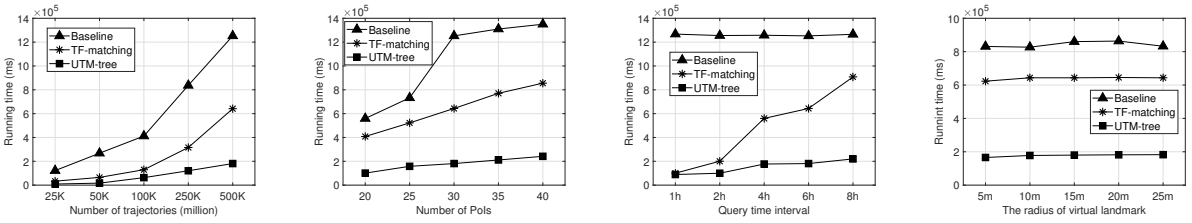
4.2 Performance Evaluation

This section compares the proposed UTM-tree with the baseline and the TF-matching in terms of query running time and the number of visited trajectories. The number of visited trajectories means how many trajectories from the original database still need to be considered after using the UTM-tree for spatial filtering and temporal filtering.

First of all, for the three approaches, the query running time (in Fig. 6 (a)) and the number of visited trajectories (in Fig. 7 (a)) are increasing as $\mathtt{Num}_\mathsf{T}$ increase. Second, we can see that the UTM-tree is much faster than the baseline method and the TF-matching method. For instance, the UTM-tree is 6.9× faster than the baseline method and 3.5× faster than the TF-matching method with 500K trajectories. Third, we found that for the UTM-tree, as $\mathtt{Num}_\mathsf{T}$ becomes larger, the increase for the query running time and the number of visited trajectories is not significant.

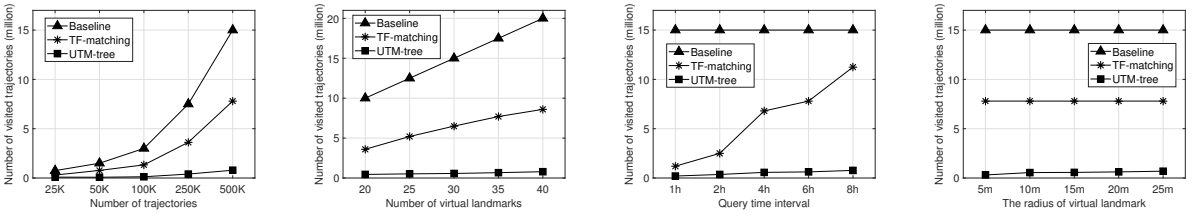
Next, the comparison results for three approaches under the different $\mathtt{Num}_\mathsf{P}$ are shown in both Fig. 6 (b) and Fig. 7 (b). We can see that $\mathtt{Num}_\mathsf{P}$ has the least influence on the performance of the UTM-tree. In contrast, the performance of the baseline method and the TF-matching approach is degraded dramatically.

The influence of τ_q on the three approaches under different experimental settings are shown in both Fig. 6 (c) and 7 (c). The running time and the number of visited trajectories in TF-matching



(a) Query running time vs. $\mathsf{Num_T}$ (b) Query running time vs. $\mathsf{Num_P}$ (c) Query running time vs. τ_q (d) Query running time vs. r_n^c

Figure 6: The comparison of baseline method, TF-matching, and UTM-tree for query running time



(a) # of visited trajectories vs. $\mathsf{Num_T}$ (b) # of visited trajectories vs. $\mathsf{Num_P}$ (c) # of visited trajectories vs. τ_q (d) # of visited trajectories vs. r_n^c

Figure 7: The comparison of baseline method, TF-matching, and UTM-tree for number of visited trajectories

approach increase significantly when τ_q becomes wider. However, the UTM-tree is more stable against the changes in τ_q.

Last, Fig. 6 (d) and 7 (d) compare the performance of the three approaches under different r_k^c. Both the three approaches do not change significantly with different r_k^c. Overall speaking, the UTM-tree is more efficient and stable than the baseline method and the TF-matching approach in terms of running time and the number of visited trajectories under different experiment settings. Specifically, the UTM-tree runs faster than other approaches and is less sensitive to query time intervals, virtual landmark radius, and the number of virtual landmarks in each query.

5 RELATED WORK

(1) *Indexing uncertain trajectories.* There are a number of indexing structures, which have been proposed for uncertain spatio-temporal data, such as UTH [13], Grid-based indexing [3], and UST-tree [5]. However, UTH-tree was used for indexing uncertain trajectories on the road network. UST-tree was used for approximating diamond-based moving objects that follow the Markov-chain model. Grid-based approach was not efficient for indexing beads and necklaces since it is time-consuming to compute the overlapped region between grids and ellipses. Therefore, we devise a novel indexing structure called UTM-tree, which is based on the classic M-tree and is efficient for indexing the uncertain trajectories in the form of beads.

(2) *Queries for uncertain trajectories.* There are many studies that were proposed for querying uncertain trajectories, such as spatio-temporal similarity join [9], semantic similarity join [3], nearest-neighbor queries [11], and top-k similarity query [6]. However, most of them retrieved qualified trajectories based on some spatial/temporal criteria. None of the previous works study the problem of contact similarity in terms of spatial intersection and longest contact time duration among trajectories. This work is the first research to formally define the problem of contact similarity and propose the corresponding *CSQ* for the problem.

6 CONCLUSION

In this work, we have formally defined the concept of contact similarity and proposed a novel query, called *CSQ*. Next, we designed a novel indexing structure called UTM-tree, for managing and querying uncertain trajectories. Besides, we conducted extensive experiments on the Beijing Taxi dataset. The experimental results demonstrated the efficiency and stability of the UTM-tree on *CSQ*. There are many interesting future directions, e.g., (1) contact modeling between MOs on road networks, (2) indoor contact modeling between MOs, (3) *CSQ* in terms of contact frequency, (4) second-generation contact between MOs, and (5) performance evaluation with more real-world datasets.

Short Paper

AdCom: Adaptive Combiner for Streaming Aggregations

Felipe Gutierrez[1] Kaustubh Beedkar[1] Abel Souza[2] Volker Markl[1]
[1]Technische Universität Berlin, Germany [2]Umeå University, Sweden
firstname.lastname@tu-berlin.de firstname.lastname@cs.umu.se

ABSTRACT

Continuous applications such as device monitoring and anomaly detection often require real-time aggregated statistics over unbounded data streams. While existing stream processing systems such as Flink, Spark, and Storm support processing of streaming aggregations, their optimizations are limited with respect to the dynamic nature of the data, and therefore are suboptimal when the workload changes and/or when there is data skew. In this paper we present AdCom, which is an adaptive combiner for stream processing engines. The use of AdCom in aggregation queries enables pre-aggregating tuples upstream (i.e., before data shuffling) followed by global aggregation downstream. In contrast to existing approaches, AdCom can automatically adjust the number of tuples to pre-aggregate depending on the data rate and available network. Our experimental study using real-world streaming workloads shows that using AdCom leads to 2.5–9× higher sustainable throughput without compromising latency.

1 INTRODUCTION

Continuous or real-time applications often require real-time aggregated statistics over an unbounded stream of events or tuples. For example, ride-sharing platforms such as Uber and Lyft utilize real-time aggregated statistics about traffic conditions to provide suggestions on trip routes [1, 27]. As another example, interactive entertainment platforms such as King.com provide their data science teams with real-time aggregated statistics over billions of user events from different games and systems [11].

To efficiently process continuous streams of data in real-time, applications rely on Distributed Stream Processing Engines (SPEs) such as Spark Streaming [29], Apache Flink [5], Apache Samza [19], or Apache Storm [24]. These systems enable data stream processing with low-latency and high throughput, and can scale by distributing computations among a cluster of machines.

In the particular case of *streaming aggregations*, which are `groupBy-aggregation` queries on continuous data, query execution involves shuffling of data stream tuples among compute machines of the cluster. This data shuffling involves communication between machines via network, which incurs a performance overhead in terms of a decrease in throughput and an increase in end-to-end latency. The shuffling overhead—of which the network bandwidth between machines is an important factor—also increases as the degree of parallel processing increases. Therefore, it is essential to reduce the shuffling overhead to improve the overall performance of SPEs for streaming aggregations.

Current SPEs optimize data shuffling by extending the "combine plus reduce" pattern of MapReduce (batch) to streaming. In particular, SPEs first pre-aggregate upstream (i.e., locally aggregate tuples in each partition before shuffling over the network) and then perform a global aggregation operation downstream. To cater to the needs of continuous applications, the number of input tuples accumulated prior to applying local aggregation is based on a pre-configured mini-batch interval (e.g., for every 1000 tuples or every 5 seconds).

While SPEs allow configuring the mini-batch interval, its fixed size during query execution is not ideal for real-time applications. This is because, it lacks adaptability to the dynamic nature (w.r.t. data rate changes and/or data skew) of datastreams. For example, if the throughput of a data stream suddenly increases to what the SPE cannot sustain (i.e., when the network gets saturated), SPE inflicts a "backpressure" on the upstream operators. Backpressure leads to an increase in the system's latency. Likewise, if there is (sudden) data skew in the stream, some instances of the (downstream) aggregation operation will process more records than others leading to saturation of network buffers and consequently affecting latency. One way to deal with the unpredictable nature of datastreams is to re-configure the size of the network buffers and/or mini-batch intervals to pre-aggregate. However, this requires re-starting the query, which is expensive and undesirable for continuous applications.

In this paper, we propose AdCom, which is an adaptive combiner for SPEs. In contrast to pre-aggregating tuples based on a fixed mini-batch interval, AdCom uses dynamic mini-batch intervals. This allows "on-the-fly" adjusting of the number of tuples to pre-aggregate. To deal with sudden changes in data rate, AdCom utilizes a feedback mechanism consisting of a proportional-integral controller that continuously monitors its network buffers, and an actuator that signals AdCom to adjusts its mini-batch interval. Thus, a high network usage results in pre-aggregating more number of tuples and vice-versa. This allows SPEs to adapt to sudden data rate changes and/or skew, and achieve a higher sustainable throughput without compromising latency.

We implemented AdCom in Apache Flink[1], which we considered as a representative SPE, and performed an extensive evaluation using real-world and synthetic datasets. Our results indicate that with AdCom, Flink can autonomously adapt to data rate changes and can execute aggregation queries with higher sustainable throughput (up to 2.5×) compared to existing approaches.

2 BACKGROUND

We start with a discussion on streaming aggregations that we consider in this paper. We then describe the limitations of SPEs in execution aggregation queries. We use Apache Flink as a representative SPE to explain key concepts. These concepts also generalize to other SPEs like Spark Streaming or Apache Storm.

2.1 Streaming Aggregations

We focus on the computing of streaming aggregates that are most common in stream analytics applications. More specifically, we consider unbounded aggregations on continuous queries that have the following general form:

```
dataStream.groupBy(...).aggregate(...)
```

In the above general form, the `groupBy(...)` transformation first groups elements of the data stream by the specified key(s).

[1]https://github.com/TU-Berlin-DIMA/AdCom

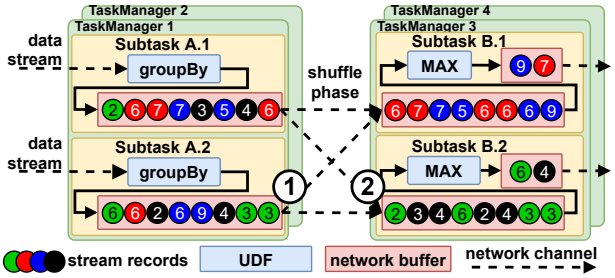

Figure 1: Illustration of executing a `groupBy-max` query.

Then, the `aggregate(...)` transformation computes a "rolling" aggregate as an output data stream. Such queries are the backbone of many common data analytic tasks such as retrieving, gathering, and organizing data. Common aggregate functions supported by SPEs include `sum()`, `min()`, `max()`, and `avg()` among others. SPEs also support parameterizing aggregate transformations with User Defined Functions (UDFs).

As an example, consider a weather analytics dashboard that continuously updates the maximum temperature of all regions in a neighborhood. The application receives as an input, a data stream S of `<timeStamp,regionId,temperature>` events, and executes the aggregation query[2]:

`S.groupBy(regionId).max(temperature)`

For a given stream such as:

$$[1, A, 23], [2, A, 25], [1, B, 19], [1, C, 28], [2, B, 18], \ldots$$

the aggregation query produces the following resulting stream:

$$[A, 23], [A, 25], [B, 19], [C, 28], [B, 19], \ldots$$

Figure 1 gives a high level overview of executing such an aggregation query on a Flink cluster. It includes two tasks A and B with their respective subtasks running in parallel. In this example, subtasks A.1 and A.2, which perform the `groupBy` transformation, communicate with the two instances of task B, which perform the `max()` transformation. The `groupBy()` operations leads to shuffling of stream elements over the network[3]. Before shuffling, the output of the upstream (or sender) task is first queued in a (network) buffer at ①. The events, which are already grouped by key, are then flushed on to the network after a pre-configured timeout (e.g., 100ms) or when the buffers are full. Likewise, on the receiver side, the data is first queued in a buffer at ②, which is then consumed by the downstream subtasks.

2.2 Limitations of SPEs

SPEs strive to achieve a high sustainable throughput and low end-to-end latency. In real-world workloads, however, SPEs have to deal with two scenarios that affect its throughput and latency: (1) When the data stream's arrival rate increases to what a system can not handle, and (2) when there is data skew, which causes some instances of the aggregation tasks to process many more records than others. In both these scenarios, SPEs exhibit a backpressure mechanism, where the stream of events is queued up in network buffers before being processed. This leads to an increase in end-to-end latency, and in the worst case stalls the dataflow.

In the case of aggregation queries, backpressure on the sender tasks, either due to a high arrival rate or data skew, can be mitigated to some extent by first locally aggregating. This is akin to the use of a combiner in MapReduce [8]. In the context of data

[2]for brevity, we suppress the `map()` (or `project()`) transformation to project out the `timeStamp` attribute

[3]Other similar transformation are `keyBy()` and `reduceByKey()`.

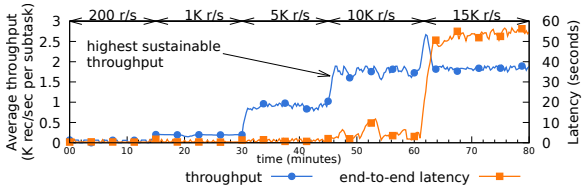

Figure 2: Limitations of SPE w.r.t. data rate changes when executing a `groupBy-sum` query.

streaming, SPEs pre-aggregate records based on small mini-batch interval (e.g., for every 5 seconds) before shuffling them over the network. However, this pre-aggregation is suboptimal as using a fixed mini-batch interval leads to an increased end-to-end latency when workload changes and/or when there is skew.

We illustrate this limitation with an experiment that we performed using Apache Flink. We considered a `groupBy-sum` query and a setup comprising four local (pre-) aggregation tasks and four global aggregation tasks. The mini-batch interval to pre-aggregate was set to 5s and 5K records. Figure 2 shows the system's throughput (in blue; left axis) and its end-to-end latency (in orange; right axis).

As we observe in Figure 2, the end-to-end latency remains constant (~0.5s) as the data rate increases from 200 records/s to 5K records/s. Also, the system achieves its highest sustainable throughput of ~8K records/sec. Note that when the arrival rate further increases to 15K records/s, we see a spike in end-to-end latency. This is because, the system exhibits a backpressure mechanism and consequently an increased (up to 60s) end-to-end latency when it can no longer cope with the arrival rate.

One way to deal with the changes in workload is to re-configure the number of tuples to pre-aggregate and/or the size of the network buffers. However, this requires restarting the query each time the workload changes, which is expensive and undesirable for real-time applications.

3 ADAPTIVE COMBINER

We now present `AdCom`, an adaptive combiner for SPEs that overcomes the limitations mentioned above. The use of `AdCom` aids in optimizing aggregation queries in SPEs by dynamically adjusting the mini-batch interval to pre-aggregate prior to data shuffling, which enables the SPE to constantly achieve the highest sustainable throughput without compromising latency.

The key challenge in designing `AdCom` is to determine when to emit locally aggregated tuples. As discussed above, using a fixed mini-batch interval is useful, but when the arrival rate of records is higher than what the network can handle, the backpressure mechanism is activated and leads to high latency. On the other hand, if the arrival rate is too low, then a large mini-batch interval will diminish the lowest achievable latency for the query.

3.1 The Feedback Mechanism

We tackle the above challenge by making use of a feedback mechanism, which comprises (1) a controller and (2) an actuator. The controller continuously monitors the network buffers and computes an optimal mini-batch interval for the current workload. The actuator periodically sends "signals" (i.e., the new configuration for the mini-batch interval) to the parallel instances of `AdCom`. This feedback mechanism allows `AdCom` to dynamically adjust the time (and/or number of tuples) for which it should locally aggregate tuples.

Figure 3 gives an overview of executing an aggregate query using AdCom. Before we delve into its details, recall that backpressure is inflicted when the incoming arrival rate of records surpasses what the system can handle. In the context of query execution, this happens when the (sender's) network buffer is queued up with records that it cannot flush to the network (i.e., shuffle). More formally, denote by λ the rate at which a pre-aggregation task writes records to its buffer (i.e., the mini-batch interval) and by μ the rate at which the records are flushed out from the buffer. Further, let $\rho = \frac{\lambda}{\mu}$ denote the fraction of buffer utilized. Intuitively, a backpressure situation arises when $\rho \geq 1$. The key idea of our approach is to always keep $\rho < 1$ by continuously updating λ, which translates to adapting the mini-batch interval to pre-aggregate[4].

3.2 AdCom's Controller and Actuator

We now detail the working of the controller and actuator. As shown in Figure 3, the controller and the actuator are part of Flink's job manager. This allows us to globally control all (parallel) AdCom instances (i.e., pre-aggregation subtasks) that are executed in the same phase. This is crucial for preserving the query semantics with respect to the order in which the records are processed downstream. Otherwise, having a controller for each of AdCom's parallel instance would result in writing records (to its buffers) at different time intervals. This may lead to a change in the order that records are processed downstream, which may be undesirable depending on the application.

We use a proportional-integral (PI) controller to continuously compute the optimal λ. PI controllers have been widely used in control systems and applications that require continuous modulated control[5]. We refer interested readers to [12] for a comprehensive overview. In what follows, we discuss how we use a PI controller in the context of performing streaming aggregations.

At high level, and as illustrated in Figure 3, the controller continuously calculates an error value $e(t)$ for each time t, which is the difference between the desired value ρ_d of the network buffer utilization and the measured current buffer utilization ρ. Based on the error value, it updates λ based on a proportional (K_P) and integral (K_I) terms. The proportional control term determines the correction in λ, which is proportional to $e(t)$. The integral term further applies a correction based on past values of $e(t)$, to diminish the residual error (i.e., when $e(t) > 0$ or $e(t) < 0$ after applying the proportional correction).

In more detail, we compute $e(t)$ as follows. Denote by $A_1, \ldots, A_n$ the parallel instances of AdCom, and by ρ_{A_i} the buffer utilization for instance A_i. Since we want to globally control all instances (as mentioned above), we compute the error value as:

$$e(t) = -\begin{cases} \rho_d - \text{avg}(\rho_{A_1}, \ldots, \rho_{A_n}) \text{ if } \nexists A_i \text{ s.t. } \rho_{A_i=1} \\ \rho_d - 1 \text{ otherwise} \end{cases}$$

In other words, we compute $e(t)$ using the average buffer utilization across AdCom's parallel instances. To cope with data skew, we compute $e(t)$ as $\rho_d - 1$, i.e., when there is at least one AdCom instance with 100% buffer utilization. The desired value ρ_d is set based on the Service-Level Objective (SLO) to keep low or medium backpressure on the upstream operators, which usually corresponds to 50–80% usage of the network buffers.

When $e(t) > 0$, the ρ signals are too high, then the controller produces an input signal that decreases ρ. This materializes by

[4]Alternatively, one can continuously update μ or both.

[5]Some control systems additionally make use of a derivative component, i.e., a PID controller; we do not use it as it is suitable only for slow moving loops.

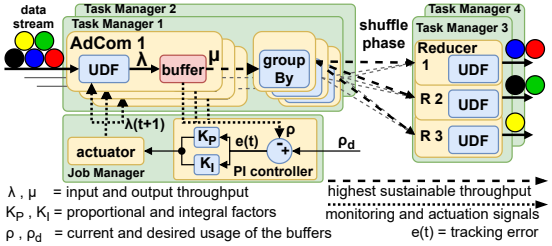

Figure 3: Overview of AdCom.

increasing the pre-aggregating time (and decreasing λ) at AdCom. Vice-versa, when $e(t) < 0$, the controller produces an input signal that increases the usage of the buffers. This leads to "less aggregation" and increase in λ at AdCom. Finally, based on the $e(t)$, the controller applies a correction based on proportional (K_P) and integral (K_I) terms, which we explain next.

Proportional Factor (K_P). It is crucial for any controller to let the magnitude of the corrective action depend upon the magnitude of the error. This states how quickly AdCom responds to errors. For instance, small errors lead to small adjustments, whereas larger errors result in greater corrective actions. This is accomplished by the proportional factor K_P (Equation 1). It helps the controller apply the largest control action if $e(t)$ is large and not making the system unstable if $e(t)$ is small. The next proportional parameter (i.e., the mini-batch interval) to pre-aggregate records is denoted by $\lambda(t+1)$ and it is computed based on the current parameter $\lambda(t)$ summed with the proportional factor K_P times the error $t(e)$, as follows:

$$\lambda(t+1) = \lambda(t) + [K_P.e(t)] \quad (1)$$

The controller estimates a proportional correction if $e(t)$ is within the desired min and max values of ρ_d. However, since we consider average buffer utilization, it may be possible that $e(t)$ becomes zero. Therefore, no correction is taken in this case. One way to fix this is to reduce the desired range or increase K_P. However, this leads to AdCom making rapid and unstable adjustments, which is very undesirable. Therefore, we further use an integral factor K_I to determine the corrective action.

Integral Factor (K_I). The integral factor makes the controller not react only based on the momentary $e(t)$ but also based on its previous values. It provides a way to amplify small errors and keep adding them up over time. The accumulated values provide a significant control signal and help the system not oscillate when it reaches the optimal time to locally aggregate tuples. We compute the integral factor based the three last values of $e(t)$ with a sliding window-based histogram that implements the reservoir algorithm. In our experiments, this window size was enough to achieve a steady-state on the pre-aggregation parameter of AdCom (see Section 4). Equation 2 composes the AdCom' *PI controller* with its proportional and integral factors that we use to calculate the new pre-aggregation parameter λ.

$$\lambda(t+1) = [\lambda(t) + (K_P.e(t))] + [\lambda(t) + (K_I.\int_{t}^{(t-3)} e(\tau).d\tau)] \quad (2)$$

3.3 Using AdCom in Flink

One can make use of AdCom at the API level, by parameterizing it with the `groupBy()` key and a query specific UDF for pre-aggregation. For example, our modifications to Flink allow us to write the example aggregate query of Section 2 as:

```
S.adcom(regionId, max(temperature))
 .groupBy(regionId).max(temperature)
```

4 EXPERIMENTS

We conducted an experimental study using a real-world dataset in the context of a ride-sharing application. Our goal was to compare the performance of Flink when using AdCom and other existing optimizations. In particular, we investigated: (i) how well AdCom adapts when data rate changes; (ii) how well AdCom fares when there is data skew; (iii) AdCom's resource efficiency, and; (iv) how distributive and user-defined aggregate functions affect its performance. We found that:

- Flink+AdCom achieved up to 2.5–9× higher sustainable throughput when data rate increased by 4×.
- AdCom is competitive to state-of-the-art when handling skew.
- Flink+AdCom with 8 reducers achieved 9× higher throughput than Flink+noOptimization, and 3× higher throughput than state-of-the-art.
- Flink+AdCom achieved similar throughput but lower latency when using distributive and user-defined aggregate functions.

4.1 Experimental Setup

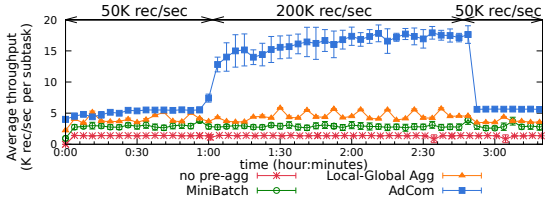
Implementation and cluster. We implemented AdCom as a new operator in Apache Flink. The PI controller and the actuator are implemented as components of Flink's job manager and use Flink's job monitoring API to monitor network buffer usage of AdCom. All of our experiments were run on a local Flink cluster consisting of four machines, each with 16GB of main memory, one hard disk of 2TB, one Intel Xeon 2.66GHz 64-bit 8 core CPU, and Ubuntu 16.04.6 (kernel GNU/Linux 4.4.0) as the operating system. The machines in the cluster are connected via 1 Gbps Ethernet. We used Apache Flink 1.11.2 and Java 1.8 for our implementation. We configured the Flink cluster with four Task Managers and one Job Manager, and set the maximum sub-task parallelism to 8 per node (i.e., the same number of CPU cores).

Datasets and aggregation queries. We used the New York City Taxi and Limousine Commission (TLC) [22] dataset. It consists of three million taxi trip records with fields capturing pick-up and drop-off dates/times, pick-up and drop-off locations, trip distances, itemized fares, rate types, payment types, and driver-reported passenger counts. We additionally considered the TPC-H benchmark dataset [4] with scale factor 5.

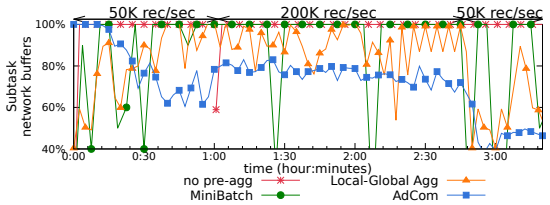
For the TLC dataset, we considered queries with algebraic and distributive aggregate functions. In particular: (i) we considered an event-count query (which we denote by Q1 in the text below) that sums the number of passengers for each taxi driver, and (ii) and an aggregation query that computes for each taxi driver the average number of passengers, trip distance, and trip time (denoted by Q2). For the TPC-H data we considered the TPC-H query 1, which is an aggregation query over a single table (lineitem) consisting of COUNT, SUM, and AVG aggregate functions.

We followed Karimov et al. [15] to generate on-the-fly data streams for benchmarking streaming applications. In particular, we load the datasets in memory and implement a streaming data source that can emit events with different characteristics (see Sections 4.2 and 4.3 below).

Baseline. To evaluate the performance of AdCom, we compare it with no pre-aggregation, and with the state-of-the-art streaming aggregation optimizations available in Flink [13]. In more detail, we compare against (i) MiniBatch, which buffers input records before the shuffle phase, and (ii) Local-Global Aggregation, which executes the MiniBatch and then pre-aggregates records locally (akin to Combine plus Reduce in MapReduce).



(a) Throughput



(b) Network buffer usage

Figure 4: Effect of change in data rate.

We set the maximum latency and the maximum number of input records that can be used for MiniBatch and Local-Global aggregation to 3 seconds and 3K events, respectively.

4.2 Effect of Change in Data Rate

We first study how well Flink adapts to a sudden surge in data arrival rate when using AdCom and compare its performance with the baseline approaches. We consider the TLC dataset, and a stream data source that for the first 60 mins generates events at 50K records/sec, then for the next 100 mins at 200K records/sec, and finally again reverts to a rate of 50K records/sec. We considered the aggregation query Q1 and measured its throughput and latency, for which the results are shown in Figure 4.

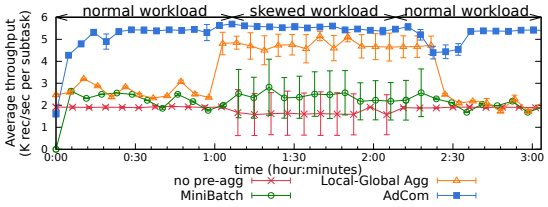
We observed that Flink+AdCom achieved a higher throughput than Flink+MiniBatch and Flink+LocalGlobal (see Figure 4(a)). More specifically, when the input throughput is 50K rec/sec, AdCom achieved an optimal mini-batch interval of 3.5s (starting from the default value of 500ms) compared to a fixed interval (of 3s and 3K events) for Flink+LocalGlobal. This allows us to obtain a slightly higher throughput for the first 60mins. As the input rate surges to 200K records/sec, AdCom further adapts its mini-batch interval (from 3.5s to 8.5s), which allows Flink+AdCom to achieve much higher throughput (from 3.6× up to 9×).

Figure 4(b) also shows the percentage of Flink's network buffer utilization for such a workload, which correlates to its latency. High buffer utilization indicates high backpressure and increased latency, whereas a lower buffer utilization indicates a low backpressure and lower latency. We observed that with AdCom, Flink had an overall lower buffer utilization due to AdCom constantly adjusting its mini-batch interval. When the workload suddenly surges to 200K records/sec, AdCom had a buffer utilization (up to 80%) but stabilizes after it reaches a sustainable throughput of 18K records/sec per subtask (see Figure 4(a)) pre-aggregating records every 8.5s. With baseline approaches, we observe that pre-configured mini-batch intervals are not ideal for dynamic workloads and lead to high buffer usage with surges in data rate.

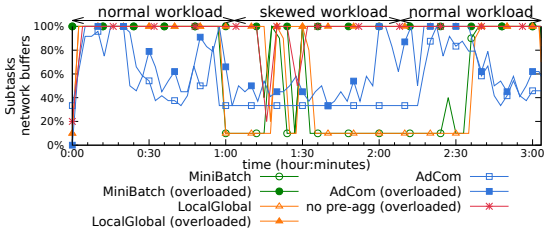
Our results indicate that AdCom allows Flink to adapt to data rate changes and achieve a higher sustainable throughput.

4.3 Effect of Skew Workloads

We now proceed to evaluate how well Flink performs in the presence of skew workloads. We consider the TLC dataset, and a stream data source at 50K records/sec that for the first 60 mins



(a) Throughput



(b) Network buffer usage

Figure 5: Effect of data skew.

generates tuples following a uniform key distribution, then for the next 70 mins following a skewed distribution, and finally again reverts to a normal distribution. We considered the aggregation query Q1 and measured its throughput and Flink's network buffer utilization, for which the results are shown in Figure 5.

We observed that the LocalGlobal optimization allowed Flink to reduce the network shuffle and cost of global aggregation in the presence of skew. However, as shown in Figure 5(a), we observed that throughput across subtasks had some variation. Flink+AdCom also responded well to skew as it also first locally aggregates, and achieved a slightly higher throughput with negligible variation. This is because, AdCom adjusted its mini-batch interval to 3.5s compared to (pre-configured) 3s of LocalGlobal. We also show the network buffer utilization for this setting in Figure 5(b). Note that different subtasks have different buffer utilization, and hence we show two lines (one for the overloaded task and other for remaining tasks). As observed in Figure 5(b), AdCom leads to lower buffer utilization and hence lower backpressure.

Overall, our experiments indicate that AdCom is competitive to LocalGlobal aggregation in dealing with data skew.

4.4 Resource Efficiency

We now evaluate the resource efficiency of Flink when using AdCom for data streams with high arrival rate. A common strategy to cope with high arrival rate is to add more resources, i.e., increase the degree of parallelism. When we add more global (i.e.: reducer) subtasks after the shuffle phase, it helps the query to avoid backpressure. Hence, it can sustain a higher throughput.

We consider the TLC dataset and a streaming source that generates events at a fixed rate of 200K rec/sec and process query Q1 with different aggregation optimizations. To deal with a higher workload, we set the maximum latency and the maximum number of input records that can be used for MiniBatch and LocalGlobal aggregation to 7 seconds and 7K events, respectively.

Figure 6 shows the throughput of the query for different strategies. We observed that Flink+AdCom with 8 reducers achieved 9× higher throughput than Flink+noOptimization, and 3× higher throughput than Flink+MiniBatch and Flink+LocalGlobal. Further, Flink+AdCom required only 8 reducers to achieve the same throughput that Flink+LocalGlobal achieves with 24 reducers. This is because the MiniBatch and the LocalGlobal approaches

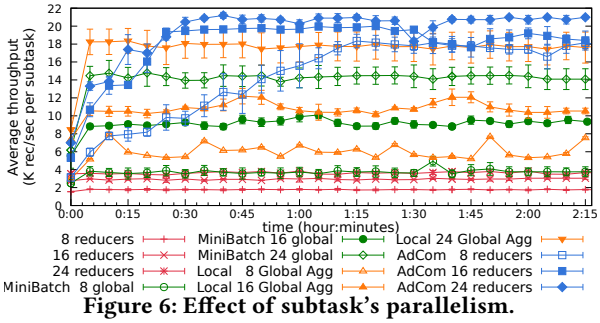


Figure 6: Effect of subtask's parallelism.

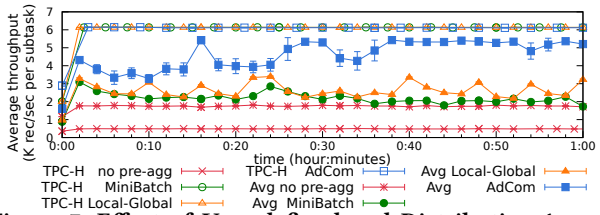

Figure 7: Effect of User-defined and Distributive Aggregate Functions.

first accumulates (mini-batches) records every 7 seconds, and then aggregate every 7K tuples. In contrast, AdCom leverages a hash-based data structure, which allows us to consume and pre-aggregate tuples in a single pass and hence requires less resources.

Based on these experiments, we conclude that AdCom is more resource efficient compared to MiniBatch and LocalGlobal.

4.5 Results for User-defined and Distributive Aggregate Functions

Lastly, we evaluate the performance of AdCom for aggregation queries with both distributive and algebraic aggregate functions. We considered queries Q2 (on the TLC dataset) and TPC-H Q1 and set the maximum latency and the maximum number of input records that can be used for MiniBatch and LocalGlobal aggregation to 1s and 1K events, respectively. The arrival rate for each stream was 50K records/sec. The results are shown in Figure 7.

We first discuss the results for TPC-H query Q1. We observed that Flink achieves the same throughput when using either of AdCom, MiniBatch, or LocalGlobal. This is because the configured maximum latency of 1s and the maximum number of input records of 1K events that configured for MiniBatch and LocalGlobal aggregation was sufficient to handle the workload and the user-defined aggregate function. Although Flink+AdCom achieved a similar throughput, it adapts its mini-batch interval from 1s to 50ms, and thus achieving a lower latency than Flink+MiniBach and Flink+LocalGlobal (not shown here).

For query Q2, which involves an algebraic aggregate, we observed that Flink+AdCom again achieves a higher throughput than Flink+MiniBatch and Flink+LocalGlobal. We note that, other than AVG(), Flink+LocalGlobal cannot optimize queries with algebraic aggregate functions. In contrast, AdCom allows specifying any UDF for pre-aggregating which makes it suitable to aggregation queries that accept a "useful" combiner.

Overall, we found that Flink+AdCom achieves a higher throughput without compromising on latency even for distributive aggregate functions. We also performed experiments (not shown here due to space constraints) considering queries involving other distributive and algebraic aggregate functions such (e.g., sum, max, min, and top-k) and observed similar performance.

5 RELATED WORK

We now discuss how ideas presented in this paper are related to prior work on adaptive stream processing. Due to space constraints, we discuss works that are most related.

Das et al. [7] studied the effect of batch sizes on throughput and latency, and proposed a control algorithm based on fixed point iteration. Their work focuses on determining the optimal batch size for ingesting the data into SPE and relies on past queries. Zhang et al. [31] proposed Dynamic Block and Batch Sizing (DyBBS) using an online control algorithm integrated with isotonic regression. Besides adjusting the micro-batch size, DyBBS also adjusts the execution parallelism (i.e., batch size/block size in Spark). Instead of adapting the batch size, Drizzle [26] focuses on optimally scheduling multiple batches (or a group), and automatically tunes the group size. A-scheduler [6] further extended this approach by dynamically changing the batch sizes using an expert fuzzy control mechanism. Wu et al. [28] studied the impact of batch size on Kafka streams that are then ingested into SPEs, and proposed a reactive batching strategy to cope with variable network conditions. Lohrmann et al. [17] proposed strategies to switch between adaptive buffer (re-)sizing and dynamic task chaining to optimize execution plans. All these approaches focus on adjusting the batch size w.r.t. the entire query or prior to ingesting the data stream into the SPE. In contrast, we focus on the batch size specific to an (aggregation) operator. `AdCom` is thus complementary to the above approaches.

Apart from dynamically configuring the batch size, many works have also focused on adapting the execution plan. WASP [14] uses a network-aware framework that is able to adapt the query plan to the resources available in run-time via task re-assignment, operator scaling, and query re-planning. Nasir et al. [18] proposed a hash-based algorithm to partition data that optimizes network shuffle and deals with skew workloads. While [3, 16, 20, 25] have studied eliminating redundant computations via dynamically sharing of data and/or compute, [10, 21] focused on adaptability via query complication. Eddies [2] also tackled the problem of unpredictable workloads by reordering operators at runtime.

Feedback mechanisms have been a central component in enabling adaptive stream processing. FAST [9] uses adaptive sampling methods based on a PID controller to adjust the sampling rate for processing streams. Tolosana-Calasanz et al. [23] uses a feedback mechanism based solely on proportional factor to minimize resource utilization. In `AdCom`, we leverage a PI controller, which is specific to optimizing local-aggregations.

6 CONCLUSION AND FUTURE WORK

Adaptability of SPEs to varying workloads is important for real-time applications. In this paper, we considered streaming aggregations, which are the backbone of many real-time applications. We have proposed `AdCom`, an adaptive combiner for SPEs, which improves the performance of aggregation queries under variable workloads. We have proposed a lightweight feedback mechanism that continuously monitors the network buffers, and allows `AdCom` to autonomously adapt to varying workloads. In our experimental evaluation using a real-world dataset, we have shown that `AdCom` achieves a higher sustainable throughput (up to 9×) without compromising latency, is resilient to data skew, and is resource efficient when compared to existing optimizations.

As future work, we plan to extend our work to fog and edge computing environments [30]. In particular, we plan to study how to adapt `AdCom` for nodes that are resource (e.g., memory) constrained. We also plan to make `AdCom` adaptive to hybrid environments that include unreliable compute nodes and network channels. Lastly, we plan to extend existing optimizers to create the `AdCom` UDF during compile time, so it can relieve the developers of this task.

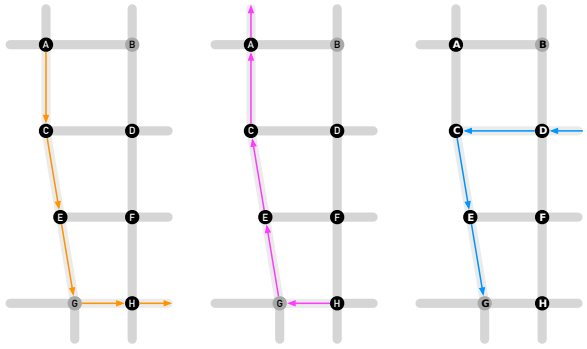
ABSTRACT

With the ever-increasing urbanization, managing traffic and avoiding congestion becomes more and more challenging. Analysing the dynamics of vehicles is a crucial aspect of alleviating the problem of traffic congestion. One key aspect in assessing the traffic situation is to identify *dominant flows*, which are subject to high traffic volumes, and hence, are most prone to generate congestion. Real-world traffic data tracking vehicles in an urban network are proved to be extensive, subject to inconsistencies, and often detections are missing. These render many of the prior techniques inapplicable, highlighting the need for a novel robust and scalable technique. In this paper, we propose IST, an indexing technique for real-life traffic data, a scoring function for identifying the dominant flows and Flow-Scan, an algorithm for querying the dominant flows from the proposed index. Our experimental results demonstrate the efficiency and effectiveness of the presented method. Robustness and effectiveness were tested querying top-k dominant flows on a real-life dataset. In addition, with synthetic data, we demonstrate that our method is scalable while comparing it to related existing methods.

1 INTRODUCTION

Predicting and preventing traffic congestion is important for multiple reasons, such as reducing the driving time from place to place, reducing pollution, reducing waste of fuel, and in general improving the efficiency of urban mobility. In order to prevent traffic congestion in urban roads, it is necessary to analyse the traffic dynamics and identify the areas where traffic jams are more likely to happen. Identifying these potentially problematic areas is the first step to pursue solutions alleviating the issue using traffic optimization techniques.

Dominant flows refer to the longest possible sequences of road segments where a significant number of vehicles travel in a given time window. They are crucial information to enable regional traffic optimization techniques and to coordinate traffic light plans in order to calibrate the capacity of roads. Detecting dominant flows enables smart traffic light plans optimization, allowing on the one hand to increase the throughput of vehicles crossing intersections in the directions affected by the dominant flows (traffic throttling), and on the other hand slow down traffic along with the dominant flows when road capacity cannot be further extended and backpressure must be applied to avoid saturation of road edges, i.e., congestions. Congestions can be interpreted as multiple overlapping flows that constrain each other and so creating traffic jams. In addition, the longer the dominant flows are the more areas they affect. Thus, detecting these flows allows adjusting the traffic light plans to avoid these traffic jams. Once the dominant flows are detected, dedicated analytics can be applied to them for further traffic and movement pattern analysis and for understanding macroscopic traffic trends. Additionally, knowing the dominant flows can be a powerful analytical tool for defining strategies for traffic management and control of traffic authorities.



(a) 03:00-04:00 (b) 08:00-09:00 (c) 13:00-14:00

Figure 1: Example of dominant flows in an area during three different times of a day.

As vehicles are used by people, it is not always straightforward to model their behaviour and moving patterns. For example, Figure 1 presents the dominant flows in an area at three different times of a day. As we can see, the flows are conflicting, especially between the one from 03:00-04:00 that goes from intersection A to intersection H and the one from 08:00-09:00 where it goes from intersection H to intersection A. The most common traffic light systems allow traffic engineers to adjust traffic light plans during the day to accommodate different flows. Thus, existing adaptive traffic light systems seek dominant flow information during the day to avoid traffic jams and shorten commute time.

Our case study concerns an area in one of the largest Chinese metropolis where installed cameras allow to monitor traffic at intersections. Automated video processing allows detecting trajectories of vehicles across intersections, while detecting and tracking their plate number. Summaries of the information extracted from videos are made available for traffic optimization processes at 1 second frequency. The inherent complexity of real-life environment, video processing and software pipelines make the process prone to errors and failures that must be accounted for. This work is part of a solution combining cloud technologies and AI which strives for analysing and coordinating the traffic in the city to alleviate the traffic congestion.

Working with real-life data is a challenging task. Real-life data can be highly incomplete, with respect to missing values, and high noise. Our case study uses data from camera sensors that

*Work done during an internship at Huawei Munich Research Center.

cover only certain parts of the road network, leading to missing information. For example, in Figure 1, there are no camera sensors located in intersection B, so if multiple vehicles traveling from intersection D to intersection B create a dominant flow, this flow will be probably missed. Furthermore, camera sensors might suffer from various problems during their lifetime. Malfunction, bad visibility due to the weather or dirt may prevent precise detection of plate numbers. The aforementioned issues generate various types of inconsistencies in the detection data, and thus making the dominant flow identification more challenging.

The top-k dominant flow extraction is not a new problem. Yet, the previous work [1–3, 6, 9] is considering only the frequency of the flows and not their length. However, if the length of the flows are ignored, single very frequent road segment flows would dominate the top-k results and not allow the longer and more important flows to be identified and analysed. The PSSS method [3] suggests the use of a variant of a fundamental sequential pattern mining method [5, 8]. However, this technique is not applicable in our context due to our challenging real-life data where missing values in the detections are not rare. The method proposed in [3] is using the successor list of each sensor in order to find "hot routes", but in our setting where missing values are common and not all road edges are monitored, the successor lists will not achieve the desired outcome and end up giving wrong results.

This work is focused on identifying dominant flows in given time windows during the day, to support an adaptive traffic light system aimed at optimizing traffic by controlling road capacity and prevent congestion of vehicles on urban roads. In this paper, we aim to discover dominant flows occurring during ad-hoc time windows based on the frequency and length of the flow. The approach we are presenting in this work enables to overcome the issues that the previous methods have with the imperfect real-life data. Furthermore, we consider not only the frequency of a flow, but also its length. The main idea of this work is to use simple data structures to store all the vehicle detections from the camera sensors based both on their timestamps and their location. We adopt a combination of an inverted index and suffix trees to index only the necessary vehicle trip detections. From the index, we are then able to identify the most dominant flows very efficiently in multiple ad-hoc time windows.

Contributions and Outline. In summary, in this work we make the following contributions:

- We introduce a novel scoring function to determine the flows based on a weighted factor between their frequency and length.
- We propose a simple indexing technique for vehicle detections on road networks.
- We propose an efficient algorithm to identify dominant flows on multiple ad-hoc time windows from the proposed index.
- With thorough experiments, we demonstrate that our indexing and querying methods are efficient and viable solutions to our case study.

The rest of the paper is organised as follows. Section 2 reviews the related work, while in Section 3 the problem of finding the top-k dominant flows is introduced. Then, Section 4 describes the indexing function for detecting the dominant flows. We evaluate our approach with the state-of-the-art approaches in Section 5. Finally, Section 6 concludes the paper with the final remarks and provides directions for future work.

2 RELATED WORK

A vehicle trip can be seen as an ordered sequence of detections where each detection represents a single itemset of the sequence. Thus, the identification of dominant flows can be abstracted, and therefore, can be related to the frequent sequential pattern mining topic. One of the early works on this topic is [10] in which the authors made a generalization of a sequential pattern and proposed the GSP algorithm to discover the frequent patterns. Later, two different methods, SPADE [12] and PrefixSpan [5, 8], were proposed that outperformed the GSP method. SPADE [12] was introduced as a method of frequent sequence mining using a lattice structure. PrefixSpan [5, 8] algorithm was later used in other works [3] for various applications like ours. We chose to use this method as our baseline, and not SPADE since this method was used in other works as well, even though none of them perfectly apply in our application, as described in the following Section 5.

An adaptation of PrefixSpan algorithm, the PSSS [3] method was proposed in order to mine hot routes on a road network using private vehicle Electronic Registration Identification data. The problem addressed in [3] can be considered similar to our work and we use the PSSS method as a baseline in our experiments. However, there are two main differences which make PSSS not applicable for our case. First, only the frequency of a route is considered; in our method we use a combination of the frequency and the length of a flow to define it as "hot" or dominant. Second, in PSSS method successor lists for each road node are introduced that determine the neighbouring road nodes where a following detection could happen. These successor lists are used to restrict the search of hot flows only on the neighbouring road edges. Although this makes PSSS method more efficient compared to the PrefixSpan, it cannot be applied in our case. In a real case scenario, we have missing data and gaps in the detections that prevent the successor list of each road node to benefit the identification of hot flows. For example, in Figure 1, the successor list of intersection A includes intersections B and C. If a dominant flow is from intersection A to intersection E through intersection C, and the camera on intersection C is temporarily not giving any detections, this flow would be missed since the search from intersection A will be stopped once there won't be any detections in intersection C. Furthermore, in our case study scenario, there are intersections that do not have detectors and thus by default there are detections missing. The adjacency property of the road network detections is also utilized in the GBM method [6], where it is assumed that the objects are moving in a grid space and each next move is happening to adjacent grid cells. Again, this property is not true for the real case scenarios with incomplete vehicle detection, that, as mentioned before, are due to factor like missing detectors, faulty hardware, poor weather conditions or network failure and the inherent complexity of real-time image processing.

Other works related to the frequent pattern on trajectories include [1, 2, 9] focus on detecting frequent patterns on trajectories that are based on GPS coordinates. These problems are incomparable to ours, with their biggest difference being their use of coordinates floating point data instead of fixed road network point data. Furthermore, only the frequency of the patterns is considered, in contrast to the combination of the length and the frequency that our work adopts.

3 PRELIMINARIES

Let $G = (U, E)$ be a directed unweighted graph that represents a road network. A node $u_i \in U$ represents a road intersection and a directed edge $e_i = (u_x, u_y) \in E$ represents a road segment that starts from intersection u_x and ends in intersection u_y. In each edge of an intersection a detector is located, which gives information as a tuple in the form of (c, t, e), where c is the vehicle id or vehicle plate number, t is the timestamp of the detection and e is the directed road edge where the detection happened. In a real setting where each detector sends data every $1sec$, we can create sequences of detections for each vehicle, defined as vehicle trips.

Definition 3.1 (Trip). A vehicle trip T is an ordered sequence of $o_i = (t_i, e_i)$, where t_i is the timestamp and e_i is the road edge of a detection that the vehicle moved on. To be considered part of the same trip, the time difference between two sequential entries must be less than a manually-defined time threshold t_{min}. Hence, we define a trip as $T = \{o_1, o_2, \ldots, o_{|T|}\}$, where $t_{i+1} - t_i \leq t_{min} \forall i, 1 \leq i \leq |T|$.

A flow $s = \{e_1, e_2, \ldots, e_{|s|}\}$ is an ordered sequence of road edges and its length is defined as the number of road edges that it contains, i.e. $len(s) = |e \in s|$. A trip T contains a flow s at time window $W = [t_a, t_b]$, denoted as $(s, W) \sqsubseteq T$ if and only if the trip T has at least one index i where the sequence of road edges starting at i is the same sequence of ordered road edges during that time window W. More formally $\exists i, 1 \leq i \leq |T| : e_j = o_{i+j-1}.e \; \forall 1 \leq j \leq |s|$ and $[o_i.t, o_{i+|s|}.t] \subseteq W$ and $o_{i+j-1} \in T$ and $e_j \in s$. Given a time window W and a set of trips D_T, we can define the frequency of a flow as the number of trips in which it is contained, i.e. $freq(s, W) = |T_i \sqsubseteq s|$.

In order to avoid considering not useful flows, we use minimum length, l_{min}, and minimum frequency, f_{min}, limits. If a flow has less frequency or less length than the minimum, we ignore it. In addition, we consider only maximal flows, where a flow is considered maximal if there are no sub-flows with the same frequency. A score can get assigned to a flow, based on its frequency and length. In this work the score is the following:

Definition 3.2 (Flow Score). Given a flow s, a time window W, a set of trips D_T, and a parameter $0 \leq \alpha \leq 1$, the score of the flow is the weighted combination of its frequency and length, i.e. $score(s, W, \alpha) = \alpha * freq(s, W) + (1 - \alpha) * len(s)$

Given a number $k \geq 1$, a set of trips D_T, a time window W and a parameter α, the $k-$Flows problem is to identify all the k flows with the highest score.

4 METHOD FLOW-SCAN

The main idea of the proposed method is based on two observations. First, we need to identify the flows, or sub-trips, from the vehicle trips based on their frequency and length. For this purpose, we adopt a structure that utilizes a variant of the suffix tree [11]. Second, we don't need to maintain all the trips from the vehicles, but only the ones that are candidates for the results. In other words, we can discard the trips that have less than the required l_{min}. The trips with less than the required f_{min} need to get retained, since their sub-trips could potentially have more than the required f_{min}.

IST Index. The main data structure of the method is an inverted index. The keys of the inverted index store all the sub-flows with l_{min} that appear in the data. The values of the inverted index are suffix trees with all the sub-flows longer than l_{min} having the key as prefix. The adopted suffix tree, is a compact version of the known suffix tree. Essentially, the nodes that have only one sub-tree are merged with the root of their sub-tree. In this way, the suffix tree has less nodes without loss of the necessary information. In addition, each node of the suffix tree has a pointer to a list of all the trip ids that contain the sub-flow of the node. Using this list, the frequency of the sub-flow can be easily determined.

ID	Path	Vehicle	Timestamps
t1	abcdef	A1	2020/03/20 07:12 – 2020/03/20 07:28
t2	abcg	A2	2020/03/20 07:25 – 2020/03/20 07:41
t3	hdebc	A3	2020/03/20 08:03 – 2020/03/20 08:23

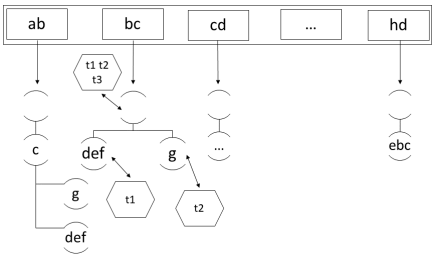


Figure 2: IST index example using $l_{min} = 2$.

An auxiliary data structure is used to store the information of all the trips; *trip id, vehicle id* that made the trip, and the starting and ending timestamps. This data structure is a simple list that is used as supplementary information of the main index. By scanning this list, the trips inside the time window can be identified.

Example 4.1. An example is shown in Figure 2 where the IST index is visualized for three vehicle trips. For this example, we use $l_{min} = 2$. All the sub-flows with length = 2 are indexed as keys in the IST, depicted as rectangles. Each key of the IST index is pointing to a suffix tree, depicted as circles, where all the sub-flows that have the certain keys as prefix are indexed. Furthermore, in the nodes of the suffix trees there are the pointers to the trip ids lists, depicted as hexagons. The IST index is not fully illustrated for presentation reasons. As seen in the figure the sub-flows *bcdef*, *bcg* and *bc* are indexed in the second key of the IST index *bc*. The suffix tree from that key includes the suffixes of the mentioned sub-flows *def* and *g*. The root of the tree is pointing to the list with the trip ids $\{t1, t2, t3\}$, since the sub-flow *bc* is contained in all the trips of our example. Accordingly, the other nodes of the suffix tree contain the respected trip ids in their id lists.

Flow-Scan Query Method. By indexing the trips using the IST data structure, we make sure that no unnecessary trips will become candidates for the dominant flows result and that no information of the trips is lost. In order to query the desired dominant flows, the Flow-Scan process of reading the data from the IST data structure is divided into four steps, shown in Algorithm 1. The first step is the identification of the trips that happen inside the time window W (line 3). This step uses the auxiliary data structure where all the trips are stored is used. Once the trips inside the time window W are retrieved, the keys from the IST inverted index are selected (line 4). This step is important in order to avoid traversing all the data in the IST data structure, but only the elements that could give candidate flows for the result. The third step is to retrieve all the maximal sub-flows that are longer than the l_{min} and more frequent than the f_{min} from

the suffix trees of the keys (lines 5-7). Lastly, the fourth step is to score the retrieved sub-flows using the scoring function from the Definition 3.2 (lines 8-9) and return the k sub-flows with the highest scores.

Algorithm 1 Flow-Scan Algorithm

```
1: function QUERY(IST index, query parameters α, k, W)
2:     Flows ← ∅
3:     D_{T,W} ← FindTripsInWindow(IST, W);
4:     KEYS ← FindIndexKeys(IST, D_{T,W});
5:     for each key ∈ KEYS do
6:         F ← from key.SuffixTree find all maximal flows with
       more than f_min
7:         add all F in Flows
8:     for each s ∈ Flows do
9:         score(s)
       return max_k[Flows]
```

5 EXPERIMENTS

In this section, we report the experimental evaluation of the proposed method, especially for what concerns efficiency and scalability. We first describe the experimental setup, the baseline methods and the datasets used for the evaluation. Then, we describe each experiment, report and discuss the results.

5.1 Environment and Setup

Hardware and Implementation. Our experiments were evaluated on a machine with 24 cores 3.40GHz Intel(R) Core(TM) i7-6700 CPUs, with 16GB memory, using Ubuntu 18.04.4 LTS, and all algorithms are implemented in Java 8.

Compared Algorithms. In our experiments, we use a Naive baseline algorithm to evaluate the efficiency of the Flow-Scan algorithm proposed in this work. The baseline method, Naive, utilizes the structure of the road network to store a list of detections in each road edge e of the network. The list consists of tuples (t, c, p) representing a detection of a vehicle c at time t at the given road edge e. The last, p, is a pointer to the next data point (detection) of the same vehicle c within the same trip T, i.e. the two consequent detections occurred within t_{min}. In this way, the vehicle's trip can be recreated by traversing the vehicle's detections following the pointers p. During the query process, the algorithm scans all the road edges e for detections that occur inside the time window W and it constructs flows by traversing the detections using the pointers p. After identifying all flows, it calculates a score for each flow and returns the k flows with the highest score. The Naive method can handle the missing data from the detections since it uses the road network only to store the detections and not to extract the flows from it, as opposed to the PSSS method [3]. In the Naive method, the search of the flows is happening by following the pointers of the tuples and not following the road network structure.

Additionally with the baseline Naive, we compare the proposed method Flow-Scan with the PrefixSpan method described in [5, 8] and with the PSSS method described in [3]. Since the PrefixSpan and the PSSS methods identify the dominant flows based only on their frequency, we use $\alpha = 1$ for the Naive and Flow-Scan methods in the experiments that all four algorithms are present. Furthermore, since the PrefixSpan and the PSSS methods were proposed for applications that didn't use incomplete data, we use these algorithms only in the experiments with the synthetic datasets as described in the following sections.

Datasets. For the evaluation of the aforementioned methods, we use four different datasets [4], two including real-life data and two synthetic data. The first dataset, RM, is a real-life dataset collected in a period of a month from traffic detectors in an area of a Chinese city. The detectors were located in 6 intersections monitoring the traffic on 44 road edges. Each detector was collecting data every 1 second for all the road edges in its radius. In total, 2894174 detections were collected, from 337089 different vehicles. The second dataset, RD, includes the data from RM for one of the days in that month. The data from that day include 116268 detections from 44643 vehicles.

As already mentioned, these real-life data are incomplete and the PSSS method [3] is not suitable for identifying the dominant flows over them. In order to be able to apply the PSSS and the PrefixSpan [5, 8] algorithms and to experiment with the scalability of the proposed algorithm Flow-Scan we use two datasets, with synthetic data. The synthetic data COM were generated in the same road network as the real-life data RM and RD, with the difference that we included detectors in the 2 intersections where the real scenario was missing. Then we generated equally random trips over the road network. In total we generated 18910 detections from 7500 vehicles. In order to evaluate the scalability of the methods in bigger road networks, we generated the synthetic data GRID using the SUMO Simulation of Urban Mobility [7]. We randomly generated trips on a $10x10$ intersections grid road network (having 100 intersections and 360 road edges) using a utility from SUMO that equally generates trips over the road network. Then, running the simulation and using TraCI Traffic Control Interface library[1] we read the simulation data and collect the detections. The simulation collected data include 1806141 detections from 135618 different vehicles.

5.2 Results and Discussion

Following, the experimental analysis is reported. We show the performance of the methods described based on their building and querying times, and discuss the effect that the various parameters have on the running time of the algorithms. The building time for each algorithm depends on the nature of the algorithm. For all of them the building time includes the reading of the data into memory. For Naive and Flow-Scan it also includes the time for building their respective index. The query time is the time used for each algorithm in order to retrieve the dominant flows from the data or the index. For all algorithms this time includes also the scoring of each flow. For PSSS algorithm the time for creating the successor list *only* for the road edges used in the dominant flows detection is measured in the query time. Note that the experimental results reported are the ones we believe are representative and not the exhaustive set of experiments performed.

Dataset Size Scalability. For testing the scalability, we run the four algorithms, PrefixSpan, PSSS, Naive, Flow-Scan, using the two synthetic datasets COM and GRID for different number of detections and vehicles. All algorithms were run with $t_{min} = 200$ sec, $\alpha = 1, k = 1$, $l_{min} = 2$ and $f_{min} = 2$.

Figure 3 shows the scalability of the building and query times for the four algorithms by changing the number of vehicles in the COM dataset. As expected, the more vehicles there are in

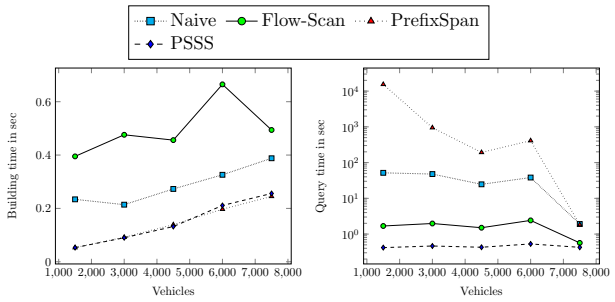

Figure 3: Running times for the COM dataset changing the number of vehicles.

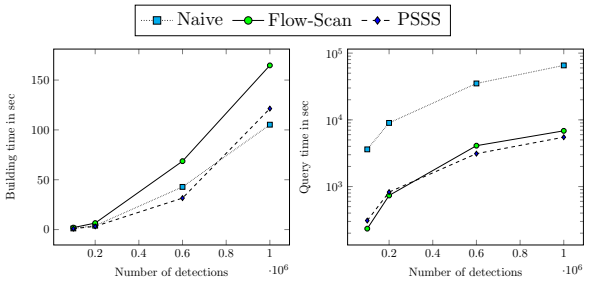

Figure 4: Running times for the GRID dataset changing the number of detections.

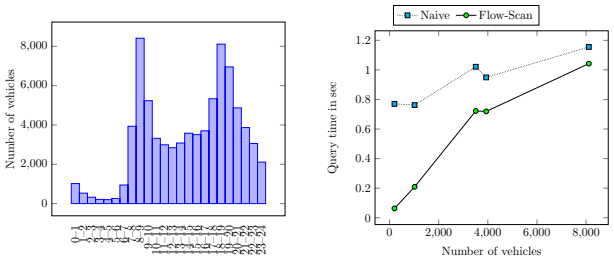

(a) Histogram of number of vehicles per hour.

(b) Query time for changing time window W.

Figure 5: Time window analysis for the RD dataset.

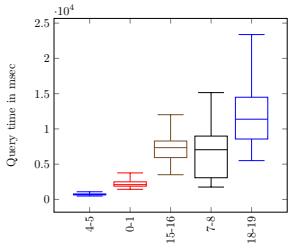

Figure 6: Query time for Flow-Scan method using the RM dataset.

the dataset, the more time the algorithms need for their building step. Method PrefixSpan and PSSS have the same performance on their building phase since they only read the data into memory in this step. On the other hand, the query time does not get affected by the number of the vehicles, excepting the PrefixSpan method that has to iterate multiple times through the vehicle trips to find the candidates for the result.

In Figure 4, the building and query times for the Naive, Flow-Scan and PSSS algorithms are shown by changing the number of detections in the GRID dataset. This dataset was too large for the PrefixSpan method and so we do not report running times for it. Similarly as the COM dataset, with the increase of the number of detections in the data, the building time of the methods is increased. For bigger scale of data, such as the GRID dataset, the building of the IST index is as efficient as the reading of the data into memory that the PSSS method is using, while in the query time the performance is also similar.

Value of Time Window W. The time window W is the query parameter that affects the query time. It is used to restricts the dominant flows in the result, so that they are happening during the time window period. Intuitively, when the time window is in a rush hour period of the day, a significant number of vehicles will travel in the road edges, more flows will become candidates for the result and so, more time will be necessary for the query process. Figure 5a shows a histogram with the number of vehicles per hour for the RD dataset. The peak rush hours are 08:00-09:00 and 18:00-19:00 and the hours with the least traffic are 01:00-06:00.

We run the Naive and the Flow-Scan algorithms for five different time windows that had different number of vehicles. In this experiment we don't use the PrefixSpan and PSSS algorithms since we use the real-life RD dataset that is incomplete. The rest of the parameters were $t_{min} = 200$ sec, $\alpha = 0.5, k = 10, l_{min} = 1$ and $f_{min} = 1$. Figure 5b shows the query times in respect to the number of vehicles that were in each time window. We can see that with more vehicles in the time window, the query time increases. Furthermore, Naive algorithm is affected more by the number of vehicles in the time window, while Flow-Scan algorithm can handle better the increase.

In addition, for validating our method Flow-Scan over one month of data, we run the algorithm for the same time windows for all the days of a month using the RM dataset. The number of vehicles for each hour for all the different days of the month follow the same trend as in Figure 5a. Figure 6 shows the query times for each time window for 30 days. As seen in the figure, the different traffic conditions in the different days do not affect the time windows with small number of vehicles, like the time windows of 04:00-05:00 and 00:00-01:00. As the number of vehicles increases in the time window, the query time differences also increase.

Value of Time Threshold t_{min}. The time threshold affects the indexing time because the higher it is, the more detections will be connected into a single trip. Figure 7 shows the running times for the Naive and Flow-Scan algorithms, run for the RD dataset. Again, the PrefixSpan and PSSS algorithms are not present because of the incomplete real-life dataset. We chose as time window W the period between 07:00-08:00 since this is the period with average number of vehicles. The rest of the parameters were $\alpha = 0.5, k = 10, l_{min} = 1$ and $f_{min} = 1$.

When the time threshold t_{min} is increased, the building time for the Naive index is not affected compared to the building time for the IST index. When the t_{min} is increased, as mentioned, more detections get connected into single trips and the trips grow in length. However, since the vehicle detections stay the same, we get less trips in total, and so the building of the IST index is decreased.

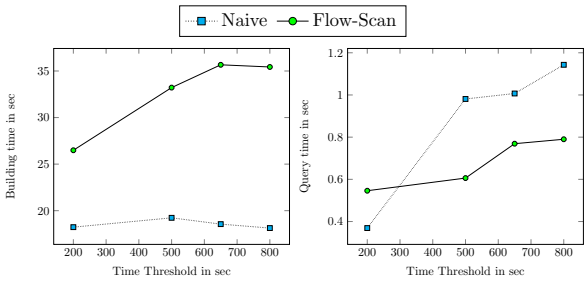

Figure 7: Running times for the RD dataset changing the t_{min} parameter.

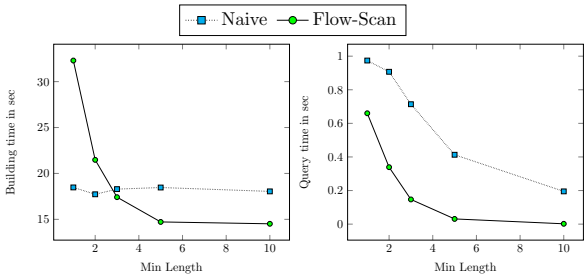

Figure 8: Running times for the RD dataset changing the l_{min} of the trips.

On the contrary, the query time the Naive algorithm gets more affected by the increase of the t_{min} since the trips become longer. The Naive query phase needs to iterate more times in the length of the trips than the Flow-Scan algorithm, and so the increase of the t_{min} increases the query time of Naive.

Value of Minimum Length l_{min}. The l_{min} of the trips controls the length of the flows that can be candidates as dominant flows and thus, indirectly can control how many trips can be considered from the dataset. If a flow is shorter than the l_{min} then it is ignored in the result. In addition, the l_{min} is the value that controls the length of the sub-flows stored as inverted index keys in the IST index. For evaluating how the value of the l_{min} is affecting the Naive and the Flow-Scan methods, we run the algorithms for the RD dataset, with $t_{min} = 500$ sec, $\alpha = 0.5, k = 10$, $f_{min} = 1$ and time window W = 07:00-08:00. As mentioned before, the PrefixSpan and PSSS algorithms are not included in this experiment because of the use of the real-life dataset.

Figure 8 shows the running times for the Naive and the Flow-Scan algorithms. When $l_{min} = 1$, all the flows and subflows are considered as candidates to be dominant, but when the l_{min} increases, the number of flows longer than the threshold decrease, thus reducing the candidate flows. This shows in the query time for both Naive and Flow-Scan algorithms. For both algorithms as the l_{min} is increasing, the query time is decreasing since less flows needs to be analysed. The IST index stores only the trips that have more than the l_{min}, and when the l_{min} is increasing, the index building time is decreasing. The Naive algorithm has more stable building time with the change of the l_{min} and that is because it does not check for l_{min} of the trips before indexing them. However, Naive needs more time for querying than the Flow-Scan, approximately 30% more time, since it keeps all trips and not only the ones longer than l_{min}.

Values of k, α and f_{min}. The parameters k, α and f_{min} affect which of the flows will be detected as the result dominant flows, but do not affect the running time of the algorithms. The parameter k does not affect the algorithms' running times, since the algorithms do not use any pruning or early stopping condition. Similarly, changing α and f_{min} affect only the scoring function of the flows and not the query process of the algorithms.

6 CONCLUSIONS

In this paper, we focused on the real-life scenario of identifying dominant traffic flows, which is crucial for traffic optimization techniques, such as avoiding traffic congestion on urban road networks. We introduced a scoring function that ranks the flows, proposed a simple data structure called IST, and proposed the Flow-Scan algorithm to identify the highest-ranking flows by utilizing the proposed IST index. Our experimental evaluation shows that the Flow-Scan method is efficient and scalable. It is equally efficient on the synthetic datasets with the state-of-the-art PSSS method while at the same time our method enables to overcome the limitations of the PSSS method that does not consider the length of a flow as an important factor and is incapable to handle missing values of the real-life data. Furthermore, although the Flow-Scan method uses more time to build the IST index compared to the Naive method, it outperforms the baseline in the query time and thus, it is a viable solutions for the large scale real-life urban road network scenario studied in this paper.

ABSTRACT

Driven by the exponential growth in data volume and complexity, and the increasing demand to extract concealed value from it, interactive data exploration (IDE) approaches have recently received a great amount of attention in both industry and academia. To achieve interactiveness, most existing active learning-based IDE systems operate on main-memory databases, which inherently limits the scalability of these IDE systems. In this paper, we propose a novel indexing mechanism, called *Uncertainty Estimation Index* (`UEI`), which supports the interactivity and scalability of the active learning-based IDE systems. `UEI` combines hierarchical in-memory indexing with columnar and inverted-indexing based secondary storage mechanism. It achieves scalability and efficiency through a dynamic estimation of the set of data that are most beneficial to the current exploration. By intelligently manage the in-memory cache, `UEI` enables active learning-based IDE systems to scale beyond the main memory restriction, while maintains the desired accuracy and convergency speed. We experimentally evaluated `UEI` using a state-of-the-art IDE system with two schemes, one incorporating `UEI`, and one utilizing a standard DBMS. We measure the efficiency of the proposed solution using a large real-world dataset placed on the secondary storage. Our experiments show that (1) `UEI` version outperforms the DBMS one by providing more than 50x runtime efficiency when the size of the dataset exceeds the main memory capacity, and (2) is capable of achieving sub-second interactive response time for data that is 100 times larger than the available memory while achieving the desired exploration accuracy and effectiveness.

1 INTRODUCTION

In recent years, as the data has grown rapidly in both complexity and volume, the traditional search methods relying on explicit keywords or queries can quickly lose their effectiveness. As reported in previous studies [15], it is often difficult for users to construct precise articulations that describe their interests. In such cases, traditional search methods usually fail to deliver satisfying results, and the user often needs to deal with results that are too big in size due to loose queries or keywords. Consequently, to obtain a satisfying result, users need to execute numerous ad-hoc queries with tightened conditionals to reduce the search space, which requires a considerable amount of time and human effort. Thus, novel *interactive data exploration* (IDE) techniques that aim to assist users in finding their intended items has generated a significant amount of interest in research communities [2, 7, 9, 10, 12, 13, 16].

One of the core features of these IDE systems is to employ *human-in-the-loop* (HIL) exploration processes to minimize the overall user effort and time in finding the relevant data items. Instead of providing inaccurate results with one generic predictive model (i.e., engine), by leveraging human-in-the-loop, a uniquely learned predictive model can be created rapidly for each individual user and task. To do so, a common solution to support effective human-in-the-loop operations is to leverage active learning techniques [20]—active learning refers to a set of machine learning approaches that aim to learn an accurate predictive model with minimum labeled data for regression and classification tasks. Clearly, the goal of active learning naturally aligns with the needs of many human-in-the-loop techniques as they seek to quickly and accurately deliver the results that the user needs with a personalized, predictive model.

In previous works, numerous active learning techniques [5, 8, 14, 20–22] have been proposed to boost the convergence of training a predictive model. Among these query strategies, *uncertainty sampling* is the most commonly used one because of its simplicity and efficiency, as pointed out in [20]. Uncertainty sampling trains each predictive model in an iterative fashion, wherein each iteration, it identifies the unlabeled items that are closest to the current decision boundary of the predictive model as these items are believed to be most *uncertain*. Uncertainty Sampling then solicits the user's label on the identified sample and utilizes it in the training of the predictive model.

Although uncertainty sampling is more efficient than alternative active learning methods, in order to find the most uncertain object, it still needs to perform an exhaustive search over the entire database. Therefore, in the case where the size of the data is larger than the main memory capacity, those data that resides on the secondary storage must be loaded into memory at each interation. Due to the limitation imposed by physical I/O of the secondary storages, it takes a significant amount of time for active learning techniques to scan datasets that are considerably larger than the main memory. This essentially makes it impossible for any active learning-based IDE system to explore datasets that are larger than the available memory. As pointed in [15], run time efficiency is critical for the IDE systems as any response time excesses 500ms will severely impact the user's engagement, and hence hinders the usability of the system. Moreover, as the exploration could occur on any subset of the attributes of the dataset, it is nearly impossible to apply any typical indexing in advance to support the exploration task over any arbitrary combination of the attributes.

In order to achieve interactiveness, existing uncertainty sampling-based IDE systems rely on main memory to cache the entire dataset. For datasets that are larger than the main memory, a subset of data objects will need to be sampled from the original dataset on secondary storage (e.g., [7]). While simple and intuitive, this approach could easily lead to very inaccurate results and a waste of user effort since the boundaries of the interesting data regions in the sampled space is likely to be different from the original space [9]. Moreover, small sets of relevant data regions may even be ignored in the resulting sample set.

To overcome this problem, we propose a novel indexing mechanism coined *Uncertainty Estimation Index* (UEI), to facilitate the interactivity and scalability of active learning-based IDE systems. To our knowledge, UEI is the first approach in extending the scalability of active learning-based IDE systems beyond the main memory capacity.

Instead of relying solely on the main memory to cache the whole dataset during the exploration, UEI enables caching in memory only the necessary subsets of the data that are needed by the current stage of the exploration. This is achieved through the combination of an effective estimation of the uncertainty of each data object and an efficient data storage mechanism. The essential observation that UEI is based on is that data objects often have additional information that can be used to infer their relationship with other objects, one of which is the *similarity* among data objects. Since the uncertainty essentially represents its distance to the current decision boundary in the high-dimensional data space, thus the uncertainty of an object x is strongly related to the uncertainty of the surrounding objects [14]. This observation allows UEI to informatively select the set of highly uncertain data objects to be loaded into memory before it is needed by the predictive model. Hence, the amount of memory needed to explore a dataset in real-time is significantly reduced.

To evaluate UEI, we employed a state-of-the-art data exploration system REQUEST [9], and compare the performance of UEI against MySQL, which is used by the existing interactive data exploration systems [7, 12]. Our results using a large real-world dataset, namely the Sloan Digital Sky Survey (SDSS) [1], show that UEI outperforms existing solutions by more than 50X in runtime efficiency when the size of the dataset goes beyond the main memory capacity. Furthermore, UEI is well capable of meeting the sub 500 millisecond interactive response time requirement for data that is at least 100 times larger than the main memory capacity, while achieving minimum impact on the convergence of the predictive model.

It should be noted that even though UEI is designed for the IDE systems, where response time and run time efficiency is critical, it can also be used in combination with any active learning-based human-in-the-loop (HIL) applications. Examples of such human-in-the-loop applications including but not limited to: record matching [3], entity resolution [18, 19], and facts checking [4].

2 BACKGROUND

In this section, we provide the necessary background of our `UEI`.

2.1 Active Learning

Active learning refers to a set of approaches that aim to learn an accurate model with minimum labeled data for regression and classification tasks. One key component of active learning is the *query strategy* that sequentially selects the most informative unlabeled sample (i.e., data object) from the entire database to be labeled by the user.

In previous works, a number of active learning techniques have been proposed to define the "informativenes" of samples [20], including: *Uncertainty Sampling* [14], *Query-By-Committee* [21], *Expected Model Change* [5], *Expected Error Reduction* [22], and *Expected Model Output Change* [8]. These techniques are often interchangeable, providing the applications the flexibility to choose the most appropriate query strategy that fits their needs. Among the query strategies, *Uncertainty Sampling* [14] is the most commonly used because of its simplicity and efficiency [20].

Uncertainty Sampling is a query strategy that can be used with any probability-based predictive model (e.g., Naive Bayes, SVM, etc.). The intuition of *Uncertainty Sampling* is that patterns with high uncertainty are hard to classify, and thus, if the labels of those patterns are obtained, they can boost the accuracy of the classification models. Particularly, in binary classification models (e.g., with class labels 0 and 1), the most uncertain example $\mathbf{x}$ is the one which can be assigned to either class label $z(\mathbf{x})$ with probability 0.5. Inspired by the idea of uncertainty, also known as *least confidence* (lc), [14] proposes a measurement of uncertainty for binary classification models:

$$u^{(lc)}(\mathbf{x}) = 1 - p(\hat{y}|\mathbf{x}) \tag{1}$$

where $u^{(lc)}(\mathbf{x})$ is the uncertainty score with the least confidence measurement of $\mathbf{x}$, and $\hat{y}$ is the predicted class label of the unlabeled $\mathbf{x}$. Accordingly, after measuring the uncertainty of each unlabeled sample, the unlabeled sample with highest uncertainty is selected:

$$\mathbf{x}^* = \text{argmax}_{\mathbf{x}} u(\mathbf{x}) \tag{2}$$

where $u(\mathbf{x})$ can be any other measurement of informativeness over the unlabeled sample $\mathbf{x}$.

Algorithm 1 Typical Workflow of Active Learning-based IDE

Require: The raw data set D; Batch Size B
Ensure: A set of results R
1: Labeled set $L \leftarrow \emptyset$
2: Unlabeled set $U \leftarrow D$
3: $M \leftarrow$ initialize query strategy
4: **while** user continues the exploration **do**
5: **for** $i = 1$ to B **do**
6: Choose one x from U using M
7: Solicit user's label on x
8: $L \leftarrow L \cup \{x\}$
9: $U \leftarrow U - \{x\}$
10: **end for**
11: $M \leftarrow$ trained with L to update M.
12: **end while**
13: Return the set of results R classified as positive by M.

2.2 Interactive Data Exploration

Active learning-based IDE systems can effectively find relevant items that are often undiscoverable using traditional search methods [7, 9, 10, 12]. In particular, active learning-based IDE systems do not require users to formulate any complex queries, nor does it need any form of description of the target items. The entire exploration can be done by answering simple binary (i.e., yes or no) questions. More importantly, active learning-based IDE systems can further be used to enhance traditional search results. For instance, they can be used to address the problem of having overwhelming results due to a broad query or search conditions.

As shown in Algorithm 1, a typical active learning-based IDE system works in the following steps: first it incorporates a query strategy (e.g., uncertainty sampling), which is used for selecting the example objects to be presented to the user for labeling (line 3). As long as the user is willing to label more examples (line 4), active learning-based IDE system will keep invoking the query strategy M to select a new example object x from D, and present it to the user to label it as *relevant* or *irrelevant* (lines 5-9). Once the amount of labeled samples received from the user reaches a sample batch size (denoted as B), which is a tunable parameter of the active learning-based IDE balancing the effectiveness and efficiency, then the classifier model employed by the query strategy will be updated according to the label assigned to x (line 11). In particular, the label assigned to x will be used for retraining the classifier model, which is an essential step towards selecting the object presented to the user in the next iteration. Once the iterative labeling process is completed, the obtained results will be presented to the user (line 13).

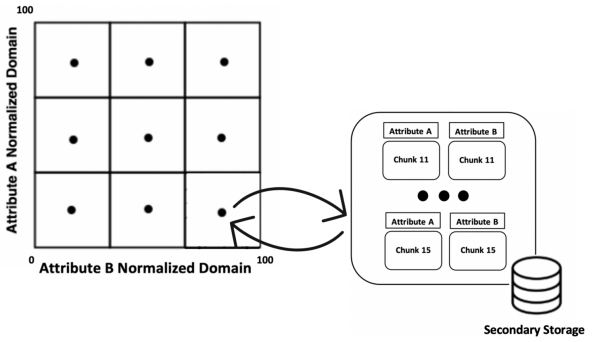

Figure 1: Illustrates UEI with a 2D data space, each grid represents a subspace, the dot in the center of each grid represents a symbolic point p. With chunks stored as separated files on the secondary storage.

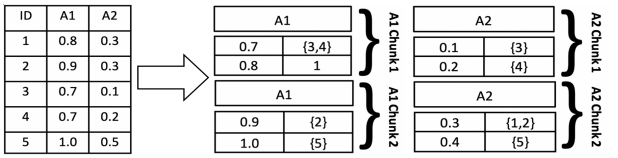

Figure 2: Before storing the data, UEI vertically decompose the data into an inverted index form, and then store them in separate chunks.

3 UNCERTAINTY ESTIMATION INDEX

Maintaining interactive response time for large datasets that are beyond the main memory capacity has always been one of the major challenges of active learning-based IDE systems. In tackling this problem, we focused our efforts on uncertainty sampling and proposed a novel index approach coined *Uncertainty Estimation Index* (UEI). Our UEI can be easily incorporated in any existing systems that leverage the uncertainty sampling and can be used in conjunction with any probabilistic-based classifiers as discussed in [14]. In the next section (Section 3.1) we provide the details of UEI's main component, and discuss how UEI leverages the inverted index-based data secondary storages to support scalable exploration. Following that, in Section 3.2, we provide a walk-through of a complete example to illustrate how a typical active learning-based IDE workflow (i.e., Algorithm 1) performs when enhanced with UEI.

3.1 UEI Components

A key observation underlying UEI is that data objects often have additional information that can be used to inference their relationship with other objects, one of which is the similarity (i.e., distance) between data objects [14]. In other words, the uncertainty value of an object x is strongly related to the uncertainty of the surrounding objects. For example, if x is located near to one of the current decision boundaries, then x would have higher uncertainty due to a mixed set of relevant and irrelevant neighbors. Such continuity between data points is also generally assumed in both supervised and semi-supervised learning algorithms where data points that are closer to each other are more likely to share a label [23]. More precisely, we observed that the uncertainty of a data object x can be approximated through its spatial relationships with the labeled data objects. UEI explores this spatial relationship to load into memory the set of highly uncertain data objects before they are needed by the query strategy.

Specifically, as illustrated in Figure 1, the main idea of UEI is to divide the exploration space D into equal-size subspaces (i.e., d-dimensional grids) g_i's of D ($g_i \in D$), and build a set of symbolic (virtual) index points $P = \{p_1, ...p_c\}$, such that each index point p_i represents a subspace g_i. In each iteration, UEI estimates the uncertainty of each subspace based on the uncertainty of its corresponding index point p, then loads only the data in the subspace that is predicted to be most uncertain into memory. Conceptually, UEI is based on the same principle as hash-based multidimensional indexing, such as the traditional grid file structures, which splits the space into a non-periodic grid where one or more cells of the grid refer to a small set of points. As opposed to a grid file, designed to efficiently reference a single value with multiple keys, UEI is designed to scale out the uncertainty sampling by estimating the distribution of the uncertainty of data objects through the set of symbolic index points.

To do so, UEI comprises five components: 1) an index set P of symbolic index points p_i; 2) a mapping method $m : p \longmapsto C$ that maps each index point p to a set of data chunk C; 3) a data cache U that caches a subset of uniformly sampled unlabeled data; 4) a set of labeled data L that contains all data that has been labeled by the user, and 5) the exploration dataset D stored in a fully inverted columnar format on a hard drive. The first four components reside in the main memory.

UEI divides the operation of exploration into two phases: an *Index Initialization* phase, and *Interactive Exploration* phase. The first phase only needs to be executed once per each new dataset. The second phase is specific to each exploration and discussed in the next section (Section 3.2).

Index Initialization Phase: As illustrated in Algorithm 2, to work with a new dataset, UEI first vertically (i.e., attribute-wise) decompose the whole data set and sort each dimension (i.e., attribute) based on the values in ascending order (lines 2 - 4). Since each dimension of a typical exploratory dataset (e.g., scientific, business analysis) can contain values of an arbitrary length, and one specific value for a dimension may appear multiple times, we compress the data by organizing it in a key-value fashion ($< key, \{values\} >$), where each value of the dimension would be used as a key and the ids of the corresponding objects as $values$ (as illustrated in Figure 2). Note that for each exploration task, UEI stores all needed data in one location, thus when exploring data that are distributed in multiple locations (e.g., tables, files), the data needs to be merged before being utilized in the exploration.

During the process of storing the data, UEI splits the distinct values of each dimension d into a set of equal-sized data chunks $C^d = \{c^d{}_i, ..., c^d{}_u\}$, where each chunk will be stored as a separate file on the disk, and the size of each chunk can be adjusted based on the size of the data and the available hardware resources (line 5). UEI also ensures that the values of each dimension are stored in a sequential order, meaning values stored in each subsequence chunk $c^d{}_{i+1}$ will be larger than the values that have been stored in $c^d{}_i$ for efficient lookup.

Once the data are partitioned and stored on the disk, UEI would start construct the set of symbolic index points P by divide the original data space D into a set of equilateral d-dimensional subspaces $G = \{g_i, ..., g_j\}$, where $|G| = |P|$, then for each subspace g_i, UEI constructs a symbolic index point p_i that represents g_i by using the coordinates of the "virtual" center point of g_i (lines 7-11). To ensure UEI can be deployed in resource restricted environments, the number of symbolic index point can be adjusted based on the size of the dataset and the available hardware resources.

In order to construct and load each subspace g_i into memory, UEI employed a hash-based mapping method m that records for

Algorithm 2 Typical Exploration Flow with UEI

25: **end while**
26: $T \leftarrow resultRetrieval(L)$
27: Return the set of interesting data objects T

each symbolic index point p_i, the set of chunks that are needed to construct g_i. As chunks are stored separately on the disk, this approach allows UEI to quickly identify the data that needs to be loaded. Since each data subspace g is stored as series of one-dimensional data chunks, to reconstruct each g when needed, UEI utilizes a hash table for efficiently merge of those data chunks. During the merge process, UEI iterates through each dimension and loads the corresponding chunks to the memory one at a time, and each entry in the chunk would be visited in a sequential manner. For each object ID that is recorded in a loaded data chunk c_i, the value associated with the ID will be inserted into the corresponding entry in the hash table. Once a chunk has been examined, UEI will release the memory space used to hold the data chunk and reuse the space for the subsequent chunk.

3.2 UEI in Action

In the previous section, we have discussed the components of UEI, as well as how the data are being stored and indexed, which essentially covers the first half (i.e., lines 1 - 11) of the exploration workflow, shown in Algorithm 2. In this section, we will discuss the interactive exploration phase of UEI, which illustrates how a typical active learning-based IDE task (i.e., Algorithm 1) can be performed when incorporating UEI (lines 12 - 27, Algorithm 2).

Interactive Exploration Phase: After the index set has been constructed, UEI begins the exploration by filling the unlabeled set U. Specifically, for the original data space D, UEI would uniformly sample a set of data from the underlying dataset (line 12), where the size of the samples γ can be adjusted based on the system hardware specs (e.g., available main memory size). As a result, a set of unlabeled objects U would be sampled and cached in the main memory. These unlabeled objects will then be used in the acquisition of the set of initial examples that will be labeled by the user to construct the initial predictive model M_0 for uncertainty estimation. Query strategy will randomly sample examples from U until the set of initial examples contains at least one positive example and one negative example (line 13).

In each iteration, UEI updates the uncertainty of all index points $p_i \in P$ based on the most recently trained predictive model M_{t-1} (line 17), which serves as the uncertainty estimator. Here the uncertainty of a data object is essentially equals to the probability of one object being either positive or negative class, with a value that equal to 50% being the most uncertain. Then, the index point p_i^* for which the current exploration model is most uncertain, will be chosen (line 18), such that:

$$p_i^* = \underset{p_i \in P}{\text{Argmax}}\, M_{t-1}(Y|p_i) \tag{3}$$

where Y = {0,1} is set of binary labels.

Based on the chosen p_i^*, UEI uses the mapping method m to identify and load (into the memory) all data chunks that correspond to the subspace g_i^*, which was represented by p_i^* (line 19). As mentioned earlier, the mapping method m is simply a hash table that maps a single index point p into a set of data chunks located on the disk. Later, the data of subspace g_i^* together with the unlabeled dataset U will be used by the query strategy (i.e., uncertainty sampling) in the selection of the example to be labeled in the current iteration (lines 20 - 22). To reduce memory usage, by default UEI kept only one uncertain data region g_i^* in the memory at any given time. Once the user is satisfied with the exploration result, the *resultRetrieval* method will be invoked to retrieve the exploration results and present them to the user (lines 26 - 27).

Tuning Interactive Exploration: In addition to the above typical exploration flow, UEI further allows the user to specify a response latency threshold σ that determines the latency between each exploration iteration (i.e., two subsequent examples). Using the user-specified σ, UEI determines whether or not to defer the swap between the current in-memory uncertain region g_i^* and the next uncertain region g_{i+1}^*, when g_i^* is no longer the most uncertain region.

In the case when an extremely low σ is specified that makes it impossible for the system to load the entire subspace g_i^* into main memory, UEI would start fetching the corresponding data chunks that associated with g_{i+1}^* (in the background) θ iterations before g_{i+1}^* is loaded into the memory. Here, θ is a tunable variable that can also be inferred based on the average loading time τ of data regions, and the configurable latency threshold σ, such that $\theta = \left\lceil \frac{\tau}{\sigma} \right\rceil$.

3.3 Time Complexity of UEI

Clearly, the time complexity of UEI is dominated by the interactive exploration phase. As discussed in Section 3.1, the initialization phase is done once for each dataset and the time required for UEI to prepare and store a dataset D on secondary storage is simply *linear* with respect to the number items n stored in D.

As discussed in Section 3.2, each iteration of the interactive exploration phase in UEI is dominated by the time taken to load the data from the chunks stored on the disk into the memory, which is *linear* with respect to the number of dimensions k and the number entries e stored in the loaded chunks. In contrast, each iteration in the current IDE approaches needs to load and examine all data items n ($e <<< n$).

Therefore, the time complexity of the UEI-enhanced data exploration generally is reduced from $O(kn)$ where n is the number of data objects to $O(ke)$ where e is the number entries associated

4 EXPERIMENTAL EVALUATION

In our experimental evaluation of our UEI, we use REQUEST [9], a state-of-the-art IDE system, with two schemes, one incorporating UEI, and one utilizing MySQL, used in the existing IDE systems [7, 12]. After describing our experimental setup in Section 4.1, we present the findings of our experimental evaluation in Section 4.2.

4.1 Experiment Setup

Dataset: We used 40 GB of real-world dataset from Sloan Digital Sky Survey (SDSS) [1] that consists of 10×10^6 tuples.

IDE System: In our experiments, we employed our REQUEST [9] with traditional uncertainty sampling and the *dual weighted k-nearest neighbor* (DWKNN) [11] as the uncertainty estimator.

Environment: We implemented both REQUEST and UEI with Java JRE 1.7. All the experiments were run on a machine with Intel Core i7 Processor, 32 GiB RAM and 2 TB of NVMe SSD. The fast NVMe SSD was used to eliminate any potential bottleneck due to physical IO limitation. All experiments reported are averages of 10 complete runs. We have considered five numerical attributes *rowc, colc, ra, dec* and *field* of the PhotoObjAll table.

Target Interest Regions: The exploration task characterizes user interests and eventually predicts the relevant regions by iteratively gathering user labeled tuples. We experimented with 1 region per each exploration task. In addition, we vary the single region complexity based on the data space coverage of the relevant regions. Specifically, we categorize relevant regions to small, medium and large. Small regions have cardinality with an average of 0.1% of the entire experimental dataset, medium regions a cardinality of 0.4%, and large regions a cardinality of 0.8%. Furthermore, the dimensionality of the target interest regions is the same as the dimensionality of the dataset across the entire experiment.

User Simulation For experiment evaluation purpose, we simulate the user behavior using the following method. For each target interest region, we simulate the user by executing the corresponding range query to collect the exact target set of relevant tuples. We rely on this "oracle" set to assign confidence score p to the tuples we extract in each iteration based on their location in the data space against the target region.

More specifically, for each relevant region, there is a region center and a set of region widths, one for each dimension. We define the *maximum relative distance d* of an example against the region center as:

$$d = max_{i=1..l}(|x_i - c_i|/w_i) \quad (4)$$

where l is the dimension number, $|\cdot|$ is the absolute value operator, x_i, c_i and w_i are the attribute value of the example, of the center and region width in each dimension.

Parameters: Table 1 summarizes the important settings in the experiments.

4.2 Experiment Results

In our experiments we aimed to test UEI's ability to provide an interactive response time for datasets that are beyond the size of main memory capacity, and to illustrate the benefit of searching only a small set of cached objects with UEI against performing an exhaustive search over the entire dataset. In our experiments, we stored 10 million data items with both UEI and MySQL, and restricted the memory footprint for both UEI and MySQL to be within 400MB, which is $\sim$ 1% of the entire dataset. Figures 3 to 6 illustrates the effectiveness and efficiency of our proposed UEI.

UEI Accuracy (Figures 3 to 5): Compared to MySQL, we have noticed that our proposed UEI requires more labeled examples in the early stage of the experiment (e.g., below 70% of accuracy). This is due to the fact that in the early stage, the classifier does not have enough training samples to learn an accurate uncertainty estimator (i.e., DWKNN classifier) that captures precisely the user's interesting regions. This causes the predictive model to select less informative examples to be labeled by the user. Since UEI uses uncertainty as the criteria for both the example selection and the loading of data regions (i.e., subspaces), therefore the negative effect of an inaccurate classifier has been magnified.

However, as the accuracy of the uncertainty estimator improves with more labeled examples, we observed a significant boost in performance of UEI in the later stages (e.g., above 80% accuracy) of the exploration. This is expected as the the predictive model gets more and more accurate with respect to the decision boundaries, and thus can estimate more accurate uncertainties. Since UEI rely on the uncertainty estimation for both the query strategy and cache management, therefore, it benefits more noticeably than the MySQL, which only rely on uncertainty estimation for query strategy.

UEI Response time (Figure 6): Finally, we have measured the response time for both UEI and MySQL based schemes. As shown in Figure 6, UEI achieves 50*x* faster response time than MySQL, and ensures the sub-second interactive response time across all data region sizes. Note the response time remains the same across all three target interest regions sizes, which is as expected because the runtime complexity of the uncertainty sampling-based systems only depends on the size of the dataset and not the size of the target interest regions.

From the experiments, it is clear that due to the fact that uncertainty sampling requires an exhaustive search over the entire data spare, thus the physical bandwidth of the secondary storage has become the major bottleneck that severely limits the scalability of active learning-based IDE systems.

Even though in our experiments, we have used NVMe based SSD with I/O throughput of around 3.4GB/s, the uncertainty sampling still takes over 12 seconds to complete the exhaustive search in each iteration. Therefore, it is still impossible to explore datasets that exceed the main memory capacity without UEI.

5 RELATED WORK

Traditionally, indexing has been the core technique for optimizing response time in database systems. Recently, main-memory indexing and specialized access methods have been proposed to support domain-specific query processing and analytics (e.g., [6, 17]). UEI is based on similar principles as these specialized access methods. However, UEI, to the best of our knowledge, is the first domain-specific access method with in-memory and disk components that support interactivity and scalability of active learning-based IDE systems.

The active learning-based IDE systems that can leverage our proposed UEI for better scalability includes *REQUEST* [9], the first active learning-based IDE system, and the two more recently proposed systems, *Dual-Space Model* [12] and *ExNav* [10]. REQUEST utilizes a two stages approach; a data reduction stage aims to selectively reduce the search space while keeping all relevant data regions, and a query selection stage that utilizes an active learning-based predictive model to iteratively improve the accuracy of the constructed exploratory query through interactions with the user. Dual-Space Model uses a new uncertainty sampling-based predictive model and a new dual-space pruning technique that focuses solely on exploration tasks with a single relevant region. It also optimizes these tasks for faster model convergence. ExNav is the first uncertainty sampling-based IDE system that specializes in exploring a variety of unstructured data sets by leveraging the corresponding data embedding methods for each unstructured data type [10].

In addition to the active learning-based IDE systems, UEI can also be utilized in other active learning-based *Human-in-the-loop* (HIL) systems. For example, in [18], the authors have proposed an active learning-based HIL system, called SystemER, for learning Entity Resolution models through user interactions. Another example of an active learning-based HIL application is fact-checking. In [4], the author has proposed an effective active learning-based HIL system for identifying various types of potentially misleading or false information for news contents. Most recently, [19] has proposed to use active learning for learning the implicit structured representations of entity names, which can be useful for many entity-related tasks such as entity normalization and variant generation. To facilitate the process of learning such structured representations, a user-friendly interface called PARTNER has been designed to enhance the user's interaction experience.

6 CONCLUSION

In this paper, we present the *Uncertainty Estimation Index* (UEI), the first indexing mechanism that enables active learning-based IDE systems to explore datasets that exceed the main memory capacity. Instead of requiring all data to be loaded into the main memory as in existing active learning-based IDE systems for sub-second respond times, UEI enables the scalability by dynamically identify and caching the set of objects that are most uncertain to the current stage of the exploration. It achieves this by maintaining a small in-memory index that estimates the aggregated uncertainty value of the data items in the entire data subspaces. UEI also employees columnar-based secondary storage and combines it with an inverted index to support efficient loading of the necessary data items at each iteration.

Our experimental evaluation using real-world data show that a state-of-the-art IDE systems using UEI greatly outperforms a DBMS-based version of the same IDE system by provide more than 50x runtime efficiency when the size of the dataset exceed the main memory capacity, and is capable of achieving sub-second response time for data that is 100 times larger than the available memory while achieving the desired exploration accuracy and effectiveness. In conclusions, UEI can be used not only with existing active learning-based IDE but with other active learning-based Human-in-the-loop systems as well to achieve significantly higher scalability by removing the main memory restriction.

ABSTRACT

Order dependencies (ODs) capture relationships between ordered domains of attributes. Approximate ODs (AODs) capture such relationships even when there exist exceptions in the data. During automated discovery of dependencies, *validation* is the process of verifying whether a dependency holds. We present an algorithm for validating AODs with significantly improved runtime performance over existing methods, and prove that it is *minimal* and has *optimal* runtime. By replacing the validation step in a recent algorithm for AOD discovery with ours, we achieve orders-of-magnitude improvements in performance.

1 INTRODUCTION

1.1 Motivation

Functional dependencies (FDs) specify that the values of given attributes *functionally determine* the value of a target attribute. *Order dependencies* extend FDs to state that, additionally, the *order* of tuples with respect to the values from the domains of given attributes determines the *order* of the values from the domain of the target attribute. Table 1 shows a dataset with employee salaries. In this table, the OD that sal *orders* taxGrp holds. If one sorts the table by sal, it is sorted by taxGrp as well.

An OD implies the corresponding FD; e.g., that sal orders taxGrp implies that sal *functionally determines* taxGrp. *Order compatibility* (OC) captures the *co-ordering* aspect of an OD *without* the corresponding FD. Two lists of attributes are *order compatible* if there exists an arrangement for the tuples in the table in which the tuples are sorted according to both. Any OD can thus be equivalently represented by a pair of an OC and an FD [13]. In Table 1, that taxGrp is *order compatible* with sal holds. Note that taxGrp does *not* order sal, as an FD does not hold.

There has been recent work to automate the *discovery* of ODs from data [1, 4, 6, 10, 11]. In practice, however, constraints rarely hold *perfectly* in the data. Real data are dirty, containing wrong and inconsistent values that may violate semantically valid dependencies. This motivates the need for discovering *approximate* ODs (AODs), ODs that hold in the data but with *exceptions*. Discovered ODs deemed semantically valid can be used for data cleaning, to detect erroneous tuples, where measures are then taken to repair the errors [8]. AODs are useful even when the data are not dirty, as there can be exceptions to general rules. AODs help avoid overfitting by discovering more general dependencies.

In Table 1, tax is a fixed percentage of salary in each tax group; i.e., one, three, or eight percent. However, perc includes a concatenated zero in some rows due to data entry errors (e.g., 10% instead of 1% in t_1). Because of this, the OC that salary is order compatible with tax does *not* hold, even though this OC is intended. Similarly, the FD that pos, exp functionally determines sal does *not* hold, due to the exception of tuples t_6 and t_7, two employees with the same position and years of experience but having different salaries. With approximate ODs, we can still discover such concise and meaningful rules in these instances.

Table 1: Employee salaries

#	pos	exp	sal	taxGrp	perc	tax	bonus
t_1	sec	1	20K	A	10%	2K	1K
t_2	sec	3	25K	A	10%	2.5K	1K
t_3	dev	1	30K	A	1%	0.3K	3K
t_4	sec	5	40K	B	30%	12K	2K
t_5	dev	3	50K	B	3%	1.5K	4K
t_6	dev	5	55K	B	30%	16.5K	4K
t_7	dev	5	60K	B	3%	1.8K	4K
t_8	dev	-1	90K	C	8%	7.2K	7K
t_9	dir	8	200K	C	8%	16K	10K

Approximate ODs were introduced in [10]. Their definition of AODs, as is ours herein, is based on the concept of "tuple removal." Given a table and an OD, a *removal set* is a set of tuples which, if removed from the table, results in the OD holding. A *minimal* removal set is one with the smallest cardinality. An *approximation factor* can be defined with respect to a table and an OD, as the ratio of the size of a minimal removal set over the size of the table. For instance, for Table 1 and the OC that pos, exp is order compatible with pos, sal, the minimal removal set and the approximation factor are $\{t_8\}$ and $1/9 \approx 0.11$, respectively.

Given a table $\mathbf{r}$ and an approximation threshold $0 \leq \epsilon \leq 1$, the *discovery problem* for AODs is to find the complete set of minimal *valid* AODs in $\mathbf{r}$ w.r.t. ϵ. Exact ODs are a special case of AODs with an approximation factor of zero. Given a table $\mathbf{r}$, an OD φ, and a threshold ϵ, the problem of *validating* the candidate OD as an AOD involves verifying whether the approximation factor of φ, denoted by $e(\varphi)$, is less than or equal to ϵ.

1.2 Contributions

The extension for AOD discovery in [10, 11], however, is impractical due to its performance. While the approximate FD component can be validated in linear time [3, 10], to validate the approximate OC (AOC) component in the search, they iteratively remove the tuple—or one of the tuples, in the case of a tie—that causes the largest number of violations. This has two weaknesses: the runtime is quadratic in the number of tuples, and it is not guaranteed to find a minimal removal set.

That it is quadratic makes it prohibitively expensive to run on larger datasets. (The validation step for a candidate exact OD has a linear runtime in the number of tuples.) So while the OD discovery algorithm in [10, 11] is shown to scale to datasets with millions of tuples, it is infeasible to run their adapted AOC discovery algorithm over even moderately sized datasets. During

benchmarking, we found in some discovery runs that more than 99% of the running time is spent on validating AOC candidates.

That it deliberately does not guarantee finding a minimal removal set means that the algorithm may overestimate the approximation factor of an AOC candidate. Thus, *true* AOCs with respect to the approximation threshold can be eliminated (while the exact OD discovery algorithm is complete).

In this paper, we resolve this major bottleneck in AOD discovery via an algorithm with optimal runtime and guaranteed minimal removal set for validating AOC candidates. This brings performance of AOD discovery on par with that of OD discovery, while making the AOD discovery complete.

The paper is structured as follows, with the following key contributions. In Sec. 2, we provide background and discuss related work. In Sec. 3.1, we illustrate the established OD and AOD discovery framework—which we then adapt herein—and, in Sec. 3.2, the *iterative validation algorithm* [10, 11] it employs. In Sec. 3.3, we contribute a minimal and optimal validation algorithm based on longest increasing subsequences that decreases the runtime from quadratic to log-linear. In Sec. 4, we present our experimental results, with the following contributions. We demonstrate that AOD discovery using our validation algorithm scales to datasets with millions of tuples and tens of attributes (Exp-1 and Exp-2). We compare our adapted AOC discovery against the previous approach and demonstrate that ours is orders of magnitude faster (Exp-3). As discovering AODs enables the application of pruning rules earlier than for discovering ODs, AOD discovery can be just as efficient, if not more so. Our AOD discovery algorithm gains up to 76% improvement in runtime compared against the (exact) OD discovery algorithm (Exp-5). Given our AOD discovery algorithm is complete, we discover more AODs, and *semantically more general* AODs (thus, of higher quality). We show that we find more AODs, both due to our better scalability and the minimality of our removal sets (Exp-4 and Exp-6). Finally, in Section 5, we conclude with suggestions for future work.

2 PRELIMINARIES AND RELATED WORK

2.1 Definitions and Notation

$\mathbf{R}$ denotes a relational schema, $\mathbf{r}$ represents a table instance, and s and t denote tuples. A and B denote individual attributes and $\mathcal{X}$ and $\mathcal{Y}$ *sets* of attributes. *Lists* of attributes are presented using $\mathbf{X}$ and $\mathbf{Y}$; [] denotes the empty list and $[A \mid \mathbf{T}]$ denotes a list with *head* attribute A and *tail* list $\mathbf{T}$. Tuples t_A and $t_{\mathcal{X}}$ denote the projections of tuple t on A and $\mathcal{X}$, respectively. Wherever a set is expected but a list appears, the list is cast to a set; e.g., $t_{\mathbf{X}}$ is equivalent to $t_{\mathcal{X}}$. $\mathbf{X}'$ represents an arbitrary permutation of the values of a list $\mathbf{X}$ or set $\mathcal{X}$.

Definition 2.1. (nested order) Let $\mathbf{X}$ be a list of attributes where $\mathcal{X} \in \mathbf{R}$. Given two tuples, s and t, $s \preceq_{\mathbf{X}} t$ *iff*

- $\mathbf{X} = [\,]$; *or*
- $\mathbf{X} = [A \mid \mathbf{T}]$ and $s_A < t_A$; or
- $\mathbf{X} = [A \mid \mathbf{T}]$, $s_A = t_A$, and $s \preceq_{\mathbf{T}} t$.

Let $s \prec_{\mathbf{X}} t$ *iff* $s \preceq_{\mathbf{X}} t$ but $t \not\preceq_{\mathbf{X}} s$.

Next, we define order dependencies [1, 4, 6, 10, 11, 13].

Definition 2.2. (order dependency) Let $\mathbf{X}$ and $\mathbf{Y}$ be lists of attributes where $\mathcal{X}, \mathcal{Y} \subseteq \mathbf{R}$. $\mathbf{X} \mapsto \mathbf{Y}$ denotes an *order dependency*, read as $\mathbf{X}$ *orders* $\mathbf{Y}$. Table $\mathbf{r}$ satisfies $\mathbf{X} \mapsto \mathbf{Y}$ ($\mathbf{r} \models \mathbf{X} \mapsto \mathbf{Y}$) iff, for all $s, t \in \mathbf{r}$, $s \preceq_{\mathbf{X}} t$ implies $s \preceq_{\mathbf{Y}} t$. $\mathbf{X}$ and $\mathbf{Y}$ are *order equivalent* (denoted as $\mathbf{X} \leftrightarrow \mathbf{Y}$), iff $\mathbf{X} \mapsto \mathbf{Y}$ and $\mathbf{Y} \mapsto \mathbf{X}$.

Definition 2.3. (order compatibility) Let $\mathbf{X}$ and $\mathbf{Y}$ be lists of attributes where $\mathcal{X}, \mathcal{Y} \subseteq \mathbf{R}$. $\mathbf{X}$ and $\mathbf{Y}$ are *order compatible*, denoted as $\mathbf{X} \sim \mathbf{Y}$, iff $\mathbf{XY} \leftrightarrow \mathbf{YX}$.

The order dependency $\mathbf{X} \mapsto \mathbf{Y}$ means that $\mathbf{Y}$'s values are monotonically non-decreasing with respect to $\mathbf{X}$'s values. Therefore, if one orders the tuples by $\mathbf{X}$, they are also ordered by $\mathbf{Y}$. The order compatibility (OC) $\mathbf{X} \sim \mathbf{Y}$ means that there exists a total order of the tuples in which they are ordered according to both $\mathbf{X}$ and $\mathbf{Y}$.

Example 2.4. In Table 1, the OD sal $\mapsto$ taxGrp holds. The OC taxGrp $\sim$ sal holds, even though the OD taxGrp $\mapsto$ sal does not.

ODs have a strong correspondence with OCs and FDs. An OD $\mathbf{X} \mapsto \mathbf{Y}$ holds *iff* $\mathbf{X} \sim \mathbf{Y}$ (OC) and $\mathcal{X} \rightarrow \mathcal{Y}$ (FD) hold. This gives two sources of violations for ODs: *swap*s and *split*s [13].

Definition 2.5. (swap) A *swap* with respect to OC $\mathbf{X} \sim \mathbf{Y}$ is a pair of tuples s and t such that $s \prec_{\mathbf{X}} t$ but $t \prec_{\mathbf{Y}} s$.

Definition 2.6. (split) A *split* with respect to FD $\mathcal{X} \rightarrow \mathcal{Y}$ is a pair of tuples s and t such that $s_{\mathcal{X}} = t_{\mathcal{X}}$ but $s_{\mathcal{Y}} \neq t_{\mathcal{Y}}$

Example 2.7. In Table 1, given the OD pos, exp $\mapsto$ pos, sal, tuples t_7 and t_8 constitute a swap (the OC pos, exp $\sim$ pos, sal), and tuples t_6 and t_7 constitute a split (the FD pos, exp $\rightarrow$ pos, sal).

Definition 2.8. tuples s and t are *equivalent* w.r.t. set of attributes $\mathcal{X}$ *iff* $s_{\mathcal{X}} = t_{\mathcal{X}}$. An attribute set $\mathcal{X}$ partitions tuples into *equivalence classes* [3]. The *equivalence class* of tuple $t \in \mathbf{r}$ w.r.t. $\mathcal{X}$ is denoted by $\mathcal{E}(t_{\mathcal{X}})$; i.e., $\mathcal{E}(t_{\mathcal{X}}) = \{s \in \mathbf{r} \mid s_{\mathcal{X}} = t_{\mathcal{X}}\}$. Given a set of attributes $\mathcal{X}$, a *partition* of the table with respect to $\mathcal{X}$ is the set of all equivalence classes; i.e., $\Pi_{\mathcal{X}} = \{\mathcal{E}(t_{\mathcal{X}}) \mid t \in \mathbf{r}\}$.

Example 2.9. In Table 1, $\mathcal{E}(t_{1\{\text{pos}\}}) = \mathcal{E}(t_{2\{\text{pos}\}}) = \mathcal{E}(t_{4\{\text{pos}\}}) = \{t_1, t_2, t_4\}$, and $\Pi_{\text{pos}} = \{\{t_1, t_2, t_4\}, \{t_3, t_5, t_6, t_7, t_8\}, \{t_9\}\}$.

2.2 A Canonical Mapping

A natural representation of ODs relies on lists of attributes, as in the ORDER BY statement in SQL, where the order of attributes in the list matters; e.g., the OD pos, sal $\mapsto$ pos, exp is different than the OD pos, sal $\mapsto$ exp, pos. This is unlike FDs, where the order of attributes does not matter, as with the GROUP BY statement in SQL. Working within this list-based representation, however, has led to discovery frameworks with factorial worst-case runtimes in the number of attributes [6]. Fortunately, lists are *not* inherently necessary to express ODs. In [10, 11], the authors rely on a polynomial mapping of list-based ODs into a logically *equivalent* collection of set-based *canonical* ODs to devise a discovery framework with exponential worst-case runtime in the number of attributes and linear in the number of tuples.

Definition 2.10. (canonical order compatibility) Given a set of attributes $\mathcal{X}$, $\mathbf{X}'A \sim \mathbf{X}'B$ is the OC that states that attributes A and B are *order compatible* within each equivalence class of $\mathcal{X}$. We write this as $\mathcal{X}$: A $\sim$ B in the canonical notation, factoring out the common prefix, and refer to this as a *canonical* OC.

Definition 2.11. (order functional dependency) Given a set of attributes $\mathcal{X}$, the FD that states that an attribute A is *constant* within each equivalence class of $\mathcal{X}$ is equivalent to the list-based OD $\mathbf{X}' \mapsto \mathbf{X}'A$. We write this as $\mathcal{X}$: [] $\mapsto$ A in the canonical notation, and refer to this as an *order functional dependency* (OFD).

Given a canonical OC of $\mathcal{X}$: A $\sim$ B or an OFD of $\mathcal{X}$: [] $\mapsto$ A, the set $\mathcal{X}$ is referred to as the *context* of the respective canonical OC or OFD. Intuitively, the context is the common prefix on the left- and right-side of the corresponding list-based OC or OD.

Canonical OCs and OFDs constitute the canonical ODs; i.e., OD ≡ OC + OFD. The OD of $\mathbf{X}'A \mapsto \mathbf{X}'B$ is logically equivalent to the canonical OC of $\mathcal{X}$: A ∼ B and OFD of $\mathcal{X}$A: [] ↦ B. This is $\mathcal{X}$: A ↦ B written in the canonical form.

Example 2.12. In Table 1, sal and bonus are order compatible w.r.t. the context pos; i.e., {pos}: sal ∼ bonus. In the same table, bonus is constant w.r.t. the context pos, sal; i.e., {pos, sal}: [] ↦ bonus. Therefore, sal orders bonus w.r.t. the context pos; i.e., {pos}: sal ↦ bonus.

This mapping generalizes: an OD $\mathbf{X} \mapsto \mathbf{Y}$ holds *iff* $\mathbf{X} \mapsto \mathbf{XY}$ *and* $\mathbf{X} \sim \mathbf{Y}$. These can be encoded into an equivalent set of canonical OFDs and OCs as follows. In the context of $\mathcal{X}$, all attributes in $\mathcal{Y}$ must be constants. In the context of all prefixes of **X** and of **Y**, the trailing attributes must be order compatible:

$$\mathbf{R} \models \mathbf{X} \mapsto \mathbf{XY} \textit{ iff } \forall A \in \mathbf{Y}.\ \mathbf{R} \models \mathcal{X}\text{: } [] \mapsto A \text{ and}$$

$$\mathbf{R} \models \mathbf{X} \sim \mathbf{Y} \textit{ iff } \forall i, j.\ \mathbf{R} \models [X_1, \ldots, X_{i-1}][Y_1, \ldots, Y_{j-1}]\text{: } X_i \sim Y_j.$$

Thus, list-based ODs can be polynomially *mapped* to a set of *equivalent* canonical ODs; i.e., canonical OCs and OFDs [10, 11]. In this work, we refer to canonical OCs simply as OCs.

Example 2.13. The OD [A, B] ↦ [C, D] is equivalent to the following canonical ODs: {A, B}: [] ↦ C, {A, B}: [] ↦ D, {}: A ∼ C, {A}: B ∼ C, {C}: A ∼ D, and {A, C}: B ∼ D.

While various algorithms have been proposed for discovering ODs, most are not *complete*. The algorithm described in [6] relies on the list-based definition and employs aggressive pruning rules to compensate for its factorial time complexity, but which make it deliberately incomplete. The authors in [4] claim completeness but their algorithm misses ODs in which the same attributes are repeated on the left- and right-hand side. A similar completeness claim has been made in [1], which was shown to be incorrect in [12]. The set-based OD discovery algorithm proposed in [10] does offer a sound and complete discovery of ODs. Thus, we build our algorithm atop the framework introduced in [10].

2.3 Definition of Approximate ODs

We refer to canonical AOCs and approximate OFDs (AOFDs) collectively as AODs. We define AODs based on the fewest tuples that must be removed from a table for an OD to hold. This definition was used for AODs in [10]; their AOC validation step (for the only currently existing AOD discovery algorithm) has a quadratic runtime. For AOFDs, validation takes linear time [3].

Definition 2.14. Given a table **r** and an OD φ, a set of tuples **s** is a *removal set* w.r.t. φ *iff* $\mathbf{r} \setminus \mathbf{s} \models \varphi$. Let $|\mathbf{r}|$ denote the *cardinality* of **r**, the number of tuples in **r**. A removal set **s** is a *minimal* removal set *iff* it has the smallest cardinality over all removal sets; i.e., $|\mathbf{s}| = \min(\{|\mathbf{s}| \mid \mathbf{s} \subseteq \mathbf{r},\ \mathbf{r} \setminus \mathbf{s} \models \varphi\})$. Given **s**, the *approximation factor* $e(\varphi)$ is defined as $|\mathbf{s}|/|\mathbf{r}|$.

Example 2.15. Consider Table 1 and the OC of sal ∼ tax. Here, $\mathbf{s} = \{t_1, t_2, t_4, t_6\}$ and $e(\text{sal} \sim \text{tax}) = 4/9 \approx 0.44$, as $\mathbf{r} \setminus \mathbf{s} = \{t_3, t_5, t_7, t_8, t_9\}$ does not contain any swaps with respect to sal ∼ tax and no smaller set $\mathbf{s}'$ exists such that $\mathbf{r} \setminus \mathbf{s}' \models$ sal ∼ tax.

Given a table **r** and an approximation threshold ϵ, $0 \leq \epsilon \leq 1$, the problem of discovering AODs involves finding all minimal (non-redundant that follow from others) ODs φ such that $e(\varphi) \leq \epsilon$. In this work, we focus on the problem of validating AODs; i.e., verifying whether the approximation factor of a given AOD is less than or equal to a provided threshold. We present an optimal algorithm for doing so and incorporate it into an existing OD discovery framework.

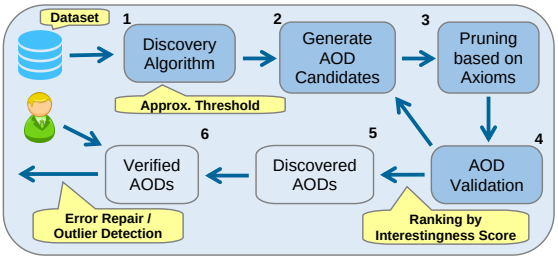

Figure 1: System framework.

As discussed in Sec. 2.2, OCs and OFDs constitute canonical ODs; i.e., OD ≡ OC + OFD. There already exists an efficient linear-time algorithm for validating AOFDs, as described in [3]. In this work, we present an optimal validation algorithm for AOCs. Note that when discovering *approximate* OCs and OFDs given an approximation threshold ϵ, AOD ≡ AOC + AOFD does not necessarily hold. If AOC $\mathcal{X}$: A ∼ B and AOFD $\mathcal{X}$A: [] ↦ B hold with approximation factors $e_1, e_2 \leq \epsilon$, respectively, it is not guaranteed for the corresponding AOD of $\mathcal{X}$: A ↦ B to also hold with respect to ϵ. As to be discussed in Sec. 3.3, however, our validation algorithm can easily be extended to validate list-based approximate ODs as well.

3 DISCOVERING APPROXIMATE OD'S

In Sec. 3.1, we describe our framework to discover set-based canonical AODs. In Sec. 3.2, we describe the iterative validation algorithm proposed in [10, 11], analyze its runtime, and provide an example of it failing to find a minimal removal set and thus overestimating the number of tuples that must be removed. In Sec. 3.3, we present our efficient validation algorithm, based on the longest increasing subsequence (LIS) problem, analyze its runtime, and prove its minimality and optimality.

3.1 Discovery Framework

The algorithm starts the search from singleton sets of attributes and proceeds to traverse the set-based attribute lattice in a level-wise manner [10, 11]. At each level, and when processing the attribute set $\mathcal{X}$, the algorithm verifies AOCs of the form $\mathcal{X} \setminus \{A, B\}$: A ∼ B for which A, B ∈ $\mathcal{X}$ and A ≠ B, and AOFDs of the form $\mathcal{X} \setminus \{A\}$: [] ↦ A for which A ∈ $\mathcal{X}$.

Figure 1 illustrates the framework. Candidate AODs are generated based on the attribute sets at the current level of the lattice. Using the dependencies found in previous levels of the lattice, these candidates are then pruned by axioms to avoid redundant dependencies that follow from already discovered ones [10]. Our algorithm validates whether each candidate dependency holds approximately, given the approximation threshold as input. Valid AODs are then scored and ranked, using the measure of interestingness introduced in [10]. These discovered AODs can then be manually verified by domain experts, to be then used for tasks such as error repair or outlier detection, which is an easier task than manual specification.

3.2 The Iterative Validation Algorithm

We first discuss the algorithm described in [10, 11] to validate an AOC given a threshold ϵ. To validate an AOC, the authors compute a removal set **s** by iteratively removing a tuple with the largest number of swaps, which does not guarantee to produce the minimal removal set. This is repeated until either the OC

Algorithm 1 Approx-OC-iterative

Input: Table $\mathbf{r}$, OC $\mathcal{X}$: A ∼ B, and approximation threshold ϵ.
Output: Approximation factor e and removal set $\mathbf{s}$, or "INVALID"

```
1:  s = {}
2:  for all E ∈ Π_X do
3:      t = order E by [A ASC, B ASC]
4:      t_swapCnt = countInversions(t_B)
5:      order t by swapCnt ASC
6:      while t is not empty do
7:          t = t.dropLast()
8:          if t_swapCnt == 0 then break
9:          for all s ∈ t do
10:             if s_A,B and t_A,B are swapped then s_swapCnt −= 1
11:         end for
12:         order t by swapCnt ASC
13:         add t to s
14:         if |s| > ε|r| then return "INVALID"
15:     end while
16: end for
17: return |s|/|r|, s
```

holds or the number of removed tuples crosses the threshold $\epsilon|\mathbf{r}|$, in which case the AOC candidate is considered invalid. Note that after removing each tuple, the number of swaps for the remaining tuples must be updated.

Algorithm 1 validates a candidate using the iterative approach. The steps in Lines 3 to 15 are repeated on tuples within each equivalence class with respect to the context. Line 4 uses a variant of merge sort to count the number of *inversions* in the projection of sorted tuples over B, which is equivalent to the number of swaps for each tuple. Line 7 removes a tuple with the most swaps and Lines 9 to 11 update the number of swaps for the remaining tuples. Line 14 exits if the approximation threshold is crossed.

Example 3.1. Consider Table 1 and the OC sal ∼ tax. Tuple t_7 has swaps with tuples t_1, t_2, t_4, and t_6, which is more than any tuple in the table, and is thus removed. In following steps, tuples t_5, t_3, t_6, and t_4 are removed. Therefore, $\mathbf{s} = \{t_3, t_4, t_5, t_6, t_7\}$ is reported as a removal set for this AOC, and the approximation factor is computed as $5/9 \approx 0.56$. This is larger than the actual approximation factor for this AOC; i.e., 0.44.

Let m denote the number of tuples in an equivalence class. Lines 3 to 5 have runtime $O(m \log m)$. Lines 7 to 14 inside the loop take $O(m)$ time. Note that since the value of swapCnt for each tuple is bounded by m, sorting the tuples in Line 12 (as well as Line 5) can be done in $O(m)$ time using counting sort. In the worst case, this loop is repeated ϵn times, where ϵ and n denote the approximation threshold and the number of tuples in the table, respectively. Therefore, in the worst case, where $m = n$, the runtime of this algorithm is $O(n \log n + \epsilon n^2)$.

3.3 Our Optimal Validation Algorithm

We now present Algorithm 2 based on the *longest increasing subsequence* (LIS) problem to validate an AOC candidate. Lines 3 to 5 are repeated for the tuples in each equivalence class with respect to the context. Line 3 orders the tuples by [A, B] in ascending order. Next, Line 4 finds a longest non-decreasing subsequence (LNDS) of the projection of tuples over B. (As OCs are symmetric, we can also sort by [B, A] and find a LNDS of projections over A.) Line 5 adds the tuples that are *not* in the LNDS to the removal set. Finally, Line 7 checks whether the OC holds approximately with respect to the threshold, and returns the appropriate output.

Algorithm 2 Approx-OC-optimal

Input: Table $\mathbf{r}$, OC $\mathcal{X}$: A ∼ B, and approximation threshold ϵ.
Output: Approximation factor e and removal set $\mathbf{s}$, or "INVALID"

```
1: s = {}
2: for all E ∈ Π_X do
3:     t = order E by [A ASC, B ASC]
4:     L = computeLNDS(t_B)
5:     s = s ∪ (t_B \ L)
6: end for
7: if |s| ≤ ε|r| then return |s|/|r|, s else return "INVALID"
```

Example 3.2. Consider Table 1 and the OD sal ∼ tax. After ordering the tuples according to sal and breaking ties by tax, the projection of the tuples over tax is the list [2K, 2.5K, 0.3K, 12K, 1.5K, 16.5K, 1.8K, 7.2K, 16K]. The LNDS of this list is [0.3K, 1.5K, 1.8K, 7.2K, 16K] and thus, the removal set is $\mathbf{s} = \{t_1, t_2, t_4, t_6\}$. Thus, the approximation factor is $4/9 \approx 0.44$.

Again, let m denote the number of tuples in an equivalence class. Sorting the tuples in each equivalence class takes $O(m \log m)$ time (Line 3). To compute a LNDS of a list with length m, a dynamic programming algorithm from [2] with small modifications and with runtime $O(m \log m)$ is employed (Line 4). In Line 5, since L is a subsequence of $\mathbf{t}_B$, $\mathbf{t}_B \setminus L$ can be computed in $O(m)$ time by traversing both lists once. Therefore, the worst case runtime of this algorithm, which occurs when $m = n$, is $O(n \log n)$.

We now prove minimality and optimality of our algorithm. [1]

Theorem 3.3. *The set* $\mathbf{s}$ *generated using Algorithm 2 is a minimal removal set with respect to the given* AOC.

Theorem 3.4. *Algorithm 2 has the optimal runtime for validating an* AOC *candidate.*

Our validation algorithm easily extends to AODs of the form $\mathcal{X}$: A ↦ B. We again use Algorithm 2, but in Line 3, tuples are ordered according to the ascending order over A, but ties are broken according to the *descending* order over B. Intuitively, this forces the solution to the LNDS problem in Algorithm 2 to remove all *splits* in the table (removal of *swaps* is already ensured similar to Algorithm 2 for AOCs).[2]

4 EXPERIMENTS

We implemented our approximate OC validation algorithm on top of a Java implementation of the set-based OD discovery framework from [10]. We implemented our new LIS-based algorithm as well as the iterative algorithm using the same technologies to ensure that the improvements in runtime are not due to implementation differences. Unless mentioned otherwise, we set the approximation threshold to 10% and use ten attributes. We run our experiments on a machine with Xeon CPU 2.4GHz with 64GB RAM, and use datasets from the Bureau of Transportation Statistics and the North Carolina State Board of Elections:

(1) **flight** contains information such as date, origin, destination, and airline about flights in the United States and has 1M tuples and 35 attributes (https://www.bts.gov).
(2) **ncvoter** contains information such as registration number, age, and address about voters in North Carolina and has 5M tuples and 30 attributes (https://www.ncsbe.gov).

[1] Due to space limits, proofs of theorems can be found in the technical report [5].
[2] This idea can be extended to list-based AODs of the form $\mathbf{X} \mapsto \mathbf{Y}$, by ordering tuples in ascending order of $\mathbf{X}$ and breaking ties using the descending order over $\mathbf{Y}$.

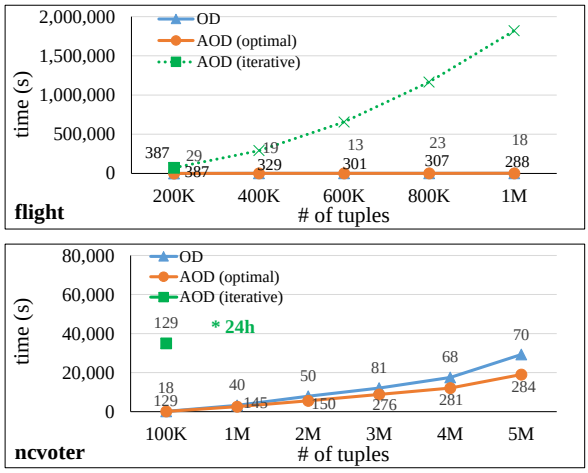

Figure 2: Scalability in |r|.

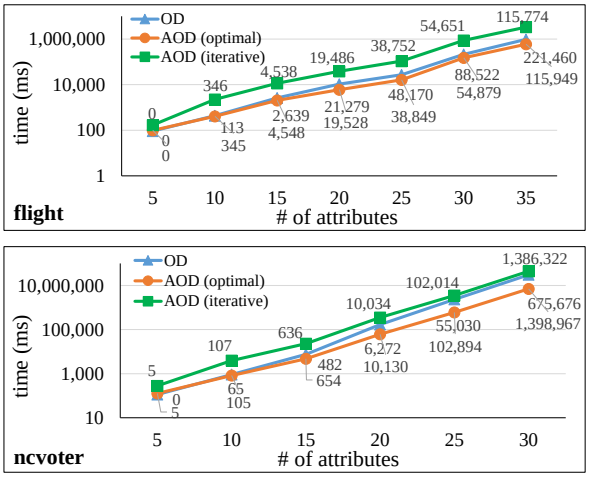

Figure 3: Scalability in |R|.

4.1 Scalability

Exp-1: Scalability in |r|. We measure the runtime (in seconds) of the AOD discovery framework that uses our validation algorithm by varying the number of tuples in our datasets, as reported in Figure 2. For now, ignore the curves labeled "OD" and "AOD (iterative)", as well as the numbers next to the datapoints. The AOD discovery framework implemented using our optimal algorithm scales up to millions of tuples.

Exp-2: Scalability in |R|. Next, we measure the runtime of the discovery framework in milliseconds, by varying the number of attributes in our datasets, as illustrated in Figure 3. We use 1K tuples of our datasets (to allow experiments with a large number of attributes in reasonable time) and vary the number of attributes in multiples of five. In this experiment, the runtime has an exponential growth (the Y-axis in Figure 3 is in log scale). This is expected since the number of ODs increases exponentially with the number of attributes.

4.2 Comparison with the Iterative Algorithm

Exp-3: Runtime comparison with the iterative algorithm. As discussed in Section 3, our AOC validation algorithm has time complexity $O(n \log n)$, while the iterative algorithm proposed in [10, 11] has time complexity $O(n \log n + \epsilon n^2)$. Figures 2, 3, and 4 illustrate the running times of the AOD discovery framework when using these two validation algorithms.

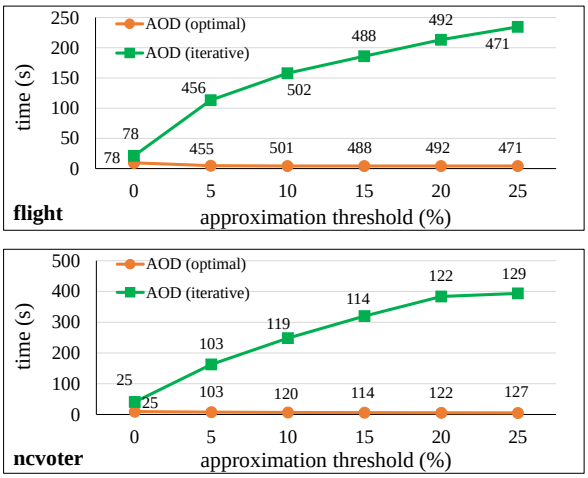

Figure 4: The effect of the approximation threshold.

As shown in Figure 2, while when using our algorithm, the framework can discover AOCs in datasets with up to millions of tuples, when using the iterative algorithm, it does not terminate within 24 hours on 400K and 1M tuples of the flight and ncvoter datasets, respectively (the running times for the flight dataset have been projected with dashed lines for better comparison). In cases where the framework equipped with the iterative algorithm terminates within the time limit, it is orders of magnitude slower. In Figure 3, while the differences are not as pronounced (as the number of tuples is too small), using our validation algorithm still makes the framework almost an order of magnitude faster.

We next experiment with the approximation threshold, by using 10K tuples from our datasets and setting the approximation threshold to 0, 5, 10, 15, 20, and 25 percent. As Figure 4 illustrates, while a larger approximation threshold does not increase the runtime of our algorithm, (the runtime decreases in some cases due to better pruning opportunities), it increases the runtime of the iterative approach at an almost linear rate. This aligns with the time complexity of these algorithms, as analyzed in Section 3.

As mentioned in Section 1, validating AOCs becomes the bottleneck of the AOD discovery framework when using the iterative algorithm. This is verified in our experiments, as up to 99.6% of the total runtime is spent on validation. Using our LIS-based validation algorithm, we reduce the time spent on validating AOCs by up to 99.8%, which results in the orders-of-magnitude improvement in runtime discussed before.

Exp-4: Removal sets and validating AOCs using the iterative algorithm. While our validation algorithm guarantees finding a minimal removal set for a given OC (as is proved in Section 3.3), the iterative algorithm may *overestimate* the size of a minimal removal set. This results in removal sets which are on average around 1% larger than the true minimal removal set.

Overestimating the approximation factor may result in missing valid AOCs if the true approximation factor is close to the input threshold. In Fig. 2, 3, and 4, the numbers inside the plots indicate the number of OCs or AOCs found by an algorithm. We have not listed the number of AOFDs since this work focuses on discovering AOCs. (Wherever the plots for our algorithm and the algorithm for exact ODs overlap, the numbers on the bottom correspond to our approach.) The iterative approach misses up to 2% of the valid AOCs found using our optimal approach.

Missing these AOCs could have potentially severe consequences. For instance, in the flight dataset, the AOC of arrivalDelay ~ lateAircraftDelay holds with an approximation factor of 9.5%.

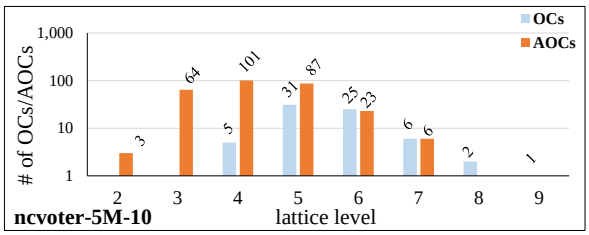

Figure 5: Number of discovered OCs/AOCs in each level.

This AOC points out that generally, delays in arrival are due to the aircraft and not other causes; e.g., security or weather delays. However, the iterative algorithm overestimates the approximation factor as 10.5%. This results in the framework missing this valid AOC when using an approximation threshold of 10%. Note that missing some AOCs results in different pruning opportunities, and, as a result, the set of discovered AOCs, which explains why the iterative algorithm discovers more AOCs in some cases.

Furthermore, as has been discussed for Exp-3, the running time of the iterative algorithm on larger datasets is prohibitively long. On such datasets, using the iterative algorithm results in missing *all* valid AOCs. For instance, in the ncvoter dataset with 5M tuples and with the approximation threshold set to 20%, the AOC of municipalityAbbrv ∼ municipalityDesc is discovered, which points to exceptions in creating abbreviations for municipalities; e.g., "Raleigh" is abbreviated as "RAL", while "Charlotte" is abbreviated as "CLT". However, this AOC does not hold in our 100K sample of tuples when using this threshold. Therefore, this dependency would have been missed by using the iterative validation algorithm, as it exceeds the time limit on the full dataset.

4.3 Comparison with Exact OD Discovery

Exp-5: Lattice level of AOCs and runtime improvements. AOCs tend to reside in lower levels of the lattice (with smaller contexts). In our scalability experiments in the number of tuples (Exp-1), the AOCs are on average 1.2 levels lower on the lattice. Similarly, in experiments in the number of attributes (Exp-2), the AOCs are on average 0.5 levels lower on the lattice. Figure 5 shows the number of OCs or AOCs found at each level of the lattice, when using 5M tuples and 10 attributes of the ncvoter dataset. On this dataset, the average lattice level of the discovered dependencies drops from 5.6 to 4.3 when using our approximate algorithm. As discussed in [10, 11], dependencies found in lower levels of the lattice are likely to be more interesting.

Furthermore, as discussed in Section 3.1, our discovery framework first validates candidates on lower levels of the lattice, and then applies pruning rules to generate the candidates on higher levels of the lattice (step 3 in Figure 1). Therefore, by finding AOCs in lower levels, the algorithm can use pruning rules more effectively earlier in the discovery process, resulting in pruning some candidates on higher levels of the lattice and validating fewer candidates in total. The effects of such pruning opportunities are not noticed when using the iterative validation algorithm, due to its prohibitively long running time. However, we optimally reduce the runtime of the validation step, resulting in runtime improvements for the discovery framework.

Figures 2 and 3 show the running times of the algorithms for discovering exact and approximate ODs. Even though validation of AOCs has a worse runtime compared to exact OCs, i.e., $O(n \log n)$, as opposed to $O(n)$, due to the extra pruning opportunities described above, the total runtime of the discovery framework for AODs can even be lower than the discovery framework for exact ODs; i.e., up to 34% and 76% faster in experiments in the number of tuples and attributes, respectively. The pronounced effect in the experiments in the number of attributes is due to having a smaller number of tuples.

Exp-6: Discovered AOCs compared to OCs. The exact algorithm fails to discover meaningful OCs in presence of anomalies, or even if a single value is erroneous. However, valid AOCs may hold in such instances. Other than the AOCs discussed in Exp-4, in the flight dataset, we discovered the AOC city ∼ airportName with a 27% approximation factor, which indicates that the names of airports usually begin with the name of the corresponding cities. Furthermore, the AOC streetAddress ∼ mailAddress holds in the ncvoter dataset with an approximation factor of 18%. These AOCs can point to anomalies and data quality issues, e.g., wrong address formats, misaligned mailing and residence addresses, and non-standard / erroneous airport names.

As shown in Figures 2 and 3, by discovering AOCs, we can find more dependencies in the data. Even if there are fewer AOCs than OCs (e.g., the flight dataset in Exp-2), the discovered dependencies are on lower levels of the lattice, as shown in Exp-5, which makes them more interesting [10, 11]. If the number of discovered dependencies is too large, the interestingness measure proposed in [11] can be used to rank the AOCs. In fact, the example AOCs that we have identified in Exp-4 and in this experiment, were all ranked as the most interesting AOCs.

5 CONCLUSIONS

We proposed a new validation algorithm for approximate ODs and proved its minimality and runtime optimality. We then implemented our approach in an existing canonical OD discovery framework and demonstrated significant gains compared to existing frameworks for discovering exact and approximate ODs. In future work, we will study new approaches for discovering approximate ODs, such as hybrid sampling, as done in [7] for FDs. We will also extend our approximate OD discovery framework to distributed settings, similar to the work in [9].

ABSTRACT

We study the problem of discovering joinable datasets at scale. We approach the problem from a learning perspective relying on profiles. These are succinct representations that capture the underlying characteristics of the schemata and data values of datasets, which can be efficiently extracted in a distributed and parallel fashion. Profiles are then compared, to predict the quality of a join operation among a pair of attributes from different datasets. In contrast to the state-of-the-art, we define a novel notion of join quality that relies on a metric considering both the containment and cardinality proportion between join candidate attributes. We implement our approach in a system called Nextia$_{JD}$, and present experiments to show the predictive performance and computational efficiency of our method. Our experiments show that Nextia$_{JD}$ obtains similar predictive performance to that of hash-based methods, yet we are able to scale-up to larger volumes of data. Also, Nextia$_{JD}$ generates a considerably less amount of false positives, which is a desirable feature at scale.

1 INTRODUCTION

Data discovery requires to identify interesting or relevant datasets that enable informed data analysis [2, 9]. Discovery and integration of datasets is nowadays a largely manual and arduous task that consumes up to 80% of a data scientists' time [19]. This only gets aggravated by the proliferation of large repositories of heterogeneous data, such as *data lakes* [15] or open data-related initiatives [14]. Due to the unprecedented web-scale volumes of heterogeneous data sources, manual data discovery becomes an unfeasible task that calls for automation [11]. Hence, we focus on the very first task of data discovery: the problem of discovering joinable attributes among structured datasets in a data lake. We distinguish three approaches: *comparison by value*, *comparison by hash* and *comparison by profile*. Table 1, overviews recent contributions. Comparison by value relies on auxiliary data structures such as inverted indices or dictionaries to minimize the lookup cost. Alternatively, the comparison by hash approach expects that similar values will collision in the same bucket, also employing index structures for efficient threshold index. Comparison by profile methods leverage on profiles extracted from datasets and their attributes. These are compared to predict whether a given pair of attributes will join.

Search accuracy		
Exact ..... Approximate		
Comp. by value [6, 20, 22]	Comp. by hash [4, 10, 21, 23]	Comp. by profile [5, 7, 8, 12]
Expensive ..... Efficient		
Algorithmic complexity		

Table 1: Overview of approaches by technique, arranged according to accuracy and algorithmic complexity

1.1 Data discovery at scale

Unfortunately, as we experimentally show in Section 3, the state-of-the-art in data discovery does not meet the expectations for web-scale scenarios. Unlike traditional relational databases, these are characterized by *a)* a wide heterogeneity among datasets (e.g., large differences on the number of attributes and / or their cardinalities); *b)* massive volumes of data; and *c)* the presence of a variety of topics, or domains. Overall, these distinguishing features deem current solutions ineffective due to their inability to scale-up as well as the low precision of the results obtained.

Inability to scale-up. Solutions that yield exact results or with a bounded error (i.e., comparison by value and hash) require the construction and maintenance of index structures for efficient lookup. This is a task that becomes highly demanding in terms of computing resources on large-scale datasets. In fact, as we have empirically observed, the available implementations fail to handle datasets of few GBs. Furthermore, most available approaches do not allow incremental maintenance.

Low precision. Comparison by hash solutions employ either containment or Jaccard distance as similarity measures to decide joinability among pairs of attributes. It has been reported, however, that the estimation of such measures is highly imprecise when the cardinality (i.e., the number of distinct values) of an attribute is comparatively larger than the other's [16], which is a common characteristic in real-world web-scale applications. As result, the precision of current approaches is highly affected due to the large number of false positives. To showcase this fact, we designed an experiment collecting 138 datasets from open repositories such as Kaggle and OpenML[1]. Precisely, we devised an heterogeneous collection of datasets ranging different topics, which yielded a total of 110, 378 candidate pairs of string attributes, where 4, 404 of those have a containment higher or

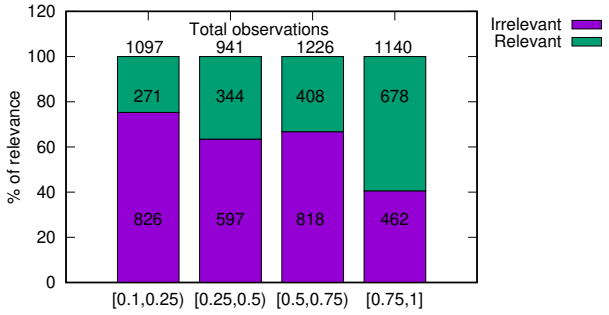

Figure 1: Distribution of relevant and irrelevant results for different containment values on a web-scale repository

[1]Repository available at https://mydisk.cs.upc.edu/s/GeYwdYH7xsGqbaX

equal than 0.1. Indeed, as shown in Figure 1, even for very high containment values (i.e., above 0.75), the number of irrelevant results (i.e., false positives) represents 40% of the total. Such results were obtained by manually analyzing the proposed candidate pairs. However, this approach is unfeasible for large scenarios and better join metrics are needed.

1.2 Profile-based methods to the rescue

The above discussion highlights the limitations of value and hash-based data discovery over web-scale scenarios. Alternatively, the comparison by profile approach suits betters for large scale scenarios as they rely on the detection of similarities or discrepancies between profiles. Working with summaries instead of data values is much more efficient from a complexity point of view. Yet, despite the clear performance benefits of profile-based approaches, there is nowadays a large gap in the trade-off regarding the quality of their results mainly due to the adoption of rather basic profiles (e.g. [8]) that do not accurately describe the underlying data or representative profiles (e.g. [5]) that are used to discover a binary class (e.g. joinable or non-joinable). To that end, we propose a novel approach to data discovery which aims to cover the gap generated by the low predictive performance of profile-based methods, as well as the limited precision and scalability of hash-based systems on large data lakes.

We, first, propose a novel metric to denote the quality of a join. Opposite to the related work, mostly focused on containment or Jaccard distance, we also consider the cardinality proportion between attributes as an indicator of a higher join quality. This allows us to get rid of a substantial amount of false positives, reducing the number of pairs to analyze. This is specially relevant in large-scale settings, where as shown in Figure 1, the number of candidate pairs is too large to manually disregard false positives. Second, we propose a novel learning-based method based on profiles to discover joinable attributes for large-scale data lakes. Our assumptions apply to scenarios where data is typically denormalized and file formats embed tabular data (i.e., not nested). We rely on state-of-the-art relational data profiling techniques [1] to compute informative profiles for datasets. This task, which can be done offline and parallelized over distributed computing frameworks (e.g., Apache Spark), allows us to extract and model the underlying characteristics of attributes. Next, profiles are compared in order to predict their expected join quality. The predictive model is based on random forest classifiers, which are highly expressive and robust to outliers and noise [3]. Additionally, such models can be trained and evaluated in a distributed fashion [17], thus yielding a fully distributed end-to-end framework for data discovery. We show that our method is generalizable and that proposes a meaningful ranking of pairs of attributes based on the predicted join quality.

Contributions. We summarize our contributions as follows:

- We introduce a qualitative metric for join quality, which considers containment and cardinality proportion between attributes.
- We learn a model based on random forest classifiers to efficiently rank candidate pairs of joinable attributes.
- We show that our approach is scalable and outperforms the current state of the art, yielding higher predictive performance results than profile-based solutions and similar quality (F_1-score) to hash-based ones. Yet, our approach yields better precision than hash-based approaches and produce less false positives.

2 MEASURING THE QUALITY OF A JOIN

Unlike the state-of-the-art, which mainly uses containment and Jaccard similarities to decide the degree of joinability among pairs of attributes, we define a qualitative metric to measure the expected join quality. We consider containment as a desirable metric to maximize. Yet, we make the observation that datasets on a data lake do not relate to each other as in a relational database. In such scenarios, it is common to find datasets with few data values in common that, in turn, may represent different semantic concepts. In order to exemplify this idea, let us consider the datasets depicted in Table 2. In this example, the reference dataset D_{ref} might be joined with any of the two candidate datasets D_1 (at the EU level) and D_2 (worldwide). Current approaches would propose both as joinable pairs, since they yield the same containment. However, we aim at distinguishing the join quality between them and use their *cardinality proportion* for that purpose. Let us consider the following cardinalities corresponding to the city attributes: $|D_{ref}|$ = 8124, $|D_1|$ = 54500 and $|D_2|$ = 982921. We use the cardinality proportion as a measure to infer whether their data granularities are similar. In this sense, the third dataset is much larger than $|D_{ref}|$ and yield a worse proportion and therefore we rank it worse. Importantly, we assume these datasets store independently generated events and such big difference in their cardinality most probably mean they embed different semantics or sit at different granularity levels. In general, such situations are a source of false positives for current solutions, specially, when considering small tables.

2.1 Join quality

We now formalize the metric for join quality as a rule-based measure combining both containment and cardinality proportion. We define a totally-ordered set of quality classes S = {`None`, `Poor`, `Moderate`, `Good`, `High`} as indicator of the quality of the resulting join. Indeed, we advocate not to define a binary class (i.e., either joinable or not), since we would not be able to rank the positive ones. As experienced with the state-of-the-art, in realistic large scenarios, a binary class yields a long list of results, which

(a) D_{ref} – Tourism income in Spain

City	Seaside	Amount
Barcelona	Y	350M
Girona	Y	110M
Lleida	N	75M
Tarragona	Y	83M
…	…	…

(b) D_1 – EU demographic data

Unit	Population	Avg. salary	Cost of living
Antwerp	1,120,000	44,000€	2,896€
Barcelona	1,620,343	31,000€	2,422€
Berlin	4,725,000	49,000€	2,737€

…	…	…	…

(c) D_2 – Worldwide demographic data

Name	Country	Population
Barcelona	Spain	1,620,343
Canberra	Australia	426,704
Chicago	United States	2,695,598
Curitiba	Brasil	1,908,359
…	…	…

Table 2: A reference dataset (D_{ref}) and two candidate datasets to be joined. D_1 is curated with extensive data at european level, while D_2 is curated at the worldwide level with less details

are difficult to explore and compare. Therefore, we propose the following multi-class join quality metric.

Definition 2.1. Let A, B be sets of values, respectively the *reference* and *candidate* attributes. The join quality among A and B is defined by the expression

$$Quality(A,B) = \begin{cases} (4)\ \texttt{High}, & C(A,B) \geq C_H \wedge \frac{|A|}{|B|} \geq K_H \\ (3)\ \texttt{Good}, & C(A,B) \geq C_G \wedge \frac{|A|}{|B|} \geq K_G \\ (2)\ \texttt{Moderate}, & C(A,B) \geq C_M \wedge \frac{|A|}{|B|} \geq K_M \\ (1)\ \texttt{Poor}, & C(A,B) \geq C_P \\ (0)\ \texttt{None}, & \text{otherwise} \end{cases}$$

The rationale behind the quality metric is to constrain the candidate pairs of attributes to two thresholds per class: containment (C_i) and cardinality proportion (K_i). Precisely, we fix that for any pair of classes $S_i, S_j \in S$ where $S_i > S_j$, the containment and cardinality proportion must be higher (i.e., $C_H > C_G > C_M > C_P$ and $K_H > K_G > K_M$). Intuitively, a larger containment and a similar cardinality proportion guarantees that the two attributes share common values and their cardinalities are alike. Consequently, most probably, they have a semantic relationship. We consider the values $C_H = 3/4 = 0.75, C_G = 2/4 = 0.5, C_M = 1/4 = 0.25, C_P = 0.1$ for containment, and $K_H = 1/4 = 0.25, K_G = 1/8 = 0.125, K_M = 1/12 = 0.083$ for cardinality proportion. These have been empirically defined from our training set, yet, as we show in Section 3 they are generalizable to other datasets.

To demonstrate the benefits of the proposed metric, we ran an experiment following the same methodology as that depicted in Section 1.1. Using the same collection of 110,378 candidate pairs, we evaluated their join quality. As a result, in Figure 2 we depict the distribution of the join quality distinguishing relevant and irrelevant results. There are two key observations to be made. On the one hand, the number of results labeled with higher quality classes is considerably smaller than those for high containment values. Thus, the largest number of observations are labeled as of *Poor* quality or *None*. On the other hand, the proportion of relevant cases is, in general, much larger than irrelevant ones but specially significative for higher quality classes. As expected, the lower the quality class, the more irrelevant cases will be found. Drilling down in the obtained results, we have manually studied these irrelevant cases where the quality class is High. We have observed that these situations occur when the proposed pairs do not have a semantic relationship but they share a syntactic one (e.g., some artists use a country name). Thus, it would only be possible to disregard them considering semantics.

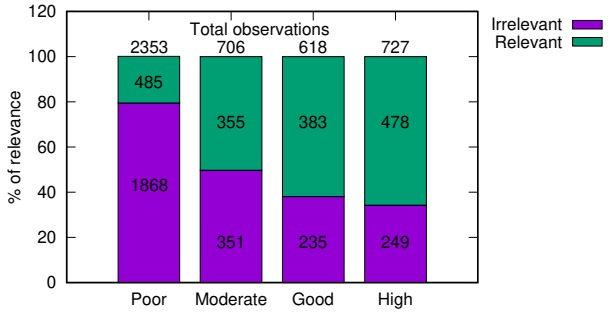

Figure 2: Distribution of relevant and irrelevant results for different quality classes on a web-scale repository

2.2 A learning approach to join discovery

Here, we describe our approach and present the process of building profiles and the predictive model.

Attribute profiling. Profiles are composed of meta-features that represent the underlying characteristics of attributes. Such profiles are the key ingredient for high accuracy predictions, thus we require an exhaustive summary of attributes. To this end, we base our profiling on state-of-the-art relational data profiling techniques [1]. We distinguish meta-features corresponding to unary and binary profiles. We further distinguish the former into meta-features modeling cardinalities, value distribution and syntax. Before comparing profiles and due to the fact attribute meta-features are represented in different magnitudes, we normalize them to guarantee a meaningful comparison using the Z-score. Finally, once meta-features have been normalized we compute the distances among pairs of attributes. Here, we also compute binary meta-features. The result of this stage is a set of distance vectors D where, for each D_i, values closer to 0 denote high similarities.

Predictive model. Once distance vectors are computed, we can train the predictive model. Precisely, the goal is to train a model that, for a pair of attributes A, B, its prediction is highly correlated to the true class (i.e., $Quality(A,B)$). The training process was performed using the collection of datasets discussed in Section 1.1. The ground truth was labeled using the newly proposed quality metric (Definition 2.1), which served as training dataset for the random forest classifiers. In order to reduce the false positive rate, the different classifiers are connected in a classifier chain architecture. This is an effective approach for multi-label classification [18]. Each classifier predicting the probability of class i is trained with the set of distance vectors D and the probabilities of classes $0, \ldots, i-1$, improving the predictive accuracy of the classifier. Figure 3 depicts a high-level overview of the architecture used for training. Then, the prediction returned by the classifier is the one with highest probability from each RF_i. To assign the predicted quality class to a candidate attribute, we assign the label considering the highest probabilities from all classifiers.

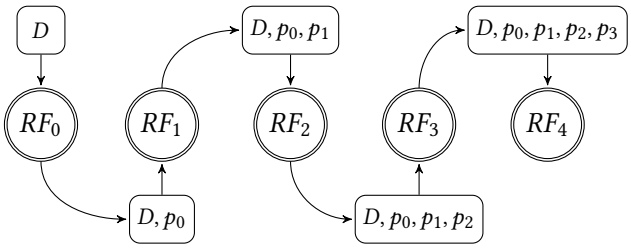

Figure 3: Chain of 5 random forest classifiers, each RF_i is fed with the distances vectors D and the probabilities from the previous classifiers $p_0, \ldots, p_{i-1}$

3 EVALUATION

In this section, we present the evaluation of our approach. On the one hand, we evaluate the ability of the model to discover quality joins through several experiments as well as its generalizability. On the other hand, we compare its performance with representative state-of-the-art solutions. In order to present transparent experiments and guarantee the reproducibility of results, we created an informative companion website[2].

[2]https://www.essi.upc.edu/dtim/nextiajd/

Implementation. Nextia$_{JD}$ is implemented as an extension of Apache Spark. The classification model was trained using its distributed machine learning library MLlib. The runtime methods (i.e., profiling and ranking) are implemented as new operators over the structured data processing library SparkSQL. We leverage on the Catalyst optimizer to efficiently compute the profiles and compare them. Our implementation supports two modes of operation *discovery-by-attribute* and *discovery-by-dataset*. The former receives as input a reference Spark dataframe (i.e., a dataset) and one of its attributes, and generates a ranking against a collection of dataframes (i.e., other datasets). The *discovery-by-dataset* mode does not receive as input a reference attribute, so it runs the discovery process for all attributes from the reference dataframe. Notably, implementing Nextia$_{JD}$ on top of Spark brings many other benefits. Firstly, we can benefit from many source connectors and we can easily ingest the most common data formats (e.g., CSV, JSON, XML, Parquet, Avro, etc.). Secondly, our extension benefits from the inherent capacity of Spark to parallelize tasks on top of distributed data.

Test set. For evaluation purposes, we collected 139 independent datasets from those used for the ground truth. We further divided such datasets into 4 testbeds (extra-small, small, medium and large) according to their file size. Table 3 shows the characteristics of each testbed.

Testbed	***XS***	***S***	***M***	***L***
File size	$0-1$ MB	$1-100$ MB	100 MB -1 GB	>1 GB
Datasets	28	46	46	19
Attributes	159	590	600	331

Table 3: Characteristics per testbed

Alternatives. We compare our approach with the following state-of-the-art data discovery solutions representatives of, respectively, hash-based and profile-based methods whose source code is openly available: LSH Ensemble [23] and FlexMatcher [5]. No fine tuning was performed in such systems, running the code as provided out-of-the-box. These systems differ in their mode of operation, the former being an approach based on comparison by hash, while the latter on comparison by profile. Note that, for computational performance reasons, we rule out approaches based on comparison by value. Such solutions are not comparable to ours, since their kind of search accuracy is exact and by nature they are not suitable for large-scale scenarios.

3.1 Predictive performance

Here we assess the classifier's predictive performance evaluating the ranking of candidate equi-join predicates for each testbed.

Methodology. We depict a confusion matrix to capture the relationship between the true and predicted classes. We also provide performance metrics for the classifier such as precision, recall and F_1 score. We first discuss the experiment for all testbeds together, and later do a fine-grained discussion for each testbed.

Results. Figure 4 and Table 4, show, respectively, the confusion matrix and performance metrics for all testbeds. Overall, we evaluated 467,965 attributes pairs. We can validate the good performance of the proposed approach by the fact that class 4, denoting the highest quality joins, has the best precision. Our method aims at proposing a ranking according to the predicted join quality, which for the highest value it has almost no false positives. It is also relevant to note that the prediction for class 0, denoting the no join quality, also has both high precision and recall. This is particularly relevant to filter out irrelevant results, and thus reduce the search space when presenting a ranking to the user. We additionally note that, as depicted by the precision and recall measures, predictions corresponding to classes 1 and 2 are highly inaccurate. Nevertheless, Nextia$_{JD}$ is prepared to be used as an interactive tool. Thus, if we analyze these results from the point of view of a user, most misclassifications are between similar classes and thus irrelevant. Nextia$_{JD}$ shows the results in strict order. First, classes 4 and 3, and then classes 2 and 1 on demand. In this sense, a binary classification meaning *likely relevant* or *likely irrelevant* would be a fairer way to evaluate Nextia$_{JD}$. When considering these results as a binary problem (relevant: classes 3-4; irrelevant: classes 0-2), the evaluated metrics improve considerably, as shown in Figure 9 and Table 5. Relevantly, we note that Nextia$_{JD}$ generates very few false positives; a desirable property for large-scale data discovery problems. We nevertheless highlight the relevance of distinguishing classes 1 and 2 from 0, either for advanced users or because Nextia$_{JD}$ could be used for other automatic data discovery problems where such distinction would be relevant.

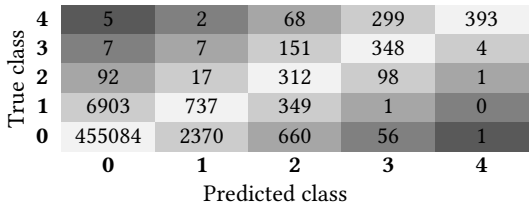

Figure 4: Confusion matrix for all testbeds (clearer cells denote a closer proximity w.r.t. the true class)

	Precision	**Recall**	**F_1 score**
(0) None	0.9848	0.9933	0.9890
(1) Poor	0.2352	0.0922	0.1325
(2) Moderate	0.2025	0.6000	0.3029
(3) Good	0.4339	0.6731	0.5276
(4) High	0.9849	0.5123	0.6740

Table 4: Performance metrics per class for all testbeds

3.2 Comparison with the state-of-the-art

In this experiment we aim at comparing our approach to other data discovery approaches. We perform such evaluation by measuring and comparing their computational complexity and predictive performance.

Methodology. All systems under evaluation, including ours, implement data discovery in two steps. The first step, which we denote *pre*, builds the core data structures from the datasets. For hash-based methods, such as LSH Ensemble, building the index, while profile-based methods, such as FlexMatcher and ours, create the profiles. Additionally, FlexMatcher will create the predictive models for each new data discovery task. Then, the second step, which we denote as *query*, consists of computing the prediction leveraging on the previously built data structures. Whenever possible, we decouple both steps and thus read the data structures from disk. This is, however, not the case for LSH

Ensemble, as it does not offer any resources to store the index on disk, forcing us to maintain it in memory.

The three systems analyzed have slightly different objectives. In order to perform a fair comparison, we analyze the results from the user perspective. That is, the number of results provided and its degree of relevantness. For that, we use a binary scale, which maps to the output obtained in LSH Ensemble and FlexMatcher. For Nextia$_{JD}$, we will reuse the relevantness mapping discussed in the previous experiment: we map classes $\{0, 1, 2\}$ to the irrelevant class, and classes $\{3, 4\}$ to the relevant one. Applying the same rationale, in LSH Ensemble we consider relevant those pairs with a containment above 50% (i.e., the threshold we considered for our class 3). Finally, FlexMatcher is not parameterizable with a quality threshold and already provides a binary output (i.e., non-joinable/joinable). In this case, non-joinable maps to irrelevant and joinable to relevant.

Results. We evaluated the performance of Nextia$_{JD}$, LSH Ensemble and FlexMatcher on each testbed. Both LSH Ensemble and FlexMatcher suffered from scalability issues and were not able to execute testbed *L*. Figure 6, depicts the runtime of the *pre* phase for each testbed. We can observe that the runtime of all systems is in the same orders of magnitude, however our *pre* is larger than the rest. This is mainly due to the fact that, to ensure a fair comparison, we did not set Spark on cluster mode. It is well-known that using Spark on centralized mode adds extra overhead of tasks when generating the required data structures, managing partitions, etc. This is not the case for the other systems, which are provided as standalone programs. Nevertheless, Nextia$_{JD}$ benefits from Spark's robustness and it is the only approach, even in centralized mode, capable of dealing with a large-scale testbed. Furthermore, we note that Nextia$_{JD}$ is the only solution able to precompute its *pre* step (except for binary meta-features).

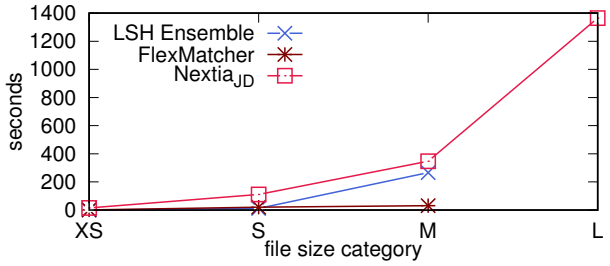

Figure 6: Pre runtime

Regarding the computational performance of the *query* phase, we distinguish the *discovery-by-attribute* and *discovery-by-dataset* scenarios, respectively in Figures 7 and 8. Note that *discovery-by-attribute* is not available in FlexMatcher. LSH Ensemble excels in both *query* tasks. This is due to the fact there is no mechanism to persist the index and this task is reduced to an in-memory lookup. FlexMatcher also benefits from fully running in memory but, in this case, the *query* step suffers from the need to compute some on-the-fly learning models. As general observation, both approaches are thought to compute their core structures and run in memory, which is the main reason hindering their ability to scale-up. Overall, Nextia$_{JD}$ shows a good behaviour in the *query* step. Importantly, Nextia$_{JD}$ is not affected by the dataset cardinality at *query* time. Indeed, the runtime is directly proportional to the number of attributes, or profiles, to compare.

We now put the focus on comparing the predictive performance of the three approaches. Figure 9 and Table 5, depict,

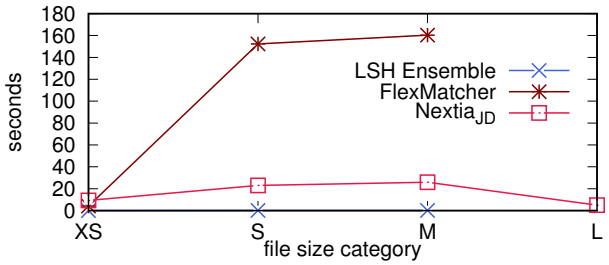

Figure 7: Query runtime (*discovery-by-dataset*)

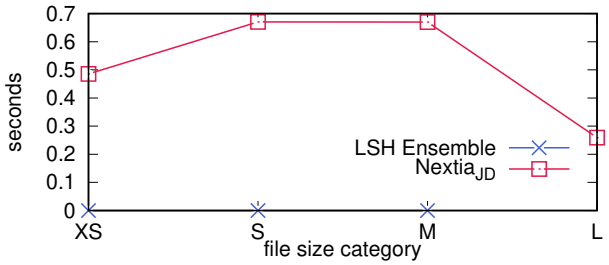

Figure 8: Query runtime (*discovery-by-attribute*)

respectively, the confusion matrices and performance metrics using the binary class mapping. Relevantly, the predictive quality of Nextia$_{JD}$ and LSH Ensemble are comparable. While LSH Ensemble finds more true positives, it generates much more false positives. As result, Nextia$_{JD}$ precision is better. Finally, and aligned with our claim that contemporary profile-based data discovery methods fall short in terms of quality, FlexMatcher generates an extremely large number of false positives reducing its overall quality and making it unfeasible for large-scale scenarios.

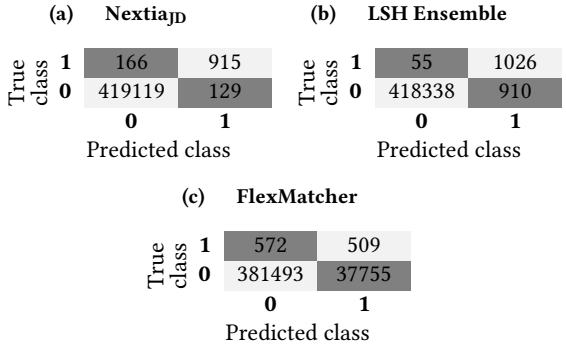

Figure 9: Combined confusion matrices for each system on testbeds *XS*, *S*, *M*

	Precision	Recall	F_1 score
Nextia$_{JD}$	0.8764	0.8464	0.8611
LSH Ensemble	0.5299	0.9491	0.6800
FlexMatcher	0.0133	0.4708	0.0258

Table 5: Performance metrics using binary classes for each system under evaluation on testbeds *XS*, *S*, *M*

Then, Figure 10 drills deeper into the comparison between Nextia$_{JD}$ and LSH Ensemble. We assigned a quality class to LSH Ensemble by running it several times and using a different containment threshold each time, as defined in our quality classes

(i.e., 0.75, 0.5, 0.25 and 0.1). There, we observe relevant differences on the predictions computed. In general, our approach is more conservative, in the sense that we produce less false positives at expenses of sacrificing some true positives. Overall, this improves the precision of our approach by reducing the number of false positives shown to the user. As general observation, both approaches follow slightly different objectives and Nextia$_{JD}$ is more suitable for large-scale scenarios, both for its scale-up capacity and high precision, which guarantees the user will not be overwhelmed with large rankings including false positives.

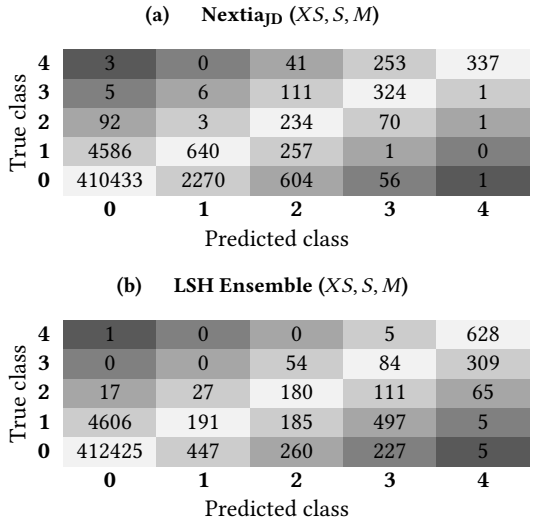

Figure 10: Confusion matrices using 5 quality classes for Nextia$_{JD}$ and LSH Ensemble

4 CONCLUSIONS AND FUTURE WORK

We have presented a novel learning-based approach for data discovery on large-scale repositories of heterogeneous, independently created datasets. Our work is motivated by (i) the poor predictive performance of current profile-based solutions, and (ii) the inability to scale-up and low precision of hash-based ones, which is undesirable for large-scale scenarios. In order to overcome these limitations, we propose a scalable method yielding good precision, and grounded on a novel qualitative definition of join quality. We implemented our approach in a tool called Nextia$_{JD}$. We have experimentally shown that despite being a profile-based approach, Nextia$_{JD}$ presents a similar predictive performance to that of hash-based solutions, yet better adapted for large-scale scenarios, while benefiting from linear scalability.

We do believe profile-based solutions are the right way to go at scale. However, there are some open problems that should be addressed in the future. First, a better join definition metric able to discriminate semantic joins. Current metrics are based on containment / Jaccard similarity and, as previously discussed, these metrics have a very good recall but very low precision. Annotating the required ground truth based on these metrics bias the learning due to the amount of false positives. Current annotated semantic ground truths are unfortunately too small (e.g., Valentine [13]), or generated from approximate metrics like ours, which smoothes the problem but still suffers from it. Last, but not least, profile-based approaches are promising to detect non-syntactic (i.e., with a different encoding per value) semantic join relationships. These are pairs of attributes that maintain the same underlying data distribution but require some transformation in order to join. Based on such predictions, it should be possible to propose such required transformations to join.

ABSTRACT

Mainstream DBMSs provide hundreds of knobs for performance tuning. Tuning those knobs requires experienced database administrators (DBA), who are often unavailable for owners of small-scale databases, a common scenario in the era of cloud computing. Therefore, algorithms that can automatically tune the database performance with minimum human guidance is of increasing importance. Developing an automatic database tuner poses a number of challenges that need to be addressed. First, out-of-the-box machine learning solutions cannot be directly applied to this problem and, therefore, need to be modified to perform well on this specific problem. Second, training samples are scarce due to the time it takes to collect each data point and the limited accessibility to query data submitted by the database users. Third, databases are complicated systems with unstable performance, which leads to noisy training data. Furthermore, in a realistic online environment, workloads can change when users run different applications at different times. Although there are several research projects for automatic database tuning, they have not fully addressed this challenge, and they are mainly designed for offline training where the workloads do not change. In this paper, we aim to tackle the challenge of online tuning in evolving workloads environment by proposing a multi-model tuning algorithm that leverages multiple Deep Deterministic Policy Gradient (DDPG) reinforcement learning models trained on varying workloads. To evaluate our approach, we have implemented a system for tuning a PostgreSQL database. The results show that we can automatically tune a PostgreSQL database and improve its performance on OLTP workloads and can adapt to changing workloads using our multi-model approach.

1 INTRODUCTION

Modern DBMSs have hundreds of configuration knobs that affect their performance. A DBMS that is not configured properly for the current workload may lead to sub-optimal performance and inefficient usage of system resources that may result in hundreds of users that are not getting the performance they need for their applications. The role of monitoring and configuring a DBMS was traditionally done by a database administrator (DBA), an expert dedicated to this task. However, nowadays, multiple DMBS instances are deployed on the cloud and each instance could host hundreds of databases, therefore, the task of monitoring and configuring a large-scale database infrastructure requires a large number of DBAs, which would lead to high operation costs.

Over the last few years, several database vendors have identified the potential of using machine learning to automate different database tasks on the cloud, such as automatic indexing, configuration, and provisioning. A few examples include the autonomous database from Oracle [11] and the self-driving database from Alibaba [1]. The study of autonomous databases using AI is a very active research area that already yielded a large number of papers, where the most popular machine-learning paradigm in recent works is reinforcement-learning [7, 9, 14, 18]. Born as a machine-learning branch for solving complex control problems, reinforcement learning is a natural choice the automatic database tuning tasks.

One of the main challenges of operating an automatic DBMS tuning system on the cloud is the fact that the database environment is dynamic: system resources, workloads, and database size could change in the course of the day, therefore, a system for automatic tuning needs to be flexible and adapt to these changes to provide the optimal performance for a given environment state. In this paper, we address the problem of changing workloads in an online tuning setting, and we employ reinforcement learning for this task. While query-aware formulations for tuning were previously proposed [7, 16], the problem of changing workloads in an online tuning setting was not fully addressed.

Our main contributions in this paper are as follows:

- We propose a multi-model online tuning algorithm, sensitive to workload changes, that leverages multiple DDPG reinforcement learning models and selects the optimal model for evolving workloads.
- We propose a simple reward function formulation for offline and online tuning and show that it yields a more stable learning curve compared to previous art [18].
- We demonstrate the offline and online tuning algorithms on a PostgreSQL database and show that the performance of the database can be significantly improved over the baseline default performance.

2 RELATED WORK

In recent years, multiple studies have addressed the problem of automatic DBMS tuning using various machine-learning techniques. In [5] a method called adaptive sampling was used to automate the knob configuration selection by sampling from past experience and in OtterTune [16] Gaussian Process (GP) regression was used to recommend the best knob settings. Reinforcement learning over continuous action configuration space

using the DDPG algorithm was utilized in CDBTune [18]. This method was further extended in QTune [7] where a new algorithm dubbed DS-DDPG was introduced together with a database state change predictor and a query classification algorithm. The approach in this paper also uses DDPG to learn a policy function for the tuning agent, but instead of one model, uses multiple DDPG models for evolving workloads in an online tuning setting.

Reinforcement learning is not limited to database automatic tuning. In several papers, problems such as query optimization [9, 10, 12], index tuning [2, 14] and data partitioning [17] are also solved using this machine learning paradigm.

3 RL FOR DATABASE TUNING

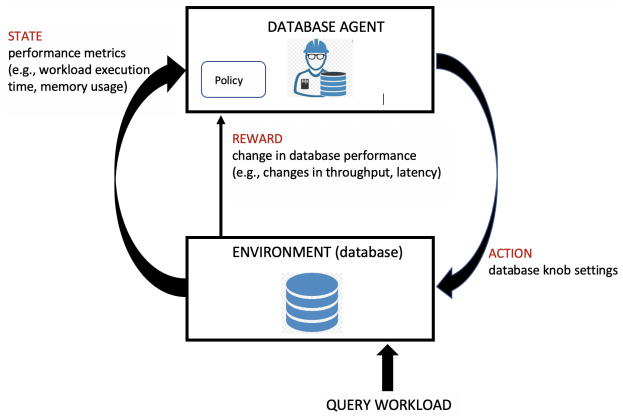

Figure 1: Reinforcement learning applied to database tuning.

A reinforcement learning system is composed of an agent and an environment. The agent takes an action on the environment and the action changes the state of the environment and generates a reward. The state and the reward are fed back into the agent that uses this input to compute the next action. The agent tries to increase the reward in every feedback loop. Reinforcement learning gained its popularity from video games, where the agent simulates a player that takes actions in the game environment and tries to win the game by maximizing a reward function.

As shown in Figure 1, in a database setting, the DBMS represents the environment and the agent represents the DBA. The state at time t, s_t, is described by a set of pre-selected database monitors (statistics collectors) and the reward, r_t, is a function of the database performance metrics (such as throughput and latency). Finally, the action a_t is the change in the configuration knobs selected for automatic tuning. The agent seeks to improve the performance of the database by changing the knob values and sensing the database state and reward.

3.1 DDPG: Knobs tuning in continuous action space

There are many algorithms for reinforcement learning, and each one of them has different variations. One criterion for choosing the right algorithm is whether the action space is discrete or continuous. In discrete action space, the agent selects one action out of a pre-defined set of actions, whereas in the latter case, the agent can pick any action from a continuous action space (e.g., a continuous value). In our case, there are potentially hundreds of knobs to be tuned, and many of them can be tuned to any value in the allowed range of the knob. Therefore, similarly to previous works [7, 18], we selected the Deep Deterministic Policy Gradient (DDPG) RL algorithm, which was developed to tackle the challenge of control problems with a continuous action space [8]. As shown in Figure 2, the agent in the DDPG framework is composed of actor and critic neural networks. Based on the state and reward observations from the environment, the critic estimates a Q-value using the Bellman equation and target networks, and the actor computes the tuning action based on the estimated Q-value. In every tuning iteration, the actor and critic networks are updated n times using batches of samples from a replay buffer that stores the (s_t, a_t, r_t, s_{t+1}) experience tuples. The batch size and the number of update iterations are hyperparameters determined by the user of the algorithm.

Here we describe the selections we made for the key elements of the algorithm:

Reward function. To train the agent, one must define a meaningful reward function to model the database performance. Different reward function formulations had been proposed in previous works [7, 18]. These formulations take into account the initial throughput and latency and the throughput and latency in the previous iteration. In this work, we rely on these formulations, but we use a simpler function that only represents a change in the performance relative to an initial throughput and latency. Our reward function is defined as follows:

$$r_{T,L} = c_T \left(\frac{T}{T_0} - 1 \right) + c_L \left(\frac{L_0}{L} - 1 \right) \quad (1)$$

where T and L stands for throughput and latency, respectively, and $C_T + C_L = 1$. Improvement in the throughput and latency yields positive reward values, whereas negative values indicate a decline in the database performance. T_0 and L_0 are set up as baseline performance values, for example, the throughput and latency obtained by the DBMS default configuration. Due to the typical oscillatory behavior of an RL training process, omitting the dependency on previous iterations adds stability to the tuning process. As will be shown in the experiments section, this formulation together with the selection of $\gamma = 0$ (discount factor) results in a more stable tuning curve compared to [18].

Replay buffer. In a traditional replay buffer, the order in which the experience tuples are saved in the buffer has no importance, and the batch of samples is selected randomly. In this work, we use a prioritized replay buffer in which tuples are prioritized based on the agent's training loss error, therefore, samples are selected based on their importance, and the ones that are more valuable for the learning process would be selected more frequently. It was shown in [8] that prioritized replay buffers lead to a more efficient learning process.

Finally, we followed the idea proposed in [8] and added Gaussian action space exploration noise using the *Ornstein-Uhlenbeck process* [15].

3.2 Offline training

In offline training, the RL agent is trained using databases built specifically for this task and the workloads that are being submitted are configured by the user. The offline training process allows us to generate preliminary models and knob settings for specific workloads, and to tune the algorithm hyperparameters in a controlled environment.

The workload in offline training can be generated and submitted using a benchmarking tool for example, such as Sysbench

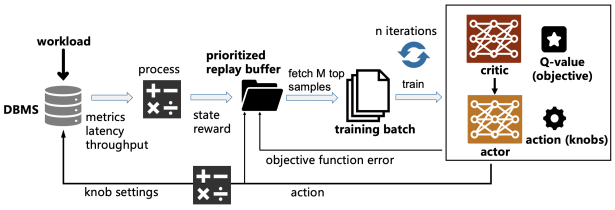

Figure 2: Database tuning with model training using the DDPG reinforcement learning algorithm.

and OLTPBench [4, 6], and the throughput and latency measures can be retrieved from the output log files generated by the tool. Once a workload is chosen, it will not be modified during the training phase. When the training phase is completed, a trained DDPG model for the workload is generated and this model can be used as a starting point for training on a different workload (transfer learning), or as a preliminary model for online tuning, a process we will describe in the next section.

The process of offline training is described in Figure 2. A submitted workload and a change in the knob settings by the action a_t cause a change in the database state and yield s_{t+1}. The throughput and latency measured over a certain time interval obtain r_t using the reward function defined in Eq. 1. The state s_{t+1} and r_t form a state transition tuple with the action a_t and the previous state s_t, and this transition tuple is added to the replay buffer. Then, a batch from the replay buffer is sampled and used to update the actor and critic networks for n iterations. Finally, a new knob settings action a_{t+1} is computed. As part of this process, the batch sample priorities are updated based on the critic loss function. The training process continues for a number of iterations that is determined by the time it takes the learning curve to stabilize.

Offline training was used in previous works for building preliminary machine learning tuning models [7, 16, 18].

3.3 Model deployment

When a trained model is deployed, the algorithm described in Figure 4 is used to recommend the knob settings. When the agent receives the database state and performance metrics, the actor predicts an action that is being translated to knob settings after a Gaussian noise is generated using the OU process and added to the action. These knob settings are then applied to the database.

4 ADAPTIVE MULTI-MODEL ALGORITHM FOR ONLINE TUNING

Tuning online is a challenging task, since workloads can change at anytime. Suppose that a database runs OLAP queries at night and OLTP queries during the daytime, its optimal memory allocation strategy would be different for each workload. Therefore, the training data from an OLAP workload cannot be used for training a model for an OLTP workload, and if the tuning system cannot detect workload changes and adapt, it would perform poorly on new workloads.

To deal with the challenge of changing workloads, we have developed a system for adaptive online tuning based on a multi-model algorithm. This algorithm tracks the database state and performance and the agent uses a set of pre-trained models and dynamically creates new models to tune the knobs if required. The performance measures (latency, throughput) in this case can be computed using database views such as *pg_stat_activity* in PostgreSQL.

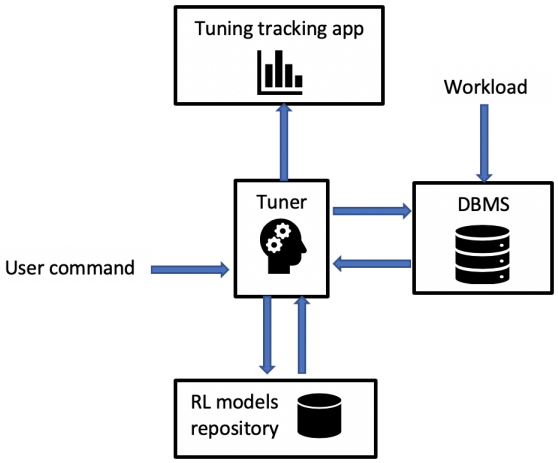

Figure 3: The multi-model database online tuning system.

The main components of our system described in Figure 3 are the tuner and the RL model repository. The tuner refers to the DDPG reinforcement learning algorithm presented in Section 3. The repository of model contains a collection of RL models, pre-trained on workloads that are as similar as possible to the workloads in the deployment environment, as well as models that are created during online tuning. The models in this repository are persisted with their weights, replay buffer, and a log file that contains the knob settings that resulted in the best database performance during training. In addition, each model is accompanied by a workload representation vector that allows to retrieve the most similar models in Algorithm 1. The last component is a web-based app we implemented using Bokeh [3] that uses the log files created during training to display in real-time the database performance measures and the values of the knobs being tuned.

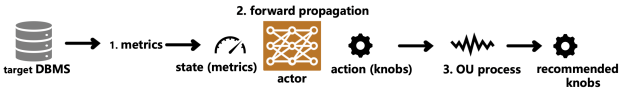

Figure 4: Knobs recommendation in deployment environment using DDPG. 1. The agent receives state and performance metrics. 2. The actor network predicts an action based on this input. 3. Exploration noise is added to the action using the Ornstein-Uhlenbeck process and a new knobs configuration is recommended.

4.1 Workload representation vectors

To generate the workload representation vectors we used an autoencoder neural network. We generated training data of state vectors that combine the database state metrics, latency, throughput, and queries per second (qps): $V = (M_0, M_1, \ldots, M_i, T, L, Q)$. These vectors were collected at different time points and for different workloads. Then, we reduced their dimension by training a simple 3-layer autoencoder and used the compressed representation from the hidden layer as the new state vectors. Since these vectors were often sparse, this procedure allowed us to obtain a

compact workload representation. The autoencoder architecture is shown in Figure 5.

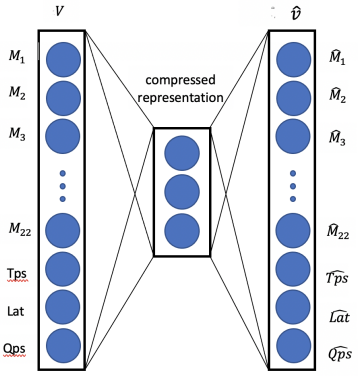

Figure 5: Workload representation dimensionality reduction using an autoencoder. V and $\hat{V}$ represents the original and reconstructed vectors, respectively. We used a 25-dimensional state vector compressed to a three-dimensional representation.

4.2 Multi-model tuning algorithm

For a given workload, Algorithm 1 selects from the N models in the repository, M_i, the ones that have high cosine similarity between the workload representation vector of the current workload, V_w and the vectors persisted with the models, V_i, and form a set of models, S. The similarity threshold is denoted by T, and was set empirically to $T = 0.8$.

Given $\tilde{N}$ models in S, we use an algorithm denoted as *Best(S)* to select the model for recommending the knob settings in every tuning iteration. The model that has the highest probability for increasing the reward (improving the database performance) is chosen to recommend the knob settings. Model selection probabilities are assigned by generating random numbers from the Beta distribution:

$$f(x; \alpha, \beta) = Cx^{\alpha-1}(1-x)^{\beta-1} \quad (2)$$

where C is a normalization constant and α, β are the distribution shape parameters. For values of $\alpha = \beta$, the distribution is symmetric and the mean is at the center of the distribution. When $\alpha > \beta$, the mean moves to the right side of the axis, and the random generator has a higher probability of yielding values larger than 0.5. We use α and β to compare the performance of the models, such that the model that performs better, has a higher α value, and therefore a higher probability to be selected in the next tuning iteration. When comparing two models, α and β counts the number of times each model produced a reward higher than the average reward from the beginning of the workload cycle to the point of measurement.

The models from the repository would always compete against a model trained from scratch (fresh model) to guarantee that the best model is being selected in cases where the model retrieved from the repository does not perform optimally. If a model M from the repository was selected and fine-tuned during the online tuning process, its fine-tuned version M' would be persisted instead of model M. The process continues as long as the online tuning phase runs. If a workload shift is detected, the model that was selected the highest number of times to predict the action within the workload cycle is persisted in the models' repository. A model selected from the repository and updated during training will be persisted with the compressed workload representation vector, the updated weights, the replay buffer experience, and the best knob settings.

Algorithm 1 Adaptive multi-model algorithm for online tuning

```
while Tune do
  S = []
  for i=0 to N do
    if cos(V_i, V_w) > T then
      S.append[M_i]
    end if
  end for
  S.append[M_new]
  while True do
    Compute a_t using Best(S) and apply it
    Wait
    Collect s_{t+1} and r_t and update the models in S
    if workload shift then
      Persist Best(S)
      Break
    end if
  end while
end while
```

5 EXPERIMENTS

In the following section, we evaluate the offline tuning algorithm and our online tuning algorithm on PostgreSQL. In the offline phase, we use the Sysbench benchmarking tool [6] to submit queries and measure the throughput and latency. Sysbench is a multi-threaded configurable benchmarking tool for OLTP workloads, where the major ones are OLTP Read/Write (R/W), OLTP Read-Only (R/O) and OLTP Write-Only (W/O). The workloads are composed of SELECT, INSERT, DELETE and UPDATE queries, where the number and mixture of the queries in each workload can be modified via command line or by modifying a Lua script that defines the workload. In addition, Sysbench allows the user to control the benchmarking duration time, the size of the database, and the number of workers.

5.1 Single-model: Static workload

In this case, a single RL model is trained and is responsible for tuning the database, regardless of the workload that is being submitted to the database. This approach works well if the database environment is relatively stable and workloads are not changing. However, if workloads are changing, the model needs to adapt to a new workload when a workload shift occurs, and it uses its past experience to recommend knobs for the new workload.

In the first experiment, we demonstrate the performance of the RL agent using the DDPG algorithm described in Figure 2. This experiment demonstrates offline training using OLTP R/W workload. We ran the algorithm for 150 episodes with the main hyperparameters setup as follows: $\gamma = 0$ (discount factor), $\sigma = 0.2$ (OUProcess noise variance), and replay buffer sampling batch size of 32 samples. To represent the DBMS state we picked 22 PostgreSQL metrics from 3 different views that provide statistics at the instance and database levels: *pg_stat_bgwriter*, *pg_stat_database*,

and *pg_stat_database_conflicts*. These views monitor various database elements such as checkpoints, buffers, deadlocks, and transactions' activity. To get the reward in the offline tuning stage, we used the throughput and latency calculated by Sysbench.

Based on experiments with different number of knobs, and expert blogs on tuning PostgreSQL (e.g., [13]), we have selected for tuning 16 knobs that had the most impact on the database performance. These knobs control various aspects of the database, such as working memory (e.g., *work_mem*, *maintenance_work_mem*), checkpoints (e.g., *checkpoint_segments*, *checkpoint_timeout*), deadlocks (*deadlock_timeout*), and auto_vaccum (*autovacuum_cost_delay*, *vacuum_cost_limit*). They do not require database restart to be updated, one of the criteria for selecting them.

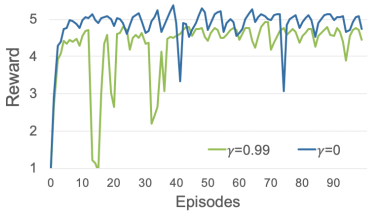

Figure 6: Reward function comparison for the OLTP R/W workload experiment. The green reward curve was obtained using the CDBTune reward [18] with $\gamma = 0.99$. The blue reward curve was obtained using our simplified reward function with $\gamma = 0$.

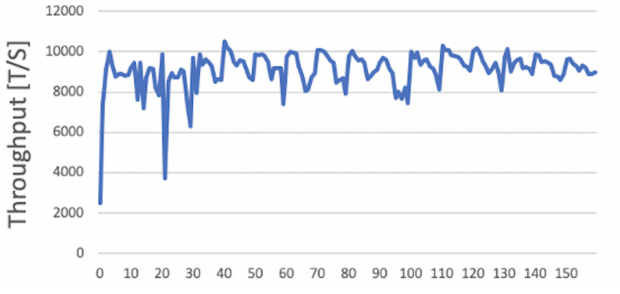
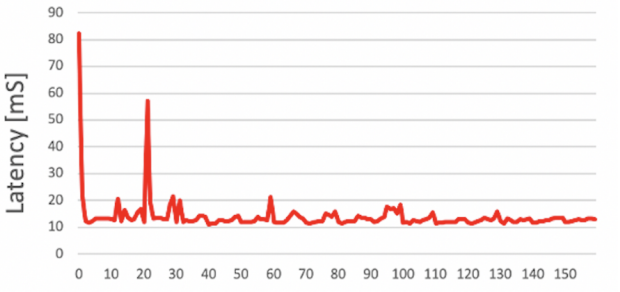


(a) Throughput



(b) Latency

Figure 7: Offline training: Throughput and latency plots of a PostgreSQL database tuned on an OLTP R/W workload.

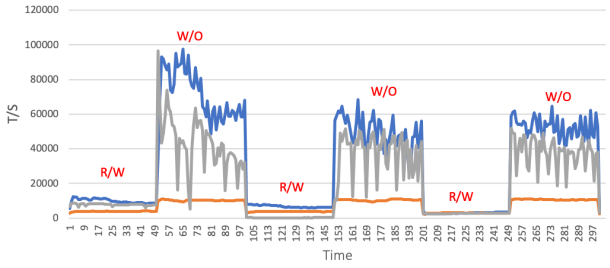
In all the experiments described in this section, the tuning starting point was the database default configuration. As Figure 7 shows, the default performance for OLTP R/W was a throughput of approximately 2000 TPS and a latency of 80 ms. As the agent explored different knob settings, we observed a 5x improvement in throughput and 8x improvement in latency. In the first iterations, the performance significantly oscillated, but the magnitude of the oscillation decreased as the agent learned the right policy for tuning the knobs. In the OLTP R/W experiment, we also compared the simplified formulation of the reward function (Eq. 1) to the formulation and γ parameter setup in [18] and observed that the simplified formulation with $\gamma = 0$ resulted in a more stable learning curve and a higher reward value (better database performance). The reward curves of the first 100 iterations are shown in Figure 6.

The offline tuning process can be repeated with any workload, such as OLTP W/O, and the models trained in the offline training phase can be used as initial pre-trained models in the multi-model online tuning experiment we describe next.

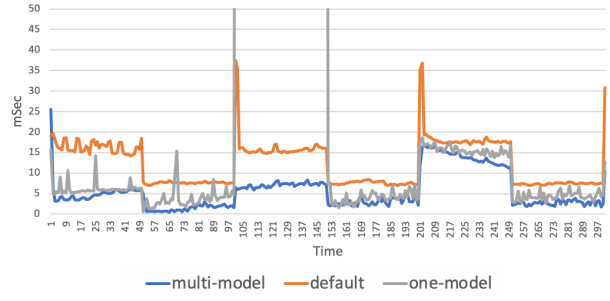
5.2 Single and multi-model approach: Changing workloads

In this experiment, we used the same knobs selected for tuning in the offline training experiment and the same 22 database metrics were used as state indicators. We created an environment in which two alternating Sysbench workloads are submitted to the database: R/W and W/O workloads and we compared the single-model, multi-model, and default database performance over 3 alternating workload cycles. At each time point in Figure 8, a workload is submitted, the state and performance metrics are collected, the RL models are updated, and finally, a knob changing action is computed by the agent to update the knobs using Algorithm 1. Each time point takes approximately 60 seconds to complete, hence, workloads are changing approximately every 60 minutes. We used a three-dimensional compressed representation of the workload vectors, obtained by the autoencoder, to detect workload changes by measuring the distance between vectors at adjacent time points and identifying large deviations. This representation was also used to select the most similar models using cosine similarity. The knob settings saved with the most similar model were applied to the database and used as a starting point for tuning.

As shown in Figure 8, the multi-model algorithm performed far better than the baseline default configuration performance, increasing the throughput of the R/W workload by a factor 2x and the throughput of the W/O by a factor of 5x. The single-model approach, on the other hand, produced inferior performance compared to the multi-model approach and was less stable. In the second cycle, for instance, presumably due to bad knob settings, the throughput dropped to approximately 300 TPS, and the latency jumped to very high values. We assume that this is related to the fact that the replay experience (state, action, reward transitions) collected in the first cycle could not be properly leveraged by the agent for learning a good configuration in the next cycle. This could be related to the fact that the single model approach uses a single replay buffer for multiple workloads, therefore, experiences from different workloads with different reward scales are mixed, and similar experiences are mapped to completely different rewards. Therefore, the agent cannot learn a good policy for tuning the knobs. In the multi-model approach, each model was trained on a different workload and used experiences unique to the workload it was trained on. This models' separation helps the agent learn the right policy for a particular workload.



(a) Throughput



(b) Latency

Figure 8: Online tuning: Throughput and latency plots of a PostgreSQL database in changing workloads environment. The tuning results were obtained using the one- and multi-model tuning algorithms, and the default knob settings. The workloads alternate between OLTP R/W and OLTP W/O.

A potential pitfall of the multi-model algorithm is the fact that many new models can be created and lead to models' explosion and a large number of competing models for every workload. However, what we observed in our experiments, is that the pre-trained models were superior to newly created models, and therefore, new models were not persisted. Therefore, we believe that eventually, the number of models in the repository would be similar or very close to the number of different workloads the agent is tuning.

6 DISCUSSION

Automatically tuning a database on-premise or in cloud environment using reinforcement learning, or a different AI technique, poses multiple challenges. One of these challenges is the fact that the database environment is constantly changing, often in the course of the day. Changes in the database size, available system resources, and workloads may affect the performance of the database at any given time point and require an adaptive algorithm that is able to sense these changes and yield optimal performance for a given environment state. In this work, we explored the effect of changing workloads on database performance and proposed an adaptive algorithm that leverages multiple DDPG reinforcement learning models to optimize the performance for each workload. Preliminary results presented in this paper on a PostgreSQL database showed that the multi-model approach has an advantage over the single-model approach in which one model is continuously trained and needs to adapt to new workloads, similar to the approach presented in [18]. Using the multi-model approach, the algorithm was able to utilize past experiences from models trained on similar workloads and improved the database default configuration throughput by a factor of 2x when tested on an OLTP R/W workload and a factor of 5x when tested on an OLTP W/O workload.

In future work, we will explore other workload types (e.g., OLAP), and we will address the problem of fluctuating performance due to other factors, such as resource elasticity.

ABSTRACT

Improving machine learning models' fairness is an active research topic, with most approaches focusing on specific definitions of fairness. In contrast, we propose ParDS, a parametrised data sampling method by which we can optimise the *fairness ratios* observed on a test set, in a way that is agnostic to both the specific fairness definitions, and the chosen classification model. Given a training set with one binary protected attribute and a binary label, our approach involves correcting the positive rate for both the *favoured* and *unfavoured* groups through resampling of the training set. We present experimental evidence showing that the amount of resampling can be optimised to achieve target fairness ratios for a specific training set and fairness definition, while preserving most of the model's accuracy. We discuss conditions for the method to be viable, and then extend the method to include multiple protected attributes. In our experiments we use three different sampling strategies, and we report results for three commonly used definitions of fairness, and three public benchmark datasets: *Adult Income*, *COMPAS* and *German Credit*.

1 INTRODUCTION

The increasing presence of automated decisions in our lives has led to a rising concern about the way in which these decisions are taken, spurring research into the *fairness* of predictive models. These models are often learnt from biased data, reflecting historical disparities and discrimination [27]. We propose ParDS, a fairness-definition and classifier agnostic resampling method, which may be easily implemented on top of existing ML solutions and can satisfy specific classification model requirements. ParDS is modulated through the continuous parameter d, which determines the amount of resampling introduced into the training data, and has two possible use cases: to find the optimal amount of correction for a specific fairness/classifier combination and to control a classifier's fairness/accuracy trade-off.

Standard data preparation techniques may be used to correct the fairness behaviour of a classification model [29]. ParDS is based on data resampling, which is well understood and part of the typical data management pipeline [23]. Being a preprocessing operator, ParDS may easily be incorporated along data cleaning into existing database solutions. Like other resampling techniques, ParDS can be computationally inexpensive and yield reduced classifier learning times, as shown in Subsection 4.2.

Our method offers the versatility of using both generic (random undersampling, random oversampling and *SMOTE* [6]) and fairness-specific (preferential sampling [20]) methods.

Multiple definitions of fairness have been proposed [25], which are sometimes in contrast with one another. A decision rule that satisfies one of the definitions may well prove to be very unfair for a different one [10]. For example, determining university admissions through gender quotas may achieve *demographic parity*, but it makes the acceptance rates for good students of different genders disparate.

A common resampling problem is the loss of predictive accuracy caused by such interventions [3]. In our setting, such loss can also be controlled through parameter d, allowing for a decision in the amount of accuracy/fairness trade-off the user is willing to accept. Furthermore, our experiments in Section 4 show that even at high correction levels, the accuracy loss for ParDS is relatively low.

1.1 Related Work

A classifier's fairness may be corrected by *preprocessing* the training data, *in-processing* the learning algorithm [1, 5, 30–32] or *post-processing* a classifier's predictions [18]. Our method belongs to the group of preprocessing solutions.

Fairness-aware preprocessing is defined [14] as a set of techniques that modify input data so that any classifier trained on such data will be fair. There are four main ways in which to make appropriate adjustments to data in order to enforce fairness [21]: suppressing certain features, also known as *fairness through unawareness (FTU)* [15], *massaging* variable values [4, 9, 13], reweighing features [19, 24], and resampling data instances [8, 20, 28, 29].

Data resampling, the category of ParDS, is less invasive in nature than *FTU* or *massaging*, since the original data is preserved and only the frequency with which the instances are represented is modified. In contrast, *FTU* disposes of large amounts of data without a guarantee on the effect of said intervention and *massaging* effectively creates synthetic data, which does not necessarily reflect the ground truth.

Preferential Sampling (PS) [20] is a similar method to ParDS, in the sense that it resamples the favoured/unfavoured and positive/negative combinations separately in order to equalise the favoured and unfavoured groups' positive ratios. We empirically show that the optimal fairness correction depends on the selected sampling method, classifier and fairness definition. Equalising the positive ratios across protected attribute groups is not necessarily the best approach, hence we modulate our corrections via

parameter d. When using *PS* to resample, ParDS generalises it, with the unmodified *PS* corresponding to the $d = 0$ case.

SMOTEBoost [8] oversamples the minority group through synthetic data based on real data instances, with a focus on improved minority predictions and indirectly improving fairness.

Other related methods include *Capuchin* [29], a causal-fairness centric, non-parametrised resampling method and Feldman et al. [13], a *massaging* method where parameter λ is used to create linear interpolations of the original dataset and a *repaired* copy to find the optimal combination.

1.2 Contributions

We introduce ParDS, a parametrised resampling-based fairness-correcting method. ParDS is fairness-definition and classifier agnostic, and achieves close to optimal fairness correction with a small loss in predictive performance. We present extensive experiments to benchmark the effectiveness of the method using the *Adult Income*, *COMPAS* and *German Credit* datasets, and our implementation is available as a collection of *Jupyter Notebooks* at https://github.com/vladoxNCL/fairCorrect. This is a substantial extension of our preliminary workshop paper [17], presented at the *2019 KDD XAI Workshop*. Its additional contributions are four-fold:

(1) We estimate the optimal fairness correction using Bayesian optimisation.
(2) We present experimental evidence on synthetic datasets of our method's viability and effectiveness with respect to the linear separability of the training set.
(3) We make an initial investigation into extending the method to multiple protected attributes.
(4) We benchmark and compare our work with several existing fairness-correction methods.

2 DEFINITIONS

We will say a binary classifier's label can be *positive* or *negative* referring to the desirable and non-desirable outcome of a prediction, respectively.

A dataset's *protected attribute (PA)* refers to a variable that may be object of discrimination, due to historical bias or otherwise. In our particular case we will be dealing with a single binary PA.

We will call the ratio of the number of positive instances divided by the total number of instances in a specific group the *positive ratio (PR)* of the group.

Among the two PA groups, the one having the highest PR will be referred to as the *favoured* group F, while the other one will be referred to as the *unfavoured* group U. When required, we will refer to the positive and negative instances of F and U as F^+, F^-, U^+ and U^-, respectively.

We based our analyses on three ratios, *Demographic Parity Ratio (DPR)*, *Equality of Opportunity Ratio (EOR)* and *Proxy Fairness Ratio (PFR)*, associated to their respective fairness definitions [22, 25]. In these definitions, the positive label is identified with $Y = 1$ and the negative label with $Y = 0$.

Definition 2.1 (Fairness Ratios).

$$DPR := \frac{\mathbb{P}(\hat{Y} = 1 \mid \text{PA} = U)}{\mathbb{P}(\hat{Y} = 1 \mid \text{PA} = F)},$$

$$EOR := \frac{\mathbb{P}(\hat{Y} = 1 \mid \text{PA} = U, Y = 1)}{\mathbb{P}(\hat{Y} = 1 \mid \text{PA} = F, Y = 1)},$$

$$PFR := \frac{\mathbb{P}(\hat{Y} = 1 \mid do(\text{PA} = U))}{\mathbb{P}(\hat{Y} = 1 \mid do(\text{PA} = F))}.$$

For *DPR* and *EOR*, we evaluate the ratio of the positive classification probabilities for U and F. *PFR* is computed by intervening on the test set T twice, assigning every individual in T the PA-values U and F, resulting in $T_{\text{PA}=U}$ and $T_{\text{PA}=F}$, respectively. We then evaluate the quotient of the intervened sets' classification *PRs*; in all cases, the ratios quantify how close the classifier comes to optimal fairness.

3 METHODOLOGICAL APPROACH

We have focused on datasets with both binary protected attributes and labels. The plots in this section result from applying ParDS to the *Adult Income (Income)* dataset [12].

We introduce the *disparity correction* parameter $d \in [-1, 1]$, which may be used for two different objectives:

- To modulate a classifier's fairness/accuracy trade-off.
- To optimise a classifier with respect to a fairness definition.

Our main objective will be the third one, to estimate the d-value optimising a classifier's predictions with respect to a fairness definition. We summarise the method as follows:

(1) Define PR-correcting functions for F and U.
(2) Select a *sampling strategy* to correct the training set.
(3) Estimate the fairness-specific optimal d-value.

Details on each of these steps now follow.

3.1 Parametrising Correction

The first step is to define linear functions that will yield corrected PRs for both PA groups. These functions, which we will call $f^+(d)$ and $u^+(d)$, should satisfy the constraints: $f^+(1) = \text{PR}(F)$, $f^+(-1) = \text{PR}(U)$ and $u^+(d) = f^+(-d)$.

The equations for these two linear functions are

$$f^+(d) = md + b, \quad u^+(d) = -md + b,$$

with coefficients

$$m = \frac{\text{PR}(F) - \text{PR}(U)}{2}, \quad b = \frac{\text{PR}(F) + \text{PR}(U)}{2}.$$

3.2 Sampling Strategies

In the second step, we use the resulting corrected ratios $f^+(d)$ and $u^+(d)$ to produce a resampled training set $\{\hat{U}, \hat{F}\}$ satisfying these ratios. The required amount of resampling for F and U will depend on d and the selected strategy.

ParDS can use one of four different sampling methods, modified to work on specific PA-label subgroups: random undersampling (*Under*), random oversampling (*Over*), *SMOTE* [7] and preferential sampling (*PS*) [20]. Depending on the sampling method, the following subgroups will be modified:

***Under*:** Undersample F^+ and U^-.
***Over*:** Oversample F^- and U^+.
***SMOTE*:** Oversample F^- and U^+.
***PS*:** Undersample F^+ and U^-, oversample F^- and U^+.

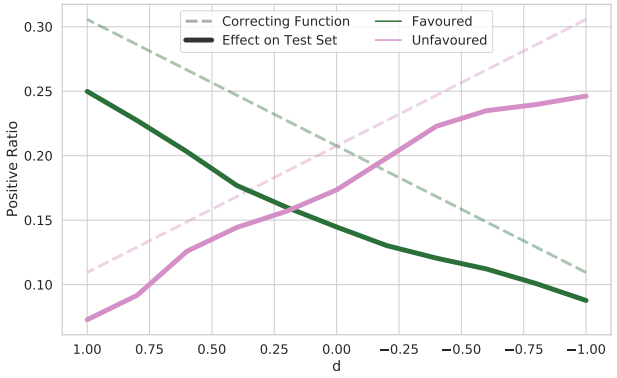

Figure 1: Correcting functions $f^+(d)$ and $u^+(d)$ applied to *Income* and their effect on the test set. The d-axis is reversed, going from 1 (no correction) to -1 (maximum correction). Note that the test-set PRs do not intersect at $d = 0$.

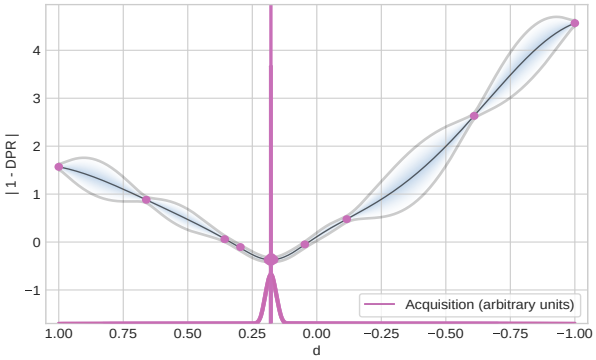

Figure 2: Plot of *GPyOpt*'s approximation of *DPR* as function of d for *Income*. The bottom red curve displays the resulting distribution for the optimal d-value.

The resampled $\hat{F}$ must satisfy

$$\frac{|\hat{F}^+|}{|\hat{F}^+| + |\hat{F}^-|} = f^+(d),$$

which may be rewritten as

$$\frac{|\hat{F}^+|}{|\hat{F}^-|} = \frac{f^+(d)}{1 - f^+(d)}. \tag{1}$$

The selected strategy will determine whether F^+ or F^- will be resampled to satisfy (1). Using *Under*, for example, $\hat{F}^+$ results from undersampling F^+, while $\hat{F}^- = F^-$. In contrast, using *Over* produces $\hat{F}^-$ from oversampling F^- while $\hat{F}^+ = F^+$. An analogous equation to (1) is used to resample U onto $\hat{U}$.

After the training-set has been resampled, a classifier learnt from the corrected training-set will display an improvement in fairness with respect to a classifier learnt from the original data. An example of the produced PR-correcting functions and their effect over *Income* is shown in Figure 1.

3.3 Finding the Optimal Amount of Sampling

Finally, the third step is to estimate the optimal correction for a specific fairness definition. As classification algorithms usually display non-linear—and sometimes unexpected—behaviours, it is not possible to deduce a closed-form solution to this optimisation problem. Hence, it becomes necessary to numerically approximate a solution.

A naïve approach is to compare the resulting fairness ratios for different values of d, and select the one producing the ratio closest to 1. As we will see on Section 4.2.1, it is easy to find d-values close to the optimal by trial and error, yet this optimal d-value will usually be different for distinct fairness definitions.

A more systematic way to approximate the optimal value of d is to use Bayesian optimisation [16]. This technique estimates the objective function on candidate values obtained from previous function estimations. The main reasons for choosing Bayesian over other optimisation methods are that every fairness ratio evaluation will be different due to the randomness in the sampling process and that Bayesian optimisation is good when estimating the objective function is expensive, e.g. our setting, since we work on large datasets and take the average over many estimations.

We have implemented a simple fairness optimiser using the *GPyOpt* [2] package, with a standard Gaussian process using d as the only parameter and the distances of the different fairness ratios to 1 as objective functions, e.g. estimate the d-value yielding the fairest *DPR* expectation:

$$\arg\min_d |1 - \mathbb{E}[DPR(d)]| \quad \text{subject to} \quad -1 \leq d \leq 1.$$

An example run, used to approximate the optimal correction for Demographic Parity on *Income* may be seen in Figure 2.

3.4 Multiple Protected Attributes

We have generalised ParDS to multi-class PAs, as well as to multiple PA variables. In some cases, this could be addressed by binning several PA labels into just two categories, u and f. However, these arbitrary assignments would imply a loss of granularity in any subsequent fairness analysis. As an alternative, we have chosen to consider a *combined* PA, which may be obtained for every datapoint $p \in$ train as follows:

(1) Evaluate $\mathrm{PR}(D)$ for the training set D.
(2) Define a set of PAs: $\{\mathrm{PA}_1, \mathrm{PA}_2, \ldots, \mathrm{PA}_k\}$.
(3) Evaluate

$$\mathrm{PR}_i(p) = \mathrm{PR}\left(\mathrm{PA}_i(p)\right) - \mathrm{PR}(D)$$

for $i \in \{1, 2, \ldots, k\}$.
(4) Aggregate the partial PRs to obtain a combined value

$$\mathrm{PR}^*(p) = \sum_{i=1}^{k} \mathrm{PR}_i(p).$$

(5) Define the combined PA of p as

$$\mathrm{PA}^*(p) = \begin{cases} F & \text{if } \mathrm{PR}^*(p) > 0, \\ U & \text{if } \mathrm{PR}^*(p) \leq 0. \end{cases}$$

This solution allows for a much more granular approach on determining a datapoint's relative "prosperity" with respect to every PA, as some PA attributes may prove to be more determining of disparate treatment than others, and the effects of several PAs may cancel each other out.

Our experiments, carried out on *Income*, provide positive results, as described next. Figure 3 compares the effects—for unfavoured groups of different PAs (Gender, Nationality, Race and Age)—of applying disparity correction based on a single PA (Gender) to doing it based on a combined PA aggregating Gender, Age, Race and Country for *Income*. As can be seen, when correcting

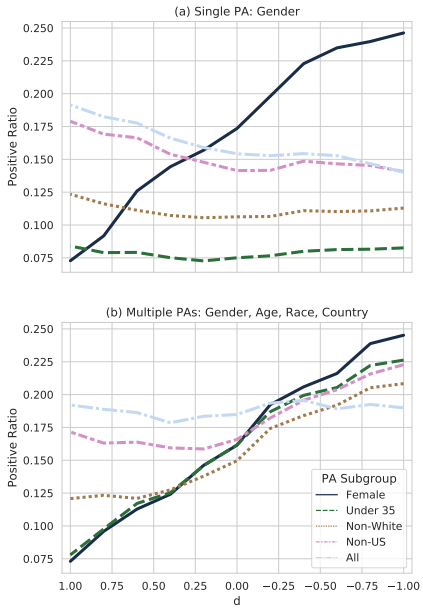

Figure 3: Positive ratios for the different PAs' unfavoured groups on *Income*, correcting for (a) one PA and (b) multiple PAs.

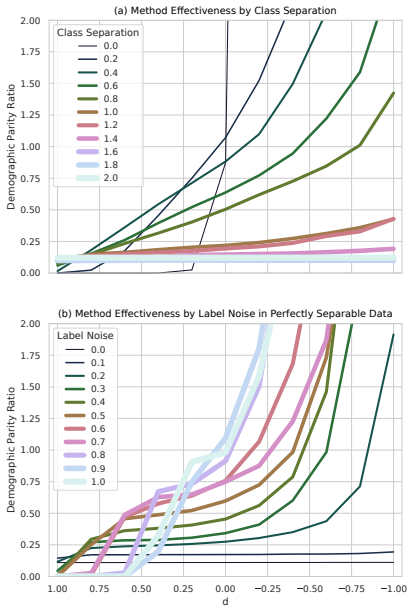

Figure 4: Correction effectiveness by separability. (a): On close-to-linearly separable data, the method becomes highly inefficient, or even stops working at all. (b): Introducing random noise into a separable dataset lets correction become effective again.

for Gender alone, the other unfavoured groups' PR remains relatively constant or gets worse. Likewise, the overall PR shows a drop on its PR as more correction is applied. When correcting for the combined PA, on the other hand, all of the unfavoured PRs improve at a similar rate, whilst the overall PR remains relatively constant across different correction levels. In short, this extension provides ParDS with the capability to correct for multiple biases simultaneously, at the individual level with similar optimal d-values across PAs. This method for combining several PAs into a single combined one, though, is not unique, and could further be improved by adding weights to the different PAs set as hyperparameters by experts.

4 EXPERIMENTAL EVALUATION

This section reports the effectiveness of ParDS regarding separability in Subsection 4.1, comparing sampling strategies and fairness definitions in Subsection 4.2 and benchmarking ParDS with existing fairness-correcting methods, in Subsection 4.3.

4.1 Separability

To verify the effect of separability on ParDS' effectiveness, we created 11 simple datasets, consisting of one continuous feature f and one binary label l. These datasets were created using the *scikit-learn*'s [11] *make_classification* function, with varying levels of class separability s, ranging from 0 (completely mixed up) to 2 (over 95% probability of complete separation). What this function does is sample feature values from normal distributions centered at s and $-s$ for the two classes, respectively. A PA was then randomly added, ensuring a fixed 50/50 proportion of F vs U datapoints, with PRs of 0.9 and 0.1 for F and U, respectively.

As may be seen in Figure 4a, the greater separability data has, the less effective our correcting method becomes (represented by a near-flat demographic parity ratio curve as a function of d). However, adding random noise to a linearly separable dataset (effectively rendering it inseparable again) restores the effectiveness of ParDS. To test this, we created a linearly separable dataset with $s = 2$, and gradually introduced noise through parameter n taking values from 0 to 1, the proportion of randomly-assigned labels. As shown in Figure 4b, this intervention can render fairness correction effective again, even with a small amount of added noise.

4.2 Method Validation

We tested ParDS on three datasets commonly used in ML fairness research literature: *Adult Income (Income)* [12], *COMPAS* [26] and *German Credit* [12].

For every dataset, we performed the following experiment 50 times, and then averaged the results for robustness:

(1) Random train/test split the data with 90/10 proportion.
(2) For Proxy Fairness checking, make two copies of the *test* set T and intervene PA as either U or F, obtaining $T_{\text{PA}=U}$ and $T_{\text{PA}=F}$, respectively.
(3) For each sampling function, obtain 11 training sets, corresponding to $d \in \{1, 0.8, 0.6, \ldots, -1\}$.
(4) For each of these training sets, fit a classifier.
(5) For every model, get predictions for T, $T_{\text{PA}=U}$ and $T_{\text{PA}=F}$.
(6) Compute metrics for accuracy, *DPR*, *EOR* and *PFR*, as well as the model coefficients.

We then proceeded to analyse the resulting fairness metrics, and compared our results with *PS*.

4.2.1 Results. As expected, fairness correction has an impact over a classifier's predictive performance. Figure 5 shows the fairness-accuracy trade-off for the different sampling strategies for the three fairness ratios over *Income*. As may be seen, the trade-off is similar across the different sampling strategies, and the loss in predictive performance for optimal fairness will be definition dependant.

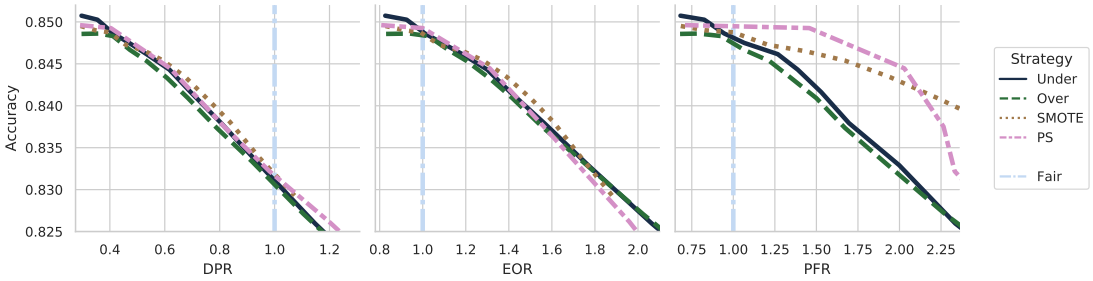

Figure 5: Fairness-accuracy trade-off for *DPR*, *EOR* and *PFR* on *Income*.

Table 1 shows diverse performance metrics for ParDS using the different sampling strategies to correct γ_{sr} on *Income*. The presented means and confidence intervals (CIs) result from 100 independent train/test splits, then using each sampling strategy with the optimal d-value for each estimated through Bayesian optimisation. As may be seen, there is a big difference in computing time across strategies, with *SMOTE* being over 10 times slower than *Under*. On the other hand, *SMOTE* produced the best scores for most performance metrics. Optimal fairness correction was achieved within the CIs for all methods, with roughly the same accuracy loss trade-off. Interestingly, running *Under* before training the classifier was 35% faster than just training the classifier over the full dataset. This would provide an additional advantage for *Under*-corrected training sets when learning models from large-scale datasets.

4.3 Comparison with Other Methods

An intrinsic advantage of ParDS is that it can optimise a classifier with respect to different group fairness definitions. Three definitions: γ_{sr} [5], *discrimination (disc)* [21] and *equalised odds (eOdds)* [19] were used for our comparisons.

Tables 2 and 3 compare ParDS with a variety of *preprocessing* [4, 8, 19, 20, 24, 29], *in-processing* [1, 5, 30–32] and *post-processing* [18] fairness-correcting methods.

Since four different classification algorithms were used on the papers we compared with—AdaBoost (AB), decision trees (DT), Gaussian naïve Bayes (GNB) and logistic regression (LR)—we present ParDS' results using all three of them. We optimised our classifiers to compare with the state-of-the-art methods, hence three of our presented methods are optimised for *DPR* and two are optimised for *eOdds*. We evaluated our metrics using the same classification algorithms as the ones used in the papers we compare with. The objective functions to optimise were $|1 - DPR|$ and $|1 - eOdds|$ for *DPR* and *eOdds*, respectively, with 0 being the best value the objective function may take in both cases.

For every tested d-value we averaged the resulting *DPR* of 50 random 90/10 train/test splits, finding optimal d-values of {0.8338, -0.1803, -1.1528, -0.6083} for AB, DT, GNB and LR, respectively. All of the classifiers were trained using the default scikit-learn hyper-parameter values; using these parameter values, we ran ParDS 10 times and averaged the resulting metrics. The fairness and accuracy metrics for the compared methods refer to the *best* reported values in [5, 19, 20, 29, 32]. Likewise, for methods evaluated on more than one classifier, we present the best one.

Our *eOdds*-optimised AdaBoost classifier produced the best overall accuracy (86%), while showing an *eOdds* value within 3% of the best performing method [24]. Regarding our *DPR* optimised classifiers, although LR performed the best overall, both ParDS' DT and GNB performed better than the other methods' DTs and GNBs, respectively. Interestingly, ParDS' LR produced the fairest classifiers with respect to definitions γ_{sr} and *disc*, even though they were actually optimised for *DPR*. While the accuracy of *DPR*-optimised ParDS LR was not the best (83%), it came within 1% of the best performing classifiers (ParDS' DT, Kamiran and Calders [20] and Zafar et al. [30], with an accuracy of 84%).

5 CONCLUSION

In this paper we define ParDS, a parametrised fairness optimisation method agnostic to both fairness definitions and classification models. Correcting through training set resampling, we have shown that ParDS produces fairness-optimal predictions with a small loss in predictive power. When compared with the existing methods, in most cases ParDS produces the best fairness performance.

In future work we intend to further improve our data resampling methods, in order to optimise for different fairness definitions at once. Although ParDS shows a relatively low impact on prediction performance and its main objective is to estimate the optimal amount of correction with respect to fairness, we would like to find a way to consider predictive performance as well, either in the form of a restriction—e.g. a maximum loss in accuracy or a minimum level of fairness—or by setting an acceptable trade-off rate between both metrics.

Short Paper

Using Landmarks for Explaining Entity Matching Models

Andrea Baraldi, Francesco Del Buono, Matteo Paganelli, Francesco Guerra
UNIMORE-DIEF

firstname.lastname@unimore.it,andrea.baraldi96@unimore.it

ABSTRACT

The state of the art approaches for performing Entity Matching (EM) rely on machine & deep learning models for inferring pairs of matching / non-matching entities. Although the experimental evaluations demonstrate that these approaches are effective, their adoption in real scenarios is limited by the fact that they are difficult to interpret. Explainable AI systems have been recently proposed for complementing deep learning approaches. Their application to the scenario offered by EM is still new and requires to address the specificity of this task, characterized by particular dataset schemas, describing a pair of entities, and imbalanced classes.

This paper introduces Landmark Explanation, a generic and extensible framework that extends the capabilities of a post-hoc perturbation-based explainer over the EM scenario. Landmark Explanation generates perturbations that take advantage of the particular schemas of the EM datasets, thus generating explanations more accurate and more *interesting* for the users than the ones generated by competing approaches.

1 INTRODUCTION

Despite the effort put in the past 30 years, Entity Matching (EM), the task that identifies data items that refer to the same real-world entity, is still an open challenge. State of the art approaches (e.g., DeepER [7], DeepMatcher [12], DITTO [10], and many others [2, 19]), based on Machine Learning (ML) and Deep Learning (DL) models, have been demonstrated to be effective in the experimental datasets. Nevertheless, their adoption in real business scenarios is hampered by several factors, including the need for large amounts of training data, the need for expert users for the configuration of their hyper-parameters and the inability to easily interpret how the models make their decisions.

Explaining the behavior of ML and DL models is now a challenging research topic [5]. Its application to EM could facilitate the adoption of EM techniques in business scenarios. An improved ability to interpret the models would increase 1) user confidence in the adoption of ML and DL techniques, 2) the ability to debug erroneous behaviors and diagnose unexpected results, and 3) improve the functionality of the approaches. Moreover, it would decrease the need for domain experts to evaluate the effectiveness of EM approaches, task that is typically executed through manual, expensive, and time-consuming processes.

Although several explanation systems have already been proposed in the literature (e.g., LIME [14], Shapley [8], Anchor [15], and Skater[1]) , their application to EM tasks is not straightforward and only few approaches have partially addressed it [4, 6, 11, 17].

Figure 1: Example of EM record to explain.

The main motivation is that EM is conceived by ML and DL systems as a binary classification problem, where the class shows if the pairs of entities described in the dataset records are matching, and the dataset entry is composed of pairs of attributes describing the same feature of different entities. This structure is "unusual" in ML and DL, where the records conversely describe single evidence. Moreover, the datasets are usually imbalanced: the number of records belonging to the matching class is far less than the non matching ones. Finally, the attributes describing the same features of different entities have close statistical distributions (or close word distributions in case of categorical attributes) even when they refer to different entities.

In this paper, we present Landmark Explanation a system for explaining EM model predictions, that extends the capabilities of a post-hoc perturbation-based local explainer over this specific scenario. Post-hoc perturbation-based explainers analyze the records to explain and build a surrogate linear model where the features are the tokens (e.g., the words in case of textual attributes) composing the attribute values. The explanation is directly generated from the surrogate model: its linear coefficients represent the importance of the tokens. This model is trained with synthetic data, generated via a two-step approach where the values of the records to explain are properly altered (in the perturbation phase) and then passed to the original model to get their class (in the reconstruction phase).

Example 1.1. Figure 1 shows an example of a record describing a pair of entities. A suffix is added to the attribute names to show which entity they are describing. The application of a DL based model to the record (e.g. DeepMatcher) let us know that the entities in the record do not refer to the same real-world entity. This is evident for a human person, being clear from the attributes that the left entity is a digital camera and the right entity is a leather case. But the EM model is not able to explain the reasons for its choice. This is the task for an explainer which takes the record to explain, transforms it into tokens (we create a token for each space-separated term), generates a number of perturbations (typically performed by casually dropping tokens), passes each perturbation to the model to get the class, and exploits the so generated dataset to train a linear model. The coefficients associated to the linear model are the ones explaining the behavior of the EM model on the target record. The tokens `sony`, `lens`, `dsira200w` can be considered by an explainer as an evidence of the fact that the record is describing a non-matching entity.

The direct application of a perturbation mechanism based on token removals is not effective for the dataset used in EM. The reason is that removing random tokens is likely to affect both the

entities represented by the dataset item. The generated synthetic records may then contain *null perturbations* where the same tokens referring to the different entities are removed. Moreover, since the EM datasets are largely imbalanced, perturbations frequently lead to records belonging to the non-matching class. To solve this issue, Mojito [4] introduces the "COPY" perturbation mechanism, where attribute values describing one of the entities in a record are substituted to the corresponding attribute values of the second entity. The aim is to introduce a perturbation that increases the match probability between pairs of entities. The aim is to create records representing matching entities. But duplicating entire attribute values does not allow the approach to discriminate among the tokens that, thanks to the copy, will provide the same contribution in the explanation.

Landmark Explanation addresses these issues by introducing two main innovations. The first is the generation of two explanations for each dataset entry, each one explaining the model decision from the perspective of one of the two entities described in the record. These explanations are generated by selecting one of the entities constituting a dataset entry in turn as a landmark. The landmark is preserved from the perturbation, which is subjected to the other entity (the varying entity). The second is a mechanism for computing explanations for records belonging to non-matching classes. Before the perturbation, we inject additional tokens extracted from the landmark entity into the varying entity. The perturbation of the varying entity with injected tokens produces a set of synthetic entities. These will all be concatenated with the landmark entity to generate the synthetic EM dataset used to train the surrogate model. The idea is to contrast the asymmetric nature of the problem: an explanation of a matching pair is always composed of "interesting" tokens since they express the reason why the entities have been considered as matching. The same does not happen for non-matching entities, since non-matching entities have many reasons to be different. So it is difficult to generate an explanation with interesting tokens for non-matching pairs. Therefore the problem is to generate the most interesting explanations. These are the ones involving tokens from one entity that if used to describe the second entity would have brought the EM model to classify the record as matching. Thanks to the injection described above non-matching pairs are pushed to be match and the resulting explanation will be more interesting.

Example 1.2. To explain the inference of an EM model applied to the record in Figure 1 , Landmark Explanation generates two explanations. The top 3 tokens generated by the explanation with the left entity as a landmark are *leather*, *nikon* and *5811*. These tokens are the ones that best differentiate entities. This means that if the left entity were described by these tokens, the record would probably be classified in the matching class by the EM model. The top 3 tokens generated by the second explanation with the right entity as a landmark are *dsira200w*, *lens* and *849.99*.

We evaluate Landmark Explanation coupled with LIME. The results of the experiments show that the explanations generated outperform the ones of the competing approaches in accuracy and "interest" for the users.

Summarizing, the main contributions of this paper are: (1) the introduction of Landmark Explanation, a tool that extends the capability of a generic post-hoc perturbation-based explainer to generate accurate local explanations of EM models; (2) the realization of an extensive experimentation of Landmark Explanation coupled with the LIME explainer [14] to demonstrate the effectiveness and the quality of the approach in comparison with different competitor systems.

The rest of the paper is organized as follows. Section 2 introduces some related work. Section 3 introduces our approach that is evaluated in Section 4. Finally, in Section 5 we sketch out conclusion and future work.

2 RELATED WORK

Explaining AI. The interpretation of machine learning techniques represents a hot topic and two main approaches for its resolution can be identified [5]. On the one hand, there are intrinsically interpretable models, such as decision trees, rule-based and linear models, which rely on structures that can be directly interpreted by humans. On the other hand, there are techniques that analyze the behavior of black-box machine learning methods via a second intermediate model built from the first. These post-hoc interpretation methods are model-agnostic (i.e. they are applicable to any ML / DL model), however they provide less faithful explanations than intrinsically interpretable models.

Regardless of the explanation technique adopted, it is further possible to distinguish between global and local interpretations [5]. In the first case, the entire functioning of an ML / DL model is examined, while in the second its behavior is studied only locally (i.e. by explaining its logic on individual predictions).

The main exponent of the category of local post-hoc interpretation techniques is LIME [14], which exploits an interpretable linear surrogate model (e.g. Lasso) to evaluate the behavior of the original model in the neighborhood of a specific data instance. It will be used in our experiments, and an extension of it is Anchor [15], which generates explanations based on if-then rules. Some examples of global explanation systems are BRL [9] and Skater[2]. Similar techniques are *permutation feature importance* and *drop-column importance* [1], which can be used to detect the global relevance of features in any model.

In this paper we focus exclusively on local post-hoc interpretation techniques (for simplicity in the rest of the paper they will also be identified as generic "explanation systems") and we propose their adaptation, through Landmark Explanation, to the Entity Matching problem.

Explainable Entity Matching. Entity matching, that is the task that identifies the records that refer to the same real-world entity in multiple datasets, represents one of the main steps of data integration and has been under study for several years. Many techniques have been proposed: from the more traditional rule-based approaches to the most modern machine learning and deep learning methods. Some examples of the first category are [16, 18]. They are intrinsically interpretable, however, the identification of the most effective set of matching rules is a complex and non-trivial task [13].

Recently, several approaches based on Deep Learning have proved particularly effective in solving this task. Some examples are DeepER [7], DeepMatcher [12], DITTO [10] and many others [2, 19]. In addition to requiring a significant amount of annotated data and a complex configuration, the main problem with these systems is the inability to interpret their behavior, affecting their usability in business environments [3].

This motivated the realization of several studies on the use of interpretation techniques in the entity matching area [11, 17], and

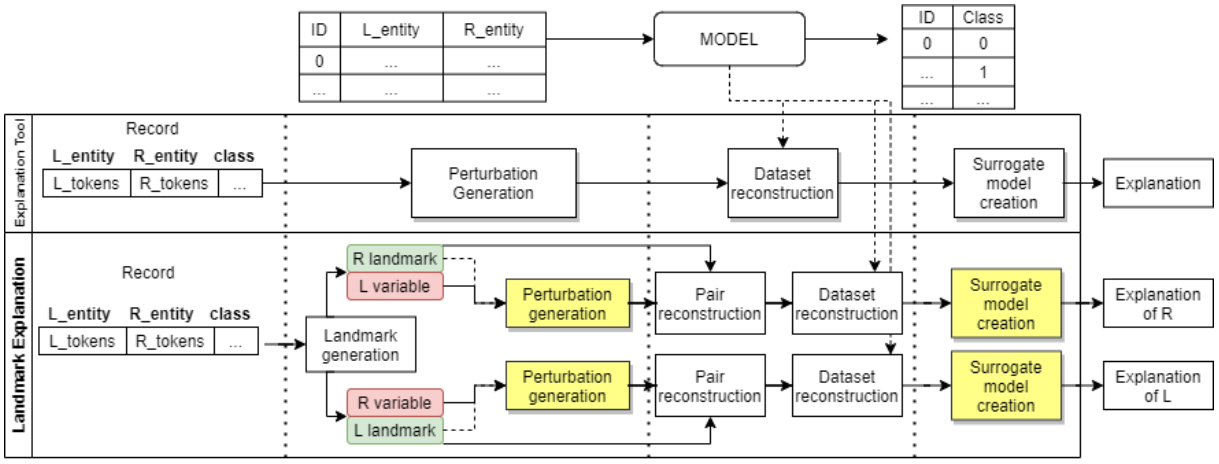

Figure 2: A generic post-hoc perturbation based explanation system (at the top of the image) compared with its extension with the Landmark Explanation **Framework (at the bottom).**

tools, like Mojito [4] and Explainer [6], have been proposed. ExplainER provides a unified interface for applying well-known interpretation techniques (e.g., LIME, Shapley, Anchor, and Skater) in the EM scenario. Mojito adapts LIME for the explanation of single EM predictions and represents the work closer to our approach. It extends LIME in two ways: 1) it exploits the subdivision of EM data into attributes, 2) it introduces a new form of data perturbation, called LIME-COPY[3], which allows generating match elements starting from non-match elements. Unlike Landmark Explanation, Mojito treats attributes atomically, distributing its impact equally to its constituent tokens. Furthermore, Landmark Explanation analyzes the diversified impact that the same token can generate depending on the entity considered as a landmark for the explanation.

3 THE LANDMARK EXPLANATION APPROACH

Landmark Explanation is a generic and extensible framework that can extend a generic local post-hoc and model-agnostic perturbation based explanation systems to the interpretation of EM model predictions. The main assumption of these generic systems is that the prediction of a model computed on a given instance can be approximated by a linear function of the predictions calculated in the neighborhood of that input instance. Their functional architecture is shown at the top of Figure 2 and can be schematized in 3 main blocks: the component for the *Perturbation generation*, for the *Dataset reconstruction* and for the *Surrogate Model Creation*.

The *Perturbation generation* component takes the record to analyze as input and generates a number of perturbations from it. These perturbations constitute a new features space, defined in the neighborhood of the record, which, once integrated by the *Dataset reconstruction* component with the predictions of the original model, can be used by the *Surrogate Model creation* component to infer its behavior in the locality of the record.

Landmark Explanation extends the generic explanation system to improve its effectiveness on datasets representing EMs. In particular, as shown at the bottom, of Figure 2, Landmark Explanation adds the *Landmark generation* component before the perturbation. This component generates for the record to explain two representations, where only one of the two entities composing the item will be subject to the perturbation and the other one will be kept fixed as a landmark. This constitutes the input for the *Perturbation generation* component that will be called twice, once for each representation. In this way, each perturbation obtained with this process will involve the attributes of one entity. The tokens of the second entity (the landmark entity) will be added by the *Pair reconstruction* component before the *Dataset reconstruction*. This allows Landmark Explanation to perturb the information of one entity at a time while preserving the pairwise structure of the EM data. A perturbation of the input entity pair is generated by varying only one of the two entities while preserving the pairwise structure of the EM data.

Note that the component performs differently when the record to explain is referring to a non-matching class. In this case, the tokens of both entities are concatenated into the varying entity and passed to the *Perturbation generation* component. The behavior of the *Pair reconstruction* component does not change, by concatenating after the perturbation the contribution of the landmark entity. This mechanism has been implemented to contrast the dataset imbalance and to generate explanations that can be more interesting for the users since based on a richer set of tokens. Finally, as for the generic explanation system, the synthetic dataset just created is used to train a linear model whose coefficients constitutes the explanation. These coefficients can be positive or negative thus indicating which tokens should be added (the one with a positive score) and which should be removed (the one with negative score) to create a description that is closed to the reference entity.

The yellow-shadowed components in the Figure are the ones provided by the explanation system we are extending. In our experiments, these components are provided by the LIME explainer. Since Landmark Explanation conceives them as black box modules, other explanations systems can be easily coupled with our approach.

3.1 Landmark Explanation components

Landmark Explanation is composed of three main components for the *Landmark generation*, the *Pairs reconstruction* and the *Dataset reconstruction*.

Landmark generation component. The goal of this component is to generate input for the *Perturbation generation* component. A

[3]In Section 4 we refer to this technique as Mojito Copy to emphasize that this technique is part of the Mojito tool.

Table 1: Magellan Benchmark

Tokenizer is firstly needed to transform the dataset entry in a format suitable for generating meaningful explanation. We implement a tokenization mechanism similar to the one adopted in other systems as Mojito [4] that preserves the structure of the pair of entities described in the record. A token is generated for each space-separated term in the attribute values. A prefix is introduced to each token to indicate the attribute where the original value is located in the entity schema. The prefix enumerates the tokens, to manage multiple occurrences of the same word in an attribute value.

After the tokenization, Landmark Explanation implements two mechanisms for performing this task. With the *single-entity generation*, the tokens composing the entities are separated and the perturbation component is called twice, each time with the element of a different entity. The output for each execution are the tokens of one entity (the landmark) and a number of perturbations for the second entity. This technique generates a perturbation that highlights the differences of one entity with respect to the other. It is then particularly effective when the record to explain is belonging to the matching class.

With the *double-entity generation*, the perturbation component receives as input the tokens of an artificial entity created by concatenating, for each attribute, the tokens of both the entities. The output for each execution are then the tokens of one entity (the landmark) and a number of perturbations of the artificial entity created by the concatenation. The idea of this technique is to generate the perturbation of a more extensive set of tokens (obtained by the union of the tokens of both the entities) that is effective for generating explanations for records classified as non-matching items.

Pair reconstruction component. The component receives as input the landmark entity and a number of perturbations of the tokens of the varying entity and "reconstructs" the corresponding pairs of entities (one for each perturbation). The prefixes introduced by the *Tokenizer* are exploited for this purpose and removed from the generated records.

Dataset reconstruction component. This component generates the synthetic dataset to be used for training the surrogate linear model. This is obtained by passing each pair of entities reconstructed by the previous component to the original EM model for getting the predicted class.

4 EXPERIMENTAL EVALUATION

We evaluated the explanations generated by Landmark Explanation according to two main perspectives: their reliability in representing the EM Model (in Section 4.2) and the "quality" of the explanation provided (in Section 4.3).

Table 2: Token-based evaluation.

4.1 Experimental setup

We run the experiments on a VM deployed on Google Cloud with 12 GB of RAM, GPU K80, and Intel(R) Xeon(R) CPU @ 2.30GHz.

Dataset and Model. The EM model explained in the experiments is a Logistic Regression Classifier. We experimented Landmark Explanation against the datasets provided by the Magellan library[4] which is considered as a standard benchmark for the evaluation of EM tasks. The datasets are listed in Table1, where the size and the percentage of records representing matching entities are shown. The records in all datasets represent pairs of entities described with the same attributes. A label is provided to express if the record represents a matching / non-matching pair of entities. In the experiments, we sampled 100 records per label and we computed their explanations. Note that all records are sampled when the dataset contains less than 100 records (see for example the dataset S-BR which contains only 68 records labeled as matching entity).

4.2 Reliability of the explanations

The goal of the experiment is to evaluate the reliability of the explanations generated by Landmark Explanation in interpreting the behavior of an EM model through single predictions. An explanation is considered reliable if it is able to consistently recognize the importance of the features with the EM model. To evaluate this, we performed two kinds of experiments, one analyzing the weights assigned by Landmark Explanation to the *tokens* it generates, the second the weights assigned by the EM model to the dataset *attributes*.

4.2.1 Token-based evaluation. Through this first kind of experiment, we evaluate if the weights assigned by Landmark Explanation to the tokens generate a surrogate model consistent with the EM model. We performed an experiment that is similar

[4]https://github.com/anhaidgroup/deepmatcher/blob/master/Datasets.md

to the one proposed in the evaluation of LIME: 25% of tokens are randomly selected and removed from the record to explain, defining a new item. We then compared the probability score obtained passing the new item to the EM model with the one of the original record, where we have subtracted the sum of the coefficients associated with the removed tokens. If the explanation model correctly represents the EM model these two values should be close. We repeated the experiment 100 times for each class (see the beginning of Section 4), and we measured the performance obtained by means of two metrics: the mean average error (MAE) and the accuracy on the predicted class. We performed the experiments for all datasets and testing all techniques for generating the perturbations as reported in Table 2. Note that column LIME shows the results obtained with LIME / Mojito Drop[5] with the same setting. Non-matching settings also include a comparison with the Mojito Copy technique, which has been designed for this kind of record.

Discussion. Table 2a shows that Landmark Explanation, applied to records labeled as matching entity, performs better than LIME in the datasets when the perturbation is generated with the single-entity technique (it obtains better accuracy in all datasets and low MAE in 11/12 datasets). The double-entity generation technique performs slightly worse: in 9/12 it obtains better accuracy and in 6/12 lower MAE). Nevertheless, the scores, when worst, are very close to LIME. Note that in some datasets there is some small contradiction between accuracy and MAE scores computed for the same dataset. For example, we observe that Landmark Explanation applied to the S-BR dataset with the double-generation configuration has a better MAE score than LIME/Mojito Drop. This is not the same for the accuracy value, where LIME performs better. This is motivated by the fact that the probability scores generated by the model are close to the decision threshold (fixed to 0.5). Then, small fluctuations in the surrogate model can generate mismatches in the class predicted by the explained model for the records, even if the EM model and the surrogate model are very close. Table 2b shows the accuracy and the MAE obtained analyzing records referring to non-matching labels. In this scenario, the double entity perturbation obtains the best scores with an accuracy better than LIME/Mojito Drop in 4/12 datasets and a lower MAE in 10/12 datasets. The reason is due to the effect of the duplicated tokens inserted in the dataset used for training the surrogate model. These tokens, being similar to the ones of the entities described in the record, push the EM model to classify the record towards a matching label even in the case of an imbalanced dataset. By using the same tokens, the entities will likely be considered by the model as similar. Conversely, the perturbations generated by LIME / Mojito drop are subsets of the original record, which, in this case, was classified as non-match. By removing tokens from descriptions of entities classified as non-matching, the probability score of the EM model usually decreases and it is unlikely to obtain descriptions of entities that a classifier evaluates as matching. If we pushed the decision threshold to 0.4 (instead of 0.5), Landmark Explanation would obtain a better performance than LIME/Mojito drop in 10/12 datasets.

Note that the copying technique introduced by Mojito to manage records associated with non-matching labels does not show high performance. The reason is that Mojito generates a perturbation by duplicating entire attributes.

The result of this operation is that the tokens of the replaced attribute have the same weights, thus decreasing the performance.

[5]the Mojito Drop technique implements the LIME approach

(a) Matching label.

	Single	Double	LIME

D-DG	**1.000**	**1.000**	**1.000**	0.813
D-WA	0.681	0.681	0.681	0.681

Table 3: Attribute-based evaluation (weighted Kendall measure applied on the ranked list of attributed as generated by the EM and the surrogate model).

Lesson learned. The surrogate model built by Landmark Explanation with the single-entity perturbation is an accurate representation of the EM model for records representing matching pairs of entities. The model built with the double-entity perturbation is an accurate representation of the EM model for record representing non-matching pairs of entities.

4.2.2 Attribute-based evaluation. The attribute-based evaluation proceeds in the opposite direction: it starts from the internal structure of the EM model and evaluates if the weights it gives to the attributes are close to the ones we can derive from the tokens obtained by Landmark Explanation. For this reason, we have analyzed the weights given to the dataset attributes by the Logistic Regression model used as EM model in the experiments and ranked the attributes according to their absolute values. We have done a similar operation with the surrogate model, where the weights of the attributes have been computed by summing the absolute weights of their composing tokens. The idea is that the order of the attributes computed on the basis of their weights should be the same in both models. In Table 3, we measured the correlation computed by applying the weighted Kendall tau correlation measure, between the ranked list of attributes of the EM and surrogate model.

Discussion. Table 3a shows the experiments on the records representing matching entity pairs. The correlation scores achieved by Landmark Explanation with the double-entity perturbation approach are better or equal to the ones achieved by LIME/Mojito for all dataset. Table 3b shows the experiments on the records representing non-matching entity pairs. In this case, the single-entity configuration obtained better/equal results than LIME/Mojito Drop in 7/12 datasets (4/12 against Mojito Copy); the double-entity configuration obtained better/equal results than LIME/Mojito drop in 9/12 datasets (the same against Mojito Copy). Note that Mojito Copy, that has been explicitly designed for non-matching entities, performs better than LIME/Mojito Drop in 5/12 datasets only and equal/close to LIME/Mojito Drop in 4/12 datasets and worst in the remaining 3 datasets.

Lesson learned. Landmark Explanation creates surrogate models that maintain a relative importance of the attributes similar to the ones of the EM model to explain.

4.3 Quality of the explanations

To introduce this experiment, let us consider an application that aims to provide the explanation for a record labeled as a non-matching entity. The tokens of non-matching are "less polarized":

(a) Matching label.

	Single	Double	LIME
S-BR	0.643	0.593	**0.686**
S-IA	0.652	0.404	**0.702**
S-FZ	0.606	0.447	**0.612**
S-DA	**1.000**	0.940	0.965
S-DG	0.660	0.610	**0.925**
S-AG	0.955	0.800	**0.990**
S-WA	**1.000**	0.785	0.870
T-AB	0.985	0.575	**0.995**
D-IA	**0.561**	0.278	0.311
D-DA	0.695	0.715	**0.800**
D-DG	0.635	0.530	**0.735**
D-WA	**0.915**	0.545	0.880

(b) Non-matching label.

	Single	Double	LIME	Mojito Copy
S-BR	0.298	**0.927**	0.331	0.011
S-IA	0.545	**0.736**	0.393	0.000
S-FZ	0.079	**0.853**	0.047	0.000
S-DA	0.000	0.030	0.000	0.005
S-DG	0.020	**0.545**	0.020	0.000
S-AG	0.075	**0.895**	0.070	0.010
S-WA	0.015	**0.955**	0.000	0.000
T-AB	0.305	**0.680**	0.340	0.045
D-IA	**0.670**	0.291	0.379	0.027
D-DA	0.205	**0.300**	0.125	0.000
D-DG	0.200	**0.375**	0.160	0.030
D-WA	0.190	**0.785**	0.130	0.005

Table 4: Evaluation of the interest associated to the computed explanations.

there are many reasons to be dissimilar for two entities. For this reason, it is easy for this application to say why two entities do not match, since there is plenty of tokens that do not match between the entities in the record. Nevertheless, the explanation would be more interesting if the tokens returned would be the ones changing class of the record from non-matching to matching. In other words, we claim that an interesting explanation for non-matching entities should return the tokens that, if shared by the second entity, would make the record classified as matching.

In this section, we describe the evaluations we performed to evaluate the aforementioned situation. The experiments are similar to the first experiments described in Section 4.2, but in this case we select the tokens to remove. For sake of completeness, we performed a similar experiment with records classified as matches even if this evaluation is less meaningful. When the record is associated with a matching label, we remove all positive tokens (all tokens that contribute to the decision). The negative tokens are removed when the label represents a non-matching record. In Table 4 to evaluate the experiment we measure the *interest*, which is the accuracy computed on the records where the removal of the tokens was able to generate a change in the label.

Discussion. Table 4a shows that Landmark Explanation is good but slightly worse than LIME in terms of interest, when the records are labeled as matching class. This happens even if the surrogate model is really accurate (the MAE score is the lowest for all experiments with the single-entity configuration). The problem is that in most of the cases, even removing all tokens, the explanation created by Landmark Explanation belongs to the same class as before the token removal. Note that if we set a decision threshold to 0.4, our approach has the best results in all datasets. Table 4b shows that the explanations of non-matching entities generated by Landmark Explanation in the setting double-entity outperform the ones of Lime/Mojito Drop and Mojito Copy.

Lesson learned. Landmark Explanation generates interesting explanations, and the perturbation made with the double-entity generation technique effectively increases "the interest" of non-matching record explanations.

5 CONCLUSION

This paper introduces Landmark Explanation a tool that makes a post-hoc perturbation-based explainer able to deal with ML and DL models describing EM datasets. The approach has been experimented coupled with the LIME explainer, which is one of the most used state of the art approaches. The results show that the explanations generated by Landmark Explanation outperform the ones generated by the competing approaches in accuracy. Moreover, the explanations generated by Landmark Explanation have been experimented to be "more interesting" for the users.

Future work includes the study of techniques for summarizing the explanations to facilitate the interpretation of the EM model as an whole.

ABSTRACT

Anomaly detection in time series is a widely studied issue in many areas. Anomalies can be detected using rule-based approaches and human-interpretable rules for anomaly detection refer to rules presented in a format that is intelligible to analysts. Learning these rules is a challenge but only a few works address the issue of detecting different types of anomalies in time-series. This paper presents an extended decision tree based on patterns to generate a minimized set of human comprehensible rules for anomaly detection in univariate times-series. This method uses Bayesian optimization to avoid manual tuning of hyper-parameters. We define a quality measure to evaluate both the accuracy and the intelligibility of the produced rules. Experiments show that our approach generates rules that outperforms the state of- the-art anomaly detection techniques.

1 INTRODUCTION

Anomaly detection in time series is a widely studied issue in many areas such as financial markets, sensor networks, habitat monitoring, network intrusion, web traffic [1], and many others. Time series are often affected by unusual events or untimely changes (e.g., measurement error or faulty sensors) that need to be detected and processed by users for analysis and exploration [7].

In a real context, experts may observe some interesting local phenomena, which can be seen as remarkable points in time series. Using their domain knowledge, the experts investigate sequences of remarkable points to detect and locate anomalies. Experts can also build decision rules manually to detect future occurrences of these anomalies. However, as the amount of collected data is increasing, the decision rules become more complex to define which makes the analysis more difficult. Automatic rule extraction and detection of different types of anomalies can be of considerable interest to an expert, leading to appropriate action that can save a lot of time and value. To overcome this challenge, rule learning algorithms have been proposed [2, 12]. Deploying such systems might reveal comprehensible information to the users to explain the root cause of anomalies better than black-box algorithms.

To address these challenges, we provide a machine learning method to generate human-interpretable rules for anomaly detection in time-series, called Composition-based Decision Tree (CDT) [1]. This method uses patterns to identify remarkable points. The compositions of remarkable points existing into time-series are learned through a specific decision tree that finally produces intelligible rules. To avoid manual tuning, we use Bayesian hyper-parameter optimization to get the best hyper-parameters for our model. The approach aims at finding the best compromise between a high accuracy during anomaly detection and a minimized set of easily human-interpretable rules. We conduct experiments on three real-world datasets and three synthetic datasets. The results show the effectiveness of our method compared to both pattern-based methods and rule-based methods for anomaly detection.

2 RELATED WORK

Numerous works on anomaly detection in time-series had been covered under various surveys and reviews [3, 13]. Several fields of study are related to pattern-based time-series data mining and rule-learning methods for anomaly detection. Pattern-based methods aim to discover frequent [4, 5] or infrequent sub-sequences [16] from a time-series. In contrast to our method, these methods are less suitable for detecting multiple anomalies and can only find a specific type of anomaly. Rule-learning methods aim to find regularities in data that can be expressed in the form of IF-THEN-like rules [2, 9, 11]. In general, the rules are evaluated based on accuracy or the number of rules produced by these algorithms. In this paper, instead of only evaluating the rules based on these criteria, we introduce a quality measure, which takes into account the number of used patterns as well as the length of rules, to make the rules simpler to interpret. We also propose a function that seeks a compromise between the interpretability of the rules and their precision.

3 METHODOLOGY

In this section, we describe our Composition-based Decision Tree (CDT) method for anomaly detection and rule extraction.

3.1 Time-Series Preprocessing

Definition 1. An univariate *time-series* is defined as $Ts = \{x_1, ..., x_n\}$ where $\forall i \in [1..n], x_i \in \mathbb{R}$ such that values x_i are uniformly spaced in time and n is the size of Ts.

The time series are collected from different sensors and the values of measures are on different ranges. To achieve scale and offset invariance, we normalize each continuous time-series Ts to values within the range $[0, 1]$. Resampling could also be used to provide additional structure or to smooth time series and remove

[1] https://github.com/IBK-TLS/CDT

any noise; e.g., downsampling reduces the frequency of time-series observations.

3.2 Time-Series Labeling

To detect anomalies, experts first analyze the neighborhood of a point (unusual variations) such as the point which precedes it and follows it to decide if is a remarkable point. Based on this idea, we label each point of the time series by checking every three successive points using patterns.

Let us considers three successive points such as x_{i-1}, x_i, x_{i+1} of a time-series. Considering all possible variations between these three points, we define nine possible variations, which can occur between successive points, as listed in Table 1 namely, PP (Positive Peak), PN (Negative Peak), SCP (Start Constant Positive), SCN (Start Constant Negative), ECP (End Constant Positive), ECN (End Constant Negative), CST (Constant), VP (Variation Positive) and VN (Variation Negative). Each of these variations can have different magnitudes into [-1,1]. To identify fine variations of values between three points, we refine each variation by defining intervals of variations into [-1,1].

Hyper-parameter (δ). We denote δ the hyper-parameter used to distinguish the different magnitudes considered for each of the nine variations (PP, PN, SCP, SCN, ECP ECN, CP, VN, and CST). δ allows the introduction of fine amplitude shifts in the variations to capture the shape complexity in time-series, typically small or large amplitudes. δ represents the number of disjointed sub-intervals considered in [-1,1] and will be determined automatically using Bayesian optimization. For a given δ, we construct $2\delta+1$ intervals : i) δ sub-intervals for positive variations in $]0,1]$, ii) δ intervals for negative variations in $[-1,0[$, and iii) 1 special case for the absence of variation (equal to 0).

For the sake of simplicity, in the rest of the paper, we only consider notation with $\delta = 2$ (other values of δ will only result in a larger variety of intervals and patterns), and we denote the 5 resulting intervals as follows: Low (L) =]0,0.5], High (H) =]0.5,1], -Low (-L) = [-0.5,0[, -High (-H) = [-1,-0.5[, and the special case, Zero (Z) = 0.

Definition 2. We define a *pattern* annotated $P = (l, \alpha, \beta)$ where l is a name (or label) identifying the pattern, and α and β are two possible intervals from [-1,1]. For each successive points x_{i-1}, x_i, x_{i+1}, the point x_i is checked by a pattern only if $x_i - x_{i-1} \in \alpha \wedge x_i - x_{i+1} \in \beta$. In this case, x_i is labeled with l. For the rest of the paper, labels are denoted by the name of the variation (PP, PN, etc.).

Fig. 1 (left) illustrates an example of a pattern $PP_{L,H}$ that helps us to find one remarkable point from a time-series. This time-series represents the consumption data of a building's calorie sensor. Fig. 1 (right) shows examples of different magnitudes of pattern such as $PP_{L,H}$, $PP_{L,L}$ and $PP_{H,H}$. Using these patterns, we can automatically label each point in time series.

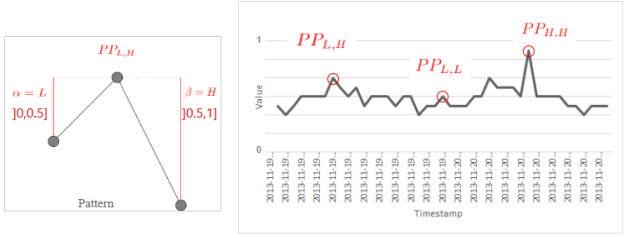

Figure 1: Example of different magnitudes of a pattern.

Definition 3. A *labeled times-series* annotated $Tsb = \{l_1, ..., l_N\}$ with $N = n - 2$ where each x_i point of the initial time-series (Ts) is replaced by the label of its corresponding pattern.

Table 1: Types of variation for labelling.

Variation	Definition	Pattern	Example
PP	$x_{i-1} < x_i \wedge x_i > x_{i+1}$		
	$\alpha, \beta \in \{L, H\}$	$PP_{\alpha,\beta}$	$PP_{L,H}$
PN	$x_{i-1} > x_i \wedge x_i < x_{i+1}$		
	$\alpha, \beta \in \{-L, -H\}$	$PN_{\alpha,\beta}$	$PN_{-H,-H}$
SCN	$x_{i-1} > x_i \wedge x_i = x_{i+1}$		
	$\beta \in \{Z\}$ $\alpha \in \{-L, -H\}$	$SCN_{\alpha,\beta}$	$SCN_{-L,0}$
SCP	$x_{i-1} < x_i \wedge x_i = x_{i+1}$		
	$\beta \in \{Z\}$ $\alpha \in \{L, H\}$	$SCP_{\alpha,\beta}$	$SCP_{H,0}$
ECN	$x_{i-1} = x_i \wedge x_i > x_{i+1}$		
	$\alpha \in \{Z\}$ $\beta \in \{L, H\}$	$ECN_{\alpha,\beta}$	$ECN_{0,L}$
ECP	$x_{i-1} = x_i \wedge x_i < x_{i+1}$		
	$\alpha \in \{Z\}$ $\beta \in \{-L, -H\}$	$ECP_{\alpha,\beta}$	$ECP_{0,-L}$
CST	$x_{i-1} = x_i \wedge x_i = x_{i+1}$		
	$\alpha, \beta \in \{Z\}$	$CST_{\alpha,\beta}$	$CST_{0,0}$
VP	$x_{i-1} < x_i \wedge x_i < x_{i+1}$		
	$\alpha \in \{L, H\}$ $\beta \in \{-L, -H\}$	$VP_{\alpha,\beta}$	$VP_{L,-L}$
VN	$x_{i-1} > x_i \wedge x_i > x_{i+1}$		
	$\alpha \in \{-L, -H\}$ $\beta \in \{L, H\}$	$VN_{\alpha,\beta}$	$VN_{-L,L}$

3.3 Composition-based Decision Tree

Given the time series labeling, we built an extension of the decision tree based on pattern compositions to produce rules able to detect anomalies.

Classically, a decision tree is induced from observations composed of feature values and a class label. It is built by splitting the training data into subsets by choosing the feature which best partitions the training data according to an evaluation criterion (e.g., Shannon's entropy, Gini index). This criterion characterizes the homogeneity of the subsets obtained by division of the data set. This process is recursively repeated on each derived subset until all instances in a subset belong to the same class label [10].

The classical decision tree considers features without any order when splitting the datasets. Conversely, in our approach, we would like to keep the order of the time series. Thus, our decision tree is built, by considering nodes as pattern compositions (ordered sequences of remarkable points) with the highest information gain. These compositions are calculated from a set of observations (sub-sequences of labeled time-series). The input of the tree is constructed by creating fixed sized sliding windows.

Definition 4. A *set of observations* annotated $D = \{d_1, d_2, ..., d_{N-\omega+1}\} = \{\{l_1, ..., l_\omega\}, \{l_2, ..., l_{\omega+1}\}, ..., \{l_{N-\omega+1}, ..., l_N\}\}$ represents the result of cutting Tsb by a sliding window of size ω, and using a fixed step size equal to one. Let M be the number of classes of observations. In our context, we consider two classes (M = 2): the abnormal class (observation with anomaly), or the normal class (observation without anomaly). Each d_i observation is associated with only one class annotated $class(d_i)$.

To determine a probability distribution of the observations over the classes, we introduce an impurity measure of a set of observations $D_j \subseteq D$. In our method, we opt to the Gini index. The *Gini impurity index*, annotated $G(D_j)$, provides a measure of the quality of D_j according to the distribution of the observations into the classes. The impurity metric is minimal (equal to 0) if a set contains only observations of one class, and it is maximal (equal to 0.5) if the set contains equally observations of all classes.

Hyper-parameter (ω). We denote $\omega <= N/2$ the window size to define observations. This hyper-parameter will be determined automatically using Bayesian optimization.

From an *observation with anomaly* we can define a composition used to split a node into two sub-nodes.

Definition 5. A *composition* annotated c is a sub-sequence of labels of an observation d_i. We denote $c \subseteq_o d_i$.

Example. Considering $d = \{l_1, l_2, l_3, l_4, l_5, l_6\}$, some compositions are $c = \{l_2, l_3, l_4\} \subseteq_o d$, $c = \{l_3, l_2, l_4\} \not\subseteq_o d$, and $c = \{l_1, l_2, l_3, l_4, l_5, l_6\} \subseteq_o d$.
We also introduce additional notations: $c \in_o D$ when $\forall d \in D, c \subseteq_o d$, and $c \notin_o D$ when $\forall d \in D, c \not\subseteq_o d$.

A decision tree is built based on features that have the highest Information Gain [10]. In CDT, the compositions are compared according to the information gain, noted IG, they provide.

The entire flow of the CDT approach we proposed is described by Algorithm 1. This algorithm builds a decision tree; we define a tree node as a quadruplet: *observations* (the set of observations considered in this node), a *composition* (used to split *observations* in two child nodes), *childTrue* (the node of observations satisfying the *composition*), and *childFalse* (the node of observations that do not satisfy the *composition*). An example corresponding to the root node is given in line 1. We introduce a function $list\_of\_all\_possible\_compositions()$ to compute all compositions deduced from a set D_j (line 6). For each composition, we calculate the information gain to split a node (line 7–15). At line 16, if $G(D_j) \neq 0$ means that the set of observations of the node is impure (observations are of different classes). Moreover, $maxGain \neq 0$ means that a composition that splits the set of observations has previously been found: in this case, we create a node N_{inc} that will determine the positive branch of the node ($c \in_o D_j$), whereas N_{exc} will be the negative one ($c \notin_o D_j$) (line 16–25). We repeat these steps until there are no more nodes to process (line 3–26).

Example. Fig. 2 illustrates an example of CDT result. The root-node is D_1, and it represents the whole training set of observations used for the construction of the CDT. The leave-nodes represent class labels and branches represent conjunctions of compositions that lead to those class labels. As shown in Fig. 2, the CDT is composed of 3 splits constructing a set of 3 leaves $\mathcal{S} = \{S_1, S_2, S_3\}$.

3.4 Rule Generation for Anomaly Detection

We convert the CDT into a set of decision rules. We only consider "pure leaf-nodes" leading to the anomaly class.

Definition 6. A *rule predicate*, annotated Rs is a branch of the decision tree leading to the anomaly class. It is constructed by combining (conjunction) the successive compositions c_i or $\neg c_i$ from the leaf-node to the root-node. For each positive branch ($c_i \in_o D_j$), the positive composition c_i is deduced whereas a negative composition $\neg c_i$ is deduced from a negative branch ($c_i \notin_o D_j$).

Algorithm 1 CDT: Composition-based Decision Tree

Input: $D = \{d_1, d_2, ..., d_{N-\omega+1}\}$ a set of observations
Output: N_{root} the root node of CDT

1: $N_{root} \leftarrow Node(D, null, null, null)$
2: $q \leftarrow [N_{root}]$ *// construct the queue of nodes to split*
3: **while** $q \neq \emptyset$ **do**
4: $N_j \leftarrow q.pop()$ *// dequeue the first node from the queue*
5: $D_j \leftarrow N_j.observations$
6: $C_j \leftarrow list\_of\_all\_possible\_compositions(D_j)$
7: $maxGain \leftarrow 0$
8: $c_{best} \leftarrow null$
9: *// Choose the composition that has the best Gain*
10: **for all** $c \in C_j$ **do**
11: **if** $IG(D_j, c) > maxGain$ **then**
12: $maxGain \leftarrow IG(D_j, c)$
13: $c_{best} \leftarrow c$
14: **end if**
15: **end for**
16: **if** $G(D_j) \neq 0$ and $maxGain \neq 0$ **then**
17: $D_{inc} \leftarrow \{d \in D_j | c_{best} \in_o d\}$
18: $D_{exc} \leftarrow \{d \in D_j | c_{best} \notin_o d\}$
19: $N_{inc} \leftarrow Node(D_{inc}, null, null, null)$
20: $N_{exc} \leftarrow Node(D_{exc}, null, null, null)$
21: $q.append(N_{inc})$ *// enqueue child nodes*
22: $q.append(N_{exc})$
23: $N_j.composition \leftarrow c_{best}$
24: $N_j.childTrue \leftarrow N_{inc}$
25: $N_j.childFalse \leftarrow N_{exc}$
26: **end if**
27: **end while**
28: **return** N_{root}

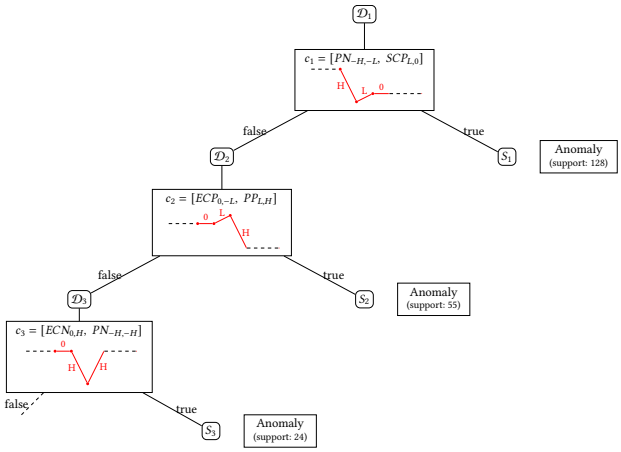

Figure 2: Illustration of a Composition-based Decision Tree (CDT).

Example. Three rules predicate are produced from the CDT in Fig. 2.

- $R_{S_1} : c_1 = [PN_{-H,-L},\ SCP_{L,0}]$
- $R_{S_2} : c_2 \wedge \neg c_1 = [ECP_{0,-L},\ PP_{L,H}] \wedge \neg[PN_{-H,-L},\ SCP_{L,0}]$
- $R_{S_3} : c_3 \wedge \neg c_2 \wedge \neg c_1 = [ECN_{0,H},\ PN_{-H,-H}] \wedge \neg[ECP_{0,-L},\ PP_{L,H}] \wedge \neg[PN_{-H,-L},\ SCP_{L,0}]$.

Using abusive notations, $c_i \wedge \neg c_j$ means that for an observation d on a time-series, we check $c_i \subseteq_o d \wedge c_j \not\subseteq_o d$.

Definition 7. A rule, annotated $\mathcal{R}$, is a disjunction of rule predicates. For instance, as shown in Fig. 2, $\mathcal{R} = R_{S_1} \vee R_{S_2} \vee R_{S_3} = (c_1) \vee (c_2 \wedge \neg c_1) \vee (c_3 \wedge \neg c_2 \wedge \neg c_1)$.

Rule Simplifications. One way to minimize CDT's rules is to post-process the produced rules through Boolean algebra simplifications. We aim to minimize the "sum-of-products" forms of Boolean functions. In our approach, this inter-branch simplification is applied until there is no longer any simplification to be made. This allows us to minimize the number of compositions in a rule. Using Boolean algebra, we can simplify the rule $\mathcal{R}$ generated from the tree in Fig. 2 as $\mathcal{R} = (c_1) \vee (c_2 \wedge \neg c_1) \vee (c_3 \wedge \neg c_2 \wedge \neg c_1) = (c_1) \vee (c_2) \vee (c_3)$.

3.5 Quality Measure

We aim to generate rules that are both accurate and comprehensible. According to experts opinion, a comprehensible rule should be short [2, 9] and should contain a minimized number of various labels. Therefore, we defined the following criteria to evaluate a quality of rules:

- $\mathcal{I}(c)$ to characterize the *quality of a composition* c depending on its length and the number of patterns used;
- $\mathcal{M}(R_S)$ to characterize the *quality of a rule predicate* R_S depending on the number of compositions and the quality of each one ($\mathcal{I}(c)$);
- $\mathcal{Q}(\mathcal{R})$ to characterize the *quality of a rule* $\mathcal{R}$ depending on the quality of rule predicate and its support.

We first calculate the interpretability of a composition as:

$$\mathcal{I}(c) = 1 - \frac{L_c.N_L}{\omega.MaxL} \tag{1}$$

where $L_c = |c|$ denotes the length of a composition c, N_L is the number of unique labels used in a composition, ω is the maximum window size, and $MaxL$ is the total number of labels. Then, we calculate the average interpretability of a rule predicate (conjunction of compositions) as:

$$\mathcal{M}(R_S) = \frac{1}{Nc} \sum_{k=1}^{Nc} \mathcal{I}(c_k) \tag{2}$$

where Nc is the number of compositions in a rule predicate R_S. Finally, extracted rules' quality is calculated as:

$$\mathcal{Q}(\mathcal{R}) = \frac{1}{S} \sum_{i=1}^{N_{Rs}} S_{R_{S_i}} . \mathcal{M}(R_{S_i}) \tag{3}$$

where N_{Rs} is the number of rule predicates in $\mathcal{R}$, $S_{R_{S_i}}$ is the support of rule predicate (true positive) and S is the support of all rules predicates (true positive and true negative). A rule predicate with high support is considered more important. Therefore, we multiplicate the average interpretability of a rule predicate with its support.

3.6 Hyper-Parameters selection

The manual tuning of hyper-parameters requires a prior knowledge. Automatic search algorithms such as grid search and random search could give good results. However, grid search is time consuming and random search might not find the optimal set. To address this problem, we use Bayesian Optimization [14] to efficiently get the best hyper-parameters (δ, ω) for our model. Indeed, we aim to find a configuration (that is, a set of parameters) that maximizes a performance metric or an objective function. Hence, we defined a search space and we try to find the hyper-parameters values of CDT that yield the highest result as measured on a validation set. Hyper-parameter optimization is presented as:

$$h^* = \arg\max_{h \in H} F(h) \tag{4}$$

where $F(h)$ represents an objective function to maximize, $h*$ is the set of optimized hyper-parameters (δ, ω) and h can take any value in search space H.

To optimize the trade-off between detection performance and good quality of rules, we defined the objective function $F(h)$ as the F-measure weighted by our $\mathcal{Q}(\mathcal{R})$ rules' quality measure.

$$F(h) = F1(h).\mathcal{Q}(\mathcal{R}) \tag{5}$$

where $F1(h)$ is the F-measure (the harmonic mean of the precision and recall) of the classification performance obtained with the set of parameters (h).

4 EXPERIMENTS

For our evaluation, we use real-world datasets from the Management and Exploitation Service (SGE) [6], and data from the Yahoo datasets [8]. We compare CDT with state-of-the-art pattern-based as well as rule-based methods for anomaly detection.

In SGE data sets, we aim to handle anomalies on calorie and electric consumption datasets. Calorie data consists of 25 consumption datasets from sensors deployed in different buildings managed by the SGE. These measurements are daily data for more than three years, about 33536 observations in total and they contain 586 anomalies. Electricity measurements are collected hourly for 10 years from one sensor (96074 in total). There are in total 10343 anomalies in the electricity dataset.

The Webscope S5 dataset, which is publicly available in [8], consists of 371 files divided into four categories, named A1/A2/A3/A4, each one containing respectively, 67/100/100/100 files. A1 Benchmark is based on real production traffic from actual web services while classes A2, A3, and A4 contain synthetic anomaly data. These datasets are represented by time-series in one-hour units. There are a total of 94778 traffic values in 67 different files and 1669 of these values are abnormal. The anomalies in the synthetic datasets are inserted at random positions. A2 Benchmark contains 142002 values with 466 anomalies while 168000 values exist in A3 and A4 Benchmarks with respectively 943 and 837 anomalies.

4.1 Evaluation Process and Metrics

The performance of all the methods is compared based upon the F1 score, the rules'quality metric $\mathcal{Q}$, and the objective function $F(h)$ used as defined in equation (5). We use the $F1$ score and $\mathcal{Q}$ score to compare the accuracy of our method against pattern-based methods. We use the $F(h)$ score to evaluate both the accuracy and the interpretability of the rules generated by our CDT method compared to those of rule learning methods. For evaluation, we split every dataset into three subsets: training set (60%), validation set (20%), and testing set (20%) ratio. We use the train and validation set to optimize the model's hyper-parameter values using Bayesian optimization. Then, we evaluate the optimized model on testing set.

Hyper-Parameters Optimization. To limit the search space of the Bayesian optimization, we constrained the parameter ω within [3,31] and δ within [1,21]. Table 2 shows the optimal hyper-parameters found with the Bayesian optimization. As we can see in Table 2, optimization on $F(h)$ tends to favors a small number of splits (δ) for patterns when compared to the $F1$ score optimization. This is due to the quality measure of rules $\mathcal{Q}(\mathcal{R})$,

which looks for short rules that include a minimum number of labels (δ). However, the size of observations (ω) needed to construct an optimal CDT remains to be comparable for $F1$ and $F(h)$ suggesting the need for presence of neighbors surrounding an anomaly to achieve good anomaly detection with CDT.

Table 2: Parameters of CDT for experiments.

Evaluation	F1-score		F(h)-score

4.2 Experiments with Pattern-based Algorithms

We employ the following three approaches as baseline methods to compare with our approach:

- Pattern-Based Anomaly Detection (PBAD) is an anomaly detection method based on frequent pattern mining techniques in mixed-type time-series [4].
- Matrix Profile (MP) is an anomaly detection method based on similarity-join to detect time series discords [15].
- Pattern Anomaly Value (PAV) is an anomaly detection algorithm based on pattern anomaly value. The anomalies are the infrequent linear pattern [16] .

To evaluate these methods, we used the implementation available in [4]. These algorithms are window-based approaches. Hence, we used the recommended settings for each of them. We split the time series into sliding windows of length 12 with a step size 6. These anomaly detection algorithms provide an anomaly score for each window. As these algorithms are unsupervised, we build the anomaly detection model on the full-time series data and we evaluate it using $F1$ score. For CDT, we used the appropriate values of hyper-parameters calculated using F1-score as provided in Table 2. All the data sets are normalized between 0 and 1 during the pre-processing phase. For Yahoo datasets and SGE-Electricity we downsampled these datasets from hours to days.

Result Analysis. Table 3 provides the $F1$ score obtained by each algorithm on each of the six univariate time-series datasets. The maximum values of $F1$ score for each dataset are given in bold type. We also calculate the average rank of each method. CDT outperforms the existing baselines in five of the six datasets. It can be observed in Table 3 that our method is more stable for different datasets than baselines. Note that for the competing algorithms, the data should be balanced otherwise, the detection results are poor. We have tested PBAD, PAV and MP on our initial datasets and on a balanced version and we have noticed that its performance highly degrades on the first case. In fact, they tend to focus on the accuracy of predictions from the majority class (normal class) which generates poor precision for the minority class (anomaly class). Therefore, the results of PBAD, PAV and MP in Table 3 are obtained on the balanced data.

Table 3: Evaluation of Anomaly Detection using F1-score for CDT and Pattern-based algorithms.

Dataset \ Algorithm	CDT	PBAD	PAV	MP

Yahoo_A4	**0.98**	0.75	0.93	0.96
Average	**0.92**	0.72	0.88	0.80

4.3 Experiments with Rule Learning Algorithms

We compare our CDT method with the following state-of-the-art rule learning algorithms:

- PART is a combination of C4.5 and RIPPER rule learning to produce rules from partial decision trees using C4.5 algorithm [9].
- JRip implements a rule learner and incremental pruning to produce error reduction (RIPPER) [12]. Rules are formed by greedily adding conditions to the antecedent of a rule.

We compare CDT with PART and JRip based on $F1$ score, $Q(\mathcal{R})$ and $F(h)$ score (Table 4) and the number of rules produced by the classifiers (Figure 3). We evaluated these methods using WEKA. We use 10-fold cross validation to test and evaluate the PART and JRip with the standard default setting of WEKA. For CDT and each competitor, we use the hyper-parameters values obtained to maximize $F(h) - score$ as provided in Table 2.

Result Analysis. Table 4 shows the comparison results for each algorithm in the six datasets using $F1$, $Q(\mathcal{R})$ and $F(h)$ score. Note that the results of the F1 score for CDT in Table 4 are different from those in Table 3 because they are not evaluated with the same hyperparameter values (Table 2).

Overall, the average scores show that our approach has got the first position in ranking followed by PART and JRip. CDT outperforms PART and JRip in all datasets in the $F1$ score, in three of the six datasets in the $Q(\mathcal{R})$ score and all datasets in the $F(h)$ score. We can observe from the Table 4 that JRip has a high quality of rules $Q(\mathcal{R})$ in three datasets as well as CDT. This is due to the size of its generated rules that are quite short. However, it is less accurate than CDT and PART in almost all datasets. We can also see that none of the baseline algorithms has good $F(h)$ overall data sets. While CDT has the best tradeoff between $F1$ score and $Q(\mathcal{R})$ score.

Fig. 3 shows a summary of the number of rules produced by each method. CDT produces a fewer number of rules between 5 and 16 rules. It is followed by JRip that produced reasonably few rules between 15 and 30 rules. However, PART highly produces rules that are between 24 and 142. This is due to the specificity of the rules generated that have low support.

We present some examples of the generated rules by our CDT algorithm from SGE data sets to detect multiple anomalies in Table 5. As we can see, the rules with visualized patterns are easy to intuitively understand and can be easily interpreted by users. The experts give the following comments: the negative peak is considered an anomaly because the energy consumption in a building cannot be negative. The positive peak has occurred following overconsumption in the building. The collective anomalies present abnormal variations in successive points. This is

Table 4: Evaluation of anomaly detection using the $F1$ score, the quality measure $Q(\mathcal{R})$ and the objective function $F(h)$.

due to a fault in the reading of the meters. Finally, the constant anomaly illustrated a stop of the meter.

Table 5: Example of rules generated for anomaly detection in the SGE_Calorie datasets.

Rule Predicate	Representation	Type of anomaly
$[PN_{-H,-H}, SCP_{-H,0}, CST, CST, CST]$ and $\neg\,[ECN_{0,-H}, SCN_{-H,0}]$		negative peak
$[ECP_{0,-L}, PP_{L,H}]$		positive peak
$[PN_{-H,-H}, PP_{H,H}]$		collective anomaly
$[SCN_{H,0}, CST, CST, CST, CST, CST]$ and $\neg\,[PN_{-H,-H}, SCP_{H,0}, CST]$		constant anomaly

5 CONCLUSION

We propose a machine learning method, CDT, that generates human-interpretable rules based on a formalisation of 9 general patterns of variations for multiple anomaly detection in time-series. The approach is based on a modified decision tree which considers nodes as pattern compositions. Using Bayesian Optimization, we optimized the hyper-parameters such that it maximizes both the rules'quality and the classification performances. The performance of the presented method was tested using the SGE and Yahoo datasets. Our approach appeared as robust compared to the existing algorithms in conducted experiments where their model accuracy decreases in case of multiple anomalies and in generating few interpretable rules.

Future work will concern the improvement of the generated rules. For instance, combine rules by a generalization and eliminate redundant rules. Moreover, we could investigate other hyper-parameters such as the size of down-sampling to improve the quality of the generated rules. We could also expand our method to suit multivariate time-series.

Acknowledgment. This PhD. was supported by the Management and Exploitation Service (SGE) of the Rangueil campus attached to the Rectorate of Toulouse and the research is made in the context of the neOCampus project (Paul Sabatier University, Toulouse).

Short Paper

DBMS Performance Troubleshooting in Cloud Computing Using SQL Transaction Clustering

Arunprasad P. Marathe
Huawei Research Canada
Markham, Ontario, Canada
arun.marathe@huawei.com,ap.marathe@gmail.com

ABSTRACT

Database management systems traditionally provide user-, table-, index-, and schema-level monitoring. For cloud-deployed applications, the research reported herein provides preliminary evidence that transaction cluster-level monitoring simplifies performance troubleshooting—especially for online transaction processing (OLTP) applications. Specifically, problematic rollbacks, performance drifts, system-wide performance problems, and system bottlenecks can be more easily debugged. The DBSCAN algorithm identifies transaction clusters based on transaction features extracted directly from a DBMS server—a job previously done using SQL log-mining. DBSCAN produces more accurate clusters when inter-transaction distances are computed using the angular cosine distance function (*ACD*) rather than the usual Euclidean distance function. Choice of *ACD* also simplifies DBSCAN parameter tuning—a task known to be nontrivial.

1 INTRODUCTION

A user books air tickets for himself and family members using an online web portal—front-end to a prototypical online transaction processing (OLTP) application. He makes several flight searches, books tickets, and provides frequent flyer numbers of the passengers. The airline reservation system implements this activity using a transaction. A second user performs different flight searches before booking a ticket for herself, but does not provide a frequent flyer number because it is not handy. The two transactions have both similarities and differences. Because they access the same tables in similar fashions, there may be a reason to believe that their performances are similar—a hypothesis that can be exploited if found true.

A study of the various applications contained in two popular OLTP benchmarking toolkits OLTP-Bench [2] and Sysbench [6] reveals that each application contains transactions that can be neatly divided into a small number of non-overlapping *transaction clusters* (between 1 and 10 for the two toolkits).

Self-similar transactions within a cluster differ in parameter values, statement orders, statement counts, statement types, rows read or updated, and so on. Nevertheless, this research shows that each cluster has a characteristic performance profile—termed its *signature*—at the level of which an OLTP application can be monitored. Sample cluster-levels metrics are average values of: transactions/sec (TPS); number of rows (read, updated, or sent to client); locking time; and so on.

Cluster-level monitoring is much simpler than transaction- or statement-level monitoring, and cluster count is independent of an OLTP application's load. Benefits of clustering multiply when that OLTP application is deployed in cloud where DBA's have to monitor performance of many applications simultaneously [17]. This paper demonstrates how transaction clustering helps a cloud DBA simplify debugging of several performance problems: identification of problematic transaction rollbacks; performance bottlenecks; system-wide performance issues; performance drifts; and so on. The cluster-level performance monitoring is not meant to replace existing tools: table-level and index-level data will continue to provide the necessary drill-downs, but help in determining where to drill-down should be valuable.

The DBSCAN algorithm [3] determines transaction clusters. DBSCAN is usually run with the Euclidean distance function, but this research demonstrates that when used with a normalized distance function called the *angular cosine distance* (*ACD*), DBSCAN finds more accurate clusters, and DBSCAN parameter tuning becomes easier—welcome news for a cloud DBA who cannot hand-tune the parameters for each OLTP application. DBSCAN parameter tuning is a known difficult task [4, 15], and therefore, suitability of *ACD* is a research contribution.

To calculate inter-transaction distances, transaction attributes are extracted into feature vectors. Previous research has relied on SQL log-mining for transaction feature extraction, whereas this research proposes to use simple server-side extensions instead. Regular-expression based SQL log mining is error-prone, and parsing SQL text may require parser duplication. Using server-side extensions, no (re)parsing of a SQL statement is required beyond the one initiated upon a statement's submission. A MySQL implementation demonstrates that server-side feature extraction is feasible. Similar infrastructure already exists in most modern DBMS engines (Oracle, SQL Server, PostgreSQL, and so on), and hence the solution has wider applicability.

2 SQL TRANSACTION CLUSTERS

SQL transactions within a cluster are similar (but not identical), and transactions in different clusters are dissimilar. Cluster determination is a three-step process. First, certain distinguishing attributes (called *features*) are extracted from a transaction, and an n-element *feature vector (FV)* is formed. Second, the distance between two transactions—defined to be the distance between their feature vectors—is computed using a distance function. Third, a clustering algorithm uses the feature vectors and the distance function to determine clusters.

2.1 Feature vector construction

In this research, extracting the following transaction features proved adequate.

(1) Statement type: `SELECT`, `INSERT`, `UPDATE`, `DELETE`, `COMMIT`, `ROLLBACK`, `BEGIN`, and so on.
(2) Table name(s)—possibly empty—referenced in the statement in 'schema.table' format.
(3) Counts associated with table names indicating frequency.

For other applications, different or additional features may need to be extracted.

A transaction X's feature vector $FV(X)$ is a concatenation of four sub-vectors FV_S, FV_I, FV_U, and FV_D for the four major SQL statement types SELECT, INSERT, UPDATE, and DELETE, respectively. All of the four sub-vectors are computed similarly, and therefore, only the construction of FV_S is described.

FV_S is of length n—the total number of tables in the OLTP system's schema, where each table is schema-qualified, and occupies a specific position in the vector to enable cross-feature vector comparisons. If a table T is referenced by *all* of the SELECT statements in a transaction a total of k times ($k \geq 0$), then the vector element for T inside FV_S has value k.

FV_I, FV_U, and FV_D are computed similarly from all of the INSERT, UPDATE, and DELETE statements in a transaction.[1]

Listing 1: Transaction X_1

```
SELECT C_ID FROM Customer WHERE C_ID_STR = '50665'
SELECT * FROM Customer WHERE C_ID = 50665
SELECT * FROM Airport, Country WHERE AP_ID = 180 AND
    AP_CO_ID = CO_ID
SELECT * FROM Frequent_Flyer WHERE FF_C_ID = 50665
UPDATE Frequent_Flyer SET FF_IATTR00 = -14751,
    FF_IATTR01 = 8902 WHERE FF_C_ID = 50665 AND
    FF_AL_ID = 1075
UPDATE Customer SET C_IATTR00 = -14751, C_IATTR01 =
    89025 WHERE C_ID = 50665
COMMIT
```

Consider the transaction X_1—taken from the SEATS workload of [2]—shown in Listing 1.

- $FV_S(X_1) = [2, 1, 1, 1]$ because SELECT statements in X_1 refer to *Customer* table twice, and the other three tables once each.
- $FV_U(X_1) = [1, 1]$ because UPDATE statements in X_1 refer to two tables once each.
- $FV_I(X_1) = FV_D(X_1) = [\ ]$ because there are no UPDATE or DELETE statements in X_1.
- $FV(X_1) = [2, 1, 1, 1] + [\ ] + [1, 1] + [\ ] = [2, 1, 1, 1, 1, 1]$

Imagine a second transaction X_2 similar X_1 that references *Customer* only once. $FV(X_2)$ will be $[1, 1, 1, 1, 1, 1]$.

2.2 Angular cosine distance

Angular cosine distance, henceforth *ACD*, measures the distance between two transactions—in particular, between their feature vectors. For two n-dimensional vectors $\mathbf{A}$ and $\mathbf{B}$, each with indices $0, 1, \cdots n-1$, and with non-negative values, *ACD* is defined as follows [21].

$$ACD(\mathbf{A}, \mathbf{B}) = \frac{2}{\pi}\left(\cos^{-1}\left(\frac{\sum_{i=0}^{n-1} \mathbf{A}_i\mathbf{B}_i}{\sqrt{\sum_{i=0}^{n-1} \mathbf{A}_i^2}\sqrt{\sum_{i=0}^{n-1} \mathbf{B}_i^2}}\right)\right) \quad (1)$$

ACD is a distance measure or *metric*, and furthermore is unitary or normalized: $0.0 \leq ACD(\mathbf{A}, \mathbf{B}) \leq 1.0$. Because *ACD* distances are unitary, a closeness threshold *Eps* (for example, 0.2) can be defined so that two transactions at most *Eps* apart are considered 'close'; otherwise, they are declared 'far'. Normalized distance functions enable easy similarity definition: $similarity = 1.0 - distance$. 'Close' transactions have 0.8 (or 80%) similarity—something even a non-expert can understand.

For X_1 and X_2 of Section 2.1, $ACD(X_1, X2) = ACD([2, 1, 1, 1, 1.1], [1, 1, 1, 1, 1, 1]) = 0.197$, or they are $1.0 - 0.197 = 0.803$ (80.3%) similar which seems intuitively correct.

[1] INSERT, UPDATE, and DELETE statements can also have embedded SELECT queries, and those are handled similarly to the way FV_S is.

Let $FV(X_3) = [1, 1, 1, 1, 1, 0]$. X_3 does not update the *Customer* table, and hence the 0. X_3 is somewhat dissimilar to X_1 and X_2, and indeed, $ACD(X_1, X_3) = 0.295$, or they are only 70.5% similar which again seems intuitive. With the closeness threshold *Eps* set to 0.2, X_1 and X_2 will be considered close, and may end up in the same cluster, whereas X_1 and X_3 will not belong to the same cluster.

2.3 DBSCAN parameter tuning

An open-source DBSCAN implementation [16]—instrumented to use *ACD*—performs transaction clustering. (By default, it uses the Euclidean distance function.) The author did not consider other clustering algorithms because DBSCAN has been found adequate for transaction clustering previously [11, 23].

DBSCAN's two tunable parameters *Eps* and *minPts* define *density*. A hyper-sphere of radius *Eps* with at least *minPts* points inside is considered *dense*. *ACD* does not eliminate hand-tuning DBSCAN parameters, but provides twofold help.

- *Eps* = 0.2 means that *independent of workload*, two transactions have to be at least 80% similar before they can belong to the same cluster. With such unnormalized distance functions as the Euclidean, *Eps* values are workload dependent.
- For many workloads, *ACD*-based DBSCAN clustering is not very sensitive to the two parameter values, and a good starting point is (*Eps*, *minPts*) = (0.2, 10). (Section 5.2.)

3 MySQL EXTENSIONS FOR TRANSACTION FEATURE EXTRACTION

Feature extraction uses the data from three in-memory tables shown in Fig. 1 that contain transaction-level, statement-level, and table-level information. The three tables will henceforth be referred to by the acronyms *e_t_h*, *e_s_h*, and *e_s_t*.

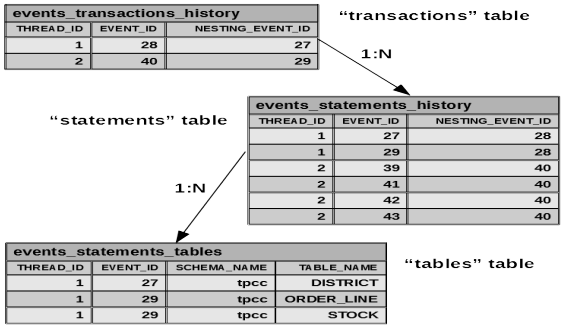

Figure 1: Relationships between the three tables.

Each completed transaction appears as a row in *e_t_h*, and the statements within are captured in *e_s_h* (1:N relationship). The newly added *e_s_t* table contains zero or more rows for each statement present in *e_s_h*—one for each distinct table reference in that statement (another 1:N relationship). Such statements as COMMIT and ROLLBACK do not refer to any tables, and therefore, have no presence in *e_s_t*. The columns in Fig. 1 only capture inter-table relationships. The other columns added to the three tables—not explicitly shown in Fig. 1—capture transaction-, statement-, and table-level statistics.

Using a SELECT query involving multi-way joins among *e_t_h*, *e_s_h*, and *e_s_t* tables, such information as transaction text; statement type; statement text; statement run-time; transaction

run-time; table names appearing in statement and their counts; number of rows examined; locking times; and so on is easily extracted.

Tables similar to the ones depicted in Fig. 1 already preexist (or can be easily created) in SQL Server [10], Oracle [12], and PostgreSQL [13], and therefore, server instrumentation of the kind described in this section is possible in those products.

4 SYSTEM ARCHITECTURE

A prototype SQL transaction clustering system has been implemented as depicted in Fig. 2. The Linux KVM virtual machine represents a hosted environment running a customer application (OLTP-Bench and Sysbench workloads during experimentation). The top MySQL instance within the Linux KVM has been instrumented as described in Section 3 to enable transaction-level data collection and feature extraction. The Windows 10 machine contains data processing components, including those performing transaction clustering and classification. (A second hosted application would require its own data processing node.)

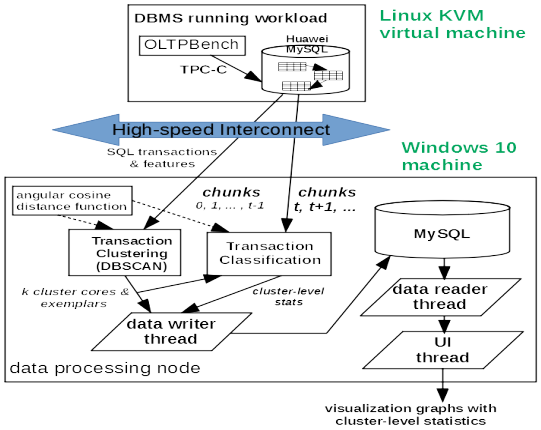

Figure 2: Architecture of a transaction clustering system.

A SQL query runs every 5 seconds on the Linux machine, and performs data collection. (The interval ensures minimal data collection overhead, but is a system parameter.) Each 5-second chunk includes feature and non-feature data: SQL statements; statement types; table names; table counts; statement durations; transaction duration; lock times; and rows examined by statements. An epoch-style Linux timestamp is associated with each chunk, and the resulting time-series is shipped to the data processing node where chunk-based iterators process it.

The first t chunks are used to perform transaction clustering. During experimentation, the first 30 seconds worth of transactions ($t = 6$) were found adequate to determine transaction clusters, but t is a system parameter. OLTP workloads do not have ad-hoc queries, and so clusters, once formed, should not change. If that assumption is violated, DBSeer's online implementation of DBSCAN can be used [5], but we leave that for future work.

Once clusters form, the rest of the streaming transactions are simply classified. The average distance (computed using *ACD*) from a transaction X to a cluster's exemplars is calculated, and X is assigned to the cluster for which that average distance is minimum, as long as that minimum value is no more than a threshold (say 0.2). If the threshold is exceeded, X is declared an outlier.

Simple roll-up operations compute cluster-level statistics from transaction statistics as long as transactions are not outliers. If necessary, data about outliers can be captured and processed similarly.

5 CLUSTERING EXPERIMENTS

These experiments demonstrate that *ACD*-based DBSCAN is effective at finding transaction clusters, and is not very sensitive to *Eps* and *minPts* parameter values. Workload consists of OLTP-Bench [2] and Sysbench [6]. Out of OLTP-Bench's 15 workloads, the author was able to run 11.[2] Clustering effectiveness requires expected cluster counts which OLTP-Bench already provides, and were manually determined for Sysbench. In Tables 1 and 2, expected cluster counts are indicated in brackets after the workload names. Actual cluster counts are not always integral because each value is an average of 5 runs, and DBSCAN sometimes produces slightly different cluster counts for different samples.

5.1 *ACD*-based DBSCAN

ACD-based DBSCAN with (*Eps*, *minPts*) = (0.2, 10)—henceforth, $ACD(0.2, 10)$—is an excellent starting point for clustering database transactions. Table 1 captures $ACD(0.2, 10)$'s performance against a baseline provided by the well-known Euclidean distance function. In the Euclidean baseline, *Eps* and *minPts* values are set using a heuristic provided by the DBSCAN authors in a subsequent paper [14]. We will term the resulting baseline *SEKX* after the author names. The heuristic itself works as follows. Let the *dimensionality* of a workload—defined to be maximum feature vector length—be *DIM*. Then:

- Heuristic value of $Eps = (2 * DIM) - 1$
- Heuristic value of $minPts = (2 * DIM)$

$ACD(0.2, 10)$ handily outperforms *SEKX* in 8 out of 13 workloads, and equally important, is never worse than *SEKX* in the remaining 5 workloads. For 9 workloads, *SEKX* puts all of the transactions into single clusters, and hence is ineffective.

The following observations—cross-referenced in the 'Comments' column of Table 1—provide reasons why $ACD(0.2, 10)$'s cluster counts are slightly off in a few cases.

(1) Epinions cluster count is off by 1 because a transaction type selects from *Review* and *Trust* tables separately, and another type selects from their joined version. Both end up in the same cluster because the feature vector construction in Section 2.1 currently does not distinguish them.
(2) YCSB cluster count is off by 1 because two of the transaction types have point and range selects, but are otherwise identical, and that difference is currently not captured as a feature.
(3) AuctionMark and SEATS produced the correct cluster counts with $ACD(0.15, 10)$ and $ACD(0.15, 15)$, respectively.

Observations 1 and 2 suggest possible features that can be extracted, and added to the feature vector.

5.2 Sensitivity analysis of *ACD*

When used along with *ACD*, DBSCAN is not very sensitive to various *Eps* and *minPts* values. Table 2 captures *ACD* results for 6 sets of parameters. Approximately, cluster membership criterion becomes more stringent as one reads across a row, and hence cluster counts can be expected to diminish from left to right. As can be seen, *ACD* is not very sensitive to parameter values for most of

[2]Wikipedia turns out to be hard to cluster because two of the transaction types have frequencies of only 0.07% each, and are rarely present in samples. One can ignore 'Wikipedia' results, but they are included for completeness.

Table 1: *ACD* (0.2, 10) versus *SEKX* ($2 * DIM - 1$, $2 * DIM$)

Workload & expected cluster count	DIM	Avg. cluster count		Comments
		ACD	*SEKX*	
AuctionMark (9)	9	9.4	1	Observation 3
Epinions (9)	2	8	1	Observation 1
SEATS (6)	8	7	1	Observation 3
SIBench (2)	1	2	2	
SmallBank (6)	5	6	1	
sysbench_ro (10)	1	10	10	
sysbench_rw (10)	5	10	10	
TATP (7)	3	7	1	
TPC-C (5)	10	5	1	
Twitter (5)	2	5	1	
Voter (1)	4	1	1	
Wikipedia (5)	7	2	1	Footnote 2
YCSB (6)	2	5	1	Observation 2

the workloads. Even when it is (AuctionMark and sysbench_rw; and to a lesser extent SEATS and TPC-C), graceful degradation is observed. Therefore, it is not crucial for a DBA to get the values of *Eps* and *minPts* spot on, and any reasonable values should perform respectably well. 'Sysbench_rw' is tricky to cluster for its highly symmetrical transactions—all of the transactions are roughly equidistant from all of the other transactions—but two *ACD* configurations perform well.

Table 2: *ACD* with different *Eps* and *minPts* values.

Workload & expected cluster count	Avg. cluster count					
	ACD (.20,10)	*ACD* (.15,10)	*ACD* (.15,15)	*ACD* (.10,10)	*ACD* (.10,15)	*ACD* (.05,20)

6 PERFORMANCE TROUBLESHOOTING USING TRANSACTION CLUSTERING

Experiments in this section demonstrate how cluster-level performance monitoring simplify debugging of several real-life problems faced by cloud DBA's.

6.1 Cluster signatures

OLTP-Bench's SmallBank workload simulates some operations of a bank, and produces the cluster signatures shown in Fig. 3 with 10-terminal workload, and scale-factor of 1. The three sub-plots capture the average values of the three transaction-cluster-level metrics: lock time (in ms); number of rows examined; and TPS

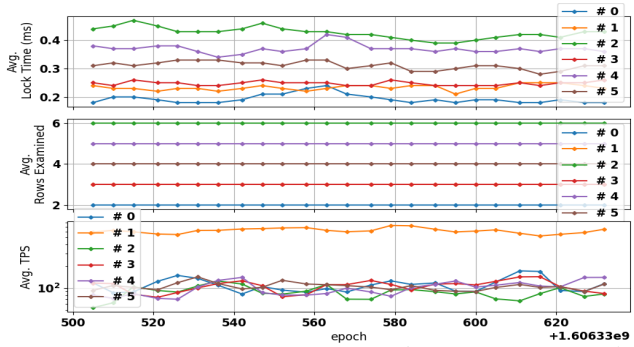

Figure 3: SmallBank's cluster signatures (10-terminal workload).

(transactions/sec). Each sub-plot contains six lines—one for each of the transaction clusters identified.[3]

From SmallBank cluster signatures, a cloud DBA can learn several things about the workload. First, six clusters means that there are six types of transactions in SmallBank—as OLTP-Bench confirms. Second, cluster signatures are discernible. Third, small signature variations exist because each data point aggregates 5 seconds worth of transactions (which themselves execute in a multi-tasking environment). Fourth, all of the transactions in a given cluster examine the same number of rows—a SmallBank peculiarity. Fifth, cluster exemplars reveal that the only cluster with read-only transactions is cluster 1—explaining its its highest TPS values. Sixth, when 100 terminals generate workload, the same six clusters form (graphs not included to save space), thereby confirming that clusters are load independent—a practically useful promise of clustering.

6.2 Identification of transaction rollbacks

Transaction rollbacks are normal DBMS occurrences, but sometimes their frequencies become problematic. If rollbacks are limited to a transaction type, cluster-level monitoring helps because unexpected additional clusters form.

The TPC-C benchmark [20] has five well-known transaction types. Rollbacks are demonstrated using the *Payment* transaction by modifying its code such that after submitting 2 out of its 7 statements, it rolls back with 20% probability—simulating a problematic high-frequency rollback. To make example even more realistic, a second rollback—simulating a normal and rare DBMS occurrence—happens after the sixth statement with 0.1% probability (overall probability $0.8 \times 0.1 = 0.08\%$). Because the problematic rollbacks are numerous, they should form their own cluster, whereas the normal rollbacks should not.

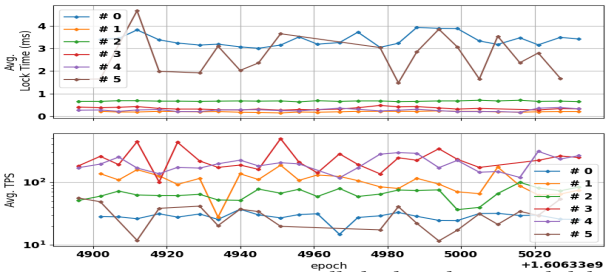

Figure 4: *Payment* transaction rolls back with 20% probability causing an unexpected sixth cluster (Cluster 1) to appear.

[3]The second subplot contains only five lines because clusters 1 and 3 examine 3 rows each, and the plotting software cannot distinguish two overlapping lines.

The modified TPC-C benchmark produces the results shown in Fig. 4. Usually, TPC-C produces five clusters, but six are found. A sample exemplar from Cluster 1 reveals the 'incomplete' *Payment* transaction with a telltale `rollback` issued after two statements.

```
UPDATE WAREHOUSE SET W_YTD = W_YTD + 1704.68994140625
    WHERE W_ID = 2
SELECT W_STREET_1, W_STREET_2, W_CITY, W_STATE, W_ZIP,
    W_NAME FROM WAREHOUSE WHERE W_ID = 2
rollback
```

The normal (rare) DBMS rollbacks (0.08% probability) do not form a cluster because they do not meet DBSCAN's density requirement mentioned in Section 2.3. High-frequency rollbacks are difficult to identify if cluster-level statistics are not kept. Applications often resubmit transactions in case of rollbacks, and users only notice and wonder about degraded performance. An incident report would cause DBA's or programmers to dig through voluminous logs to even begin suspecting a culprit.

6.3 Performance drift

Performance drift refers to a situation in which one (or just a few) cluster's performance drifts from its norm. Many situations can cause performance drifts. Here is a typical one: A DBA might forget to reinstate an index that (s)he deliberately dropped during a bulk load operation.

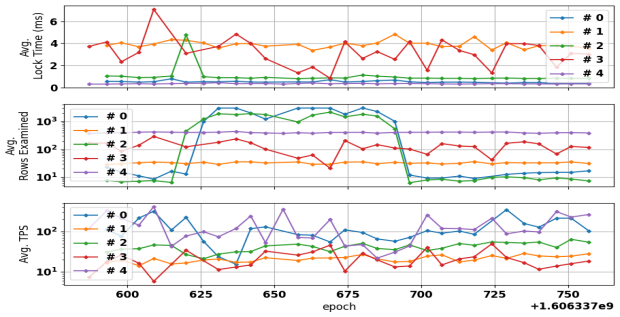

Figure 5: An index made invisible during [615, 685].

To simulate a performance drift, a secondary index (used by two out of the five TPC-C transactions) on the *CUSTOMER* table is made invisible[4] to the query optimizer during a portion of the run. When the index is made unavailable, the query optimizer has to use table scans instead of index seeks. As can be seen in Fig. 5, average row counts show dramatic increases (drifts) for clusters 0 and 2 during the interval [615, 685].[5]

When the performance of only one cluster drifts, objects related to only that cluster (e.g., tables, indexes, statistics) are good starting points for debugging. Without cluster-level statistics, such a diagnosis may require considerably more work.

6.4 System-wide performance problem

System-wide performance problems are caused by such things as a failed network card, operating system reboot, failed disk, and runaway process hogging CPU's. If all of the clusters experience simultaneous degraded performances, a system-wide issue may be the cause. One such situation is created using a CPU-hogging program that spawns as many processes as the number of CPU cores on the computer (8), and then making them run infinite 'while' loops—thereby creating a CPU bottleneck.

[4]MySQL command used was: `ALTER TABLE CUSTOMER ALTER INDEX IDX_CUSTOMER_NAME INVISIBLE;`

[5]As an aside, if an invisible index makes no difference to any cluster's performance, it might be safe to drop—the reason why that feature was added to MySQL.

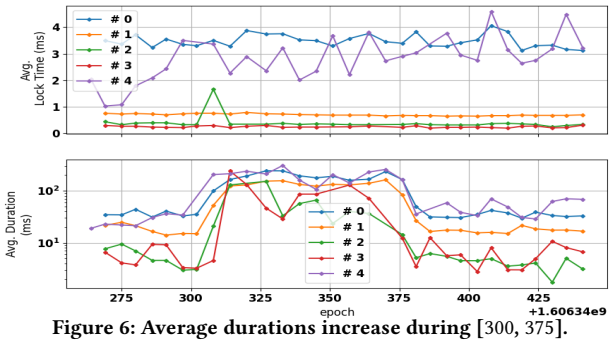

Figure 6: Average durations increase during [300, 375].

In the resulting graphs shown in Fig. 6, during the interval [300, 375], average durations of all of the clusters show unmistakable jumps. After about 375, when the offending program is killed, all five average durations return to their baseline values. Interestingly, average lock times are largely unaffected, indicating that for the few transactions that did manage to execute during CPU saturation, lock time did not take a hit. Such observations should provide the DBA a good starting point to formulate a hypothesis before beginning a detailed investigation.

6.5 Bottleneck analysis

Cloud applications run on pre-provisioned VM's. Because application behaviour is relatively unknown, a bottleneck may develop—in CPU, memory, disk I/O, network I/O, and so on. Furthermore, bottlenecks may vary by transaction types. Non-cloud DBA's are used to monitoring such operating system-level performance counters as *vmstat*, *iostat*, and *netstat* in Linux for bottleneck identification, but cluster-level statistics offer a complementary method that can provide additional help.

To study whether a VM has sufficient memory, its memory is reduced on the fly from 16 GB to 3 GB while TPC-C workload runs. Such a drastic change in memory allocation is only for demonstration: typical changes should be much smaller.

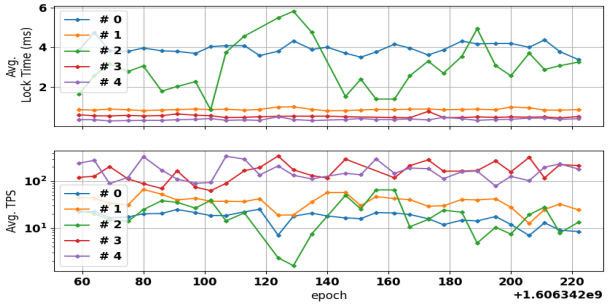

Figure 7: Memory reduces from 16 GB to 3 GB at timestamp 120.

In the results captured in Fig. 7, memory reduction happens at timestamp 120 onward. The average TPS values before and after that interval show no discernible changes. There is a noticeable drop at 120 as the operating system seems to adjust to the new memory setting, but soon, normal service resumes. The 'Avg. lock time' metric is also mostly unaffected, and therefore, one can conclude that this VM is well-provisioned for memory.

In the next variation, CPU is constrained. Changing CPU count in KVM requires a machine restart, and therefore, an approach similar to the one in Section 6.4 is taken, except that 7 out of the

8 cores are kept busy running infinite 'while' loops. The results appear in Fig. 8.

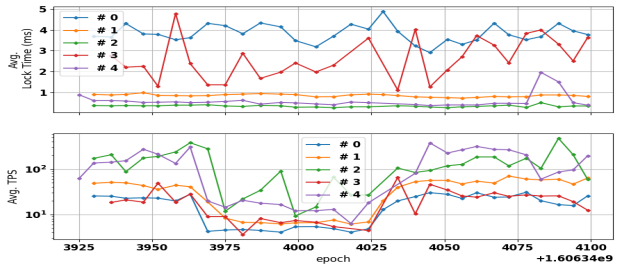

Figure 8: CPU saturation during the interval [3960, 4025].

The CPU bottleneck spans the interval [3960, 4025] during which reduced 'Avg. TPS' values are visible. The highest 'Avg. TPS' values are for clusters 2 and 4 (read-only transactions *Stock-Level* and *Order-Status*, respectively). Outside of the CPU bottleneck, those values are somewhat close, but during the bottleneck, *Order-Status* transaction's performance takes a bigger hit (Y-axis is log-scale) suggesting *Order-Status* is much more sensitive to CPU than *Stock-level* is in this environment. If *Order-Status* is deemed important (say because customers check statuses their orders often), it may make sense to over-provision for CPU rather than for memory if a choice is to be made between the two.

7 RELATED WORK

Identifying transaction clusters from SQL text arriving at a database server is important for two reasons. First, applications deployed in cloud environments are often web-applications [17] using object-relational mappings to submit SQL queries, and do not use stored procedures. Second, as noted by Stonebraker *et al.* [19], because of SQL's 'one language fits all' approach, transaction code may use a mix of stored procedures, prepared statements, and Java/C++/C# code.

Clustering itself is a broad and well-studied topic [22]. SQL query clustering and classification has been studied under two granularities: query-level and transaction-level. SQL query features previously tried include terms in `SELECT`, `JOIN`, `FROM`, `GROUP BY`, and `ORDER BY` clauses, table names, column names, normalized estimated execution costs [7, 9]; and features have been converted into vectors, graphs, or sets [7, 18]. As a general observation, fewer features suffice in self-similar OLTP workloads; ad-hoc workloads require more features. Such distance functions as cosine, Jaccard, and Hamming have been tried for clustering SQL queries [1, 9, 18], although only the Euclidean has been tried at the transaction level before [5]. Before this research, feature extraction has mined SQL text from DBMS logs [9, 18], or MaxScale proxy server [11]; server-side feature extraction is novel.

8 CONCLUSIONS AND FUTURE WORK

This research makes a case that in addition to user, table, index, and schema level monitoring provided, DBMS's should start to provide transaction-cluster-level monitoring. In applications deployed in the cloud, and for OLTP workloads, that additional level simplifies debugging of performance problems: unexpected transaction rollbacks, performance drifts, bottleneck identifications, and so on. Angular cosine distance-based DBSCAN is an improvement over Euclidean-based DBSCAN with *SEKX* heuristic [14] (better clusters and simplified DBSCAN parameter tuning).

Future work may investigate the following features for transaction clustering: column names to possibly identify index issues; predicate types (point queries vs. range queries) and counts; access paths used; isolation level; number of sorts; join tables; and so on. Multiple cluster-level signatures may help because an application may have distinct 'peak' and 'off-peak' behaviours. Whether *ACD* is suitable with such clustering algorithms as BIRCH [24] and k-means [8] remains to be seen. Server-side feature extraction can be attempted in other modern database systems using minor extensions to preexisting scaffoldings.

ACKNOWLEDGMENTS

Matthew Van Dijk implemented the server-side extensions needed for transaction feature extraction. Anonymous reviewers provided valuable feedback.

ABSTRACT

Modern applications require managing large data in main memory. *Adaptive indexing* allows for building an index incrementally in response to queries, rather than upfront; in its default form, it treats each attribute independently. However, several data exploration tasks involve multidimensional range queries. Two recent proposals, CKD and QUASII, address the need for multidimensional (especially spatial) adaptive indexing. Both adaptively build an augmented KD-Tree. Still, no previous work has compared these two methods to each other. We conduct the first experimental comparison of CKD and QUASII. Further, we propose a lightweight variant of CKD, the Lazy CKD, which performs data-driven along with query-driven actions for the sake of robustness, and a set of hybrid strategies that combine good convergence and low initialization cost. Our study on synthetic and real data and workloads shows that the enhanced variants of CKD have an advantage in terms of speed of convergence, yet QUASII may eventually achieve lower response times.

1 INTRODUCTION

Scientists and analysts need to query and explore large amounts of data in dynamic environments where new data arrive continuously, without building a full index in advance. This need calls for self-organizing DBMSs that eschew human administration. *Adaptive indexing* [8], such as *database cracking* [4, 6], accommodates this need by building and refining a main-memory index incrementally, in response to queries and arriving data. Cracking is applied within the select operator in a column-oriented database [7, 10]. A *stochastic* alternative [4] creates *random cracks* so as to perform robustly on skewed workloads.

Despite the intense interest in adaptive indexing, such methods for multidimensional data have been examined scantly. Recently, two solutions appeared: the QUery-Aware Spatial Incremental Index [12] (QUASII) and the Cracking KD-Tree (CKD) [5] (CKD). Both incrementally build an augmented KD-tree [1]; both conclude that their query response times converges to that of static approaches after processing a sufficient amount of queries; however, no comparison among these two works has been attempted.

In this paper, we conduct the first comparison of these two approaches [5, 12]; we also propose a lightweight CKD variant, the Lazy CKD (LCKD), incorporate stochastic cracking [4] strategies to improve robustness, and propose hybrid strategies that combine desirable traits of different solutions. We evaluate all methods on both synthetic and real datasets and workloads.

*The two first authors contributed equally to this work.

2 1D ADAPTIVE INDEXING

Cracking [6] progressively partitions and sorts a column by quicksort while answering range queries. A partition containing one or both query range bounds is further split, or *cracked*, up to a minimum size. A partition containing the entire interval is split into three. Cracking directly into three partitions is possible [6], yet cracking into two partitions twice instead yields better results [13]. Listing 1 presents the basic cracking algorithm.

Listing 1: Crack in two [6].

```
1  def crack_in_two(pivot p, value low, value high):
2    x1 ← point at position low
3    x2 ← point at position high
4    while (position (x1) < position((x2)):
5      if (value(x1) < p):
6        x1 ← point at next position
7      else:
8        while (value(x2) ≥ p &&
9               position (x2) > position(x1)):
10              x2 ← point at previous position
11       exchange(x1, x2)
12       x1 ← point at next position
13       x2 ← point at previous position
```

Stochastic Cracking [4] adds *data driven* cracking actions to standard *query driven* ones, which may perform poorly on skewed workloads. The Data Driven Center (DDC) algorithm cracks the partition where a query bound lies at the median recursively, until obtaining a sufficiently small partition, whereupon it cracks at the query bound. Data Driven Random (DDR) avoids median-finding by choosing a random pivot. The DD1C and DD1R variants perform only one median or random crack. Still, these strategies retain the overhead of query-driven cracking. To ameliorate it, Materialization-based DD1R (MDD1R) [4] cracks the piece in which a query bound lies only on a single random pivot and materializes the result. Progressive MDD1R [4] shares the burden across queries, allowing crackin to be partially completed. Refined variants use the median of a sample set instead of a single random pivot, with performance gains [18].

Adaptive Merging [2] splits the data into arbitrary initial partitions, from which it progressively extracts query results into to a final sorted partition by incremental mergesort; it achieves faster convergence than cracking at the cost of high initialization cost [8]. A hybrid combination of the two [8] applies cracking on initial partitions and sorting on the final one to achieve both lightweight initialization and quick convergence.

Multidimensional Cases. A first study in adaptive multidimensional index structures [16] was about reorganizing, rather *building*, data-oriented hierarchical indexes, in response to a workload, so as to improve performance. Recently, QUASII [12] and CKD [5] extended adaptive indexing to the multidimensional case, by applying cracking on one dimension per tree level to construct a KD-tree-like structure. To our knowledge, these works have not been compared. Next, we discuss them in detail.

3 MULTI-D ADAPTIVE INDEXING

Augmented KD-tree. Both QUASII [12] and CKD [5] build their indexes on top of an augmented KD-tree [1], progressively redistributing data from the root node to newly created children

nodes while processing queries, allowing for a *variable number of children per node*. As new children nodes are added irregularly, the tree may lose the property of being *balanced*.

Listing 2: QUASII query [12].

```
1  def query(query q, data D, slices S, result R):
2    S' ← ∅          // to store newly created (refined) slices
3    dim ← S[0].l    // current level/dimension of slices in S
4    i ← binarySearch(S, lower(q[dim]))
5    while (i < |S| and lower(S[i].box[dim]) ≤ upper(q[dim])):
6      if q ∩ S[i].box = ∅ then continue
7      S'' = refine(S[i], q, D)
8      for each s ∈ S'':
9        if q ∩ s.box ≠ ∅:
10         if s.l is the bottom level:
11           for j ∈ s.ids:
12             if D[j] ∩ q ≠ ∅ :
13               R ← R ∪ D[j]
14         else:
15           if |s.children| == 0 :
16             createDefaultChild (s)
17           query(q, D, s.children, R)
18     S' ← S' ∪ S''
19     i ← i + 1
20   S ← S ∪ S'
21   sort (S)
```

QUASII [12] comprises a hierarchical index structure of depth equal to the dimensionality d; the index starts off as a root node containing all data objects, unsorted, and grows while processing range select queries. A bottom-level node may be split if it contains more than τ objects; thus, QUASII slices a space with n objects up to $r = \left\lceil \sqrt[d]{n/\tau} \right\rceil$ times in each dimension; at level ℓ above the bottom the threshold becomes $\tau[\ell] = r^{\ell}\tau$. Listing 2 shows how QUASII processes a multidimensional range query q; it finds the first slice hitting q by binary search (Line 4) along dimension (tree level) dim, on which slices are sorted along. It then scans and refines (i.e., slices further) all slices intersecting q (Lines 5–7), cracking them up to size τ, by both query bounds and artificial cracks. If a resulting slice at the bottom level intersects q (Line 9), qualifying data objects therein are appended to the result R (Lines 10–13); in case the slice is at an internal level, QUASII recursively queries that slice's children (Lines 15–17). After refining all relevant slices in level (dimension) dim, QUASII resorts the slices therein (Line 21) with respect to the lower bound of their bounding boxes. After recursively traversing, cracking, and resorting slices as needed, it returns the range query result R.

Listing 3: Refine [12].

```
1  def refine ( slice s, query q, data D):
2    if (|s| ≤ τ[s.l]):
3      return {s}
4    S ← ∅
5    t ← determineSliceType(s,q)
6    switch(t):
7      case both: S' ← sliceThreeWay(s, q, D)
8      case one: S' ← sliceTwoWay(s, q, D)
9      default: S' ← sliceArtificial(s, q, D)
10   for each s ∈ S':
11     if (|s| > τ[s.l] and q[s.l] ∩ s.box[s.l] ≠ ∅):
12       S'' ← sliceArtificial(s, q, D)
13       S ← S ∪ S''
14     else:
15       S ← S ∪ s
16   return S
```

Listing 3 illustrates the process that refines each slice s that intersects the query q along the examined dimension $s.l$ and exceeds the size threshold $\tau[s.l]$. QUASII cracks on any bound of q along dimension $s.l$ that lies within s (Lines 7–8); otherwise, if q contains s along $s.l$ (i.e., both bounds of q lie outside s), it slices based on an artificially introduced coordinate $c = \lfloor (x_l + x_u)/2 \rfloor$ (Line 9), where x_l (x_u) is the lower (upper) bound of s along $s.l$; it recursively slices further each produced slice that exceeds the τ size threshold and overlaps with q (Lines 11–12), otherwise adds it to the output (Line 15). Listing 4 presents the recursive procedure for such *artificial slicing*, which configured to handle multiple points having the same coordinate when cracking (Line 5).

Listing 4: Artificial slicing.

```
1  def sliceArtificial ( slice s, query q, data D):
2    if |s| ≤ τ[s.l]:
3      return [s]
4    c = ⌊(x_l + x_u)/2⌋
5    slices = crack(s, c, s.l)
6    ret = []
7    for s' ∈ slices:
8      ret = ret ∪ sliceArtificial(s', q, D)
9    return ret
```

QUASII represents each spatial data object using its lower coordinate only along any dimension. A slice is first defined by its cracking coordinates, or *cuts*, yet obtains its own *minimum bounding box* (MBB) embracing the spatial extent of each object therein, with overlapping among slice MBBs allowed. To avoid the MBB computation overhead, QUASII computes MBB bounds for a slice s only on the dimensions s has been fully refined along. During slice refinement and binary search, to capture any result whose representative corner point lies in an unrefined slice outside the query range, QUASII extends the lower coordinate of q by the maximum object extent in each unrefined dimension, as in [15]. QUASII was designed as an adaptive spatial index for data in 2 or 3 dimensions; in our experiments we test its performance on higher dimensionality too.

Cracking KD-Tree (CKD) [5] also lets an augmented KD-Tree grow through queries, and uses a minimum node size threshold τ. However, it assigns dimensions to tree levels in round-robin fashion by a *modulo* operation, allowing for multiple levels cracking on the same dimension. Listing 5 shows how CKD processes a multidimensional range query q on a slice s; if s is fully contained within q (Line 2), it extracts the contents of the given slice s, otherwise traverses any children of s (Lines 4–5); if s has no children and contains fewer than τ elements, a check of those vs. q yields the result (Lines 6–7). If none of the above is the case, CKD cracks the slice; it further queries resulting slices lying outside the query bounds on dim, to refine the index on other dimensions (Line 13), and those within the query bounds, to obtain results (Line 16).

Listing 5: CKD query.

```
1  def query(query q, slice s, dimension dim):
2    if ( isIncluded (s, q)):
3      return extractPoints (s, q)
4    if (s.children > 0):
5      return traverseTree (s, q, dim)
6    if (|s| ≤ τ):
7      return extractPoints (s, q)
8    slices ← crack(s, q, dim)
9    nextDim ← dim + 1 mod q.maxDim
10   for s' in slices:
11     s . add_slice (s')
12     if (s' ∩ q == ∅):
13       query(q, s', nextDim)
14     else
15       relevantSlice ← s'
16   return query(q, relevantSlice, nextDim)
```

Listing 6 shows the tree taversal procedure. CKD finds the first slice within the bounds of q by binary search (Line 3) and examines all slices within those bounds (Line 4–8), adjusting query bounds for the current dimension to fit the data in the slice (Line 6) and builds the result by querying those slices (Line 7).

Listing 6: CKD and LCKD traverse tree.

```
1  def traverseTree ( slice s, query q, dimension dim):
2    res ← []
3    i ← binarySearch(S, lower(q[dim]))
4    while (i < |s| and lower(s[i]) ≤ upper(q[dim])):
5      s' ← s[i]
6      q' ← adjustQueryToSliceBoundaries(q, s', dim)
7      res ← res ∪ query(q', s', nextDim)
8      i ← i + 1
9    return res
```

4 DISCUSSION AND ENHANCEMENTS

Lazy Cracking KD-Tree. The CKD [5] gratuitously refines all resulting slices after a crack on the query range according to query bounds. This gratuitous refinement is redundant; as it suffices to crack the pieces overlapping the query. We propose a variant that does so, the *Lazy Cracking KD-Tree* (LCKD). Listing 7 displays how LCKD processes a query, the change seen in Lines 10–13. In each dimension, LCKD only cracks partitions between query bounds, rather than cracking all pieces in excess.

Listing 7: LCKD query.

```
1  def query(query q, slice s, dimension dim):
2    if (isIncluded(s, q)):
3      return extractPoints(s, q)
4    if (s.children > 0):
5      return traverseTree(s, q, dim)
6    if (|s| ≤ τ):
7      return extractPoints(s, q)
8    slices ← crack(s, q, dim)
9    nextDim ← dim + 1 mod q.maxDim
10   for s′ in slices:
11     s.add_slice(s′)
12     if (s′ ∩ q != ∅):
13       relevantSlice ← s′
14   return query(q, relevantSlice, nextDim)
```

Intuitive Comparison We now now have three strategies to compare: QUASII, CKD, and LCKD. All start with a tree consisting of a single node, and progressively build a hierarchical index while answering queries. In QUASII, the tree height is equal to the number of dimensions. In CKD and LCKD, the maximum tree height is determined by the size threshold τ for cracking a partition. Figure 1 sketches the tree structures resulting after processing a single query under these strategies in the two dimensions; each tree layer corresponds to a different dimension. In CKD, there is an initial three-way crack along dimension x, followed by cracking all resulting pieces along query bounds on y. LCKD only cracks the x-partition relevant to the query along the bounds on y. The tree LCKD builds is less balanced than that of CKD, as successive queries may refine the index in the same region. Lastly, QUASII fully refines the entire part of the index relevant to the query in each dimension, making the tree wider, down to the minimal partition size τ [12]; CKD cracks the chunk relevant to the query, as well as pieces irrelevant to the query, on all dimensions according to query bounds, yet not necessarily down to final partitions; LCKD refines only the relevant part of the data along the query bounds in each dimension.

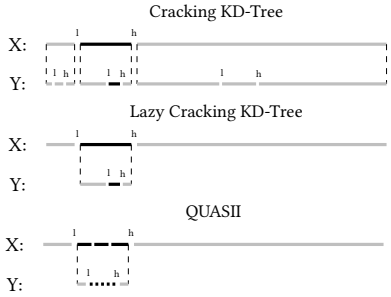

Figure 1: Three cracking strategies in action.

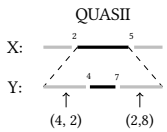

Figure 2: QUASII rigidity; Q1[(2,4)–(5,7)], Q2[(3,6)–(6,9)]

Figure 2 illustrates the problem that would arise in case QUASII did not perform full refinement. Assume a query on the range defined by lower left coordinates $(2, 4)$ and upper right coordinate $(5, 7)$, triggering a cracking of the x dimension on range $[2, 5]$ and the y dimension on range $[4, 7]$. Consider two points, $(4, 2)$ and $(2, 8)$, which belong in the x-range $[2, 5]$, but get separated by the y-interval $[4, 7]$. If a subsequent query requested the range from $(3, 6)$ to $(6, 9)$, we should crack the x dimension at 3, hence swap points $(2, 8)$ and $(4, 2)$, destroying the sorted order on y. To prevent such an eventuality, QUASII cracks exhaustively upon the first query on any data range. Given this rigidity of QUASII, we discuss *stochastic cracking* on LCKD only.

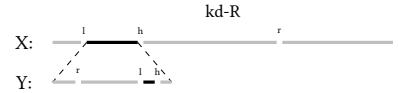

Figure 3: kd-R in action.

Multidimensional stochastic cracking As described in Section 2, we may spur query-driven cracking via data-driven cracks, to achieve faster convergence with a slight initialization overhead [4]. In [4], the DD1R strategy emerged as most commendable. We mend LCKD using DD1R in the multidimensional case; we call the resulting method kd-R, where R stands for *random*. In each dimension, when cracking a data segment, kd-R cracks at a random point in addition to the query bounds, as Figure 3 shows. Next, we examine other ways to improve upon LCKD.

Hybrid cracking We propose kd-HR, a *hybrid* strategy that aims to combine the fast convergence of QUASII and the low initialization cost of LCKD; kd-HR initially behaves as kd-R, yet switches to QUASII and stops creating new levels once the tree reaches a specified threshold. We design two kd-HR variants, depending on the nature of the threshold: kd-HR$_s$, with a threshold on node size, and kd-HR$_\ell$, with a threshold on tree height. Figure 4 shows the operation of kd-HR on the last level before switching to QUASII. kd-HR postpones QUASII-like operation until the data becomes sufficiently small (kd-HR$_s$) or the area in question has been refined enough times (kd-HR$_\ell$); this precaution should bring about faster convergence, as the tree stops growing further on branches switching to QUASII.

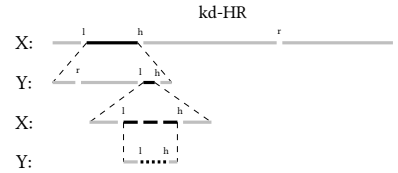

Figure 4: kd-HR in action.

5 EXPERIMENTAL STUDY

Here, we present our experimental study featuring QUASII, CKD, and their stochastic and hybrid variants. We implemented all methods[1] in C++ and compiled in g++ 7.4.0, and conducted experiments on a 10-core Intel Xeon CPU E5-2687W v3 machine at 3.10GHz with 396G RAM running Ubuntu 18.04.3 LTS.

ID	Name	Size	Distribution
0	Random	240000	Uniform distribution
1	Skyserver full	722711000	Skyserver data
2	Neuroscience	1000000	Neuronal data

Table 1: Datasets

Data. Table 1 lists our data sets. Random is a synthetic containing points distributed uniformly at random between 0 and 1 in each dimension; the default dimensionality is 2. The Skyserver data are downloaded from [14], a public astronomical data repository, by the CasJobs functionality. We chose two attributes, *declination*, dec, and *right ascension*, ra. To experiment with data

[1]The code is available at https://github.com/MULTIDAI/MultiDAI

of varying size, we construct trunacted versions of this data, selecting every ith point, $i \in \{2, 4, 8, \ldots, 512\}$. The Neuroscience dataset consists of 3-dimensional model of a neocortical column in a brain tissue with MBBs matched to neuronal axons.

Name	Size	Distribution
Random	10000	Random distribution
Sequential	1000	Queries along diagonal
Skyserver chronological	1000000	Skyserver workload
Random clusters	50000	Synthetic normal clusters

Table 2: Workloads

Workloads. Table 2 lists our query workloads. The first synthetic workload, Random, issues range queries at locations selected uniformly at random, with extent 1% of the value domain per dimension. The second synthetic workload, Sequential, issues a non-overlapping sequence of consecutive range queries along the diagonal of the domain of celestial coordinates, again with extent 1% of the value domain per dimension; as this workload explores the data space incrementally in small steps, the index constructed under its guidance never gets an opportunity to exploit previous indexing. Skyserver workloads derive from the SqlLog table [14], containing queries executed by scientists in nonrandom patterns, focusing on one sky area at a time [4]. We filtered the range selection predicates on declination dec and right ascension ra. We use three versions of this workload: chronological preserves the original order of queries; sorted on x contains the same queries, sorted on lower dec coordinate; sorted on size sorts them on total area of query range. The latter two workloads present a skewed pattern resembling the skewed sequential workload we apply on synthetic data. The Random cluster workload is synthetically generated for use with the Neuroscience data; queries belong to Gaussian clusters surrounding 5 randomly chosen centers in the range of the data values, with a maximum query volume of 0.01% of the whole data volume.

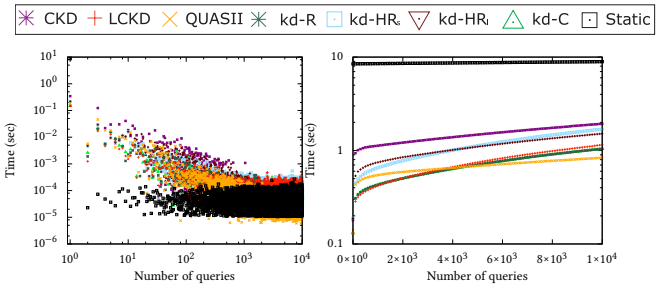
Compared methods. We juxtapose QUASII [12]; CKD [5]; LCKD; kd-R; kd-HR$_s$ switching to QUASII when nodes that are smaller than $s = 1000$; kd-HR$_\ell$ switching to QUASII after $\ell = 6$ levels; kd-C, a variation of kd-R that performs data-driven cracks on the center of the value domain; Static, a static implementation of a KD-tree. Previous works have already compared QUASII [12] to a static R-tree [3] and CKD [5] to a static KD-tree [1].

Tree	Synthetic	Skyserver	Neuroscience
QUASII	400	40	200
CKD	1000	170	400
LCKD	400	90	200
kd-R	400	80	200
kd-C	400	70	200
kd-HR	400	80	200

Table 3: Chosen τ values for synthetic and real data.

Parameter tuning. All methods require a τ parameter — the minimal cardinality of a data slice that may be further cracked. We conducted a series of experiments on the Random data (Table 1), with the Random and Synthetic workloads (Table 2). For each method, we chose as default the value of τ for which we observed best performance. Table 3 presents those choices. In size-based hybrid, kd-HR$_s$, we chose s through experimentation with several values; $s = 1000$ yielded the best performance.

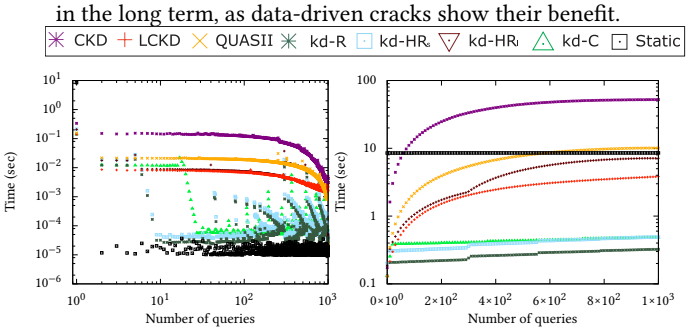
Random workload. We first examine the Random data with the Random workload. Figure 5a presents time per query. Evaluating the first query with Static counts for full index building. CKD is the slowest among adaptive methods in the first query, as it scans all data twice: once to crack on the first dimension, and again to crack the three resulting slices on the second dimension. QUASII comes second, while LCKD is the fastest. The initialization costs of stochastic and hybrid structures are almost identical, and slightly lower than that of QUASII. After the first query, CKD variants reduce time per query, yet LCKD converges faster than CKD. The time of QUASII falls intermediately, yet keeps falling further than LCKD. QUASII performs more work in early stages, yet achieves fast response times later on, traversing a shallower tree. As the workload evolves, fewer queries require additional indexing actions in QUASII, letting time per query fall to even less than that of Static. Figure 5b presents cumulative running time; the divergence between QUASII and the others is conspicuous; Static is much slower than the adaptive approaches; CKD incurs higher cumulative runtime than other adaptive structures.



(a) Time per query **(b) Cumulative time**

Figure 5: Results on Random workload.

A main takeaway from this experiment is that, over time, QUASII starts reaping the fruits of the index is has built more than other methods. We found this trend to be the same regardless of dataset: LCKD outperforms QUASII in the first queries at the expense of the quality of the index it builds, yet later queries do not benefit as much from the work done previously as they do with QUASII, and QUASII eventually outperforms LCKD. Unfortunately, the kd-HR hybrids present response times worse than LCKD, kd-R, and kd-C. We infer that the combination of kd-R and QUASII leads to a poor structure. Stochastic variants, kd-R and kd-C, present similar runtimes to LCKD, with an advantage in the long term, as data-driven cracks show their benefit.



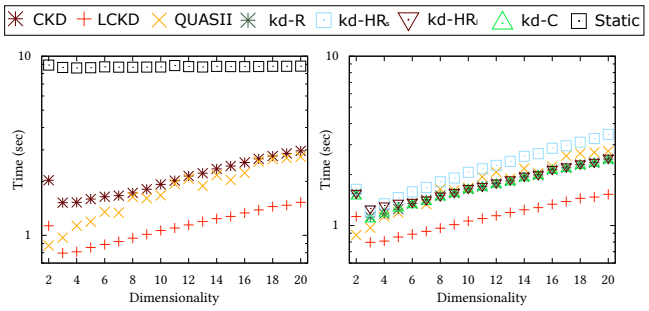
(a) Time per query **(b) Cumulative time**

Figure 6: Results on sequential workload.

Sequential workload. Now we turn to the Random data with the Sequential workload. Figure 6 shows our results. Unsurprisingly, CKD performs poorly. More surprisingly, in contrast to the preceding experiment, QUASII also performs poorly compared to LCKD; the thorough index refinement QUASII performs is a liability with the sequential workload. LCKD benefits from its lazy nature. This experiment reveals that the order of query execution has a significant effect on running time, due to the query-driven nature of these data structures: on a sequential workload, each new query processes an unindexed data region. Notably, kd-R performs best; its data-driven operation confers an advantage on this workload. The spikes in the plot arise when entering a region refined by data-driven cracks to a lesser extent. Interestingly, kd-C does not match the performance of kd-R: its center-based cracks prove to be insufficiently robust, vindicating

our choice to build hybrids on top of kd-R rather than kd-C. Yet those hybrids do not match the performance of kd-R either; their QUASII component appears to be a liability; this effect is apparent on kd-HR$_s$ and even more consequential in kd-HR$_\ell$.

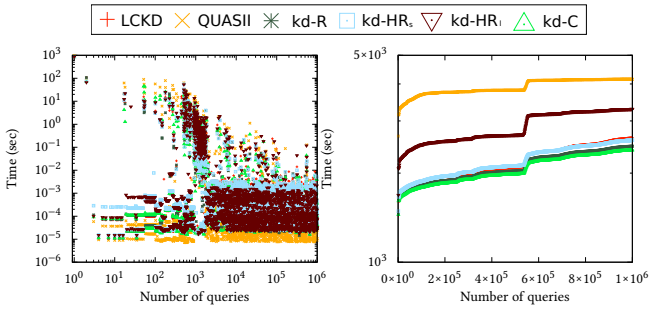
Effect of dimensionality. We now evaluate the impact of data dimensionality on the Random dataset and the Random workload. Figure 7 depicts our results in two plots for the sake of readability. As dimensionality grows, the cumulative time of QUASII rises drastically, due to the thorough refinement performed on *each* dimension. CKD and LCKD are less affected by dimensionality growth. LCKD presents a modest runtime growth with dimensionality. Surprisingly, the cumulative runtime of the KD-tree variants initially drops as dimensionality increases, as they gain from the indexing they perform. In the global trend, CKD incurs a heavier cumulative runtime burden, as additional dimensions beget a higher overhead than the benefit of cracking. QUASII, which performs well on random workloads on data of dimensionality 2, forfeits this advantage in higher dimensions. QUASII and QUASII-based hybrids, especially kd-HR$_s$, are affected by data dimensionality to a greater extent than LCKD, kd-R, and kd-C. We deduce that the QUASII strategy is detrimental on an increasing number of dimensions. Interestingly, the gap between LCKD and kd-R grows slightly with dimensionality, due to the additional random cracks performed by kd-R. On a random query workload, such random cracks bring little benefit, while incurring an overhead that rises with dimensionality.



(a) CKD, QUASII, Static. **(b) Stochastic and hybrid.**

Figure 7: Effect of dimensionality.

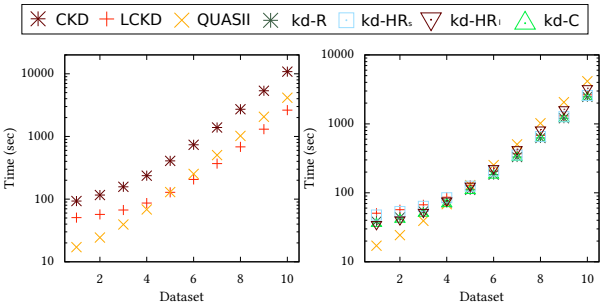
Henceforward, we use only LCKD and its stochastic and hybrid variants as representatives of cracking KD-trees and drop Static from figures for the sake of readability.



(a) Time per query **(b) Cumulative time**

Figure 8: Skyserver $^1/_4$, chronological order.

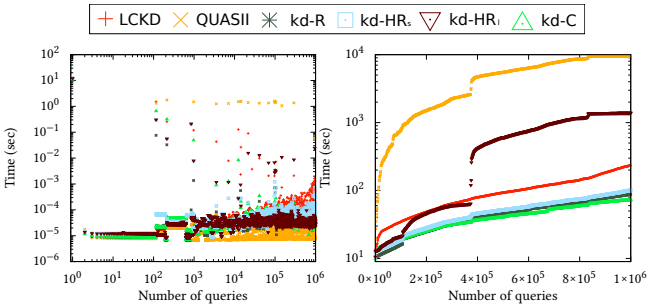
Skyserver workload, chronological. Now we apply the Skyserver chronologically ordered workload on Skyserver data. Figure 8 shows our results with the Skyserver $^1/_4$ dataset. In the first 500 queries, QUASII occasionally reaches response times comparable to the other methods, which should correspond to accessing already indexed data areas; progressively expensive queries become rarer, and eventually QUASII converges to response times lower than those of other methods. This converged response time of QUASII does not render its cumulative time lower than those of others for the entire workload in this configuration; kd-C and kd-R achieve the best cumulative times. Still, as Figure 9 shows, as we reduce the data size (10 for full, 1 for $^1/_{512}$) under the same workload so as to render the workload to data ratio larger, eventually QUASII becomes the fastest.



(a) QUASII, CKD, LCKD. **(b) Stochastic and Hybrid.**

Figure 9: Skyserver; regular workload, variable data sizes.

Figure 11 presents cumulative times with the same workload and four different Skyserver sizes. As data size falls, the time of QUASII approaches and supersedes, those of kd-HR, kd-R, and LCKD; still, kd-R and kd-C remain better options than QUASII for workloads reasonably large compared to the data.



(a) Time per query **(b) Cumulative time**

Figure 10: Skyserver $^1/_{64}$, sequential workload.

Skyserver workload, sequential. We now assess performance on the Skyserver 1/64 data against the sequential Skyserver workload, sorted by the dec celestial coordinate. Figure 10 presents our results. Despite the smaller data size compared to those we examined previously, the sequential nature of the workload bears upon QUASII, which presents the worst result in cumulative time. LCKD achieves better cumulative time than QUASII, yet its response time does not converge as well; the tree it builds grows progressively higher in a lopsided manner. The stochastic variants, kd-C and kd-R, eschew the deficiencies of query-driven methods and attain best performance, while kd-HR$_s$ follows suit. On the other hand, kd-HR$_\ell$, which resorts to QUASII quite early, inherits the liability of QUASII. This result reconfirms that the QUASII strategy is a liability more than an asset in hybrids.

Skyserver workload sorted by size Now we apply the Skyserver workload ordered by query size on the Skyserver 1/4 data. Figures 12 and 13 show the results for *ascending* and *descending* order, respectively. On the ascending order, as expected, QUASII is initially slower, but achieves better query response times later. In cumulative time, kd-C performs best, closely followed by kd-R; kd-HR$_s$ does not gain from its hybrid character, while kd-HR$_\ell$ has a clear disadvantage. LCKD is superseded by kd-Rand kd-HR. On

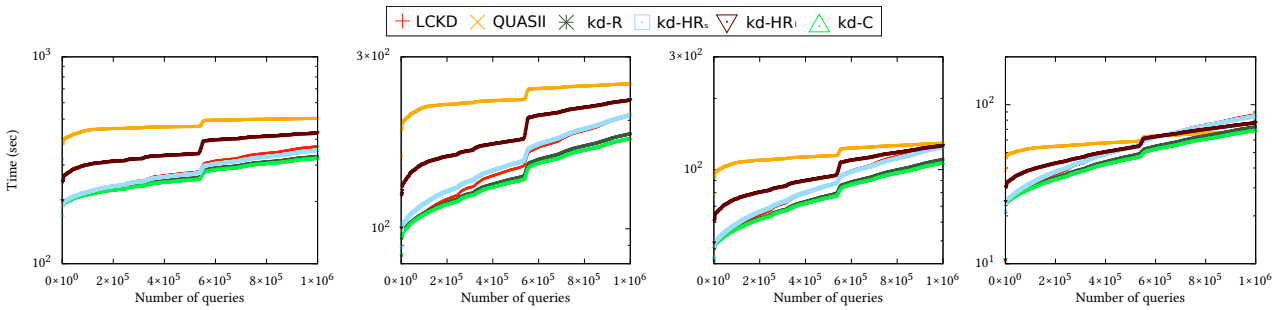


Figure 11: Skyserver, regular workload, datasets: 1/8, 1/16, 1/32, 1/64.

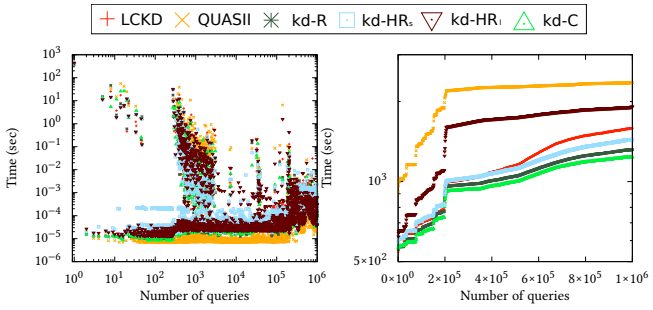
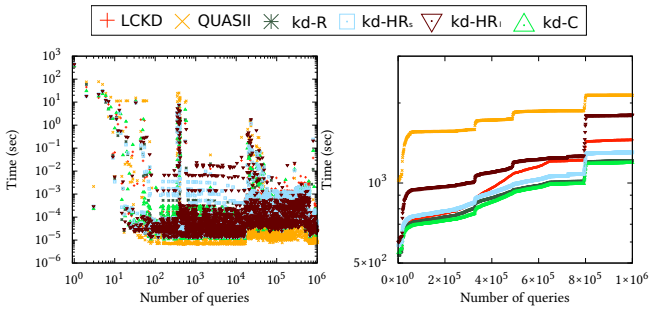
the descending order, time per query is initially higher, as queries of larger extent require more indexing work; cumulative time grows more steeply in the early stage than with the ascending order, yet performance resembles the ascending case.



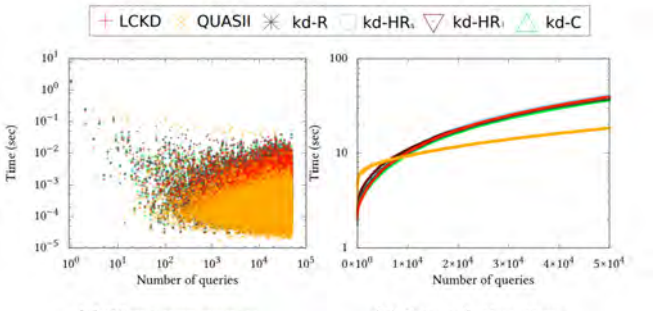
(a) Time per query **(b) Cumulative time**

Figure 12: Skyserver 1/2, workload sorted on size (asc.).



(a) Time per query **(b) Cumulative time**

Figure 13: Skyserver 1/2, workload sorted on size (desc.).



(a) Time per query **(b) Cumulative time**

Figure 14: Neuroscience data, random cluster workload.

Neuroscience data. We now assess performance on the Neuroscience data with the random clustered workload. This dataset contains objects with spatial extent rather than points; thus, we employ *query window extension* [15], as in [12]: we represent shapes by their lower coordinates per dimension and *extend* query ranges by the maximum object extent towards the lower side of each dimension, to hit the lower coordinates of any object overlapping the query's range; we filter *false hits* in a refinement step. Figure 14 presents our results. No method converges as robustly as with point data, due to the overhead caused by query extension. Still, QUASII converges more robustly than others.

6 CONCLUSION

We conducted a comparative experimental evaluation of works on multidimensional adaptive indexing and enhancements leveraging stochastic and hybrid strategies. We found that adaptations of the Cracking KD-tree achieve better performance compared to QUASII in terms of initialization and with short workloads, while QUASII yields attractive performance with long-running workloads. We combined the Cracking KD-Tree with stochastic measures that ameliorate the sensitivity to the order in which queries are posed. Further research is needed on multidimensional adaptive indexing of objects with spatial extent and accommodating updates; we also aim to investigate the adaptive indexing of graph structures with privacy constraints [11, 17] and adaptive multidimensional synopses [9].

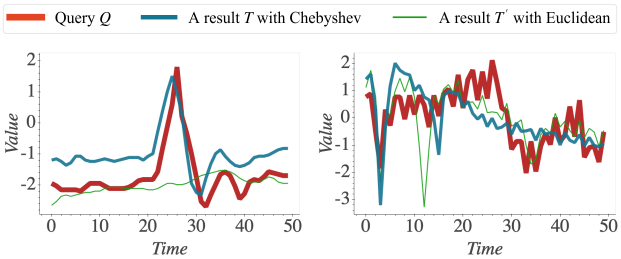
ABSTRACT

We address the problem of subsequence search in time series using Chebyshev distance, to which we refer as twin subsequence search. We first show how existing time series indices can be extended to perform twin subsequence search. Then, we introduce TS-Index, a novel index tailored to this problem. Our experimental evaluation compares these approaches against real time series datasets, and demonstrates that TS-Index can retrieve twin subsequences much faster under various query conditions.

1 INTRODUCTION

Given a time series T and a query sequence Q ($|Q| \ll |T|$), *subsequence search* finds subsequences in T that are similar to Q. Although most works rely on Euclidean distance or Dynamic Time Warping (DTW) (e.g., [17, 19]), different $\mathcal{L}_p$ norms or other similarity measures are also useful for capturing different patterns of similarity or achieving higher classification accuracy in certain datasets [6, 22]. In this work, we use the *Chebyshev* distance (i.e., $\mathcal{L}_\infty$ norm) between two subsequences, which is the maximum difference of their values across their entire duration. We call two subsequences *twins* with respect to a distance threshold ϵ, if their Chebyshev distance is not greater than ϵ. This kind of similarity search can be useful is various applications: finding *doublet* earthquakes in seismology, identifying similar traffic patterns in road networks, or detecting irregular patterns in medical applications like Electroencephalography (EEG) or Electrocardiography (ECG) sequences, etc.

The following indicative experiment on an EEG time series [12] with length of 1,801,999 timestamps provides some insight on the different results obtained using Chebyshev distance as opposed to Euclidean. Considering a query sequence Q and a Chebyshev distance threshold ϵ, we identify all twin subsequences, obtaining 1,034 results in total. We then attempt to retrieve the same results by subsequence search using Euclidean distance. To avoid any false negatives, as will be shown later in Section 3.1, we need to set the Euclidean distance threshold to $\epsilon' = \epsilon \times \sqrt{|Q|}$. The latter produces 127,887 results. Figure 1 exemplifies the intuition behind matches obtained with Chebyshev distance compared to those with Euclidean, for two different queries. Assume a query sequence Q and two matches, T and T', obtained under Chebyshev and Euclidean distance, respectively. As shown, T closely matches the query in all timestamps. Instead, T' either lacks a spike that is present in the query (Fig. 1a) or exhibits one that is not present in the query (Fig. 1b).



(a) Absence of desired spike (b) Presence of undesired spike

Figure 1: Examples of false positives obtained with Euclidean distance compared to results with Chebyshev distance on subsequences of the EEG dataset.

Given a query sequence Q and a time series T, a naïve process for finding twin subsequences of Q across T is by performing a sweepline scan. This scans T using a sliding window of length $|Q|$, comparing at each timestamp the query with the current subsequence extracted from T, and adding it to the results if it satisfies the given threshold ϵ on Chebyshev distance. However, this is clearly inefficient for long time series.

In this work, we investigate index-based methods for twin subsequence search. First, we show how two state-of-the-art time series indices, namely KV-Index [19] and *i*SAX [18] can be adapted for this task. Then, we introduce a novel index, called TS-Index, which is tailored to this problem. TS-Index is a tree structure that summarizes the subsequences contained within each node using *Minimum Bounding Time Series* (MBTS) [4], consisting of an upper and lower bounding sequence. Our experimental evaluation shows that executing twin subsequence search using TS-Index is significantly faster compared to adapting the query execution over other indices.

Specifically, our main contributions are as follows:

- We introduce the problem of twin subsequence search and propose a filter-verification algorithm that can be applied on state-of-the-art time series indices.
- We then introduce TS-Index, a tree-based index tailored to twin subsequence search, which utilizes appropriate bounds in its nodes to prune the search space.
- We experimentally evaluate our proposed methods using real-world datasets in terms of query execution, memory footprint and index construction time.

The remainder of the paper is organized as follows. Section 2 reviews related work. Section 3 formally defines the problem. Section 4 presents how it can be addressed based on existing indices. Section 5 presents the proposed TS-Index. Section 6 reports our experimental results. Finally, Section 7 concludes the paper.

2 RELATED WORK

Subsequence search can be performed with a sweepline approach that scans the time series using a sliding window. Various optimizations can be found in UCR suite [17] and Matrix Profile [21]. However, these optimizations are specific to Euclidean distance and thus cannot be applied to twin subsequences. Also, the lack of an index poses efficiency and scalability limitations.

A survey of time series indices for similarity search can be found in [7]. Several methods use Discrete Wavelet Transform to reduce dimensionality and then generate an index based on the transformed sequences (e.g., [3, 16]). More recent approaches are based on the *Symbolic Aggregate Approximation* (SAX) representation of time series [10]. A SAX *word* is a multi-resolution summary of a time series quantized on the value domain. It is derived from the Piecewise Aggregate Approximation (PAA) [8], which segments a time series on the time axis and approximates it by retaining only the mean value per segment. This has led to the *i*SAX index [18], a tree-based structure built over the SAX words of a set of time series. Each node in *i*SAX contains a SAX word that guarantees a lower bound in terms of Euclidean distance for all the time series indexed by it. To answer similarity search queries, the index is traversed in a top-down fashion, comparing at each step the SAX representation of the query against the ones contained in each visited node. Several extensions to *i*SAX have been proposed [13]. *i*SAX 2.0 [1] and *i*SAX2+ [2] enable bulk loading, while ADS+ [23] builds the index adaptively, based on the query workload. DP*i*SAX [20] is a distributed index. ParIS [14] and MESSI [15] take advantage of modern multi-core architectures. Coconut [9] introduces sortable SAX representations and builds an index in a bottom-up fashion. Finally, ULISSE [11] answers queries of varying length.

Another recent method for subsequence search is KV-Index [19]. After extracting all subsequences of a given length from a time series and deriving their corresponding mean values, it generates an index containing key-value pairs. Each key represents a range of mean values for a group of subsequences, pointing to starting positions of these subsequences along the original time series.

As we show in Section 4, it is possible to execute twin subsequence search queries using *i*SAX or KV-Index. However, since these indices are tailored to similarity search using Euclidean distance, this approach is suboptimal, as indicated also in our experiments in Section 6.

An index for arbitrary $\mathcal{L}_p$ norms is described in [22]. It divides each sequence into a fixed number of equi-sized segments, and takes the mean of each segment to form a feature vector. Such a generic approach favors flexibility; instead, our focus in this paper is on optimizing performance specifically for queries using Chebyshev distance.

Finally, in a previous work [5], we have studied the problem of discovering pairs and bundles of similar time-aligned subsequences within a collection of time series, based on Chebyshev distance, using a sweepline approach. In this paper, we focus on searching for twin subsequences in an input time series T that are similar to a query subsequence Q, which is a different problem, and we propose an index-based approach. Furthermore, in another previous work [4], we have developed a hybrid index, called BTSR-Tree, which also employs the concept of Minimum Bounding Time Series (MBTS) to prune the search space. However, this is a spatial-first index specifically tailored to queries over geo-located time series, and it is based on Euclidean distance instead of Chebyshev.

3 PROBLEM DEFINITION

Next, we formally introduce the problem of twin subsequence search and describe a generic filter-verification approach.

3.1 Problem Statement

A *time series* is a time-ordered sequence $T = \{T_1, T_2, ..., T_n\}$, where T_i is the value at the i-th timestamp and $n = |T|$ is the length of the series (i.e., number of timestamps). We use $T_{p,l}$ to denote the *subsequence* $\{T_p, ..., T_{p+l-1}\}$ starting at timestamp p and having length l, where $1 \leq p \leq p + l - 1 \leq n$. For brevity, we also use S to generally refer to a (sub)sequence.

Given two sequences S and S' of equal length l, we call them *twins* if their Chebyshev distance is not greater than a given threshold ϵ. The Chebyshev distance of two vectors is their maximum difference along any dimension. Hence, if S and S' are twin sequences with respect to ϵ, their values at any timestamp should not differ by more than ϵ. Formally:

Definition 1 (Twin Sequences). *Two sequences S and S' of equal length l are called* twins *with respect to a given threshold ϵ, denoted as $S_1 \sim_\epsilon S_2$, if their Chebyshev distance d is not greater than ϵ, i.e., $d(S, S') := \max_{i=0}^{l-1}(|S_i - S'_i|) \leq \epsilon$.*

We can now formally define the problem:

Problem 1 (Twin Subsequence Search). *Given a query sequence Q of length l, a time series T of length $n \gg l$, and a distance threshold ϵ, find all subsequences S in T ($|S| = l$) such that $Q \sim_\epsilon S$.*

We note two important observations below. Given two twin sequences $S \sim_\epsilon S'$ of length l, their Euclidean distance is $ED(S, S') = \sqrt{\sum_i (S_i - S'_i)^2} \leq \sqrt{\sum_i \epsilon^2} = \epsilon \times \sqrt{l}$. This establishes a relation between a given Chebyshev distance threshold and a corresponding Euclidean distance threshold. Moreover, from Definition 1, it follows that any pair of time-aligned subsequences across two twin sequences are also twins, i.e., if $T \sim_\epsilon T'$, then $T_{p,l} \sim_\epsilon T'_{p,l}$ for any $l \in [1, |T|]$ and $p \in [1, |T| - l]$.

Often, z-normalization is applied when comparing time series. Throughout the paper, we consider various possibilities: (a) working with the raw values, (b) z-normalizing the entire time series, (c) z-normalizing each individual subsequence. We discuss the implications of each case where relevant.

3.2 Filter-Verification Approach

We can detect twin subsequences following a filter-verification framework: the first step (*filtering*) generates candidate subsequences, which are then evaluated in the second step (*verification*) to identify those satisfying the Chebyshev distance threshold. A straightforward approach for generating candidates is to scan the entire time series T with a *sweepline* and consider each subsequence $T_{p,l}$ for $p \in [1, |T| - l]$ as a candidate.

Verification is done by checking all pairwise value differences between Q and $T_{p,l}$. If the difference found at a timestamp exceeds ϵ, then candidate $T_{p,l}$ is rejected, otherwise it is accepted. Verification can be accelerated by detecting false positives as early as possible. If the values are z-normalized, we can prioritize those points in Q having the highest absolute value, since these are less likely to have a match with the respective points in $T_{p,l}$. This optimization is also used in *UCR Suite* [17], and is known as *reordering early abandoning*.

The drawback of this sweepline approach is that it generates an excessive number of candidates (specifically, $|T| - l$), thus

incurring a prohibitive cost when dealing with long series. To filter candidates more effectively, in the following sections we present methods based on indexing the subsequences of T. First, we address the problem using state-of-the-art indices; then, we introduce a novel index tailored to twin subsequence search.

4 TWIN SUBSEQUENCE SEARCH WITH EXISTING INDICES

Next, we focus on two representative state-of-the-art indices for time series similarity search, namely KV-Index [19] and *i*SAX [2], showing how they can be used for twin subsequence search without altering their structure.

4.1 KV-Index

Given a time series T, KV-Index [19] is built by considering all its subsequences of a pre-defined length l. Each subsequence S is represented by a pair (p, μ), where p is its starting position (i.e., timestamp) in T and μ is its mean value over the next l timestamps. KV-Index is an inverted index constructed over these pairs. Each key is a range of mean values, whereas each inverted list entry contains intervals of positions.

Twin subsequence search can be performed with KV-Index based on the following observation. If two subsequences S and S' of length l are twins with respect to ϵ, i.e., $S \sim_\epsilon S'$, then their mean values μ and μ' cannot differ by more than ϵ, i.e., $|\mu - \mu'| \leq \epsilon$. Based on this, we can use a KV-Index built over a time series T to generate candidates for detecting twin subsequences. Specifically, assume a query sequence Q with mean value μ_q. The candidate subsequences in T are those included in the inverted lists with keys $[\mu_{min}, \mu_{max}]$, such that $\mu_{min} - \epsilon \leq \mu_q \leq \mu_{max} + \epsilon$. Then, the obtained candidates must be verified to derive the final results. Notice that this property is not effective if each individual subsequence has been z-normalized, because then all mean values are zero. Hence, KV-Index is applicable when working with raw values or if the entire sequence is z-normalized.

4.2 *i*SAX Index

*i*SAX is a tree index structure for time series similarity search [2]. Time series are z-normalized and indexed using their *Symbolic Aggregate approXimation (SAX)* [18]. The SAX representation of a series is derived in two steps. The first applies *Piecewise Aggregate Approximation* (PAA) [8], which splits the series in a specified number m of segments and approximates each one with the mean value over the corresponding time interval. The second step applies quantization to assign each mean value to a discrete SAX *symbol*. Hence, each SAX symbol X corresponds to a range of mean values $[\mu_{X_{min}}, \mu_{X_{max}})$. The SAX representation of a series is a sequence of m SAX symbols (one symbol per segment), and is called SAX *word*. Notice that, by default, SAX words are derived using precomputed breakpoints that are selected assuming z-normalized values; nevertheless, non-normalized values can also be handled by adjusting the breakpoints accordingly.

Twin subsequence search can be enabled over *i*SAX by reasoning as follows. Assume two subsequences S and S' of length l, and their SAX representations $SAX(S) = \{X_1, X_2, ..., X_m\}$ and $SAX(S') = \{X'_1, X'_2, ..., X'_m\}$. As we have observed earlier, (a) if two sequences are twins with respect to a threshold ϵ, then the difference between their mean values is also bounded by ϵ, and (b) any pair of time-aligned segments across two twin sequences are also twins. Combining these two properties, we can see that if $S \sim_\epsilon S'$, then for each pair of symbols X_i and X'_i in the respective SAX representations, the mean values denoted by these symbols must not differ by more than ϵ. Hence, if $S \sim_\epsilon S'$, then $\mu_{X_{i\,max}} \geq \mu_{X'_{i\,min}} - \epsilon$ and $\mu_{X_{i\,min}} \leq \mu_{X'_{i\,max}} + \epsilon$ for any $i \in [1, m]$.

Consequently, we can perform twin subsequence search using *i*SAX as follows. Given a time series T, we construct an *i*SAX index over all its l-length subsequences. Then, for a query sequence Q, we traverse the *i*SAX index starting from its root. At each node, we check the SAX word of Q against the SAX word of that node, applying the property mentioned above. If the check fails, the node and its subtree can be safely pruned; otherwise, the search continues at the node's children. Once a leaf node is reached, and qualifies according to this check, all subsequences indexed therein are retrieved as candidates for verification.

5 THE TS-INDEX

As discussed in Section 4, it is possible to use KV-Index or *i*SAX to identify candidates for twin subsequence queries. However, since these indices are not tailored to the matching criterion, they tend to generate a large number of false positives, incurring a significant verification cost, as confirmed in our experiments. In the following, we introduce TS-Index, which is specifically designed for twin subsequence search. First, we provide an overview of its structure and explain how it is constructed. Then, we present an algorithm to evaluate twin subsequence queries specifying a distance threshold.

5.1 Index Structure

The core concept in TS-Index is that of *Minimum Bounding Time Series* (MBTS) [4]. An MBTS is a pair of sequences that fully encloses a set of time series $\mathcal{T}$ by indicating the maximum and minimum values at each timestamp. Figure 2a depicts an example of an MBTS enclosing a set of four time series. Formally:

Definition 2 (MBTS). *Given a set $\mathcal{T}$ of time series with equal length l, its MBTS $B = (B^{\sqcap}, B^{\sqcup})$ consists of an* upper bounding time series $B^{\sqcap}$ *and a* lower bounding time series $B^{\sqcup}$, *constructed by respectively selecting the maximum and minimum values at each timestamp $i \in \{1, \ldots, l\}$ among all time series in $\mathcal{T}$ as follows:*

$$B^{\sqcap} = \{\max_{T \in \mathcal{T}} T_1, \ldots, \max_{T \in \mathcal{T}} T_l\}$$
$$B^{\sqcup} = \{\min_{T \in \mathcal{T}} T_1, \ldots, \min_{T \in \mathcal{T}} T_l\} \quad (1)$$

The TS-Index has a tree structure. Each internal node points to a set of children nodes, whereas each leaf node points to a set of subsequences (more specifically, to the starting positions of its indexed subsequences along the input time series T). All leaf nodes are at the same level. Each node is associated with an MBTS, which encloses all the sequences indexed therein. Clearly, MBTS get tighter when descending from the root to the leaf level. Figure 3a illustrates an example of TS-Index for nine input sequences. The MBTS of each node is depicted as a grey band.

5.2 Index Construction

Assume an input time series T and a subsequence length l. The TS-Index over T is constructed in a top-down fashion, by sequentially inserting all l-length subsequences of T. When inserting a sequence S, we traverse the index from the root, selecting at each level the node whose MBTS has the smallest distance from S, until a leaf node is reached. The distance between a sequence S and an MBTS B is calculated using the following formula:

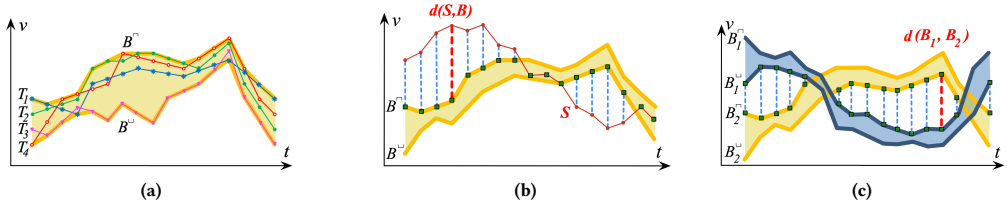


Figure 2: (a) MBTS enclosing a set of 4 time series. Distance between (b) a sequence S and an MBTS B, (c) MBTS B_1 and B_2.

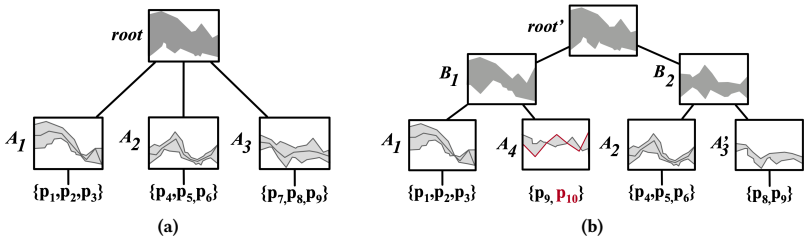

Figure 3: (a) TS-Index for 9 input sequences. (b) Inserting p_{10} causes a split at leaf A_3 and splits propagate upwards.

$$d(S,B) = \max_i \begin{cases} S_i - B_i^{\sqcap} & \text{if } S_i > B_i^{\sqcap} \\ B_i^{\sqcup} - S_i & \text{if } S_i < B_i^{\sqcup} \\ 0 & \text{otherwise} \end{cases} \quad (2)$$

where $B_i^{\sqcap}$ and $B_i^{\sqcup}$ are the i^{th} values of the upper and lower bounds of the MBTS B, respectively.

Each node has a minimum capacity μ_c and a maximum *capacity* M_c, specifying the minimum and maximum number of children it can point to. Once a node exceeds M_c, it is split in two nodes. This may cause the parent node to also exceed the maximum capacity M_c, in which case it is split too. Hence, this process recursively propagates upwards until no further splits occur. This procedure ensures that all leaves are placed on the same level of the tree.

During node splitting, the goal is to make the MBTS of each new sibling node as tight as possible. If this is a leaf node, we identify the two subsequences within the original node having the highest Chebyshev distance and use them as seeds for the two sibling nodes. Each remaining subsequence is assigned to the node where it causes the smallest expansion of its MBTS, which gets updated accordingly. For an internal node, the process is similar. Yet, adjusting its MBTS in this case involves the MBTS of children nodes instead of individual sequences. To accommodate this, the distance between two MBTS B_1 and B_2 is defined as:

$$d(B_1,B_2) = \max_i \begin{cases} B_{1,i}^{\sqcup} - B_{2,i}^{\sqcap} & \text{if } B_{1,i}^{\sqcup} > B_{2,i}^{\sqcap} \\ B_{2,i}^{\sqcup} - B_{1,i}^{\sqcap} & \text{if } B_{1,i}^{\sqcap} < B_{2,i}^{\sqcup} \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

where $B_{1,i}^{\sqcup}$, $B_{1,i}^{\sqcap}$ and $B_{2,i}^{\sqcup}$, $B_{2,i}^{\sqcap}$ are the i^{th} values of the upper and lower bounds of the MBTS B_1 and B_2, respectively. Figures 2b and 2c exemplify the calculation of the distance of a sequence S to an MBTS B and the calculation of the distance between two MBTS (B_1, B_2) respectively; in both cases, the distance is the length of the dashed red line.

Figure 3b depicts an example where inserting subsequence p_{10} into leaf node A_3 of the TS-Index in Figure 3a, causes it to split into two new nodes, A_3' and A_4 (we assume $\mu_c = 2$ and M_c=3). This process is then propagated upwards, splitting the root into B_1 and B_2. To keep the MBTS tight –according to Equation 3–, nodes A_1, A_4 have become children of B_1 and A_2, A_3' are now children of B_2. Finally, a new root is added, increasing the index height by one.

5.3 Query Execution

Twin subsequence search can be performed with TS-Index based on the following lemma.

Lemma 1. *Assume a query sequence Q and a node N of the TS-Index with MBTS B. If there exists a sequence S indexed at N such that $Q \sim_\epsilon S$, then $d(Q,B) \leq \epsilon$.*

Proof. Assume that $Q \sim_\epsilon S$ for a sequence S indexed by node N. From Definition 2, it follows that $S_i \in [B_i^{\sqcup}, B_i^{\sqcap}]$ for each timestamp i. Moreover, from Definition 1, it follows that $|Q_i - S_i| \leq \epsilon$. Hence, from Equation 2, we derive $d(Q,B) \leq \epsilon$. □

Given a query sequence Q, we traverse the index in a top-down fashion, starting from its root. For each visited node N, we compare Q against N's MBTS, applying Lemma 1 to prune its subtree. Note that this check can be accelerated, since it is not necessary to fully compute distance $d(Q,B)$; instead, if the indexed values have been z-normalized, we apply early abandoning (see Section 3.2) to prune the node as soon as the value difference exceeds ϵ in at least one timestamp. Multiple paths starting from the root may need to be explored, depending on the query and the tightness of the bounds in the visited nodes.

Algorithm 1 describes the search process. The input includes the query sequence Q, the constructed TS-Index I, the given time series T and the threshold ϵ. We start by initializing a list L with the root's children (Line 2). Then, we traverse the index by iterating over this list (Lines 3-12). For each node N currently in the list, we obtain its MBTS (Lines 4-5). Then, we check whether the distance between this MBTS and the query is higher than the specified threshold ϵ (Line 6). If so, the subtree under the current node N is pruned; otherwise, it is examined as explained next. If N is not a leaf node, we insert its children in list L for probing (Lines 7-8). Once a leaf node is reached, we iterate over all the subsequence positions it contains and check whether each corresponding subsequence is a twin of Q with respect to ϵ. If so, we add this subsequence to the final results (Lines 9-12). The results are returned once all candidate nodes in list L have been either probed or pruned (Line 13).

Algorithm 1: `TwinSubsequenceSearch`

Input : Time series T, TS-Index I, query Q, threshold ϵ
Output: List R of twin subsequences to Q

```
1  R ← ∅
2  L ← I.root.getChildren()
3  while L ≠ ∅ do
4      N ← L.getNext()
5      B ← N.MBTS
6      if d((Q, B) ≤ ε then
7          if N is not leaf then
8              L ← L ∪ {N.getChildren()}
9          else
10             foreach p ∈ N.getPositions() do
11                 if d((Q, T_{p,l}) ≤ ε then
12                     R ← R ∪ T_{p,l}
13 return R
```

Table 1: Datasets and distance thresholds.

Dataset	n	ϵ (norm)	ϵ (non-norm)
Insect	64,436	0.5,**0.75**,1,1.25,1.5	50, **100**,150,200,250

Parameter	*Value*
Number m of segments	5, **10**, 20, 25, 50
Sequence length l	50, **100**, 150, 200, 250

6 EXPERIMENTAL EVALUATION

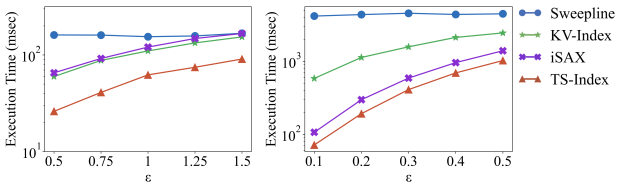
Next, we present an experimental evaluation of our methods against two real-world datasets.

6.1 Experimental Setup

We performed experiments against two real-world time series (see Table 1), which contain diverse patterns and differ in their total duration. In particular, the *Insect Movement* [12] series contains 64,436 insect telemetry readings spanning around 30 minutes (36 readings/sec), whereas the *Electroencephalography (EEG)* [12] series comprises 1,801,999 EEG readings at 500Hz lasting one hour. Unless stated otherwise, we z-normalize the time series to facilitate selection of distance thresholds.

Table 1 indicates the different values for the distance threshold ϵ used in the experiments against each dataset, for z-normalized (*norm*) or original values (*non-norm*). Table 2 contains the values for subsequence length l and number of segments m, which are common in the experiments on both datasets. In both tables, default values are in bold. These values have been selected after running several preliminary tests, which also guided selection of other parameters. Specifically, for *i*SAX, the maximum node capacity is set to 10,000 to enable index construction in reasonable time even for larger datasets. The default values for minimum and maximum node capacity in TS-Index are set to $\mu_c = 10$ and $M_c = 30$, respectively.

For each dataset, we randomly picked 100 subsequences, each of length $l = 100$ points, and used them as the query workload in all tests against that dataset. We report average response time per query (in milliseconds). We implemented all methods, including KV-Index, *i*SAX, and TS-Index, in Java. In all implementations, the structure of the index is kept in memory, while the original input dataset is stored on disk. Leaf nodes in the index contain the starting positions of the subsequences in the input time series. Thus, when a leaf is reached at query time, its corresponding subsequences are obtained from the input time series file using random access. All experiments were conducted on a server with 4 CPUs, each equipped with 8 cores clocked at 2.13GHz, and 256 GB RAM running Debian Linux.



(a) Insect Dataset (b) EEG Dataset

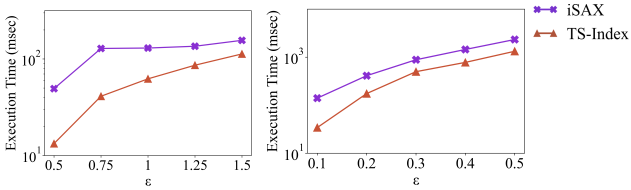
Figure 5: Varying subsequence length l.



(a) Insect Dataset (b) EEG Dataset

Figure 6: Varying ϵ on z-normalized subsequences.

6.2 Performance

We compare the average execution time per query for varying values of each parameter, setting the rest to their default values.

6.2.1 Varying threshold ϵ. Figure 4 depicts query execution time (in logarithmic scale) for varying threshold ϵ. As expected, searching with the Sweepline approach has a fixed cost per dataset regardless of ϵ, since it needs to scan all subsequences extracted from the input time series. Relaxing the threshold incurs an overhead when an index is involved. Queries against KV-Index perform poorly compared to other indices, since filtering based on mean values achieves less pruning. Searching with TS-Index outperforms the rest in every setting for both tested datasets. Overall, TS-Index is at least an order of magnitude more efficient in twin subsequence search compared to the KV-Index and Sweepline approaches. It is also consistently better than *i*SAX as it is less susceptible to fluctuations in the input sequences.

6.2.2 Varying Subsequence Length. Figure 5 plots performance results with a varying length l for subsequences obtained from the input time series. Increasing l seems to slightly negatively affect all approaches, except for TS-Index. Since longer subsequences are extracted, more checks are required, both in nodes (in case of *i*SAX) and raw subsequences during verification. Instead, TS-Index is faster when longer subsequences are specified, as it becomes less likely to find matching twins. In particular, TS-Index has higher pruning capability and can skip non-qualifying subtrees earlier at higher levels in the tree hierarchy. Thus, fewer

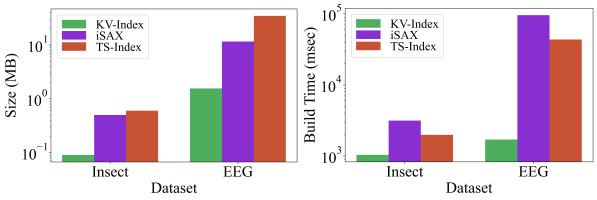
Figure 7: Varying ϵ on non-normalized data.



(a) Memory Footprint (b) Build Time

Figure 8: Memory footprint and build time per index.

leaf nodes are accessed and need to be verified, saving much of the verification cost for checks per timestamp.

6.2.3 Searching over z-normalized subsequences. We repeat the experiment for varying distance threshold ϵ, this time applying z-normalization over each individual subsequence, before inserting it in the index. As mentioned in Section 4.1, KV-Index cannot be built on such data since the mean value per subsequence would always be zero; thus, we only compare TS-Index with *i*SAX. The results are depicted in Figure 6. Clearly, z-normalizing the subsequences separately has no significant effect on the performance of TS-Index; the results are similar to those in Figure 4, with TS-Index outperforming *i*SAX in all cases.

6.2.4 Searching on Non-Normalized Data. Query execution cost for identifying twin subsequences against the raw (non-normalized) time series is depicted in Figure 7. Overall, TS-Index copes better than all the rest even for raw data, confirming its suitability for twin subsequence search in various settings.

6.2.5 Index Size. Figure 8a presents the memory footprint of TS-Index, *i*SAX and KV-Index for each dataset. KV-Index requires less space than TS-Index and *i*SAX, as it only keeps in memory the mean value and position range per subsequence. Instead, TS-Index and *i*SAX occupy more space due to their more complex structures. Specifically, *i*SAX requires two to three times less space than TS-Index. Indeed, *i*SAX needs to store one SAX word per node, whereas a node in TS-Index is represented by an MBTS, hence its increased memory footprint. Nevertheless, all indices, including TS-Index, have sizes that easily fit in main memory.

6.2.6 Build Time. Similarly to the index size, and due to the significantly less required calculations (i.e., only subsequence mean values need be calculated and no node splitting is needed), KV-Index requires significantly less time to be constructed than *i*SAX and TS-Index (Figure 8b). *i*SAX is the slowest index to be built, since it needs to additionally convert the PAA of each subsequence to a SAX word for each extracted subsequence.

7 CONCLUSIONS

In this paper, we have introduced the twin subsequence search problem. Given a query sequence Q, an input time series T and a distance threshold ϵ, this task retrieves all subsequences in T with Chebyshev distance to Q not higher than ϵ. To answer this query efficiently, we have introduced the TS-Index. We have described the index structure and proposed algorithms for efficient index construction and query answering. Our experimental evaluation assesses the TS-Index in terms of construction cost and confirms its superiority for twin subsequence search queries when compared to the state-of-the-art.

ABSTRACT

Interactive exploratory data analysis consists of workloads that are composed of filter-aggregate queries with highly selective filters [1]. Hence, their performance is dependent on how much data they can skip during their scans, with indexes being the most efficient technique for aggressive data-skipping. Progressive Indexes are the state-of-the-art on automatic index creation for interactive exploratory data analysis. These indexes are partially constructed during query execution, eventually refining to a full index. However, progressive indexes have been designed for static databases, while in exploratory data analysis updates — usually batch-appends of newly acquired data — are frequent.

In this paper, we propose *Progressive Mergesort*, a novel merging technique to make Progressive Indexes cope with updates. Progressive Mergesort differs from other merging techniques for partial indexes as it incorporates the index budget strategy design from Progressive Indexing. It follows the same three principles as Progressive Indexes: (1) fast query execution, (2) high robustness,(3) guaranteed convergence.

Our experimental evaluation demonstrates that Progressive Mergesort is capable of achieving a 2x speedup when merging updates and up to 3 orders of magnitude lower variance than the state of the art.

1 INTRODUCTION

Data scientists perform interactive exploratory data analysis to discover unexpected patterns in large collections of data. This process is done using hypothesis-driven trial-and-error queries [10]. Given the result of a query, the data scientists refine their original hypothesis and either zoom in on the same data segment or move to a different one depending on the insights gained.

In the typical interactive exploratory data analysis workload, the data scientist inspects a massive amount of data by issuing selective analytical queries (usually via a visualization tool) to test their hypothesis. Battle et al. [1] depict that the most demanding type of interactive queries are cross filter applications (i.e., grouping data after applying selective filters). In these workloads, users expect almost immediate responses from the system, and each movement on the visualization tool will immediately submit another query to the database system.

Figure 1 depicts an example of a cross filter application. Here the data scientist uses a dataset that contains multiple attributes of flight information. The user visualizes each attribute as one histogram figure (e.g., departure time or airtime in minutes). The range slider on the top of the figure allows the users to change the filter used to construct these histograms, and the graphs are automatically updated depending on the new filter input.

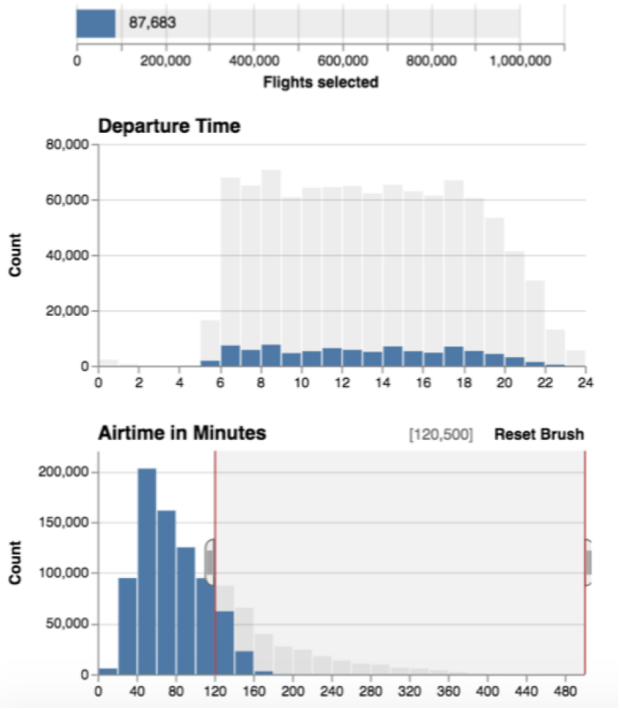

Figure 1: Interactive Data Analysis Example [1]

Since these workloads are dependent on a filter, when these filters are selective (e.g., wanting to know the information of a small number of flights), aggressive data skipping techniques can significantly improve the query performance.

Index structures are frequently used to boost workloads that depend on data skipping. There are two main strategies that automatically create indexes for interactive data analysis.

(1) Adaptive Indexing [6, 9] automatically creates indexes based on query predicates of range queries. They perform quicksort iterations with query predicates as pivots, indexing the accessed pieces during query execution, efficiently smearing out the index creation cost over a workload.

Adaptive Indexing follows a philosophy of only indexing the minimum amount of data necessary to the currently executing query. Although this strategy allows for fast convergence on skewed workloads (i.e., workloads where the same piece is frequently accessed), it has no control over the amount of indexing that one query can perform. When accessing pieces with different levels of refinement, query execution time spikes, resulting in a highly unpredictable query cost, which is undesirable for interactive data analysis since the user expects the query to be executed within a time limit.

(2) Progressive Indexes [3, 5, 8] are designed to be highly robust, have a predictable convergence, and present a low total cost during the entire workload execution. Their main difference

from Adaptive Indexing is the introduction of an indexing budget δ. With this indexing budget, the data scientist sets a value for δ, and the index invests a fixed amount of time into per-query index creation, being the state-of-the-art algorithm developed for interactive exploratory data analysis.

The major drawback of Progressive Indexes is that they are only designed for static-databases. However, in the interactive data analysis scenario, the data is not static but rather frequently updated with batches of data that must be appended. As an example, in our flight dataset we can consider the scenario where batches of data are regularly appended since new flights happen all the time (e.g., either data is appended every few minutes, hours, days, depending on how critical is to analyze recent data).

One way of adapting the current Progressive Indexing strategy to support updates is to use the techniques developed for merging updates on Adaptive Indexes since they produce similar partial-indexes up-to full index convergence. However, these merging techniques follow Adaptive Indexing's philosophy of lazy query execution, drastically decreasing robustness (i.e., it creates performance spikes that vary the per-query response time in orders of magnitudes up and down), with no guaranteed convergence and high penalties for larger batches of appends.

In this paper, we introduce *Progressive Mergesort*. Progressive Mergesort is designed to efficiently merge batches of appends while following the core design decisions of progressive indexing. It presents a low-query impact even for large batches, high robustness, and guaranteed convergence (i.e., all elements are merged into one array).

2 RELATED WORK

In this section, we will cover how Progressive Indexing, in particular progressive quicksort, works and will present the Adaptive Merges algorithms that merge updates into Adaptive Indexing.

2.1 Progressive Indexing

Progressive Indexes are inspired by Adaptive Indexes. Both techniques perform index creation during query execution, aiming to smear out the index creation cost over the workload. Consequently, the indexes produced by both techniques have a similar format (i.e., both are partial indexes), except that once fully converged, progressive indexing turns into a standard B-tree. One major difference between Progressive Indexes and Adaptive Indexes is that Progressive Indexes use an index budget constraint δ that indicates the amount of data that can be indexed, in one sorting iteration, per query, while Adaptive Indexes only performs full sorting iterations (e.g., adaptive indexing will fully partition one column around a pivot in one query, while progressive indexing will partition a δ fraction of the column.).

Progressive Indexes come in two flavors, the fixed-δ where the user picks a fraction of the data, and the same fraction is indexed per query, and a greedy version, where the user sets a desired query execution time. The greedy algorithm uses a cost-model to select a suitable δ tailored for each query automatically. In this paper, we will focus on the fixed-δ version of Progressive Indexing and will leave the greedy version as future work.

Figure 2 depicts an example of Progressive Quicksort with $\delta = 0.5$ (i.e., half the data is pivoted in each query), a progressive indexing technique inspired by the quicksort algorithm. Progressive quicksort is triggered when a filter is executed on a column. In its first phase (*Initialize*), an uninitialized array is allocated with the same space as the original column. A pivot is then selected, and the data is copied to either the bottom or the top of the new array considering the pivot. The subsequent step (*Initialize 2*) can already take advantage of this information and only scan the necessary parts (either top, bottom, neither, or both) relevant to the query. It also continues the copy process until our progressive indexing array is completely populated. At the end of the *initialize phase*, the column is partitioned into two pieces. In the example ≤ 10 and > 10. We now start the *refinement phase* where pivots are selected for each piece, and they are ordered in-place. When pieces are sufficiently small, we fully sort them. This phase results in a completely sorted array. When reaching a completely sorted array, the *consolidation phase* starts building a bottom-up B-Tree on top of the array.

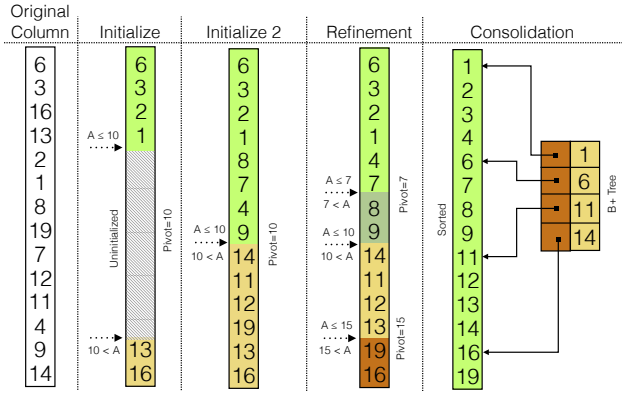

Figure 2: Progressive Quicksort [5]

2.2 Adaptive Merges

There are three main algorithms designed to efficiently merge appends into adaptive indexes [7], the *Merge Complete*, *Merge Gradual*, and *Merge Ripple*, and we will refer to these algorithms as *Adaptive Merges* from now on. They follow the same philosophy of Adaptive Indexing by only merging appends when necessary. They differ from each other in terms of what data they will merge and how they merge it. In the following subsections, we overview each algorithm and present an example of their execution. Besides the strategies to efficiently merge appends into the index's column, Holanda et al. [4] present a strategy to prune cold data from the cracker index to boost updates. However, we do not explore this strategy in this paper since it directly goes against our full convergence philosophy.

Merge Complete (MC) This algorithm completely merges the full *Appends* vector into the *Cracker Column* (i.e., the cracker column is a full copy of the original column owned by the adaptive indexing structure) as soon as a query requests data that is also present in the *Appends* vector.

Merge Gradual (MG) Merge Gradual differs from Merge Complete with respect to the amount of data merged per query. It only merges items that qualify for the currently executing query.

Merge Ripple (MR) Like Merge Complete, the Merge Ripple algorithm only merges the elements that qualify for the query predicates. They differ on how they merge them. In the Merge Ripple, instead of resizing the Cracker Column and appending the element to its end as its first step, it starts by swapping the to-be inserted element with the first element in the next greater-neighboring piece from its correct piece.

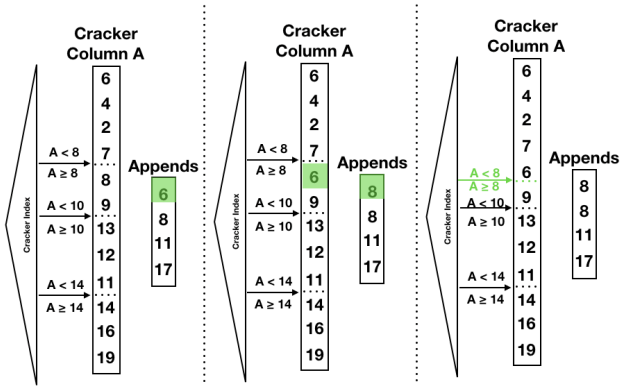

Figure 3: Merge Ripple on query A < 8

Figure 3 depicts an example of Merge Ripple executing the query $A < 8$. In our example, the column is already partitioned around three pivot points (8, 10, 14) and the appends array contains four values (6, 8, 11, 17). Since we only need to insert element 6 from the appends array, we perform a cracker index lookup and identify the element's piece (i.e., the first piece holding 6, 4, 2, and 7). We then go to the successor piece (i.e., piece 2 with elements 8 and 9) and swap the first element of that piece (8) with the element in our appends (6). After that, we only need to update the cracker index node that points to the value 8. In this case, we only had to perform 1 swap and update 1 node in the cracker index to merge 25% of our appends. Merge Ripple performs fewer swaps and updates than the previous algorithms while merging the necessary amount of data to our index.

3 PROGRESSIVE MERGESORT

Progressive Mergesort is a progressive indexing technique inspired by the mergesort algorithm [2] and used for merging appends into the main progressive indexing structure. It follows the three pillars of progressive indexes: (1) low impact on query execution, (2) robust performance, and (3) guaranteed convergence. It relies on an index-budget δ that represents the percentage of the data that is indexed per-query, guaranteeing that the same amount of effort will be distributed for the entire workload.

In practice, during query execution, the δ defined for our Progressive Indexing algorithm is used for both the main index structure and progressive mergesort.

Progressive mergesort follows two distinct canonical phases, the refinement phase, and the merge phase, which are described in this section.

Refinement. In the refinement phase, we can use any of the other proposed progressive indexing algorithms, getting the most performance depending on data distribution and workload. Our budget is used as described in the original Progressive Indexing paper [5] depending on the algorithm executing the refinement. In this paper, we decided to experiment with Progressive Quicksort as our algorithm of choice. Utilizing the other algorithms is left as an engineering exercise for future work.

Merge. At the end of the refinement phase of any progressive indexing algorithm, the result is a sorted list. When all merge chunks are fully sorted, we progressively merge them into one sorted chunk. We perform a progressive two-way-merge in order to merge said chunks.

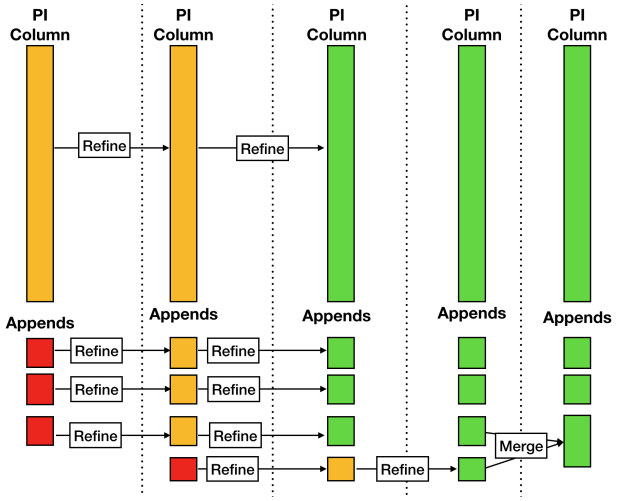

Figure 4: Progressive Mergesort

Figure 4 depicts a high-level concept of Progressive Mergesort. In this figure, red vectors are completely unsorted vectors, yellow are partially sorted vectors, and green are completely sorted. We start with our main index structure only partially sorted and with a new batch of appends.

It starts with the refinement phase. At this step, any Progressive Indexing technique can be used and will continue their execution until reaching completely sorted lists. When all chunks are entirely sorted, the second phase of Progressive Mergesort starts. Here, the *Appends* arrays are progressively merged into one array. One might note that new batches can be introduced while other batches are already being refined. In this case, a Progressive Mergesort run will be initiated to newly appended chunks. All these chunks use the same δ as our main progressive index but normalized to the chunk size. Only when the original Progressive Indexing column and the appends are fully sorted (i.e., we have one sorted column for the Progressive Indexing and one sorted column for all the appends) and the appends have the same or bigger size as the Progressive Indexing column we merge them.

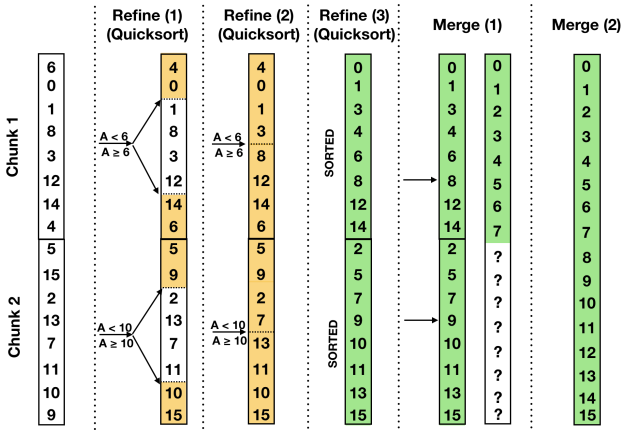

Figure 5: Progressive Mergesort Example ($\delta = 0.5$)

Figure 5 depicts an example of Progressive Mergesort with *delta* = 0.5. We start with two batches of updates. In the initial iterations, we execute Progressive Quicksort as the refinement phase. In *Refine (1)*, a Progressive Quicksort iteration is initiated

for each chunk, since $\delta = 0.5$ both iterations index half of each chunk around one pivot. In *Refine (3)* both Progressive Quicksort iterations ended, and both chunks are fully sorted. Hence we will start the merge phase of Progressive Mergesort in the following query. In *Merge (1)* we start to merge both lists using a two-way merge algorithm, and we stop when the resulting list is half complete due to our δ. For the chunks that are being merged, we must store the offsets where we stopped merging. Finally, in *Merge (2)* we end the merge phase with one completely sorted append list and delete the previous chunks.

Query Processing. When executing a query on a column with progressive indexing, we might encounter several arrays (i.e., the original Progressive Indexing column and batches of appends that started to be refined but are not yet merged) with different levels of refinement.

During the query execution, each array must be checked to return the elements that fit the query predicates. If the array is already fully sorted, a binary search will be executed to return the result. Otherwise, the array will be at some step of the refinement phase. Hence a lookup on the binary tree is necessary to return the offsets that match the query predicates.

When to Merge. In this paper, we decided to first completely merge all appends into one, fully sorted, append array. If this array has a size equal to or bigger than the current Progressive Indexing column, we merge both. This decision was made to avoid frequent resizes of large arrays (e.g., if we merged the Progressive Indexing column with every append first, this would result in a resize for the progressive column at every batch, which would be prohibitively expensive).

However, this decision is not necessarily optimal for all workloads. Having multiple arrays increase the random access to respond to the workload while diminishing the merge costs creating a trade-off depending on when and how these merges are performed. Creating an algorithm that decides when is the appropriate moment to merge these different arrays and which arrays should be merged is out of this paper's scope, and we leave it as future work.

4 EXPERIMENTAL ANALYSIS

This section provides an experimental evaluation of Progressive Mergesort and compares it with the Adaptive Merges techniques.

4.1 Setup

We implemented the Progressive Mergesort algorithm and the Adaptive Merges in a stand-alone program written in C++. The Progressive Mergesort uses Progressive Quicksort in its refinement phase.

Compilation. This application was compiled with GNU g++ version 7.2.1 using optimization level `-O3`.

Machine. All experiments were conducted on a machine equipped with 256 GB main memory and an 8-core Intel Xeon E5-2650 v2 CPU @ 2.6 GHz with 20480 KB L3 cache.

Appends. All experiments have 3 parameters regarding the appends, (1) the *batch_size* that represents the size of a batch of appends, (2) the *frequency* which represents an interval of queries where a new batch of appends is executed, and (3) *start_after* that describes how many queries need to be executed before the first append happens. With these 3 parameters we calculate the number of appends that will be executed $total\_appends = \frac{total\_queries - start\_after}{frequency} * batch\_size$, and divide our data set into the *original_column* set that represents our initially loaded column and the *appends* set that represent the appends that will be inserted.

Data set. We generate a synthetic data set composed of $N + total\_appends$ unique 8-byte integers, with $N \in \{10^7, 10^8, 10^9\}$ and representing the original column size. After generating the data set, we shuffle it following a uniform-random distribution and divide it into our original column and a list of appends.

Workload. Unless stated otherwise, all experiments consist of a synthetic workload with 10^4 queries in the form `SELECT SUM(R.A) FROM R WHERE R.A BETWEEN` V_1 `AND` V_2. A random value is selected for V_1 and $V_2 = V_1 + (N + total\_appends) * 1\%$.

Configuration. We experiment with 3 main configurations.

- High Frequency Low Volume (HFLV): A batch of appends with $batch\_size = 0.001\% * N$ executed every 10 queries.
- Medium Frequency Medium Volume (MFMV): A batch of appends with $batch\_size = 0.01\% * N$ executed every 100 queries.
- Low Frequency High Volume (LFHV): A batch of appends with $batch\_size = 0.1\% * N$ executed every 1000 queries.

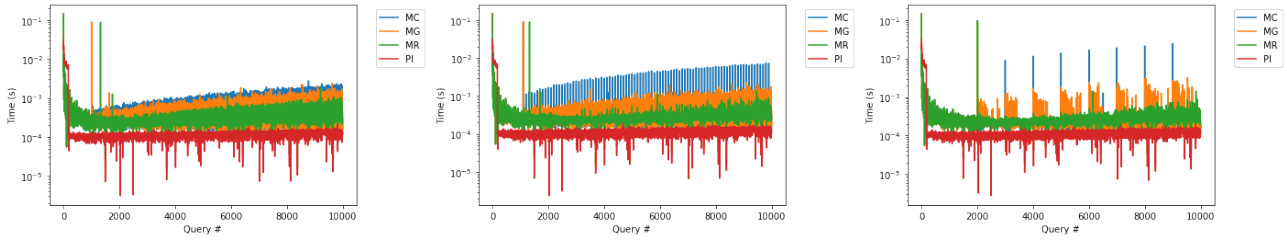
4.2 Performance Comparison

In this paper, we decided to use the Adaptive Merges algorithms only with Adaptive Indexing due to the increased complexity of implementing them to work with Progressive Indexing and leave this task as an engineering exercise for future work. Since the base indexing algorithm is different for the Adaptive Merges and Progressive Mergesort, we decided to start appending data after 1000 queries to have refined indexes and better isolate the actual append cost from early index creation. Hence we avoid the noise of partitioning the *original_column* and focus on the actual merges from the appends. Our Progressive Mergesort uses a fixed δ of 0.1 in all experiments. It is also important to notice that our Progressive Indexing implementation stops its convergence when it becomes a fully sorted list. We leave merging appends into the concise B+-Tree format as future work.

Figure 6 depicts a per-query performance comparison of Progressive Mergesort and Adaptive Merges. In this experiment, we use a data set with $N = 10^7$ and run all 3 configurations described in the previous section. We continue this section by describing two observations present in all experiments, (1) regarding the column resizes and (2) an overall analysis of query robustness.

Resizes. In all three configurations, HFLV, MFMV, and LFHV, we can notice that all three Adaptive Merges present a performance spike right after the start of the updates around query 1000. The main reason for this spike is the need to resize the *Cracker Column* when appending new data. Since this resize reserves 2 times the space of the original *Cracker Column*, it only happens once. It is also possible to notice that with Merge Ripple, the spike occurs 100 queries later than with Merge Complete and Merge Gradual. This is because Merge Ripple avoids resizing the *Cracker Column* by swapping the data from the *Appends* and the Column with the actual resize only happening when we are in the last piece. This problem does not exist with Progressive Mergesort since we perform a *vector.reserve()* to allocate memory to the merge vector, and filling out the merge vector is completed over multiple queries.

Robustness. The Merge Complete presents the lowest robustness from all algorithms. Whenever a merge happens, it has a big spike upwards since it completely merges it. Merge Gradual is the second-worst. Since it completely merges all elements that qualify the predicate, it does not have one big performance spike,



(a) HFLV (b) MFMV (c) LFHV

Figure 6: Progressive Mergesort and Adaptive Merges ($N = 10^7$ and $start\_after = 1000$)

spreading those merges through many queries. This is particularly visible in Figure 6c that depicts the low-frequency high volume experiment (i.e., at every 1000 queries, a batch of size 10^4 is inserted. One can see that at every 1000 queries, there is an upwards spike that slowly decreases for 500 queries, and then has a slop down since most of the *Appends* array was merged by that point. From the Adaptive Merges, the Merge Ripple presents the least variance. All queries slightly increase their cost with increasing updates. Finally, the Progressive Mergesort presents the lowest variance, with no performance spikes up.

One can notice that all algorithms present downwards spikes at the same queries overall 3 configurations. These are caused by noise due to the way we select our query predicates to fix our workload selectivity. Since we create our second query predicate as $V_2 = V_1 + (N + total\_appends) * 1\%$. Queries might not have exactly 1% selectivity if the data is not completely merged in the column. Since the figures are with the y-axis in log scale, small differences in the selectivity produce these downwards performance spikes.

4.3 Varying Data Sizes

	Workload	MC	MG	MR	PM
10^7	HFLV	2.72	3.52	2.57	1.07
	MFMV	2.18	3.39	2.45	1.07
	LFHV	2.00	2.55	2.34	1.06
10^8	HFLV	22.76	26.16	26.61	10.64
	MFMV	20.25	26.14	25.19	10.72
	LFHV	22.14	22.42	23.89	10.63
10^9	HFLV	209.25	221.67	295.39	104.77
	MFMV	206.39	219.39	267.94	104.96
	LFHV	197.89	200.62	250.62	103.95

Table 1: Cumulative Time (s)

Table 1 depicts the total execution cost for the workload, excluding the initial 1000 queries. On all experiments, Progressive Mergesort presented approximately 2x better performance than the best performing Adaptive Merge algorithm. The main reason for this performance difference is that all Merge Adaptive algorithms must keep the appends sorted to merge them efficiently. This problem impacts Merge Ripple the most since it tends to keep a larger appends array due to its lazier merging property. That means that a larger array must be re-sorted at every append insertion. One might notice that the results of Adaptive Merges seem to directly contradict Idreos et al. [7], where Merge Ripple was the best performing algorithm of the three. The HFLV with $N = 10^7$ is the only experiment with the same parameters as the original paper and showcases a similar result, with Merge Ripple being the fastest of the Adaptive Merges. However, as discussed before, with larger appends Merge Ripple starts to lose its benefit of fewer swaps to keep the append vector sorted.

One other interesting result is the variance in the total cost depending on the configuration of the workload. The Adaptive Merges algorithms present a much higher variance than Progressive Mergesort for the same data size. This is more prominent with larger data sizes. Taking $N = 10^9$ as an example, Merge Complete presents a variance of 11.36s, Merge Gradual of 21.05s, Merge Ripple of 44.72s, and Progressive Mergesort of 1.01s.

Compared to the Adaptive Merges algorithms, Progressive Mergesort has a very low variance from configurations at the same data size. This is due to the Progressive Mergesort algorithm not performing a complete sort in the append list but rather properly refining and merging it depending on their data size.

	Workload	MC	MG	MR	PM
10^7	HFLV	e-07	e-07	e-07	e-10
	MFMV	e-06	e-07	e-07	e-10
	LFHV	e-06	e-07	e-07	e-10
10^8	HFLV	e-05	e-05	e-05	e-07
	MFMV	e-05	e-05	e-05	e-07
	LFHV	e-04	e-05	e-05	e-07
10^9	HFLV	e-03	e-03	e-03	e-06
	MFMV	e-03	e-03	e-03	e-06
	LFHV	e-02	e-03	e-03	e-06

Table 2: Robustness (Orders of Magnitude)

Table 2 depicts the order of magnitude of the query variance of each workload on all 3 data sizes. We only calculate the query variance after executing the first 1000 queries. Note that the lower the variance the more robust the algorithm is. As expected, Merge Complete presents the lowest robustness since it completely merges the *Appends* array to the *Cracker Column* causing a huge performance spike. The Merge Gradual/Ripple are better than the Merge Complete, since it only merges that tuples that qualify the query predicates. Progressive Mergesort present the highest robustness due to its indexing budget, effectively offering a more fine-grained control over the stream of queries.

4.4 Appends during Index Creation

To perform a fair comparison of the Adaptive Merges and Progressive Mergesort, we only initiated the updates after 1000 queries to minimize the initial index creation cost of Adaptive Indexing and Progressive Indexing. However, after 1000 queries, the progressive indexing is already fully converged (i.e., the main index is a sorted list).

In this experiment, we want to evaluate Progressive Mergesort's impact during Progressive Indexing's creation phase (i.e.,

Initialization and Refinement phases). In our setup, we use a dataset with $N = 10^7$, a workload with 1% selectivity and 200 queries, and three different update setups. All update setups start at the first query and perform appends at every 10 queries, they differ on the size of the batches, with batches of size 100, 1000 and 10000.

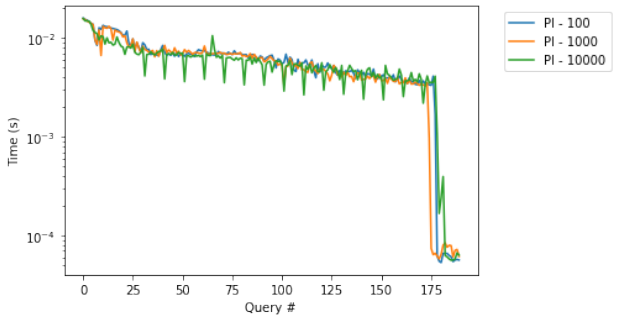


Figure 7: Progressive Mergesort before index convergence.

Figure 7 depicts the per-query cost for the 200 queries. The height of the performance spikes are strongly correlated to the batch sizes, with larger batches introducing a higher spike. This happens due to our strategy using a fixed δ (i.e., a % of the total size of the data that is indexed per-query) for the entire workload. Hence the more data we ingest, the actual per-query cost will increase since the data size increases. One way of minimizing this issue is to extend the cost models proposed in Holanda et al. [5] to automatically generate a value for δ to reduce query variance. We leave that algorithm as an exercise for future work.

5 CONCLUSION & FUTURE WORK

In this paper, we introduce the *Progressive Mergesort*, a novel progressive algorithm used to merge batches of appends. We compare it to the state-of-the-art merging algorithms from adaptive indexing techniques and show how they perform under multiple synthetic benchmarks. Our solution is more robust and faster than the state-of-the-art.

We point out the following as the main aspects to be explored in Progressive Mergesort's future work:

- **Integrating Merge Ripple With Progressive Indexing.** In our experiments we compare against adaptive indexing using the merge gradual/complete/ripple algorithms. However, this comparison would be even more significant if these algorithms were implemented directly into progressive indexing. For example, if the main index algorithm is Progressive Quicksort, by using an AVL-Tree, similar merge algorithms could be used.
- **Refinement Method.** In this paper, we only use Progressive Quicksort as our refinement strategy within Progressive Mergesort. However, in the Progressive Indexing work, it is demonstrated that different progressive indexing algorithms can present better performance depending on the data distribution and workload. With mergesort, we also have the opportunity of selecting a different algorithm for each chunk in the refinement step. Deciding which algorithm to use could drastically improve performance.
- **Merge Strategy.** Deciding when to merge and which arrays to merge can be beneficial to the cumulative cost of the workload since there is a trade-off on the random access vs merging costs (i.e., keeping many smaller arrays or frequently merging them in order to maintain only a small number of bigger arrays). Designing an algorithm that takes that this trade-off into consideration is left as future work.
- **Greedy Progressive Mergesort.** Our current implementation of progressive mergesort relies on a fixed δ for the entire workload. The development of a cost-model to the merge phase will allow it to also be integrated with progressive indexing algorithms that use an interactivity threshold and automatically adapt the δ value to boost robustness. Hence, as future work, a greedy version of our progressive mergesort can bring even fewer performance spikes to our algorithm.
- **Handling Updates.** In this paper, we describe how to efficiently merge appends, since these are the most common types of updates in interactive data analysis. However, although deletes and updates are not frequent, they might still occur, therefore progressive mergesort must be capable of properly handling them.
- **Multidimensional Updates.** Until now, we only focused on unidimensional progressive indexing. However, multidimensional progressive indexing [8] was recently proposed to efficiently index columns for queries with multiple selective filters. In this algorithm, a KD-Tree is used to store and navigate the partitions created by progressive indexing. To support updates on this structure, progressive mergesort must be extended to consider the KD-Tree nodes to merge multiple batches of updates correctly.
- **Real Benchmarks.** The Sloan Digital Sky Survey [1] is an open-source project that maps the universe with an open data set and interactive-exploratory query logs. Capturing the updates on this database can depict a good representation of real patterns of updates on interactive data.

ABSTRACT

Context-Free Path Querying (CFPQ) allows one to express path constraints in navigational graph queries as context-free grammars. Although there are many algorithms for CFPQ developed, no graph database provides full-stack support of CFPQ. The Azimov's CFPQ algorithm is applicable for real-world graph analyses, as shown by Arseniy Terekhov. In this work we provide a modification to Azimov's algorithm for multiple-source CFPQ which makes the algorithm more practical and eases the integration into RedisGraph graph database. We also implement a Cypher graph query language extension for context-free constraints. Thus we provide the first full-stack support of CFPQ for graph databases. Our evaluation shows that the provided solution is suitable for real-world graph analyses.

1 INTRODUCTION

Language-constrained path querying [2] is a way to search for paths in edge-labeled graphs where constraints are formulated in terms of a formal language. The language restricts the set of accepted paths: the sentence formed by the labels of a path should be in the language. Regular languages are the most popular class of constraints used as navigational queries in graph databases. In some cases, regular languages are not expressive enough and context-free languages are used instead. Context-free path querying (CFPQ), can be used for RDF analysis [23], biological data analysis [18], static code analysis [16, 24], and in other areas.

CFPQ have been studied a lot since the problem was first stated by Mihalis Yannakakis in 1990 [22]. Jelle Hellings investigates various aspects of CFPQ in [6–8]. A number of CFPQ algorithms were proposed: (G)LL and (G)LR-based algorithms by Ciro M. Medeiros et al. [12], Fred C. Santos et al. [17], Semyon Grigorev et al. [5], and Ekaterina Verbitskaia et al. [20]; CYK-based algorithm by Xiaowang Zhang et al. [23]; combinators-based approach to CFPQ by Ekaterina Verbitskaia et al. [21]. Nevertheless, the application of context-free constraints for real-world data analysis still faces many problems. The first problem is bad performance of the proposed algorithms on real-world data, as shown by Jochem Kuijpers et al. [11]. The second problem is that no graph database provides full-stack support of CFPQ, since most effort was made in developing algorithms and researching their theoretical properties. This fact hinders research of problems which can be reduced to CFPQ, thus it hinders the development of new solutions for them. For example, graph segmentation in data provenance analysis was recently reduced to CFPQ [14], but the evaluation of the proposed approach was complicated by the fact that no graph database supported CFPQ.

Rustam Azimov proposed a matrix-based algorithm for CFPQ in [1]. This algorithm provides a solution performant enough for real-world data analyses, as shown by Nikita Mishim et al. in [15] and Arseniy Terekhov et al. in [19]. This algorithm computes reachability and provides a single path which satisfies constraints for *every* vertex pair in the graph. Namely it solves *all-pairs* context-free path querying problem. In many real-world scenarios it is redundant to handle all possible pairs, instead one can provide one or a relatively small set of start vertices.

While all-pairs context-free path querying is a problem well studied, best to our knowledge, there is no solutions for the single-source and multiple-source CFPQ. In this work we propose a matrix-based *multiple-source* (and *single-source* as a partial case) CFPQ algorithm and provide full-stack support of CFPQ based on the proposed algorithm.

To sum up, we make the following contributions in this paper.

(1) We modify the Azimov's matrix-based CFPQ algorithm and provide a multiple-source matrix-based CFPQ algorithm. As a partial case, it is possible to use our algorithm in a single-source scenario. Our modification is still based on linear algebra, hence it is simple to implement and allows one to use high-performance libraries and utilize modern parallel hardware for queries evaluation.
(2) We provide full-stack support of CFPQ by extending the RedisGraph[1] [3] graph database. To do it, we implement a Cypher query language extension[2] that makes it possible to use context-free constraints, implemented the proposed algorithm in a RedisGraph backend, and supported the

[1] RedisGraph graph database Web-page: https://redislabs.com/redis-enterprise/redis-graph/. Access date: 19.07.2020.
[2] Proposal which describes path patterns specification syntax for Cypher query language: https://github.com/thobe/openCypher/blob/rpq/cip/1.accepted/CIP2017-02-06-Path-Patterns.adoc. The proposed syntax allows one to specify context-free constraints. Access date: 19.07.2020.

new syntax in the RedisGraph query execution engine. As far as we know, it is the first full-stack implementation of CFPQ. Finally, we evaluate the proposed solution and show that it is performant and memory-efficient enough to be applicable for real-world graph querying.

2 PRELIMINARIES

In this section we introduce common definitions in graph theory and formal language theory which are used in this paper. Also, we provide a brief description of Azimov's algorithm which is used as a base of our solution.

2.1 Basic Definitions of Graph Theory

In this paper we use a labeled directed graph as a data model and define it as follows.

Definition 2.1. Labeled directed graph is a tuple of six elements $D = (V, E, \Sigma_V, \Sigma_E, \lambda_V, \lambda_E)$, where

- V is a finite set of vertices. For simplicity, we assume that the vertices are natural numbers ranging from 0 to $|V| - 1$.
- $E \subseteq V \times V$ is a set of edges.
- Σ_V and Σ_E are sets of labels of vertices and edges respectively, such that $\Sigma_V \cap \Sigma_E = \varnothing$.
- $\lambda_V : V \to 2^{\Sigma_V}$ is a function that maps a vertex to a set of its labels, which can be empty.
- $\lambda_E : E \to 2^{\Sigma_E} \setminus \{\varnothing\}$ is a function that maps an edge to a non-empty set of its labels, so each edge must have at least one label.

Labeled graph is the basis of the widely-used *property graph* data model and allows one to use not only edge labels but also vertex labels in navigation queries.

An example of the labeled directed graph D_1 is presented in figure 1. Here the sets of labels $\Sigma_V = \{x, y\}$ and $\Sigma_E = \{a, b, c, d\}$. We omit the sets of vertex labels whenever they are empty.

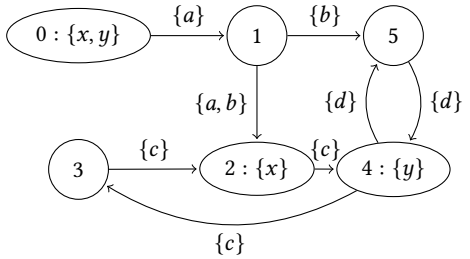

Figure 1: The input graph D_1

Definition 2.2. Path π in the graph $D = (V, E, \Sigma_V, \Sigma_E, \lambda_V, \lambda_E)$ is a finite sequence of vertices and edges $(v_0, e_0, v_1, e_1, ..., e_{n-1}, v_n)$, where $\forall i, 0 \le i \le n : v_i \in V; \forall j, 1 \le j \le n : e_j = (v_j, v_{j+1}) \in E$.

Definition 2.3. An *adjacency matrix* M of the graph D is a matrix of size $|V| \times |V|$, such that

$$M[i,j] = \begin{cases} \lambda_E((i,j)) & , (i,j) \in E \\ \varnothing & , otherwise \end{cases}$$

The adjacency matrix M of the graph D_1 (fig. 1) is the following:

$$M = \begin{pmatrix} \varnothing & \{a\} & \varnothing & \varnothing & \varnothing & \varnothing \\ \varnothing & \varnothing & \{a,b\} & \varnothing & \varnothing & \{b\} \\ \varnothing & \varnothing & \varnothing & \varnothing & \{c\} & \varnothing \\ \varnothing & \varnothing & \{c\} & \varnothing & \varnothing & \varnothing \\ \varnothing & \varnothing & \varnothing & \{c\} & \varnothing & \{d\} \\ \varnothing & \varnothing & \varnothing & \varnothing & \{d\} & \varnothing \end{pmatrix}.$$

Definition 2.4. Let M be an adjacency matrix of the graph D. Then the *adjacency matrix of label* $l \in \Sigma_E$ of graph D is a matrix $\mathcal{E}^l$ of size $|V| \times |V|$, such that

$$\mathcal{E}^l[i,j] = \begin{cases} 1 & , l \in M[i,j] \\ 0 & , otherwise \end{cases}$$

Definition 2.5. A *boolean decomposition of adjacency matrix* M of the graph D is a set of Boolean matrices $\mathcal{E} = \{\mathcal{E}^l \mid l \in \Sigma_E\}$, where $\mathcal{E}^l$ is the adjacency matrix of label l.

For example, the boolean decomposition of the adjacency matrix M of the graph D_1 is the set of matrices $\mathcal{E}^a, \mathcal{E}^b, \mathcal{E}^c, \mathcal{E}^d$:

$$\mathcal{E}^a = \begin{pmatrix} \cdot & 1 & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & 1 & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{pmatrix}, \ \mathcal{E}^b = \begin{pmatrix} \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & 1 & \cdot & \cdot & 1 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{pmatrix},$$

$$\mathcal{E}^c = \begin{pmatrix} \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & 1 & \cdot \\ \cdot & 1 & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & 1 & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{pmatrix}, \ \mathcal{E}^d = \begin{pmatrix} \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & 1 \\ \cdot & \cdot & \cdot & \cdot & 1 & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{pmatrix}.$$

Definition 2.6. A *vertex label matrix* H of the graph D is a matrix of size $|V| \times |V|$, such that

$$H[i,j] = \begin{cases} \lambda_V(i) & , i = j \\ \varnothing & , otherwize \end{cases}$$

The vertex label matrix H of the example graph D_1 is

$$H = \begin{pmatrix} \{x,y\} & \varnothing & \varnothing & \varnothing & \varnothing & \varnothing \\ \varnothing & \varnothing & \varnothing & \varnothing & \varnothing & \varnothing \\ \varnothing & \varnothing & \{x\} & \varnothing & \varnothing & \varnothing \\ \varnothing & \varnothing & \varnothing & \varnothing & \varnothing & \varnothing \\ \varnothing & \varnothing & \varnothing & \varnothing & \{y\} & \varnothing \\ \varnothing & \varnothing & \varnothing & \varnothing & \varnothing & \varnothing \end{pmatrix}.$$

Definition 2.7. Let H be a vertex label matrix of graph D. Then the *vertices matrix of label* l is a matrix $\mathcal{V}^l$ of size $|V| \times |V|$, such that

$$\mathcal{V}^l[i,j] = \begin{cases} 1 & , l \in H[i,j] \\ 0 & , otherwise \end{cases}$$

Definition 2.8. A *boolean decomposition of vertex label matrix* H of the graph D is the set of Boolean matrices $\mathcal{V} = \{V^l \mid l \in \Sigma\}$, where $\mathcal{V}^l$ is a vertices matrix of label l.

Vertex label matrix H of the graph D_1 can be decomposed into a set of the following Boolean matrices:

$$\mathcal{V}^x = \begin{pmatrix} 1 & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & 1 & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{pmatrix}, \ \mathcal{V}^y = \begin{pmatrix} 1 & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & 1 & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{pmatrix}.$$

2.2 Basic Definitions of Formal Languages

We use context-free grammars as paths constraints, thus in this subsection we define context-free languages and grammars.

Definition 2.9. A *context-free grammar* G is a tuple (N, Σ, P, S), where

- N is a finite set of nonterminals
- Σ is a finite set of terminals, $N \cap \Sigma = \varnothing$
- P is a finite set of productions of the form $A \to \alpha$, where $A \in N$, $\alpha \in (N \cup \Sigma)^*$
- S is the start nonterminal

Definition 2.10. A *context-free language* is a language generated by a context-free grammar G: $L(G) = \{w \in \Sigma^* \mid S \overset{*}{\underset{G}{\Longrightarrow}} w\}$

Where $S \overset{*}{\underset{G}{\Longrightarrow}} w$ denotes that a string w can be generated from a starting non-terminal S using a sequence of productions from P.

Definition 2.11. A context-free grammar $G = (N, \Sigma, P, S)$ is in *weak Chomsky normal form* (WCNF) if every production in P has one of the following forms:

- $A \to BC$, where $A, B, C \in N$
- $A \to a$, where $A \in N, a \in \Sigma$
- $A \to \varepsilon$, where $A \in N$

Note that weak Chomsky normal form differs from Chomsky normal form in the following:

- ε can be derived from any non-terminal;
- S can occur in the right-hand side of productions.

The matrix-based CFPQ algorithms process grammars only in weak Chomsky normal form, but every context-free grammar can be transformed into the equivalent grammar in this form.

Consider the context-free grammar $G_1 = (\{S\}, \{c, d, y\}, P, S)$, where P contains two rules: $S \to c\ S\ d$; $\quad S \to c\ y\ d$.

This grammar generates the context-free language:

$$L(G_1) = \{c^n y d^n, n \in \mathbb{N}\}.$$

The following grammar G_1^{wcnf} is a result of the transformation of G_1 to weak Chomsky normal form:

$$S \to C\ E \qquad E \to Y\ D \qquad C \to c \qquad D \to d$$
$$S \to C\ S_1 \qquad S_1 \to S\ D \qquad Y \to y$$

2.3 Context-Free Path Querying

Definition 2.12. Let $D = (V, E, \Sigma_V, \Sigma_E, \lambda_V, \lambda_E)$ be a labeled graph, $G = (N, \Sigma_V \cup \Sigma_E, P, S)$ be a context free grammar. Then a *context free relation* with grammar G on the labeled graph D is the relation $R_{G,D} \subseteq V \times V$:

$$R_{G,D} = \{(v_1, v_n) \in V \times V \mid \exists \pi = (v_1, e_1, v_2, \ldots, e_n, v_n) \in \pi(D) : l(\pi) \cap L(G) \neq \varnothing\},$$

where $l(\pi) \subset (\Sigma_V \cup \Sigma_E)^*$ is the set of labels along the path π:

$$l(\pi) = \lambda_V(v_1)^* \cdot \lambda_E(e_1) \cdot \lambda_V(v_2)^* \cdot \ldots \cdot \lambda_E(e_n) \cdot \lambda_V(v_n)^*$$

For example, π is a path from vertex 2 to vertex 5 in the labeled graph presented in figure 1: $\pi = 2 : \{x\} \xrightarrow{\{c\}} 4 : \{y\} \xrightarrow{\{d\}} 5$.

Labels along π form the set of sequences $l(\pi) = \{x^m c y^n d \mid n \geq 0, m \geq 0\}$. Only one of these sequences satisfies context-free constraints of the grammar G_1: cyd. Hence $l(\pi) \cap L(G_1) \neq \varnothing$ and the pair $(3, 6) \in R_{G_1,D}$.

Note that the definition of path labels allows for zero or more repetitions of a label of each vertex. This makes it possible to omit vertex labels or, if there are many vertex labels, to use them in an arbitrary order. It also permits to write a query which uses one vertex label multiple times. This definition may appear strange in some cases, but it depends on the semantics of the graph query language. Semantics formalization is planned for a future work, so we will stick to this definition in this paper.

Finally, we can define context-free path querying problem.

Definition 2.13. Context-free path querying problem is the problem of finding context-free relation $R_{G,D}$ for a given directed labeled graph D and a context-free grammar G.

In other words, the result of context-free path query evaluation is a set of vertex pairs such that there is a path between them and this path forms a word from the given language.

The context-free relation R_{G_1,D_1} for the graph D_1 and the context-free free grammar G_1 is the following:

$$R_{G_1,D_1} = \{(2, 4), (2, 5), (3, 4), (3, 5), (4, 4), (4, 5)\}.$$

Note that any relation $R_{G,D}$ can be represented as a Boolean matrix: $T[i, j] = 1 \iff (i, j) \in R_{G,D}$. In our example, R_{G_1,D_1} can be represented as follows:

$$T = \begin{pmatrix} \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & 1 & 1 \\ \cdot & \cdot & \cdot & \cdot & 1 & 1 \\ \cdot & \cdot & \cdot & \cdot & 1 & 1 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \end{pmatrix}.$$

Definition 2.14. Suppose Src is a given set of start vertices, then *multiple-source context-free path querying problem* for the given Src, directed labeled graph D and context-free grammar G is to find a context-free relation $R_{G,D}^{Src} \subseteq Src \times V \subseteq R_{G,D}$. Thus we restrict start vertices of the paths of interest to be vertices from the given set.

As a special case, a *single-source CFPQ* is when Src is a singleton set. If we set $Src = \{2\}$ in the previous example, then the result is: $R_{G_1,D_1}^{\{2\}} = \{(2, 4), (2, 5)\}$.

2.4 Matrix-Based Algorithm

Our algorithm is based on the Azimov's CFPQ algorithm [1] which is based on matrix operations. This algorithm reduce CFPQ to operations over Boolean matrices and as a result allows one to use high-performance linear algebra libraries and utilize modern parallel hardware for CFPQ. Moreover, utilization of Boolean matrices simplifies the implementation of the algorithm.

Note, that the algorithm computes not only the context-free relation $R_{G,D}$ but also a set of context-free relations $R_{A,D} \subseteq V \times V$ for every $A \in N$. Thus it provides information about paths which form words derivable from any nonterminal in the given grammar. Also, this algorithm handles only the edge labels.

As was shown by Nikita Mishin et al. [15] and Arseniy Terekhov et al. [19], this algorithm can be implemented using various high-performance programming techniques (including GPGPU utilization), and it is applicable for real-world graph analysis. But this algorithm solves *all-pairs* version of CFPQ: it finds all pairs of vertices in the given graph, such that there exist a path between them which forms a word in the given language. Thus it is impractical in cases when we are only interested in paths which start from the specific set of vertices, especially if this set is relatively small. Moreover, Azimov's algorithm operates over an adjacency matrix of the whole input graph, and as a result it requires a huge amount of memory which may be a problem for a real-world graph database.

3 MATRIX-BASED MULTIPLE-SOURCE CFPQ ALGORITHM

In this section we introduce a multiple-source matrix-based CFPQ algorithm. This algorithm is a modification of Azimov's matrix-based algorithm for CFPQ and its core idea is to cut off those vertices which are not in the selected set of start vertices.

Let $G = (N, \Sigma, P, S)$ be the input context-free grammar, $D = (V, E, \Sigma_V, \Sigma_E, \lambda_V, \lambda_E)$ be the input graph and Src be the input set of start vertices. The result of the algorithm is a Boolean matrix which represents relation $R_{G,D}^{Src}$.

Algorithm 1 Multiple-source CFPQ algorithm

```
1:  function MultiSrcCFPQNaive(
        D = (V, E, Σ_V, Σ_E, λ_V, λ_E),
        G = (N, Σ, P, S),                          ▷ Grammar in WCNF
        Src)
2:      T ← {T^A | A ∈ N, T^A[i, j] ← false, for all i, j}
3:      TSrc ← {TSrc^A | A ∈ N, TSrc^A[i, j] ← false, for all i, j}
4:      for all v ∈ Src do                         ▷ Input matrix initialization
5:          TSrc^S[v, v] ← true
6:      MSrc ← TSrc^S
7:      for all A → x ∈ P | x ∈ Σ_E do             ▷ Simple rules initialization
8:          for all (v, to) ∈ E | x ∈ λ_E(v, to) do
9:              T^A[v, to] ← true
10:     for all A → x ∈ P | x ∈ Σ_V do
11:         for all v ∈ V | x ∈ λ_V(v) do
12:             T^A[v, v] ← true
13:     while T or TSrc is changing do             ▷ Algorithm's body
14:         for all A → BC ∈ P do
15:             M ← TSrc^A * T^B
16:             T^A ← T^A + M * T^C
17:             TSrc^B ← TSrc^B + TSrc^A
18:             TSrc^C ← TSrc^C + getDst(M)
19:     return MSrc * T^S
20: function getDst(M)
21:     A[i, j] ← false
22:     for all (v, to) ∈ V^2 | M[v, to] = true do
23:         A[to, to] ← true
24:     return A
```

In order to solve the single-source and multiple-source CFPQ problem, we modified the Azimov's algorithm. Each time, when a grammar rule is applied, only vertices of interest should be stored. To do it, we added one more matrix multiplication: $T^A = T^A + (TSrc^A \cdot T^B) \cdot T^C$, where $TSrc^A$ is a matrix of start vertices for the current iteration (lines **15-16** of the Algorithm 1). In the end of each iteration of the for loop, it is necessary to update the set of source vertices. To do it, we call the function getDst (see lines **20-24**), in line **18**. Thus, the modified algorithm supports the frontier of the vertices of interest and updates it on each iteration. Thus, it only computes the paths which start from the small set of selected vertices.

4 CFPQ FULL-STACK SUPPORT

To provide full-stack support of CFPQ, it is necessary to choose an appropriate graph database. It was shown by Arseniy Terekhov et al. [19] that matrix-based algorithm can be naturally integrated into RedisGraph because the algorithm and the database both operate over a matrix representation of graphs. Moreover, RedisGraph supports Cypher as a query language and there is a proposal which describes Cypher extension for context-free constraints. Thus we chose RedisGraph as a base for our solution.

4.1 Cypher Extension

The first thing to do is to extend the Cypher parser to support the context-free constraints. Tobias Lindaaker proposed an extension for context free constraints to the Cypher syntax[3], which is not implemented in the Cypher parsers yet.

This extension introduces path patterns, which are a powerful alternative to the original Cypher relationship patterns. Path patterns allow one to express regular constrains over the basic patterns such as relationship and node patterns. Like relationship patterns, they can be specified in the `MATCH` clause.

Listing 2 Query based on the example grammar G_1 written in Cypher with path patterns

```
1: PATH PATTERN S = ()-/ [:c ~S :d] | [:c (:y) :d] /->()
2: MATCH (v:x)-[:a | :c]->()-/ :b ~S /->(to)
3: RETURN v, to
```

The feature which allows one to specify context-free constraints is *named path patterns*: a path pattern can be assigned a name which can be used in other patterns or within the same pattern. Named patterns is defined in the `PATH PATTERN` clause. Using this feature, the structure of queries is pretty similar to a grammar in the Extended Backus-Naur Form (EBNF) [9].

An example of a query which uses named path patters is presented in listing 2. This query is based on the context-free grammar G_1. Namely, the path pattern `S` specifies exactly the same constraint as the grammar G_1. The `MATCH` clause consists of the relation pattern `[:a | :c]` and the path pattern `/:b ~S/`, and this path pattern references the named pattern `S`. The constraint specifies that a path of interest starts in a vertex labelled `x`, goes through an edge labelled either `a` or `c`, then the rest of the path is constrainted by a path pattern which starts with an edge `b` and follows with a path matched with `S`. The `RETURN` clause specifies what the result of the query is supposed to be. For the example graph D_1, this query returns the set of vertex pairs $\{(0, 4), (0, 5)\}$.

RedisGraph database supports a subset of the Cypher language and uses `libcypher-parser`[4] library to parse queries. We extend this library with the new syntax described in the proposal. Note that we implement[5] the complete syntax extension, not only the part necessary for simple CFPQ.

4.2 RedisGraph Extension

We implemented the multiple-source algorithm in the RedisGraph. We partially supported the proposed syntax extension in RedisGraph query execution engine so that one can specify the labels of edges and vertices and use named path patterns.

Processing the input as a whole may require a lot of memory. RedisGraph implements lazy evaluation: it creates execution strategy in terms of elementary operations each of which processes the input sequentially in *chunks*. This reduces memory consumption so that it does not depend on the input size which is crucial when dealing with big real-world graphs. However processing chunks comes with a time overhead. By changing the size of a chunk, a developer may adjust the ratio between the time and memory consumption so that it fits their needs.

We use subsets of the start vertices as chunks since it is most natural in the multiple source algorithm. We study how the size of a chunk affects the performance in the evaluation.

4.3 Evaluation

For RedisGraph evaluation, we used a PC with Ubuntu 18.04 installed. It has Intel Core i7-6700 CPU, 3.4GHz, and DDR4 64Gb RAM. RedisGraph with our extensions is installed[6].

[4]The `libcypher-parser` is an open-source parser library for Cypher query language. GitHub repository of the project: https://github.com/cleishm/libcypher-parser. Access date: 19.07.2020.

[5]The modified libcypher-parser library with support of syntax for path patterns: https://github.com/YaccConstructor/libcypher-parser. Access date: 19.07.2020.

[6]Sources of RedisGraph database with full-stack CFPQ support:https://github.com/YaccConstructor/RedisGraph/tree/path_patterns_dev. Access date: 19.07.2020.

4.3.1 Data Preparation. We use the graphs and respective queries g_1 and *geo* from [19] to evaluate the RedisGraph-based solution. The graphs are loaded into the RedisGraph database so that each vertex has a unique property `id` in the range $[0, \ldots, |V|-1]$, where $|V|$ is a number of vertices in the graph to load. This allows us to generate queries for a start vertex set with specific size using templates. The template for the g_1 query is provided in listing 3. Here `{id_from}` and `{id_to}` are placeholders for the lower and the upper bounds for `id`.

Listing 3 Cypher query pattern for g_1

```
PATH PATTERN S =
        ()-/ [<:SubClassOf [~S | ()] :SubClassOf]
        | [<:Type [~S | ()] :Type] /->()
MATCH (src)-/ ~S /->()
WHERE {id_from} <= src.id and src.id <= {id_to}
RETURN count(*)
```

We implemented a query generator for the queries g_1 and *geo* to create concrete queries for all the start sets which are used in the previous experiment.

4.3.2 Evaluation Results. We use *geo* query for *geospecies* graph as one of the hardest queries, and g_1 query for other graphs. We measure time and memory consumption for each start set.

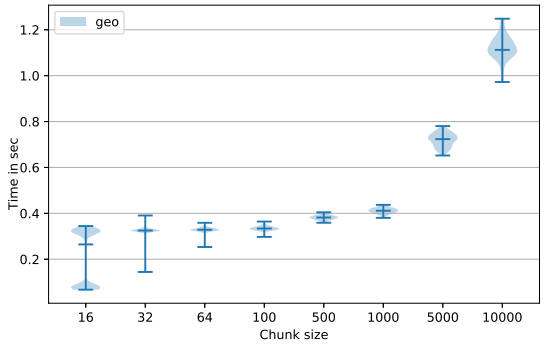

Figure 2: RedisGraph performance on *geospecies* graph

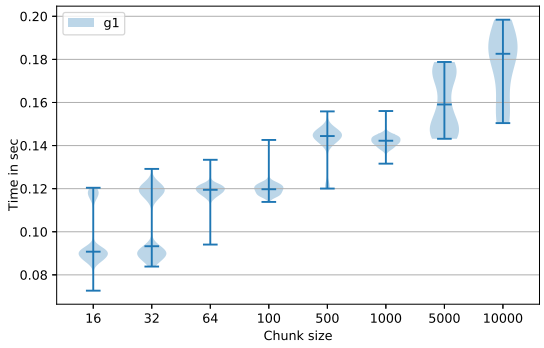

Figure 3: RedisGraph performance on *eclass_514en* graph

The execution time for all sets, except the set of size 10 000 for *geospecies* graph (fig. 2), is less than 1 second. Moreover, for smaller graph (*eclass_514en*), processing time is less than 0.2 second for all chunks (fig. 2).

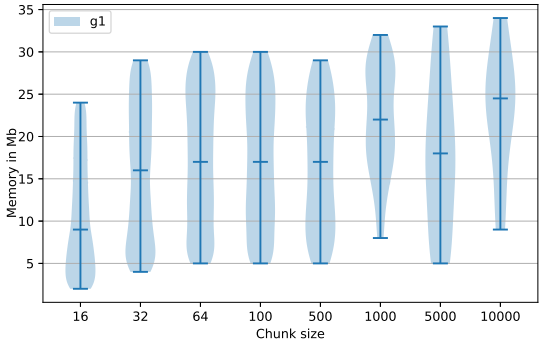

Figure 4: Memory consumption on *eclass_514en*

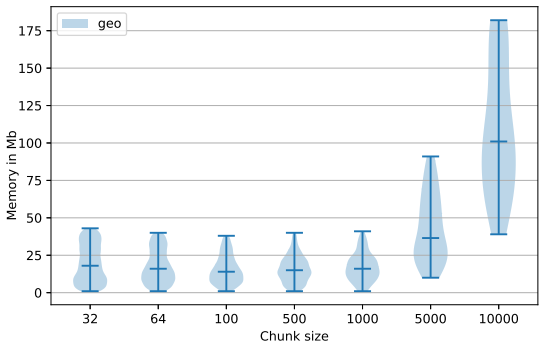

Figure 5: Memory consumption on *geospecies*

Memory consumption for the big graphs *eclass_514en* and *geospecies* is presented in figures 4 and 5 respectively. The amount of memory used depends on the graph and the query, but RedisGraph uses less that 50Mb of RAM to process graphs with relatively small chunks (≤ 1000). Note that RedisGraph includes memory management system, thus we measured all allocated memory, not only the memory really used for the query evaluation. As a result, we can conclude that the multiple-source CFPQ is significantly more memory efficient than creation of the complete reachability index and its filtering: processing the set of size 10 000 on *geospecies* graph requires less than 200Mb, while full index creation requires 16Gb [19].

We also evaluate how chunking affects the performance on the all-pairs reachability problem. We fix the size of a chunk to be 1000 for graphs of different sizes and measure time and memory required to process queries. Namely, we evaluate the query which is similar to the query from the previous scenario, but it does not constraint vertices ids (it does not have the `WHERE` clause). We measure total processing time (in seconds) and total required memory (in Mb). Also, we compare our solution with the results of Arseniy Terekhov et al. from [19] in which the Azimov's algorithm was naively integrated with RedisGraph without support of lazy query evaluation and query language. Similar hardware and the same input graphs and queries were used. Results are provided in table 1.

Although chunk-by-chunk processing is slower, it still requires reasonable time. Moreover, if the chunk size is comparable with the graph size (*core* and *pathways* graphs), then the execution time is comparable with the monolithic processing. Thus one can decrease execution time by increasing the chunk size. On the other hand, even with relatively small chunks (*eclass_514*, *go* and *geospecies* graphs), when for chunk-by-chunk processing is

Table 1: Full graph processing with chunks of size 1000

Graph	#V	#E	Q	Chunks		Mono [19]
				T (sec)	Mem (Mb)	T (sec)
core	1323	4342	g_1	0.003	2	0.004
pathways	6238	18 598	g_1	0.031	6	0.011
gohierarchy	45 007	980 218	g_1	0.847	62	0.091
enzyme	48 815	109 695	g_1	0.698	13	0.018
eclass_514en	239 111	523 727	g_1	18.825	35	0.067
geospecies	450 609	2 311 461	*geo*	80.979	196	7.146
go	272 770	534 311	g_1	72.034	40	0.604

100 times slower, our results are still reasonable for some cases. For example, it requires over 70 times less time for *geospecies* graph processing than the solution of Jochem Kuijpers et al. [11] which is based on Neo4j and requires more than 6000 seconds. Moreover, while the solution from [19] requires huge amount of memory (more than 16Gb for *geospecies* graph and *geo* query), our solution requires only 196Mb. We argue, that our solution is more suitable for general-purpose graph databases. First of all, the core scenario when the set of start vertices is relatively small can be handled efficiently. Second, all-pairs reachability, which is not a massive case, can be solved in reasonable time with low memory consumption. One can easily tune our solution to get the optimal time and memory consumption for their specific case.

5 CONCLUSION AND FUTURE WORK

In this paper we propose a multiple-source modifications of Azimov's CFPQ algorithm and utilize it to provide full-stack support of CFPQ. For our solution, we implement a Cypher extension as a part of `libcypher-parser`, integrate the proposed algorithm into RedisGraph, and extend RedisGraph execution plan builder to support the extended Cypher queries. We demonstrate that our solution is applicable for real-world graph analyses.

In the future, it is necessary to provide formal translation of Cypher to linear algebra, or to determine a maximal subset of Cypher which can be translated to linear algebra. There is a number of works on the translation of a subset of SPARQL to linear algebra, such as [4, 10, 13]. Most of them are practical-oriented and do not provide full theoretical basis to translate querying language to linear algebra. Others discuss only partial cases and should be extended to cover real-world query languages. Deep investigation of this topic can help to determine the restrictions of linear algebra utilization for graph databases.

ACKNOWLEDGEMENTS

The research was supported by the Russian Science Foundation, grant №18-11-00100.

We thank Roi Lipman for his help with investigation of the RedisGraph internals and pointing out the impractical memory consumption of the original Azimov's algorithm which gave us the motivation to develop the presented solution.

We thank Ekaterina Verbitskaia for the fruitful discussion and feedback which helped us to improve the paper.

ABSTRACT

Our *answer-graph method* to evaluate SPARQL *conjunctive queries* (CQs) finds a *factorized* answer set first, an *answer graph*, and then finds the embedding tuples from this. This approach can reduce greatly the cost to evaluate CQs. This affords us a second advantage: we can construct a cost-based planner. We present the answer-graph approach, and overview our prototype system, Wireframe. We then offer *proof of concept* via a micro-benchmark over the YAGO2s dataset with two prevalent *shapes* of queries, snowflake and diamond. We compare Wireframe's performance over these against PostgreSQL, Virtuoso, MonetDB, and Neo4J to illustrate the performance advantages of our answer-graph approach.

1 INTRODUCTION

Science is, of course, driven by observation. It is now becoming also ever more driven by data. Some of the datasets involved are unimaginably large. The data is often wildly heterogeneous, and rarely well structured as in business applications. This demands new skills, methods, and approaches of scientists, and challenges computer scientists with devising new data models, query languages, systems, and tools that better support this.

Graph-like data has become prevalent among scientific data stores and elsewhere. The data-science research community has begun to focus on how best to support the management of graph data and its analysis. One *data model* for graph databases is the *Resource Description Framework* (RDF) [18], paired with the *query language* SPARQL [8]. These have evolved as W3C standards, initially for addressing the Semantic Web. An RDF store conceptually consists of a set of *triples* to represent a directed, edge-labeled multi-graph. The triple $\langle s, p, o \rangle$ represents the directed, labeled edge from *subject* node "s" to *target* node "o" with *label* (*predicate*) "p". In RDF, nodes have unique identity. The semantics, however, is carried by the labels and how the nodes are connected. The UniProt [16] SPARQL Endpoint (dataset) [17], for example, consists of 63,376,853,475 RDF triples as of this writing. UniProt (Universal Protein resource) is a freely accessible, popular repository of protein data.

The SPARQL query language provides a formal way to query over such graph databases. Types of SPARQL queries can be thought about as small graphs themselves, so-called *query graphs*. In a SPARQL *conjunctive query* (CQ), the "nodes" are the query's *binding variables* and the "edges" between these are the labels

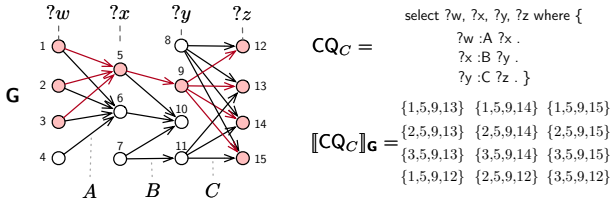

Figure 1: Example of an answer graph (shaded red).

to be matched. An "answer" to a CQ over a *data graph* **G** (that is, the graph database), denoted as $[\![\mathrm{CQ}]\!]_{\mathbf{G}}$, is a homomorphic *embedding* of the query graph into the data graph that matches the query's labels to the data graph's labeled edges. An answer is then a tuple of node ID's as a binding of the query's node variables. As such, each answer can be considered as a sub-graph matched in the data graph.

A CQ can be quite expensive to evaluate and may require extreme resources, given both the potentially immense size of the data graph and the relative complexity of the CQ's query graph. The challenge is to reduce the expense and needed machinery. We present a novel approach to *query optimization* and *evaluation* for CQs that we call Wireframe. A set of embeddings is the CQ's answer; this in itself is *not* a graph. In Wireframe's approach, as an intermediate step, we instead find the *answer graph*, the subset of edges from the data graph that suffices to compose the CQ's embeddings. This affords us powerful advantages: the answer graph is essentially the ideal *factorization* of the embeddings;[1] and we can find a best plan by estimated cost to evaluate this answer graph by *cost-based plan enumeration* via dynamic programming.

Wireframe's runtime evaluation employs two reduction mechanisms over the accumulating answer graph—*node burnback* and *edge burnback*—to guarantee a minimal factorized edge set. Given this evaluation paradigm, it is possible to devise a cost-based planner. Wireframe's optimization and evaluation is implementation agnostic; it can be easily implemented on any RDF-system architecture.

We presented the vision of Wireframe's approach in [9]. We have since developed and implemented the approach. Herein, we demonstrate Wireframe's key advantages via a prototype implementation, and compare its performance over a micro-benchmark against competing approaches.

[1] Wireframe can guarantee the minimum answer graph for *acyclic* CQs, and the minimum answer graph modulo the choice of triangulation of the CQ for *cyclic* CQs.

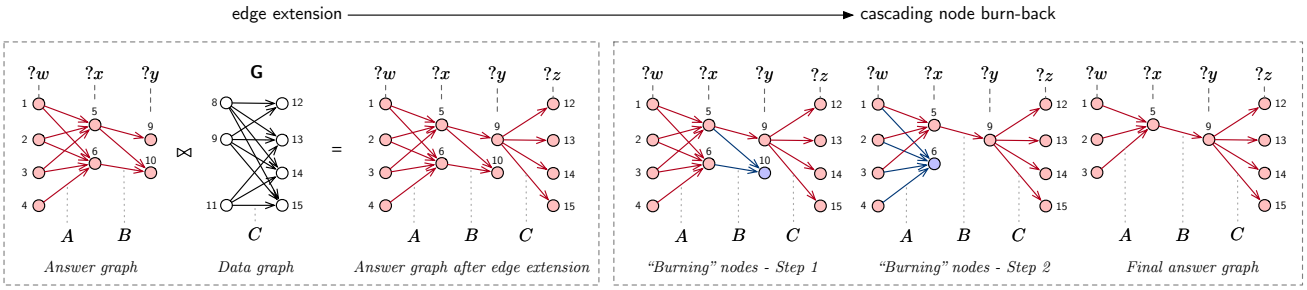

Figure 2: An example of the evaluation model for the answer graph generation.

2 RELATED WORK

RDF Systems. Over the past decade, a number of RDF systems have been developed. We can categorize them into: triple stores; property tables; column-based stores; and graph-based stores.

In triple stores, RDF data is stored in a long, but slim table with three columns where each row is a triple, $\langle s, p, o\rangle$, of RDF data [12]. For conjunctive queries (CQs), this single long, slim table approach requires self-joins over the table many times, which can lead to bad query performance. Large table scans and index look-ups can also lead to bad selectivity estimation, and, therefore, poor query optimization [1]. To overcome this, an index over the triple store for each of the six permutations over S, P, and O is often maintained [12, 24]. RDF-3x uses this approach by building a clustered B++ trees for each permutation of $\langle s, p, o\rangle$: $\langle s, p, o\rangle$, $\langle s, o, p\rangle$, $\langle p, s, o\rangle$, $\langle p, o, s\rangle$, $\langle o, s, p\rangle$, and $\langle o, p, s\rangle$ [12, 13]. It also maintains additional nine aggregate indexes to include the six binary and three unary projections of $\langle s, p, o\rangle$, which is useful for selectivity estimation. The aggregate indexes eliminate the need for expensive self-joins, therefore, improving query performance. TripleBit [26] constructs a compact triple matrix to minimize the use of indexes during query evaluation.

In contrast to triple stores, property tables use a flat but fat table where each row represents a subject value with columns for distinct property values [20]. In large, sparse RDF data, many cells of this single flat-fat table can be *null*, due to the absence of object values for the given subjects and predicates. To overcome this, Jena [20] clusters properties into different groups, and creates multiple property tables accordingly. BitMat [3] proposed a 3-D bit cube to represent subjects, predicates, and objects.

In column-based stores, RDF data is stored using multiple two-column tables [1]. There is a table for each unique property, with one column for the subject, and the other for the object. The tables can be stored using either physical row-store or column-store. This approach provides superior performance whenever there are value-based restrictions on properties. It can scale poorly, however, when the size of tables varies [15].

Graph-based stores are designed to handle graph manipulation over RDF data generally outside of the scope of SPARQL queries [6, 11]. These systems focus on specialized graph operations over RDF data [19]. For better performance, gStore [27] constructs VS-tree and VS*-tree index to evaluate both exact and wildcard SPARQL queries using subgraph matches. In [2], a compressed k^2-triples technique is used to run SPARQL queries in memory.

Factorization and Join Algorithms. Factorized databases are compact representations of relational tables [4]. They not only reduce the memory footprint while evaluating queries, but also reduce the query processing time by avoiding redundancy. This idea is even more effective for graph databases and queries, as we can show that our answer graph is an ideal factorization.

The *semijoin* operator can improve performance by ensuring everything in the *outer* (left) table *joins* with the *inner* (right) table. Wireframe's burnback mechanisms implement a form of semijoin, in a way. We likely could re-engineer our Wireframe burnback mechanisms via semijoin, were we to implement atop a platform providing a highly efficient semijoin.[2]

Worst-case optimal join algorithms use query decompositions for joins, accounting for the structural properties of the query along with the input relation statistics. This is in contrast to a traditional database where joins are evaluated "one join at a time" without taking the structure of the query into account [14].

Work that is related to ours in its mechanics is that of [25]. In [25], they reduce the transmission cost in distributed environments by generating a plan—*i.e.*, a sequence of semijoins—to evaluate acyclic conjunctive queries over datasets partitioned across different servers. Of course, our objectives in Wireframe and that of [25] are different, necessitating different methodologies. That said, our approach has advantages. Their algorithm for an acyclic CQ requires traversing the query tree *twice*. Wireframe does not need to. Their work does not apply to cyclic queries, whereas Wireframe does.

3 THE ANSWER-GRAPH APPROACH

In [4], the authors introduce the concept of *factorization* as a query-optimization technique for relational databases. Their technique is designed, and works exceptionally well, for schema and queries for which cross products of projections of the answer tuples all show up as answer tuples. This happens, for instance, in schema not in *fourth normal form*. Evaluating for these projected tuples first and then cross-producting them later can be a much more efficient strategy. Deciding how best to *factorize*—how to project into sub-tuples—is difficult, however.

For CQs, this last part is trivial: the factorization of the embedding tuples is fully down to component node pairs, corresponding to the labeled edges. This is our *answer graph*.[3] Factorization is *sometimes* a significant win for evaluating relational queries; it is *virtually always* a win for evaluating graph CQs.

An answer graph, AG, for a CQ is a subset of the data graph **G** that suffices to compute the embeddings for the CQ. We call the *minimum* such subset the *ideal answer graph*, iAG. The iAG is often quite small, significantly smaller than the set of embeddings, and extremely much smaller than **G**. Thus, we evaluate a CQ's embeddings in two steps: first, we find its iAG; then we compose

[2] This is future work of ours.

[3] This is demonstrably true when the CQ is *tree* shaped. This is arguable when the CQ has cycles. In the latter case, the factorization can be characterized as projections to tuples of node pairs and node triples (*triangles*).

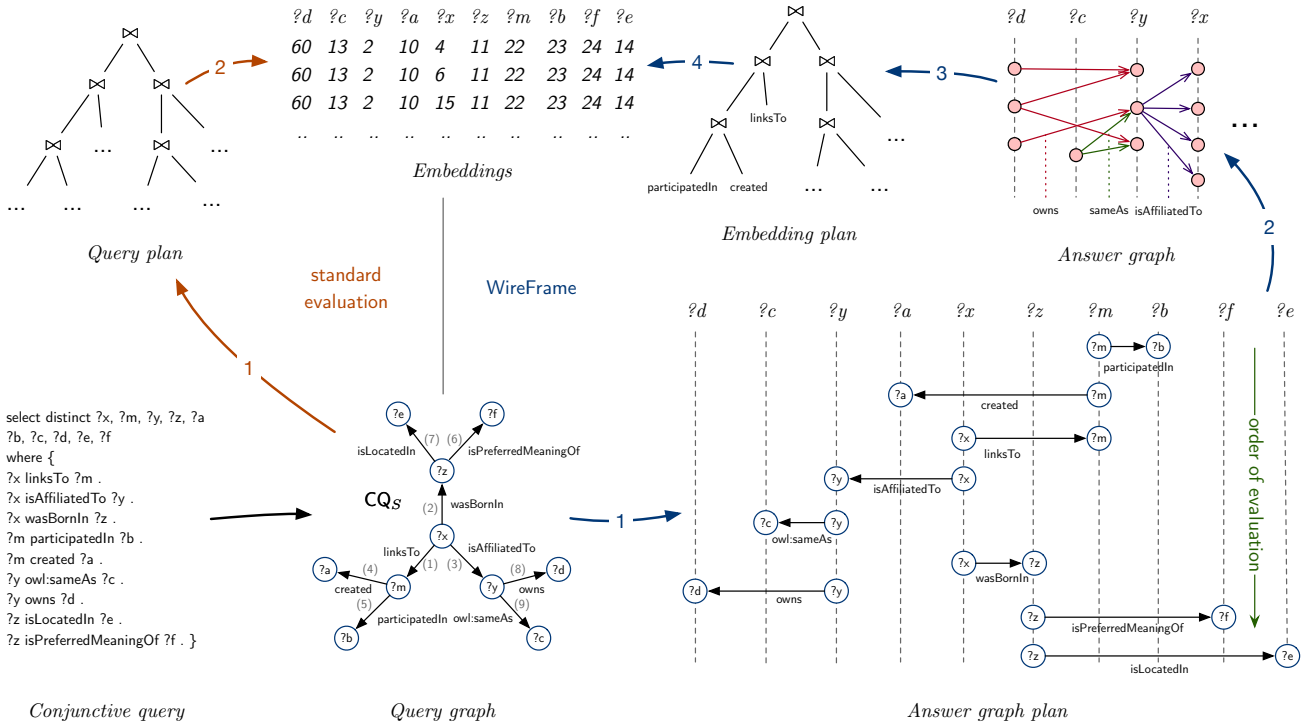

Figure 3: WIREFRAME: a two-phase cost-based optimizer for conjunctive queries.

the embeddings, which we call *defactorization*, from the iAG, rather than from **G**. This two-step approach can be significantly more efficient.

Consider the data graph **G** and the *chain* query CQ_C in Fig. 1. The query finds all tuples of nodes $\langle w, x, y, z\rangle$ from **G** such that $\langle w, x\rangle$ is connected by an edge labeled A, $\langle x, y\rangle$ by B, and $\langle y, z\rangle$ by C. Due to multiplicity from A-edges *fanning in* to, and C-edges *fanning out* of, B values, the embedding set is *twelve* tuples. Our answer graph consists of just *eight* labeled node pairs (in red). Such differences are greatly magnified when on a larger scale.

Our answer-graph approach affords us a second key advantage. We can devise a cost-based query optimizer based on dynamic programming to construct a *query plan*. A plan for us is simply a specified order of the CQ's query edges with which to evaluate to matching answer-graph edges. Our evaluation strategy for such plans is explained next, and our WIREFRAME optimizer for choosing plans is presented in Section 5.

4 THE EVALUATION MODEL

Our evaluation model for CQs then becomes two phase: *answer-graph generation* and *embedding generation*.

Answer-graph generation. For each query edge of the plan, in turn, our answer graph (AG) is populated with the matching labeled edges from **G** that meet the join constraints with the current state of the AG. Call this an *edge-extension* step. Then nodes in the AG that failed to extend are *removed*, and this "node burnback" cascades.

Consider the CQ with query edges $\langle ?w, A, ?x\rangle$, $\langle ?x, B, ?y\rangle$, and $\langle ?y, C, ?z\rangle$ in Fig. 2. Assume that the state of the AG after evaluating for query edges $\langle ?w, A, ?x\rangle$ and $\langle ?x, B, ?y\rangle$ is as shown in the figure, and that the next query edge to be evaluated is $\langle ?y, C, ?z\rangle$. This next edge is connected to the previously evaluated edges by the node variable $?y$. When retrieving data edges from **G** with label C (the query edge's label), one needs to ensure that the sources of retrieved data edges match to one of nodes bound to $?y$ in AG. After populating AG thusly, many nodes of $?y$ in AG may be "unattached" to any of the new edges; these nodes are marked to be removed during the node burnback procedure. In Fig. 2, the new answer graph has an unattached node, 10. During node burnback, this node is removed along with all of its edges, $\langle 5, 10\rangle$ and $\langle 6, 10\rangle$. Removing these edges can result in more unattached nodes, such as node 6, which no longer has any edge with the label A (contrasted with node 5). Thus, in the next iteration, node 6 is removed with all of its edges, $\langle 1, 6\rangle$, $\langle 2, 6\rangle$, $\langle 3, 6\rangle$, and $\langle 4, 6\rangle$. The node burnback procedure then terminates, as no further unattached nodes result.

Embedding generation. The embedding tuples are then generated over the answer graph by joining the answer edges appropriately. Given the *ideal* answer graph iAG and an acyclic CQ, the order in which we join is immaterial. No k-ary tuple is ever eliminated during a join with a next query edge from the iAG. This step is often quite fast, given the iAG is small. Evaluating this directly from the data graph **G**, on the other hand—which is what other evaluation methods for CQs do—can be exceedingly expensive. Fig. 3 illustrates, comparing a standard evaluation with our two-phase answer-graph approach.

5 THE PLANNERS

5.1 The Answer-Graph Planner

Plan Cost. The *edge walk* is our unit for estimating a plan's cost: the retrieval of a matching edge from **G**. To estimate the number of edge walks, *node* and *edge* cardinality estimations are made for each successive edge extension. Note that the cost of node burnback is amortised: every edge added that does not survive

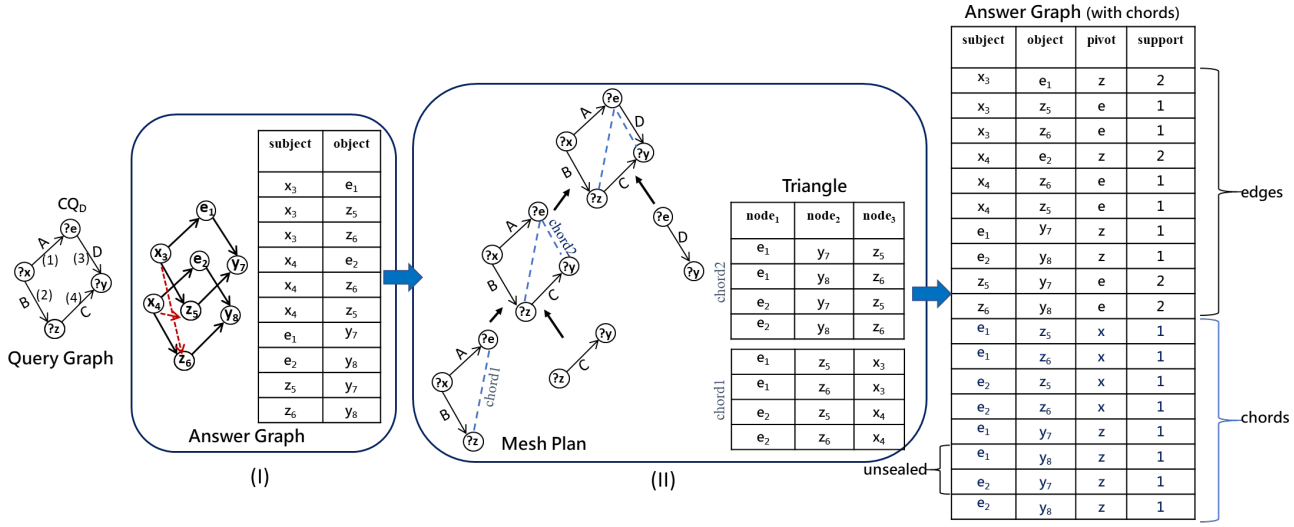

Figure 4: Triangulating a cyclic CQ using a mesh plan

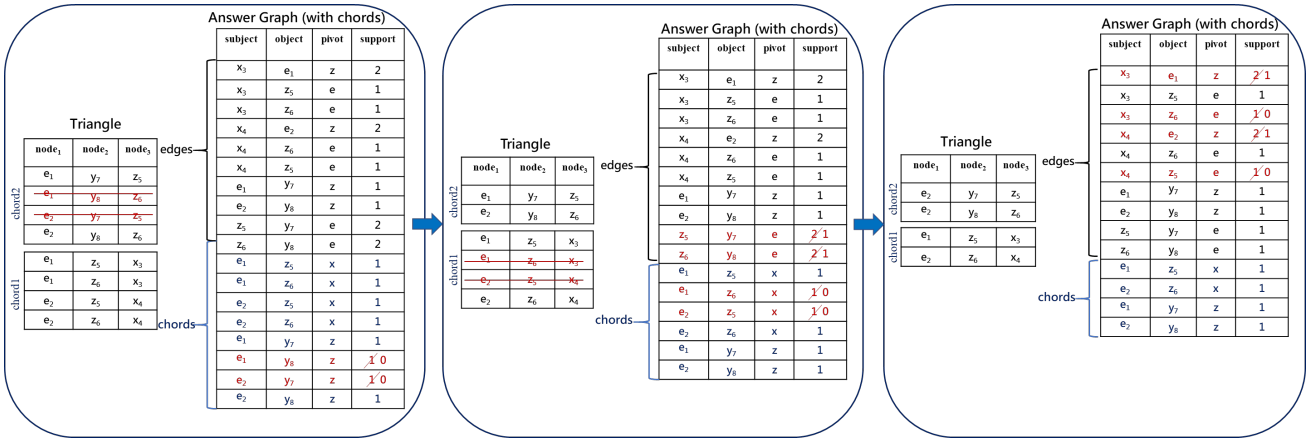

Figure 5: A running example of edge burnback procedure

to the iAG is, at some point, removed. WIREFRAME employs cardinality estimators drawn from a catalog consisting of 1-gram and 2-gram edge-label statistics computed offline [7, 10, 22, 23].

The Edgifier. A plan is a sequence of the CQ's query edges to be materialized. We employ a bottom-up, dynamic-programming algorithm to construct the edge order based on cost estimation (which relies upon the cardinality estimations).

When the query graph of a CQ has cycles—a *cyclic* query—there is an additional part to planning. Node burn-back suffices to generate the ideal answer graph for acyclic queries, but not for cyclic. The example in Fig. 4(I) illustrates why. *Spurious* edges (in red)—e.g., $\langle x_3, z_6 \rangle$ and $\langle x_4, z_5 \rangle$—can remain that do not participate in any final embeddings—i.e., $\langle x_3, z_5, y_7, e_1 \rangle$ and $\langle x_4, z_6, y_8, e_2 \rangle$. Nevertheless, one can still use this non-ideal answer graph to generate the embeddings using defactorization.

Even so, it is possible to reduce significantly further the answer graph. To cull spurious edges requires an *edge burnback* procedure in addition to node burnback. This requires the CQ's cycles have been *triangulated*; node *triples* are materialized in addition to the node *doubles* (the AG edges) during evaluation. Triangulation is the choice of which additional "query edges", which we call *chords*, to add.

The Triangulator. For cyclic CQs, in addition to the query-edge enumeration, cycles in the query graph of length greater than three are *triangulated* by adding *chord* edges. During evaluation, a chord is maintained as the intersection of the materialized joins of the opposite two edges for each triangle in which it participates. There are many different ways one can triangulate a CQ; the materialization cost depends on the order and choice of chord bisection of cycles (down to triangles). We employ a bottom-up dynamic programming algorithm to generate a bushy plan—we call this a *mesh plan*—that dictates such an order and choices.

The mesh plan, when executed with node burnback but not edge burnback, guarantees that the node sets, but not necessarily the edge sets, will always be minimal. A correct answer graph, AG, will be found, but it is no longer guaranteed to be ideal. as spurious edges may remain in the AG, as demonstrated in Fig. 4(I). The embeddings can, of course, be found from this non-ideal AG.

Edge Burnback. With the addition of *edge burnback* mechanism at runtime, we can guarantee again that we find the ideal AG (iAG) when answering cyclic CQs, *modulo* the choice of chords that were added. This works by checking the chords' materializations to chase what needs to be removed on cascade. This ensures that spurious edges are removed.

Fig. 4(II) shows a mesh plan which establishes as sequence of chords to triangulate the given query graph CQ_D. At the bottom of the plan, the first chord $\langle ?e, ?z\rangle$ is added, which creates the triangle $\bigtriangleup_{?e,?x,?z}$ by joining two query edges $\langle ?x, ?z\rangle$ and $\langle ?x, ?e\rangle$ on their common node $?x$. At the next step up, a second chord $\langle ?e, ?y\rangle$ is added to create a triangle $\bigtriangleup_{?e,?z,?y}$ by joining the previous chord $\langle ?e, ?z\rangle$ and the query edge $\langle ?z, ?y\rangle$ on their common node $?z$. At the root of the plan, a "seal" process occurs between the chord $\langle ?e, ?y\rangle$ of the left subplan and the query edge $\langle ?e, ?y\rangle$ of the right subplan, where it constructs the full cycle of the query graph. Each time we triangulate, we record the node triples (as triangles) drawn accordingly from **G** in the Triangle table, and the data chords in the Answer Graph table. We also record in the support column of the Answer Graph table the number of different triangles that each data edge (or data chord) participate, grouped by its opposite node label (which we call the *pivot*). For example, in the Answer Graph table, the edge $\langle x_3, e_1\rangle$ has a support of 2 with the pivot of z; that is, it is part of two triangles where the opposite node is of the label z. We can find these from the Triangle table: $\bigtriangleup_{e_1 z_5 x_3}$ and $\bigtriangleup_{e_1 z_6 x_3}$.

The seal process marks all uncommon data edges and data chords between the right and left subplans—we call these *unsealed* edges—by updating their supports in the Answer Graph table to 0. Unsealed edges represent the arcs that are not part of any cycle. Data edges that reside only on such arcs cannot be part of the ideal AG. The task of edge burnback is to remove these edges. It begins by removing all unsealed edges, along with triangles in which they participate. Removing a triangle involves removing all its data edges, which might also belong to other triangles in the query graph, thereby removing those triangles too. This process cascades until no unsupported triangle is left to be removed. Whenever we remove a triangle, we decrease the support of all of its constituent edges by one in the Answer Graph table. When the support of any data edge or chord in the Answer Graph becomes 0, then it is safe to remove it along with the triangles in which it participates. The process cascades until there are no edges with zero-support remaining in the Answer Graph table.

Fig. 5 demonstrates the process of edge burnback. After the sealing process, the unsealed set of edges are $\{\langle e_1, y_8\rangle, \langle e_2, y_7\rangle\}$, as shown in the Answer Graph table of Fig. 4(II). We next update the support of these two edges to 0 in the Answer Graph table. We then call the edge burnback procedure. This first removes the zero-support edges from the Answer Graph table. Next, this deletes triangles $\bigtriangleup_{e_1 y_8 z_6}$ and $\bigtriangleup_{e_2 y_7 z_5}$ which those edges participated from the Triangle table. The support for each of the edges in the Answer Graph table that was part of a recently deleted triangle is decremented by 1. For example, for the removed triangle $\bigtriangleup_{e_1 y_8 z_6}$, the support is decremented for edges $\langle z_6, y_8\rangle$ and $\langle e_1, z_6\rangle$. For the removed triangle $\bigtriangleup_{e_2 y_7 z_5}$, the support is decremented for edges $\langle e_2, z_5\rangle$ and $\langle z_5, y_7\rangle$. In the next iteration, the zero-support edges are removed from the Answer Graph table, which leads, in turn, to triangles $\bigtriangleup_{e_1 z_6 x_3}$ and $\bigtriangleup_{e_2 z_5 x_4}$ being deleted from the Triangle table. The support is then decremented for the edges that participated in those deleted triangles. And so forth. This process halts once there is no edge left with zero-support in the Answer Graph table. The resulting answer graph is then the ideal AG (iAG).

The overhead of edge burnback must be balanced off against the benefit of obtaining the iAG versus a larger, non-ideal AG. This is work in progress. In our experiments, our evaluation over cyclic CQs is without edge burnback.

5.2 The Embedding Planner

Plan Cost. When generating the embeddings for an acyclic CQ from its iAG, the order in which we join (connected) answer edges is immaterial. As the k-ary tuples are extended, no intermediate results are ever lost. Thus, for this, no planning is required.

The Defactorizer. On the other hand, when the CQ is cyclic, or when the AG provided is non-ideal, intermediate results can be lost. The join order then matters. We call this process *defactorization*. Alternative plans for embedding materialization are synonymous with choosing this join order. It is possible to do this again via a cost-based approach via a bottom-up, dynamic programming algorithm, using our catalog statistics.

6 EXPERIMENTS

Prototype. We have implemented a prototype, Wireframe, that runs on top of PostgreSQL, a popular relation database system. Wireframe implements the two phases described in Section 5, each with a separate planner and evaluator. The planner for the first phase outputs an optimal left-deep tree plan that indicates the execution order of the query edges. The evaluator then takes the tree plan to evaluate the query edges in sequence. For the second phase, we presently use a greedy approach to generate a tree plan based on the available statistics from the AG phase. The node burnback procedure is implemented via procedural SQL.

Environment. To evaluate Wireframe's performance, we use the YAGO2s dataset [21] containing 242M triples with 104 distinct predicates. With a select set of 10 acyclic and 10 cyclic CQs, we compare query execution times against PostgreSQL v11.0 (PG), Virtuoso v6.01 (VT), MonetDB v11.31 (MD), and Neo4J v.3.5 (NJ). All experiments were conducted on a server running Ubuntu 18.04 LTS with two Intel Xeon X5670 processors and 192GB of RAM.

Micro-benchmark. For the queries, we implemented a query miner that generates valid, non-empty queries over a dataset using query templates (with placeholders for edge labels). For our experiments, we use two templates, CQ_S and CQ_D, as shown in Figures 3 and 4, respectively. With these two templates, we mined 218,014 snowflake-shaped queries and 18,743 diamond-shaped queries. For our preliminary experimental study, we chose top ten queries in the size of final embeddings for each shape.

While in [5], it is argued that there are no use cases for cyclic queries, many, including us, have argued there certainly are. In [14], they discuss how triangle queries, the simplest of cyclic, have become increasingly popular for social networks, biological motifs, and graph databases. And that cyclic queries have not been used much yet in practice has been due in large part to that they have been too expensive to evaluate.

Comparators. For PostgreSQL and MonetDB, the dataset was imported as a triple store, with indexes on the string dictionary, and six composite indexes over the permutations of *subject*, *predicate*, and *object*. We set the size of the memory pool to eight GB for all of the systems, except for MonetDB (which sets its own resource allocations based on the server). We repeat execution of each query five times, taking the average of the last four runs (*i.e.,* warm cache), as reported in Table 1. The execution time is the time spent to retrieve all the result tuples for a query.

Results. One can observe from Table 1 that the size of the answer graph is exceedingly smaller than the number of embeddings. For instance, for the second snowflake-shaped query, the AG is 2,867 times smaller than the number of embeddings. It is no surprise, therefore, that Wireframe (WF) achieves good performance; it

Table 1: Query execution time (sec) in different systems (* denotes terminating the query after 300 seconds).

avoids the redundant edge-walks that arise from many-many joins. While the second snowflake-shaped query took 63 seconds on PostgreSQL, it only took three seconds on Wireframe. The AG approach requires a much smaller memory footprint, which can be beneficial for traditional database systems that heavily use secondary storage. The approach also competes well against main-memory intense systems such as Neo4J and Virtuoso. For the cyclic, diamond-shaped queries, employing only node burnback does not guarantee the ideal answer graph, as discussed above. We have found that the resulting AGs can be significantly larger than the ideal, sometimes close to the number of embeddings. For this reason, Wireframe was slower for some of the cyclic queries, notably 18 and 19. Even so, its performance over cyclic queries is quite good. With further plan- and run-time optimization with edge burnback, we believe that the performance will be stellar. One can view our approach as an additional optimization technique on top of traditional databases to handle SPARQL CQs or to boost the performance of existing RDF systems.

7 CONCLUSIONS

We have clear objectives for our next steps. *First*, one has a richer plan space when considering bushy plans for both our first and second phases. The challenge is to devise a suitable cost model for searching the bushy-plan space via dynamic programming. *Second*, when the size of an answer graph is distant from the ideal, generating the embeddings can be costly. Triangulation promises to reduce this significantly. This requires investigating the trade-offs between the added cost for maintaining the triangle materializations and the reduced cost from generating the embeddings from the significantly smaller ideal AG. *Lastly*, we are to explore further optimizations within this space. Large graphs are meant to be queried.

Abstract

Graphs are pervasive in many applications in which interconnected data are used to represent, explore and predict digital and real-world phenomena. Oftentimes, graph data comes without a predefined structure and in a constraint-less fashion, thus leading to inconsistency and poor quality. In this paper, we present a novel end-to-end schema inference method for property graph schemas that tackles complex and nested property values, multi-labeled nodes and node hierarchies. Our method consists of three main steps, the first of which builds upon Cypher queries to extract the node and edge serialization of a property graph. The second step builds over a MapReduce type inference system, working on the serialized output obtained during the first step. The third step analyzes subtypes and supertypes to infer node hierarchies. We present our schema inference pipeline under two variants, namely a label- and a property-oriented variant. Finally, we experimentally evaluate and compare its scalability and accuracy on several real-life datasets. To the best of our knowledge, our work is the first to address schema inference for property graphs.

1 Introduction

Over the past decade, graph-based knowledge representation has been becoming increasingly popular, be it with the advent of graph databases [4] as an alternative to relational databases, or to model complex systems, from social and fraud detection networks to smart city grids or neuronal networks. Graphs are applicable to all settings in which interconnected data are used to represent, explore and predict digital and real phenomena. Understanding the connections in the data is fundamental for companies to carry out analytical and machine learning tasks.

Oftentimes, graph data comes without a structure and in a constraint-less fashion, thus leading to inconsistency and poor quality. According to a recent survey [12], the most recurrent task for users of real-world graphs is data integration. As a matter of fact, graphs naturally lend themselves to information reconciliation and integration. However, the integration of large-scale graphs, e.g. in knowledge bases such as DBPedia, Wikipedia or the more recent CovidGraph, might turn out to be incorrect and error-prone if not guided by means of schema constraints. These constraints are also important pillars for query optimization and metadata management, the latter being unexplored topics in graph databases. There are several models for representing graphs. Among the most popular is the property graph (PG) data model, which is a multigraph with both labeled nodes and edges, along with property value pairs associated to both. It has gained adoption with systems such as ArangoDB, HANA Graph, Neo4j, Oracle PGX, TigerGraph, Titan, etc.

However, due to the lack of a standard schema, PG instances are typically built without a predefined schema. Although it ensures great flexibility, it can also become a great impediment, notably whenever the structure of the underlying instance has to be stabilized as in many data management settings. Indeed, schemas succinctly represent the structure of the PG instances and allow to set constraints, such as the types of nodes, edges and properties as well as the cardinality of a relationship or property value data types. Moreover, schemas can be used to build relevant graph features based on types as needed in many Machine Learning pipelines [3]. Yet, given that PG instances usually exist prior to the schema definition, extracting a schema from those instances in a principled way might become a non-trivial and challenging task. Existing PG schema inference methods in available graph databases (such as Neo4j) are simplistic in that they can only output basic edge types and node types and do not take into account the complexity of the PG data model. In particular, they cannot handle complex data types, overlapping node types or node hierarchies. A principled approach to PG schema inference is currently missing and highly desirable given the interest in an ongoing ISO SC32/ WG3 standardization process of PG schemas, involving people from academia and industry in the LDBC community[1].

In this work, we address this problem and present a novel end-to-end schema inference method covering the entire spectrum of features of the PG data model. Our method tackles complex and nested property values, multi-labeled and unlabeled nodes, node hierarchies and overlapping node types as well as edge cardinality constraints and optionality of properties. We also introduce two variants of our method, a label-oriented and a property-oriented one and investigate their pros and cons.

To enable scalability, our method leverages a MapReduce approach [2] developed for schema inference from JSON datasets, which both aggregates types and identifies data types. However, the JSON data model and the PG data model are significantly different. While the former can be seen as an edge-labeled tree-structured data model, the latter is more expressive as it is a multi-graph with novel schema components such as subtyping and edge cardinality constraints. Because of that, schema inference for property graph is a challenging and non-trivial problem that we tackle in this paper for the first time.

The schema inference pipeline we designed[2] can be divided into three main steps. First, we employ Cypher queries to extract and serialize the nodes and edges of the input PG, in addition to gathering information needed to infer edge cardinality constraints. Cypher[3] is an open-source graph query language developed by Neo4j, inspired from SQL and adopted by several graph database vendors. Afterward, we infer node and edge types, together with the property value data types, using the output from the first step to input the MapReduce algorithm. The last step consists in analyzing subtypes and supertypes to infer node

[1] More information can be found at: https://www.gqlstandards.org
[2] The source code is available at: https://gitlab.com/Hgit/pgsinference
[3] http://www.opencypher.org

hierarchies. Our schema inference method is generic and can be adapted to other graph database platforms, insofar as the input PG can be appropriately serialized to JSON. Furthermore, our work can serve as a basis to inform the ongoing discussion of the working groups within the ISO SC32/ WG3 standardization process about the impact of the schema inference process on the PG schema design choices. After describing our schema inference method, we experimentally evaluate the accuracy and scalability of our schema inference method on real-life datasets.

2 Related Work

Several vendors propose graph databases supporting the PG data model, such as Neo4j, Oracle PGX, TigerGraph, RedisGraph and GraphQL. Neo4j offers a limited possibility to view a schema of the database via a Cypher query that outputs a single-labeled directed graph displaying which types of nodes can be connected together and through which types of edges. However, there is a lack of support of the PG data model in its full potential [4]. In particular, multi-labeled nodes in the graph instance are duplicated in the graph schema so that each node is assigned a single label, hence loosing label co-occurrence information, which is a crucial capability of the PG data model. Furthermore, properties, edge cardinality constraints and node type hierarchies are disregarded. Nonetheless, other Cypher queries output for each node (or edge) type its corresponding properties and their data types, in addition to whether or not they are mandatory. Nevertheless, in the case of multi-valued or nested properties, only the data type of the data structure containing them is inferred. In addition, GraphQL schemas can be inferred from Neo4j databases [7] via a Neo4j Desktop GraphQL plugin or neo4j-graphql-js. Node and edge types and node properties data types are inferred, unlike overlapping types, node hierarchies and nested property values—in contrast with our method. Furthermore, some Neo4j-specific data types, such as Locations or Dates, produce an error.

Many schema inference approaches consist in identifying structural graph summaries by grouping *equivalent* nodes together [10]. Typical examples are clustering techniques, like [9] and [6], which infer *types* in RDF datasets. Both are based on the assumption that the more *properties* two *entities* share, the likelier they belong to the same *type*. To this end, they group entities according to a similarity metric. They also both handle hierarchical and overlapping types. In [6], a density-based clustering method, DBSCAN, is adopted. In [9] a faster and more accurate clustering method, called StaTIX, is proposed. It uses the cosine similarity metric and is based on community detection. However, none of these techniques are suitable for PGs.

In [2], the authors propose a scalable MapReduce approach for schema inference in JSON datasets, which infers all data types before merging types according to an equivalence relation. Our pipeline repurposes it for PG type inference. However, in JSON, type hierarchies only exist in a very limited capacity and [2] does not tackle explicitly the problem of overlapping types. Due to the remarkable differences between the JSON data model and the PG data model, their method is not directly applicable to PGs.

In summary, none of the above approaches fully satisfy our criteria for PG schema inference: inference of types, basic and complex data types, overlapping types and node hierarchies, and, to the best of our knowledge, ours is the first work presenting a schema inference method specifically tailored to PGs.

3 Preliminaries

In this section, we recall the definition of property graphs [1, 4, 5] and extend a PG schema definition to best fit the schema inference process presented in this paper.

Let $\mathcal{O}$ be a set of *objects*, $\mathcal{L}$ be a finite set of *labels*, $\mathcal{K}$ be a set of *property keys*, and $\mathcal{N}$ be a set of *values*. We assume these sets to be pairwise disjoint.

Definition 3.1. A *property graph* is a structure $(V, E, \eta, \lambda, \nu)$ where

- $V \subseteq \mathcal{O}$ is a finite set of objects, called vertices;
- $E \subseteq \mathcal{O}$ is a finite set of objects, called edges;
- $\eta : E \to V \times V$ is a function assigning to each edge an ordered pair of vertices;
- $\lambda : V \cup E \to \mathcal{P}(\mathcal{L})$ is a function assigning to each object a finite set of labels (i.e., $\mathcal{P}(S)$ denotes the set of finite subsets of set S); and,
- $\nu : (V \cup E) \times \mathcal{K} \to \mathcal{N}$ is a partial function assigning values for properties to objects;

such that $V \cap E = \emptyset$ and the domain of ν is finite.

In [5], a Data Definition Language (DDL) for PGs is proposed where the obtained schema is a PG itself. We expand it to introduce *edge cardinality*, *subtypes* and *supertypes* and the concept of *inheritance edge type*. All these are key concepts to make our inferred PG schemas as expressive and accurate as possible.

Definition 3.2. (**Property Graph Schema**) A Property Graph Schema is a Property Graph Type, which is a triple $(\mathcal{BT}, \mathcal{NT}, \mathcal{ET})$ with $\mathcal{BT}$ a set of element types, $\mathcal{NT}$ a set of *node types*, $\mathcal{ET}$ a set of *edge types*.

- **Property type**: A property type is a pair (k, t), where $k \in \mathcal{K}$ is the property key and $t \in \mathcal{T}$ is its data type.
- **Element type**: An element type $b \in \mathcal{BT}$ is a quadruple (l, P, M, E), where $l \in \mathcal{L}$ is a label, P is a set of property types, $M \subseteq P$ is a subset of mandatory property types and $E \subseteq \mathcal{BT}$ is the set of element types that b extends.
- **Subtypes**: A subtype is an element type such that it inherits from another element type—called the **supertype**.
- **Node Type**: A node type is a pair (b, H), with $b \in \mathcal{BT}$, $H \subseteq \mathcal{BT}$ the set of **supertypes** b inherit from.
- **Inheritance Edge Type**: An inheritance edge type is a triple (s, e, t), where $s = (b, H) \in \mathcal{NT}$, $t \in H$, $e \in \mathcal{BT}$ with a label that we denote "SubtypeOf". Inheritance edge types do not have any cardinality.
- **Ordinary Edge Type**: An ordinary edge type is a quadruple (s, e, t, c), with $s \in \mathcal{NT}$ the source node, $t \in \mathcal{NT}$ the target node, $e \in \mathcal{BT}$, $c = ((i, k), (j, l)) \in (\{0, 1\} \times \{1, N\})^2$ the **cardinality**.
- **Edge Type**: the disjoint union of ordinary edge and inheritance edge types.

In the remainder of the paper, unless stated otherwise, *edge type* refers to *ordinary edge type*. Let us define overlapping types:

Definition 3.3. (**Overlapping Type**) An overlapping type is an element type which is a subtype of two or more supertypes.

4 Inferring Property Graph Schemas

In this section we present our method to infer a PG schema. We assume all nodes and edges in the PG are labeled. Nodes are of the same type if and only if they have the same set of labels, while edges are of the same type if and only if they share their set of source nodes, target nodes and edge labels. These assumptions

may be too strong in some cases. We will present in Section 4.4 an alternative that deals with some of its shortcomings.

Our PG schema inference pipeline can be divided into three main steps (cf. Fig. 1).

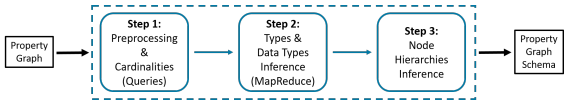

Figure 1: Schema inference main steps.

4.1 Step 1: Preprocessing

To begin with, the input PG needs to be serialized into JSON—the format required by the MapReduce algorithm. To this end, the graph is queried to match nodes and edges. To infer edge cardinality constraints, statistics are also collected. Then, the matched nodes and edges are serialized in such a way that proper node and edge type inference is guaranteed. From there, they are stored in `jsonline` files that will be input into the next step.

4.1.1 Preprocessing Queries. First, nodes are matched according to their labels via Cypher queries. Similarly, edges are matched according to their source, target node and edge labels. Node and edge types such that none of their instances have properties are stored separately. As there is no need to infer their property data types, the MapReduce step can be skipped in these cases and they can be directly processed by the third step.

4.1.2 Edge Cardinalities. Edge cardinality constraints are then inferred using rules comparing the number of instances of the source nodes, target nodes and a given edge type. These are collected by the preprocessing queries. Let us denote this edge type $E = (s, e, t, c)$, with $s, t \in \mathcal{NT}$, $e \in \mathcal{BT}$ and c the cardinality. For instance, if there are more target nodes than source nodes and there are as many target nodes as edges of type E, then the cardinality of E is *one-to-many*. This means that an instance of the source node type s can be linked to many instances of the target node type t via the edge type E but that an instance of t can only be linked to one instance of s via E. These rules can be similarly declined for *one-to-one*, *many-to-one* and *many-to-many* relationships. The cardinality constraints can be further refined to take into account optional relationships. For the given edge type E, if there are fewer instances of source nodes than of its corresponding node type, s, then this edge type is *optional* for the source node type s (otherwise, the edge type is *mandatory* for s). This means that there may be nodes of type s that are not linked to nodes of type t via an edge of type E. The same rule can be applied for target nodes.

In our pipeline, the cardinality constraint information is stored as an edge property with the key `meta_cardinality` and a `string` data type (e.g., `meta_cardinality` : "0..1:1..*" encodes a *one-to-many* relationship with the edge type *optional* for the source node type and *mandatory* for the target node type).

4.1.3 Serialization to JSON. The Cypher queries output node and edge `neo4j` objects where property values are sometimes incorrectly stored (e.g., a dictionary as a `string`). They are identified and converted accordingly to ensure a correct data type inference. Nodes and edges are then converted to dictionaries that are stored in `jsonline` files in such a way that correct type inference by the MapReduce method is guaranteed (cf. Section 4.2). The nodes file contains a single dictionary where each key-value pair represents a node. The key corresponds to its labels, sorted in alphabetical order and separated by colons. The value is a dictionary storing the properties as key-value pairs. Similarly, the edges file contains a single dictionary where each key-value pair represents an edge, with the value a dictionary storing the properties as key-value pairs. This time, the key corresponds to its starting node labels, its own labels and its target node labels, all separated by colons.

4.1.4 Example. Let us set a PG instance G of a social network of patients and doctors who can create and like posts and comments as well as reply to them. This is partially inspired by the LDBC Social Network Benchmark database [8]. Listings 1 and 2 are dictionaries encoding a node and edge instance.

```
{'Patient:Person': {
    'name': 'Alice',
    'birthday': {'day':29,
                 'month':'May',
                 'year':2000},
    'StudentNumber': 42,
    'address': ['Market Street', 'Lyon'] }}
```

Listing 1: Dictionary storing a node instance.

```
{'Patient:Person::KNOWS::Doctor:Person':
    {'date': '1993-06-02' }}
```

Listing 2: Dictionary storing an edge instance.

At the end of Step 1, we have two `jsonline` files ready to be input into the MapReduce algorithm, a list of node types with no properties and a list of all edge types containing edge cardinality information but no properties (they will be added in Step 2).

4.2 Step 2: Types and Data Types Inference (MapReduce)

In this step, we aggregate nodes and edges by type and infer the property data types by relying on MapReduce [2]. It can be summarized in two steps : i) a **Map** phase where all property value data types are inferred (cf. Listing 3) and ii) a **Reduce** phase where types are fused according to an equivalence relation. Here, we use the *kind-equivalence* relation described in [2] (cf. Listing 4). It fuses recursively types of the same *kind*, i.e. records with records, arrays with arrays and basic types (`String`, `Number` and `Boolean`) with basic types. The fusion of two basic types produces their union. The fusion of arrays outputs an array containing the fusion of their content. In the case of records, the different values of the two records are fused if and only if they share the same key. If one of the records contains keys that are not present in the other, then this particular key-value pair is deemed optional. Therefore, nodes will have their properties merged if and only if they share the same set of labels. Additionally, edges will have their properties merged if and only if they share the same set of source node, target node and arc labels. This complies with our assumption stated at the beginning of Section 4. The fusion function is recursively called so as to handle nested values.

The output of the algorithm, which is a JSON record, is then parsed and stored in a human-readable dictionary where question marks are affixed to optional properties' data types. A property "`meta_mandatory` : False" is instead added to optional records. Next, the dictionary is merged with the node types with no properties and the list of edge types containing cardinality constraints. Thus, the output of this step is a preliminary PG schema of the input PG, but it is still missing subtyping information.

4.2.1 Example. Listing 3 and 4 illustrate the fusion of two {`Person`, `Patient`} nodes using the *kind-equivalence* detailed above.

```
{'Patient:Person': {
  'name': STRING,
  'birthday':{'day': NUMBER,
    'month': STRING,
     'year': NUMBER},
  'StudentNumber': NUMBER
  'address': [STRING] }}
{'Patient:Person': {
  'name': STRING,
  'address': [NUMBER] }}
```

Listing 3: Two JSON record types corresponding to two nodes present in G.

```
{'Patient:Person': {
  'name': STRING,
  'birthday':
    {'day': NUMBER,
      'month': STRING,
      'year': NUMBER,
      'meta_mandatory': FALSE},
  'address': [NUMBER + STRING],
  'StudentNumber': NUMBER ? }}
```

Listing 4: Fusion of the two JSON record types on the left-hand side using the *kind-equivalence*.

4.3 Step 3: Inference of Node Hierarchies

The final step is to infer node type hierarchies so as to obtain a schema satisfying Definition 3.2. Inferring edge hierarchies is unnecessary in Neo4j graphs, since edges can only be associated with a single label. Nevertheless, we expect our hierarchy inference technique to straightforwardly extend to edge hierarchies.

Algorithm 1: Node Hierarchy Inference (Label-Oriented Variant)

```
   input : schema nodes and edges dictionaries from Step 2
   output: updated schema nodes and edges dictionaries and schema file
1                                                  ▷ Identify supertypes
2  supertypes = list of the pairwise intersections of the node label sets
3  for stype in supertypes do
4      add stype to nodes if needed
5                                                  ▷ Identify subtypes
6  nodeLabels = list of node label sets
7  for i ← 0 to length(nodeLabels) − 1 do
8      nset0 = nodeLabels[i]
9      for j ← 0 to length(nodeLabels[i :]) − 1 do
10                                  ▷ Two given node types are compared only once
11         nset1 = nodeLabels[j]
12         if nset0 ≠ nset1 then
13             if nset0 ⊂ nset1 then
14                 add nset1::SubtypeOf::nset0 edge
15             else if nset1 ⊂ nset0 then
16                 add nset0::SubtypeOf::nset1 edge
```

First, node **supertypes** corresponding to subsets of labels present in two or more node type label sets are inferred (l. 1-4). To this end, we take the pairwise intersection of the label sets of all node types inferred during Step 2. For instance, let us consider a {`Person`, `Doctor`} and a {`Person`, `Patient`} node type. The node type labeled {`Person`} is thus identified as a *supertype*.

The second step is to identify all **subtypes** (l. 5-16). We assumed earlier that node types are characterized by their labels. We thus consider a node type (with label set A) to be a *subtype* of a distinct node type (with label set B) if $B \subsetneq A$. This enables us to automatically handle overlapping types and hierarchies of arbitrary depths, as long as they are reflected in the labels. Thus, the label sets of all node types, including those inferred previously, are compared in pairwise fashion to identify subtypes. For example, {`Person`, `Patient`, `Doctor`} is a *subtype* of {`Person`, `Doctor`}. The corresponding inheritance edges are then created and added to the schema. The time complexity of the node hierarchy inference is quadratic in the number of node types inferred in the previous steps. However, since the number of node types is typically smaller than the size of the PG, this complexity remains bearable in practice, as also shown by our evaluation.

With the node type hierarchy inferred, the PG schema is complete. It is stored in a JSON file using the format described earlier.

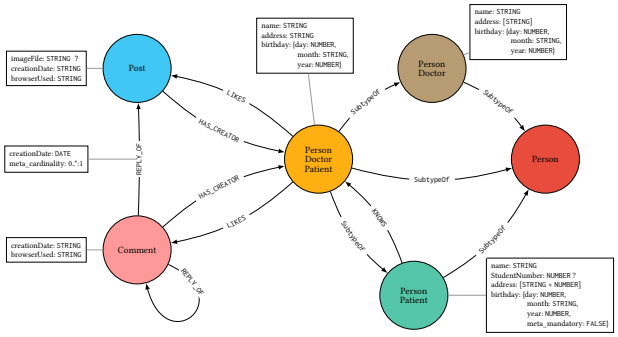

Figure 2: An excerpt of the PG schema inferred from the PG G using our label-oriented variant.

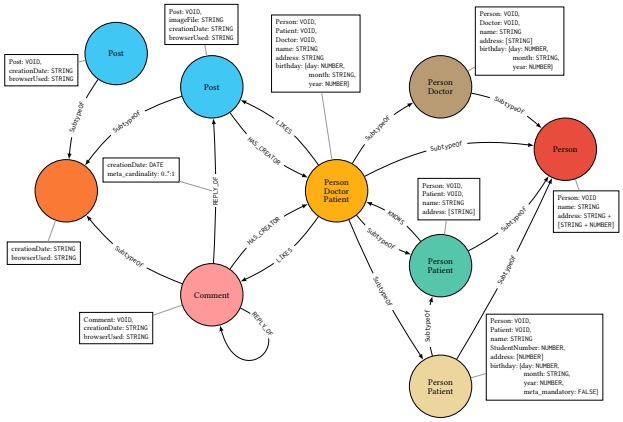

Figure 3: An excerpt of the PG schema inferred from the PG G using our property-oriented variant.

4.4 Method Variant: Labels as Properties

So far, we have assumed that all nodes in the input PG are labeled and that node labels characterize node types. However, these assumptions may sometimes be unsuitable. Indeed, some graphs may contain unlabeled nodes and information provided by the properties may be lost when only taking labels into account. For example, let us consider the PG G (cf. Example 4.1.4) and assume that the nodes labeled {`Person`, `Patient`} can be partitioned into two groups: those with a `StudentNumber` property key, corresponding to patients who are students, and those without one. With the previous approach, we had missed this subtlety and only identified a single {`Person`, `Patient`} node type with an optional `StudentNumber` key (cf. Listings 3 and 4 and Fig. 2). Therefore, we propose to consider labels as properties with a `Void` data type and to use property key sets (which now include labels) instead of label sets to characterize node types and thus identify node types and hierarchies. To merge nodes, we hence use $\mathcal{L}$*-driven reduction* [2], which fuses two records if and only if they share the same property key sets. As a result, no optional property can be inferred but rather property key co-occurrence information is identified. Moreover, unlabeled nodes can henceforth be considered on the same level as labeled nodes. In Neo4j, edges must have exactly one label. So, all the input PGs we considered contain single-labeled edges. We thus continue to utilize our label-oriented approach to handle them. If the source node or

target node is unlabeled, it is referred to by its property keys in place of labels. Our PG schema inference pipeline in this paradigm is very similar to the former and can be divided into the same three steps.

4.4.1 Example. Fig. 2 and 3 depict the schemas inferred from the PG G using both variants. As discussed above, the first approach overlooks the information provided by the properties, resulting in missing node types (e.g., a supertype of the `Post` and `Comment` nodes could not be inferred). This is resolved with the property-oriented variant where an unlabeled supertype could be inferred (the unlabeled orange node in Fig. 3).

5 Evaluation

Our method is implemented in Python 3 and is based on Neo4j 3.5. The graphs are queried with Cypher through the Neo4j Python driver. The MapReduce step is based on the implementation in [2], which runs with Spark 2.4.5. All experiments were performed on an Openstack Virtual Machine with twelve 2GHz 64-bits Intel Xeon CPUs, 62 GB of memory and a 1.5 TB hard drive.

5.1 Datasets and Metrics

We have used several datasets in our experimental study (cf. Table 1). We evaluated our schema inference method on the **LDBC Social Network Benchmark** (**LDBC**) [8], a synthetic social network. It contains single-labeled nodes and comes equipped with a ground truth schema incorporating node hierarchies. We also used two **Neuprint** datasets, corresponding to neuronal networks of different parts of the fruit fly brain: i) the mushroombody (**mb6**) [14] and ii) the medulla (**fib25**) [13]. Accompanied by a ground truth schema, they contain multi-labeled nodes (as opposed to LDBC) and a large diversity of property value data types, such as JSON records or `neo4j` cartesian 3D points. We tested as well our pipeline on a **Covid-19 graph** (**covid19**) (https://covidgraph.org/). This graph is being assembled by the CovidGraph project, which is currently ongoing. The graph is continuously evolving and hence so are the corresponding schemas. The results presented in this paper are those obtained with the April 2020 version, which notably holds multi-labeled nodes and five unlabeled nodes. No ground truth is available for the schema of the latter graph.

To assess the quality of our schema inference, we have used the precision, recall and F1-score of the node types and edge types. We consider an inferred type that is (not) present in the ground truth schema as a True Positive (TP) (False Positive (FP), respectively). A type that is present in the ground truth but not in the inferred schema is considered as a False Negative (FN). Precision accounts for the proportion of identified types that are present in the ground truth, while the recall gives the proportion of ground truth types that were inferred. The F1-score provides an average of precision and recall.

5.2 Experimental Results and Discussion

In this section, we present and discuss the results of our evaluation (cf. Table 2 and 3). We recall edge type refers to the union of ordinary and inheritance edge types (cf. Definition 3.2).

5.2.1 Quality of the Schema Inference. In both the Neuprint and LDBC datasets, the property value data types, as well as the edge cardinality constraints of the correctly identified edge types, have been inferred accurately. The precision, recall and F1-score of the node and edge types (cf. Table 4) demonstrate the overall good quality of the types inferred with our label-oriented approach. We could not compute these metrics for the Covid19 dataset due to the lack of a ground truth on this schema.

Dataset	Nodes	Edges	Node Labels	Edge Labels	Unlabel. Nodes	Nested or Multiple Values
mb6	486,267	961,571	10	3	0	Yes
fib25	802,479	1,625,439	10	3	0	Yes
covid19	10,447,251	25,340,047	60	73	5	Yes
LDBC	1,577,397	8,179,418	7	14	0	No

Table 1: Characteristics of the datasets used in the study.

	Baseline		label-oriented-variant				
Dataset	**Node Types**	**Edge Types**	**Node Types**	**Edges Types**	**Inheritance Edges Types**	**Max Node Hierarchies Depth**	**Overlapping Types**
mb6	10	64	5	10	1	1	No

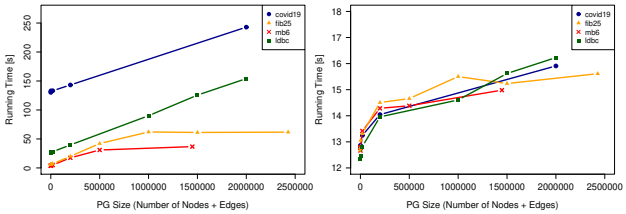
Table 4: Precision, recall and F1 of the inferred types (N is for node types, E is for edge types).

Baseline Comparison. We first compare the schemas inferred by our label-oriented approach with a baseline, the schemas returned by the Neo4j `call db.schema` query (cf. Table 2). The latter outputs many spurious types as it only targets single-labeled node types, even in the presence of multi-labeled node instances. Moreover, no property types or cardinality constraints can be captured, as opposed to our proposed method. As a result, the baseline schema is not accurate and error-prone.

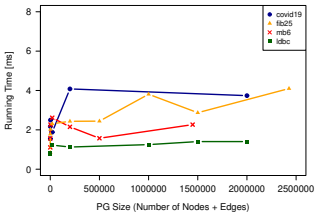
Label-Oriented Approach. All three metrics—notably the precision, with a 0.80 to 1.00 range—are reasonably high. They are identical for both Neuprint datasets (mb6 and fib25), as they share both the ground-truth and inferred types. Only one node type and its corresponding inheritance edge type absent in the ground-truth schema have been mistakenly identified. This is due to an inconsistency in the labeling of this particular node type where some of its instances have more labels than others. Hence, our algorithm incorrectly aggregated them into distinct node types. This highlights the sensitivity of our method to noisy labels. A statistical approach to the type inference, such as clustering methods [9], would allow to group together nodes that share similar, but not identical, label sets. Combining it with graph embedding [15], which maps the input graph to a low-dimension space while preserving the inherent characteristics of the graph to the best possible extent, like in [11], could also emerge as a promising solution. Data types and node hierarchies would still need to be inferred, possibly by integrating such approaches with our schema inference method.

In the LDBC graph, all inferred types exist in the ground-truth schema but none of the ground-truth hierarchies were discovered. Indeed, they were either defined via a `type` property, instead of labels, or identifiable only through properties in common. The former might be addressed with a semantic approach, while the latter is partially overcome with our property-oriented variant.

Property-Oriented Approach. The low precision and F1 scores obtained with the property-oriented approach may stem from the inference of numerous spurious types—in addition to the correct ones. For instance, in the mushroombody dataset (mb6)



(a) Step 1: Preprocessing Queries. (b) Step 2: Types inference.



(c) Step 3: Node hierarchy inference.

Figure 4: Average running times for various graphs.

63 additional node types were inferred. Indeed, since we are considering property sets to infer node types, for a given label set, we infer as many node types as there are combinations of properties—although in some cases, this behavior is expected (cf. Example 4.4.1). Furthermore, different node types may have common property keys even if they are not subtypes of a common supertype. For example, in the LDBC graph, the node types `Place` and `Person` both hold a property with the key `name`.

Nonetheless, in the Neuprint graphs, the number of TPs and FPs remain unchanged from one variant to the other. The recall remains thus constant. Even more remarkably, in the LDBC graph, more types present in the ground-truth are identified than with the label-oriented variant. They correspond to supertypes that could not be inferred using solely the node labels. This is reflected in the recall scores, which increase from 0.54 to 0.62, for nodes, and from 0.70 to 0.75, for edges.

Label-Oriented vs Property-Oriented Approaches. To summarize, the label-oriented variant outputs schemas with a very good precision. However, it is missing node types that can only be inferred through property-related information. This is partially overcome by the property-oriented variant, which is marked by an improved recall. Nonetheless, since many spurious types are inferred as well, this is done at the expense of the precision. Hence, the label-oriented variant should be preferred, either when the node hierarchies in the input PG are defined through labels, or when there are no hierarchies—such as in the Neuprint graphs. On the other hand, the property-oriented variant should be picked when properties are crucial to the inference process, such as in the presence of unlabeled nodes or when hierarchies are determined by property co-occurrence information.

5.2.2 Scalability We obtained the average running times of our schema inference pipeline for portions of different sizes of the datasets. The times discussed in this section were acquired with our label-oriented implementation. Those from our property-oriented implementation are of the same order of magnitude. The first step (cf. Fig. 4a), where we match every single node and edge of the input PG, brings to light the problem of the overhead caused by the Cypher queries, which increases with the size of the input PG. Indeed, the running times can go up to about 1900s for the complete covid19 dataset, with its 10M nodes and 25M edges (this data point is not represented in Fig. 4a to improve legibility). As such, the pipeline running time is dominated by this step. Still, it seems that it is at worst linear in the input size. Fig. 4b displays the sublinear behavior of the running times of Step 2, which is as expected with regards to [2]. Moreover, our parsing function has an average running time smaller than 2ms, which is satisfactory. On average, Step 3 (cf. Fig. 4c) runs in less than 5ms and is constant when the input PG size increases, which comforts our complexity analysis carried out in Section 4.3. Additionally, Step 2 and 3 are not sensitive to the heterogeneity in the complexity of data types and structures displayed in the different datasets.

6 Conclusion and Future Work

We have presented a novel end-to-end schema inference method for PGs that handles complex and nested property values, multi-labeled nodes, node hierarchies overlapping node types, edge cardinality constraints and optionality of properties.

We have proposed and empirically evaluated two variants that both scale well. The *label-oriented* variant provides an inferred schema of good quality. One of its main shortcomings is the loss of property co-occurrence information that could lead to additional supertype identification. This is resolved by our *property-oriented* approach, which concurrently improves recall scores. However, in the process, many extraneous types are inferred. A solution worth exploring in future work would be to find a non-trivial way to combine the outputs of these two variants to exclusively retain the wanted node types.

Our schema inference method remains sensitive to variation in the labels and property keys, be it due to inconsistent or multilingual naming. To overcome this, it would be interesting to consider a clustering step on the nodes and edges of the input instances, possibly combined with graph embeddings taking into account semantic information to simplify graph representations.

ABSTRACT

With the growing popularity of storing data in native RDF, we witness more and more diverse use cases with complex SPARQL queries. As a consequence, query optimization – and in particular cardinality estimation and join ordering – becomes even more crucial. Classical methods exploit global statistics covering the entire RDF graph as a whole, which naturally fails to correctly capture correlations that are very common in RDF datasets, which then leads to erroneous cardinality estimations and suboptimal query execution plans. The alternative of trying to capture correlations in a fine-granular manner, on the other hand, results in very costly preprocessing steps to create these statistics. Hence, in this paper we propose *shapes statistics*, which extend the recent SHACL standard with statistic information to capture the correlation between classes and properties. Our extensive experiments on synthetic and real data show that shapes statistics can be generated and managed with only little overhead without disadvantages in query runtime while leading to noticeable improvements in cardinality estimation.

1 INTRODUCTION

Driven by diverse movements, such as Linked Open Government Data, Open Street Map, DBpedia [3], and YAGO [21], more and more data is being published in RDF [7] capturing a multitude of diverse information. Along with the growing popularity, increasingly complex queries formulated in SPARQL [6] are being executed over such data to answer business and research questions. Query logs of the public DBpedia SPARQL endpoint, for instance, contain SPARQL queries with up to 10 joins [4] and analytic queries in the biomedical field can involve more than 50 joins per query [9]. Therefore, the need for high-performance SPARQL query processing is now more pressing than ever.

Existing approaches for query optimization in RDF stores often adapt techniques from relational databases modeling an RDF dataset as a single large table with three column [5, 16] (one column for each of the components of an RDF triple: subject, predicate, and object). Nevertheless, accurate cardinality estimation is at the heart of any query optimizer that does not rely on heuristics but instead uses a cost model to find the best query execution plan for a given query. Cardinality estimation then relies on the availability of statistics describing the characteristics of the data to estimate the sizes of intermediate results produced while query execution. However, general statistics typically result in highly imprecise estimations since they are mostly gathered on the RDF graph as a whole, in contrast to the relational case where it is possible to create such statistics with higher precision since data is separated into multiple tables [15]. Furthermore, assuming independence when joining parts of SPARQL queries (triple patterns) leads to erroneous estimations [9] as co-occurrences of certain predicates are highly correlated [19].

Hence, exploiting more fine-grained statistics capturing correlations among RDF triples leads to more accurate join cardinality estimations [19]. However, creating such statistics comes at the price of a very time and resource-intensive preprocessing step. On the other hand, the alternative of online, query-dependent, sampling [20] results in overheads during query optimization. Instead, what we propose in this paper is to better exploit the information that is often provided along with an RDF dataset: SHACL (Shapes Constraint Language) [14] constraints, which is a recent standard for validating RDF datasets that are becoming more and more popular. SHACL defines so-called shapes describing the relationships between entities of a specific class, their properties, and their connections to other classes of entities. Although they are currently only used for validation purposes, we show in this paper that by slightly extending them with basic statistics, they can also be exploited for join cardinality estimation.

In summary, this paper makes the following contributions. First, we extend the SHACL definition to capture statistical information to replace the need for creating complex (and expensive) statistics over RDF datasets. To the best of our knowledge, this is the first proposal of this kind. Second, we introduce an algorithm to enhance SHACL shapes with statistical information and to exploit these statistics for join cardinality estimation and query optimization. Third, we study the impact of our approach using both synthetic (LUBM [10], WatDiv [2]) and real (YAGO-4 [21]) datasets, demonstrating that shapes statistics can provide higher precision for query optimization with only a little overhead.

This paper is structured as follows. While Sections 2 and 3 discuss related work and introduce preliminaries, Section 4 formally defines the problem. Section 5 then describes our proposed extension of the SHACL standards, and Section 6 presents techniques to exploit the additional information for cardinality estimation and query optimization. Section 7 discusses the results of our extensive experimental study, and Section 8 concludes the paper with an outlook to future work.

2 RELATED WORK

Cardinality estimation has been studied extensively in the context of relational databases [20]. For SPARQL queries, existing techniques adapt relational approaches [13, 24] and focus mostly on specific type of queries [19]. Usually, these approaches construct different kinds of single or multidimensional synopses over databases that can be used to estimate cardinalities [23]. While algorithms designed to generate synopsis for unlabelled graphs are not applicable here (as the edges in RDF graphs are labeled), consequently approaches to generate RDF summaries either produce very large summaries [23], have very high computational complexities, or they are unable to preserve the RDF schema while constructing the summaries [23]. Therefore, the most promising approaches aim at using statistics computed directly from edge label frequencies. In particular, RDF-3X proposes a histogram-based technique for cardinality estimation based on edge label frequencies. This technique was later extended by exploiting the statistical information of Characteristic Sets [19], which compute frequencies of sets of predicates sharing the same

subject to estimate the cardinalities. This approach shows high performance for star-shaped queries while it suffers from significant underestimation due to the independence assumption in the general case [20]. This approach was extended as Characteristic Pairs [18] to overcome this limitation, but it could only support multi-chain star queries. Moreover, extracting Characteristic Sets from large heterogeneous graphs is computationally expensive. SumRDF [23] is another cardinality estimation approach based on a graph summarization. It fails to handle large queries due to a prohibitive computation cost, and it is costly to construct such summaries over large RDF graphs [20].

A recent benchmark, G-CARE [20], analyzed the performance of existing cardinality estimation techniques for subgraph matching. This analysis revealed that the techniques based on sampling and designed for online aggregation outperform the cardinality estimation techniques for RDF graphs. *This calls for a more in-depth study on how to perform cardinality estimation for SPARQL query optimization appropriately.*

In a recent work, Shape Expressions (ShEx) [22] have been used to reorder triple patterns to enable SPARQL query optimization [1], i.e., it estimates an order of execution for the triple patterns based on some heuristic inference on which triples are more selective. For instance, if a shape definition says that every instructor has one or more courses, but every course has exactly one instructor, it infers that the cardinality of courses is at least the same as the cardinality of instructors and probably larger. Hence, this optimization procedure is not based on actual data.

Therefore, contrary to existing works, we aim at exploiting fine-grained statistics based on shapes to produce more precise cardinality estimations for query planning. This will allow us to overcome the limitations of existing methods that only use the global-statistics [11]. To this end, instead of creating large expensive summaries and characteristic sets over the RDF graphs to estimate the cardinalities, we exploit SHACL shapes constraints (which are as expressive as ShEx [22]) and annotate the *Node* and *Property Shapes* with the statistics of the input RDF graph. Compared to other solutions, it requires a lightweight preprocessing and retains the structure of original RDF and SHACL shapes graphs. Moreover, *this allow us to study more closely the effect of more fine-grained statistics, and more accurate cardinality estimation for the task of SPARQL query optimization.*

3 PRELIMINARIES

RDF Graphs: RDF graphs model entities and their relationships in the form of triples consisting of SPO <*subjects, predicates, objects*>. We present a simplified example of an RDF graph G based on the LUBM [10] dataset in Figure 1, where oval and rectangular shapes represent IRIs and literal nodes, respectively. An RDF graph is formally defined as:

Definition 3.1 (RDF Graph). Given pairwise disjoint sets of IRIs I, blank nodes B, and literals L, an RDF Graph G is a finite set of RDF triples $\langle s, p, o\rangle \in (I \cup B) \times I \times (I \cup B \cup L)$.

SPARQL: SPARQL [6] is a standard query language for RDF. A SPARQL query consists of a finite set of triple patterns (known as basic graph pattern, BGP) and some conditions that have to be met in order for data to be selected and returned from an RDF graph. Each SPO position in a triple pattern can be concrete (i.e., bound) or a variable (i.e., unbound). The variable names in a SPARQL query are prefixed by a '?' symbol, e.g., ?X. To answer a BGP, we require *a mapping between variables to values in an RDF graph*, all the resulting triples existing in the RDF graph

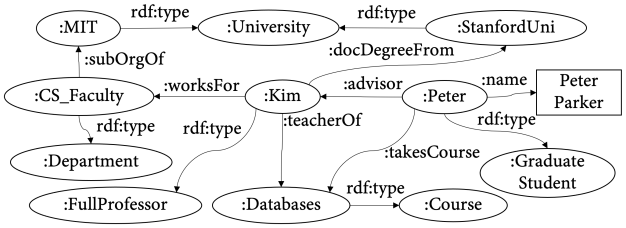

Figure 1: An RDF Graph G

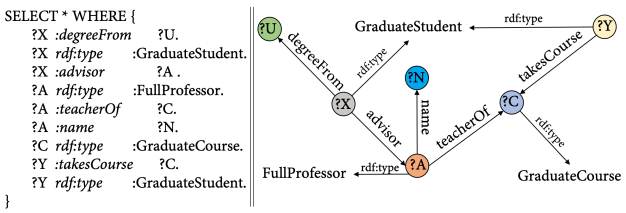

Figure 2: Query Q and its Graph Q_G

obtained by replacing the variables with values are answers to the BGP. Figure 2 shows an example SPARQL query (Q) and its query graph Q_G on the graph of Figure 1. A BGP is defined as:

Definition 3.2 (BGP). Given a set of IRIs I, literals L, and variables V, a BGP is defined as $T \subseteq (I \cup L \cup V) \times (I \cup V) \times (I \cup L \cup V)$, whose elements are called triple patterns.

Shapes Graphs: Several schema languages have been proposed for RDF in the past, where the most common are RDF Schema (RDFS[1]) and OWL [17]. RDFS is primarily used to infer implicit facts, and OWL is an extension of RDF and RDFS to represent ontologies. The declarative Shapes Constraint Language (SHACL) [14] became a W3C standard recently. SHACL schema provides high-level information about the structure and contents of an RDF graph. It allows to define and validate structural constraints over RDF graphs. SHACL models the data in two components: the *data graph* and the *shape graph*. The *data graph* contains the actual data to be validated, while the *shape graph* contains the constraints against which resources in the *data graph* are validated. These constraints are modeled as node and property shapes, which consist of attributes encoding the constraints. The node shapes constraints are applicable on nodes that are instances of a specific type in the *data graph* while the property shapes constraints are applicable to predicates associated with nodes of specific types. We define a SHACL shapes graph as follows:

Definition 3.3 (SHACL Shapes Graph). A SHACL shapes graph G_{sh} is an RDF graph describing a set of node shapes S and a set of property shapes P, such that $target_S : S \mapsto I$ and $target_P : P \mapsto I$ are injective functions mapping each node shape $s_i \in S$ and each property shape $p_i \in P$ to the IRI of a target class and a target predicate in G respectively, and $\phi : S \mapsto 2^P$ is a surjective function assigning to each node shape s_i a subset $P_i \subseteq P$ of property shapes.

For example in Figure 3, node shape constraints are applicable on node `ub:GraduateStudent` and its property shapes constraints are applicable on predicates like `takesCourse`, and `advisor`. This information is declared with attributes *sh: targetClass* for node shapes and *sh:path* for property shapes. Note that the attributes in the dark shaded boxes are part of our extension of the SHACL definition, explained in Section 5.

[1] https://www.w3.org/TR/rdf-schema/

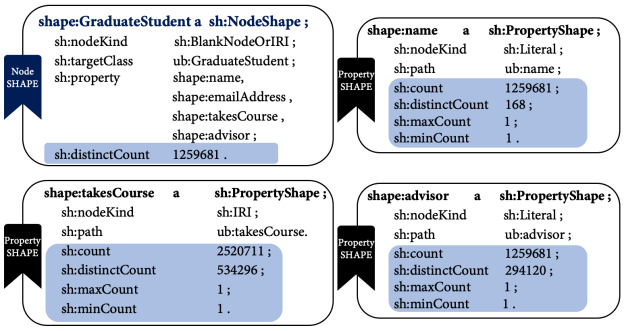

Figure 3: SHACL Shapes Graph

The Shapes Expression (ShEx [22]) language also serves a similar purpose as SHACL to validate RDF graphs. Nonetheless, the two formulations diverge mostly at the syntactic level [12], and our approach can be extended to work using ShEx or other constraints languages as well without the loss of generality.

4 PROBLEM FORMULATION

Given an input query Q, a query optimizer has the goal to find a query plan expected to answer Q in the minimum amount of time [15]. Constructing a SPARQL query plan includes finding a join ordering between triple patterns of its BGPs. In this paper, we focus on the join ordering of BGPs defined as follows:

Definition 4.1 (Join Ordering). Given a set of triple patterns $T=\{tp_1, tp_2, ..., tp_n\} \subseteq (I \cup L \cup V) \times (I \cup V) \times (I \cup L \cup V)$, the join order O for BGPs is defined as a total ordering O of T so that for every $t_i, t_j \in T$ either $t_i \prec_O t_j$ or $t_j \prec_O t_i$.

To find an optimal plan, a query optimizer needs to explore the search space of semantically equivalent join orders and choose the optimal (cheapest) plan according to some cost function. It is crucial to accurately estimate the join cardinality between triple patterns of a given query to construct a query plan with an efficient join ordering [9]. In line with the related work [20], we neglect other cost factors and focus on join cardinality as the most dominant cost factor to find a join ordering. We formally define the problem of estimating join cardinalities as follows:

Problem 1 (Join Cardinality Estimation). *Given a set of triple patterns $T=\{tp_1, tp_2, ..., tp_n\}$, apply a cardinality estimation function $\bar{J} : T \times T \mapsto \mathbb{N}$ such that for every pair of triple patterns $(tp_i, tp_j) \in T$, $\bar{J}(tp_i, tp_j) \approx |tp_i \bowtie tp_j|$.*

We extend the above estimation problem also to the case of joining a triple pattern with the intermediate results of prior join operations, e.g., to estimate the total cardinality $\bar{J}((tp_i \bowtie tp_j), tp_k) \approx |(tp_i \bowtie tp_j) \bowtie tp_k|$. Then, given such estimates, an optimal query plan minimizes the total number of operations to compute, i.e., the execution costs $Cost(T, O)$ of the order O for the set T. In practice, this total join cost is obtained by summing up the intermediate cardinalities of each join operation in their respective join order. Hence, we formalize the problem of join order optimization as follows:

Problem 2 (Join Order Optimization). *Given a set of triple patterns $T=\{tp_1, tp_2, ..., tp_n\}$ and a join cardinality estimation function $\bar{J}$, find the join order O obtained as* $\arg\min_O Cost(T, O)$.

5 EXTENDING SHACL WITH STATISTICS

To compute more accurate join cardinality estimations (Problem 1), we capture the correlations between RDF triples by extending SHACL's node and property shapes with fine-grained statistics of the RDF graph. We denote these statistics as *shapes statistics*. These include the total triple count (*sh:count*), minimum (*sh:minCount*) and maximum (*sh:maxCount*) number of triples for each instance, and the number of distinct objects for property instantiations (*sh:distinctCount*). The attributes shown in the dark shaded boxes in Figure 3 are the annotated statistical attributes of their respective node and property shapes. These statistics are computed by executing analytical SPARQL queries over the RDF graph. For instance, to compute the number of instances of *GraduateStudent* in the dataset, i.e, the value of attribute *sh:count* of node shape *GraduateStudent*, the annotator issues the SPARQL query: `SELECT COUNT(*) WHERE {?x a ub:GraduateStudent}`.

Along with *shapes statistics*, we also define *global statistics* by extending VOID[2] statistics with more precise statistics of RDF properties, i.e., the distinct subject count (DSC) and distinct object count (DOC) of each property of the RDF graph.

6 QUERY PLANNING

In this section, we present our approach to exploit global and shapes statistics to obtain more accurate join cardinality estimates (Problem 1). These estimates, in turn, are used for join order optimization (Problem 2).

6.1 Cardinality Estimation of Triple Patterns

A SPARQL query contains joins between multiple triple patterns. Hence, the first step is to estimate how many triples match every triple pattern individually. We exploit the statistical information contained in the extended SHACL shapes graph (Section 5) to obtain this estimate. Hence, for each triple pattern, we obtain their corresponding node or property shapes using the values of the *sh:targetClass* and *sh:path* attributes.

First, all triples of the type *<?x, a, [Class]>* (i.e., instances with *rdf:type [Class]*) are mapped to the node shape having that class as the value of the attribute *sh:targetClass*. Then, triples having variable *?x* as a subject are also assigned to that node shape. The triple predicate determines instead its corresponding candidate property shapes, i.e., those with a matching value for *sh:path*. For example, given triples tp_1=*<?x, rdf:type, ub:GraduateStudent>* and tp_2=*<?x, ub:name, ?n>*, the subject *?x* is assigned to node *shape:GraduateStudent*, while the predicate in tp_2 matches *shape:name* (Figure 3, top left and top right).

Once the candidate shapes for all the triple patterns are identified, their statistical information combined with the distinct subject and object count (DSC & DOC) from the *global statistics* are used in combination with the formulas shown in Table 1 to compute their expected cardinality. These formulas, inspired by a previous work [11], cover all possible types of triple patterns. The term c_X in the formulas denotes the count of X in the RDF graph; $c_{triples}$ denotes the count of all triples and $c_{objects}$ the count of all objects. Similarly, c_{X_Y} represents the count of X having Y. This can be used, for instance, to derive that there are ~ 85K triples matching *<?x, rdf:type, ub:FullProfessor>* (Table 2a). While both global and shapes statistics can be used to estimate the cardinality of triple patterns using these formulas, they can lead to different estimated cardinalities. When the query does not contain any type-defined triple, only global statistics are used.

Table 1: Cardinality estimation of triple patterns

6.2 Cardinality Estimation of Joins

The join operation is performed on a common variable between two triple patterns. We consider three possible types of joins between two triple patterns based on the position of the common variable, namely: Subject-Subject (SS), Subject-Object (SO), and Object-Object (OO). If there is no common variable between two triple patterns, the join will result in a Cartesian product. Inspired by related work [8], we estimate the SS, SO, and OO join cardinalities using the formulas stated in Equations 1, 2, and 3. Note that DSC_i and DOC_i in the formulas represent the distinct subject and object count of triple pattern i respectively.

$$\widehat{card}\,(tp_i \bowtie_{SS} tp_j) = \frac{card_i \times card_j}{max\,(DSC_i, DSC_j)} \quad (1)$$

$$\widehat{card}\,(tp_i \bowtie_{SO} tp_j) = \frac{card_i \times card_j}{max\,(DSC_i, DOC_j)} \quad (2)$$

$$\widehat{card}\,(tp_i \bowtie_{OO} tp_j) = \frac{card_i \times card_j}{max\,(DOC_i, DOC_j)} \quad (3)$$

6.3 Join Ordering

Given an RDF graph G, its shapes statistics graph (G_{sh}), and global statistics graph (G_{gs}), we propose an algorithm to compute the join ordering for an input query Q (Algorithm 1). In the first step, the triple patterns of Q are sorted in ascending order of their estimated cardinalities using only global statistics. The algorithm starts with the triple pattern having the least cardinality and then estimates its join cardinality with the rest of the triple patterns using the formulas from Section 6.2. The algorithm iterates over all the triple patterns and chooses a triple pattern with the least estimated join cardinality (size of intermediate result) given the triple already selected. This produces a first join ordering based on global statistics. In the second step, shapes statistics are taken into account, and both the estimated cardinalities and the join ordering proposed in the first step are revised using these shapes specific fine-grained statistics. The algorithm also computes the cost of each join ordering by adding the estimated join cardinalities in each iteration. Its complexity is cubic to the number of triple patterns in the query, i.e., $O(n^3)$.

Given our example query Q, and the cardinalities of its triple patterns T=$\{tp_1, tp_2, ..., tp_9\}$ estimated with both global and shape statistics, Tables 2a and 2b show the join ordering computed only using global statistics (O_{gs}) and via shapes statistics (O_{ss}), respectively. There is a significant difference between the estimated and true join cardinalities and their final total cost. The estimated join cardinalities for O_{ss} are much closer to the true cardinalities of the query than the estimates for O_{gs} with two exceptions for tp_5 and tp_8 where shapes statistics largely overestimate their cardinalities due to skewed distribution of data.

  $queue.add(index)$; $p.add(tps'.get(index))$;
  $r.remove(tps'.get(index))$;
$O \leftarrow queue.poll()$;

7 EXPERIMENTAL EVALUATION

We investigated the performance of query plans proposed using our algorithm (with global and shapes statistics) compared to the plans proposed by two state-of-the-art query engines (Apache Jena ARQ[3] and GraphDB[4]) as well as two state-of-the-art RDF cardinality estimation approaches (Characteristic Sets [19] and SumRDF [23]). All experiments are performed on a single machine with Ubuntu 18.04, having 16 cores and 256GB RAM.

Datasets: We used LUBM [10], WatDiv [2], and YAGO-4 [21] to study various query plans on different datasets and sizes (Table 3). In particular, we used LUBM-500, two variants of WatDiv datasets (WATDIV-S (Small) with ~108.9 M triples and WATDIV-L (Large) with 1 billion triples), and for YAGO-4 we used the subset containing instances that have an English Wikipedia article.

Implementation: Nowadays, constraints languages are having widespread application to validate RDF graphs [21]. We assume the availability of SHACL shapes graph with the dataset and provide a *Shapes Annotator* to extend it with statistics of the graph. For cases where they are not present, the SHACLGEN[5] library is commonly used to generate shapes graphs and we also use it in our case (e.g., for YAGO-4). All shapes are then extended with the required statistics using our *Shapes Annotator* (implemented in Java). The SHACL shapes graph for LUBM, for instance, is 45 KB, and the size of extended shapes is 68 KB. The time required to extend the SHACL shapes depends on the number of its nodes and property shapes. The process of extending LUBM shapes graph took 16 minutes, WATDIV-S took 8 minutes, and for YAGO-4 (which consists of 8888 nodes and 80831 property shapes) it took 62 minutes. We implemented our join ordering algorithm in Java using Jena[3]. The source code is available on our website[6].

We loaded all three datasets and their relevant SHACL shapes graphs into Jena TDBs[3]. We used our join ordering algorithm to construct query plans using global and shapes statistics. For Jena, we used its ARQ query engine to obtain the query plans. For GraphDB, we loaded all datasets in GraphDB and used its *onto:explain* feature to obtain the query plans. For Characteristic Sets [19] approach, we generated characteristic sets of each

Table 3: Size and characteristic of the datasets

dataset and used Extended Characteristic Sets [18] to optimize query plans for non-star type queries. Generating characteristic sets for large RDF graphs is computationally expensive. For instance, it took 6.2 hours to generate Characteristic Sets for LUBM, 1.2 hours for WATDIV-S, and 8.2 hours for YAGO-4.

For SumRDF [23], we generated the summaries of each dataset and adapted our join ordering algorithm to exploit their estimates. Similar to Characteristic Sets, the generated summaries require a few GBs of memory and their generation time depends on the size and heterogeneity of the dataset, e.g., it took 4.5 minutes to generate the summary for the LUBM, 14 minutes for WATDIV-S, and 4.3 hours for YAGO-4. We use the same size of LUBM and WatDiv datasets as used in SumRDF [23]. Hence, we used the same parameters to generate their summaries. It is suggested that a reasonable default size for the target SumRDF's summary should be in the order of tens of thousands [23]. Therefore, for YAGO-4, to generate the summary in a reasonable amount of time, we chose 100K as the target size of the summary.

All query plans obtained using these approaches are executed 10x in Jena TDB and each query is interrupted after a timeout of 10 minutes. Since for some approaches the order in which triples are stated in the query matters we shuffle the triple patterns in the BGPs randomly in each iteration before proceeding with query optimization. As the query planning time is always less than 20 milliseconds for all approaches and queries, in the following we focus on analyzing the precision of the cardinality estimation and the resulting query performance.

Queries: We distinguish complex (C), snowflake (F), and star (S) queries. LUBM provides 14 default queries that have relatively simple structures. Therefore, we selected queries Q2, Q4, Q8, Q9, Q12 and then created a few additional queries for each category C, F, and S. The WatDiv benchmark includes 3 C, 7 S, and 5 F queries. For YAGO-4 there are no available standard queries or query logs available for benchmarking. Therefore, we have handcrafted 13 queries following the C, F, and S graph patterns from the WatDiv Benchmark. These queries are available on our website[6].

Query Runtime: Due to space constraints, here we only report our findings on LUBM and YAGO-4, results on WatDiv datasets are discussed in the appendix of the extended version[6]. These experiments offer analogous insights to those obtained from the other datasets. Figure 4a shows the query runtime analysis for query plans proposed using the SS approach *(plans constructed by our join ordering algorithm using shapes statistics)*, GS approach *(plans constructed by our join ordering algorithm using global statistics)*, Jena, GraphDB (GDB), Characteristic Sets (CS), and SumRDF on LUBM queries. The query runtime shows that: (i) the plans proposed by the SS approach are more efficient than those obtained with GS for queries having at least one type-defined triple pattern, (ii) the plans proposed by the GS approach are competitive in comparison to the plans of GDB, CS, and SumRDF, (iii) the CS approach is not well suited for large snowflake queries (e.g., F1, F2 (timeout), & F5), and (iv) the plans proposed by Jena are often suboptimal and non-deterministic (shown in the size of the error bars) as it is based on a heuristics-based query optimizer that takes into account the given order of triple patterns in the input query.

Similarly, Figure 4b shows the query runtime for queries on YAGO-4. The query runtime for complex queries (C1, C2, C3) using SS and GS are competitive to the plans proposed by GDB, CS, and SumRDF. Snowflake queries provide interesting insights where each approach behaves differently for every single query. For instance, CS could not find the optimal query plan for queries F1, F3, F4, F5, and SS and GS could not find the most efficient query plan for query F4 due to underestimation of the join cardinalities. However, GDB and SumRDF found almost optimal query plans for all snowflake queries except F1 (GraphDB) and F4 (SumRDF). For star queries, almost all approaches identify plans with comparable good performances. Similar to LUBM, the plans proposed by Jena are rarely the most efficient.

In addition to query runtime, we also report the q-error, which is used to measure the precision of the final query result cardinality estimates [19]. It quantifies the ratio between the estimated ($\hat{c}$) and true result cardinality (c) and is computed as the ratio $max(max(1,c)/max(1,\hat{c}),\ max(1,\hat{c})/max(1,c))$. Ideally, the lower the value of the q-error, the better the estimates are. We analyze the q-error values for SS, GS, GDB, CS, and SumRDF. Figure 4c shows the q-error analysis for LUBM queries. For SS, 15 queries have q-errors lower than 15, 8 queries have q-errors lowever than 250, and only 3 queries have q-errors greater than 250. For GS, 14 queries have q-errors lowever than 15, 8 queries have q-errors lower than 250, and only 4 queries have q-errors greater than 250. Overall, the q-errors for GS and SS are competitive to GDB and CS with few exceptions. However, overall the q-error is very low for SumRDF except queries Q9 and C5. Figure 4d shows the q-error analysis for YAGO-4. For GS and SS, 14 queries have q-errors lower than 15, 2 queries have q-errors lowever than 250, and only 4 queries have q-errors greater than 250. Similar to LUBM, the q-errors of GS and SS are competitive with GDB, CS, and SumRDF with few exceptions.

Finally, Figure 4e and 4f present the analysis between actual and true costs of query plans produced by SS and GS on the LUBM and YAGO-4 datasets. For LUBM, the cost estimated by SS is closer to the actual cost for Q4, Q9, C0, C1, C5, F7, F8, and all

star queries. However, for YAGO-4, the cost estimated by SS is closer to the true cost for almost all queries except C2, F4, and S4. **Summary:** Our results showed that, with only a few exceptions, the query plans proposed using SS and GS are competitive with the other tested approaches on both the synthetic and real data. Overall, the results revealed that our approach is efficient for all examined types of SPARQL queries while requiring only very little overhead to extend SHACL graphs with statistics, which is more efficient and feasible than generating extensive summaries or Characteristic Sets. On average, our approach finds the best query plans for 75% cases on both datasets. For the remaining cases, our approach proposes query plans having an overhead from 14% to 30% on average query runtime w.r.t. the best query plan. Our approach requires 2-4x less preprocessing time, this implies 2 to 6 hours less preprocessing time in our experiments, and 2 orders of magnitude less space.

8 CONCLUSION AND FUTURE WORK

In this paper, we have presented an alternative approach to cardinality estimation for SPARQL query optimization. In particular, we have proposed novel light-weight statistics to capture the correlation in RDF graphs, a cardinality estimation approach, and a join ordering algorithm. We have performed extensive experiments on synthetic and real data to show our approach's effectiveness against two SPARQL query engines and two state-of-the-art RDF cardinality estimators. The results revealed that our approach is efficient in terms of both the preprocessing steps to generate statistics and the cardinality estimation to optimize query plans. Going forward, we plan to integrate our approach with one of the state-of-the-art query engines and enable the support of additional SPARQL query operators.

ABSTRACT

Recent privacy legislation has aimed to restrict and control the amount of personal data published by companies and shared with third parties. Much of this real data is not only sensitive requiring anonymization but also contains characteristic details from a variety of individuals. This diversity is desirable in many applications ranging from Web search to drug and product development. Unfortunately, data anonymization techniques have largely ignored diversity in its published result. This inadvertently propagates underlying bias in subsequent data analysis. We study the problem of finding a diverse anonymized data instance where diversity is measured via a set of diversity constraints. We formalize diversity constraints, and present a clustering-based algorithm for finding a diverse anonymized instance. We show the effectiveness and efficiency of our techniques against existing baselines. Our work aligns with recent trends towards responsible data science by coupling diversity with privacy-preserving data publishing.

1 INTRODUCTION

Organizations often share user information with third parties to analyze collective user behaviour and for targeted marketing. Protecting user privacy is critical to safeguard personal and sensitive data. The European Union General Data Protection Regulation (GDPR), and variants such as the California Consumer Protection Act (CCPA) aim to control how organizations manage user data. For example, a major tenet in GDPR is *data minimization* that states companies should collect and share only a minimal amount of personal data sufficient for their purpose. Given the impossibility of knowing how a published data instance will be used in the future, determining a minimal amount of personal data to share is a challenge.

Privacy-preserving data publishing (PPDP) safeguards individual privacy while ensuring the published data remains practically useful for analysis. Anonymization is the most common form of PPDP, where quasi-identifiers and/or sensitive values are obfuscated via suppression or generalization [11]. As anonymized instances are shared with third parties for decision making and analysis, there is growing interest to ensure that data (and the algorithms that generate and use the data) are diverse and fair. Diversity is a rather established notion in data analytics that refers to the property of a selected set of individuals. Diversity requires the selected set to have a minimum representation from each group of individuals [9, 23] while determining the minimum bound for each group is often domain and user dependent.

To avoid biased decision making, incorporating diversity into computational models is essential to prevent and minimize discrimination against minority groups. In this paper, we focus on diversity, and study how diversity requirements can be modeled and satisfied in PPDP. In PPDP, non-diverse data instances that obfuscate characteristic attributes of a minority group give an inaccurate representation of the population in subsequent data analysis. Unfortunately, early PPDP work [11, 22, 24], and recent work on PPDP for graphs [12, 13], and interactive settings [14, 15] have not considered diversity in published instances.

Example 1.1. Table 1 shows relation R containing patients' medical records describing gender (GEN), ethnicity (ETH), age (AGE), province (PRV), city (CTY), and diagnosed disease (DIAG). Third-parties such as pharmaceuticals, insurance firms are interested in an anonymized R containing patients from diverse geographies, gender, and ethnicities. Let GEN, ETH, AGE, PRV, CTY be quasi-identifier (QI) attributes, and let DIAG be a sensitive attribute. Existing PPDP methods such as k-anonymity prevent re-identification of an individual along the QI attributes from $k-1$ other tuples. Table 2 shows a k-anonymized instance for $k=3$ where tuples are clustered along the QI attributes via value suppression [22, 24].

The k-anonymization problem is to generate a k-anonymous relation through an anonymization process, such as generalization and suppression, while incurring minimum information loss. Suppression replaces some QI attribute values with $\star$s to achieve k-anonymity, and is often considered to be a maximal form of generalization that obscures a value completely. There are several measures of information loss [7, 11], e.g., counting the number of $\star$s. Existing k-anonymization techniques do not preserve diversity in R since these measures do not capture diversity. □

Unfortunately, existing methods fail to provide any diversity guarantees in published, privatized data instances, leading to inaccurate and biased decision making. For example, in Table 2, we have lost the African and Caucasian ethnicity from the (second) group of Male, and the Female gender from the (first) group of Caucasian. These records, which exclude characteristic features of minority groups, misrepresent the true patient population. Efforts to obtain a diverse instance of patients, for example, to obtain minimum proportions of patients along GEN and ETH attributes, are hindered due to these missing values.

To model diversity, existing work has proposed declarative methods in the form of *diversity constraints*, which define the expected frequencies that characteristic values (of a group) must satisfy [23]. Similar to previous work, we consider one or more discrete value attributes to be of particular concern, and we define diversity with respect to the values of these attributes. Using k-anonymity as our privacy definition, and given a relation R, constant k, and a set of diversity constraints Σ, we study the problem of publishing a k-anonymized and diverse instance R^*. An example of a diversity constraint $\sigma_1 = (ETH[Asian], 2, 5)$ requires an anonymized instance to contain between two and five Asian individuals, which is satisfied by Table 1 and Table 2. Diversity constraints provide a declarative definition of the minimum and maximum frequency bounds that specific attribute domain values should appear in R^* [23].

We define the (k, Σ)-anonymization problem, which seeks an optimal k-anonymous instance R^* that satisfies a set of diversity constraints Σ. We propose the *DIVA* algorithm to compute a DIVerse and Anonymized R^*. *DIVA* integrates anonymization with diversity by applying value suppression to find a k-anonymous instance satisfying a set of diversity constraints.

Contributions. We make the following contributions:

(1) We formalize diversity constraitns in PPDP, and we define the (k, Σ)-anonymization problem that seeks a k-anonymous relation with value generalization that satisfies Σ.
(2) We introduce *DIVA*, a clustering-based algorithm that solves the (k, Σ)-anonymization problem with minimal suppression.
(3) We evaluate the effectiveness and efficiency of our selection strategies over the basic version of *DIVA*. We show that *DIVA* achieves improved performance over existing baselines.

2 PRELIMINARIES

Basic Notations. A *relation* R with a *schema* $\mathcal{R} = \{A_1, ..., A_n\}$ is a finite set of n-ary tuples $\{t_1, ..., t_N\}$. A, B, C refer to single attributes and X, Y, Z as sets of attributes.

Privacy-Preserving Data Publishing. k-anonymity prevents re-identification of an individual in an anonymized data set [22, 24]. Attributes in a relation are either *identifiers* such as SSN that uniquely identify an individual, *quasi-identifier* (QI) attributes such as ethnicity, address, age that together can identify an individual, or *sensitive* attributes that contain personal information.

Definition 2.1 (QI-group and k-anonymity). A relation R is k-anonymous if every tuple in R is in a QI-group with at least k tuples. A QI-group is a set of tuples with the same values in the QI attributes. □

For example, $\{r_1, r_2, r_3\}$, $\{r_2, r_3\}$, $\{r_4, r_5\}$, and $\{r_{10}\}$ are QI-groups in Table 2, and the table is 3-anonymous since every tuple in the table is in one of the QI-groups $\{r_1, r_2, r_3\}$, $\{r_4, r_5, r_6, r_7\}$, and $\{r_8, r_9, r_{10}\}$ with at least 3 tuples. Extensions of k-anonymity include l-diversity, t-closeness, and (X, Y)-anonymity, which provide improved privacy confidence (cf. [11] for a survey). We apply k-anonymity for its ease of presentation, however, our definitions and techniques are extensible to include recent PPDP models.

Suppression. Suppression generates an anonymized relation R' from a relation R by replacing some QI values in R with ⋆. We denote this by $R \sqsubseteq R'$. Suppression clearly causes information loss which is typically measured by the number of ⋆s in R'.

Definition 2.2 (k-anonymization problem [24]). Given R, the k-anonymization problem is to find R^* such that (1) $R \sqsubseteq R^*$; (2) R^* is k-anonymous; and (3) R^* has minimum information loss. □

Diversity Constraints. Diversity constraints are originally proposed for the set selection problem defined as follows [23]. Given a set of N items, each associated with a characteristic attribute and a utility score, the *set selection problem* is to select M items to maximize a utility score subject to diversity constraints. The utility score is the sum of scores of each selected item. Let there be d distinct values of the characteristic attribute and m_i with $i \in [1, d]$ be the number of selected items with each distinct value such that $m_i \in [0, M]$ and $\sum_i(m_i) = M$. A diversity constraint ϕ of the form $floor_i \leq m_i \leq ceiling_i$ specifies upper and lower bounds on m_i, i.e. the number of items with the i-th characteristic value. These constraints ensure representation from each category known as coverage-based diversity. To avoid tokenism, where there is only a single representative from each category, we can increase the lower bound, e.g., $m_i > 1$.

Problem Definition. We apply the concept of diversity constraints as proposed by Stoyanovich et. al [23], and introduce a formal definition of diversity constraints in relational data.

Definition 2.3 (Diversity Constraints). A diversity constraint over a relation schema $\mathcal{R}$ is of the form $\sigma = (A[a], \lambda_l, \lambda_r)$ in which $A \in \mathcal{R}$, $a \in dom(A)$ and λ_l, λ_r are non-negative integers. The diversity constraint σ is satisfied by a relation R of schema $\mathcal{R}$ denoted $R \models \sigma$ if and only if there are at least λ_l and at most λ_r occurrences of the value a in attribute A of relation R. We call $[\lambda_l, \lambda_r]$ the frequency range and $A[a]$ the characteristic (or target) value of σ. A set of diversity constraints Σ is satisfied by R, denoted by $R \models \Sigma$, iff R satisfies every $\sigma \in \Sigma$. □

Diversity constraints can be extended to multiple attributes by replacing $A[a]$ with $X[t]$, where X is a set of attributes and t is a tuple with values from these attributes. This extended diversity constraint $\sigma = (X[t], \lambda_l, \lambda_r)$ is satisfied by R if there are at least λ_l and at most λ_r tuples in R with the same attribute values in t. To validate that R satisfies σ, we can run a query that counts the number of occurrences of the target values t in attributes X of R and then check if this number lies in the frequency range $[\lambda_l, \lambda_r]$. Given a set of diversity constraints Σ, we define our problem.

Definition 2.4 (Problem Statement ((k, Σ)-anonymization)). Consider a relation R, a constant k, a set of diversity constraints Σ. The *(k, Σ)-anonymization problem* is to find a relation R^* where: (1) $R \sqsubseteq R^*$, (2) R^* is k-anonymous, (3) $R^* \models \Sigma$, and (4) R^* has minimal information loss, i.e., a minimum number of ⋆'s. □

3 THE DIVA ALGORITHM

We present the DIVersity and Anonymization algorithm (*DIVA*) that solves the (k, Σ)-anonymization problem. *DIVA* takes as input a relation R, a set of diversity constraints Σ, constant k, and returns a k-anonymous and diverse relation R' that satisfies Σ. *DIVA* work in two phases: (i) *clustering*, by partitioning R into disjoint clusters of size greater than or equal to k, while considering Σ; and (ii) *suppression*, by suppressing a minimal number of QI values in each cluster such that they have the same QI values, and form a QI-group of size $\geq k$. The result is a k-anonymous relation, as every QI-group is of size $\geq k$.

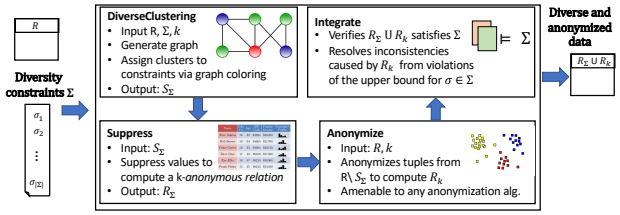

Figure 1: *DIVA* overview.

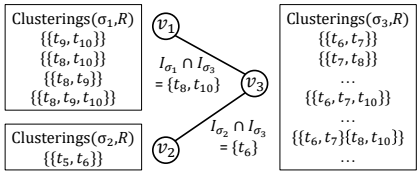

Figure 2: Graph representation of constraints.

3.1 Overview

Figure 1 presents an overview of *DIVA*. The algorithm begins in *DiverseClustering*, which generates a diverse clustering $\mathcal{S}_\Sigma$ that clusters tuples in R such that each $\sigma \in \Sigma$ is satisfied. We note that the clustering $\mathcal{S}_\Sigma$ may involve a subset of tuples in R, which are necessary to satisfy Σ. In *Suppress*, *DIVA* anonymizes the tuples in $\mathcal{S}_\Sigma$ using value suppression. The result is a relation R_Σ that satisfies Σ and is k-anonymous, however, may not represent all tuples in R. In the *Anonymize* step, *DIVA* runs an existing off-the-shelf anonymization algorithm to generate R_k by anonymizing the tuples of R that do not exist in $\mathcal{S}_\Sigma$ and R_Σ. Lastly, the *Integrate* phase integrates R_Σ and R_k to validate that $R_\Sigma \cup R_k$ doesn't violate the constraints' upper bounds.

Algorithm 1 presents *DIVA* details. *DiverseClustering* is a search algorithm that generates the diverse clustering $\mathcal{S}_\Sigma$. For each diversity constraint $\sigma \in \Sigma$, it computes a clustering that ensures the satisfaction of σ. If no diverse clustering exists, i.e., there is no diverse k-anonymous relation R', *DiverseClustering* returns $\mathcal{S}_\Sigma := \emptyset$, and *DIVA* returns an error. Algorithm 2 provides *Suppress* details that takes a clustering $\mathcal{S}$ and returns a relation R_s. For every tuple t in a cluster $C \in \mathcal{S}$, there is a corresponding tuple $r \in R_s$ with the same sensitive values as t. For every QI attribute A_i, $r[A_i]$ is suppressed, i.e. $r[A_i] = \star$, if the tuples in C have different values of A_i (Line 4). Due to this value suppression, R_s contains QI groups corresponding to the clusters in $\mathcal{S}$. In Line 3, we call *Suppress* with input $\mathcal{S}_\Sigma$ and output R_Σ.

Returning to Algorithm 1, there may be tuples of R that do not exist in $\mathcal{S}_\Sigma$. The *Anonymize* routine anonymizes these remaining tuples by applying an existing k-anonymization algorithm to compute R_k. In our evaluation, we use the k-member algorithm [6], but *DIVA* is amenable to any k-anonymization algorithm. Lastly, *Integrate* computes $R' = R_\Sigma \cup R_k$ and checks whether $R' \models \Sigma$. If there exists a violation, R' falsifies the upper bound of some constraint(s) in Σ due to R_k. *Integrate* resolves this by suppressing minimal values in R' to satisfy Σ. We return R' as the final output.

Example 3.1. Consider an execution of *DIVA* with relation R in Table 1, $k = 2$, and $\Sigma = \{\sigma_1, \sigma_2, \sigma_3\}$, where $\sigma_1 = (ETH[Asian], 2, 5)$, $\sigma_2 = (ETH[African], 1, 3)$, $\sigma_3 = (CTY[Vancouver], 2, 4)$. *DiverseClustering* returns $\mathcal{S}_\Sigma = \{C_1, C_2, C_3\}$ where $C_1 = \{t_9, t_{10}\}$, $C_2 = \{t_5, t_6\}$, and $C_3 = \{t_7, t_8\}$. R_Σ contains suppressed tuples $g_5, ..., g_{10}$ in Table 3 with QI groups $\{g_5, g_6\}$, $\{g_7, g_8\}$, and $\{g_9, g_{10}\}$ that correspond to the clusters in $\mathcal{S}_\Sigma$. R_Σ satisfies Σ where each QI group satisfies a constraint. The *Anonymize* procedure generates

Algorithm 1: *DIVA* (R, Σ, k)

Output: k-anonymous and diverse relation.
1 $\mathcal{S}_\Sigma := DiverseClustering(R, \Sigma, k)$;
2 **if** $\mathcal{S}_\Sigma = \emptyset$ **then return "relation does not exist"**;
3 $R_\Sigma := Suppress(\mathcal{S}_\Sigma)$;
4 **foreach** $C_i \in \mathcal{S}_\Sigma$ **do** $R := R \setminus C_i$;
5 $R_k := Anonymize(R, k)$;
6 **return** $Integrate(R_\Sigma, R_k)$;

Algorithm 2: *Suppress*$(\mathcal{S})$

Input: A clustering $\mathcal{S}$ of tuples with schema $\mathcal{R}$.
Output: Relation R_s (initialized to $\emptyset$).
1 **foreach** $C \in \mathcal{S}$ **and** $t \in C$ **do**
2 $\quad r := t$; $R_s := R_s \cup \{r\}$;
3 $\quad$ **foreach QI Attribute** $A_i \in \mathcal{R}$ **do**
4 $\quad\quad$ **if** $|C[A_i]| > 1$ **then** $r[A_i] := \star$;
5 **return** R_s;

$R_k = \{g_1, ..., g_4\}$, and the *Integrate* procedure returns $R' = R_k \cup R_\Sigma$ (Table 3) which is $k = 2$-anonymous and satisfies Σ. □

3.2 Diverse Clustering

We describe how *DiverseClustering* computes a clustering $\mathcal{S}_\Sigma$ that satisfies Σ. We first define the semantics of how a clustering satisfies a diversity constraint.

Definition 3.2. Given σ defined over R, and a clustering $\mathcal{S}$, $\mathcal{S}$ satisfies σ, denoted as $\mathcal{S} \Vdash \sigma$, if $Suppress(\mathcal{S}) \models \sigma$. The clustering $\mathcal{S}$ satisfies a set of constraints Σ, if $\mathcal{S} \Vdash \sigma_i$ for every $\sigma_i \in \Sigma$. □

Intuitively, $\mathcal{S} \Vdash \sigma$ if the relation returned from $Suppress(\mathcal{S})$ in Algorithm 2 satisfies σ according to Definition 2.3. In Example 3.1, $\mathcal{S}_\Sigma = \{\{t_5, t_6\}, \{t_7, t_8\}, \{t_9, t_{10}\}\} \Vdash \Sigma$ because $Suppress(\mathcal{S}_\Sigma) = \{g_5, ..., g_{10}\} \models \Sigma$.

DiverseClustering finds $\mathcal{S}_\Sigma \Vdash \Sigma$ by computing clusterings $\mathcal{S}_{\sigma_i}$ that satisfy each diversity constraint $\sigma_i \in \Sigma$ and merging them to generate $\mathcal{S}_\Sigma$. In Example 3.1, $\mathcal{S}_{\sigma_1} = \{C_1\} = \{t_9, t_{10}\} \Vdash \sigma_1$, $\mathcal{S}_{\sigma_2} = \{C_2\} = \{t_5, t_6\} \Vdash \sigma_2$, $\mathcal{S}_{\sigma_3} = \{C_3\} = \{t_7, t_8\} \Vdash \sigma_3$, and $\mathcal{S}_\Sigma = \mathcal{S}_{\sigma_1} \cup \mathcal{S}_{\sigma_2} \cup \mathcal{S}_{\sigma_3} = \{C_1, C_2, C_3\} \Vdash \Sigma$. Two conditions must hold while we search for $\mathcal{S}_{\sigma_i}$. First, the clusters in $\mathcal{S}_{\sigma_i}$ must be disjoint, unless they are equal. Specfically, for every pair of clusters $C \in \mathcal{S}_{\sigma_i}$ and $C' \in \mathcal{S}_{\sigma_j}$, either $C' \cap C = \emptyset$ or $C' = C$. For overlapping cluster pairs, the result of *Suppress* will not form QI groups. If we merge the clusters, then the result may not satisfy the conditions. For example, if $\mathcal{S}_{\sigma_2} = \{\{t_5, t_6\}\}$, $\mathcal{S}_{\sigma_3} = \{\{t_6, t_7\}\}$, and $\Sigma = \{\sigma_2, \sigma_3\}$, and we merge them into $\mathcal{S}_\Sigma = \{\{t_5, t_6, t_7\}\}$, then $\mathcal{S}_\Sigma \nVdash \Sigma$, although $\mathcal{S}_{\sigma_2} \Vdash \sigma_2$ and $\mathcal{S}_{\sigma_3} \Vdash \sigma_3$. Second, we select each $\mathcal{S}_{\sigma_i}$ such that it does not falsify the upper bounds of other constraints. In Example 3.1, consider $\Sigma = \{\sigma_2, \sigma_4\}$ with a new constraint $\sigma_4 = (GEN[\text{Male}], 1, 3)$, which requires at least one but not more than 3 men. Then, $\{\{t_5, t_6\}\} \Vdash \sigma_2$, and $\{\{t_3, t_4\}\} \Vdash \sigma_4$, but $\{\{t_5, t_6\}, \{t_3, t_4\}\} \nVdash \{\sigma_2, \sigma_4\}$ since the upper bound of σ_4 is falsified. The clustering $\mathcal{S}_{\sigma_2}$ preserves two more Male values, and falsifying the upper bound in σ_4. This means we cannot build the $\mathcal{S}_{\sigma_i}$ separately, and we must consider the interactions between the constraints. This is clearly a local condition where choosing each $\mathcal{S}_{\sigma_i}$, we consider the related constraints that have overlapping tuples with σ_i, and use this property to convert diverse clustering to graph coloring.

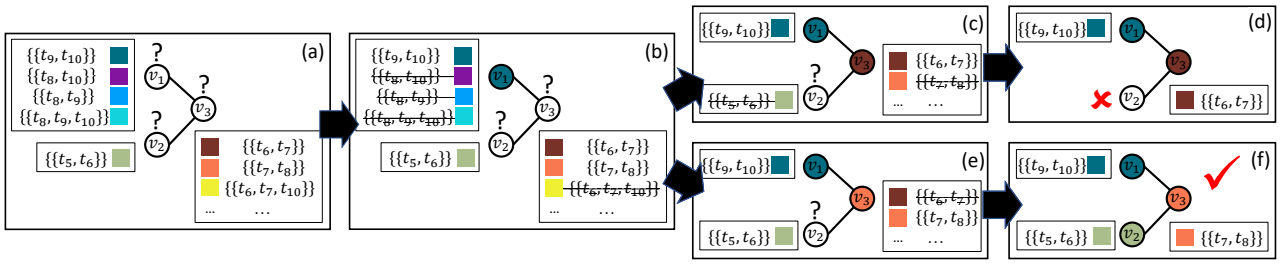

Figure 3: Graph coloring for diverse clustering. Nodes are colored in the order v_1, v_3, v_2.

Algorithm 3: *DiverseClustering*(R, Σ, k)

Output: Clustering $\mathcal{S}_\Sigma$.

1 $G :=$ *BuildGraph*(R, Σ); $V := \emptyset$; $\mathcal{S}_\Sigma := \emptyset$;
2 **if** *Coloring*(G, V, R) **then**
3 | **foreach** $\langle v_i, c_i \rangle \in V$ **do** $\mathcal{S}_\Sigma := \mathcal{S}_\Sigma \cup c_i.clustering$;
4 **return** $\mathcal{S}_\Sigma$;

Algorithm 4: *Coloring*(G, V, R)

Output: true if there is a coloring of G, otherwise **false**.

1 **if** V **contains all nodes of** G **then return true**;
2 $v :=$ *NextNode*(G, V);
3 **foreach** $\mathcal{S} \in$ *Clusterings*$(v.constraint, R)$ **do**
4 | **if** *IsConsistent*$(\mathcal{S}, v)$ **then**
5 | | $c :=$ **new color with clustering** $\mathcal{S}$;
6 | | $V := V \cup \{\langle v, c \rangle\}$;
7 | | **if** *Coloring*(G, V, R) **then return true** ;
8 | | $V := V \setminus \{\langle v, c \rangle\}$;
9 **return false**

3.3 Modeling as Graph Coloring

Given an undirected graph $G = (\Gamma, E)$, where Γ and E denote the set of nodes and edges, respectively, and m distinct colors, the graph coloring problem is to color all nodes subject to certain constraints, e.g., no two adjacent nodes can have the same color. For relation R and diversity constraints Σ, we model each diversity constraint $\sigma_i \in \Sigma$ as a node $v_i \in \Gamma$. We use $v_i.constraint$ to refer to σ_i. An undirected edge $e_{ij} = \{v_i, v_j\} \in E$ exists between nodes v_i and v_j if σ_i and σ_j have overlapping target tuples, i.e., $I_{\sigma_i} \cap I_{\sigma_j}$, where the target tuples of a constraint σ_i, denoted by I_{σ_i}, is the set of tuples in R that have the target values in σ_i.

Example 3.3. Figure 2 shows G with three nodes corresponding to $\sigma_1, \sigma_2, \sigma_3$, and each of their neighboring constraints modeled via edges $E = \{\{v_1, v_3\}, \{v_2, v_3\}\}$. The edge labels show the non-empty intersections between their target tuple sets. The sets of target tuples are $I_{\sigma_1} = \{t_8, t_9, t_{10}\}$, $I_{\sigma_2} = \{t_5, t_6\}$, and $I_{\sigma_3} = \{t_6, t_7, t_8, t_{10}\}$, which means σ_1, σ_3 and σ_2, σ_3 are neighboring constraints, but there is no edge between v_1 and v_2 because $I_{\sigma_1} \cap I_{\sigma_3} = \{t_8, t_{10}\}$ and $I_{\sigma_2} \cap I_{\sigma_3} = \{t_6\}$, and $I_{\sigma_1} \cap I_{\sigma_2} = \emptyset$. Beside each node, we show the clusterings that satisfy the corresponding constraint.

Choosing a color for node v_i is analogous to finding a clustering $\mathcal{S}_{\sigma_i}$ for σ_i. The goal is to color all nodes, while the color of each node is *consistent* with the color of its neighboring nodes. This means the corresponding clusterings must satisfy the two conditions that we mentioned earlier. For a color c, $c.clustering$ refers to its corresponding clustering.

Algorithm 3 presents the details of *DiverseClustering*. We build the graph G for Σ and R (Line 1). We then initialize the clustering $\mathcal{S}_\Sigma$ and a mapping V that stores the color (assigned clustering) for each node, and check if a coloring exists via *Coloring*.

Algorithm 4 presents the recursive function, *Coloring*, that takes a graph G, the mapping V (specifying the colored nodes), relation R, and returns *true* if the remaining nodes of G can be colored; otherwise it returns *false*. Note that choosing a color for a node, can restrict the choice of colors for neighboring nodes when the clusterings have overlap. *Coloring* iterates over every uncolored node and assigns a color (clustering) that is consistent with its neighboring nodes (constraints). Specifically, we check that the two search conditions mentioned earlier are satisfied. We propose three versions of *DIVA*: (1) DIVA-Basic: *Coloring* randomly selects an uncolored node (Line 2) to color using *NextNode*; (2) MaxFanOut: selects constraints with a minimal number of clusterings; and (3) MinChoice: selects constraints with a maximal overlap with neighboring constraints. We describe the latter two versions later in this section.

Given a node v, we color v by checking whether its candidate clustering, and its adjacent nodes are consistent (Alg. 4, Lines 3-8). The *Clusterings* routine returns minimal clusterings $\mathcal{S}$ that satisfy $v.constraint$ ($Suppress(\mathcal{S}) \vDash v.constraint$). For example, $Clusterings(\sigma_1, R)$ contains four clusterings $\{\{t_8, t_9\}\}$, $\{\{t_8, t_{10}\}\}$, $\{\{t_9, t_{10}\}\}$, $\{\{t_8,\ t_9, t_{10}\}\}$, while $Clusterings(\sigma_2, R)$ contains one clustering $\{\{t_5, t_6\}\}$. In Lines 4-8, we check whether $\mathcal{S}$ is consistent with the clusterings of the neighboring constraints. If so, we assign a new color c to the clustering $\mathcal{S}$, and we temporarily color v with c by adding $\langle v, c \rangle$ to V. We then recursively call *Coloring* to check whether the remaining nodes in G can be colored. If color c does not work, i.e. *Coloring* returns false, we remove $\langle v, c \rangle$ from V, and try another color. If all clusterings are inconsistent, i.e., there is no successful coloring of v, we return false (Line 9), to backtrack and evaluate a different node. To compute a satisfying clustering depends not only on k, and the frequency of characteristic values in R with respect to $[\lambda_l, \lambda_r]$ in σ, but also on the distribution of these characteristic values. We empirically study the impact of data distribution on accuracy in Section 4.

Example 3.4. Figure 3 shows an execution of *Coloring* over graph G with nodes $\{v_1, v_3, v_2\}$. Figure 3(a) initializes nodes as uncolored. We first consider v_1, and select $S_{\sigma_1} = \{\{t_9, t_{10}\}\}$ (Figure 3(b)). We color nodes v_2 and v_3 by recursively calling *Coloring*. Coloring one node may restrict the color choice of neighboring nodes, e.g. after we select $\{\{t_9, t_{10}\}\}$ for v_1, we cannot select $\{\{t_6, t_7, t_{10}\}\}$ for v_3 due to the overlapping tuple t_{10}. For node v_3, we have several choices including $\{\{t_6, t_7\}\}$ and $\{\{t_7, t_8\}\}$. In Figure 3(c), we assume the coloring algorithm chooses $\{\{t_6, t_7\}\}$ for v_3. As a result, $\{\{t_5, t_6\}\}$, which was the only choice for v_2, cannot be used due to the overlapping tuple t_6. This leads the algorithm towards an unsatisfying clustering (Figure 3(d)). *DIVA* backtracks its last decision for v_3 by selecting a different color, $\{\{t_7, t_8\}\}$ for v_3 in Figure 3(e). In this case, the clustering $\{\{t_5, t_6\}\}$ for v_2 does

Table 4: Data characteristics.

	Pantheon	Census	Credit	Pop-Syn
$\|R\|$	11,341	299,285	1000	100,000
n	17	40	20	7
$\|\Pi_{QI}(R)\|$	5,636	12,405	60	24,630
$\|\Sigma\|$	24	21	18	10

not overlap with $\{\{t_7, t_8\}\}$. Since we have found a clustering that satisfies all the constraints (i.e., a coloring of all nodes), *Coloring* returns *true* with V containing the nodes and their colors (i.e., clusterings). *DiverseClustering* uses V to compute the final clustering as $\mathcal{S}_\Sigma = \{\{t_5, t_6\}, \{t_7, t_8\}, \{t_9, t_{10}\}\}$. □

DIVA runs in polynomial time w.r.t. the size of R. The runtime is split between *DiverseClustering* and *Anonymize*. *DiverseClustering* runs in polynomial time as the number of clusters considered in coloring for each constraint is polynomial w.r.t. R. *Anonymize* runs an off-the-shelf algorithm. We use the k-member anonymization algorithm, which runs in polynomial time [6].

Selection Strategies. In the basic version of *DIVA*, we randomly select a constraint and a clustering to evaluate. These choices impact performance as poor initial selections can lead to increased backtracking operations downstream. We selectively order the constraints (nodes) and clusterings (colors) that most likely lead to a graph coloring while minimizing the need to backtrack.

MinChoice: We select the most restrictive constraints first, i.e., in *Nextnode*, we select v with minimum $|Clusterings(v.constraint, R)|$. As we visit nodes and assign (colors) clusterings, we update the candidate clusterings for their neighbors.

MaxFanOut: We select constraints with maximum overlap with other constraints, i.e, nodes with the maximum number of uncolored neighbors. We preferentially select these constraints due to their high number of interactions, which lead to an increased number of target attributes, and bounds that the relevant tuples must satisfy. This heuristic aims to prune unsatisfiable clusterings early to reduce the number of clustering evaluations downstream.

4 EXPERIMENTS

We evaluate the accuracy and performance of *DIVA*, and compare against three k-anonymization baselines to evaluate the cost of incorporating diversity constraints.

Experimental Setup. We implement *DIVA* using Python 3.6 on a server with 32 Core Intel Xeon 2.2 GHz processor with 32GB RAM. We use three real datasets: (1) *Pantheon* describes individuals on Wikipedia [1]; (2) *Census* from the U.S. Census Bureau describes population data [3]; and (3) *German Credit* describes credit risk according to demographic attributes [3]. We also generate a synthetic population dataset, *Pop-Syn* to specify population characteristics using Synner.io [18]. Table 4 summarizes the dataset characteristics. We implement three notions of diversity via three classes of diversity constraints, namely, minimum frequency, average, and proportional representation from the attribute domain [23]. We found proportion constraints capture the relative distribution in the attribute domain with less sensitivity than average, and run our experiments using proportion constraints. The set of defined constraints, datasets and our source code are available at [2, 19].

Metrics and Parameters. We compute the average runtime over five executions. To quantify accuracy, we seek anonymizations with indistinguishable tuples, and minimize information loss. We use the *discernibility metric*, $disc(R', k)$, which assigns a penalty to each tuple based on the number of tuples that are indistinguishable from it in R' for a given k, reflecting its information loss [4]. We measure the *conflict rate* between a pair of diversity constraints as the number of overlapping relevant tuples, and we extend this definition to a set of diversity constraints. Conflict values range from [0,1], where 0 indicates no overlap. The discernibility metric and conflict rate definitions can be found in [19]. Table 5 lists parameter ranges and default values.

Table 5: Parameter values (defaults in bold)

Symbol	Description	Values
$\|R\|$	#tuples	60k, 120k, **180k**, 240k, 300k
$\|\Sigma\|$	#constraints	4, **8**, 12, 16, 20

Figure 4: *DIVA* **efficiency and effectiveness.**

4.1 Accuracy and Performance

Figure 4a and 4b show *DIVA* runtime and accuracy, respectively, as we vary $|\Sigma|$. DIVA-Basic shows exponential growth in runtime since we can assign $O(|R|)$ different clusterings to each constraint. Our selection strategies to restrict clusterings and perform early pruning, MinChoice and MaxFanOut, show linear scale-up. Figure 4b shows as $|\Sigma|$ increases, we see accuracy decline at a linear rate. As new $\sigma \notin \Sigma$ are added, we observe new relevant tuples join existing clusters of relevant tuples from Σ leading to a smaller decline in accuracy. This occurs with multi-attribute constraints that share target attributes with single attribute constraints. The alignment of QI and target attribute values between new and existing tuples influence the rate of decline.

Figure 4c shows *DIVA* accuracy as we vary conflict rate, cf. As expected, accuracy declines for increasing cf, with MaxFanOut and MinChoice outperforming DIVA-Basic by +17% and +9%, respectively. MaxFanOut outperforms MinChoice since targeting constraints with a high number of interactions eliminates unsatisfying clusterings sooner, while satisfying dependent constraints.

To measure accuracy for different data distributions, we generate attribute values according to the Zipfian, uniform, and Gaussian distributions with $|R| = 100k$, $|\Sigma| = 8$. Figure 4d shows that MaxFanOut performs best across all distributions by 8% and 17% over MinChoice and DIVA-Basic, respectively. The target uniform distribution performs best as domain values are spread evenly across the tuples, avoiding contention among a small set

Figure 5: Comparative study: anonymization baselines.

of tuples. This conflict occurs more often in the Zipfian case than the Gaussian, leading to lower accuracy.

4.2 Baseline Comparison

Figure 5a and Figure 5b show the comparative accuracy and runtime, respectively, of *DIVA* against three baseline k-anonymization algorithms: k-member [6], OKA [17], and Mondrian [16]. MinChoice and MaxFanOut incur higher runtimes reflecting the cost of computing a *diverse* data instance. We expect this to be acceptable in practice since constraint validation and anonymization is often done offline. As k increases, we expect more tuples to be anonymized leading to higher penalty costs. We note that runtimes decrease for increasing k as more values are suppressed to satisfy k-anonymity on each cluster. This improves the efficiency of consistency checking in the coloring algorithm since we can prune clusterings with size less than k during backtracking.

Figures 5c and 5d show that *DIVA* and the baselines are sensitive to $|R|$. Figure 5c shows that *DIVA* achieves improved accuracy over the baseline algorithms, in addition to satisfying diversity constraints. As new attribute values are introduced, they may not align with existing values in the clusters, requiring further suppression, and decreasing accuracy. In Figure 5d, all techniques incur increased runtimes due to evaluating a larger number of clusters. For *DIVA*, a larger number of tuples and clusters also increases the likelihood of potential conflicts among clusterings.

5 RELATED WORK

Privacy Preserving Data Publishing. Extensions of k-anonymity include *l-diversity*, *t-closeness*, and *(X,Y)-anonymity* with tighter privacy guarantees [11]. *DIVA* is extensible to re-define the clustering criteria according to these privacy semantics. Our empirical study has shown that *DIVA* generates anonymized instances comparable to existing baselines, but also guarantees diversity requirements are satisfied.

Fairness and Diversity. Data sharing of private data has been studied along two primary lines. First, causality reasoning aims to recognize discrimination to achieve algorithmic transparency and fairness. Recent techniques have proposed influence measures to identify correlated attributes [8], and statistical reasoning about discrimination [20]. Secondly, recent work have studied variants of DP to release synthetic data with similar statistical properties to the input data [5], and studying the impact of DP algorithms on equitable resource allocation [21]. Our work is complementary but with a different goal; to publish diverse and anonymized versions of the original data with minimal information loss for applications where statistical summaries, synthetic data, and aggregate queries are inadequate. Recent work by Stoyanovich et. al., study diversity in the set selection problem and introduce diversity constraints to guarantee representation in the selected set [23, 25]. We build upon this work, and are the first to formalize diversity constraints. Our algorithms couple diversity with data anonymization, a problem not considered in existing work.

6 CONCLUSION AND FUTURE WORK

We formalize diversity constraints, and introduce *DIVA*, a DIVersity-driven Anonymization algorithm that computes a privatized data instance satisfying a set of diversity constraints. Our evaluation show the performance benefits of our optimizations, and the overhead of enforcing diversity constraints over baselines. As future work, we intend to study privacy extensions beyond k-anonymity, e.g. randomization algorithms to satisfy both diversity constraints and *Differential privacy (DP)* to provide a higher level of protection for individuals [10]. We also intend to explore a distributed version of the coloring algorithm to improve scalability by satisfying constraints in parallel.

ABSTRACT

The Internet of Things provides applications with data streams from billions of sensor devices in real-time. Usually, sensor devices serve multiple queries simultaneously despite having limited computational capabilities. This paper presents a solution for reducing the number of data reads and transmissions by increasing the potential for sharing reads among concurrent streaming queries. Existing read-scheduling techniques on sensor nodes dynamically adjust the data-acquisition rate depending on the data's variability. However, they leave the definition of read-time tolerances to the user. Such read-time tolerances are crucial for sharing reads among queries. We extend previous work by presenting a generally-applicable algorithm that defines read-time tolerances and adapts them on-the-fly depending on observed data characteristics. We evaluate our solution on real-world data and show that it reduces the sensing error by up to 60% compared to existing approaches with the same number of data reads. Respectively, our technique reduces the number of data reads to achieve the same sensing error as existing techniques. To the best of our knowledge, we are the first to automatically set and tune read-time tolerances to reduce sensor readings and data transmissions on sensor nodes.

1 INTRODUCTION

With the advance in communication and information technologies, we can easily access the internet with laptops, tablets, smartphones, and other mobile devices. The network of smart devices, vehicles, and other network-attached sensors forms the Internet of Things (IoT) [16]. In a general IoT setup, multiple sensors are attached to a single device, the sensor node. The sensor node gathers data from the attached sensors and then transmits them to the Stream Processing Engine, enabling it to answer queries.

IoT applications make decisions in real-time based on dynamically changing surroundings. With a vast amount of sensors and the need for real-time data processing, several efficient data acquisition and transmission techniques are proposed to provide data streams to applications [8, 11, 21, 22, 26].

There exist several solutions for making data acquisition and transmission from sensor nodes more efficient. These solutions aim at reducing the number of sensor reads conducted (adaptive sampling) or values transmitted (adaptive filtering) [8]. The key idea of *adaptive sampling* is to modify the read-time frequency based on the recent history of sensor readings. If the values read from the sensor behave unexpectedly (i.e., have a high variability), samples are collected at a higher rate. In contrast, if values barely change, the sampling rate is reduced. *Adaptive filtering* techniques reduce the number of transmitted values by discarding values that evolve predictably. Adaptive sampling and adaptive filtering usually operate on a per-query basis. Instead, *multi-query read-sharing* saves transmissions by scheduling reads that satisfy multiple concurrent queries simultaneously.

Adaptive sampling and adaptive filtering techniques have to be selected and configured in accordance with the corresponding query's *data demand*, i.e., reflecting the consumer's sensitivity to observing changes in the data. It is crucial to note that queries may possess different data demands. For example, the adaptive sampling technique AdaM [23] reacts very fast to abrupt value changes, while FAST [6] incorporates differential privacy features. This is where multi-query optimization becomes necessary.

In previous works, we propose considering the queries' data demand during multi-query optimization by combining adaptive sampling and filtering techniques with multi-query read sharing in a unified framework [9, 20]. User-defined stateful functions (e.g., adaptive sampling techniques) iteratively suggest a query's read-times, and a multi-query read-scheduler exploits read-time tolerances around suggested read-times for sharing reads among queries respecting their data demand.

Figure 1 shows an overview of these two steps of read-time suggestion and read-fusion. As we can see from steps ② and ③, specifying read-time tolerances is essential to read-fusion. However, it is hard for users to manually specify and tune such tolerances. While well-known adaptive sampling techniques provide the desired read-time, they do not define tolerances. Ideally, tolerances for each read request should adjust automatically based on current data characteristics. Intuitively, tolerances should increase if values remain constant or follow an expected trend. Tolerances should shrink if sensor values change rapidly.

In this paper, we introduce an Adaptive Read-Time Tolerance Controller (ARTC), a general algorithm that adjusts read-time tolerances on-the-fly, based on the recent history of sensor readings. ARTC enhances arbitrary adaptive sampling techniques with automated control of read-time tolerances. Such read-time tolerances enable the sharing of sensor values among multiple queries on the same sensor node and thus lead to reading and transmission savings in distributed sensor networks. We design our solution to be generally applicable – independent of the algorithm defining the desired read-times. Therefore, we divide the task of setting read-time tolerances into two parts: Iteratively adapting the read-time tolerance's diameter, and shifting the read-time tolerance interval around the desired read-time: We capture statistics on the data's variability based on which we adapt the read-time tolerance. We use a proportional-integral-derivative controller (PID controller) [2, 3], which is a commonly used form of feedback control [4] to shift the read-time tolerance.

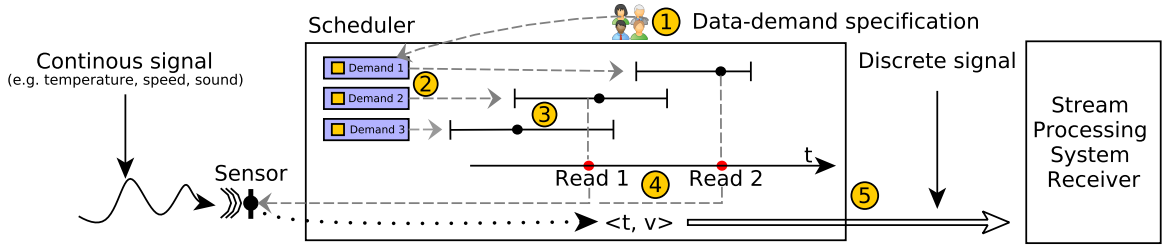

Figure 1: Overview of Optimized On-Demand Data-Streaming from Sensor Nodes [20]: ① The sensor node's scheduler receives the *data demand* of new queries. ② A query's *data demand* defines the next (desired) read-time • at which it requires the next sensor reading and optionally, a read-time tolerance. ③ The scheduler determines the time for the next sensor reading •, fusing requests, if possible. The device wakes up to ④ read a value from the sensor, and ⑤ transmits it to the receivers.

Our implementation is available as an open-source project[1]. We evaluate our solution by simulating sensor sharing based on multiple real-world IoT datasets. We analyze the error and the read-time tolerance induced by read-sharing for different configurations of our algorithm, compare it to setups with fixed read-time tolerances, and show that our solution outperforms fixed read-time tolerance specifications.

The remainder of this paper is structured as follows: We first present our solution in Section 2, which we evaluate in Section 3 on three real-world datasets. After discussing Related Work in Section 4 we conclude in Section 5.

2 ADAPTIVE READ-TIME TOLERANCE

This section explains how our adaptive read-time tolerance controller ARTC adapts the read-time tolerance to the sensed data's variability. We first showcase how to use ARTC in Section 2.1 and subsequently present our solution's internals in Section 2.2.

2.1 The User's Perspective

The user configures ARTC with two parameters: Firstly, E, indicating the permissible inaccuracy in the data-representation relative to the data's average magnitude. Secondly, the optional parameter `dMax`, which specifies a maximal read-time tolerance.

It is essential to highlight that the complexity of using ARTC is transparent to users. They can define streaming queries in declarative languages to the Stream Processing Engine (SPE). The user parametrizes ARTC as part of the query as sketched below:

```
SELECT [t, speed, position]    // SENSOR IDENTIFIERS
FROM [bus 1]                   // SENSOR NODE IDENTIFIER
USING [AdaM]          // READ-TIME SUGGESTION ALGORITHM
WITH [ARTC(E=0.1)] ON [speed]   // CONFIGURATION ARTC
```

As outlined in Figure 1, users can submit queries to the SPE, which then forwards the data demand specification and involved sensors to the specified sensor device ①. The device can thus schedule reads according to the specified data-requirements ③ and to dispatch the data stream to the user ⑤. The user receives a data stream $(t_i, \text{speed}_i, \text{position}_i)_{i \in \mathbb{N}}$ until terminating the query.

2.2 Architecture

We first show how our solution integrates within the multi-query read-scheduling framework executed on the sensor device [20] and then present the internals of ARTC. Table 1 summarizes the newly introduced nomenclature.

[1]https://github.com/TU-Berlin-DIMA/ARTC

Internal Architecture. Once the sensor device receives at least one query from the SPE, it schedules reads, as shown in Algorithm 1. For each new query, the sensor device first performs a read in Line 4. The sensor device then reports the value v gathered from the sensor at time t back to the client who issued the query. It then feeds the read-time and value into the read-time suggestion algorithm (Line 7), which generates the next desired read-time t_D. In the example query in Section 2.1, the read-time suggestion is performed through the adaptive sampling algorithm AdaM. Then, we forward the desired read-time and the last sensor reading to the read-time tolerance algorithm (Line 7), which computes a read-time tolerance by specifying interval boundaries t_s and t_e that enclose the desired read-time. Together with the desired read-time t_D, the interval boundaries constitute the next read request of the query. Lastly, the multi-query read-scheduler schedules reads according to all read requests. We refer the reader to our previous work for details on the optimizations the multi-query read scheduler performs and different optimization objectives [20]. The sensor device reduces its energy consumption by then sleeping until the next read is due. The process of updating the read request is repeated for all queries which received the last sensor reading.

Adaptive Read-Time Tolerance Controller (ARTC). A read-time tolerance algorithm has to meet the following requirements: (i) Despite advances in hardware technologies, sensor devices are still restricted in computational capabilities compared to sinks. As they need to schedule reads very precisely and are often battery-powered, the algorithm has to be energy-efficient. (ii) The algorithm has to adapt to changes in the distribution of the data quickly. Otherwise, the user misses important events. (iii) The algorithm has to be easy to configure and should not be entirely dependent on the read-time suggestion algorithm.

As a lightweight means of keeping track of the distribution of gathered sensor values, we use the iterative Probabilistic Exponentially Weighted Moving Average (PEWMA) algorithm. We use two instances of PEWMA; firstly, we monitor the distribution of the magnitude of sensor readings $\|v\|_2$. We refer to the probabilistic moving average by μ_v and to the estimated standard deviation of the used normal distribution by σ_v. We use the second instance of PEWMA to monitor moving average μ_δ and standard deviation σ_δ of the difference between consecutive read-times $\delta := \|v - v_l\|_2$. In order to be less dependent on the read-time suggestion algorithm, we divide our solution into two parts: (1) the adaptation of the read-time tolerance Δ based on the predictability of the data distribution and (2) shifting of the read-time interval $s \in [-0.5, 0.5]$ based on the value deviation between consecutive sensor readings as shown in Equation 1:

Algorithm 1: Multi-query read-sharing algorithm.

```
t = now();  involvedQueries = newQueries;  u = {};
while running do
    sleepUntil(t);
    v = sensor.read();
    involvedQueries.forwardToSink(t, v);
    while query in involvedQueries do
        t_D = readTimeSuggestion.next(t, v);
        t_s, t_e = readTimeToleranceAlgorithm.next(t, v, t_D);
        u[query] = (t_s, t_D, t_e);
    end
    t, involvedQueries = mqrs.select(u);
end
```

$$t_s = t_D + \Delta \cdot \left(s - \frac{1}{2}\right), \qquad t_e = t_D + \Delta \cdot \left(s + \frac{1}{2}\right) \tag{1}$$

In the next sections, we discuss separately how read-time tolerances Δ and shifts s are computed.

Adaptation of read-time tolerance. We use the variation of δ to assess the predictability of the distribution. If the variation exceeds the threshold E specified by the user,

$$\begin{aligned} & \sigma_\delta && > E \cdot \mu_v \\ \Leftrightarrow \quad & \sigma_\delta - E \cdot \mu_v && > 0, \end{aligned} \tag{2}$$

we reduce the read-time tolerance Δ by the damping factor in Equation 3. This way, it decreases exponentially in the number of consecutive times that the variation exceeds E.

$$\Delta \leftarrow \Delta \cdot \frac{1}{2}. \tag{3}$$

Otherwise, we increase the read-time tolerance by a value proportional to the difference between the user-indicated deviation E and σ_δ, which we denote the step-size δ_E. In order to make the step-size independent of the magnitude of both E and the sensor values, we scale the threshold by the multiplicative inverse of E and μ_v and define the step size in Equation 4.

$$\delta_E := \frac{\sigma_\delta - E \cdot \mu_v}{E \cdot \mu_v} = \frac{\sigma_\delta}{E \cdot \mu_v} - 1. \tag{4}$$

Shifting of read-time interval. We shift the read-time interval around the desired read-time t_D to reduce the algorithm's dependence on the read-time suggestion algorithm's performance. We use a PID controller with `setpoint` E to assess whether the deviation between consecutive sensor readings is within the range specified by the user. That way, we obtain a long-term estimation of the read-time suggestion algorithm's performance and exert limited control over the read-time difference. We scale the controller's output with a factor of 0.1 we determined empirically, which achieves good results for all evaluated datasets.

Complete Algorithm. The overall algorithm is summarized in Algorithm 2: We restate Condition 2 in terms of δ_E and also ensure the user-defined boundaries of Δ and the range of s.

3 EXPERIMENTAL EVALUATION

In this section, we evaluate ARTC on three real-world IoT datasets. We picked the different datasets to portray various data characteristics, which we lay out in Section 3.1. We then introduce our experimental setup in Section 3.2, present the experiments and their results in Section 3.3, and close with a discussion in Section 3.4.

Variable	Description
t,t_l,v,v_l	Current / last sensor reading (time and value).
t_s,t_e	Read-time tolerance interval boundaries.
$t_D \in [t_s,t_e]$	Desired read-time.
δ	eukl. distance between consecutive values.
μ_v,σ_v μ_δ,σ_δ	PEWMA and estimated standard deviation of the magnitude of v, respectively δ.

Table 1: Overview of subsequently used nomenclature.

PEWMA	AdaM	PID Controller	ARTC
$\alpha = 0.5,\ \beta = 0.5,$ $d_{\text{init}} = 20$	$\gamma = 0.2$	$P = 2, I = 2e\text{-}3,$ $D = 0.3$	dMax = 175

Table 2: Configuration of AdaM's and ARTC's components.

3.1 Datasets

We evaluate our solution on three IoT sensor datasets [17]. We provide a brief description for each dataset and state which of the multiple sensors in the dataset we use for our experiments.

The **football monitoring dataset [14]** provided within the scope of the ACM DEBS 2013 Grand Challenge consists of data gathered during a football training game at the Nuremberg Stadium in Germany. We replay the football's absolute velocity in m/s, which is available at 2000 Hz for the match's first half-hour. We evaluate our solution on this dataset as it is very volatile, and the speed of the football spikes abruptly when kicked by a player.

The **daily and sports activities dataset [1]** contains multiple time-series, constituting different individuals performing a total of 19 activities such as sitting, standing, and jumping. We replay data from the torso acceleration sensor in m/s^2, which is available at 25 Hz frequency for 5 minutes per person and activity. We select two daily activities sitting and standing, and two sports activities descending stairs and exercising on a stepper, and concatenate the corresponding time-series. As different activities alternate in the resulting time series, we can observe a drastic shift in the distribution of values each time the performed activity changes.

The **gas dataset [7]** holds concentration levels of dynamic gas mixtures. The data is collected continuously at a frequency of 100 Hz, and we use the first hour of the available data. We replay the gas mixture of ethylene and CO, and the unit of the measurement is *parts per million* (ppm). The variability in this dataset is low, as the distribution of the different chemicals only changes gradually.

3.2 Evaluation Setup

In a production setup, a read-sharing algorithm's performance on a sensor device is measured by counting the number of saved reads of the corresponding query under heavy load. However, this quantity largely depends on the configuration and number of concurrent queries. To assess the performance of read-sharing more objectively, we measure the suggested read-time tolerance Δ instead, while operating only a single query. We simulate heavy load by sampling at random within the proposed read-time tolerance to obtain a realistic view of the induced error. For each experiment, we conduct multiple runs and combine the results.

We record two performance measures during the conducted experiments to evaluate the functionality and effectiveness of ARTC. Firstly, we keep track of the average read-time tolerance μ_Δ, which indicates the read-sharing potential enabled by the algorithm for a total of M suggested read-time tolerances Δ_i: Secondly, we record the induced error for each point in time t, i.e., the distance between the last performed sensor reading $\hat{v}$ prior to t and the actual sensor

Algorithm 2: ARTC.next

Parameters: setpoint E, maximal interval diameter $dMax$
State : shift $s=0$, diameter $\Delta=0$, last value v_l
Input: read-time t, value v, desired read-time t_D
Output: next interval borders $[t_s,t_e]$,

```
μ_v = pewma.next(‖v‖_2);
if v_l is set then
    μ_δ, σ_δ = pewmaDiff.next(‖v−v_l‖_2);
    s += pid.next((μ_δ/μ_v)) · 0.1;
    δ_E = σ_δ/(μ_v·E) − 1;
    if (δ_E > 0) Δ ·= 1/2 else Δ −= δ_E;
    ensure s ∈ [−1/2, 1/2] and Δ ∈ [0,dMax];
else
    Δ = 0;
end
t_e, t_s = t_D + Δ · (s ± 1/2);
v_l = v;
return t_s, t_e;
```

value v_i at time t. We label ϵ the average error over the entire experiment trace, and denote the error's moving average with window size k in percent of the data's average magnitude via ϵ^k.

During all conducted experiments, we compare the induced error ϵ of ARTC to the error of fixed read-time tolerance algorithms that we configured to achieve the same average read-time tolerance μ_Δ as ARTC. We use the read-time suggestion algorithm AdaM throughout the experiments, and only vary the parameter E of ARTC and the fixed read-time tolerance algorithm accordingly. The parameters that are fixed throughout the experiments are provided in Table 2.

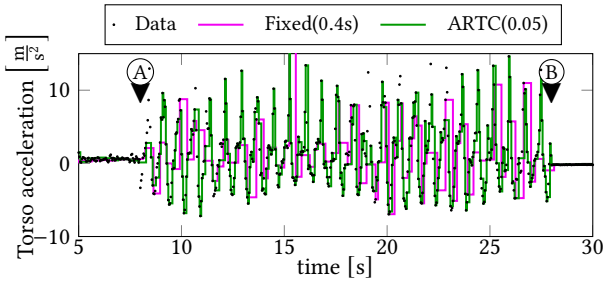
3.3 Experimental Evaluation

We first present the evaluation on an experiment trace on an excerpt from the activities dataset and then provide quantitative results for all three datasets.

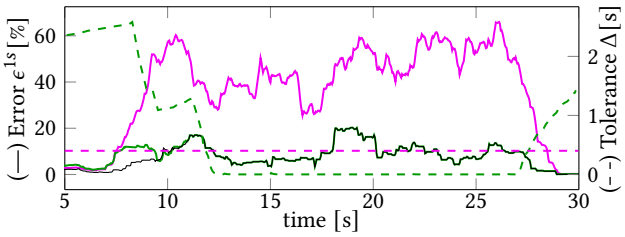
Experiment Trace. Figure 2 shows the performance of ARTC through an experiment trace excerpt from the activities dataset. We execute a total of three query-configurations on the dataset (i) A baseline query without read-sharing, which executes only the read-time suggestion algorithm AdaM, (ii) ARTC configured with $E = 0.05$, and (iii) A fixed read-time tolerance algorithm configured with $\Delta = 0.4$ seconds (s).

In Figure 2a, we visualize the raw sensor data at the highest possible rate as black dots. The representation of the sensor provided through configurations (ii) and (iii) is visualized as solid lines, which indicate the last performed sensor reading $\hat{v}_i$ at any given point in time. At any point in time, the difference between the solid lines and the data points is the error induced by the respective query. Figure 2b visualizes the moving average of the relative error over one second and the read-time tolerance Δ_i.

During the visualized experiment trace, a person performs three operations: standing in an elevator still until Ⓐ, exercising on a stepper until Ⓑ, and sitting. Every time the performed activity changes, we observe a dramatic change in the distribution of the replayed data. While exercising, the variability of the replayed torso acceleration measurements increases significantly.
At the beginning of the experiment, the variability of the data is relatively low. Both the fixed read-time tolerance algorithm and



(a) The black dots show acceleration measurements at the highest available rate. Solid lines visualize the last sensor reading performed with ARTC resp. the fixed read-time tolerance algorithm.



(b) Diameter Δ and 1-second moving average of the error ϵ induced by ARTC, the fixed read-time tolerance algorithm, and without read-sharing (black) altogether. During volatile phases, ARTC decreases Δ and thus reduces ϵ to the error without read-sharing.

Figure 2: Experiment trace of ARTC and baselines.

ARTC achieve a similar error ϵ of less than 5%. However, during this low variability phase, ARTC enables a read-time tolerance larger than 2.4s, which is more than six times larger than those achieved by the fixed read-time tolerance algorithm.
A brief spike in the torso acceleration precedes the individual's exercising routine at the 5-second mark, which leads to ARTC reducing the read-time tolerance. Once the torso acceleration starts to oscillate (Ⓐ), ARTC reduces the read-time tolerance to a minimum, such that the error levels with those induced by the read-time tolerance algorithm AdaM. During this phase, the read-time tolerance proposed by the fixed algorithm is higher than those proposed by ARTC at the cost of an error ϵ of approximately 50% of the data's magnitude, while ARTC causes no additional error. Once the individual sits (Ⓑ), ARTC increases the read-time tolerance again.

By controlling the read-time tolerance based on the data's variability, ARTC is able to outperform the fixed read-time tolerance algorithm in both depicted performance metrics: When considering the entirety of the depicted trace, the read-time tolerance of the fixed read-time tolerance algorithm is approximately doubled by ARTC, while ARTC can reduce the average error by 75%.

Quantitative Experiments. To assess the performance of ARTC under different circumstances, we run multiple experiments on the gas, activities, and football datasets. We compare ARTC to fixed read-time tolerance algorithms achieving the same average read-time tolerance Δ in Figure 3. Throughout the experiments, we observe that ARTC outperforms or at least levels the fixed read-time tolerance algorithm. Overall, ARTC outperforms the fixed read-time tolerance algorithm by the largest margin on the activities dataset: on average, it reduces the error by 31% compared to approximately 15% on the other two datasets. However, the additional error induced by ARTC for enabling read-sharing is smallest on the gas dataset (1.3 percentage points for $\Delta > 4$s). This relatively small induced error reflects the relatively steady nature

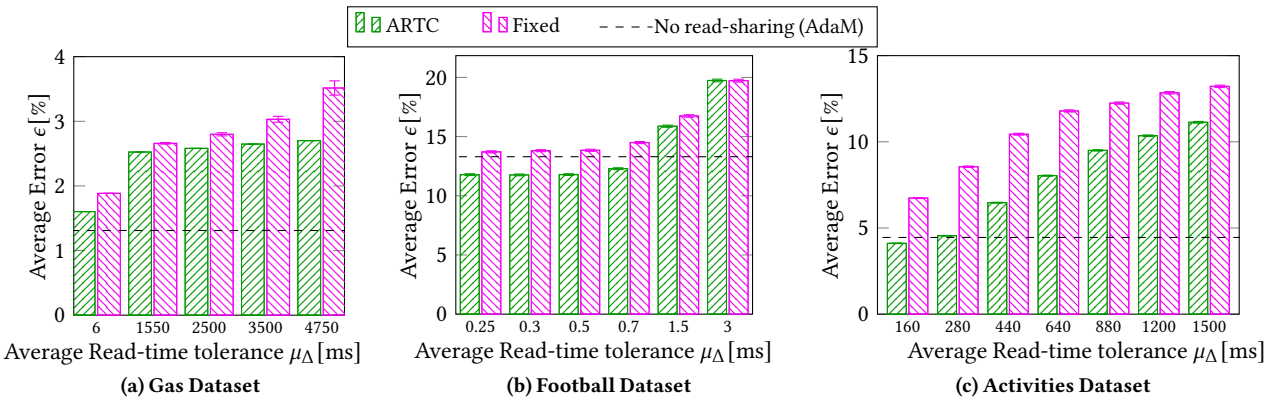


Figure 3: Performance of queries with different configurations of ARTC and the two baselines on the introduced datasets.

of the gas data. We discuss the experimental results in detail for each dataset in the following paragraphs.

The gas dataset (Figure 3a) contains sensor values with the lowest variability of all three datasets. The error of the read-time suggestion algorithm AdaM without read-sharing is approximately 1.4% of the data's average magnitude. With the configurations of ARTC visualized in Figure 3, large read-time tolerances of up to 4.75s are possible.
While small deviations on the dataset can only be captured when enabling read-sharing only to a limited extent of 6ms, we observe that ARTC is able to allow for large read-time tolerances of 2−5s without a significant increase in the average error. On the other hand, the fixed read-time tolerance algorithm's performance deteriorates, such that the error of the fixed algorithm is 30% larger than those caused by ARTC for a read-time tolerance of 4.75s. The additional error of read-sharing through ARTC stays below the error induced by the read-time suggestion algorithm for all executed configurations.

The football dataset (Figure 3b) has the highest variability of all presented datasets. The error of the read-time suggestion algorithm alone is 13% of the data's average magnitude. As most of the configurations of ARTC indicate an average error below or at the same level as the error of the read-time suggestion algorithm, read-sharing is only enabled to a very limited extent, up to 3ms. On this dataset, we observe that ARTC is able to reduce the error of the read-time tolerance algorithm slightly by up to 13% when enabling read-sharing to a limited extent. For read-time tolerances of 1.5ms, the error of the query configured with ARTC (15.8%) draws nearer to those of the fixed algorithm (16.7%). For a read-time tolerance of 3ms, the performance of both algorithms levels.

The read-time suggestion algorithm on the activities dataset (Figure 3c) has an error of 4.4%, matched for ARTC up to a read-time tolerance of 280ms. The executed configurations of ARTC achieve a read-time tolerance of up to 1.5s. On this dataset, ARTC outperforms the fixed read-time suggestion algorithm by the largest margin. ARTC is able to adapt to changes in the variability of the data during the experiment that occur whenever the individuum starts performing a different activity. While the error of the fixed read-time tolerance algorithm is approximately 90% larger than those of ARTC for a read-time tolerance of 280ms, the margin between the performance of both algorithms continuously shrinks to 20% for a read-time tolerance of 1.5s. This is because the algorithm misses small fluctuations in the data and takes a long time to adapt to brief periods of activity, which only last for several seconds.

3.4 Discussion

The evaluation of the single trace experiment executed on the activities dataset shows that ARTC can quickly adapt to a change in the distribution of values gathered from the sensor. During the quantitative analysis conducted on the three different datasets, ARTC outperforms the corresponding fixed configuration. For our experiment configurations, it is even possible to enable read sharing to a limited extent without a detrimental effect on the accuracy of the data representation altogether.

4 RELATED WORK

To the best of our knowledge, we are the first to propose a general, adaptive demand-based read-time tolerance controller. However, the underlying problem of reducing the number of reads and transmissions has been studied from various angles. Therefore, we first present existing work on read- and transmission sharing. We then present adaptive sampling techniques, as they are an integral building block of ARTC and share a similar objective.

Read- and transmission sharing. TinyDB [12] introduces the concept of acquisitional query processing (ACQP) to control the sampling frequency during *Single-Query Optimization*. ACQP arranges database operators and sensor readings in a common processing pipeline. Operators with low selectivity reduce the acquisition frequency by filtering out sensor readings before succeeding read operations. However, TinyDB only allows for periodic sampling algorithms at the processing pipeline's source.

Multiple approaches known from the literature conduct *spatial resource sharing*, i.e., optimize the set of deployed queries through a global view into a single query. Li et al. [10] allow the user to define query priorities and -deadlines. They fuse aggregate queries accordingly, perform utility-driven compression, and global transmission-scheduling to save reads and transmissions. However, they do not adapt to the variability of the distribution in scheduling and fusing sensor readings.

As opposed to spatial resource sharing, *data sharing techniques* perform local optimizations using a single sensor reading for multiple queries [13, 24, 25]. Tavakoli et al. [18] model the overlaps of tolerance intervals in an online evolving interval-cover graph, which they use to determine read-times. All four approaches are unable to adapt to changes in the distribution of the data both in scheduling reads and in computing read-time tolerances. We advanced data sharing in the context of adaptive sampling techniques [19, 20]. To that end, we proposed to combine demand-based adaptive read-time suggestion and read-time fusion in a

single framework. We were able to report savings of 87% in reads and transmissions, which we further increase through ARTC.

Adaptive sampling tailors the sampling frequency to the distribution of the data [8]. Padhy et al. propose a confidence-based adaptive sampling method called Utility-based Sensing and Communication (USAC) [15]. They apply linear regression to predict the next sensor value with a bounded error-range, the so-called confidence interval (CI). If a value is outside the CI, the sensor starts sampling at maximal frequency. Otherwise, the frequency decreases exponentially by a factor $\alpha \in [0,1]$ until it reaches the minimum sampling frequency.

Aiming to provide an energy-efficient solution in the realm of Big Data and IoT, Trihinas et al. propose the Adaptive Monitoring Framework (AdaM) [23]. They use an ad-hoc forecasting method called PEWMA to produce one-step forecasts, which they then use to compute the metric stream's variability.

Fan et al. propose Filtering and Adaptive sampling for Differentially Private Time Series Monitoring (FAST) [6]. They define a so-called privacy budget to add Laplace noise to the original observations to achieve differential privacy. Then they generate estimates, the quality of which is then used by the sampling component to adjust the sampling rate using a PID controller. Compared to AdaM and USAC, FAST is slower to adapt to changes in the distribution of the data but achieves comparable results.

We design our adaptive read-time tolerance controller ARTC using ideas from all three of the aforementioned adaptive sampling algorithms. We use a PID controller [3] in order to assess whether the read-time suggestion algorithm achieves the data-quality ARTC targets. Similar to AdaM, we use PEWMA [5] in order to monitor the distribution of samples. We use the idea presented by Padhy et al. of decreasing tolerances rapidly if the desired data accuracy is missed, which enables us to adapt to changes in the distribution quickly.

5 CONCLUSION

We previously developed a multi-query read-scheduling algorithm that enables adaptive sampling in a sensor network [20]. In this paper, we now extend our work by proposing the easy to configure adaptive read-time tolerance controller ARTC. Our experimental evaluation shows that ARTC tailors the extent of read-sharing to the data-accuracy demands of end-applications. ARTC is generally-applicable for defining read-time tolerances when scheduling sensor read-times. Thus, it enables multi-query optimization through sharing sensor readings for arbitrary adaptive sampling techniques. We evaluate ARTC on three real-world IoT datasets with different data characteristics and shifts in the data distribution. Our solution reduces the error in the representation by up to 60% compared to fixed read-time tolerance algorithms by adapting to the sensed data's variability. ARTC not only reduces the number of reads and transmissions while achieving the same sensing error as existing techniques, but also enables multi-query read-sharing for queries issued by users without domain-knowledge. We make our code and evaluation available open-source. We also provide detailed instructions on how to execute custom experiments. In our previous work, we allow the user to define a so-called penalty-function [20] to further increase the read-sharing potential under specific circumstances. We plan to extend our solution to adaptively tune such penalty-functions based on the data's variability as well.

ABSTRACT

The join is a fundamental and widely used operation in data analytics but equally, it is also one of the most expensive ones. Considerable work has been carried out to improve and evaluate join approaches based on popular distributed processing systems such as Spark and Hadoop, however, it has not been widely studied on MPI.

In this paper, we first implement, analyse and compare existing algorithms for the common small-large outer join operation and develop a novel approach, the swap-based outer join algorithm (SOJA). SOJA is designed to minimise the expensive communication between the distributed nodes while also reducing the cost of the local join operations. We demonstrate the benefits of SOJA experimentally, showing that it achieves at worst an execution time similar to its competitors. More importantly, SOJA requires substantially less memory (typically half the memory compared to the best competitor) and that memory usage scales very well.

1 INTRODUCTION

Collecting and storing data has never been as easy and as cheap as today. It comes as no surprise that vast amounts of data are being stored today and it is predicted that all known data worldwide will grow to 250 Zettabytes by 2025. Many real-world applications benefit from the efficient analysis of large amounts of data, be it for medical applications [1, 2, 13], scientific applications [11] or commercial applications such as traffic analysis [7] and others. Analysing this data efficiently and at scale has thus never been more important than today and is also a considerable challenge.

Crucial in the analysis of large amounts of data is the combination of multiple datasets before analysis. One central operation thus is the join operation which combines multiple datasets (or one with itself) by matching tuples with a shared attribute. More specifically, a join on datasets R and S based on equality (or a different relationship) will pair tuples $r \in R$ and $s \in S$ if $r.c_1 = s.c_2$ where c_1 and c_2 are attributes of the tuples. The operation is frequently used but very costly due to computational overhead but also because of I/O.

In this paper, we develop the swap-based outer join algorithm (SOJA), a new approach to the specific problem of the small-large outer join where a small and a large dataset are joined. We develop SOJA for Message Passing Interface (MPI) on HPC infrastructure as such large-scale parallel infrastructure is one of the few efficient ways to join large datasets [3]. MPI is a message-passing standard which is widely used in high performance applications [10]. The standard defines the syntax and semantics of approximately 250 library routines that allow users to develop a wide variety of communication operations on different types of parallel computing infrastructure[8, 9]. Point to point communication between two MPI processes (ranks) and collective communication among MPI processes are most commonly used. For each of them, MPI also provides multiple communication modes that fall into either blocking or non-blocking communication according to whether constituent operations of the communication complete synchronously. Additionally, MPI supports a derived datatype and a virtual topology which allows users to control data movement among processes efficiently and flexibly. MPI thus is a promising tool to design and implement algorithms to handle and analyze massive amounts of data efficiently.

We use MPI running on HPC infrastructure to efficiently execute a small-large left outer join. The small-large left outer join can be denoted as $R \bowtie S$ with $|R| << |S|$ where $|R|$ and $|S|$ are number of tuples in tables or, more generally, datasets R and S. In the query below, R and S represent the left table and right table, and a join is performed between R and S based on join keys $R.a$ and $S.b$:

```
SELECT * FROM R LEFT OUTER JOIN S ON R.a = S.b;
```

For parallelising the left outer join, we assume that R and S are distributed among the N processes in a round-robin fashion. Each partition R_i is assigned to the $i-th$ process, and has the same number of elements $|R_i| = \frac{|R|}{N}$. The same applies to all S_i.

The parallel left outer join with partitioned data then has two goals: (1) find all matching tuples from the two tables; (2) find all dangling tuples from the left table and output them with no matching tuple from the right table.

Existing approaches mainly adopt two methods, redistribution and broadcast, to produce the entire join results while guaranteeing data locality. Redistribution refers to redistributing both tables among all processes to make tuples such that the same join keys are placed in the same process. Broadcast, in this context, means the left table in each process is duplicated and sent to all other processes, so that each process holds the complete left table. These two methods either lead to inevitable skewness or duplication. SOJA adopts a novel method, *swap*, to ensures tuples in the left table can join all possible matching tuples in the right table by swapping the left table among processes. Based on the swap method, SOJA can also perform other types of parallel joins such as inner or right outer joins by replacing local join methods.

As our extensive set of experiments shows, SOJA in many cases outperforms its competitors and at worst has an execution time similar to its competitors. Most importantly, however, SOJA requires substantially less memory which in a supercomputing environment is crucial (as data cannot easily be swapped to disk). SOJA typically requires only half the memory and, as our experiments show, scales extremely well.

In the remainder of this paper we first review the state of the art in Section 2, present our approach SOJA in Section 3.1, analyse SOJA experimentally in Section 4 and conclude in Section 5.

2 RELATED WORK

In this section, we first describe four related parallel outer join algorithms (Figure 1) and then discuss their limitations and communication implementations on MPI .

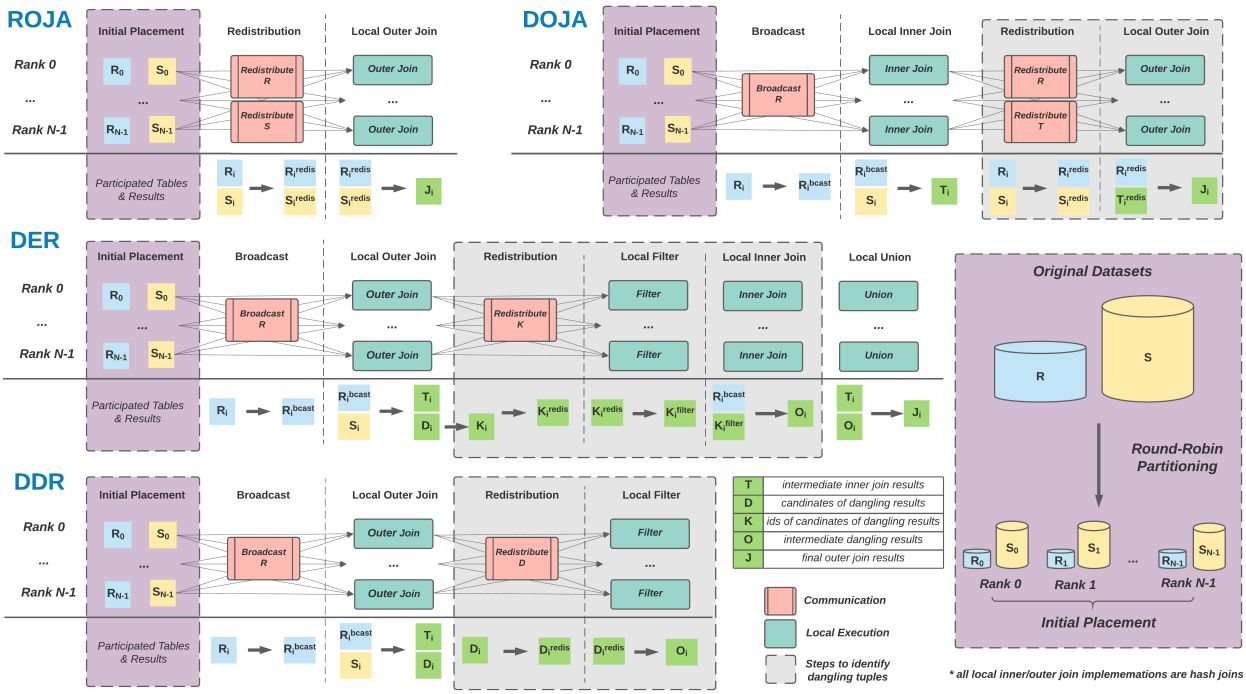

Figure 1: Illustration of ROJA, DOJA, DER and DDR

2.1 Redistribution Outer Join Algorithm (ROJA)

ROJA uses the redistribution approach to execute the local outer join, it has two steps, redistribution and local outer join, which can be considered as an extension of a typical re-partition join algorithm [4, 12]. The only difference to a typical re-partition join algorithm is that ROJA adopts the local outer join in the second step instead of local inner join. ROJA proceeds as follows:

(1) all tuples of R_i and S_i in each process are redistributed based on the join keys ($R_i.a$ and $S_i.b$).
(2) each process performs a local outer join between reallocated two tables denoted as R_i^{redis} and S_i^{redis}.

2.2 Duplication Outer Join Algorithm (DOJA)

DOJA is a variation of the broadcast join algorithm [4, 12]. It obtains inner join results by performing inner join after broadcasting the tables similar to broadcast join algorithms. However, DOJA needs to execute two additional steps to identify dangling tuples:

(1) each process broadcasts the smaller left table R_i to all other processes, which results in each process now having an entire table R denoted as R_i^{bcast}.
(2) local inner join in each process between R_i^{bcast} and S_i outputs inner join results stored in T_i.
(3) T_i and R_i are redistributed based on join keys ($T_i.a$ and $R_i.a$).
(4) after receiving redistributed T_i^{redis} and R_i^{redis}, each process executes local outer join to output complete result.

2.3 Duplication and Efficient Redistribution (DER)

DER [14] improves DOJA by reducing the size of the redistributed data. DER executes as follows:

(1) this step is same as step 1 for DOJA with the only difference being the addition of ids. DDR needs to add keys to tuples, if there is no global identifier in R_i.
(2) a local outer join between R_i^{bcast} and S_i generates inner join results (T_i) as well as non-matching tuples.
(3) each process in DER redistributes ids (K_i) extracted from non-matching tuples (D_i).
(4) after redistribution, K_i^{redis} is filtered so that only keys that appear N times are stored, because a dangling tuple in R will not be matched in all N processes. The result is in K_i^{filter}.
(5) truly dangling tuples O_i in the left table can be retrieved by a local inner join between K_i^{filter} and R_i^{bcast}.
(6) the union of O_i and T_i in each process is the final results.

2.4 Duplication and Direct Redistribution (DDR)

DDR [5] is a broadcast-based outer join algorithm focusing on optimizing the identification of dangling tuples. Its steps are:

(1) the first two steps of DDR are identical to DER.
(2) each process outputs matched join results (T_i) and redistributes non-matching results (D_i).
(3) similar to step 4 of DER, dangling tuples after redistribution (D_i^{redis}) are kept if they occur N times. The results O^i is directly outputted.

2.5 Discussion

We will compare the communication cost and local execution cost between the different approaches.

2.5.1 Communication. The two main methods for communicating among processes are: (1) redistributing where the tuples are categorized and sent to their respective destinations; (2) broadcasting, where a table is duplicated across all of the

processes. Redistribution requires additional calculation of destination, thus, the redistribution cost is higher than broadcast cost ($t^{redis} > t^{trans}$). To compare communication cost of algorithms, we develop a simple cost model.

$$comm \begin{cases} (R+S) \times t^{redis} & \text{(ROJA)} \\ R \times (N-1) \times t^{trans} + (R+T) \times t^{redis} & \text{(DOJA)} \\ R \times (N-1) \times t^{trans} + K \times t^{redis} & \text{(DER)} \\ R \times (N-1) \times t^{trans} + D \times t^{redis} & \text{(DDR)} \end{cases} \quad (1)$$

In small-large joins, based on the above equation, the communication cost of ROJA can be very high, since each process in ROJA has to redistribute the large right table S_i. The other three algorithms share a similar broadcast cost. The cost may appear low initially, but with an increase in the number of processes N and the size of left table ($|R|$), the cost can grow significantly. The difference in communication cost between the three broadcast-based algorithms is that they redistribute different intermediate data. DOJA redistributes the left table R and the inner join result T (the size of T depends on the selectivity ratio σ_j). With an increasing σ_j, the redistribution cost will increase significantly, thereby dominating the overall performance of DOJA. As a consequence, two improved methods, DDR and DER, were developed to optimize this stage by redistributing dangling results. DER uses ids of dangling tuples (K) and DDR uses dangling tuples (D). The number of dangling ids ($|K|$) is the same as the number of dangling tuples ($|D|$), however, the storage size of K may be smaller than D. Thus, from the perspective of communication, DER can outperform DDR. The overall redistribution cost of DDR and DER is not significant. However, the number of dangling tuples will increase when the number of processes (N) increase simply due to the fact that the R is duplicated in more processes. It is worth mentioning that redistributing may potentially result in an unbalanced workload due to skewness. In the presence of data skew, the overall performance is adversely impacted by the redistribution stage as well as subsequent operations. Additionally, both redistribution and broadcast require more memory.

2.5.2 Local Execution. The existing algorithm mainly involve two local operations: join (inner join and outer join) and filter. Their time costs are denoted as t^{join} and t^{filter}.

$$local \begin{cases} (R_i^{redis} + S_i^{redis}) \times t^{join} & \text{(ROJA)} \\ (R + S_i + R_i^{redis} + T_i^{redis}) \times t^{join} & \text{(DOJA)} \\ (2R + S_i + K_i^{filter}) \times t^{join} + K_i^{redis} \times t^{filter} & \text{(DER)} \\ (R + S_i) \times t^{join} + D_i^{redis} \times t^{filter} & \text{(DDR)} \end{cases} \quad (2)$$

As we mentioned before, the skewness in the data can result in an unbalanced workload in subsequent operations and the performance of ROJA is highly affected by data skew (as data in some processes after redistribution (R_i^{redis}, S_i^{redis}) may be significantly bigger than the initial placement (S_i , R_i)). DOJA not only needs to perform a local join after the broadcast to compute all inner join results but also needs to identify non-matching tuples in the left table by joining the redistributed left table (R_i^{redis}) and inner join results (T_i^{redis}). The cost of a second join strongly depends on the inner join ratio (σ_j) and skewness degree (θ). For DER and DER, a filter step is required after the local join. DER needs to filter keys which may have a smaller size in bytes than the tuples filtered by DDR. Thus, in terms of cost of the filter stage, DER has an advantage. However, after the filter stage, DDR can directly output dangling tuples while DER has to retrieve dangling tuples by performing an additional join. In addition, DER has extra local update costs ($R_i \times t^{update}$) if no ids are assigned to the left table R_i.

2.6 Broadcast and Redistribution on MPI

Both broadcast and redistribution are collective communication in which all processes are participating. For broadcasting in DOJA, DER and DDR, all processes need to send their participating partitions to all other processes. From the point of view of the receiver, all processes gather data from all other processes, which can be achieved by the MPI routine `MPI_Allgather`. Different processes may hold data of different size, we implement the broadcast by using `MPI_Allgatherv` which allows each process to contribute different amounts of data. As for redistribution, all processes could be the destination of the redistributed data in all processes. Such a communication pattern can be supported by `MPI_Alltoall` and `MPI_Alltoallv` which send data from all processes to all processes. To implement hash redistribution, before calling these routines, the data needs to be reorganized based on its corresponding destinations which is determined by the hash function.

3 SWAP-BASED OUTER JOIN ALGORITHM (SOJA)

3.1 Approach & Design of SOJA

Compared to existing algorithms that mainly uses redistribution and broadcasting, SOJA adopts a novel *swap* approach using a ring topology to perform the parallel outer join. Additionally, SOJA decomposes the traditional local outer hash join operations to hash (create hash table from right table) and lookup (loop over tuples in R_i to look up the hash table). Hashing the right table allows the dangling tuples in the left table to be determined with a single loop for a left outer join. The steps for SOJA are:

(1) each process creates a hash table (HS_i) for the right table (S_i). It then loops over the tuples in the left table (R_i) to query the hash table HS_i, meanwhile marking non-matching tuples in the R_i as candidates for dangling tuples. Finally, the intermediate inner join results will be directly returned.
(2) each process sends the updated R_i to the next process ($i+1$) in the ring topology. Note, the $(N-1)-th$ process will send R_{N-1} to process 0.
(3) a lookup would be carried out on the new set of R_i and HS_i, and the intermediate results would be outputted. The non-matching mark will be removed if the candidate tuple is able to find a match.
(4) repeat steps 2 & 3 $N-1$ times, and output the tuples in each of the R_i with marks as dangling tuples in the last iteration.

The cost model of the iterative operations is the following:

$$SOJA \begin{cases} R \times (N-1) \times t^{trans} & \text{(comm)} \\ (R + S_i) \times t^{join} + R \times t^{update} & \text{(local)} \end{cases} \quad (3)$$

From perspective of cost model, the communication cost is the same as the broadcast operation, the total join cost of SOJA is also the same as outer join after the broadcast in DER and DDR. However, no redistribution, filter, or additional joins are required by SOJA. It identifies non-matching tuples in the left table and updates the left table R while looping. Additionally, the cost of t^{update} is not significant, due to the left table being small.

Further, compared to existing methods, SOJA saves memory for the following reasons: (1) directly outputs of the intermediate

results after each iteration, (2) no duplication of tables, and (3) no temporary dangling data as the size of temporary data can increase with the number of processes as well as with the selectivity ratio in the left table σ_R. In addition, SOJA can easily be extended to perform other types of joins such as inner join or right outer joins. For example, inner join is executed by performing a local lookup without marking and updating dangling tuples in the left table. For right outer joins, SOJA simply flips the operation by creating a hash table for the left table and updating the marks on the right table.

Although, there is no redistribution in SOJA, its performance is still sensitive to an imbalanced workload among processes, especially due to imbalanced initial placement as there are synchronization costs for communication. Therefore, for SOJA, initially placing partitions of equal size is a prerequisite for achieving ideal performance.

3.2 Swap of SOJA on MPI

We use Cartesian topology routines `MPI_Cart_create` with 1-dimension to construct SOJA's ring topology in which each process is logically connected to two other processes ($left$ and $right$ process) in a circle. In the ring topology, point to point communication routines (`MPI_Send` and `MPI_Recv`) can be used to swap data between adjacent processes. To reduce the synchronization costs, we use non-blocking mode (`MPI_Isend` and `MPI_Irecv`) to transfer data that can overlap other local operations, such as result output or other operations based on intermediate results. The swap stage of SOJA is shown in Algorithm 1.

Algorithm 1: Swap in SOJA

```
1:  Require: R_i, N, left and right neighbour left and right
2:  recv_buffer = R_i
3:  for i = 1 to i = N-1 do
4:      send_buffer = lookup_and_update(recv_buffer)
5:      MPI_Isend(send_buffer, dest = left, send_Request)
6:      MPI_Irecv(recv_buffer, source = right, recv_Request)
7:      overlapping: output result
8:      MPI_Wait(send_Request)
9:      MPI_Wait(recv_Request)
10: end for
11: result = lookup_and_update(recv_buffer)
```

4 EXPERIMENTAL EVALUATION

In the following section, we analyse SOJA using experiments with changing the size of left table ($|R|$), selectivity ratio of left table (σ_R), and skewness degree (θ). We focus on execution time and memory usage.

4.1 Setup

4.1.1 Platform. We use an HPC cluster with Intel E5-2680 v3 @ 2.50GHz running Centos 8. The MPI version is 3.3.2.

4.1.2 Datasets. The experiments are based on `customer` and `supplier` tables from the TPC-H benchmark [6]. For simplicity and consistency of presentation, we use R and S to represent `customer` and `supplier` respectively. To test the algorithms with different scenarios, we modify the data in two ways: first, we scale up or scale down the table size ($|R|$ and $|S|$) by sampling data from the two initial tables (uniform with replacement). Second, we vary the selectivity ratios, i.e., the join selectivity ratio (σ_j) and the selectivity ratio in the left table (σ_R). The selectivity ratio affects the number of join results ($|T|$) and can be roughly controlled by the sample population of join key n with uniform distribution, which can be explained using Equations 4 to 6.

The definition of σ_j is:

$$\sigma_j = \frac{|T|}{|R| \times |S|} \tag{4}$$

If we sample the join key from a population that contains n values and denote the probability of choosing $i-th$ item as p_i, then:

$$\sigma_j = \frac{\sum_{i=1}^{n} p_i \times |R| \times p_i \times |S|}{|R| \times |S|} = \sum_{i=1}^{n} p_i^2 \tag{5}$$

If p_i is a uniform distribution, $p_i = \frac{1}{n}$, then:

$$\sigma_j = \frac{1}{n} \tag{6}$$

The selectivity ratio in the left table (σ_R) determines the number of dangling tuples in the left table. With the involvement of σ_R, the number of results can be estimated by Equation 7.

$$|T| = \underbrace{|R| \times \sigma_R \times |S| \times \sigma_j}_{\textit{inner join results}} + \underbrace{(1-\sigma_R) \times |R|}_{\textit{dangling results}} \tag{7}$$

If σ_R equals to 0, this means no tuples in table R are selected to perform the join with table S. Therefore, table R will be the result. As σ_R increases, the number of matching results increases whereas the non-matching results decrease until all tuples in R are involved in the join when σ_R equals to 1. We assign a negative join key to number of tuples in table R based on 1 - σ_R [5]. Therefore, any tuple with a negative key in the left table (R) will not have any matching results. Both σ_j and σ_R can influence $|T|$, but in outer joins, σ_R will provide more insights (dangling tuples), so our experiments focus on σ_R to study changes of $|T|$ and only use σ_j to keep the number of potential inner join results (when σ_R = 1) unchanged when varying the input data size.

To achieve the parallel IO, we split the data into N partitions and processes load their partition from disk in parallel.

4.2 Impact of the Size of the Left Table

To examine how the performance of approaches changes when the size of left table increases, we conduct the experiment in which we vary $|R|$ and keep all other parameters such as $|S|$, σ_R, fixed. All five algorithms are executed on 32 cores and 64 cores and we measure execution time and memory usage.

In this experiment, we set $|S|$ to 5×10^7, σ_R to 0.5, and increase $|R|$ with a coarser granularity (10×) from 10^3 to 10^7. Figure 2 shows that all algorithms maintain a stable performance until $|R|$ reaches 10^6. We further explored changes of the performance with a fine-grained increase of $|R|$ (increment of 10^6 tuples) in the interval between 10^6 and 10^7. The result from 32 processes and 64 processes (Figure 2 A & C) shows that the execution time of ROJA is steady whereas execution time of all other algorithms has a clear upward trend. Figures 2 B & D indicate that SOJA has an advantage in terms of memory usage across all experiments. Although ROJA has the highest memory usage when $|R|$ is small, the memory usage level stays quite constant with increasing $|R|$. The other three broadcast-based algorithms show that their memory usage increases significantly, particularly DDR. It is worth pointing out that when $|R|$ is relatively large, the performance of DDR on 64 processes is worse than itself on 32 processes.

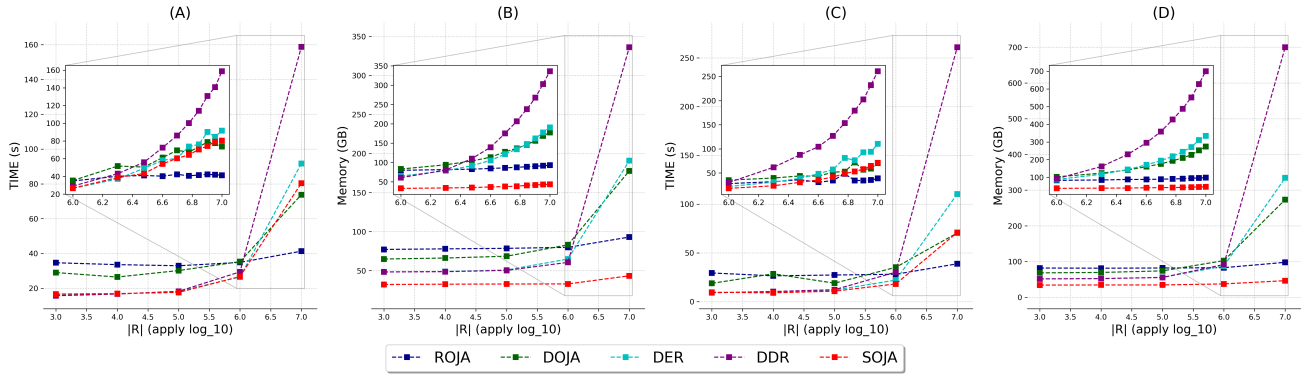

Figure 2: Execution time and memory usage against $|R|$, wide ranges $|R|$ from 10^3 to 10^7, narrow is from 10^6 to 10^7. (A) time vs N for 32; (B) memory usage vs N for 32; (C) time vs N for 64; (B) memory usage vs N for 64;

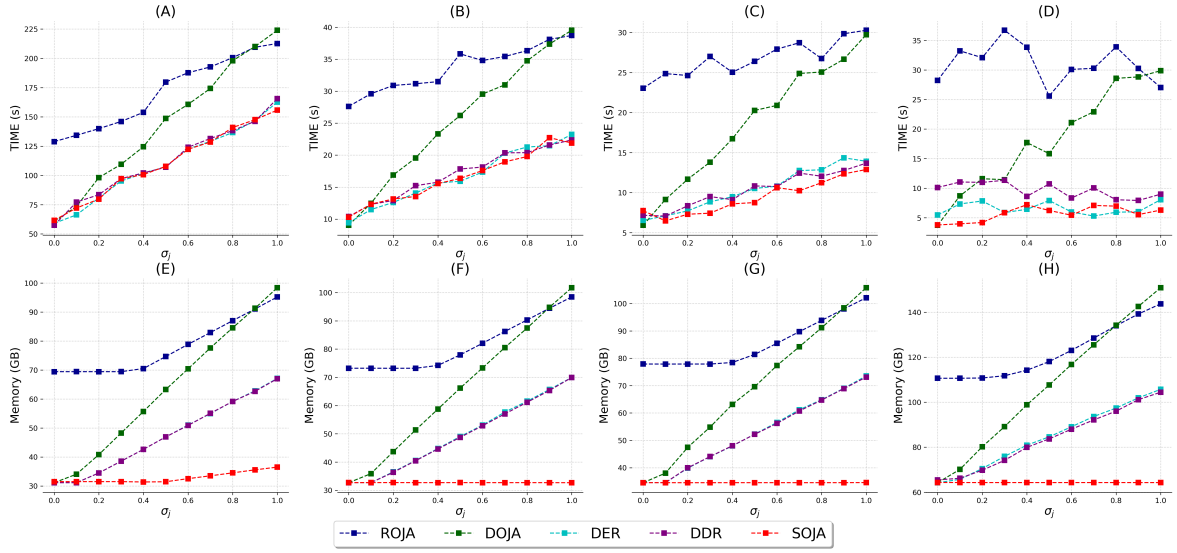

Figure 3: Execution time against selectivity ratio of left table over varying number of processes: (A - D): execution time for N = 4, 32, 64, 512; (E - H): memory usage for N = 4, 32, 64, 512;

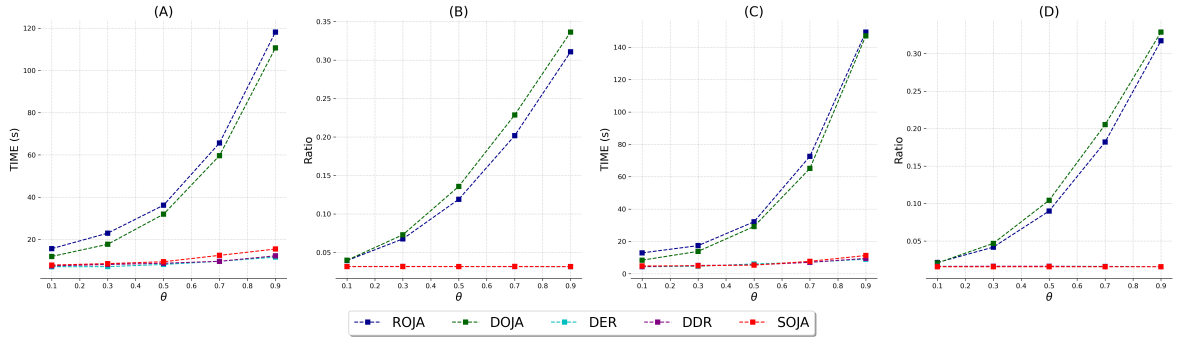

Figure 4: Execution time and memory usage ratio against skewness degree: (A) execution time for N = 32; (B) memory usage ratio N = 32; (C) execution time for N = 64; (D) memory usage ratio for N = 64;

Both execution time and memory usage in ROJA are not considerably affected by changes in $|R|$, because the cost of ROJA is dominated by the large table (although R increases, it is still at least 5 times smaller than $|S|$). The broadcast cost and subsequent local join between R and S_i in DOJA, DER and DDR increases with the growth of R, increasing both execution time and memory usage. Furthermore, dangling tuples candidates after the first local outer join will also increase as R increases. Therefore, DER and DDR have to redistribute and filter more data to identify non-matching tuples. The number of candidates is roughly

$|R| \times (1-\sigma_R) \times N$. Unlike DER which use ids, DDR directly works with tuples; therefore, its execution time and memory usage increases dramatically with an increase of $|R|$ and N. As for SOJA, the swap step becomes more expensive with the growth of $|R|$. Overall, we can see that when $|R|$ is 10 times less than $|S|$, DER, DDR and SOJA outperform ROJA in both time and memory.

4.3 Effect of Selectivity Ratio of Left Table

These experiments examine the algorithms' performance with different σ_R from 0.0 to 1.0 using a varying number of processes (4, 32, 64, 512). We set $|R|$ to 10^5 and $|S|$ as 5×10^7, and the σ_j to 10^{-5}.

The results in Figure 3 (A - D) show that the overall execution time has an upward trend with an increase of σ_R as a high σ_R leads to an increase of the result size and thereby increasing IO costs. The execution time of DOJA increases dramatically since DOJA has to redistribute and perform a second local join based on increasing inner join results. Overall, DER, DDR and SOJA share a similar performance which outperform the two conventional algorithms. The upward trend stabilizes with increasing number of processes due to reduction of local IO costs. Figure 3 (E - H) shows the change of memory usage with increase of σ_R. When σ_R is small, the redistribution cost in ROJA takes a considerable amount of memory, and it require even more memory to hold join results as σ_R increases. DOJA uses more memory compared to the other two broadcast algorithms because it redistributes the inner join results rather than the dangling tuples.

4.4 Effect of Data Skewness

To test the effect of skewness, we use the Zipf distribution model and the number of tuples for both tables after redistribution in the $i-th$ process ($|R_i^{redis}|$ and $|S_i^{redis}|$) is the following:

$$|R_i^{redis}| = \frac{|R|}{i^\theta * \sum_{j=1}^{N} \frac{1}{j^\theta}} \tag{8}$$

To generate data with skew, we sample multiple datasets with the join key using a Zipfian distribution with different degrees θ from 0.1 to 0.9. We set $|R|$ as 10^5, $|S|$ as 2×10^7, and σ_R as 0.5. In this experiment, we examine how execution time as well as memory usage changes on 32 and 64 processes with an increase of θ. In case of skewness, the execution time is determined by the process with the biggest workload. To make the memory usage results meaningful, we use a memory usage ratio, which is the maximum memory usage among all processes over the total memory usage, instead of total memory usage.

Experiments on both 32 and 64 processes (Figure 4) show that the degree of skewness has a significant impact on execution time and memory usage ratio of ROJA and DOJA due to unbalanced workload caused by the redistribution step. Although DER and DDR also feature a redistribution operation, their performance remains stable as θ changes. This is because, in this experiment, the number of dangling tuples/ids to redistribute is relatively small due to the small $|R|$. The memory ratio in Figure 4 (B & D) also reflects that both DER and DDR have a relatively balanced memory usage. Since this skewness is about data skew in the join key rather than the initial placement, both memory and execution performance of SOJA are not much affected by θ.

4.5 Discussion

ROJA, as a general-purpose outer join algorithm, does not have an outstanding performance when the left table's size is very small. Although ROJA is less affected by changes in the selectivity ratio in the left table, its performance with high data skew drops dramatically. Another conventional algorithm, DOJA, has no outstanding performance in most cases because it has to broadcast the entire left table and redistribute the entire inner results, which is particularly bad when the join selectivity ratio is large.

In small-large outer joins, DER shows an outstanding performance over most cases as it optimizes the redistribution by focusing on ids to identify dangling tuples. Using ids of dangling tuples makes DER less affected by the selectivity ratio and skewness. As a DER competitor, DDR adopts a simpler procedure, directly redistributing and filtering based on the dangling tuples itself. DER and DDR share the core methodology and their performance in both time and memory aspects is also similar in most cases. However, when the number of the tuples in the left table increases, the performance of DDR becomes the worst since the size of candidates of dangling tuple in bytes increases both computation and memory costs.

SOJA achieves a similar (sometimes better) performance than DER and DDR in terms of time costs in most cases and outperforms all competitors in terms of memory usage. Additionally, SOJA is less affected by data skewness and selectivity ratio since there is no redistribution operation in SOJA.

5 CONCLUSIONS

In this paper, we implemented four existing parallel outer join algorithms in MPI and proposed a new algorithm SOJA. SOJA does not simply optimize one specific part of existing algorithms; it provides an entirely novel approach, *swap*, to perform outer joins. The experiment based on HPC infrastructure shows that the performance of SOJA is outstanding, especially in memory usage. Further, we will investigate whether SOJA can be used in other joins, such as inner join, with the same benefits. Additionally, the feasibility of the swap approach in parallel spatial joins will be explored in future works.

ABSTRACT

Machine learning (ML) is increasingly used to automate decision making in various domains. Almost all common ML models are susceptible to data errors in the serving data (for which the model makes predictions). Such errors frequently occur in practice, caused for example by program bugs in data preprocessing code or non-anticipated schema changes in external data sources. These errors can have devastating effects on the prediction quality of ML models, and are, at the same time, hard to anticipate and capture.

In order to empower data scientists to study the impact as well as mitigation techniques for data errors in ML models, we propose Jenga, a light-weight, open source, experimentation library. Jenga allows its users to easily test their models for robustness against common data errors. Jenga contains an abstraction for prediction tasks based on a dataset and a model, an easily extendable set of synthethic data corruptions (e.g., for missing values, outliers, typos and noisy measurements) as well as evaluation functionality to experiment with different data corruptions.

Jenga supports researchers and practitioners in the difficult task of data validation for ML applications. As a showcase for this, we discuss two use cases of Jenga: studying the robustness of a model against incomplete data, as well as automatically stress testing integrity constraints for ML data expressed with tensorflow data validation.

1 INTRODUCTION

Many companies and organisations are moving to a data-driven approach, where machine learning (ML) is used to assist and automate decision making in various domains. Yet the application of ML in production settings often faces a number of pitfalls. Almost all common ML models are susceptible to data errors in the serving data (for which the model makes predictions). Such errors frequently occur in practice, caused for example by program bugs in data preprocessing code or non-anticipated schema changes in external data sources. These errors can have devastating effects on the prediction quality of ML models [12], and are, at the same time, hard to anticipate and capture. While many aspects of the impact of data changes on ML models are studied in the ML literature [1, 7, 9], it can be difficult to relate this research to the errors occurring in practical ML applications, as these approaches all require distributional assumptions about the change.

Data errors in production machine learning. Frequently, the errors in production deployments do not originate from changes in the data generating real-world processes, but from programming errors in the data pipelines constructing the serving data [4] or from errors during data integration from different sources [6, 21]. Such errors often only become apparent once models are deployed in complex production use cases [16].

We have come across several real world instances of such data errors. In one case, a linear model had been trained on demographic data (including a person's age), and the age value had been missing for some records for which the model should supply predictions. A software engineer (without knowledge of the model intricacies) then wrote preprocessing code to replace all missing age values with zeroes, the default value for initialising integers in many programming languages. This led to a unwanted misbehavior of the model, which effectively treated all these records as "toddlers". In another case, we learned about an ML model where the pipelines for training and serving data were running in different cloud environments. As a result, the code bases for data preparation on the training and serving side accidentally diverged, which introduced hard to detect data errors. Such errors can have devastating impact, as all guarantees about the reliability of the predictions of the ML model may be lost, which can lead to monetary losses (e.g., if buying decisions are made based on the predictions of a forecasting model) and bad user experiences (e.g., if users are presented with non-sensical recommendations in an online shop).

Evaluating the robustness of models against common data errors. These examples show the need for testing the robustness of ML models to data errors before they are deployed to production. Recent research focuses on detecting and handling such data errors, e.g., by proposing unit tests and integrity constraints for ML data [4, 17], ML-based missing value imputation [2] and validating the predictions of black box models [19]. In our experience, it is difficult to provide broadly valid empirical evaluations of these approaches, and to generate synthetically corrupted data that represents the scenarios that we encounter in the real world.

To address this need, we design the *Jenga* library, which we present in this paper. Jenga enables data scientists to study the robustness of their models against errors commonly observed in production scenarios. Based on the findings from experimenting with Jenga, users can take appropriate measures to protect their deployed models against impactful data errors, e.g., with custom integrity constraints implemented via tensorflow data validation [4].

In summary, this paper provides the following contributions.

- We introduce our open source framework Jenga to study the impact of data errors on ML models (Section 2).
- We describe how to implement custom prediction tasks and synthetic data corruptions in Jenga (Section 3).
- We discuss two use cases for Jenga: studying the robustness of a model against incomplete data, and automatically stress testing integrity constraints for ML data expressed with tensorflow data validation (Section 4).

Jenga is publicly available under an open source license at https://github.com/schelterlabs/jenga.

2 FRAMEWORK DESIGN

We introduce the design of Jenga. The goal of Jenga is to enable data scientists to evaluate the impact of data errors on their models, and to evaluate techniques that make these models more robust. We design Jenga around three core abstractions: (*i*) *tasks* contain a raw dataset, an ML model, and represent a prediction task; (*ii*) *data corruptions* take raw input data and randomly apply certain data errors to them (e.g., missing values); (*iii*) *evaluators* take a task and data corruptions, and execute the evaluation by repeatedly corrupting the test data of the task, and recording the predictive performance of the model on the corrupted test data.

We provide three sample tasks (Section 2.1), several data corruptions (Section 2.2) and two different evaluators (Section 2.3) as part of the framework.

2.1 Example Tasks

We provide three exemplary prediction tasks in Jenga. Note that users can define and implement their own custom tasks with low effort (see Section 3 for details). We choose simple binary classification tasks for product review classification (predicting whether the review of a video game was deemed helpful), income estimation (predicting whether a person earns more than $50,000 per year based on demographic data) and image recognition (distinguishing sneakers from ankle boots), which resemble real world use cases, and leverage publicly available datasets and widely used ML models. We focus on relatively small-scale problems, which do not require costly infrastructure (e.g., the models can be trained in a couple of minutes on a multicore CPU), in order to allow users to rapidly experiment and play with our framework. These tasks are meant as examples to enable users to test our data corruptions and evaluators, and serve as a template for our users to integrate Jenga with their own custom prediction tasks.

2.2 Data Corruptions

In the following, we describe the types of data corruptions available in Jenga. Each error type requires the specification of a column c to be affected by the error and a fraction of rows $r \in [0, 1]$ that should be affected.

Corruption sampling.: Whether or not a value is affected by a corruption is often the result of errors in complex preprocessing pipelines. In order to account for realistic corruption patterns we model the fraction of rows affected by a corruption as follows. A value x_c in column c is corrupted (*i*) *independent of other values* (corrupted values are sampled *completely at random*), (*ii*) dependent on values in columns other than c (corrupted values are sampled *at random*), or (*iii*) dependent on values in column c (corrupted values are sampled *not at random*). This modelling is inspired by literature on missing value imputation, where three types of missingness are commonly distinguished [10]. As these three sampling procedures a can capture the complex error patterns often observed in practice we chose to make it applicable not only to missing value corruptions, but to all other error types as well.

Missing values. Missing values are amongst the most common data errors in practice. Missing values can have devastating effects on training and prediction, depending on how a data pipeline deals with missing values before feeding the data to a downstream ML model. An important factor for the impact of missing values are the missingness patterns, described in the previous paragraph, *missing completely at random (MCAR)*, *missing at random (MAR)* and *missing not at random (MNAR)*.

We additionally support the injection of *missing values based on "prediction difficulty"*, where we consider the fact that there ML model downstream that is affected by missing data. This error type considers the entropy of the ML model predictions for the data rows and discards values based on their difficulty for the model, akin to uncertainty sampling in active learning.

Swapped values. We replace a specified ratio of values in one column with values in another column. This corruption mimics users mixing up entries in input forms [6] or programming errors in data preparation code, where a programmer accidentally swaps target columns to write to.

Scaling. We randomly scale a subset of the values by 10, 100 or 1000. This perturbation mimics cases where the scale of an attribute is accidentally changed in preprocessing code (e.g., because a developer accidentally changes the code to record durations in milliseconds instead of seconds).

Noise. We corrupt a fraction of a column's values by adding gaussian noise centered at the data point with a standard deviation randomly selected from the interval of 2 to 5. This corruption is intended to mimic measurement errors.

Encoding errors. This corruption replaces certain characters in string attributes (e.g., a with á), and is meant to simulate encoding errors, e.g., for data retrieved from web pages which indicate a false encoding.

Image corruptions. Dealing with corrupted training images is a well studied problem in computer vision [3] for which a lot of tooling exists already. We therefore integrate existing image corruptions from the *augmentor*[1] library into jenga.

2.3 Evaluators

Finally, Jenga provides so-called *evaluators*, which measure the impact of data corruptions on the model's predictive performance. Jenga currently features two evaluators: The `CorruptionImpactEvaluator` takes a provided task, a trained model and a manually specified list of corruptions. It applies each data corruption to the held-out test set of the task and computes the predictive performance of the model in light of the data corruption. We show how to use this evaluator with a few lines of code in Section 3.1, and discuss a detailed example of measuring the impact of missing values on a task in Section 4.1.

The second evaluator allows users to additionally integrate a data validation schema into the evaluation. In many cases, it is not possible to make an ML model completely robust against data errors [19]. A common approach to prevent feeding corrupted data to deployed ML models is to run data validation checks on the serving data on which the model is applied. Popular libraries for this task are *tensorflow data validation (TFDV)*[2] [4] or Deequ[3] [18]. They allow users to define a schema and constraints for the serving data (e.g., that a given attribute must not contain missing values), and efficiently execute this check before passing the data to an ML model. Jenga contains a custom `SchemaStresstestEvaluator` for feature data validation with a TFDV schema. This evaluator works analogous to the previous

[1] https://github.com/mdbloice/Augmentor
[2] https://www.tensorflow.org/tfx/guide/tfdv
[3] https://github.com/awslabs/deequ

one, but additionally records whether the check of a provided data validation schema would have correctly detected the negative impact of the data corruption. We provide an extensive example for this evaluator in Section 4.2.

3 USAGE AND CUSTOMISATION

We implement Jenga based on several popular open source ML frameworks in python. We leverage *pandas* for data wrangling, and *numpy* for numerical computations. We implement feature extraction and preprocessing via *scikit-learn*'s pipeline abstraction, and also use classical ML models from this library. We rely on *keras* and *tensorflow* for defining and training neural networks.

In the following we first give an example of how to use Jenga to evaluate the impact of data corruptions (Section 3.1), and subsequently discuss how to implement custom tasks and data corruptions in Jenga's API in Section 3.2.

3.1 Evaluating the Impact of Data Errors

The core use case of jenga is to evaluate the impact of certain data corruptions on a prediction task. This can be implemented with a few lines of code: We have to instantiate the task and data corruptions that we want to evaluate, and can execute the evaluation with Jenga's `CorruptionImpactEvaluator`. This allows us to measure the impact of a predefined list of data corruptions on the predictive performance of a model.

```
# Create the prediction task
task = IncomeEstimationTask()
# Train a baseline model
model = task.fit_model(task.train_data,
 task.train_labels)
# Specify the data corruption to test
corruption = MissingValues(column='age',
 missingness='mcar', fraction=0.05)
# Create the evaluator
evaluator = CorruptionImpactEvaluator(task)
# Run the evaluation with 10 repetitions
result = evaluator.evaluate(model,
 num_repetitions=10, corruption)
# Impact on predictive performance
print(f""" Score on
  clean data:     {result.baseline_score}
  corrupted data: {result.corrupted_scores} """)
```

Here, we setup a task, train the corresponding model and define the corruption that we are interested in. We provide these to the evaluator together with the specification of the number of repetitions to execute for each corruption. The evaluator repeatedly corrupts the (copied) test data of the task, computes the prediction quality of the model on the corrupted data and finally provides a result object with the corresponding scores for each corruption to investigate. Note that we could also have specified more than one data corruption to evaluate.

3.2 Custom Tasks and Data Corruptions

We design Jenga with the goal to make it easy for data scientists to wrap their existing code as a prediction task, which allows them to reuse our data corruptions and evaluators. In addition, we also make it easy to design custom data corruptions. Therefore, we next describe how to implement the two basic building blocks of Jenga, a `Task` and a `DataCorruption`.

Implementing a custom task. Jenga allows data scientists to implement custom tasks with low effort. We provide an abstract base class `ClassificationTask` with two methods that users must implement. In the constructor, users have to load the input data for the task. Next, they have to implement the `fit_model` method, which trains the accompanying prediction model for the task from training data provided in a pandas dataframe. The model produced by this must support scikit-learns predictor API. Finally, the `score_on_test_data` must be implemented, which computes the desired metric for the task (e.g., ROC AUC) from the predicted label probabilities of the model.

Implementing a custom data corruption. At the core of Jenga are data corruptions, whose impact on the predictive performance of a model we want to investigate. Data corruptions transform a dataframe into another dataframe with potentially corrupted values. We provide an abstract base class, `DataCorruption`, that users can extend by providing only a single method, called `transform`. In the following listing, we implement a data corruption that mimics a case where duration that needs be expressed in seconds is accidentally recorded in milliseconds (e.g., scaled by a factor of 1000) in a fraction for the rows.

```
class MillisInsteadOfSeconds(DataCorruption):
 ...
 def transform(self, data):
  # Operate on a copy of the data
  corrupted_data = data.copy(deep=True)
  # Pick a random fraction of the rows
  rows = np.random.uniform(len(data)) < self.fraction
  # Multiply the column values of the chosen rows
  corrupted_data.loc[rows, self.column] *= 1000
  return corrupted_data
```

We first conduct a deep copy of the input data, which we will corrupt later on. Then, we randomly pick the indexes of the rows that we want to corrupt, and finally mulitply their values by a 1000 to mimic milliseconds. Note that tasks and data corruptions implemented with our API can be readily used in the existing evaluators from Jenga, as outlined in Section 3.1.

4 EXAMPLE USE CASES

We discuss two examplary use cases of our framework that resemble real world problems which we encountered in production ML applications. Note that we provide implementations (in the form of Jupyter notebooks) for all these use cases in our github repository at https://github.com/schelterlabs/jenga.

4.1 Measuring the Robustness of a Model against Incomplete Data

Overview. In our first experiment, we showcase how to study the impact of missing values on the predictions of a model. This targets a common usage scenario, where data scientists, who have a trained model in production (or ready for production), want to study its robustness towards incomplete data with Jenga. They want to reach a conclusion on how well the model itself (in combination with different missing value imputation methods) can mitigate the impact of missing values in the serving data. Incomplete data is a very common issue in real world deployments, where data is often missing as a result of programming errors, data integration issues or unanticipated schema changes in an external data source.

Setup. We experiment with a logistic regression model for our income estimation task from Section 2.1. The goal of this task is to predict from demographic data whether an individual has a high income. We train a model on clean training data, and evaluate its predictive performance (in terms of ROC AUC) on test data with synthetically injected missing values. We focus on four categorical attributes in the data: `education`, `marital_status`,

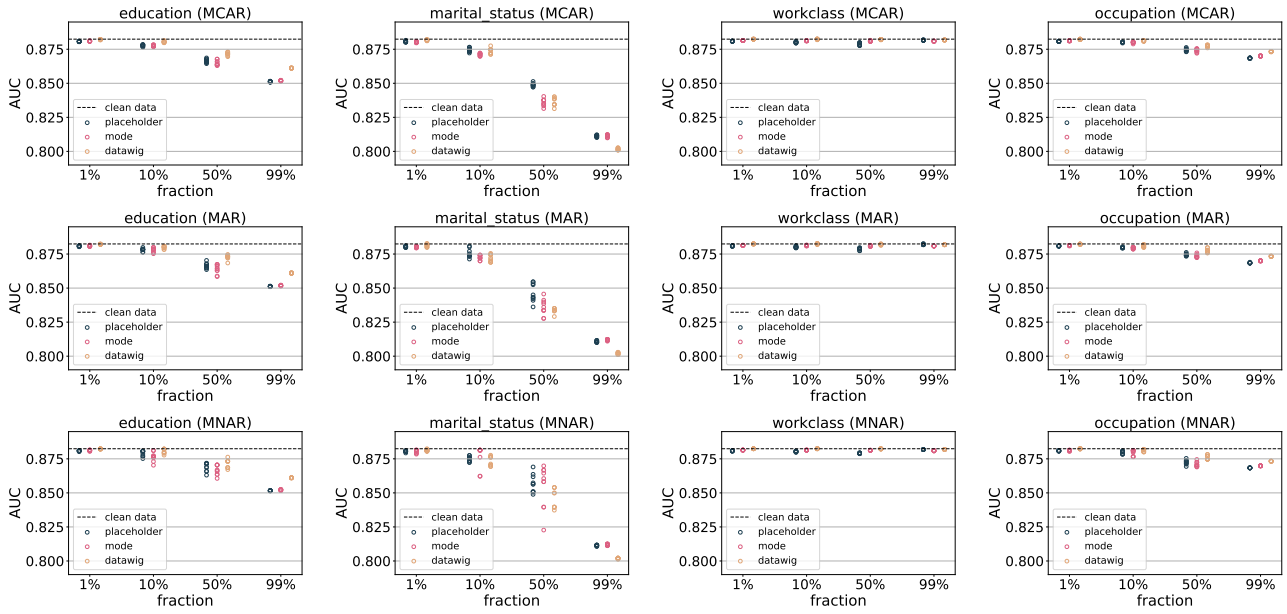

Figure 1: Evaluation of the robustness of a model for the income estimation task against incomplete data. We plot the AUC score achieved with different missing value imputation strategies (*placeholder*, *mode* and *datawig*) against the fraction of injected missing values. The impact differs by attribute and there is no clear dominating imputation strategy, indicating that it is difficult to make the model fully robust against this type of data error.

`workclass`, and `occupation`, and inject missing values into 1%, 10%, 50% and 99% of randomly chosen values of a given attribute.

We repeat this process for all three kinds of missing values ("missing completely at random" (MCAR), "missing at random" (MAR), "missing not at random" (MNAR)) as discussed in Section 2.2. We repeat each individual configuration ten times, and report the performance on corrupted test data (in comparison to the performance on clean data), where we differentiate between three different ways to make the model handle the missing values:

- First, we replace missing values with a constant *placeholder* symbol.
- Secondly, we replace missing values with the *mode* (the most frequent value in the column) via scikit-learn's `SimpleImputer`
- Thirdly, we train a dedicated ML model to impute missing values based on the structure present in the complete records [2]. We leverage the *datawig* library[4], which automatically featurises tabular data and trains a neural network to predict the missing values.

Results. The experimental results are shown in Figure 1. We find that the impact of the missing values is highly dependent on the attribute we target. There is nearly no impact for `workclass`, a very minor impact for `occupation` for less than 50% missing values, a much stronger impact for `education`, and we encounter the highest impact for missing values in `marital_status`. We additionally see that the impact is in some cases different for different types of missing values, e.g., values "missing not at random" in the `marital_status` attribute seem to be easier to handle than the other types of missingness.

In summary, we find no clear dominating strategy for handling the missing values in this particular task. Having the model deal with the missing values via a placeholder symbol is simple and works well in many cases. However, there are some setups where leveraging a dedicated missing value imputation strategy helps, e.g., datawig for a high fraction of missing values in `education` or for `occupation`. We conclude that the model itself cannot handle missing values reliably in all cases, even in combination with imputation. Thus, the data scientists need to put checks in place to safeguard the serving data on which the model is applied.

4.2 Stresstesting Integrity Constraints for ML data

Overview. Our next experiment shows how to put safeguards in place for an ML model. This experiment applies a schema and constraints for ML data, and executes a stresstest for them, as discussed in Section 2.3. We leverage the product review classification task discussed in Section 2.1, where the goal is to predict whether uses found the review of a videogame helpful or not.

We train a model for this task, and additionally create a schema with integrity constraints for the test data in TFDV. Next, we run Jenga's `SchemaStresstest` which generates random data corruptions for the test data, and determines whether our schema catches these errors, and what the impact of these on the prediction quality of the model (in terms of ROC AUC) would have been.

In real world use cases, it is difficult for data scientists to come up with an appropriate schema and constraints for their data, and we develop our stresstest to uncover errors which are not caught by the current schema. As a consequence, data scientists can iteratively improve their integrity constraints until they pass the stresstest.

[4]https://github.com/awslabs/datawig

```
from jenga.tasks.reviews import VideogameReviewsTask
from jenga.evaluation.schema import SchemaStresstest
import tensorflow_data_validation as tfdv
# Setup task
task = VideogameReviewsTask()
# Create a schema to test
train_data_stats =
 tfdv.generate_statistics_from_df(task.train_data)
# Auto-infer schema from training data
schema = tfdv.infer_schema(statistics=train_data_stats)
# Manually adjust schema
review_date_feature =
 tfdv.get_feature(schema, 'review_date')
review_date_feature.distribution_constraints
 .min_domain_mass = 0.0
# Define model to include in stress test
model = task.fit(task.train_data, task.train_labels)
# Run stress test with 250 randomly generated
# data corruptions
stress_test = SchemaStresstest()
results = stress_test.run(task, model, schema,
 num_corruptions=250, performance_threshold=.03)
```

Setup. The code above shows the setup of the experiment. We generate a schema for the feature data of the task, with a semi-automatic approach, where we first have TFDV automatically infer a schema for the data (via `tfdv.infer_schema`).

The schema correctly identifies the data types and categorical domains of most of the attributes of the data. It is too strict however, as it does not account for the fact that all the values in the `review_date` column will change for future data. We manually adjust the schema for this attribute by setting the minimum domain mass that must be shared between the values found at schema inference time and the future values to zero, allowing new values to appear in the column. The following listing shows an excerpt of the schema and constraints for the data, containing type information, completeness requirements and domain values for the data attributes.

```
...
feature {
 name: "star_rating"
 type: INT
 presence { min_fraction: 1.0 } }

feature {
 name: "verified_purchase"
 type: BYTES
 domain: "verified_purchase"
 presence { min_fraction: 1.0 } }

feature {
 name: "review_date"
 type: BYTES
 domain: "review_date"
 presence { min_fraction: 1.0 }
 distribution_constraints { min_domain_mass: 0.0 } }
...
string_domain {
 name: "verified_purchase"
 value: "N"
 value: "Y"
}
...
```

We evaluate the schema with a stress test which applies 250 randomly generated data corruptions to the serving data of the model and measures their impact on the prediction quality.

Results. The model achieves an AUC of 0.78828 on clean data, and we consider all predictions on corrupted data with more than 3% decrease in prediction performance as failures. Jenga categorizes the results as following:

- True positives, where TFDV reports a schema violation and the prediction quality on the corrupt test data drops below the threshold.
- True negatives, where TFDV reports no schema violation and the prediction quality on the corrupt test data is within the threshold.
- False positives, where TFDV reports a schema violation, but the prediction quality on the corrupt test data does not drop below the threshold. Note that it might still make sense to capture and investigate these data errors, as they can be indicators of problems in preprocessing code or external data sources.
- False negatives, where TFDV reports does not report a schema violation, but the prediction quality on the corrupt test data does drop below the threshold. These are the most important findings from a stress test as they indicate data errors to which the model would be vulnerable in production. It is imperative to adjust the schema to catch these errors.

In the following, we list several findings from our stress test example in Table 1 and discuss them.

True positives. Out of the 250 corruptions, we find 88 true positives. For example, we find that the model crashes for missing values in the numeric `star_rating` column, and that the prediction quality drops more than 3% for gaussian noise in this column and for a large number of swapped values between the `verified_purchase` and `title` column. Note that all of these errors are correctly detected by TFDV.

error type	*column(s)*	*frac*	*comment*
True positives			
missing values	`star_rating`	.25	crash
swapped values	`review_body, vine`	.75	unseen values
swapped values	`verified_purchase, title`	.45	unseen values
missing values	`vine`	.53	incompleteness
gaussian noise	`star_rating`	.25	type (int to float)
True negatives			
encoding	`vine`	.72	no changes
encoding	`review_id`	.83	column not used
swapped values	`review_id, product_parent`	.17	columns not used
missing values	`product_id`	.27	column not used
False positives			
missing values	`vine`	.93	unseen values
gaussian noise	`star_rating`	.16	type (int to float)
swapped values	`product_id, marketplace`	.35	unseen values
encoding	`marketplace`	.72	unseen values
False negatives			
scaling	`star_rating`	.92	range check missing
encoding	`title_and_review`	.76	no encoding checks
missing values	`title_and_review`	.80	no length checks
swapped values	`title_and_review, review_headline`	.75	no length checks

Table 1: Results found by the schema stress test for detecting impactful data errors on the product review task.

True negatives. We additionally find 75 true negatives, which mostly include cases where a textual column is being corrupted which is ignored by TFDV, but also not used by the model, whose prediction quality is therefore not affected by the corruption.

False positives. We encounter 39 false positives. We for example see that even a high number of missing values in the `vine` column

do not strongly affect the prediction quality, as well as a low number of noisy values in the `star_rating` column or encoding errors in the `marketplace` column, which is not used by the model.

False negatives. The most important results from the stress test are false negatives, e.g., data corruptions that are not detected by our TFDV schema, but strongly affect the prediction quality of the model. In a real world use case, we need to extend our schema to catch all these errors. We see that scaling values in the `star_rating` column strongly affects the prediction quality. This is an indicator that we should add a range check for this column to our schema. Furthermore, all kinds of errors in the `title_and_review` column negatively affect the prediction quality. This is a textual column for which TFDV does not generate constraints automatically. Checks for both the length and encoding of the values in that column are required to capture the outlined errors.

We argue that it should become a best practice to execute such stresstests for data errors before putting ML models into production, and we think that such testing capabilities should be integrated into common ML deployment pipelines.

5 RELATED WORK

Addressing the challenges in productionizing ML models is a field with growing interest in recent years [2, 8, 12, 16, 20]. Several solutions were proposed for validating ML models and their predictions. Most of these originate from a statistical ML or a data management perspective. Approaches from the ML community are based on distributional assumptions about the data shift, such as label shift [13], and covariate shift [1]. These assumptions often seem inapt to describe practically relevant data changes for engineers, such as the errors described above. Moreover, the proposed methods often limit themselves to adapting a particular model or learning paradigm.

There exist several approaches from the data management community to validate the input data of ML pipelines. For example, Google's TFX platform [4] offers validation for input data via a feature schema, and Deequ [17] enables unit tests for data, but both of them do not quantify the potential impact of errors on the model predictions. On a related note, there is a growing body of work on model monitoring [19], model diagnosis [5] and model unit testing for neural networks [11].

6 LEARNINGS & CONCLUSION

During our work on real world ML deployments, we have repeatedly come across scenarios where data errors heavily impacted deployed models and applications.

Missing values in data can in some cases, propagate through various connected pipelines until a customer facing model crashes, and it is very tedious to trace these errors back to the original data source which introduced the missing values. In internationalised applications, which operate on text in non-western languages, it is common to encounter encoding issues which are often introduced by a wrongly configured intermediate data store, and are again very hard to pinpoint and fix. Another common source of errors is calendar-related data, where dates and durations are often incorrect, e.g., due to movable holidays. Furthermore, often ML models are trained by specialised teams, and then handed over to business teams. In such cases, we often experienced that the data provided to the ML experts had not been sampled in a representative way by the business team, and as a consequence, the resulting model will not perform well later on due to the dataset shift introduced by the non-representative sampling.

These experiences motivate our presented library Jenga, which enables data scientists to evaluate the performance of ML models under data errors. Jenga builds on existing ML libraries, and allows practitioners and researchers to quickly build ML testing suites for their models with a broad range of data errors that we observed over several years of maintaining ML applications. We think that is is necessary to establish a set of best practices for testing ML models, analogous to established best practices like unit testing and integration test in software engineering. The goal of Jenga is to collect a huge library of data corruptions that occur in the real world, and uses these to automate the testing of ML models, ideally with an integration into upcoming systems for continuous integration for ML [14].

In the future, we aim to extend Jenga to extend more diverse tasks (e.g., regression problems or ranking problems). We will continue to work on Jenga as part of our recently proposed vision for automated ML model monitoring with respect to data quality [15]. We hope that Jenga can contribute to future research on data governance for end-to-end management platforms for ML.

ABSTRACT

Many distributed databases deploy primary-copy asynchronous replication, and offer programmer control so reads can be directed to either the primary node (which is always up-to-date, but may be heavily loaded by all the writes) or the secondaries (which may be less loaded, but perhaps have stale data). One example is MongoDB, a popular document store that is both available as a cloud-hosted service and can be deployed on-premises. The state-of-practice is to express where the reads are routed directly in the code, at application development time, based on the programmers' imperfect expectations of what workload will be applied to the system and what hardware will be running the code. In this approach, the programmers' choice may perform badly under some workload patterns which could arise during run-time. Furthermore, it might not be able to utilize the given resources to their full potential – meaning database customers pay more money than needed.

In this paper, we present Decongestant: a system which will automatically and dynamically, as the application is running, choose where to direct reads, sending enough reads to secondaries when this will reduce load on a congested primary and boost the performance of the database as a whole, but without exceeding the maximum data staleness that the clients are willing to accept. A central insight is to use measured latency of read operations on primary and secondaries to determine whether the primary is congested.

In an experimental evaluation, we demonstrate our system adapts well to dynamically changing workloads, obtaining performance benefits when they can arise from use of the secondaries, while ensuring that returned values are fresh enough given client requirements. Our approach is decentralised and can be used by both cloud-consumers and on-premises users: it uses only client observations and the limited diagnostic data provided by the database to its clients.

1 INTRODUCTION

Distributed databases have become a popular offering due to their scalability and elasticity. Distributed databases typically deploy a combination of data sharding and replication over multiple nodes to provide both scalability and availability. Thus, there are typically multiple copies of data, and some distributed database offerings expose those to programmers via a performance tuning parameter where one can decide to which node (primary or secondary) the read requests should get routed. The challenge is to use this tuning knob wisely to balance the load, for good performance, while minimizing its pitfalls, namely access to potentially stale data. One typical example in this space is MongoDB, a popular NoSQL distributed database management system. MongoDB Atlas[1] is the corresponding cloud-hosted MongoDB service.

MongoDB internally is a classic log-based, primary-copy replication system. It is usually run as a replica set, where each node keeps a logical copy of the database [35]. Each replica set is a log-replicated state machine [34]. In cloud settings, all nodes are usually placed within one geographical region, but spread in different availability zones. There is one primary copy which processes all write operations. Each secondary copy pulls the updated log from the primary and then replays it to keep up with the primary. Thus, data on the secondary copies might be stale compared to that on the primary copy in a workload with frequent write operations. During a fail-over, one secondary copy is elected as the new primary.

Clients can direct read operations to either the primary copy or to a secondary copy (this is called *Read Preference* [24] and is indicated in the API as an optional parameter of a read request call). When reading from the primary copy on a healthy cluster with default settings, fresh data is returned. But if the primary copy is saturated, the read latency can be huge. In that case, a user can gain larger throughput and lower read latency by reading from secondary copies; however, data returned might be stale.

The state-of-the-art practice is to "hard-code" the Read Preference, making a choice explicitly when writing the application program. This is not ideal for several reasons. Firstly, developers may have insufficient information about workload and hardware capabilities for them to make a sensible choice when the code is written. Also, the "sensible" choice may differ over time as workload changes, but hard-coding is not able to adapt dynamically. Furthermore, the standard Read Preference options are limited to either primary or secondary, so that the nodes in a MongoDB cluster will never do the heavy-lifting together.

This paper shows how to capture knowledge *at run-time* of the current condition, and change the Read Preference dynamically, so that the overall performance of MongoDB can be improved. We adjust the proportion of secondary reads sent, in order to distribute work among the nodes of a MongoDB cluster. Our goal is to gain extra performance by reducing problems of congested nodes, so that the database can serve more clients without upgrading its hardware. This should help lower the cost of MongoDB for users. But we need to ensure each client sees data values that are "fresh enough" for the client's requirements, so we must avoid directing reads to a secondary when that node is too stale.

Achieving this is not easy. We must make the decision on where to direct a read on client-side information. Our approach

[1] https://www.mongodb.com/cloud/atlas

aims at both MongoDB cloud-consumers and on-premises users – there is no need to alter server code, or monitor the database's internal state. We only take measurements from the outside, as operations are submitted, or call the service API for the limited statistics it provides on the current status of servers. Our key insight to overcome this challenge is to measure the latency of read operations that were recently submitted by the client, for those sent to the primary and also for those sent to the secondary. In this paper we look at reads individually; if the client also needs session properties such as read-your-own-writes, or transaction-respecting snapshots, those can be obtained through capabilities of MongoDB, e.g. causal consistency[37].

Our key contributions are

- A mechanism to determine at run-time as either a cloud-consumer, or an on-premises user, whether the primary, or the secondaries, are currently congested with reads. This uses client-side measurements of the latency of recent read operations with each Read Preference, estimates the server-side component of that by subtracting network round-trip latency, and compares these estimates from the primary versus from the secondaries. This ratio is used in a simple feedback control. A high ratio indicates too much load on the primary, so more reads should go to the secondaries as long as those are not too stale. On a low ratio, indicating too much load on the secondaries, fewer reads should be sent to the secondaries in future.
- A system design and prototype implementation, called Decongestant, which uses this mechanism. It chooses at run-time to send a client's reads to primary or secondary as appropriate, for good performance while respecting a client-assigned limit on acceptable staleness of values returned.
- Experimental evaluation of Decongestant, to show that it maintains good performance while workloads vary (and it can do better than either hard-coded approach), and that it respects a client-assigned limit on staleness.

Our earlier poster paper [21] presented initial ideas in this direction. Here we adapt some of the text from there, describing motivation, background, and related work. Novel features of Decongestant, compared to [21], are: avoiding use of a secondary when it would give values that are too stale for client requirements (and never send reads to the secondaries when the clients can not tolerate any stale reads); capability to deliberately, in a controlled way, mix use of primary and secondaries in the same period, in order to outperform either hard-coded approach; improved latency estimate that separates network effects from those of server congestion; evaluations that show run-time adaptation to workloads that change in various aspects; a new S workload we use to demonstrate the validity of staleness reports from the servers (which Decongestant uses) as estimate of client-observed staleness.

The remainder of the paper is structured as follows. Section 2 introduces relevant concepts in MongoDB. Section 3 presents the design of Decongestant. We provide an evaluation of Decongestant in Section 4. Section 5 highlights, and contrasts with, related work. We conclude in Section 6.

2 BACKGROUND

Some text in this section already appeared in [21].

2.1 A brief overview of MongoDB and MongoDB-as-a-Service

As we have already discussed in section 1, MongoDB internally uses asynchronous primary-copy replication for fault-tolerance. This means it usually runs as a replica set. Fail-overs are rare [35]. This justifies our approach that exploits some of the capacity of the secondary nodes.

MongoDB also provides a sharding mechanism to enable horizontal scaling [22]. The entire database can be sharded into a number of shards, where each shard is a distinct subset of the whole database. Each shard can be deployed as a replica set, geographically far away from one another. MongoDB sharding is not used in this paper but the techniques we describe can be applied to sharded clusters, which support the same Read Preference API as standalone replica sets.

MongoDB Atlas is a "containerized" version of MongoDB, provided as a service. MongoDB Atlas has the same core as the open source Community Server, but with some additional, closed source functionality (e.g., security features). Customers are able to use MongoDB Atlas in a pay-as-you-go model. MongoDB Atlas is hosted on diverse cloud service platforms: Amazon Web Service (AWS), Microsoft Azure, or Google Cloud Platform (GCP). Customers can select the service locations, memory and storage size, number of vCPUs, etc. The database can be deployed with a few clicks. It is also trivial to scale-up if more computational power or storage are needed. MongoDB Atlas has various APIs for different programming languages and applications.

The main source of operational metrics offered by both MongoDB and MongoDB Atlas is via calling MongoDB `serverStatus` command. The MongoDB metrics can be queried frequently, but these deal only with internal properties, and do not report on hardware/OS/network aspects. MongoDB Atlas provides extra sources of operational metrics through MongoDB Atlas web API. This supplies some hardware metrics. However, those metrics only update once per minute, and can only be queried at a limited rate (100 requests per minute per project).

2.2 Read Preference

The Read Preference setting on read operations determines where they will be sent by MongoDB clients [24]. Read Preference options include `primary` (default), `primaryPreferred`, `secondary`, `secondaryPreferred`, and `nearest`. If the Read Preference `primary`, or `secondary`, is selected, then the reading request is directed to the primary copy, or to one of the secondary copies, respectively. Note that in MongoDB the users can not specify which of the secondary copies a read request will be sent to. `PrimaryPreferred` and `secondaryPreferred` provide users the option that in most cases the reads are sent to the primary or the secondary copies. However, in the situations where the preferred copy is not available, the reads are routed to the other option. When Read Preference `nearest` is chosen, the reading requests are directed to the nearest copy to the client based on client-measured network latency. The MongoDB client libraries periodically check which node is nearest. In our research, we use options `primary` and `secondary` to balance the workload among all MongoDB nodes.

When requesting a read on secondary copies, the clients can include a `maxStalenessSeconds` value to specify the maximum data staleness the client is happy to accept [25]. However, the `maxStalenessSeconds` value must be set to 90 seconds

or larger. As we will show later, Decongestant is able to bound the data staleness to substantially lower levels (eg 10 seconds).

The client driver randomly chooses a secondary copy to route a secondary read, as long as the latency between the secondary nodes do not differ by more than 15 milliseconds [28]. In our experiments, all secondary reads are directed to one secondary copy randomly.

There is another tuning knob in MongoDB called Read Concern which determines the durability, consistency, and isolation properties of the data read from MongoDB [23]. We use `local` Read Concern, which is the default setting, in all our experiments.

2.3 Data staleness in MongoDB

Let's first look at how MongoDB performs a write operation. When a write request reaches the primary copy of MongoDB, there will be an atomic transaction issued doing two things: 1) applying the database operation to the primary; 2) recording operations on the primary's operation log (called `oplog`). Once that transaction commits on the primary (and after waiting for any other transactions with earlier `oplog` entries to also commit), the `oplog` entry is visible to secondaries, and it will then be pulled by the secondaries and written to their `oplog`. After that the secondaries will apply the operations. Each node records the timestamp of the latest `oplog` applied (called `lastAppliedOpTime`). The `lastAppliedOpTime` of each node are known by all others.

By calculating the difference between the `lastAppliedOpTime` of a secondary node and the `lastAppliedOpTime` of the primary node, we can estimate the data staleness of the secondary node. Since the `lastAppliedOpTime` of one node is known by all other nodes, the comparison can take place at any of the MongoDB copies. This information can be provided to a client in the `serverStatus` command.

There is a potential source of error here. The `lastAppliedOpTime` for a secondary copy as recorded on the primary copy, might be earlier than the truth. This is because that the latest `lastAppliedOpTime` of the secondary copies might not yet have been transmitted to the primary copy. So the data staleness of the secondary, when calculated using statistics reported by the primary copy, might be larger than reality. Similarly, the `lastAppliedOpTime` of the primary copy as known on some secondary copy may be earlier than the current truth. So data staleness as calculated from the status at a secondary node can be smaller than reality. In Decongestant, we use the `serverStatus` information from the primary for this calculation, to be conservative in enforcing a client-requested limit on staleness.

3 DESIGN OF DECONGESTANT

In this section, we describe the design of Decongestant, an automated system to direct the reads dynamically for MongoDB during run-time of the application.

Our design needs to overcome some challenges. The foremost challenge is to have a single mechanism that can detect a variety of congestion situations. The bottleneck resource of a node of MongoDB, when it saturates, varies with different DBMS's hardware, configurations, and workload. It may be CPU usage, memory usage, even having a large number of Write Ahead Logs (WAL) waiting to be flushed to the disk. We also need a mechanism to detect when a secondary is too stale to be usable, considering the client's freshness requirement. An important challenge is that our mechanisms need to use only information readily available to the consumers of the MongoDB, as we do not do any modification of the server. On the client-side, we can observe requests and responses for the operations submitted to the service, and we also have some limited access to server information through available status reports (but this is much less detailed than what a server-side design could exploit).

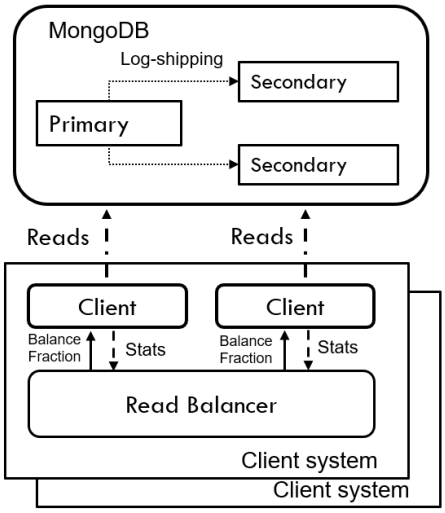

Figure 1: A simplified architecture of Decongestant

In this section, we first present an overview of Decongestant and we briefly introduce the decision-making component of the system, called Read Balancer. Then, we describe how the client application works in Decongestant. After that, we depict how Read Balancer does its job. Finally, we discuss some of the design details and considerations of Decongestant.

3.1 System Architecture

Figure 1 shows a simplified architecture of Decongestant. A component called Read Balancer resides on each client system where (maybe multiple) client applications are executing. The Read Balancer decides the percentage of read operations to be sent to the secondary copies. This percentage is to be chosen so as to improve the overall performance, by redirecting reads when one of the servers is congested, but not using secondaries at all if their data would be too stale to meet the client's specified demand for data freshness. The Read Balancer communicates with the clients via a few shared variables:

- The latest decision for each client on what percentage of the read-only transaction should be directed to the secondary copies, called *Balance Fraction*. The range of the Balance Fraction is between 10% to 90%, inclusive; or 0%. Balance Fraction is set to 0 when Decongestant estimates some secondary's data staleness exceeds the client's limit, so they will stop sending any read requests to the secondaries till this is remedied. The clients can express that they are not willing to accept any stale data, by setting the data staleness limit to 0.
- Two lists which keep track of client-observed transaction latencies (for reads that were sent to Primary and to Secondaries, respectively).

3.2 How do the client applications work in Decongestant?

In Decongestant, a client is expected to cooperate with the Read Balancer, as follows. Before invoking any read-only transaction call, the client first examines the most recent decision on the Balance Fraction from the Read Balancer. Then the client should flip a biased coin, and with a probability equal to the Balance Fraction, the call should to be directed the secondary copies of MongoDB. The clients keep track of the latency of their read-only transactions, and report them to the Read Balancer through one of the shared queues (depending on which Read Preference was actually used in the call).

3.3 How does the Read Balancer work?

In this section, we show how the Read Balancer acts. We first provide a high level overview of the Read Balancer and how it changes the Balance Fraction. Then, we discuss some technical details and considerations. Algorithm 1 shows the pseudo code for Read Balancer.

The Read Balancer periodically updates suggestions on the Balance Fraction, i.e. the percentage of read-only transactions that should go to the secondary copies. On system start up, the Read Balancer initializes the Balance Fraction as 10%. The Balance Fraction will be updated periodically (every 10 seconds in our implementation). We keep the Balance Fraction so it is never 0, except when this is needed because a secondary is too stale to use given the client-defined limit, or when the clients are not willing to accept any stale data. Similarly, Balance Fraction is never 100%. The reason to exclude the extreme values is to ensure that some reads are regularly using each server, so that the system has up-to-date data on the situation of the servers.

Within each period (when there is no need for the Read Balancer to recalculate its recommended fraction), the Read Balancer pings all nodes of the MongoDB cluster regularly, in order to record the Round Trip Time (RTT) between the client system and each node. In addition, the Read Balancer queries the primary node of the MongoDB replica set once per second, using the `serverStatus` command to get the latest data staleness estimation of each secondary node. Whenever the data staleness estimation on *any* secondary node exceeds the maximum data staleness the clients are willing to except, the recommended Balance Fraction will become 0, and so all read requests will be directed to the primary, until the data staleness situation on secondary nodes improves. (See detailed discussions in section 4.)

By the end of each period, the Read Balancer retrieves, from the shared lists, the recorded latencies of those read-only transactions that were sent to the primary during the period, and it calculates the median ("P50") value of these latencies; similarly it takes the list of latencies for read-only transactions sent to the secondaries, and determines the median of those. The Read Balancer then calculates a value called Server-Side Latency, for the reads on primary and secondaries, respectively. Server-Side Latency for a corresponding Read Preference option equals the median ("P50") latency of the read requests with that Read Preference option minus the median ("P50") Round Trip Time (RTT) of all MongoDB nodes corresponding to that the Read Preference option. See subsubsection 3.3.1 for details. These numbers act as estimates for the delay experienced by operations as they are performed on the server, including time spent within executing the MongoDB instance and also delays in the operating system or disk. The intuition here is that when a node is congested, this

Algorithm 1: Algorithm for Read Balancer

SharedVars: StaleBound - Client-set limit on data staleness
$L_{client,primary}$ - list of client-observed latencies of primary-sent ops
$L_{client,secondary}$ - list of client-observed latencies of secondary-sent ops
Bal - current Balance Fraction; initially LOWBAL

PrivateVars: RecentBal - list of 4 recent periods' Balance Fractions; initially all LOWBAL
Staleness - array of staleness reported by primary for each secondary
RTT - array of round-trip times to each server

Constants: DELTA - one-period change in Balance Fraction (10%)
LOWBAL - lowest value for non-zero Balance Fraction (10%)
HIGHBAL - highest value for Balance Fraction (90%)
LOWRATIO - latency ratio above which we increase Balance Fraction (0.75)
HIGHRATIO - latency ratio below which we decrease Balance Fraction (1.3)

```
1  Function Rcv-ServerStatus():
2      Update Staleness from ServerStatus
3      if (StaleBound == 0) or (max(Staleness) > StaleBound) then
4          Bal ← 0
5      else
6          Bal ← RecentBal.latest()
7      end
8  end
9  Function OnPeriodEnd():
10     L_ss,primary ← P50(L_client,primary) - P50(RTTprimary)
11     L_ss,secondary ← P50(L_client,secondary) - P50(RTTsecondary)
12     Ratio ← L_ss,primary / L_ss,secondary
13     if Ratio > HIGHRATIO then
14         NewBal ← min(RecentBal.latest() + DELTA, HIGHBAL)
15     else if Ratio < LOWRATIO then
16         NewBal ← max(RecentBal.latest() - DELTA, LOWBAL)
17     else if All RecentBal entries are the same then
18         NewBal ← max(RecentBal.latest() - DELTA, LOWBAL)
19     else
20         NewBal ← RecentBal.latest()
21     end
22     RecentBal.dequeue().enqueue(NewBal)
23     if (StaleBound == 0) or (max(Staleness) > StaleBound) then
24         Bal ← 0
25     else
26         Bal ← RecentBal.latest()
27     end
28 end
```

figure will increase, no matter whether the bottleneck resource is in MongoDB or elsewhere on the server.

The Read Balancer uses the ratio of the Server-Side Latency of reads on the primary, to the Server-Side Latency of reads on the secondary. To achieve the maximum performance possible of the MongoDB Cluster, all the nodes in the cluster should do the heavy-lifting together, sharing the work. This means, ideally, the ratio should be close to 1. If the ratio is much larger than 1, it means the primary copy is congested compared to the secondary copies. In this case, the Read Balancer increases the Balance Fraction for the next period, directing more reads to the secondary nodes. On the other hand, if the ratio of Server-Side Latency is much less than 1, indicating that the secondary nodes are congested more than the primary nodes, then the Read Balancer would decrease the Balance Fraction, sending less reads to the secondary copies in the next period. If the ratio is close to 1 and it has been close to 1 for quite a while, Read Balancer would also decrease the Balance Fraction to explore "downward". This is to make sure the reads go to the primary node as much as possible, in order to improve the data freshness and avoid potential stale reads [26]. Unlike our previous work [21], the Read Balancer does not look for one "correct" Read Preference in each period. Instead, it tries to balance the workload among all the nodes to achieve the best performance possible.

3.3.1 Server-Side Latency. As discussed before, the Read Balancer utilises Server-Side Latency to make decisions. Server-Side Latency of a Read Preference option is found as follows: we take the median latency of all read-only invocations with that Read Preference as observed on the client side in the previous period, minus the median Round Trip Time (RTT) of all MongoDB nodes corresponding to that Read Preference choice.

$$L_{ss} = P_{50}(L_{client}) - P_{50}(RTT)$$

In MongoDB, all nodes are spread across different availability zones within a region as much as possible, when deployed in a public cloud. The Round Trip Time (RTT) between a certain client and nodes in different availability zone varies. Although the difference is usually less than 2 milliseconds, it is enough to impact the latency observed on the client side for those workloads with light read-only transactions, such as YCSB, where the latencies themselves are sometimes only 1 to 2 milliseconds.

3.3.2 Bounded Data Staleness. The Read Balancer also talks to the primary node of the MongoDB replica set several times each period, to call `serverStatus` at the primary. It uses this information as described in subsection 2.3 to conservatively estimate the data staleness of each secondary node.

The clients can tell the Read Balancer the maximum data staleness they are happy to accept. As we have explained before, the MongoDB clients can only choose to read from either the primary node or from any secondary node, they can not specify which secondary node they would like the read requests to be sent to. So, as long as the Read Balancer finds the estimated data staleness of any secondary node is larger than the threshold set by the clients, the Read Balancer immediately notifies every client, that all future read requests should only be sent to the primary copy - the Balance Fraction is set to be zero. The Read Balancer resumes a non-zero Balance Fraction once the maximum estimated data staleness of the secondary copies drops below the threshold set by the clients.

One concern may be raised here. The Read Balancer restarts sending read requests to the secondary nodes once the maximum data staleness of all secondary nodes drops below the threshold. Would that extra work cause the data staleness to quickly go beyond the limit again? We had the same concern. Our empirical study shows that in MongoDB, data staleness increases gradually on the secondaries, but when it goes down, it drops swiftly, to nearly zero. The high-level idea is that the gradually increasing data staleness is caused by a congested primary node, which is too busy processing data requests so it is not able to provide the `oplog` to the secondary copies. But once the `oplog` is sent, the secondary nodes catch up quickly. See Section 4.5.

The data staleness for secondaries which is estimated by this method may be larger than what a client actually observes. As well as the possible overestimate from the primary copy not yet knowing very recent activity updating the secondary, there is also the possibility that there are `oplog` entries not yet applied to the secondary copies but these might not modify the particular data the MongoDB client queries. We are conservative, and avoid using a secondary if our (perhaps over-) estimate breaches the client-set limit on staleness. Section 4.5 reports experiments to check the alignment between the data staleness estimate used in our decision, and measurements in a targeted S-workload that observes latency at clients.

4 EVALUATION

In the following, we present an evaluation of Decongestant. We first introduce the methodology and settings we use in Section 4.1. We then demonstrate Decongestant's ability to detect and adapt to variation of workloads in Section 4.2. We explore Decongestant's ability of balancing the load among all MongoDB nodes to achieve better performance than using current practice in a read-intensive workload (Section 4.3), and Decongestant's capability of trading data freshness for performance in the workloads with a mixture of reads and writes (Section 4.4). Section 4.5 covers Decongestant's competence of bounding the data staleness. Finally, we show that running S workload concurrently has low impact on performance measurements of standard workloads, in Section 4.6.

4.1 Method

4.1.1 Platform. The experiments are executed on AWS. The MongoDB clients are on an AWS c4.4xlarge instance (16 vCPUs and 30 GB RAM), located in the region ap-southeast-2.

We deploy our own MongoDB cluster on AWS, in order to maintain consistent results independent of infrastructure and software version changes that are out of our control in MongoDB Atlas. We replicate the configurations from MongoDB Atlas in June 2020. The MongoDB version is 4.2.6. A 3-node MongoDB cluster is deployed on 3 AWS r4.2xlarge instances, which has 8 vCPUs and 61 GB RAM, located in the same region as the clients but different Availability Zones: ap-southeast-2a, ap-southeast-2b, and ap-southeast-2c, respectively.

4.1.2 Decongestant settings. In all following experiments, Decongestant considers the ratio of Server-Side Latency of the reads on the primary to the Server-Side Latency of the reads on the secondaries as being normal when the value ranges from 0.75 to 1.30. When the ratio is greater than 1.30, Decongestant considers that the primary is congested, and thus it increases the percentage of reads sent to the secondaries in the next period by 10%. A ratio less than 0.75 leads Decongestant to send 10% fewer reads to the secondary nodes in the next period, as it shows that the secondaries are more congested. Balance Fraction starts at 10%

Table 1: Percentage of transactions in the original TPC-C workload versus the read-write TPC-C workload used in the experiments.

	TPC-C	Read-Write TPC-C
Stock Level	4%	**50%**
Delivery	4%	4%
Order Status	4%	4%
Payment	43%	**20%**
New Order	45%	**22%**

and is capped at 90%. Decongestant revisits the Balance Fraction decision every 10 seconds. In our experiments, unless stated explicitly, the maximum data staleness the clients are willing to accept is set to be 10 seconds.

Read Balancer keeps the four previous records of the Balance Fraction. If they remains the same, Read Balancer pushes down the Balance Fraction by 10% in the next round.

4.1.3 Baselines. As well as showing the performance of our prototype system Decongestant, we also look at two baselines corresponding to current practice. In these, the clients run against MongoDB, without any Read Balancer installed, or any of the possible overheads of communicating with it; in the baseline Primary, each read is hard-coded with Read Preference set to `primary`. In baseline Secondary, each read is hard-coded with Read Preference as `secondary`.

4.1.4 Workloads. Two different sets of transactions are used here to evaluate the performance of Decongestant. We use YCSB [12] with varying read-write percentage: YCSB-A (50% reads and 50% writes) and YCSB-B (95% reads and 5% writes). YCSB represents a light-weight workload, with simple get and put operations. As a more demanding workload, we also use a variant of TPC-C (we call it read-write TPC-C). This uses the transactions from TPC-C, but unlike write-heavy traditional TPC-C, we aim here for a balance between read-only and update transactions. To do so, the percentage of Stock Level transaction, which represents a read-only transaction, is set to 50%. Table 1 shows the detailed breakdown of the read-write TPC-C workload as compared to standard TPC-C. The TPC-C queries are implemented by Kamsky [29] who has adapted the TPC-C benchmark to the MongoDB query language and transaction semantics, as well as adapting it to MongoDB's best practices.

4.1.5 S workload to monitor data staleness. In order to check whether Decongestant keeps the maximum data staleness promise, we need a method to sample the data staleness from the client side. While Decongestant uses estimates for staleness based on MongoDB's internal information on the status of oplog application, we want to validate our system's success using real measurements. So, we propose S workload (S stands for staleness). The S workload could be run standalone, but, in all our experiments[2], we generate this S workload alongside the main performance-focused OLTP workloads, such as YCSB, TPC-C.

The high-level idea of S workload is similar to our previous work [20, 40]. The S workload includes two workers (each worker can be implemented as a separate process or a thread): one writer and one reader. The job of the writer is to keep writing the current timestamp to a dedicated item in the database at a high frequency. It is not necessarily to write as fast as possible, but it should work at least as fast as the reader does.

Periodically, the reader probes the contents from the various copies of the dedicated cell. In each probe, the reader sends out two read requests: one with the Read Preference Primary and the other with the Read Preference Secondary. The reader records the results. Then, in the analysis phase (after the experiment), we can determine the freshness of the data returned from the secondary reads by comparing the results between the primary read and the secondary read. A slight variation is done at times when the main application is not using the secondaries at all (and so clients will see no staleness at these times): the second read in each probe of S workload can be simply directed to the primary copy again.

The staleness monitoring approach used by S workload is a bit different from the one used by [20, 40]. In those prior works, the reader only sends one read request in each probe, with the Read Preference Secondary; during the analysis phase, the timestamp when the read is sent and the read value are compared, to determine the staleness gap. The assumption in their approach was that the timestamp in the dedicated cell in the object database keeps advancing smoothly. This assumption doesn't always hold when monitoring is run together with another existing OLTP workload. There are times when a write takes a long time to finish, causing the value in the dedicated cell of the primary copy to be unchanged for a while. By definition, the value in the primary copy is fresh. However, the timestamp when the read request is sent keeps going forward as the S-reads are generated continuously. So, if the approach described in [20, 40] is used, fake staleness might be reported.

Note that the data staleness measured by this S workload might be larger than the data staleness seen by any given application client, as S workload frequently updates the item being read, while some application read may be on slowly-changing data, where the returned value is correct even if the secondary is far behind in applying the oplog. Still, if we succeed in bounding staleness seen in S reads, we can be sure that any other application also has data that is at least this fresh.

4.1.6 Measurements. The experiments have two distinct styles. In some, we report on the time-varying properties through a run of a system when a workload is applied (perhaps the workload changes at specific points during the run). In those experiments, we report for each separate 10 second period on throughput of appropriate transactions during the period, P_{80} latency (that is, the time within which were completed 80% of reads of the period), the percentage of reads that were sent with Read Preference Secondary during the period, and sometimes data staleness, either as measured by S workload, or as estimated conservatively using reports from the primary of the max difference between any secondary's `lastAppliedOpTime` and that of the primary. Although Server-Side Latency is used by Read Balancer to make decisions, all latency reported in the following figures are end-to-end latency observed by the clients. Measuring the actual percent of reads sent to the secondary copies is done by counting the read operations which were sent to the primary copy and those sent to secondary nodes; we do not simply echo what Decongestant suggests through Balance Fraction.

Other experiments give a single data point for overall performance (throughput, latency or staleness) for runs in some situation, typically shown in a figure where some important parameter of the workload (eg number of clients) varies along the

[2] except in one experiment of Section 4.6.

x-axis. In these experiments, except where stated explicitly, each data point is taken from the average over 3 runs; in each run, measurements exclude the first 100 seconds, which is treated as a warm-up period.

4.2 Adapting to dynamic workload

We first claim that Decongestant is able to adapt well to variation of workloads. We compare it to the outcomes for the two baseline systems, where all reads have hard-coded read preference setting, so either all go to the primary, or all to the secondaries.

Figure 2 shows the throughput of read operations, 80-percentile latency (end-to-end) of read operations, and the actual percentage of reads which are sent to the secondary copies, during a run with a dynamically-changing workload. The workload in this run starts with YCSB-A (50% reads) with 180 clients, and swaps to YCSB-B (95% reads) at the 620^{th} second. S workload is running as well, throughout. For the first 90 seconds, Decongestant warms up shifting from its initial setting with 10% of reads on secondaries, over time sending more and more read operations to the secondaries (Figure 2 (c)), until the highest amount we allow (90%) of the reads are secondary ones. During this period, the throughput increases (Figure 2 (a)) and the 80-percentile latency drops (Figure 2 (b)). From the 90^{th} second to the 620^{th} second, the percentage of reads sent to the secondary copies stabilises at 90%. This is the same performance we achieved in previous work [21]. At the 620^{th} second, the workload shifts from YCSB-A (50% reads) to a read-dominated YCSB-B (95% reads). Decongestant quickly responds by sending less reads to the secondary. The percentage of reads routed to the secondary nodes stables at 70% under this workload. The intuition is that the primary node deals with 5% writes and a bit less than 1/3 of reads, and two secondary nodes process between them a bit more than 2/3 of the reads. Recall that our MongoDB cluster is a three-node cluster with the same capacity in each node. This shows that Decongestant successfully balances the read load proportionally to the capacity behind each Read Preference option. As a result, the throughput (Figure 2 (a)) of the read operations is higher than either baseline (only sending read requests to the primary or secondaries); and the 80-percentile (Figure 2 (b)) latency is better than baselines.

Once the system has adjusted to the changed workload, the ratio of Server-Side Latency of the reads on the primary to the Server-Side Latency of the reads on the secondaries remains between 0.75 to 1.30. During this period, Read Balancer tries to push more reads to the primary on every fifth period. But as the Read Balancer finds it does not work well, the Read Balancer bring the Balance Fraction back to 70%.

Figure 3 is another example showing that Decongestant successfully notices and adjusts to the workload shifts; here both read-intensity and total load change. At the beginning the workload is YCSB-B (95% reads) with 180 clients. Then, after 230 seconds, it shifts to YCSB-A with 20 clients. On system start up, Decongestant increases the percentage of reads sent to the secondaries (Figure 3 (c)). The percentage soon reaches an optimised state at 70%. During this period, the throughput of read operations in Decongestant is higher (Figure 3 (a)) and the 80-percentile latency of those reads (Figure 3 (b)) is lower than when the Read Preference is hard-coded as Primary or Secondary. At the 230^{th} second, the workload switches to YCSB-A (50% reads) with 20 clients. Decongestant quickly decreases the percentage of reads sent to the secondary, as the primary can now handle all the load. The allocation becomes stable at the minimum we allow (10%), to make sure Read Balancer keeps getting enough recent information on the state of the secondaries, so we will detect future congestion if it were to happen.

Figure 4 shows the performance of Decongestant with the dynamic read-write TPC-C workload. Unlike previous experiments on YCSB, the throughput and 80-percentile latency (end-to-end) here are reported for each 1 minute interval, and the actual percentage of secondary Stock Level transactions are recorded every 10 seconds. The workload starts with 20 clients, and then at the 5^{th} minutes the client number increases to 200. After 5 more minutes, it goes down to 20 clients. Figure 4 (c) shows the actual percentage of secondary Stock Level transactions. It starts at around 10%. From the 5^{th} minute, Read Balancer is able to notice the high contention environment, and quickly pushes up the percentage of secondary Stock Level transactions. This soon brings the throughput (Figure 4 (a)) and 80-percentile latency (Figure 4 (b)) of Decongestant to a level similar to the situation where the Read Preference is "hard-coded" as Secondary. During the 5^{th} minute to the 10^{th} minute, there are a few downward spikes in the actual percentage of secondary Stock Level transactions. They are caused when the maximum data staleness on the secondary copies exceeds the clients' threshold, which is 10 seconds; this is detected by Read Balancer, so we stop sending Stock Level transactions to the Secondary copies. The measured percentage is not 0, as the staleness check is run once per second, while the percentage reported here is taken over 10 seconds. The pink vertical lines in the figure shows the seconds where all reads are directed to the primary, due to exceeding data staleness. After the 10^{th} minute, the number of clients drops to 20. Read Balancer gradually brings back most of the Stock Level transactions to the now-uncongested primary node, to provide lower staleness.

4.3 Achieving better performance by sharing load in read intensive workloads

In this section, we show how Decongestant's capability of balancing the read load among *all* the nodes of MongoDB cluster, achieves a better peak performance for read-intensive workloads, compared to hard-coding Read Preference as either Primary or Secondary. Each hard-code approach leaves some node underloaded. Decongestant does not try to specially identify whether the workload is read intensive; instead, the exact same approach is used throughout. Each data point in a plot is the average over three runs, excluding the warm-up period.

Figure 5 shows the throughput of reads, 80-percentile latency (end-to-end) of reads, and the actual percentage of reads sent to the secondary copies, plotted against number of clients, in YCSB-B (95% reads). We first discuss the actual percentage of reads sent to the secondary copies (Figure 5 (c)) over a varying number of clients. We can see with a low load of between 10 to 50 clients, Decongestant sends most read requests to the primary node. Decongestant sends more reads to the secondary copies, with the percentage growing corresponding to client number, in the range between 50 to 100 clients. The percentage of secondary reads is roughly stable at around 70% when the number of clients ranges from 120 to 200. This means, in a MongoDB cluster with 3 nodes of the same capacity, the primary nodes deals with 5% write operations and around 30% read operations; while the two secondary nodes between them process 70% read requests. This shows that all three nodes do the heavy-lifting together.

When the client number is between 120 to 200, all three nodes work together, instead of the primary node or the secondary

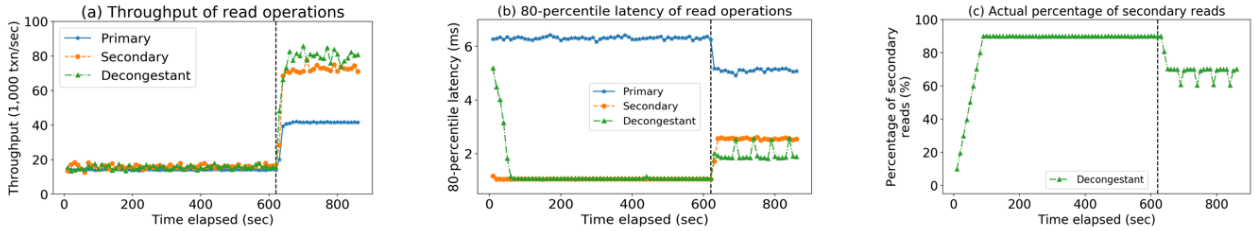

Figure 2: Decongestant's ability to respond to sudden increase of the read-write ratio in YCSB. The plots show the throughput of read operations, 80-percentile latency (end-to-end) of read operations, and the actual percentage of reads sent to the secondary copies, in a dynamic workload. The dynamic workload starts with YCSB-A (50% reads) with 180 clients, and swaps to YCSB-B (95% reads) at the 620th second. The vertical dotted line shows the time when the variation happens.

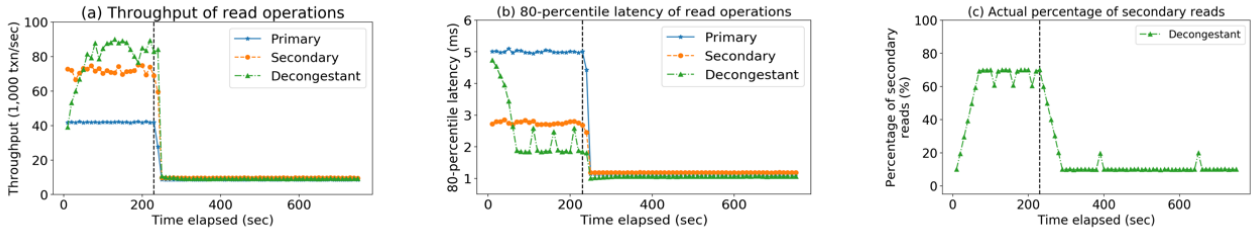

Figure 3: Decongestant's ability to respond to sudden decrease of both the read-write ratio and the number of clients, at the same time, in YCSB. The plots show the throughput of reads, 80-percentile latency (end-to-end) of reads, and the actual percentage of reads sent to the secondary copies, in a dynamic workload. The dynamic workload starts with YCSB-B (95% reads) with 180 clients, and swaps to YCSB-A (50% reads) with 20 clients at the 230th second (indicated by the vertical dotted line).

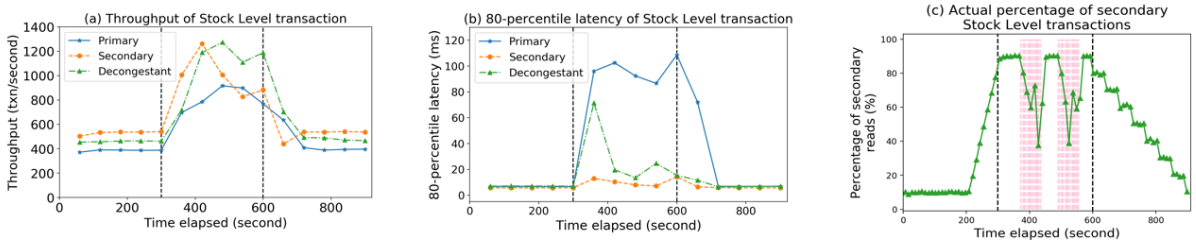

Figure 4: Decongestant's response to variations of client number in read-write TPC-C. The client number starts at 20. It bursts to 200 clients at the 5th minute. The client number drops back to 20 at the 10th minute. The black vertical dotted lines show the times when the variations of the client number happen. The plots display the throughput of Stock Level transactions, their 80-percentile latency (end-to-end), and the actual percentage of Stock Level transactions sent to the secondary copies. The throughput and the 80-percentile latency (end-to-end) are reported on per-minute bases, while the actual percentage of secondary Stock Level transactions are recorded once per 10 seconds. The pink vertical dotted line shows the seconds where all reads are directed to the primary, due to exceeding data staleness.

nodes only, so it is not surprising that Decongestant is able to achieve a throughput (Figure 5 (a)) that is around 30% higher than only routing the read requests to the secondary copies, and around 2.5 times than only sending read operations to the primary node. We also see that the 80-percentile latency for Decongestant is lower that the two hard-coded systems when the load is high.

We do not plot data staleness for YCSB-B (95% reads) here. The 80-percentile data staleness, measured both by S workload and Decongestant, for YCSB-B are constantly zero in all our experiments. This situation is not very surprising, as there are only 5% of writes in the workload. There are occasionally one or two data staleness values observed to be one second by the S workload, when the Read Preference is "hard-coded" as Secondary. Since the granularity for the data staleness is one second, we do not feel it is very meaningful.

4.4 Trading data freshness for performance

In this section, we show that Decongestant is able to trade data freshness for performance when needed in the workloads with a mixture of reads and writes. Again, we point out that Decongestant never tries to identify whether a workload has a mixture of

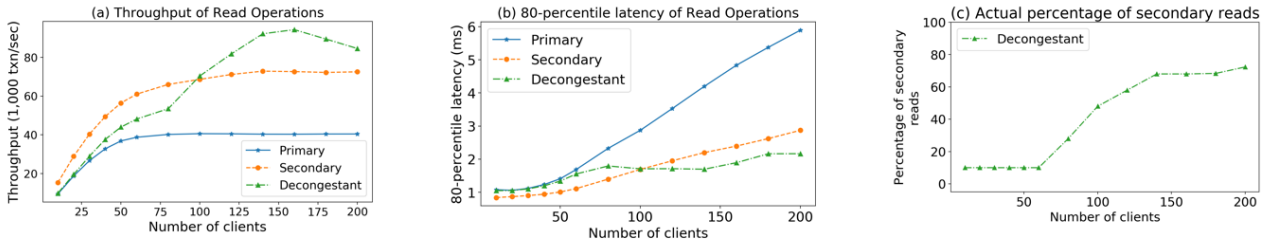

Figure 5: Performance trends with increasing client count. The plots show the throughput of reads, their 80-percentile latency (end-to-end), and actual percentage of reads sent to the secondary copies, against the number of clients in YCSB-B (95% reads).

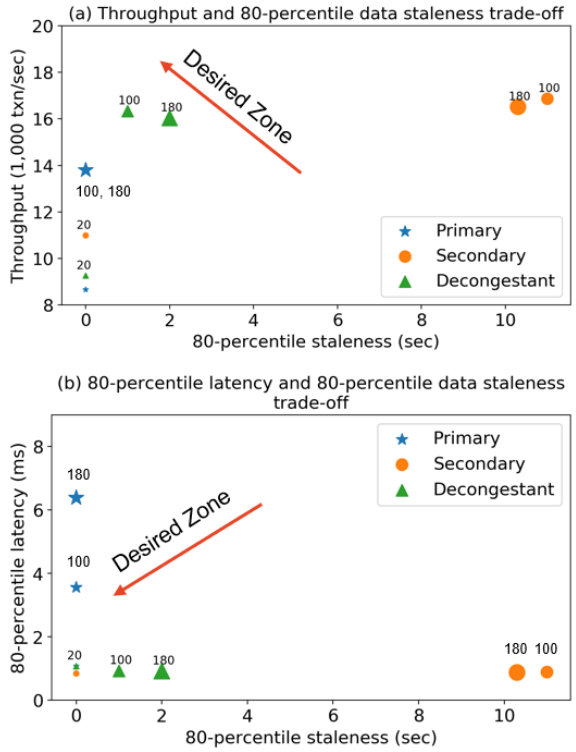

Figure 6: Performance and 80-percentile data staleness trade-off in YCSB-A for read operations. (a) shows the trade-off between the throughput and the 80-percentile data staleness of the read requests. The number above the marks and the size of them indicates the number of clients. The upper left corner is the desired area for Decongestant, with large throughput and small data staleness. (b) shows the trade-off between 80-percentile latency (end-to-end) and 80-percentile data staleness for read operations. The lower left corner is the target zone for Decongestant, with small latency and data staleness.

reads and writes or it is a read-intensive one: the same method works for either scenario. The experiments in this section are each run three times for each setting, and the average value is taken and shown as a point in the charts.

Figure 6 shows the performance and the data staleness trade-off for YCSB-A (50% reads). To avoid the figures being too cluttered, we only include 3 groups of data points here. The number above the marks and the size of them indicates the number of clients. Three client numbers are chosen: 20, 100, and 180, representing light, medium, and heavy load, respectively. Figure 6 (a) demonstrates the trade-off between the throughput of reads and the 80-percentile data staleness of them. The upper left corner is the desired zone in Figure 6 (a), with small data staleness and large throughput. When the load is low (20 clients), the data points for the three situations, whether always directed to either the primary or secondary nodes or with Decongestant, are close. When the load is medium (100 clients) and large (180 clients), Decongestant is able to push the data point close to the desired zone while the baselines are far away (Primary having low throughput, and Secondary seeing high staleness).

Similar conclusions can be reached for the trade-off between latency and data staleness from Figure 6 (b). The lower left corner is now the ideal area, as it shows small values in both latency and data staleness. The advantage of using Decongestant is clear, offering a sweet spot in terms of 80-percentile latency and 80-percentile staleness.

Figure 7 shows the performance and the data staleness trade-off in a read-write TPC-C workload (50% reads). Figure 7 (a) reports the trade-off between the throughput of the Stock Level transaction and the data staleness, where the upper left corner is desirable. Figure 7 (b) depicts the trade-off between latency of Stock Level transactions and data staleness, where the lower left corner is the target. Decongestant is able to push the data points toward the desired zone.

4.5 Bounding data staleness

In this section, we discuss the data staleness issue. We make two claims here:

- Decongestant's estimation of data staleness, from `serverStatus` reports, closely aligns with the data staleness seen by the clients.
- When the maximum data staleness of a secondaries copy exceeds the threshold set by the clients, the clients of Decongestant will not see this.

The largest data staleness the clients are willing to accept is set to 10 seconds, and we measure the staleness seen by clients, with S workload from Section 4.1.5.

Figure 8 compares the data staleness from `serverStatus` to the one seen by the clients, against time elapsed. The workload is one run of YCSB-A together with S workload, with. 100 clients. This figure shows that maximal data staleness known by the Decongestant via MongoDB `serverStatus` (and used by Decongestant to detect cases where excessive staleness means that reads should avoid the secondary nodes), aligns quite well

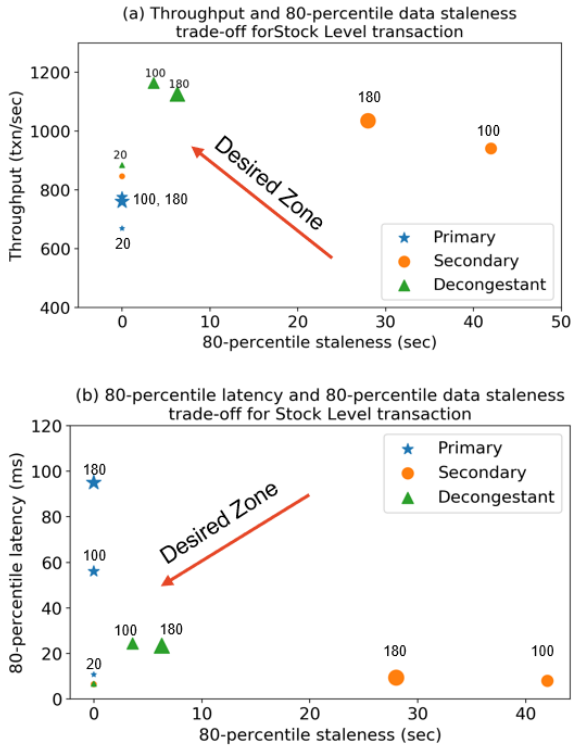

Figure 7: Performance and 80-percentile data staleness trade-off for Stock Level transacts with read-write TPC-C. (a) shows the trade-off between throughput of Stock Level transacts and 80-percentile data staleness. The number above the marks and the size indicates the number of clients. The upper left corner is the desired area for Decongestant with both large throughput and small data staleness. (b) shows the trade-off between 80-percentile latency (end-to-end) of Stock Level transactions, and 80-percentile data staleness. The lower left corner is the target zone for Decongestant with both small latency and data staleness.

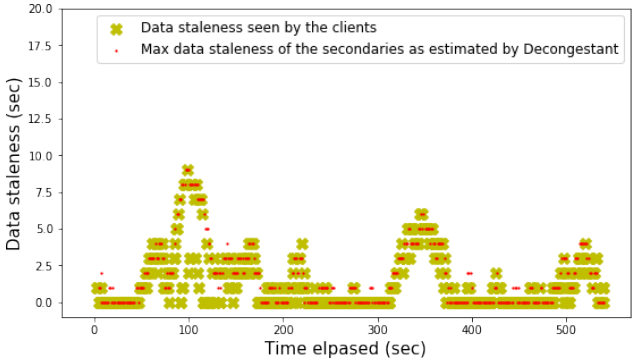

Figure 8: The maximum data staleness of the secondaries estimated by the Decongestant versus the one seen by the clients, against time elapsed. The workload is YCSB-A together run with S workload, from 100 clients. The data staleness estimated by Decongestant is good as long as it is not smaller than the one seen by the clients.

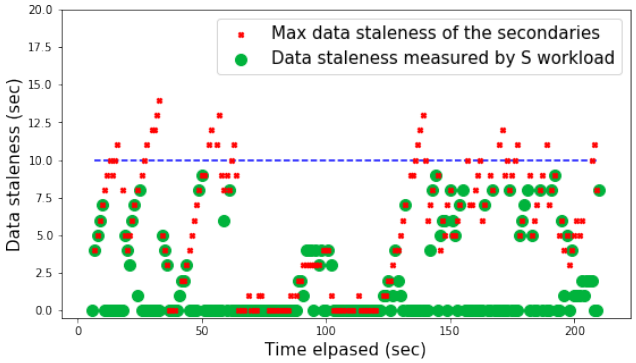

Figure 9: Data staleness measured by S workload versus the max data staleness of the secondaries in Decongestant, with the data staleness limit set to be 10 seconds. The workload used here is read-write TPC-C with 60 clients.

with the data staleness seen by the clients. In some cases, we can see that the data staleness estimated by the Decongestant is larger than the ones seen by the clients. This is acceptable, as the Decongestant records the maximum data staleness among all secondaries, while the S workload measures the data staleness on an arbitrary secondary node.

Figure 9 shows that when data staleness of a secondary copy exceeds the threshold set by the clients, the clients of Decongestant will not see this: Decongestant reacts in time and sends their reads to the primary. The workload used here is read-write TPC-C with S workload, on 60 clients. The blue horizontal dashed line shows the data staleness limit set by the clients, which is 10 seconds. The red squares in the figure depict the maximum data staleness of the secondaries, which sometimes goes beyond the threshold. However, the Decongestant clients are protected from this — all green circles are below their data staleness limit.

We have done a more detailed analysis on the MongoDB internal diagnostic data, trying to understand what happens behind this data staleness pattern (Figure 9). The high-level idea is that when the primary is overloaded, the secondaries trying to read the oplog from the primary can stall. That is, a secondary has a cursor open on the primary's oplog and calls the "getMore" operation. When the primary is overloaded, it can take a long time to service this operation, and during that time, the secondary can't move forward because it does not know about the newer operations (i.e., it gets more and more stale). Eventually the primary gets around to servicing the "getMore" request and sends a large batch of operations to the secondary. Since the secondary isn't overloaded, it can apply the operations quickly and catch up.

Now we discuss how the primary is stalled. During this period, several checkpoints completed on the primary and the disk of it was 100% utilised. The checkpoints took a long time to complete (around 30 seconds on average). During that time the latency grows. MongoDB had noticed the lag and was deliberately throttling update operations via a mechanism called "flow control" [27]. This might be part of the reason for the throughput of read-write TPC-C workload being unstable (Figure 4 (a)). Once the flush completes, the primary comes back to life and serves a batch of "getMore" operations quickly.

Our method to bound the data staleness still works reasonably well when the clients set the data staleness limit to a very low value, such as 3 seconds (see Figure 10). Such a low data staleness limit is challenging, as the granularity of the data staleness reported by MongoDB `serverStatus` is one second. So a system has little time to react to increasing staleness before the limit

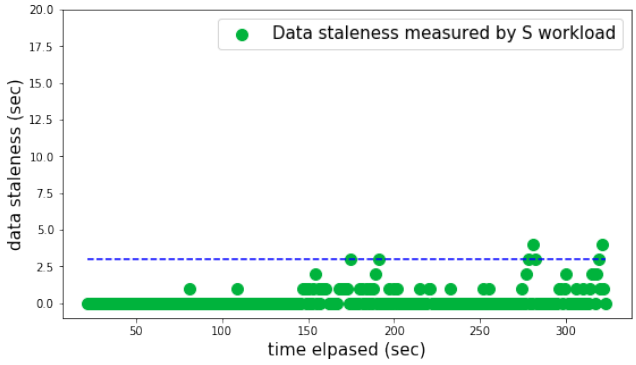

Figure 10: Data staleness measured by S workload in Decongestant with the data staleness limit set to be 3 seconds. The workload used here is read-write TPC-C with 200 clients.

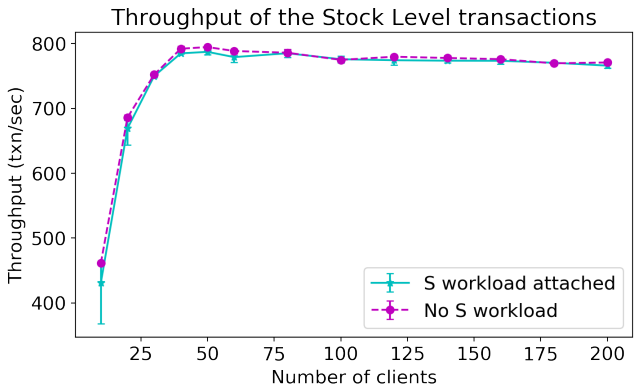

Figure 11: Throughput of Stock Level transactions when running the read-write TPC-C workload, with or without S workload.

is breached. The workload used in Figure 10 is read-write TPC-C with 200 clients. We can see, in most cases, the client-observed data staleness are bounded as requested, though two data points have staleness value 4 seconds.

4.6 Impact of S workload

Lastly, we claim that running S workload alongside a performance benchmark (such as read-write TPC-C), causes little distortion on the results recorded for performance. Figure 11 shows the throughput of Stock Level transactions, when running the read-write TPC-C workload with the S workload (as it does in our previous experiments), compared to what is measured when the read-write TPC workload is run alone. The Read Preference used here is Primary. We can see that the throughput of the performance benchmark remains at a similar level when running with or without the S workload.

5 RELATED WORK

Some text in this section already appeared in [21].

The trade-off between performance and consistency in distributed storage system has been studied for a very long time. This body of work is profoundly influenced by CAP theorem [9] and its later PACELC formulation [1].

Various storage systems offer different consistency properties. Some make the choice for the users, such as BigTable [10] and Spanner [13], which guarantee some form of strong consistency. Others give users some freedom to make their own decisions, including Amazon Dynamo [16], Cassandra [30], as well as MongoDB. There is also a trend that Database-as-a-Service is hosted on top of shared-disks systems (usually provided by large cloud computing vendors), such as Amazon Aurora [39] and Microsoft Socrates [3], whose features usually impact on the exposed consistency characteristics of these Database-as-a-Service.

There is a huge amount of work evaluating the behaviour of distributed storage systems, in order to help users make more informed choices. Wada et al and Bermbach et al benchmark a large variety of distributed storage systems from the customers' view [5–8, 40]. These works treat the distributed storage system as a black-box, and send read and write requests to it, just like normal customers would do. Our previous work [20] measured the inconsistency window between the primary copy and secondary copies of MongoDB Atlas at around 25 ms.

There are works which, rather than comparing the read and write results (as client-centric methods do), capture the trace of operations on various entities (chosen by the user), and then post-execution analysis determines whether an equivalent serial execution would give the same result in each read; if not an anomaly is reported [2, 17, 31].

Trading performance for data freshness for read-only transactions / queries has been explored [11, 18, 33]. For example [33] applied this idea to mix OLAP and OLTP workloads in a database cluster providing freshness guarantees, though requiring a central coordinator which sees all transactions. In contrast, our proposed Decongestant is decentralised, which can be used both by on-premises and cloud users, and can deduce overload situations by probing rather than seeing the complete workload.

Pileus is a self-configuring system based on a Service Level Agreement (SLA) [36]. Within one SLA, there are a few subSLAs. Each subSLA includes a consistency requirement, a latency bound, and a utility score. Similar to our work, Pileus has "monitors" residing on the client nodes (each client has one monitor), and these probe periodically to decide which node a reading request should be directed to, so that the highest utility score among all subSLAs is achieved. Tuba [4] is an extension for Pileus. Tuba is a DBMS which is able to reconfigure itself, based on the observed latency and subSLA hit and miss ratio from all clients. Possible reconfiguration includes: changing primary replica, adding or removing secondaries, and varying synchronization periods between the primary and secondary copies.

Some recent work for self-configuring database applies machine learning technologies. There are automated systems able to tune large number of database knobs [38], adding and deleting indices [14], forecasting workloads [32], scaling resources [15], providing advice on partitioning [19], etc.

6 CONCLUSION

We presented the design and evaluation of Decongestant, a system which is able to automatically and dynamically determine Read Preference settings for read operations in MongoDB, in order to get good performance while delivering fresh-enough data to clients. Our solution works for both on-premises MongoDB deployments and MongoDB-as-a-Service. The key innovation is a client-based way to detect when either the primary, or one of the secondaries, are congested, by comparing estimates of the

time taken on the relevant server for performing recent read operations. When congestion is detected through these estimates, the system shifts reads away from the congested server; however, this decision is also constrained by estimates of the current data staleness on the secondaries.

This design avoids the need in current practice for application programmers to hard-code the decision of whether reads should go to primary or to secondaries (and thus risk seeing stale values). Instead the decision is made dynamically at run time by Decongestant, adapting to the recent situation in the servers.

Our experimental evaluation is done with YCSB-A, YCSB-B, and with workloads that run TPC-C transactions with a balance between read-only and updating transactions. We showed that Decongestant is able to adapt to workload shifts as they occur, and that it delivers good performance that respects client-chosen limits on data staleness. Indeed, in read-intensive workloads such as YCSB-B, we can outperform both hard-coded alternatives.

In future work, we plan to look at more sophisticated feedback control when adjusting read preference, and to support richer client SLAs as well as maximum staleness. We will explore the possibility of extending Decongestant to other database systems, which have a leader-follower architecture similar to MongoDB.

ABSTRACT

Many big data systems employ LSM (Log-Structured Merge)-tree-based key-value stores, such as RocksDB and Cassandra. LSM-tree has a multi-level data structure and can transform random writes into sequential ones by compaction operations. However, the compaction operations in LSM-tree introduce the read/write amplification issue, which will increase the processing latency and incur throughput drops. In this paper, to eliminate the impact of compaction on the throughput stability and latency of LSM-tree, we propose a new compaction method called DLC (Delay Level-0 Compaction). We notice that workloads like OLTP are periodically high. For example, an electronic business platform may have high requests at noon and night but have few requests in the early morning. When the workload becomes high, many data will be flushed to Level-0 of LSM-tree from memory, which will trigger frequent Level-0 compaction and lower the system's throughput. The main idea of DLC is to delay Level-0 compaction at a high load and resume compaction when the system becomes low-loaded. As the low-loaded system generally has enough free CPU cores and I/O bandwidths, performing the delayed compaction will not affect the system's overall performance. Therefore, we can maintain stable throughput even when the system is high-loaded. To implement DLC, we first define a new I/O estimation model to characterize the workload. Then, we determine whether to delay Level-0 compaction according to the characteristics of the current workload. Moreover, to deal with sustained high workloads, we invent a burst compaction strategy to reduce throughput dropping and present two implementations for the bursty compaction. We implemented DLC on Myrocks and experimentally compared DLC with the original MyRocks and a state-of-the-art scheme called SILK under various OLTP workloads. The results show that DLC outperforms MyRocks and SILK in both latency and throughput stability.

1 INTRODUCTION

LSM-tree (Log-Structure Merge tree)[17] has been widely used in key-value stores, such as RocksDB and Cassandra. LSM-tree maintains a multi-level data structure, and all data in each level are stored using Sorted String Tables (SSTables), in which all key-values are sorted in order. Data are flushed from memory to the SSTables in the first level (Level-0, or L0 for simplicity) through sequential writes. As sequential writes are much faster than random writes, LSM-tree can offer high writing performance. However, when the SSTables in Level-0 exceeds a threshold, LSM-tree performs a compaction operation to merge the SSTables in Level-0 with those in Level-1. If Level-1 also exceeds the threshold, next compaction will also be triggered to merge SSTables in Level-1 with those in Level-2. During a compaction process, both CPU and the I/O bandwidth will be highly used, resulting in the decrease of the overall throughput. To validate the influence of the compaction in LSM-tree, we ran the default OLTP workload in *sysbench*[13] (see Section 6.1 for the detailed settings) on RocksDB and tested the system's throughput. As shown in Fig. 1, there are periodical throughput-drops when the system has been running for a long time, because the system has to perform periodical compaction to merge up-level data into low levels.

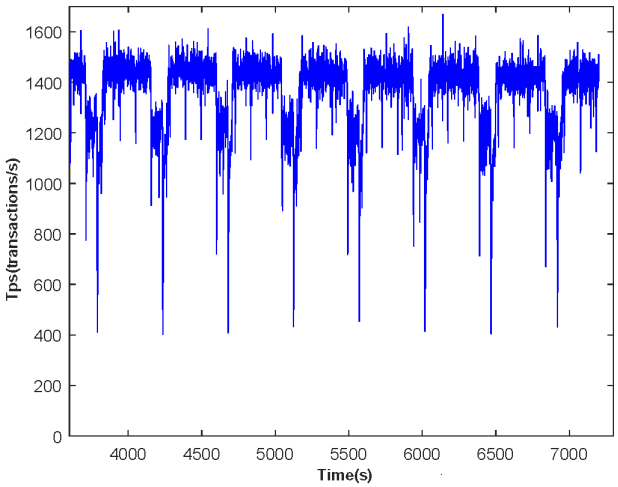

Figure 1: Throughput drops of RocksDB when running on the default OLTP workload generated by *sysbench*.

The stability of throughput is critical to many applications. For example, an online short-video social network platform like TikTok can not tolerate periodical high latency when playing videos. To improve the throughput stability of LSM-tree, various solutions [3, 6, 16, 18] have been proposed. Among them, the state-of-the-art method is SILK [3], which won the best paper of ATC 2019. The experimental results of SILK showed that it can maintain stable throughput for about 2500 seconds. However, we experimentally found that when SILK kept running for 3500 seconds, it had dramatic throughput drops and the throughput became unstable. This is mainly because the compaction scheduling in SILK can not adapt to the workload changes well.

The compaction operations in LSM-tree are known as background operations (also called internal operations), because they are scheduled on background periodically. A compaction operation consumes a great number of I/O bandwidths because it has to read and write a large amount of data. This is the main reason that affects the throughput stability of LSM-tree. The key

challenge to keep throughput stability is how to schedule compaction when the I/O bandwidth is used heavily. An intuitive solution is to reserve some I/O bandwidths for compaction operations, but different levels in LSM-tree have different needs of I/O bandwidths. Therefore, it is hard to reserve appropriate I/O bandwidths for LSM-tree to maintain throughput stability.

Basically, we can roughly divide workloads into two types, namely write-intensive workloads and read-intensive workloads. For write-intensive workloads, the competition for disk I/O between parallel compaction operations is the main reason causing the instability of throughput. In such cases, write stalls may occur and lower the throughput [16]. For this reason, most of existing studies[1, 3, 16, 18] were toward optimizing compaction for write-intensive workloads. However, so far, there is no solution that can offer continuously stable throughput for LSM-tree.

In this paper, we also focus on write-intensive workloads and aim to improve the throughput stability of LSM-tree and lower the processing latency. We propose a new compaction scheme named DLC (**D**elay **L**evel-0 **C**ompaction). DLC aims to achieve three goals. First, it should have a more stable throughput than RocksDB and SILK [3] when running for a long time. Second, it is expected to have lower latency. Third, it should adapt to periodically varying workloads, i.e., the arriving rate of requests is high for a period and then becomes low. The basic idea of DLC is to delay L0[1] compaction at a high load and to resume L0 compaction at a load load. Thus, DLC can work well on workloads with periodically varying workloads[3]. Briefly, we make the following contributions in this study:

(1) We propose a new I/O model to estimate the I/O bandwidth of the current workload effectively and precisely. Our I/O model is inspired by the model proposed by SILK [3], but we devise new estimation functions. Differing from the I/O model of SILK that simply summarizes the data size of all read and write operations, our I/O model introduces two new ideas. First, we remove the data size of write operations, because LSM-tree always writes data to in-memory Memtables, meaning that write operations will not occupy I/O bandwidths. Thus, it is not reasonable to include the written-data size in I/O bandwidth estimation. Second, we divide read operations into *Get* and *Scan* because these two read operations have different I/O costs in LSM-tree. We demonstrate that our model is more accurate than the SILK model and can allocate I/O bandwidths for background compaction more effectively.
(2) Based on the proposed I/O model, we present a new compaction scheme called DLC that delays L0 compaction at a high load and resumes L0 compaction at a load load. We use the new I/O model to characterize the I/O bandwidth need of the current workload, and determine whether the workload is high or low. When the workload is high, we delay L0 compaction. This differs from the compaction schemes in RocksDB and SILK. RocksDB uses a threshold-based compaction scheme and will trigger many compaction operations at a high load, leading to frequent throughput drops. SILK also claims to delay compaction, but it delays the bottom level[2].
(3) Although DLC works well for periodically high workloads, the SSTables in L0 may accumulate under sustained high load, leading to write stalls/stops and serious throughput drops. Thus, we devise a bursty compaction strategy to make DLC suitable for sustained high workloads. We present two implementations for the bursty compaction, namely "resume full compaction" and "resume part compaction". The former is to compact all the SSTables in L0, while the latter is to compact selected part SSTables in L0.
(4) We implemented DLC in MyRocks (MySQL with RocksDB) and evaluated DLC using the *sysbench* tool. We generate various OLTP workloads, including periodically varying workloads, workloads with different read-write ratios, workloads with a long time of a high load, and sustained high workload. We compare DLC with MyRocks and SILK (with the DLC I/O estimation model). The results in terms of throughput and latency show that DLC achieves the best throughput stability and the lowest latency in all experiments.

The remainder of the paper is structured as follows. Section 2 introduces the background and related work. Section 3 presents the I/O estimation model. Section 4 details the DLC strategy. Section 5 discusses the bursty compaction policy. Section 6 reports experimental results. And finally, in Section 7, we conclude the paper and discuss future work.

2 BACKGROUND AND RELATED WORK

2.1 LSM-tree

The basic client operations of LSM-tree are the same as the other NoSQL key-value databases[14, 23], which include *Insert, Delete, Update, Get*, and *Scan*. For convenience, we call *Insert, Delete*, and *Update* as write operations and *Get* and *Scan* as read operations. We take RocksDB as an example to introduce the LSM-tree structure. The RocksDB storage engine mainly consists of two part, Memtable and Immutable Memtables in memory and SSTables in the disk.

LSM-tree uses the Sorted String Table (SSTable) as the basic data structure, which stores key-value pairs in the disk. SSTable is a sorted table which mainly consists of data blocks and meta blocks. Meta blocks store indexes about data block and Bloom filter[5] for read. Data blocks store key-value pairs in sequence for quickly visited by read operations. SSTables are grouped by levels. We call the levels as L0, L1, ..., L_n in short from top to bottom. We call the levels near to the memory as up levels, e.g., L0, and the other levels as low levels. The SSTables in L0 are mainly flushed from Immutable Memtables in memory. The SStables in L1 and low levels are generated by major compaction.

There is one Memtable and one or more Immutable Memtables in memory. Memtable uses *Skiplist* as its structure. Skiplist is a data structure that uses probabilistic balancing. Its algorithms for insertion and deletion are much simpler and significantly faster than equivalent algorithms for balanced trees[19]. We can consider Memtable as an in-memory buffer for inserting, deleting, and updating. When Memtable reaches its capacity threshold, it will be transformed into Immutable Memtable, which cannot be modified by any (write) operations, and a new Memtable will be created for writing new key-value pairs. When a new Immutable Memtable is created, a background thread would be scheduled to flush the Immutable Memtable to disk as one SSTable, in which all the flushed key-value pairs are stored. The flush operation is also called minor compaction.

[1] L_i means Level-i in this paper.
[2] Here, Level-0 is the top level, and Level-i with the biggest i is the bottom level.

With SSTables being accumulated in the same level and reaching the threshold of the level, a major compaction will be triggered (in this paper, we simply use the term "compaction" to represent "major compaction" by default) and may schedule compaction for garbage collection to reduce disk usage and read cost[9][8]. Different levels have different thresholds for compaction, and when the SSTables in L_i or low levels reach the threshold of the level, compaction will be triggered. A compaction operation fetches one SSTable in the level, which triggers the compaction and the SSTables in the next level that have overlapping keys with the SSTable in the up level, then merges sort all key-value pairs in sequence. The merged key-value pairs are then written to new SSTables in the next level. When the flush and compaction of LSM-tree happen in the background, the system can answer write and read requests normally. The new data inserted by write operations can be put into Memtable directly, while read operations will visit Memtable, Immutable Memtables, and SSTables in all levels[9].

2.2 Compaction Optimizations for LSM-tree

2.2.1 Reducing Compaction Cost. There have been a lot of studies toward optimizing the compaction for LSM-tree. One idea is to reduce compaction cost. WiscKey[15] and HashKV[7] separate keys from values to maintain a smaller LSM-tree that contains keys and the pointer to the values, which is effective for large keys and write-intensive workloads. But their optimizations are not suitable for range scans. MonKey[9], Dostoevsky[10] change the structure of LSM-tree by tuning related parameters for different demands, and LSM-Bush[11] proposes a more general structure for more demands. Ahmad and Kemme[1] cope with spike caused by compaction by offloading compaction to a dedicated compaction server, and it solve the cache avalanche by smart warm-up strategy, which is a good method for a distributed database like HBase or Cassandra.

Some people proposed efficient scheduling algorithms to optimize compaction for LSM-tree. bLSM[20] bounds the write latency by using the spring-and-gear merge scheduler, which is not suitable for partitioning structure. Luo and Carey[16] suggest using 95% maximum throughput to run the experiments, which is adjusted to 90% in DLC experiments. dCompaction[18] proposes delayed compaction mainly for low-level compaction, which is a lazy compaction mechanism for write-intensive workloads. Chen et al.[8] uses a priority and fairness mixed compaction scheduling mechanism to reduce write amplification and read amplification.

LDC[6] decreases the tail latency and reduces write amplification by a novel Lower-level Driven Compaction, which is orthogonal to DLC. Most of them concentrate on low-level compaction and pay little attention to up-level compaction.

Other optimizations of compaction include LSbM-tree and TRIAD. LSbM-tree[21] adds one buffer for every level to decrease block cache miss and improve read performance after compaction, which concentrates on reducing cache miss after compaction. TRIAD[2] is designed for skewed workloads. It also delays L0 compaction until there is enough key overlap in L0 to be compacted. However, DLC delays L0 compaction according to the workload.

2.3 State-of-the-Art Optimization: SILK

SILK[3, 4] is the state-of-the-art optimization for the compaction in LSM-tree. In this paper, we mainly focus on improving SILK. Thus, in this section, we briefly introduce the details of SILK.

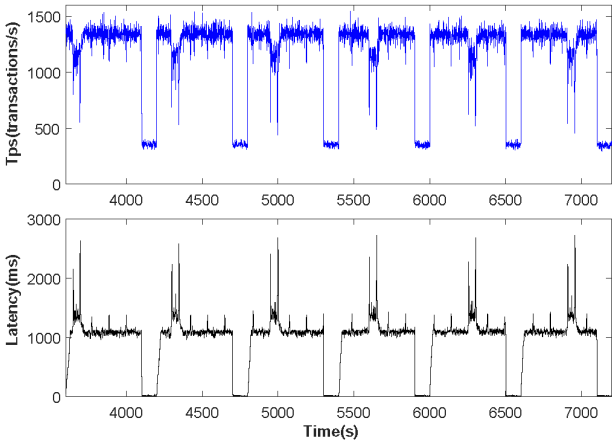

Figure 2: SILK's throughput drops and latency increasing.

SILK proposed an effective way to prevent latency spikes in RocksDB. It used an I/O scheduler for background analysis, paused scheduling low-level compaction when in high loads. The I/O scheduler in SILK can dynamically allocate bandwidth between client operations, so it can allocate more bandwidth to compaction during a low-loaded period.

2.3.1 Compaction of SILK. SILK puts forward two main methods to reduce the compaction cost in RocksDB, namely prioritizing and preempting internal operations. SILK maintains two internal thread pools, one with high priority is for flush and another with low priority is for compaction. According to the SILK I/O scheduler, when the computed bandwidth of client operations exceeds the threshold, SILK will pause compaction. As a result, only up-level compaction can be scheduled and low-level compaction will be delayed during the pausing time. Furthermore, the up-level compaction will be scheduled in the high-priority thread pools, meaning that the compaction may preempt the low-level compaction scheduled in the low-priority thread pool. The preempted compaction will recover compaction work when the thread pool is free. By this way, compaction from L0 can be scheduled along with other compaction paused, and the remaining I/O bandwidths (allocated to flush and compaction) can be allocated to the compaction from L0. When the computed bandwidth of client operations is over the threshold, SILK will resume compaction. More bandwidth will be allocated to internal operations, and parallel compaction can be scheduled. In short, SILK pauses low-level compaction at a high load and resume them at a load load.

2.3.2 Problems. As reported in the original SILK paper [3], SILK can maintain stable throughput for 2000 seconds. However, if a high workload lasts for a longer time than 2000 seconds, SILK will incur dramatic throughput drops and latency increasing. We ran SILK to see its performance and found that SILK has periodical throughput drops and latency increasing after running for more than 3500 seconds, as shown in Fig. 2. This is mainly because after a long-time running, the frequent compaction operations in SILK will consume a large amount of I/O bandwidths. In addition, the I/O analyzer of SILK fails to estimate the workload level accurately. This results in inappropriate compaction scheduling, which will finally trigger write stalls or write stops to delay writing or stop writing to the memory. For example, SILK will resume compaction even when the system runs at a high load.

Although SILK proposed to delay the low-level compaction at a high load, if the up-level compaction cannot finish in time during a load load, SSTables will accumulate in up-levels, which will incur the file retention of LSM-tree [8]. With the increasing of the number of the SSTables to be merged, SILK will finally reach the threshold of write stall or stop, resulting in throughput dropping and latency increasing.

3 I/O ESTIMATION MODEL

In this section, we propose an I/O estimation model inspired by the SILK I/O scheduler [3]. By this model, we can compute the I/O bandwidth taken by client operations more accurately than SILK. Note that the I/O bandwidth estimation is critical to compaction scheduling. If we fail to estimate the bandwidth of the current workload, we may resume compaction at a high load, like SILK, and lead to throughput drops.

3.1 The I/O Estimation Model of SILK

SILK monitors the bandwidth used by client operations and allocates the available I/O bandwidth to internal operations. It realizes its I/O scheduler by setting a separate thread on client load (which is db_bench on RocksDB actually). The I/O scheduler can get actual numbers of client operations what client has accomplished last time interval and computes client's I/O bandwidth according to Eq. 1, where N_{read} and N_{write} are the read times and write times in the last time interval, B_{kv_pairs} is the Bytes of key and value, $T_{interval}$ is the last time interval. SILK sets the limit of total bandwidth $Bandwidth_{limit}$, so it can dynamically allocate left bandwidth to internal operations easily using rate limiter according to Eq. 2, where ε is a small buffer which are not significant enough to adjust internal operation bandwidth.

$$Bandwidth_{client} = (N_{read} + N_{write}) * B_{kv\_pairs}/T_{interval} \quad (1)$$

$$Bandwidth_{internal} = Bandwidth_{limit} - Bandwidth_{client} - \varepsilon \quad (2)$$

3.2 The I/O Estimation Model of DLC

SILK has many restrictions so that it can not be applied to the OLTP workload directly. DLC optimizes the SILK I/O scheduler to make the model suit for the OLTP workload.

The separate thread used by SILK to monitor the bandwidth cannot be used for OLTP workloads.This is because SILK is toward the workloads generated by *db_bench*. But the OLTP workload is generated by *sysbench*. Therefore, we can not monitor the bandwidth of OLTP workloads with the same method as SILK. DLC uses a separate thread on RocksDB to monitor the bandwidth so that it can work on any workloads independently. Other than getting the specific counts of all client operations every time interval, which is proposed by SILK, DLC gets data from *Statistics*, which is a statistical tool provided by RocksDB. In this way, we can get the concrete counts of every client operation. As we can see in Table 1, we can get total counts of client operations according to ticker name (which is added like ticker) from *Statistics*. Based on the SILK's I/O scheduler and the total counts of client operations, we construct the I/O estimation model for DLC. This model is workload-sensitive and it can classify the current load into high or low quickly. This model has two functions, namely computation and analyzing.

3.2.1 Computation. The I/O estimation model of DLC summarizes a universal I/O cost analyzing equation based on Eq. 1 and Eq. 2. DLC computes new I/O bandwidth according to Eq. 3. In contrast to SILK, DLC adds scan s for the client bandwidth estimation because there are some scan operations on OLTP workloads. We also add weights for all client operations so as to estimate the actual I/O cost precisely. It is necessary to add weights for client operations because there exists read amplification[15]. If a *Get* operation is missed in the block cache, it will fetch at least one block from the disk. Thus, one *Get* operation will read more than one key-value pairs on average. Meanwhile, DLC ignores to compute write cost for I/O bandwidths, because write operations insert key-value pairs into memory directly, which do not consume I/O bandwidths. When flush and compaction operations happen, the bandwidth required for writing data to disk belongs to $Bandwidth_{internal}$. Though it is possible to compute the actual value of all weights for client operations, e.g., by a linear programming method, it is inconvenient in practical applications. DLC changes Eq. 3 on the basis of OLTP workloads to make it suitable for other workloads. As OLTP workloads have only one type of transaction with ten *Get* operations, four *Scan* operations, and four *Write* operations, we change Eq. 3 into Eq. 4, N_{trans} is the numbers of the committed transactions in the last time interval. Though there exists delay between operations execution and transaction commits, it is reasonable to assume that $N_{get} = 10 * N_{trans}$ and $N_{scan} = 4 * N_{trans}$. Eq. 4 shows that for OLTP with one type of transaction, all operations in the transaction have the same proportion. We only need to use one operation (*Get* or *Scan*) to compute the real client operation bandwidths. Taking the *Get* operation as an example, we can compute $Bandwidth_{client}$ easily using Eq. 5. DLC allocates the bandwidth to internal operations by using Eq. 2, which is the same as SILK.

Table 1: Some related statistical data in Statistics.

Ticker name	Description
NUMBER_KEYS_READ	Total counts of get (k)
NUMBER_KEYS_WRITTEN	Total counts of write (k, v)
NUMBER_DB_SEEK	Total counts of scan(k_1, k_2)

$$Bandwidth_{client} = (\omega_{get} * N_{get} + \omega_{scan} * N_{scan}) * \frac{B_{kv\_pairs}}{T_{interval}} \quad (3)$$

$$\begin{aligned} Bandwidth_{client} &= (\omega_{get} * 10 * N_{trans} + \omega_{scan} * 4 * N_{trans}) * \frac{B_{kv\_pairs}}{T_{interval}} \\ &= N_{scan} * (\omega_{get} * 2.5 + \omega_{scan}) * B_{kv\_pairs}/T_{interval} \\ &= N_{get} * (\omega_{get} + \omega_{scan} * 0.4) * B_{kv\_pairs}/T_{interval} \end{aligned} \quad (4)$$

$$Bandwidth_{client} = N_{get} * \omega'_{get}/T_{interval} \quad (5)$$

Though Eq. 5 is easy to compute the actual bandwidth for client operations, there is still a problem that we must compute ω'_{get} every time when we change the workload or the parameters of LSM-tree. It is difficult to change ω'_{get} when running for changeable workloads or auto-tuning LSM-tree[3]. DLC proposes a new idea to compute the actual I/O bandwidth, which is suitable for any workloads and any structures of LSM-tree. As we know, a *Get* operation gets data from the block cache and block cache gets blocks from the disk when a cache miss occurs, so the actual I/O bandwidth is consumed when the block cache gets blocks from the disk. DLC computes the actual I/O bandwidth by

[3]Changeable workload means the proportion of operations can change, auto-tuning LSM-tree means that the parameters of LSM-tree can be changed when running.

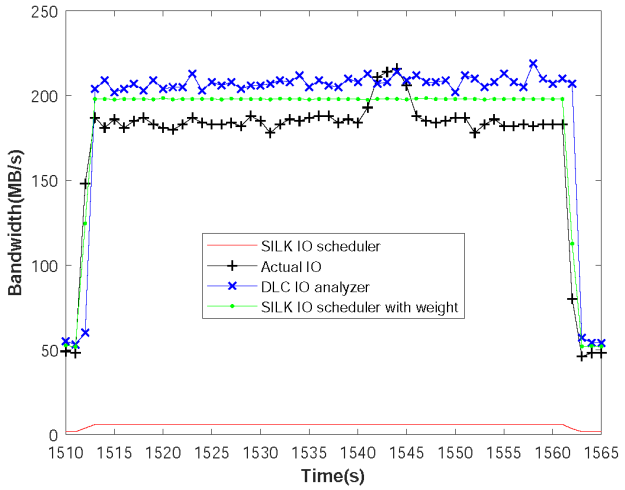

Figure 3: Comparison of various I/O estimation models (using *iostat* on RocksDB).

counting the number of the blocks added to the block cache in the time interval, as we can see from Eq. 6, where γ is the compression ratio of SSTable[4], $Sum_{block\_cache\_added}$ is the number of the blocks added to the block cache, and B_{block} is the bytes within one block.

$$Bandwidth_{client} = \gamma * Sum_{block\_cache\_added} * B_{block}/T_{interval} \quad (6)$$

We conducted an experiment on RocksDB to compare different I/O estimation models with the actual I/O bandwidth. The results are shown in Fig. 3. We can see that the SILK I/O estimation model can not suit for the workload while the DLC I/O scheduler and the SILK I/O scheduler with weights can estimate the actual I/O bandwidth with a little tolerable error, both of which can be applied to our experiments. The DLC I/O scheduler is easier to use than the SILK I/O scheduler with weights.

3.2.2 Analyzing. SILK uses a simple threshold of bandwidth to distinguish between a high load and a load load. It computes $Bandwidth_{client}$ every 10ms and allocates the remaining bandwidth to flush and compaction. DLC adds some parameters for tuning the model, which we can see in Table 2. DLC uses these parameters to distinguish a high load and a load load . For every time_interval, DLC computes the bandwidth of client operations according to Eq. 5. If the bandwidth exceeds the io_high_limit, DLC will regard the workload as a high load. However, low bandwidth is not a sufficient condition of a load load because there are many reasons like flush and compaction that will lead to low bandwidth over a period of time. Thus, even if the client bandwidth is inferior to io_low_limit, we can not judge that it is a low load. DLC uses *softness* to determine the sensitivity of the model. Only when we get several continuous times of low bandwidth can we conclude that the current workload is a low load. By using these parameters, DLC can classify the current workload more correctly than SILK.

[4]Because data in SSTable is compressed while data in the block cache is uncompressed.

4 DESIGN OF DLC

DLC is an improved version of SILK (also an optimization of RocksDB), which optimizes the I/O scheduler of SILK and proposes to delay L0 compaction, which differs from SILK that delays low-level compaction.

4.1 DLC's Compaction Policy

DLC proposes a novel idea to reduce the compaction impact to the throughput stability. The main idea of DLC is to delay L0 compaction[5] at a high load, and to resume L0 compaction when workload is low. DLC uses the I/O estimation model discussed in Section 3.2 to compute the I/O bandwidth, analyze the workload, and decide whether to delay or resume L0 compaction. As we described before, the DLC I/O estimation model can judge the workload more correctly than SILK. First, in the case of fluctuation of workload, DLC sets the time_interval to 1s by default, which can fit most workloads (including OLTP) because many of them also conclude and summarize the statistical data every one second by default. The other parameters in DLC are set according to the workload so that DLC can distinguish the actual high or low workload correctly. Second, on the basis of the actual workload, DLC gives two optional policies for scheduling compaction in a sustained high load, namely delay full L0 compaction or delay part L0 compaction.

To delay full L0 compaction means to delay compaction from L0 to both L0 and L1 under a high load and to resume compaction under a load load. Other than changing the threshold of L0, DLC changes the scheduling mechanism so that it can really delay compaction. Because of the compaction mechanism of RocksDB, up-level compaction will be triggered unexpectedly. Increasing the threshold of L0 can only delay compaction temporarily but the compaction will still be triggered, which is almost uncontrollable. DLC proposes a controllable delay mechanism so that it can delay compaction at a high load and resume compaction at a load load.

To delay part L0 compaction means DLC only delays compaction from L0 to L1. It is a trade-off between read performance and throughput stability. With the accumulation of the SSTables in L0, the read latency will increase and the throughput will decrease. Thus, DLC allows compaction to be scheduled from L0 to L0, which will impact the temporary throughput in a short time but is helpful for future performance. To delay part L0 compaction is suitable for a high load with a relatively long time, which also needs a longer low load to resume compaction. However, this method can not stop L0 compaction fully, so the throughput may drop when compaction from L0 to L0 happens. Therefore, we take "delay full L0 compaction" as the default policy. For both policies, we allow only one low-level compaction under a high load being scheduled.

DLC assumes that there are only a few bandwidths that can be allocated to internal operations at a high load and the flush operations from Immutable Memtable to L0 is unstoppable. Thus, there must be some bandwidths allocated to flush, which may cause a small fluctuation when flush happens. Compared to flush operations and low-level compaction, up-level compaction will cause longer time and bigger fluctuation. The reasons are as follows. First, up-level compaction will merge more SSTables than flush. Second, the key range of up-level compaction is wider than low-level compaction, and the access frequency of the up-level SSTtables is higher than the low-level files[9].

[5]We also call L0 compaction as up-level compaction in this paper.

Table 2: Some parameters added by DLC.

Parameter name	Description	Default Value
io_low_limit	The limitation of io bandwidth to confirm the low load	180MB/s
io_high_limit	The limitation of io bandwidth to confirm the high load	300MB/s
io_limit	The io bandwidth of disk	350MB/s
softness	The sensitivity of DLC to confirm low or high low	3
time_interval	The time interval to compute and allocate the bandwidth	1000ms
ω'_{get}	The modified weight of get operation	16000

The throughput will decrease if up-level compaction is scheduled at high load. Because up-level compaction will occupy a large quantity of I/O bandwidths, client operations cannot get enough bandwidths, yielding the drops of throughput. Thus, DLC delays up-level compaction until the next low load is detected. When there are plenty of bandwidths allocated to compaction at a load load, DLC resumes compaction to make full use of the bandwidth.

4.2 Rate Limiter for DLC

When flush happens, it merge-sorts key-value pairs in all Immutable Memtables (if only one Immutable Memtable, no merge-sort will happen) and writes them to a new SSTable in L0, so flush consumes disk I/O write bandwidth only. But when compaction happens, it first reads related SSTable from disk, merge-sorts them and writes them to a few SSTables in the corresponding level, so compaction consumes both disk I/O write and read bandwidth. Rate limiter is designed to throttle the maximum write speed within a certain limit for lots of reasons. For example, flash writes cause terrible spikes in read latency if they exceed a certain threshold. In other words, the rate limiter is to limit the speed of the data written to the disk. And the rate limiter can be modified for throttling the maximum sum speed of both read and write easily, which is used in DLC. By dynamically allocating left bandwidth is available for flush and low-level compaction but cannot quite effective for up-level compaction because bandwidth is not the only reason for the fluctuation of throughput[1, 21]. The bandwidth exceeds the limit of speed to cause terrible spikes, leads to terrible fluctuation and long latency. So to delay L0 compaction under high load may be the best for OLTP workload to maintain both high throughput and low latency and to resume L0 compaction under a load load to achieve minimal losses of throughput and latency.

5 BURSTY COMPACTION FOR DLC

DLC is mainly designed for the OLTP workload with periodical high and low loads. By delaying L0 compaction at high load and resuming L0 compaction at a load load, we can make full use of the I/O bandwidth with the least throughput loss. However, if the workload becomes continuously high, which is called a sustained high load in this paper, the SSTables in L0 will become more and more, leading to write stalls or stops. When running under a sustained high load, DLC will keep delaying L0 compaction to maintain throughput. The read performance will become worse and the throughput will decrease gradually as time goes. There is no time and bandwidth for compaction at a sustained high load; all read operations amortize the influence of delaying L0 compaction. This problem could be solved when the workload changes into a load load and DLC resumes L0 compaction. However, when running with a sustained high load, the workload will not change into a load load, which will gradually affect throughput of DLC, and cause some other unavoidable result such as write stall or write stop[8].

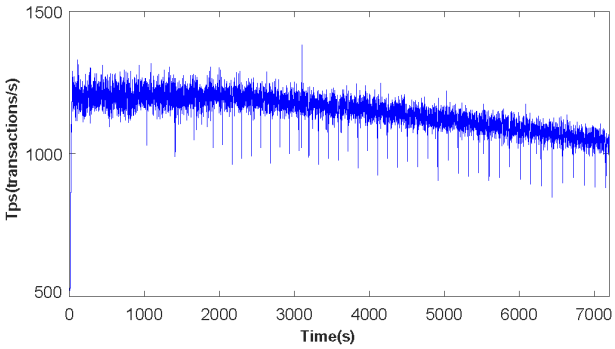

Figure 4: DLC running on the sustained high workload.

Generally, the system will not always be at a high load. Thus, we can assume that the system's throughput is limited by the number of the accumulated SSTables in L0. However, if the workload keeps high for a long time, we can infer that the system's throughput will finally decrease because more and more SSTables will be accumulated in L0. To verify our analysis, we tested DLC under a sustained high workload and the result is shown in Fig. 4, which shows that the throughput decreases with time. If we do not take any action, the sustained high workload will finally trigger write stalls or stops, which will worsen the performance of DLC.

To make DLC suitable for sustained high workload, we further propose a bursty compaction policy, which can avoid the throughput drops of DLC under the sustained high workload. The idea of bursty compaction is to compact selected SSTables in L0 to avoid the continuous accumulation of SSTables and triggering write stalls or stops. This is implemented by monitoring a threshold representing the number of accumulated SSTables in L0.

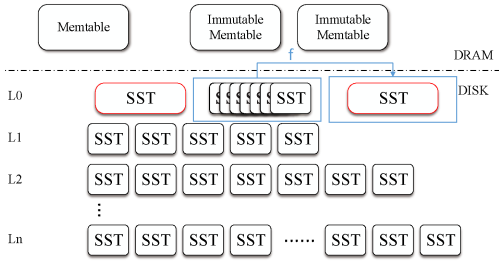

Figure 5: Bursty compaction from Immutable Memtable to L0.

Resume Full Compaction. To resume full L0 compaction is that when the amount of SSTables in L0 gets the threshold, or the total size of SSTables in L0 gets the threshold, DLC stops delaying and resumes compaction from L0 to L1, this cumulatively bursty compaction would consume plenty of time and I/O bandwidth, causing an inevitable degradation of throughput and increase in latency. As we can see in Fig. 4, we could not maintain high throughput all the time and we should schedule compaction in time to keep high throughput and low latency by sacrificing performance for a period of time.

Resume Part Compaction. To resume part L0 compaction is that when the number of the SSTables in L0 flushed from MemTable gets the threshold, DLC resumes compaction from Immutable Memtable to L0. The difference between resume part L0 compaction in the bursty compaction and normal compaction from Immutable Memtable to L0 in MyRocks is that our bursty compaction only merges and sorts the SSTables flushed from Immutable MemTable but normal compaction will merge and sort all SSTables in L0. As compaction will produce a big SSTable that reserves in L0, the bursty compaction does not merge all SSTables to reduce disk I/O bandwidth. Figure 5 shows the idea of the bursty compaction. The SSTable generated from the bursty compaction will not be scheduled again in future bursty compaction.

By controlling the parameters of the threshold, DLC can schedule both two policies easily or only one policy according to the need. Bursty compaction is a new compaction mechanism for sustained high workload, which permits schedule up-level compaction temporarily for future throughput and latency with an inevitable fluctuation for a period of time.

6 PERFORMANCE EVALUATION

6.1 Experimental Setting

We conducted experiments on the Elastic Cloud Server of Huawei Cloud running Linux CentOS 7.6. The server has four Intel Xeon 4-core CPUs with 3.0GHz and 32GB of DRAM. It has one 128GB super-high SSD for storing logs and another 640GB super-high SSD (350MB/s approximately) for storing the MyRocks data.

We use 64 tables in the experiment and each table has 10^7 records. Each key-value pair has a 16B key and a 184B value. We set a 128MB MemTable and only one Immutable Memtable. We set the threshold of L1 to 2GB, the size of SSTable to 64MB, the size-ratio of each adjacent levels to 10, the level of LSM-tree to 5, the block-cache size to 12GB, and the block size to 64KB. The database size is nearly 140GB. We set level0_slowdown_writes_trigger and level0_stop_writes_trigger to 100 both to avoid write stalls or write stops too early.

We compare DLC with two competitors, including MyRocks (MySQL 5.7.26-29 with RocksDB) and SILK. To make the comparison fair, we replace the I/O estimation model of SILK with the DLC I/O estimation model, and we use SILK*(SILK with the DLC I/O estimation model) to indicate this modification.

We use OLTP in *sysbench* [13] as the basic benchmark. The OLTP (Online Transaction Processing) workload in *sysbench* [13] is a SQL workload that can be adjusted to read-intensive or write-intensive. The OLTP workload in *sysbench* has only one type of transaction, which has ten point queries, four range queries, two update queries, one delete query, and one insert query. By using *sysbench*, we can generate OLTP workloads with periodic high and a load loads, which can satisfy most experiments in this paper.

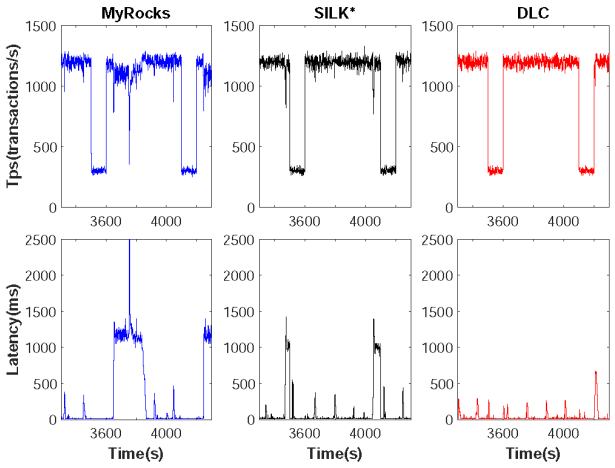

Figure 6: MyRocks, SILK* and RocksDB running on the default OLTP workload.

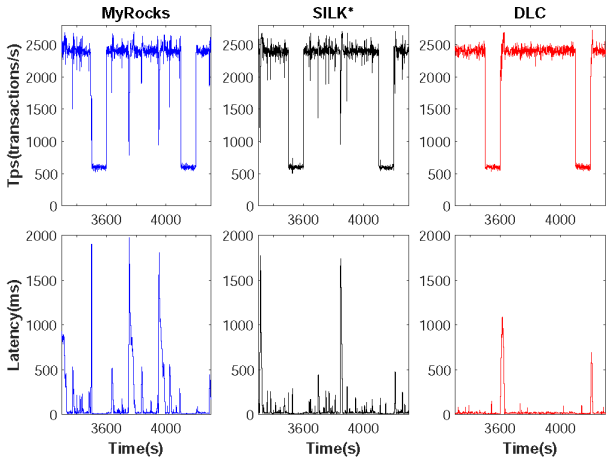
To make the workload not overwhelm the maximum capacity of the system, in our experiments, we first run the workload to measure the maximum throughput of the system, then we set 90% maximum throughput as the threshold to ensure that the workload will not overwhelm the capability of the system. We mainly evaluate two metrics, namely throughput and latency. We use transactions per second to represent throughput, and use the P99 latency to represent latency. The P99 latency refers to the 99th latency percentile, meaning that 99% of requests(transactions) will be faster than the given latency number, and only 1% of the requests will be slower than the P99 latency. These metrics have also been used in prior work like SILK[3][4].

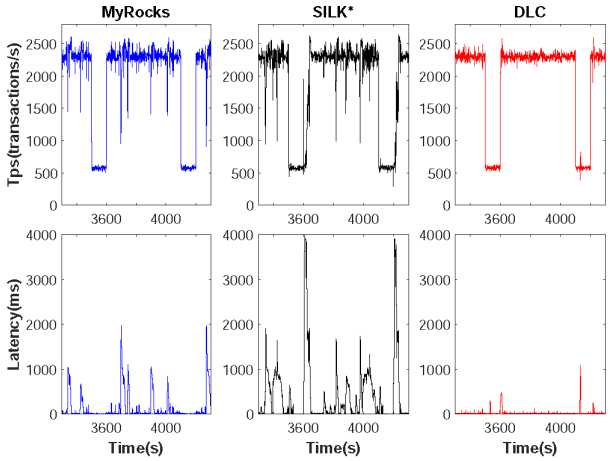
6.2 OLTP with Periodically Varying Workloads

Both DLC and SILK are designed toward periodically varying workloads, i.e., the arriving rate of requests is high for a period and then becomes low. Note that a continuously-high workload will overwhelm the maximum capacity of the system. In this situation, all approaches will fail to keep a stable throughput. On the other hand, most big-data applications like E-commerce platforms have the feature of periodically varying workloads. Another assumption of DLC and SILK is that the workload is write-intensive. This is because only frequent writes can trigger frequent compaction operations, which can be utilized to evaluate the performance of DLC and SILK. How to avoid throughput drops caused by compaction is more challenging that other issues in current LSM-tree-based systems. Although it is important to optimize the read performance of LSM-tree, e.g., under read-intensive workloads, it is orthogonal to this study. An intuitive way to improve read performance is to enlarge the block cache.

To generate appropriate workloads for DLC and SILK, we run the default OLTP workload (each transaction has ten point queries, four range queries, two update queries, one delete query, and one insert query.) in *sysbench* with a high arriving rate for 500s, followed by a low arriving rate for 100s. The high arriving rate is set to 1,200 transaction per second, and the low arriving rate is 300 transactions per second. Note that the two rates and the time period for high/low should be set according to the maximum capacity of the system to be evaluated. In our experiment, the time interval of two up-level compactions is between 400s and



(a) R:W = 5:5



(b) R:W = 1:9

Figure 7: MyRocks, SILK*, and DLC under different read-write ratios.

600s. We list the parameters of the DLC's I/O analyze model on Table 2. We execute the workload on MyRocks, SILK*, and DLC and calculate the throughput and latency continuously. Since at the beginning there is no compaction triggered, we only report the results of all systems between 3,300s and 4,300s. When each system has been running for over 3,000s, we notice that there will be frequent compaction triggered by the insertions of key-value pairs.

6.2.1 Under the Default OLTP Workload. Figure 6 shows the throughput and latency of MyRocks, SILK*, and DLC under the default OLTP workload. In this experiment, the threshold of the maximum capacity of the system is set to 1,200 tps. When the throughput is high (about 1,200 tps in the figure), the system runs at a high load. When the throughput is low (about 300 tps), the system runs at a load load. This is consistent with the periodically varying feature of the workload. MyRocks shows the worst performance. It can not keep stable throughput at a high load because it has to perform up-level compaction at a high load, which will consume additional system resources (I/O bandwidth, CPU, and memory) and lower the throughput. This also leads to the high latency of MyRocks. The throughput stability and latency of SILK* is better than MyRocks, owing to the delay of low-level compaction in SILK*. However, SILK* has a lot of throughput drops during the high-load period. We can see in Fig. 6 that there are serious throughput drops near 3,500s and 4,100s. This is mainly because when the high load runs for a long time, many up-level compactions have been triggered, but SILK* has to perform those up-level compactions even when the system runs at a high load, which also leads to the increasing of the latency of SILK*. On the contrary, DLC exhibits the most stable throughput and the lowest latency compared to MyRocks and SILK*. When the system runs at a high load, DLC can always keep the throughput around 1,200 tps, which is the arriving rate of the high load. When the system runs at a load load, DLC can keep the throughput around 300 tps, which is the arriving rate of the low load. We can see in the figure that DLC has no serious throughput drop. Moreover, the latency of DLC is much lower than others, because it always performs up-level compaction at a load load. In summary, DLC achieves a more stable throughput and higher time performance than its competitors.

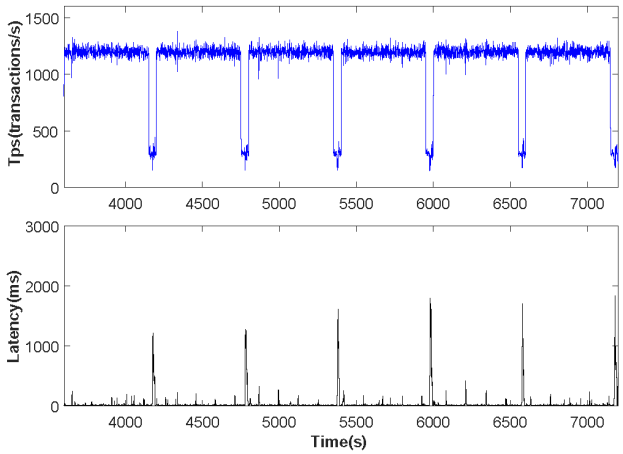
6.2.2 Varying the Read-Write Ratio. In this experiment, we test the performance of DLC under OLTP workloads with different ratios of read and write requests. As DLC is proposed for write-intensive workloads, we prepare two types of OLTP workloads with a read-write ratio of 5:5 and 1:9. Note that in this experiment, we remove the range and update queries from the OLTP workloads to make the workload easier to be generated. When the read-write ratio is set to 5:5, the threshold of the maximum capacity is set to 2,500 tps, which is determined by running the workload before the experiment. When the read-write ratio is 1:9, the threshold is set to 2,350 tps. Figure 7 shows the throughput and latency of MyRocks, SILK*, and DLC under the two read-write ratios. We can see that DLC performs better under the 1:9 read-write ratio, showing that DLC is more efficient for write-intensive workloads. For the workload with the 5:5 read-write ratio, DLC also achieves the best stable throughput and the lowest latency than MyRocks and SILK*.

6.2.3 High Load with a Long Time. Next, we evaluate the performance of DLC under a long period of a high load. This experiment is to show whether DLC can still keep high performance under a long time of a high load. For this sake, we also use the default OLTP workload but shorten the time period of a load load to only 50s, which means that we leave little time for DLC to perform delayed up-level compaction. In addition, we change the time period of a high load to 550s and 1,100, respectively. Consequently, we get two workloads, one is with 550s high load followed by 50s low load, and the other is 1,100s high load followed by 50s low load.

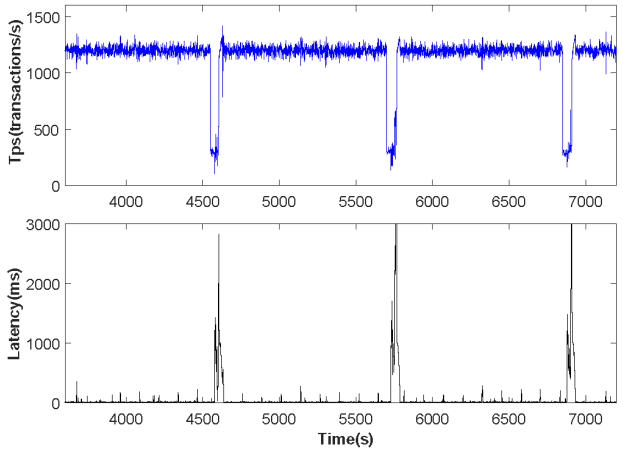
Figure 8 shows the throughput and latency of DLC under the two kinds of workloads. We can see that DLC maintains a stable throughput even when the high-load period increases from 550s to 1,100s, indicating that DLC can adapt to workloads with varying periods of a high load. This also shows that the compaction scheduling cost of DLC is relatively low and DLC can quickly detect the status change of the workload and perform the delayed up-level compaction. Note that DLC has periodic high latency arising under the 1,100s high load, as shown in Fig. 8(b). This is because there are more accumulated SSTables in L0, which cost more time of DLC to complete the compaction.

6.3 Performance of Bursty Compaction

In this experiment, we verify the efficiency of the bursty compaction of DLC. When the workload becomes continuously high

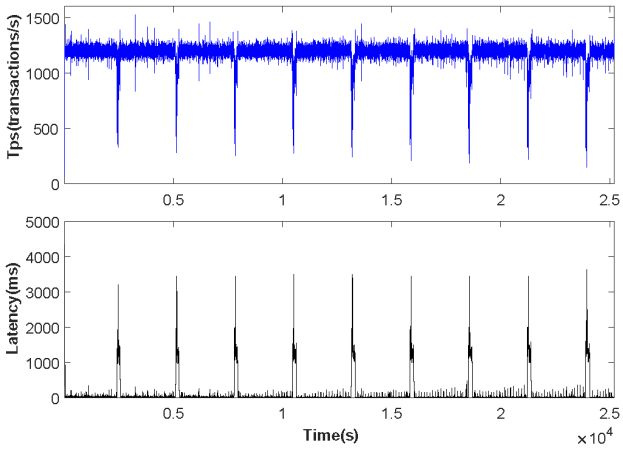


(a) 550s high load

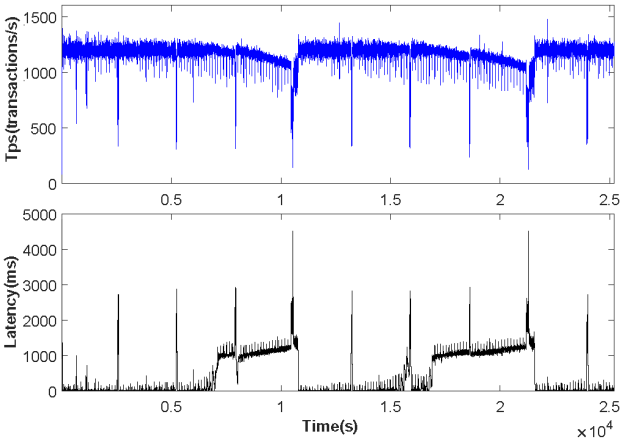


(b) 1100s high load

Figure 8: DLC under high load with a long time.



(a) resume full compaction only



(b) resume part and full compaction

Figure 9: Performance of DLC on a sustained high load.

(which is named sustained high load), the accumulated SSTables in L0 will become more and more, which will worsen the read performance and lower the throughput. DLC monitors the number of the accumulated SSTables in L0, and if the number exceeds a threshold, DLC will perform the bursty compaction to merge selected SSTables in L0 to L1.

To generate a sustained high load, we run the default OLTP workload continuously at the high arriving rate (1,200 tps), and let the system run for a long time to make the number of the SSTables in L0 increase to the threshold (which is set to 20 in this experiment). Figure 9 shows the throughout and latency trend of DLC under a sustained high load. Figure 9(a) shows the result of the "resume full compaction" policy, which is to resume full L0 compaction when the number of SSTables flushed from MemTable exceeds the threshold. Figure 9(b) shows the result of the "resume part and full compaction" policy, which is to resume part L0 compaction when the number of SSTables flushed from MemTable reaches the threshold and to resume full L0 compaction when part compaction has been scheduled for four times.

Figure 9 shows that both the two policies can maintain stable throughput for about 2,550s with a short time of throughput degradation (about 60s for the "resume full compaction" and about 40s for the "resume part compaction"). The "resume full compaction" policy can quickly resume high throughput after bursty compaction, but it has to compact all SSTables in L0, which is time-consuming. We can see in Fig. 9(a) that the latency of the "resume full compaction" becomes extremely high when DLC performs the full compaction. On the other hand, the "resume part compaction" policy only compact selected partial SSTables for maintaining a stable throughput of DLC. Thus, the cost of part compaction is lower than that of full compaction. As shown in the figure, the latency of part compaction is lower than that of full compaction. However, the "resume part compaction" policy sacrifices part of the read performance (read requests still need to read many SSTables in L0), resulting slightly dropping of throughput. To avoid continuous throughput-drops caused by the accumulation of the SSTables in L0 (even after part compaction), the "resume part compaction" in DLC performs full compaction when part compaction has been scheduled for four times. As shown in Fig. 9(b), the throughput slightly drops with time but resume to a high level after four part compactions (each serious drop in the figure indicates part compaction).

6.4 Impact on Read Performance

In this experiment, we measure the impact of DLC on the read performance. Basically, as DLC delays the up-level compaction, there may be accumulated SSTables in L0, which will worsen the read performance under read-intensive workloads.

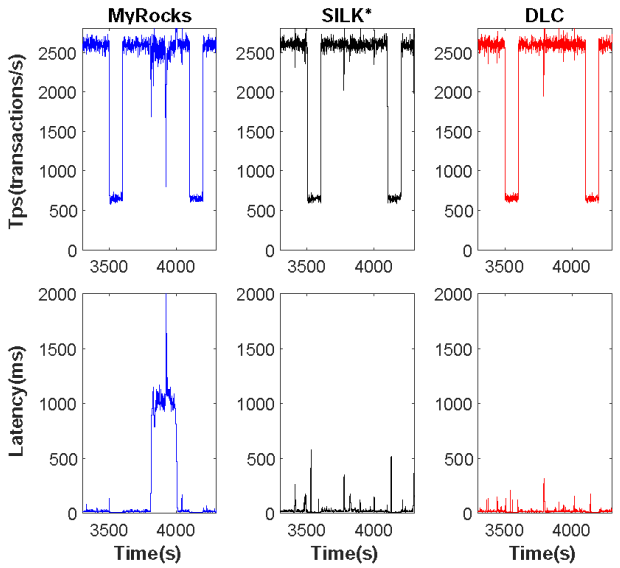


Figure 10: MyRocks, SILK*, and DLC under read-intensive workload with 90% reads and 10% writes.

We first modify the OLTP workload used in Fig. 7 by changing the read-write ratio to 9:1, preparing a read-intensive workload. Then, we run MyRocks, SILK*, and DLC to compare the throughput and latency. The results are shown in Fig. 10. Although DLC shows worse performance compared to its performance under write-intensive workloads (see Fig. 7), it still has comparable throughput stability with SILK*, and its latency is lower than that of SILK* and MyRocks. Thus, DLC can also work for read-intensive workloads.

Further, to measure the number of the SSTables in L0, we conduct an additional experiment to see the change of the number of L0 SSTables in DLC. In this experiment, we use the default benchmark tool *db_bench* in RocksDB and simply run DLC on RocksDB to calculate the number of the SSTables in L0 while DLC is running. We set one thread for inserting key-value pairs and thirty threads to perform *Get* operations. Figure 11 shows the change of the number of the SSTables in L0 as well as the read performance (in terms of QPS, because *db_bench* does not support multi-transaction processing). We can see that the number of L0 SSTables increases with time stably. Note such increase is not a linear function. We explicitly show a part of the enlarged curve in the figure, indicating that the increasing of SSTables is step-wise. This is because only when we flush Immutable Memtable to L0, the number of SSTables in L0 can increase. With the accumulation of the SSTables in L0, QPS slightly decreases while the read latency increases. Figure 12 shows the change of the number of the SSTables in L0 as well as the read performance when we use *Scan* operations and other settings remain unchanged, which shows similar results as Fig. 11.

In summary, DLC is especially suitable for write-intensive workloads, but it can also maintain comparable performance with SILK* under read-intensive workloads. Although the delay of up-level compaction results in the accumulation of the SSTables in L0, DLC can merge them to L1 at a load load or by performing bursty compaction.

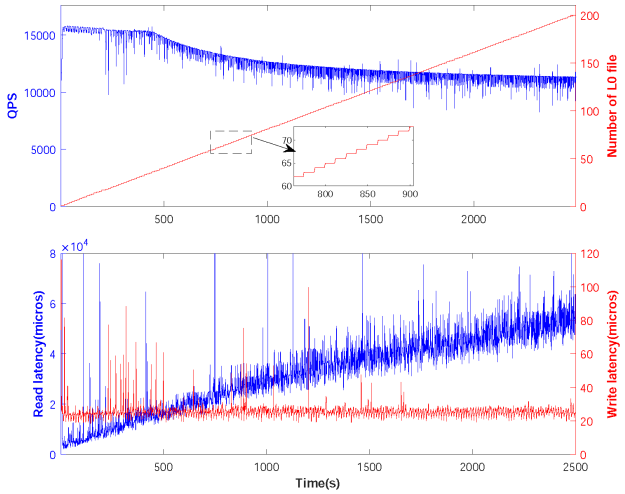

Figure 11: Accumulation of L0 SSTables and its impact on *Get* performance.

7 CONCLUSION AND FUTURE WORK

LSM-tree has been widely used in many key-value stores, due to its high writing performance. However, the compaction operations in LSM-tree highly impact the throughput of LSM-tree, especially when LSM-tree runs under write-intensive workloads. Prior work has shown that compaction will result in serious throughput drops and increasing in processing latency. In this paper, aiming to provide stable high throughput and low latency, we proposed to delay the L0 compaction in LSM-tree when the system is at a high load and perform the delayed L0 compaction at a load load. With such a mechanism, the system's throughput can maintain a high level at a high load because no up-level compaction will be executed. On the other hand, performing compaction at a load load has little impact on the throughput because the system' resources, including I/O bandwidth and CPU, are not fully used.

Following the idea of delaying L0 compaction, we presented the DLC approach to optimize the compaction scheme in LSM-tree. We first proposed a new model to estimate the I/O bandwidth that is needed by the workload. Based on the I/O estimation model, DLC decided whether to delay the up-level compaction or

to perform the delayed compaction. DLC is especially designed for periodically varying workloads, i.e., the arriving rate of requests is high for a period and then becomes low. By scheduling up-level compaction appropriately, DLC can main stable throughput and latency. Further, to solve the problem that the workload is continuously high for a long time, which is called a sustained high load in the paper, we proposed the bursty compaction policy to perform mandatory compaction of the SSTables in L0, so as to avoid the drops of the throughput. We designed two policies to implement the bursty compaction, namely "resume full compaction" and "resume part compaction". The difference between the two policies lies in the range of the L0 SSTables to be compacted.

Finally, we implemented DLC on RocksDB and compared DLC with MyRocks and SILK* (SILK with the DLC I/O estimation model), which is the state-of-the-art optimization of the compaction in LSM-tree. The experimental results under different kinds of OLTP workloads suggest that DLC has the best throughput stability and the lowest latency. We also demonstrated that DLC can achieve comparable performance with SILK* under read-intensive workloads.

In the future, we will consider optimizing the read performance of LSM-tree and building a read/write-optimized tree structure[12]. The current design of DLC is not read-friendly, making it more suitable for write-intensive workloads. We will focus on improving the block cache management scheme[22] and the Bloom filter to reduce the read amplification and block-cache miss in LSM-tree.

ACKNOWLEDGEMENT

We would like to thank the anonymous reviewers for their valuable comments on this paper. We are also grateful to Prof. Jianliang Xu for his constructive suggestions on improving the paper. ABSTRACT

Confidentiality is a crucial requirement in financial data exchange processes. On the one hand, rich microdata is needed for most AI applications, including banking supervision, anti-money laundering, etc. On the other hand, organizations may not be legally authorized to see particular data, e.g., personal data. Striking the right balance provides a number of challenges.

Motivated by our experience with the Central Bank of Italy, in this work we present Vada-SA, a reasoning-based framework for financial data exchange with statistical confidentiality. We present a production-ready and fully engineered framework, adopting a reasoning approach. The framework includes explicit consideration of the reasoning process, the business context and declarative transparency that puts the user in control. We show and discuss a number of risk measures and anonymization criteria, implemented and operated in practice.

1 INTRODUCTION

Confidentiality in financial data exchange has multiple facets and touches different business segments of the FinTech area. In *open banking* settings, where the increasingly frequent interactions between financial intermediaries motivated by the unbundling and rebundling of the banking process sees the interplay of many actors, each interested in utilizing the data about a specific portion of the process, but with limited or no access-rights to the identity of the involved customers; in European-level *banking supervision*, where data exchange between the European Central Bank and the National Central Banks needs to reveal situations that are highly critical in terms of the "financial health" of the banks, while the identity of the involved customers tends to be irrelevant; in *anti-money laundering*, where most modern approaches pinpoint fraudulent or collusive cases by inspecting high-level features of the considered actors, without accessing their identity before any judicial or law-enforcement action authorizes it; in *statistical and economic research*, with the more and more common establishment of national "Research Data Centers", data archives used by financial authorities that wish to share relevant financial data with universities and research institutes while keeping personal data reserved. Moreover, it goes without saying that the *GDPR regulation* makes the attention to the confidential transfer of personal data a central topic in Europe.

As a matter of fact, financial and statistical authorities and intermediaries look at solutions to share their own *microdata*, i.e., non-aggregated data at the finest level of granularity, while striking a good balance between their statistical relevance and the need to eliminate any possible trace of personal identities. Many situations arise in the financial segment in which a counterparty must at the same time see parts of the data (to carry out a portion of the process) and must not see other parts which they are not legally authorized to see, e.g., personal data.

This paper is motivated by our experience with the Central Bank of Italy, which, in its capacity of national central bank, banking supervision and oversight authority and Financial Intelligence Unit for Italy, is touched by the problem of *confidential financial data exchange* in all its perspectives. In this work, we present Vada-SA, the joint effort of the Applied Research Team of the Bank of Italy, TU Wien and the University of Oxford towards a reasoning-based approach to the problem.

The desiderata. We start by laying out the main desiderata for a state-of-the-art financial data exchange solution with confidentiality: (i) It should be *context aware* and take into consideration the specific business domain and the characteristics of the involved entities and features to evaluate the risk of a breach of confidentiality; (ii) At the same time it should be *schema independent*, and operate regardless of the specific dataset structure; (iii) It should be *preemptive*, in the sense that it should be able to analyze a given dataset to be exchanged and provide a confidentiality score beforehand, so that analysts can evaluate the risk of sharing it; (iv) It should be *active*, in the sense that whenever the confidentiality score is over a certain threshold (e.g., statistically inferred or defined by the domain experts), the solution should be able to alter the data and *anonymize* them so that the threshold is respected; (v) It should embody a *statistics-preserving* anonymization logic, by removing the minimum amount of information needed to guarantee confidentiality, while preserving the statistical soundness and relevance of data; (vi) It should be *fully explainable*, meaning that the confidentiality score of a candidate dataset as well as the reasons for specific anonymization choices should be completely understandable to domain experts; plus it should have a transparent semantics of confidentiality; (vii) It should be *business friendly*, by being extensible, IT-independent and at business level, i.e., domain experts should operate autonomously in defining new scoring criteria as well as anonymization logic in a high-level non-technical language; (viii) It should be *scalable* and able to handle increasing data volumes.

Statistical Disclosure Control. The area of *Statistical Disclosure Control* [26, 35, 37] (SDC) represents a relevant yardstick for our work. The SDC approach concentrates on *re-identification*, i.e., the possibility for an attacker to cross-link information it rightfully retains, in particular, every single tuple of a legitimately owned database, with other data sources so as to find out the underlying identities (of the involved people, companies and stakeholders in general). SDC adopts quantitative indicators to take decisions on data sharing by evaluating the *risk of re-identification* and balancing it with the measure of the statistical

*The views and opinions expressed in this paper are those of the authors and do not necessarily reflect the official policy or position of Banca d'Italia.

relevance of the data, so as to minimize the risk while maximizing the *statistical utility*. SDC also studies solutions to transform, namely *anonymize*, the data to be shared, balancing confidentiality and statistical relevance. Commonly adopted techniques, featured by widespread tools such as *sdcMicro* [9], *μ-ARGUS* [27], and *ARX* [33], aim at removing potential identifiers (sometimes known as *quasi-identifiers*) of the disclosed tuples and include *value suppression*, *aggregation*, and *generalization*.

Unfortunately, the approaches and the tools offered so far by the SDC community do not fulfill the desiderata of a full-fledged solution needed by the processes of financial companies and organizations, like the Bank of Italy. First, to the best of our knowledge, all the existing SDC techniques are schema dependent and anonymization risk assessment and anonymization programs are tightly coupled to the dataset structure. Then, SDC techniques are only based on value statistics within the dataset to be anonymized and are not context-aware, while it is our experience that the risk of disclosure highly depends on the characteristics of the source and target databases [18] as well as the surrounding business information, e.g., availability of specific cross-linking data, even at tuple level. As a consequence, SDC techniques tend to fall short of accuracy in this respect. Although the anonymization techniques of SDC put into action interesting ideas and, in general, preserve statistical relevance of the datasets, to the best of our knowledge, all of them lack full explainability, unacceptable for financial organizations with strong accountability constraints. The lack of explainability prevents effective feedback-based adaptivity and the improvement of disclosure control proceeds by trial and error. Furthermore, all the existing tools tend to be not business friendly: they adopt a technology- and IT-dependent language (e.g., R libraries or Java), often lack clear semantics (typically only informally explained in the documentation), require adopters to have a technical background and are hardly extensible. Finally, such tools are data-scientist oriented libraries and, while showing good performance, do not have formal scalability guarantees.

Contribution. In this work we present Vada-Sa, a *reasoning-based* framework for financial data exchange with statistical confidentiality. It is based on our long-term experience in developing AI-enhanced data-driven solutions revolving around *logic-based reasoning*. In particular, this work builds on the Vadalog System [6], a state-of-the-art *reasoning system* leveraging the Vadalog language, a member of the Datalog$^{\pm}$ family [12], exhibiting very good characteristics of scalability and expressive power. In particular, we contribute as follows.

- We present a production-ready and fully engineered framework, Vada-Sa, for financial data exchange with confidential privacy, adopting a reasoning approach. The enterprise data to be shared, along with the metadata, are modeled as the *extensional component* of the reasoning process, whereas standard risk measures and anonymization methods are modeled as the *intensional component* of the process, i.e., a set of Vadalog rules. The activation of the rules upon the extensional component —i.e., the *reasoning process*— produces the *derived extensional component*, which is either a fully explained risk measure for a given dataset to be exchanged or its anonymized version.
- We show and discuss (and through Vada-Sa ship off-the-shelf) a number of risk measures and anonymization criteria and illustrate how they can be managed in Vadalog.
- We suggest that the surrounding *business context* relevant for accurate risk measures is awarely modeled within the intensional component in terms of Vadalog rules, which are at the same time *schema independent* w.r.t. the structure of the datasets. Although the framework targets financial data as a primary application, the techniques we present are general and can be applied in any context requiring statistical confidentiality.
- We envision that the SDC techniques can be used as a solid theoretical basis to craft a statistically preserving anonymization logic, yet, unlike existing approaches, we model in a purely *declarative* way in terms of Vadalog rules.
- We embrace a *user-delegation approach*, in the sense that by means of a semantically clear, fully declarative, non-technical and IT-independent language (i.e., characteristics that Vadalog embodies by design [6]), we delegate specific users to writing their own criteria and encoding the business knowledge, with cost and operational savings.
- In our framework, we inherit a set of benefits from logic-based reasoning. In particular, we refer to the pros of declarative approaches that, unlike procedural programming, relieve the users from the need to understand the internals of anonymization methods when adopting it. Full explainability is guaranteed by standard logic entailment semantics, enforced with chase-based procedures [20] embodied in Vada-Sa. Finally, the ideal balance between computational complexity and expressive power inherited from Vadalog, allows Vada-Sa to achieve very good scalability.
- We discuss an interesting set of real-world risk measures and anonymization criteria, implemented and operated in practice.

Overview. The remainder of the paper is organized as follows. In Section 2 we pursue the industrial setting at the Bank of Italy. In Section 3 we introduce the background about Vadalog. Section 4 presents the Vada-Sa framework and Section 5 shows it in action in relevant cases from the Bank of Italy. In Section 6 we discuss some related work and Section 7 concludes the paper.

2 INDUSTRIAL SETTING

The Bank of Italy has recently set up a *Research Data Center* (RDC).[1] At its core, there are a set of relational databases that store the *microdata*, i.e., the operational finest-grained data, from many core business applications such as the credit risk register, payment systems, balance of payments, banking supervision indicators, etc. The ultimate goal of RDC is sharing statistically relevant information with other cooperating institutions such as the National Statistical Office, other central banks, the European Central Bank, universities and research centers. While all these counter-parties operate within a "circle of trust", and can thus access the mentioned microdata, the identities of the involved entities, be they companies, banks or people, should remain of the sole responsibility (and therefore visibility) of the Bank of Italy, which is legally in charge of the respective processing.

The microdata that the RDC deals with regard different business processes and originate from multiple sources, usually external to the Bank of Italy. These data are collected with a variety of methods such as statistical surveys or data flows and are organized into several *microdata DBs*, by business domain. The RDC aims at including 65 microdata DBs with operational data from 1977 to 2020 and expected size of 30-50TB, with a 1TB/month growth. The RDC currently stores 14 microdata DBs, about families and individuals, firms, and historical data, including:

- Household income and wealth
- Household finance and consumption

[1] The RDC is part of the INEXDA initiative (http://www.inexda.org/) for the exchange of granular statistical data.

- Italian housing market
- Inflation growth and expectations
- Historical archive of Italian credit.

Microdata DBs contain business data, including attributes that may disclose, directly or indirectly, the identity of the involved subjects; let us call these subjects *respondents*, by some abuse of the terminology adopted for statistical surveys. The risk for a tuple of a microdata DB to be associated (i.e., "linked") to the respective real-world identity of the respondent is named *risk of re-identification*. Indeed, the notion of re-identification revolves around the (realistic) assumption that an external data source containing all the identities of the respondents exists; let us call *identity oracle* such database. The challenge here consists in mitigating the risk that an attacker could be able to link the value of some attributes of a tuple of the microdata DB, with those of a single tuple (or a very small set thereof) of the identity oracle and therefore disclose the respondent's identity.

2.1 Setting Foundations

Let us frame our industrial context with the needed foundations.

Relational Foundations. Let $\mathbf{C}$, $\mathbf{N}$, and $\mathbf{V}$ be disjoint countably infinite sets of *constants*, *(labelled) nulls* and (regular) *variables*, respectively. A *(*relational) schema $\mathbf{S}$ is a finite set of relation symbols (or predicates) with associated arity. A *term* is either a constant or variable. An *atom* over $\mathbf{S}$ is an expression of the form $R(\bar{v})$, where $R \in \mathbf{S}$ is of arity $n > 0$ and $\bar{v}$ is an n-tuple of terms. A *database instance* (or simply *database*) over $\mathbf{S}$ associates to each relation symbol in $\mathbf{S}$ a relation of the respective arity over the domain of constants and nulls. The members of relations are called *tuples*. By some abuse of notations, we sometimes use the terms tuple and fact interchangeably.

The Microdata DB and the Identity Oracle. A microdata DB is a relation of schema $M(\bar{i}, \bar{q}, \bar{a}, W)$, where $\bar{i}$ is an n-tuple of attributes defined as *direct identifiers*, $\bar{q}$ is an n-uple of *quasi-identifiers*, $\bar{a}$ is a set of *non-identifying* attributes and W is a *sampling weight*. An identity oracle is a relation of schema $O(\bar{i}', \bar{q}', I)$, where $\bar{i}'$ is a set of direct identifiers, $\bar{q}'$ is a set of quasi-identifiers and I is the *identity* of the respondent.

- *Direct identifiers* are attributes s.t. their values (of each single attribute, separately) allow to determine the identity of the respondent, that is, for a given tuple of M, the join between M and O on an attribute of $\bar{i}$ equated to an attribute of $\bar{i}'$ selects a single tuple from O and therefore the resulting tuple discloses the respondent's identity I. Observe that a direct identifier is a key attribute for O and it is assumed that $\bar{i} \subseteq \bar{i}'$. Examples of direct identifiers are the social security number, the Italian fiscal code, the driving licence number, etc.
- *Quasi-identifiers* are attributes s.t. the values of two or more of them, jointly, are likely to disclose the identity of the respondent, that is, for a given tuple of M, the join between M and O on two or more attributes of $\bar{q}$ equated to attributes of $\bar{q}'$ selects a small set of tuples of O and therefore likely discloses the respondent's identity I. In other terms, quasi-identifiers are features that in specific combinations are enough selective to endanger the respondent's confidentiality. This selectivity depends on the attribute (as some are intrinsically more specific) and, of course, on the combination of values, which can be more or less specific for a given context. For example, the joint use of age and address can be quite selective if we refer to a context of small dwellings, whereas gender and address would be less selective. On the other hand, occupation-gender is in general not very selective, whereas it can be extremely discriminating if we are referring to a context of a survey about gendered jobs in some country.
- *Non-identifying attributes* are those that do not fall in the two previous categories. These attributes are not critical because neither individually nor in combination with others, allow to disclose the identity of the respondent, i.e., re-identification is not possible. On the one hand, this can depend on an intrinsic scarce selectivity of the attribute like in the case of age in a given context, on the other hand, a non-identifying attribute can be even intrinsically identifying, yet its value certainly unknown to the identity oracle. This is the case, for instance, of internal system identifiers which are useless for re-identification.

- *Context and sampling weight.* We have touched on the notion of context when discussing quasi-identifiers, which are more or less selective depending on the domain of discourse. The context can be seen as a selection of tuples from O based on the domain of interest. For instance, if we were surveying the population of Milan, the only tuples of O referring to people living in Milan could be used to attempt re-identification of tuples of M, thus making it easier. The *sampling weight* accounts for the context by measuring the *representativeness* of a tuple t of M w.r.t. the entire context $\mathbb{C}$ to which M refers. In this sense, R is a sample from O, and W_t is the tuple sampling weight.
  There are different options for defining the sampling weight [7, 22]. The one we take inspiration from is the expected value of the number of entities having the same characteristics as t (according to a similarity function ϕ) in the sample distribution of O according to a given context $\mathbb{C}$. Given M, the weight W_t can be estimated for each tuple t from the posterior distribution of values for $\overline{q}$ among the tuples. Many options are also possible for ϕ and the simplest one just uses equality of quasi-identifiers attributes. Higher weights denote statistically relevant tuples, likely carrying scarcely selective attributes; lower weights denote statistically less relevant tuples (outliers, as a limit case), likely with highly selective attributes.
- *Identity.* The value of such attribute stands for some universally recognized representation of one respondent's identity.

In our experience with the Bank of Italy, the categorization of microdata DB attributes as direct, quasi- and non-identifiers as well as weight estimation is a hybrid process involving human experience-based evaluation, learning from training sets, and domain-based reasoning, as we shall see.

2.2 Towards a Reasoning Framework for Statistical Disclosure Control

With the depicted context, we can achieve a straightforward definition of *re-identification risk* as the probability $\rho_t = 1/W_t$ of re-identifying t given the value of all its quasi-identifiers $\overline{q}$. We can say that, in some sense, provided that O is an abstraction, the sampling weight W_t is an estimator for the cardinality of the join $|\sigma_t(M) \bowtie_{\overline{q}} O|$, where σ denotes the selection and $\bowtie$ the join.

However, re-identification risk is an upper bound for the real disclosure risk, in the assumption that all quasi-identifiers are known to a potential attacker. As a matter of fact, for a given tuple we may be interested in evaluating the risk only wrt a subset $\hat{q} \subset \overline{q}$ of quasi-identifiers, the ones we suppose the attacker is aware of or are more selective. Moreover, we may want to apply an arbitrary *risk weight* function λ, which takes as input W_t as well as the values for quasi-identifiers of t. Whence, the following definition of a general *statistical disclosure risk*:

$$\rho_{\hat{\mathbf{q}}} = 1/\lambda(\sigma_{\hat{q}=\hat{\mathbf{q}}}M) \tag{1}$$

The function λ computes an aggregate weight over the tuples selected by $\hat{\mathbf{q}}$ and generalizes many different risk measurement techniques, as we shall see, including the re-identification-based risk (for which $\lambda(\sigma_{\hat{q}=\hat{\mathbf{q}}}R) = \sum_{\sigma_{t\in\hat{q}=\hat{\mathbf{q}}}(R)} W_t$), but also *k-anonymity* [34], *individual risk* [7], and SUDA [19].

Use cases. Our industrial goal consists in: 1. evaluating the *statistical disclosure risk* and, 2. if unacceptable, take actions to counteract possible information disclosure, while preserving statistical significance (*anonymization*). The joint performance of the two mentioned actions is known as *statistical disclosure control* [18].

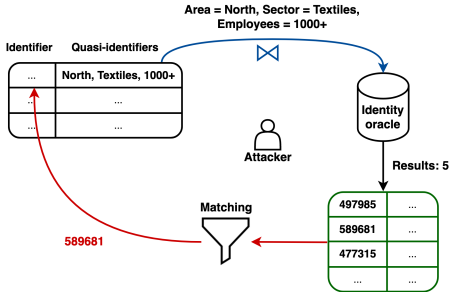

Figure 2: The attack strategy in action: by querying the identity oracle along Area, Sector and number of Employees, an attacker can narrow the search to few candidates and make a plausible guess about respondents' identity.

Figure 1 reports a fragment of a microdata DB of the Bank of Italy RDC, whose data derive from an *Inflation and Growth Survey*. This microdata DB shows the percentage growth in the last 6 months of Italian companies, spanning various sectors, with a different number of employees, different composition in revenue (residential viz. export) and a different percentage of export to Germany. The attributes of the microdata DB are the direct identifier $\overline{i} = \{Id\}$, where Id is a unique identifier for a company, the quasi-identifiers $\overline{q} = \{Area, Sector, Employees, ResidentialRevenue, ExportRevenue\}$, the non identifying attributes $\overline{a} = \{ExportToDE, Growth6mos\}$, and the weight $W = \{Weight\}$.

Re-identification risk is highest for tuple 15 (0.03) and lowest for tuple 7 (0.003). Extending to general (re-identification-based) statistical disclosure risk, we have that $\rho_{\hat{\mathbf{q}}}$ of a given tuple clearly coincides with re-identification risk if $\hat{q}$ includes the Id. It is also the case when $\hat{q}$ includes an n-uple of quasi-identifiers that happens to be unique. For example, tuple 4 is the only one located in the North, dealing in the Textiles sector, with more than 1000 employees; therefore, its re-identification and statistical disclosure risk coincide and amount to 0.016. Notice that its weight (60) witnesses the presence of multiple companies in the identity oracle having the same characteristics as tuple 4 according to the similarity function ϕ, e.g., the same/similar quasi-identifiers.

In another perspective, we are outlining a possible *attack strategy* to attempt re-identification of a given tuple t (Figure 2): 1. filter out a set of tuples C from O that match t on the values of attributes in $\overline{q}$; 2. choose the tuple $r \in C$ that best fits t w.r.t. the other attributes; 3. return r with an associated probability/score. To put the attack strategy into action, the entire toolbox from the *record linkage* literature can be adopted [13]. Efficient record linkage techniques typically operate in two steps: *blocking*, when restricting the cohort of candidate matches (step 1 of the attack strategy); *matching*, when evaluating the actual correspondences (step 2). Anonymization techniques aim at making blocking computationally expensive, by suppressing or modifying (as we shall see) selective values, which would make blocking effective restricting the cluster of candidate matches. With large clusters, exhaustive comparison is both computationally expensive, and yields an overly uncertain result, making the attack ineffective.

It is interesting to observe that the sampling weights can be used as a predictor of the effectiveness of a re-identification attack: tuples with higher weights in M will be in clusters with more candidates and thus less likely be identified, though statistically relevant; tuples with lower weights will be in smaller clusters and then will be more easy to re-identify. This gives an optimistic angle on the problem, as anonymization techniques can try to

operate on less representative tuples so as to increase overall confidentiality without hampering the statistical significance.

3 VADALOG REASONING

VADA-SA, the statistical disclosure control framework we introduce in this paper, is based on the VADALOG system, a state-of-the-art *logic-based reasoner* [6] whose core revolves around the VADALOG language, a member of the Datalog$^{\pm}$ family [12, 23]. The disclosure risk measurement techniques as well as the anonymization logic are expressed in VADALOG.

Datalog$^{\pm}$ generalizes Datalog with existential quantification in the rule conclusion, making it suitable for ontological reasoning. A *rule* is a first-order sentence of the form $\forall \bar{x} \forall \bar{y} (\varphi(\bar{x}, \bar{y}) \rightarrow \exists \bar{z}\, \psi(\bar{x}, \bar{z}))$, where φ (the *body*) and ψ (the *head*) are conjunctions of atoms. For brevity, we omit universal quantifiers and denote conjunction by comma. As usual in this context, the semantics of a set of rules is operationally defined by the well-known CHASE procedure. Intuitively, the CHASE satisfies the rules by generating new head facts for bindings of the body, possibly introducing new variable symbols in the data, in the form of *labelled nulls*, in the presence of existentially quantified head variables [21].

The core of VADALOG is based on *Warded Datalog*$^{\pm}$ [6], a syntactic restriction to Datalog$^{\pm}$ that guarantees decidability and tractability in the presence of recursion and existential quantification. In terms of expressive power, Warded Datalog$^{\pm}$ captures full Datalog and `OWL 2` direct semantics entailment regime for `OWL 2 QL`. The language underpinnings are exploited by the reasoner to allow for efficient execution of reasoning tasks. VADALOG augments Warded Datalog$^{\pm}$ with supplementary features such as aggregation, algebraic operations, and stratified negation. As we shall see, VADALOG is sufficiently expressive to support our anonymization reasoning scenarios and comprises all the needed features such as joint use of full recursion, existential quantification and aggregation, to model propagation of the disclosure risk and anonymize values. These requirements are not met by the standard relational/SQL systems, which in particular offer inefficient or no support for recursion and existentials.

4 THE VADA-SA FRAMEWORK

While statistical disclosure control has traditionally followed a procedural approach, we propose a shift towards a fully declarative one, and look at state-of-the-art reasoners, leveraging our experience on VADALOG and Knowledge Graphs applied to different problems in the financial realm e.g., link prediction [2] as well as schema-independent approaches to model management [3]. The VADA-SA framework, whose architecture is sketched in Figure 3, lies on the following basic pillars:

- A structuring of the statistical disclosure control process in the form of an *anonymization cycle*.
- The construction of a VADALOG-based enterprise *Knowledge Base* (KB) encompassing the patterns and techniques for statistical disclosure risk assessment and anonymization as well as all the surrounding business knowledge to be leveraged.
- The formulation of risk assessment and anonymization phases in the form of *reasoning tasks* upon the KB. In such reasoning tasks, the *extensional component* comprises the microdata DB as well as their basic metadata, such as schema-level information. Much care is devoted to the *intensional component*, encoding reasoning rules for: attribute categorization, risk assessment and anonymization. The intensional component is at high level of abstraction, composed of pluggable VADALOG modules, some of which are provided off-the-shelf while others can be autonomously developed by business experts. The overall statistical disclosure control process is a reasoning task itself, which relies on the mentioned ones and adaptively chooses the actions to be performed. The *derived extensional component*, i.e., the results of the reasoning process, contains the outcome of risk analysis and the anonymized microdata DBs.

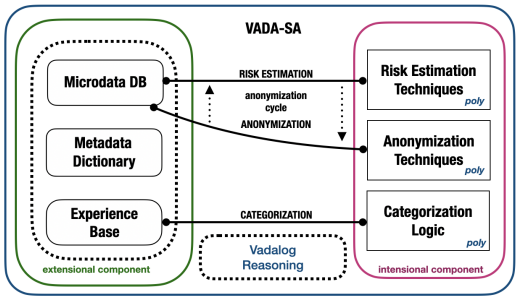

Figure 3: The VADA-SA architecture.

In this section, we first illustrate the anonymization cycle and the *metadata dictionary*, at the basis of our schema-independent approach (Section 4.1), we then focus on the evaluation of statistical disclosure risk (Section 4.2) and anonymization (Section 4.3). Finally, we show extensions and advanced applications involving complex business knowledge (Section 4.4).

4.1 The Anonymization Cycle and the Metadata Dictionary

When a microdata DB needs to be shared, it undergoes the *anonymization cycle* at the core of the VADA-SA architecture, shown in Figure 3. It consists of an iterative application of disclosure risk evaluation and anonymization until the risk is under a given threshold. Each iteration removes a minimum amount of information, and checks whether confidentiality requirements are fulfilled, in a statistics-preserving fashion.

In particular, *risk evaluation* takes as input a microdata DB. Based on its category, each attribute has a different treatment. Direct identifiers must not be disclosed and non-identifying attributes are not needed in the risk evaluation process, thus both are dropped. Quasi-identifiers and the sampling weight are used for disclosure risk estimation. Anonymization is activated until the disclosure risk is acceptable. In so doing, we aim at a trade-off between *statistical preservation* and disclosure risk, as captured by the threshold T, determined on the basis of user experience.

Metadata Dictionary and Attribute Categorization. In order to achieve schema and data independence, in VADA-SA we follow a *meta-level approach* and include a *metadata dictionary* in the KB. Facts of the form `MicroDB`(name), `Att`(microDB, name, description), `Category`(microDB,att,cat) are used to reason upon microdata DBs, their attributes and their categories, respectively. Figure 4 shows the portion of VADA-SA dictionary for the "I&G" (Inflation and Growth) microdata DB. Facts for `MicroDB` and `Attribute` are part of the extensional component and change when new microdata DBs are added into VADA-SA. Facts for `Category` are part of the derived extensional component: they are the product of a reasoning process that, for each microdata DB and each attribute, infers the most suitable category. In fact, before entering the anonymization cycle, the attributes of the microdata DB need to be categorized as identifiers, quasi-identifiers or non-identifying attributes, as we have seen in Section 2.1.

Algorithm 1 Attribute categorization

(1) $\text{Att}(M, A) \rightarrow \exists C\ \text{Cat}(M, A, C)$.
(2) $\text{Att}(M, A), \text{ExpBase}(A_1, C), A \sim A_1 \rightarrow \text{Cat}(M, A, C)$.
(3) $\text{Cat}(M, A, C) \rightarrow \text{ExpBase}(A, C)$.
(4) $\text{Cat}(M, A, C_1), \text{Cat}(M, A, C_2) \rightarrow C_1 = C_2$.

`Attribute`

Microdata DB	Attribute Name	Description
I&G	Id	Company Identifier
I&G	Area	Geographic Area
I&G	Sector	Product Sector
I&G	Employees	Num. of employees
I&G	Residential Rev.	Rev. from internal market
I&G	Export Rev.	Rev. from external market
I&G	Export to DE	Rev. from DE market
I&G	Growth	Rev. growth last 6 mths
I&G	Weight	Sampling Weight

`Category`

Microdata DB	Attribute Name	Category
I&G	Id	Identifier
I&G	Area	Quasi-identifier
I&G	Sector	Quasi-identifier
I&G	Employees	Quasi-identifier
I&G	Residential Rev.	Quasi-identifier
I&G	Export Rev.	Non-identifying
I&G	Export to DE	Quasi-identifier
I&G	Growth	Quasi-identifier
I&G	Weight	Sampling Weight

Figure 4: Metadata Dictionary: `Attribute` and `Category`.

Algorithm 1 shows the Vadalog program adopted for this purpose. It features a recursive application of experience: `ExpBase` is the extensional component and stores for an attribute name A, a known category C, according to available experts' knowledge. Assuming one category per attribute (Rule 1), if our attribute is sufficiently similar (according to a pluggable set of similarity functions or denoted by the $\sim$ symbol) to another attribute A_1 of the experience base for which the category is known, we borrow that category (Rule 2), and recursively feed the conclusion back into the experience base (Rule 3), so as to aid other decisions. Rule 4, technically an equality-generating dependency (EGD), guarantees that each attribute is assigned one single category. This Vada-Sa module lends itself to human-in-the-loop intervention in two points: when deciding whether to consolidate a decision of Rule 2 with Rule 3, as the user may consider a decision to be use-case specific, and when violations of EGD 4 arise, to allow for manual inspection of doubtful cases.

Anonymization Cycle. The interplay between evaluation of statistical disclosure risk and anonymization is at the core of our framework. Given the input microdata DB, the direct identifiers are removed and all the potentially harmful combinations of quasi-identifiers are evaluated to take countermeasures.

Algorithm 2 Anonymization cycle

(1) $\text{Val}(M, I, A, V), \text{Cat}(M, A, C), C \textit{ in } \{\text{Quasi-identifier}, \text{Weight}\}, \text{VSet} = \textit{munion}((A, V)) \rightarrow \text{Tuple}(M, I, \text{VSet})$.
(2) $\text{Tuple}(M, I, \text{VSet}), \#\text{risk}(I, R), R > T \rightarrow \#\text{anonymize}(\text{I})$.
(3) $\text{Tuple}(M, I, \text{VSet}), \#\text{risk}(I, R), R \leq T \rightarrow \text{Tuple}_A(M, I, \text{VSet})$.

The set of Vadalog rules of Algorithm 2 compactly represents this logic. Rule (1) creates `Tuple` facts for each tuple of the microdata DB M, identified by an artificial identifier I, and collects all the name-value pairs for quasi-identifiers and sample weights into the VSet variable. `Val` facts are part of the extensional component and store the value V for an attribute A of the microdata DB M. The identifiers of M are implicitly dropped. Observe that *munion* performs such aggregation, for each microdata DB M and VSet is a set-type variable. Whenever a specific tuple I violates a $[0, 1]$ risk threshold T, a fact `anonymize` is produced for I, in Rule 2. Both `risk` and `anonymize` are atoms defined in external libraries, in Vadalog (denoted by the "#" prefix). In particular, `risk` returns the risk R associated to a given tuple I; it is a compact form for the join "$\#\text{riskInput}(I), \#\text{riskOutput}(I, R)$", where `riskInput` is a fact triggering a Vadalog program producing facts of `riskOutput` for I. More simply, `anonymize` produces new facts for `Tuple`. This mechanism embeds a recursion on Rule 2, to anonymize tuples that still do not pass the risk evaluation. Only those facts for `Tuple` that pass the risk validation of Rule 3 are copied to Tuple_A, which can be considered anonymized.

The anonymization cycle in Algorithm 2 makes the approach *fully explainable* in the sense that each anonymization decision taken by Rule 2 is motivated by the specific binding of its body. It is also *preemptive* and *active*, in the sense that for each threshold violation, greedily applies a single anonymization step, at the same time minimizing the amount of suppressed statistical information. It is *schema independent*, as only atoms of the metadata dictionary are used and there is no specific reference to either schema or instance objects of the single microdata DBs. We shall see how specific values are bound to the attributes as a responsibility of `risk` and `anonymize` implementations. Finally, the algorithm offers multiple degrees of freedom: different risk and anonymization techniques can be used, and our `risk` and `anonymize` and polymorphic, in this sense; specific optimizations and execution heuristics can be adopted to choose which tuples to anonymize first (by controlling the activation order of Rule 2 against its possible bindings), and to choose which quasi-identifiers to anonymize first.

4.2 Statistical Disclosure Risk Estimation

Our `risk` atom in Algorithm 2 is polymorphic. Vada-Sa features a plug-in mechanism to opt for specific implementations at runtime. While the high-level characteristics of the Vadalog language allow to delegate users to specify their own risk logic, with extensive use of business knowledge, a number of techniques are provided off-the-shelf. In this section, we introduce the main risk disclosure evaluation techniques offered by Vada-Sa.

Re-identification-based. We start in Algorithm 3 with re-identification-based risk evaluation, that we have defined in Section 2.2.

Algorithm 3 Re-identification-based risk evaluation

(1) $\text{Tuple}(M, I, \text{VSet}), \text{riskInput}(I), \text{Cat}(M, W, \text{Weight}), R = 1/\textit{msum}(\text{VSet}[W], \langle I \rangle) \rightarrow \text{TupleA}(R, *\text{VSet}[\text{AnonSet}])$.
(2) $\text{Tuple}(M, I, \text{VSet}), \text{TupleA}(R, \text{VSet}*) \rightarrow \text{riskOutput}(I, R)$.

Whenever a tuple I needs to be evaluated (`riskInput` atom), in Rule 1, the name W of the weight atom is retrieved from the metadata dictionary and used to extract the weight value from VSet, with the *access* operator denoted by $[X]$, where X can be either a single attribute name or a collection thereof. Weights are summed (*msum*) and the risk score $1/R$ is computed. `TupleA` has

variable arity, and its terms are the computed risk R and the set of quasi-identifiers to group by when forming the summation. The expression $*$VSet[AnonSet] has the following meaning: the prefix operator "*" is *collection unpacking* and turns each element of the argument collection into a term of TupleA, essential for grouping along quasi-identifiers. Note that VSet is filtered by a set AnonSet of attribute names —the order is irrelevant in this context— that selects those that are considered of interest by business experts w.r.t. risk evaluation. Rule 2 finds those tuples I for which the risk has been computed and returns it. It uses the *packing operator*, denoted by the suffix operator "*", which packs a sequence of terms of TupleA into the set variable VSet. In this way, by joining on VSet, we can identify all the tuples to which the risk computation applies. We have already seen examples of re-identification-based risk estimation in Section 2.2.

k-anonymity is a commonly used threshold approximation of re-identification risk estimation [34]. For a given set of quasi-identifiers, whenever the number of occurrences is less than a fixed threshold k, it is considered dangerous; it is safe otherwise. For instance, in the microdata DB of Figure 1, considering the quasi-identifiers *Area* and *Sector*, we notice, e.g., that there is only one occurrence for "North" and "Public Service" (tuple 1). We say the set of pairs $\{\langle$Area, North$\rangle, \langle$Sector, Public Service$\rangle\}$ is a *sample unique* for tuple 1. The Vadalog reasoning rules for k-anonymity are reported in Algorithm 4.

Algorithm 4 k-anonymity

(1) $\text{Tuple}(M, I, \text{VSet}), \text{riskInput}(I),$
$R = \mathit{mcount}(\langle I \rangle) \rightarrow \text{TupleA}(R, *\text{VSet}[\text{AnonSet}]).$
(2) $\text{Tuple}(M, I, \text{VSet}), \text{TupleA}(R_1, \text{VSet}*)$
$R = \mathit{case}\ R_1 < k\ \mathit{then}\ 1\ \mathit{else}\ 0 \rightarrow \text{riskOutput}(I, R).$

Individual Risk. In the re-identification model the simplifying assumption is made that the sampling weight W_t corresponds to the frequency (number of occurrences) F_k of a given combination k of quasi-identifiers in the total population from which the microdata DB has been sampled; therefore we can compute the combination risk as $1/F_k$. Yet, frequencies F_k are unknown and in general different from W_t. A further inferential step is then required. The typical approach [7, 22, 38] is accounting for F_k in a Bayesian fashion, by considering the distribution of the population frequencies given the sample frequencies $F_k|f_{\hat{\mathbf{q}}}$ and obtaining $1/F_k$ as the posterior mean. In our setting, the sample frequency is the sample count in the microdata DB. Different assumptions can be made on the posterior distribution of $F_k|f_{\hat{\mathbf{q}}}$, with different techniques to accordingly estimate $\rho_{\hat{\mathbf{q}}}$. The one we adopt here is considering such distribution a negative binomial and thus we pose $\lambda = \sum W_t/f_{\hat{\mathbf{q}}}$ to estimate risk in Equation 1 of Section 2.2. Indeed, other distributions can be adopted. The individual risk estimation is formalized in Algorithm 5.

Algorithm 5 Individual risk

(1) $\text{Tuple}(M, I, \text{VSet}), \text{riskInput}(I), \text{Cat}(M, W, \text{Weight}),$
$F = \mathit{mcount}(\langle I \rangle), R = \mathit{msum}(\text{VSet}[W], \langle I \rangle) \rightarrow$
$\text{TupleA}(F/R, *\text{VSet}[\text{AnonSet}]).$
(2) $\text{Tuple}(M, I, \text{VSet}), \text{TupleA}(R, \text{VSet}*) \rightarrow \text{riskOutput}(I, R).$

While scanning through the tuples having a given combination VSet, used as a group-by key thanks to the unpacking operator, Rule 1 counts the occurrences of each combination (frequency) and sums the contributor weights. Facts for TupleA are produced only once all the contributors are available. The risk is then estimated for each combination and finally returned by Rule 2.

SUDA. With k-anonymity, we have introduced the concept of sample unique, i.e., a set of quasi-identifiers —name-value pair— that identify a tuple of a given microdata DB, i.e., they are unique. A sample unique is not the same as a database key, because it expresses a property that holds at tuple level and not at schema level. Alongside the schema-level distinction between superkey and key (a minimal superkey) in relational theory [1], here, at data level, we introduce the *minimal sample unique* (MSU) μ_t for a given tuple, that is a sample unique for which there exists no other sample unique μ'_t for the same tuple, s.t. $\mu'_t \subset \mu_t$. The *Special Unique Detection Algorithm* (SUDA) is a heuristic technique that estimates the statistical disclosure risk of a given tuple based on the size and the number of its MSUs.

Consider for example the set $\mu^1_{20} = \{\langle$Area, Center$\rangle, \langle$Sector, Financial$\rangle, \langle$Employees, 1000+$\rangle, \langle$Res. Rev., 30-60$\rangle\}$ for the microdata DB in Figure 1 for tuple 20. It is sample unique though not MSU, since the set $\mu^2_{20} = \{\langle$Sector, Financial$\rangle\}$ is sample unique and s.t. $\mu^2_{20} \subset \mu^1_{20}$. Moreover, μ^2_{20} is MSU. Similarly, $\mu^3_{20} = \{\langle$Employees, 1000+$\rangle, \langle$Res. Rev., 30-60$\rangle\}$ is another MSU. In total, tuple 20 has 2 MSUs.

Algorithm 6 encodes the Vada-Sa version of SUDA.

Algorithm 6 SUDA

(1) $\text{Tuple}(M, I, \text{VSet}), \text{riskInput}(I) \rightarrow \text{TupleI}(M, I, \text{VSet}).$
(2) $\text{TupleI}(M, I, \text{VSet}), \text{Cat}(M, A, \text{Quasi-identifier}),$
$A \in \text{VSet} \rightarrow \exists Z\ \text{Comb}(Z, I), \text{In}(A, Z).$
(3) $\text{Comb}(Z_1, I),\ \text{TupleI}(M, I, \text{VSet}), \text{Cat}(M, A, \text{Quasi-identifier}),$
$A \in \text{VSet}, \mathit{not}\ \text{In}(A, Z_1) \rightarrow$
$\exists Z\ \text{Comb}(Z, I), \text{InComb}(Z, Z_1), \text{In}(A, Z_1).$
(4) $\text{InComb}(X, Y), \text{In}(A, X) \rightarrow \text{In}(A, Y).$
(5) $\text{Comb}(Z, I), \text{In}(A, Z), \text{TupleI}(M, I, \text{VSet}),$
$\text{ASet} = \mathit{munion}(A) \rightarrow \text{TupleC}(I, *\text{VSet}[\text{ASet}]).$
(6) $\text{TupleC}(I, \text{VSet}*), \mathit{mcount}(\langle I \rangle) = 1 \rightarrow$
$\exists S\ \text{Su}(S, \text{VSet}), \text{HasSu}(I, S).$
(7) $\text{Su}(S, \text{VSet}), \text{HasSu}(I, S), \mathit{not}\ \text{HasSu}(I, S_1),$
$\text{Su}(S_1, \text{VSet}'), \text{VSet}' \subset \text{VSet} \rightarrow \text{MSU}(I, S).$
(8) $\text{TupleI}(M, I, \text{VSet}), \text{MSU}(I, S), \text{Su}(S, \text{VSet}),$
$R = \mathit{case}\ \mathit{size}(\mathit{VSet}) < k\ \mathit{then}\ 1\ \mathit{else}\ 0 \rightarrow \text{riskOutput}(I, R).$

After restricting the focus on input tuples (Rule 1), for each tuple we generate all the combinations of quasi-identifiers, first by introducing a combination Z for each of them (Rule 2), and then by constructing all the possible extensions that can be obtained by adding other quasi-identifiers (Rules 3 and 4). Then, for each combination of quasi-identifiers, generated by unpacking (Rule 5), we generate sample unique facts for Su, denoting those combinations that exactly identify one single tuple. The predicate HasSu is needed since every tuple I can have multiple sample unique sets, while the *mcount* aggregation needs to group by VSet. Rule 7 creates facts for MSU, filtering only those sample unique sets that are minimal. Finally, Rule 8 implements the logic to handle minimal sample unique sets. In this case, we evaluate the size of every MSU and if it is above a given threshold k, we consider the input tuple dangerous and thus return 1. The assumption here is that we cannot accept that the number of quasi-identifiers that can disclose the identity is too small. Clearly, more sophisticated checks could be implemented, possibly also including an overall evaluation of all the MSUs for a given tuple, for example by comparing the average size of MSUs against a threshold.

Figure 5: Local suppression and global recoding.

4.3 Smart Anonymization

In Algorithm 2 we have introduced the anonymization cycle, where Rules 2 and 3 show the interaction between risk estimation, with the main techniques introduced in Section 4.2, and anonymization, the object of this section. Tuples whose risk is considered over a given threshold T, produce facts for `anonymize`, which polymorphically triggers dedicated Vadalog programs: for each tuple I having statistical disclosure risk $R > T$, a new fact for `Tuple` is produced, with the same identifier I and statistical disclosure risk $R' < R$. The process continues recursively, until there is no tuple violating the threshold.

All the statistical disclosure evaluation techniques of Section 4.2 compute the risk associated to each tuple with monotonic aggregations, which play an important role here. In particular, all of them (e.g., *msum* in Algorithm 3, *mcount* in Algorithm 4, etc.) take as input the *aggregation contributor*, denoted by $\langle I \rangle$. According to the monotonic aggregation semantics [6], whenever two or more tuple tuples having the same value for the contributor I are aggregated (e.g., summed, counted, etc.) within the same group (defined by the bindings of head variables), only the tuple providing the least risk contribution is considered, while the others are neglected. This implies that, whenever a tuple I is replaced by a "more anonymous version", for example by suppressing a quasi-identifier, as we shall see, as the two are seen as the same contributor (they have the same value for I), only the anonymized one will be accounted for in the aggregation, so that more anonymized tuples incrementally replace the others and reduce risk, until convergence is achieved. We anonymize tuples with two main techniques: *introducing labelled nulls* to replace selective values, *applying a global recoding*.

Local Suppression with Labelled Nulls. Labelled nulls are a powerful tool from logic-based reasoning, which we effectively apply in the anonymization context. Consider the microdata DB in Figure 5a, where all the attributes are assumed to be quasi-identifiers, the sampling weight is omitted for simplicity, and the frequency of the n-uple of quasi-identifiers is showed on the right. For tuple 1 the set {⟨Area, Roma⟩, ⟨Sector, Textiles⟩, ⟨Employees, 1000+⟩, ⟨Resid. Rev., 0-30⟩} is sample unique. What if we replace the value "Textiles" for *Sector* with a labelled null $\perp_1$? As we are not aware of the underlying value of $\perp_1$, the combination of quasi-identifiers at hand may match with any among tuples 2-5, thus leading to a total frequency of 5. Likewise, tuples 2-5 see their frequency increased to 3. In total, by adding a single labelled null and hence introducing some degree of uncertainty, we have highly decreased the statistical disclosure risk of the microdata DB, as it can be seen in Figure 5b. In fact, a tuple containing one or more nulls may match with different tuples of the microdata DB, or even with none of them, depending on the specific assignment for those nulls.

Going back to what introduced in Section 2.2, in our framework in order to estimate the statistical disclosure risk, we need to compute $\lambda(\sigma_{\hat{q}=\hat{\mathbf{q}}}M)$ over a selection of the microdata DB M, based on an n-uple of values $\hat{\mathbf{q}}$ for quasi-identifiers. The risk estimation techniques of Section 4.2 apply λ to the entire microdata DB and the selection is implicit in the grouping performed by the aggregations, in the sense that, for each tuple, the aggregation forms the group by selecting only those tuples having the same values for quasi-identifiers (or subset of interest, thereof). So, $M(\bar{i}', \bar{q}', \ldots)$ is included in the selection induced by tuple $M(\bar{i}, \bar{q}, \ldots)$ iff $(q'_1, \ldots, q'_n) = (q_1, \ldots, q_n)$, and, by construction, the groups form a partition of the microdata DB. If we allow q_i to be a labelled null, a new semantics must be adopted to define whether $q_i = q'_i$ and thus form the aggregation groups.

The introduction of nulls raises non-trivial semantic issues when aggregations are involved, and theoretical work is still needed to achieve sound characterizations [25]. In Vada-Sa, for the construction of aggregation groups, we adopt a *null-tolerant semantics* inspired by the so-called *maybe-match* approach [14], and assume that $q_i =_\perp q'_i$ holds if: (i) q_i and q'_i have the same constant value, or (ii) either q_i or q'_i is a labelled null. Consequently, $(q'_1, \ldots, q'_n) =_\perp (q_1, \ldots, q_n)$ holds iff $q_i =_\perp q'_i$ holds for every $1 \leq i \leq n$. The $=_\perp$ relation is therefore used, instead of standard equality, to form groups. A tuple containing null quasi-identifiers, as a result of anonymization steps, is assigned to multiple aggregation groups (which do not partition the microdata DB anymore), increasing their cardinality and so anonymity.

We now have all the ingredients ready to encode local suppression, an anonymization method where quasi-identifiers are replaced by labelled nulls to reduce the statistical disclosure risk. The technique is expressed by Algorithm 7.

Algorithm 7 Local suppression

(1) $\text{Tuple}(M, I, \text{VSet}), \text{anonymize}(I), \text{Cat}(M, A, \text{Quasi-identifier}), \text{VSet}[A]$ *is not null* $\rightarrow \exists Z\ \text{Tuple}(M, I, (A, Z) \cup (\text{VSet} \setminus (A, \_)))$.

For a tuple I that needs to be anonymized, as witnessed by the predicate `anonymized`, for a not null quasi-identifier A, we generate a new tuple, where it is replaced by a labelled null Z.

Global Recoding. While local suppression introduces nulls, another technique to control statistical disclosure risk consists in decreasing the granularity of the values on the basis of domain knowledge. Consider again Figure 5a. Tuples 6 and 7 have the following sample unique sets, respectively: {⟨Area, Milano⟩ , ⟨Sector, Construction⟩},{⟨Area, Torino⟩, ⟨Sector, Construction⟩} and therefore have high disclosure risk. Besides the basic metadata dictionary we have seen in Section 4.1, the Vada-Sa KB contains knowledge about the attribute domains as well as the mutual relationship between their values. For instance, for the attribute *Area*, the KB comprises the following information:

Att(I&G, Area). TypeOf(Area, City). SubTypeOf(City, Region).
InstOf(Milano, City). InstOf(Torino, City).
InstOf(North, Region). IsA(Milano, North). IsA(Torino, North).

The *Area* attribute is known to be of `Type` "City", which in turn is a `SubtypeOf` "Region". Moreover we know that Milano and Torino are instances of cities and North is an instance of region. Finally, we now that both Milano and Torino are in the North. Similar knowledge is present for the entire geography.

Algorithm 8 Global recoding

(1) $\text{Tuple}(M, I, \text{VSet}), \text{anonymize}(I), \text{Cat}(M, A, \text{Quasi-identifier}), \text{TypeOf}(A, X), \text{subTypeOf}(X, Y), \text{isA}(\text{VSet}[A], Z), \text{TypeOf}(Z, Y) \rightarrow \text{Tuple}(M, I, (A, Z) \cup (\text{VSet} \setminus (A, \_)))$.

The logic for global recoding is in Algorithm 8. For a tuple that needs to be anonymized, we consider a quasi-identifier A. Based on its type, we climb the hierarchy up to its direct super-type Y. Then for the value $\text{VSet}[A]$ of A, we use the corresponding value Z of Y to replace $\text{VSet}[A]$. This form of suppression can be effectively applied to the entire microdata DB (and in this sense it is "global") and is inherently recursive as multiple hierarchical roll-ups may be needed to guarantee anonymity.

4.4 Enhancing Anonymization

We conclude the section by discussing two advanced topics: embedding of complex business knowledge, where we showcase the use of domain experience for *context aware* anonymization, and implementation of runtime heuristics, to maximize the statistical effectiveness of our approach.

Embedding complex business knowledge. The overall anonymization process can largely benefit from the surrounding business knowledge, an aspect often neglected by dedicated tools. Thanks to reasoning, we can inject business representations into different phases of Algorithm 2: in risk estimation modules, to craft ad-hoc methods; into anonymization techniques, e.g., to opt for specific values for global recoding, and so on. The setting we show here, motivated by our experience in the Bank of Italy with financial networks, consists of taking into account the relationships that exist between the respondents, say X and Y. It is in fact common that the statistical disclosure risk propagates along linked entities, e.g., companies or people, so that being able to re-identify one, makes it easier to re-identify others. In essence, all the linked entities of a given cluster, have the same disclosure risk, obtained as the probability that at least one entity of the cluster is re-identified: $1 - \prod_c (1 - \rho^c)$, where ρ^c is the risk of an entity, calculated with one of the techniques in Section 4.2. Here, along the lines of what usually done to estimate the risk of *households* and *hierarchical structures* [26], re-identification risk is interpreted as the re-identification probability.

Now, types of links that can be considered are arbitrarily complex: finding members of the same family, companies of the same company group are examples. The latter, e.g., could be encoded by the following Vadalog rules: (1) $\text{Own}(X, Y, W), W > 0.5 \rightarrow \text{rel}(X, Y)$. (2) $\text{rel}(X, Z), \text{Own}(Z, Y, W), msum(W, \langle Z \rangle) > 0.5 \rightarrow \text{rel}(X, Y)$. Clusters of companies ($\text{rel}(X, Y)$ holds where X and Y are in the same cluster) are defined by *company control relationships*: if X owns more than 50% of the shares of Y (Rule 1) or controls a set of companies Z that jointly own more than 50% of Y, than X controls Y and thus X and Y are in the same cluster.

Algorithm 9 shows an enhanced version of Algorithm 2, where the risk for a tuple I_2 is estimated as explained. Specifically, Rule 2 uses `#rel` (and we assume here $\text{rel}(X, X)$ holds) to compute the risk for I_1 as the combined risk of the entities in the same cluster. The aggregation *mprod* is the monotonic product, which considers, for each contributor I_2, the maximum contribution it provides, so as to account for the new less risky anonymized tuples produced by Rule 3, and eventually triggering Rule 4.

Runtime heuristics. We have seen how Vada-Sa operates incrementally and applies anonymization steps, only when tuples exhibit an overly high statistical disclosure risk. However, there

Algorithm 9 Enhanced anonymization cycle

(1) $\text{Val}(M, I, A, V), \text{Cat}(M, A, C), C \text{ in } \{\text{Quasi-identifier}, \text{Weight}\}, \text{VSet} = munion((A, V)) \rightarrow \text{Tuple}(M, I, \text{VSet})$.
(2) $\text{Cat}(M, A, C), C = \text{Identifier}, \text{Tuple}(M, I_1, \text{VSet}_1), \text{Tuple}(M, I_2, \text{VSet}_2), \#\text{rel}(\text{VSet}_1[A], \text{VSet}_2[A]), \#\text{risk}(I_1, R), R_{\text{clust}} = 1 - \#mprod(1 - R, \langle I_2 \rangle) \rightarrow \text{Risk}(\text{I}_1, \text{R}_{\text{clust}})$.
(3) $\text{Tuple}(M, I, \text{VSet}), \text{Risk}(I, R), R > T \rightarrow \#\text{anonymize}(\text{I})$.
(4) $\text{Tuple}(M, I, \text{VSet}), \text{Risk}(I, R), R \leq T \rightarrow \text{Tuple}_A(M, I, \text{VSet})$.

are still various open questions to be addressed, which correspond to specific degrees of freedom in anonymizing microdata. If there are two or more tuples that violate the risk threshold, which ones should be anonymized first? Moreover, if there are two or more quasi-identifiers of the same tuple, which one should be suppressed or recoded first?

As for the first question, in Vada-Sa, we adopt a *greedy* approach and choose to anonymize first the tuples that carry less statistical significance (namely, *data utility*), which can be estimated on the basis of the sampling weight. We exploit the so-called *routing strategies* [5] of the underlying Vadalog system to decide which bindings of the rule body to privilege when multiple possibilities arise. The approach here is quite intuitive: a *"less significant first"* strategy sorts the bindings of Rule 2 by risk and guides the anonymization accordingly.

The second question, namely the prioritization of quasi-identifiers, requires more care. We have seen in Algorithms 7 and 8 that either an existential or a higher-level domain value is used to replace quasi-identifiers and the specific attribute to consider is chosen as a consequence of the binding of $\text{Cat}(M, A, \text{Quasi-identifier})$. Also in this case, we can prioritize bindings by adopting a Vadalog routing strategy and the greedy approach. In particular, a *"most risky first"* strategy would first bind the rules against the attributes that affect more the tuple-level disclosure risk. So, in this case, the strategy itself would rely on a Vadalog program computing the risk, in order to take informed decisions. For instance, consider the problem of anonymizing tuple 1 of Figure 5a. Applying local suppression on *Sector* removes any sample unique of the tuple, which then occurs with frequency 5; instead, applying local suppression on *Area*, e.g., would leave the value "Textiles" for *Sector*, and would then require further local suppressions until such attribute is removed, with a consequential loss of data utility. In other terms, a greedy approach to local suppression or global recoding sustains the preservation of data utility.

5 EXPERIMENTS

Vada-Sa has been fully implemented and engineered in the Vadalog System. Towards a production application of the framework for the Research Data Center of the Bank of Italy, the system has been extensively experimented on real-world datasets from the Bank of Italy and synthetic ones to assess its *anonymization capability* (Section 5.1) and *scalability* (Section 5.2). The schema independent approach makes the framework general purpose and suitable for treating datasets in any domain.

Datasets. The microdata DBs used in the experimental analysis are reported in Figure 6. The *real-world* and *realistic datasets* derive from the *Inflation and Growth Survey* of the Bank of Italy, whose schema is shown in Figure 1. The *synthetic datasets* have been generated by fitting the real-world distribution (denoted by "W" in the figure) or by inducing specific unbalanced or very unbalanced distributions (denoted by "U" and "V"). Unbalanced

Dataset	No. Att.	No. Tuples	Dist.	Data
R6A4U	4	6k	U	Synth
R12A4U	4	12k	U	Synth
R25A4W	4	25k	W	Real-world
R25A4U	4	25k	U	Realistic
R25A4V	4	25k	V	Realistic
R50A4W	4	50k	W	Synth
R50A4U	4	50k	U	Synth
R50A5W	5	50k	W	Synth
R50A6W	6	50k	W	Synth
R50A8W	8	50k	W	Synth
R50A9W	9	50k	W	Synth
R100A4U	4	100k	U	Synth

Figure 6: Datasets used in the experimental settings.

distributions comprise many tuples with very selective combinations of quasi-identifiers, which exhibit high disclosure risk.

Hardware. We employed a memory-optimized virtual machine with 16 cores and 128 GB RAM on an Intel Xeon architecture.

5.1 Testing Anonymization Capability

We analyzed the capability of the system to detect tuples that need to be anonymized (i.e., the "risky" tuples).

Reduction of risk vs. loss of information. We applied the Vada-Sa anonymization cycle to the real-world dataset *R25A4W* with the *k-anonymity* risk evaluation technique (Section 4.2) and choosing a risk threshold $T = 0.5$. We employed *local suppression* anonymization (Section 4.3), with a *less significant first* runtime heuristic (Section 4.4). We varied the anonymity threshold k from 2 to 5. We adopted two metrics to evaluate the capability of the system to detect risky tuples: we counted the number of nulls injected by the local suppression as a result of risk evaluation, so analyzing how many values the system was able to erase (Figure 7a); we estimated the *loss of information* by weighing the number of erased values (i.e., the injected nulls) by the maximum total number of values, those of quasi-identifiers of the risky tuples w.r.t. T, that can be theoretically removed (Figure 7b) to satisfy the k-anonymity requirement. For both the measurements, we also evaluated the robustness of the approach, by applying the anonymization cycle to artificial but realistic datasets (*R25A4U* and *R25A4V*) having the same distribution of quasi-identifiers of *R25A4W*, but with an increased number of risky tuples.

The results in Figure 7a confirm what expected: when the k-anonymity threshold is increased, the anonymization cycle becomes less tolerant, and more redundancy is required to guarantee anonymity, therefore, in absolute terms, more and more labelled nulls need to be added to suppress specific values. We also observe that the number of needed nulls linearly grows with the tolerance threshold, as a consequence of an overall uniform distribution of values in the adopted combination of 4 quasi-identifiers. While an average real-world dataset requires less than 50 labelled nulls for 25k tuples with a 5-tuples tolerance threshold, more unbalanced versions require more, while confirming the trend. Figure 7b witnesses very good behaviour of Vada-Sa in terms of statistical preservation. For the real-world and the mildly unbalanced dataset, the loss of information is constantly below 20%, in particular between 12% (lower bound of *R25A4W*) and 17% (upper bound of *R25A4U*). For these two datasets, the constant trends show that when the number of risky tuples increases, the greedy approach succeeds in removing the values with a wider risk reduction effect. The loss of information for the very unbalanced dataset *R25A4V* is clearly higher, 37%, but it interestingly drops to 13% with less tolerant runs, because the high number of tuples that are considered risky on different combinations of values of quasi-identifiers, collapse in the k-anonymity comparison, when labelled nulls are introduced: so, while the number of nulls is high in absolute terms, the loss of information decreases. This result turns out to be an extremely positive guarantee of the anonymization capability of Vada-Sa.

Maybe-matching labelled nulls. In this experiment, we want to assess the effectiveness of the maybe-match semantics, which we use to compare labelled nulls with one another (and has been described in Section 4.3), as opposed to the standard semantics of labelled nulls, such as that adopted in chase-based procedures (e.g., Skolem chase [11]). According to the standard semantics, for a quasi-identifier q_i, we have that $q_i =_\perp q_i'$ holds if: (i) q_i and q_i' have the same constant value, or (ii) both q_i and q_i' are labelled with the same null symbol. We plugged this semantics into Vada-Sa, used the same real-world and realistic datasets of Figure 7b and report the number of injected nulls by k-anonymity threshold in Figure 7c. Also here, the risk threshold $T = 0.5$ has been used. The figure highlights the proliferation of symbols (the red lines) that takes place with the standard semantics, which is in fact unusable in this setting. By contrast, the probabilistic interpretation of nulls we foster, minimizes the number of labelled nulls (the light-blue lines, whose zoomed version is in Figure 7a).

Using business knowledge. We show the results of anonymization in a real-world setting where anonymization cycle is complemented with a set of Vadalog rules that produce derived extensional knowledge about control relationships between companies. The rules and the setting have been presented in detail in Section 4.4. For the test, we adopt the real-world dataset *R25A4W* and its tweaked unbalanced versions, *R25A4U* and *R25A4V*. We anonymize each of the datasets by estimating the risk with k-anonymity with $k = 2$ and $T = 0.5$. We measure the number of nulls injected by local suppression in 5 settings, with increasing number of inferred control relationships, from 0 to 400.

The results are shown in Figure 7d. With all the datasets, the number of injected nulls grows with the number of relationships between entities, which induce bigger and more risky clusters. The three distributions of the quasi-identifier values differently interact with the derived relationships: the more unbalanced the dataset is, the more tuples will be affected by the propagation of risk of the outliers, resulting into a globally risky dataset, to be severely anonymized. In real-world tests, relationships disclose many cases that deserve anonymization (from 9 in the case of 100 relationships to 38 for 400), while the propagation effect is maximized in the *R25A4V* dataset with an upper bound of 323 injected nulls for 300 relationships.

5.2 Testing Scalability

Given the characteristics of the data at hand to be anonymized, we need to make sure that our approach scales well. Although the anonymization cycle, risk estimation and anonymization of Vada-Sa are expressed in Vadalog, where reasoning is PTIME in data complexity [6], here we want to investigate on the specific runtime of the system in different settings.

By dataset size. We tested the scalability of Vada-Sa by increasing volumes, with 4 synthetic datasets (from *R6A4U* to *R100A4U*), unbalanced and having a high number of risky tuples. We measured the elapsed time for the entire anonymization cycle and also pointed out the sole risk estimation component, with 3 different risk estimation techniques (*individual risk*, *k-anonymity*, *SUDA*). We used $k = 2$ for k-anonymity, 3 as the MSU threshold

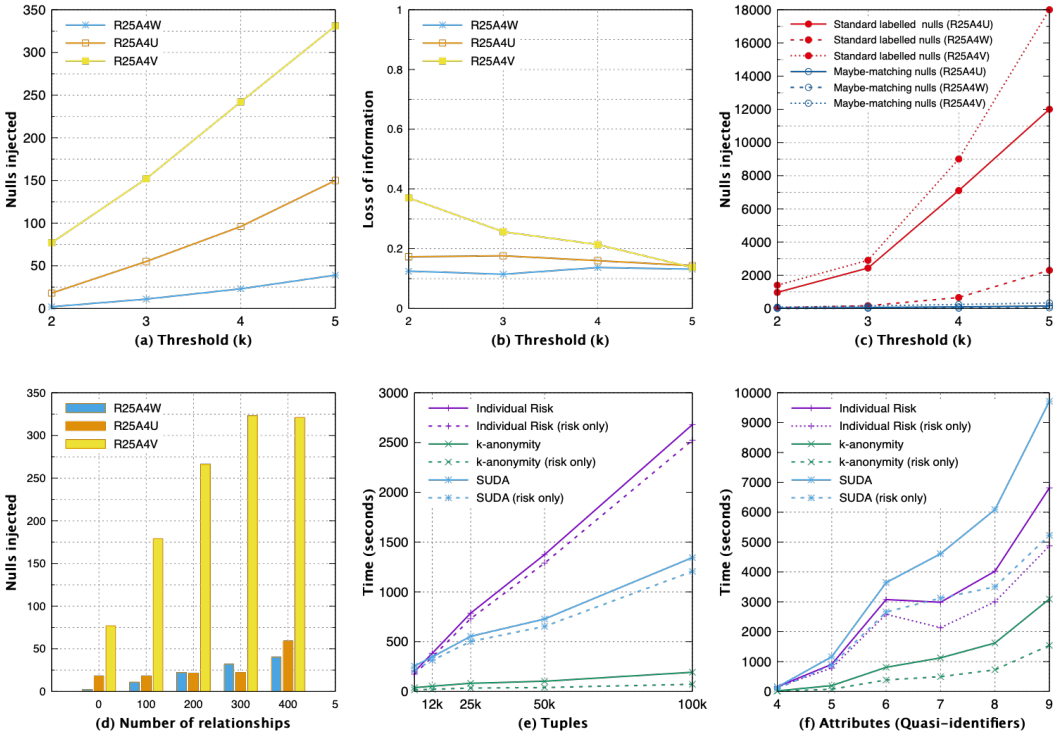

Figure 7: (a) Number of nulls injected by k-anonymity threshold. (b) Information loss by k-anonymity threshold. (c) Number of nulls injected with maybe-matching viz. standard labelled null semantics. (d) Number of nulls injected by increasing number of relationships in settings with explicit modeling of business knowledge. (e) Execution time by dataset size and risk estimation technique. (f) Execution time by number of quasi-identifiers and risk estimation technique.

for SUDA (see Section 4.3) and $T = 0.5$. We executed each run 5 times and averaged the measurements, for a total of 60 runs.

The results are shown in Figure 7e. All the three groups of trends confirm that the risk estimation component (dotted lines) dominate the elapsed time. This is reasonably expected, as the convergence of our anonymization cycle depends on a positive evaluation of risk estimation, which is then the bottleneck. The linear trend confirms the applicability of the approach. In particular, k-anonymity exhibits a very good behaviour, with elapsed time between 6 and 192 seconds for $100k$ tuples. The limited cost of estimation can be ascribed to the adoption of monotonic aggregations, which adopt incremental updates and need not be recomputed from time to time. Whilst in Algorithm 5 we have made a simple assumption to estimate the risk from the posterior distribution $F_k|f_{\hat{q}}$ (which would have led to elapsed times similar to those for k-anonymity), for this experiment we plugged into Vada-Sa an off-the-shelf statistical library and sampled from the actual negative binomial distribution. The costly trend is motivated by the interaction overhead between the native Vadalog component and the library. The trend for SUDA is less than linear, with, e.g., 727 seconds for $50k$ and 1344 seconds for $100k$ tuples since the potential blowup on the number of examined combinations of quasi-identifiers is controlled by the Vadalog optimizations.

By number of quasi-identifiers. To investigate more the dependence of performance on the number of quasi-identifiers, we stressed Vada-Sa by anonymizing 6 datasets *R50A4W-R50A9W*, so with increasing number of attributes and fixed number of tuples, $50k$, and real-world-like distribution. We used the same thresholds for k-anonymity, SUDA, and T. We measured elapsed time and the risk estimation component. We executed each run 5 times averaging the results, for a total of 90 runs.

Figure 7f reports the results. As expected, individual risk and k-anonymity are only marginally affected by the increased number of quasi-identifiers, as they do not consider all the combinations with at most k attributes, but only those with exactly k. Instead, we may expect a much worse trend for SUDA, where for each tuple, all the combinations of at most k attributes are inspected to detect potential MSU. Remarkably, no combinatorial blowup appears in the figure, witnessing a very effective behaviour of the Vadalog execution optimization: while the activation of Rules 2-5 of Algorithm 6 could in theory cause a blowup w.r.t. k, it does not happen in practice because the greedy activation of Rule 7 performed by Vadalog to detect the MSUs preempts the generation of redundant combinations of quasi-identifiers.

6 RELATED WORK

Statistical disclosure control is a broad topic to which many have contributed, especially from the Statistics community, whose work can be considered related to ours.

The concept of *Sample Uniqueness* (SU) to measuring the risk of data disclosure was introduced by Skinner [35], while *k-anonymity*, was first presented by Sweeney [37], along with the first methods of anonymization by generalization (our *global recoding*) and *local suppression*. The measure of *individual risk* in our contribution is inspired by the work of Benedetti and Franconi [7] who proposed to compute the risk of data disclosure with the sampling weights of data records.

The topic of data anonymization is related to the area of *differential privacy* [17], where an interesting concept may be adopted in our approach so as to develop a new family of risk measures,

based on the idea that an individual's privacy may be violated even knowing the absence of the individual from the microdata. Investigating such direction will be matter of future work.

While the foundations of our work are set in the theory of statistical disclosure control, our contribution is concerned with providing an industrial production ready solution for the Bank of Italy, conveying a set of properties that derive from a fully declarative reasoning approach. In this sense, we combine our experience in logic-based reasoning [6] and schema-independent solutions to model management problems [3]. None of the existing dedicated software solutions for statistical disclosure control offers the mentioned set of properties. The software pack ARGUS [27] aims at local suppression and coding, as does the Datafly system [36]. Manning et al. introduce SUDA2 (Special Unique Detection Algorithm) [29], whose objective is to detect the risk in certain unique combinations of variables. Recently, the *R* package *sdcMicro* has implemented many of the risk measures and anonymization approaches of our interest [9]. Likewise, ARX is a solution for data anonymization that has been proposed as a practical approach to Statistical disclosure control [33]. A comprehensive survey of the statistical approaches has been provided by Matthews and Harel [30]. Recent work on the risk of information disclosure in linked data, and, more in general, ontology-based data, has formalized the problem and defined its logical foundations [8], with an interest in the concept of linkage safety in RDF graphs [24]; a declarative framework for linked data anonymization has also been proposed [15]. The problem of preserving privacy in data exchange has been analyzed also in the context of information integration systems [31] where a practical solution is represented by *MapRepair* [10] and in the cryptography community, with homomorphic encryption [28].

In the AI literature, statistical disclosure control has been mostly considered within machine learning [16] and deep learning approaches [4]. Yet, they have a different focus and aim at generating anonymized clones of existing datasets while respecting the original statistical properties. An interesting deductive proposal by Øhrn and Ohno-Machado uses Boolean reasoning for data anonymization in databases [32], which however remains purely theoretical and just considers the combinatorial aspect.

7 CONCLUSION

In this paper, we presented Vada-Sa, a declarative statistical disclosure control framework. We demonstrated the anonymization workflow, metadata dictionary, and statistical disclosure risk estimation. Utilizing these components, we introduced the anonymization cycle. To maximize the statistical effectiveness of our approach, we also presented two enhancements, namely embedding of complex business knowledge and runtime heuristics. We validated the approach on real-world central bank data. As future work, we plan to further enhance the framework, and test it in a variety of other real-world scenarios.

ABSTRACT

The detection of duplicates is an essential task in data cleaning and integration and has steadily gained importance especially for researchers and practitioners that need to process and integrate large volumes of potentially unclean data on a daily basis. To evaluate the quality and performance of duplicate detection algorithms, labeled test data are required that provide information on the contained duplicates. Current approaches for generating test data, however, are either not scalable (and therefore limited to small datasets) or not able to generate realistic data values and errors, especially outdated values. In this paper, we propose a scheme for generating test datasets that addresses both these issues and present a test dataset generated with it. Our approach relies on using historical data from the North Carolina voter register which (1) is realistic as it contains actual voter data and (2) facilitates generating realistic duplicates through the fact that current data values were collected at every election through manually filled out applications. The generated test dataset comprises more than 120 million records with up to 90 attribute values each. To the best of our knowledge, we are the first who provide realistic test data for duplicate detection at this scale.

1 INTRODUCTION

Duplicates are data records (e.g., tuples in the relational case) that refer to the same real-world object. They can result from errors in data management, but also occur because separately developed data sources overlap in their universes of discourse (e.g., many actors and movies are stored in both IMDB[1] and TMDb[2]). The detection of duplicates is an important task in data cleaning [12, 16] and integration [8, 9]. Detecting duplicates is quite simple when they are exact, i.e. they agree in all of their values. However, it can be extremely difficult if some of their values disagree due to typos, phonetic or transformation errors, heterogeneous forms of presentation as well as missing or outdated values [14].

The challenge of detecting such so-called *fuzzy* duplicates has opened up its own field of research and has since been studied intensively [4, 7, 23, 31]. However, the best approach to find them strongly depends on (i) the considered domain (e.g., movies, persons, or proteins), (ii) the characteristics of the given data (e.g., volume, data model and heterogeneity), and (iii) the quality and cost requirements of the user (e.g., good results vs. short runtimes and recall vs. precision). Due to the resulting diversity of use cases, none of the existing algorithms has turned out to be a generally applicable and superior solution. Instead, in every use case, it remains a difficult (and expensive) task to choose and configure them so that they provide adequate results.

Such a configuration process requires the evaluation and comparison of different algorithms and parameter settings. This in turn requires test datasets that do not only provide a *gold standard* (a.k.a. *ground truth*) labeling the dataset's duplicates [21], but resemble the required real-life properties as well as possible. Current approaches to test data generation either (i) struggle with the generation of realistic data values and errors (especially outdated values), (ii) cannot guarantee the soundness of the gold standard[3], or (iii) scale badly and thus can only be used to generate small datasets. However, realistic values and errors as well as correctly labeled duplicates are an important prerequisite for a test dataset. Moreover, in times of big data many duplicate detection algorithms focus on scalability (e.g., [13, 17, 30]) so that an evaluation of their key functionalities requires large test datasets with millions of records.

Using a historical dataset to generate test data seems to be a straightforward solution to some of the aforementioned problems, because the mapping between records and real-world objects is part of the data so that the duplicates are already labeled. Thus, it scales much better than, for example, labeling the duplicates in an unclean dataset manually. In addition, historical datasets are perfectly suited to generate outdated values, because these values are an inherent part of the data. One of these historical datasets is provided by the State of North Carolina (short NC) [26]. This dataset contains information on voters registered to the individual elections and – at the time of our study – consisted of 45 snapshots covering a time period of 16 years with a total number of over 500 million records and a large schema with 90 attributes. These numbers make it a perfect candidate to evaluate the suitability of the aforementioned idea, because the large number of records allows us to generate a test dataset of large size and the large time span provides us many outdated values (even more than one for the same object property). Furthermore, since voters often have to re-register at regular intervals by manually filled out forms[4], the registration data contain typos, values confused between attributes, heterogeneous forms of presentation and missing values which makes this dataset particularly useful for

[1] Internet Movie Database: https://www.imdb.com
[2] The Movie Database: https://www.themoviedb.org

[3] To clearly distinguish between errors in the duplicate labels and the operational data, we use the term *soundness* w.r.t. the correctness of the gold standard.
[4] https://dl.ncsbe.gov/?prefix=Voter_Registration/

the generation of fuzzy duplicates. Finally, its large size gives us the opportunity to customize the test data to different user requirements by selecting a suitable subset of all records (the more data available, the more flexible the selection process). However, the big amount of redundant data as well as the ongoing publication of new snapshots also pose some challenges to the generation process making it a non-trivial task.

The contributions of this paper can be summarized as:

(i) A comprehensive list of desiderata for test datasets for duplicate detection.
(ii) An approach for generating and storing test data based on the historical voter register from North Carolina.
(iii) A realistic test dataset generated with our approach.
(iv) An extensive experimental evaluation to analyze the quality and prove the usability of the generated test dataset.

We provide the generated dataset to other researchers[5]. It will help them to evaluate their algorithms (such as runtime behavior or robustness against a varying number of data errors) and to compare them with those of other research projects. It is particularly valuable to the research community through a combination of properties that is unique to the best of our knowledge:

- It contains more than 120 million records and 640 million duplicate pairs making it suitable to evaluate duplicate detection algorithms at scale,
- it contains real-life errors of various types including typos, abbreviations, phonetic errors and outdated values,
- its large size qualifies it to customize the test data to different user requirements without losing necessary volume,
- it provides precalculated plausibility and heterogeneity scores, which support the user to remove (or repair) potentially unsound duplicate clusters and adapt the datas' heterogeneity to her own requirements, and
- it provides meta information that allows the user to reproduce experiments using previous versions of this dataset.

The rest of this paper is structured as follows: In Section 2, we describe the input to our study, i.e. the voter register from North Carolina. Thereafter, in Section 3, we discuss several aspects affecting the test datas' quality, usability and reproducibility. In Sections 4 and 5, we describe our approach for using the historical voter data for test data generation. In Section 6 we present an experimental study that evaluates the quality and usability of the generated test dataset. Finally, we discuss related work in Section 7 before we conclude the paper and give an outlook on future research in Section 8.

2 NORTH CAROLINA VOTER REGISTER

The voter register from North Carolina was created and is still maintained by the *North Carolina State Board of Elections*[6] according to the *Help America Vote Act* (HAVA) of 2002. The provided voter records are considered public information per NC General Statutes (§132-1, §163-82.10) [1, 25], but do not include dates of birth, driver's license numbers and social security numbers because they are confidential under state law [1, 20, 26].

In addition to current data, the register provides a voter history in the form of a series of snapshots [24]. The first publicly available snapshot is from 2005-11-25. New snapshots were (and still are) created at every New Year's Day and the date of every election (general, primary and municipal) [26]. At the time of our study, the register contained 45 snapshots. The schema of these snapshots evolved over time, but was consistent for the last 41 snapshots. Since the first four snapshots are missing necessary information to clearly identify a voter, we excluded them from our study. The characteristics of the remaining snapshots are presented (in an aggregated form) in Table 1. The whole voter history contains 522,463,029 records representing a total of 13,569,512 distinct persons.

Table 1: Overview of the snapshots included in this study

	#snap-	#total	#new		rate of new	
year	shots	records	records	objects	records	objects
2008	1	9.7 M	9.7 M	9.4 M	100%	96.8%
2009	1	9.7 M	0.7 M	37 K	6.8%	5.6%
2010	2	20.2 M	13.1 M	189 K	64.9%	1.4%
2011	1	10.3 M	2.3 M	225 K	22.2%	9.9%
2012	4	41.8 M	19.9 M	820 K	47.6%	4.1%
2013	1	11.4 M	11.1 M	41 K	97.1%	0.4%
2014	4	47.3 M	7.5 M	432 K	15.8%	5.8%
2015	4	49.0 M	6.6 M	223 K	13.5%	3.4%
2016	4	50.9 M	7.7 M	587 K	15.1%	7.6%
2017	4	54.1 M	3.6 M	245 K	6.7%	6.7%
2018	3	41.7 M	23.7 M	374 K	56.9%	1.6%
2019	7	99.8 M	5.5 M	354 K	5.5%	6.5%
2020	4	60.8 M	8.0 M	596 K	13.1%	7.4%
2021	1	15.9 M	0.8 M	62 K	5.1%	7.6%
total	41	522.5 M	120.8 M	13.57 M	23.1%	11.2%

M = million, K = thousand

Each snapshot corresponds to a large tab-separated values (TSV) file. As it turned out during data profiling, these files are formatted differently. While the older files (if not updated later) are in UTF-8, the newer files are in UTF-16. Since none of the provided attributes is expected to contain characters that are not part of the UTF-8 character set, we converted all files to UTF-8 before importing them into our dataset. Here it is important to note that occasional conversion errors do not spoil our test dataset, since they also happen in real-life, as long as they do not corrupt the correct mapping between records and objects required for the gold standard (i.e., they do not concern the NCIDs).

Every record in the snapshot files specifies an entry to the voter register and consists of 90 attributes. We grouped these attributes into four semantic categories:

- personal information (38 attributes) such as names, age, address data, phone number, race code and sex,
- information on the districts the voter is registered in (38 attributes), such as school, water and fire district,
- information on the voter that is closely related to the election she is registered to (11 attributes), such as voter status and registration date, and
- meta data for administrating the snapshots and identifying voters/records within them (3 attributes), which are the NCID as well as the snapshot and load date.

The NCID is a unique number for each voter currently or previously registered in North Carolina. A voter's NCID will follow him from one county to another when she migrates within the state of NC. Thus, the NCID can be used to uniquely identify the individual voters and therefore can serve as an object-id. To our surprise, we discovered that in every snapshot many voters are represented by more than one record. A closer look revealed that at most only one of them has not the voter status *removed* (and hence is not outdated). This means that every snapshot already corresponds to a historical dataset.

3 TEST DATA DESIDERATA

Before we describe in which way we used the history of the NC voter register to generate test data in Section 4, we will take a closer look on the desired properties of such a test dataset. A suitable test dataset has to ensure a high

- *quality*, i.e., the test data should enable meaningful evaluation results,
- *usability*, i.e., the user should be able to customize the test data according to her requirements, and
- *reproducibility*, i.e., the user should be able to reproduce the results of past evaluations that used previous versions of this dataset in order to achieve adequate comparability.

In the rest of this section, we will discuss these requirements and the problems that are related with them in more detail. The way we handled them in our generation process will be described in the remaining course of this paper.

3.1 Quality

A test dataset is of good quality if its gold standard is sound, its data contain real(istic) errors of different types and it contains only few exact duplicates.

3.1.1 Soundness of the Gold Standard. A test dataset for duplicate detection consists of a set of data records and the corresponding gold standard that specifies the duplicate status between the individual records. While errors in the actual data are quite desirable (see Section 3.1.2), it is extremely important that the gold standard is sound, because even a small number of incorrectly labeled record pairs (i.e., *false positives* and/or *false negatives*) can render evaluation results completely useless.

In a perfect world, the mappings between the voter records and actual voters are sound. However, almost no dataset is free of errors. Thus, it make sense to perform a soundness check on the test data because, as we illustrate in Figure 3, there may be clusters whose records do not seem to represent the same voter although they share the same NCID. Marking those clusters allows the user to remove or repair them before using the test dataset. Since we often cannot distinguish between sound and unsound clusters with absolute confidence, it does not seem wise to use a Boolean flag as a marker, but to compute similarities which reflect a kind of likelihood that these clusters are sound (i.e., all their records represent the same voter). The user can then use these similarities to decide which risk she wants to take to include unsound clusters into her test data. We refer to this similarity as *plausibility* in the rest of this paper and discuss a calculation of plausibility scores for the NC test dataset in Section 6.2.

3.1.2 Error Diversity. The results of an evaluation with a test dataset are only representative if this dataset contains real-life (or at least realistic) data values and errors. In our case, both are real because they originate from a real-life dataset. Moreover, users want to evaluate algorithms that should later be applied to error-prone data. This requires that the test dataset contains errors of various kinds and not only outdated values. This includes typos, abbreviations, invalid values, inconsistencies and different forms of representation. In other words a test dataset of high quality has to contain several problems of data quality.

3.1.3 Amount of Exact Duplicates. Another aspect that affects the usefulness of evaluation results is the number of exact duplicates contained in the test data. The detection of such duplicates is rather simple and every duplicate detection algorithm – no matter how primitive – should be able to detect them. Thus if this number dominates the number of fuzzy duplicates by far, an accurate detection of the latter becomes less relevant in order to achieve a good evaluation result. For example, if 90% of all duplicate pairs are exact, even the most primitive algorithm would achieve a recall of 0.9 or higher if it is able to compare values on equivalence. Moreover, an algorithm that classifies only the exact duplicates as such and all other pairs as non-duplicates (precision is 1.0) would even achieve a F_1-score of 0.9 which is a pretty good result. However those algorithms are completely useless when it comes to real-life use cases where fuzzy duplicates need to be detected. While this aspect is of little relevance in many approaches to test data generation (the number of exact duplicates is usually very small there), it is of great importance when using historical data, since many of the given snapshots overlap to a large extent, so that their combination leads to many exact duplicates. As we will see in Section 4, by simply combining the individual snapshots of the NC voter register we produced a relative amount of exact duplicates of over 90%.

The actual definition of an exact duplicate pair is that both records share the exact same value in every attribute. However, in the case of the NC voter data, solely removing those duplicates which are completely identical does not solve this problem, because often many of the remaining duplicate records only differ in some minor aspects, such as:

- *Meta Data Attributes*: Many duplicate records only differ in some date values, such as snapshot or registration date, that are less relevant for the duplicate detection process.
- *Time-related Attributes*: The voters' age values increase by one every year and thus cause that some duplicates are no longer exact, although none of the other characteristics of the corresponding person changed.
- *Whitespaces*: Many values contain leading and trailing whitespaces that are simply to detect and remove by trimming all data values in an initial preparation step.

We describe how we addressed this problem in Section 4.

3.2 Usability

Since we aim to provide test data for duplicate detection at scale, the resulting dataset should contain several million records. Besides size, the requirements of the individual users can vary from one evaluation to another. Therefore it is advantageous if the test data can be adapted to the needs of the respective use case in terms of several data characteristics, such as the number of clusters, the cluster sizes, or the degree of heterogeneity (a.k.a. *dirtiness*). This can be accomplished by applying a postprocessing step, which selects a subset of all data carefully. Further options for customization are the removal and merge of attributes, changing the character of the attributes' values. A flexible and unconstrained customization requires that the test dataset contains (i) many duplicate clusters of various sizes and (ii) duplicate records of different degrees of heterogeneity, so that the user has a large set to choose from. In addition, it requires that the user can adjust the characteristics of the test data with relative ease. This can be supported by storing all records of one cluster together and providing precalculated heterogeneity scores.

The heterogeneity of the individual duplicate clusters (or duplicate pairs) represents the degree to which the duplicate records differ from each other. At the same time, it can be considered as a measure on the difficulty of detecting the fuzzy duplicates within this dataset because duplicates are usually the more difficult to detect, the more their values differ. Thus, this information does

Table 2: Statistical results of the generation process

duplicate removal	*#records*	*#dupl. pairs*	*cluster size*		*#removed*	
			avg.	*max.*	*records*	*pairs*
no	522.5 M	12,108.2 M	38.50	399	0%	0%
exact	166.3 M	1,225.0 M	12.26	104	68.2%	89.9%
trimming	120.8 M	648.2 M	8.90	77	76.9%	94.6%
person data	58.7 M	136.7 M	4.33	51	88.8%	98.9%

*The number of objects (i.e., clusters) was always 13.57 M.

not only provide interesting insights into the nature of the test data, but also allows the user to customize the level of difficulty of her test dataset individually by filtering out clusters/records whose heterogeneity is not within a requested range. This can be useful when the user wants to test her algorithms with datasets of different degrees of dirtiness. It is important to note that such filtering can theoretically be performed on any test dataset. However, only a large number of clusters and records allows the user to compose arbitrary subsets without running into the problem of producing a too small output.

3.3 Reproducibility

The NC voter register is subject to constant change and new snapshots are published regularly. This gives the opportunity to extend the generated test dataset on a regular basis, too, which does not only provide data on new voters (i.e., more duplicate clusters), but also new data on already existing voters (i.e., larger duplicate clusters and higher degrees of duplicate heterogeneity). In general, the longer the time span covered by a test dataset, the more outdated values it contains. Moreover, a longer time span increases the chance of obtaining outdated values even for attributes that do not change very frequently (e.g., the last name).

In performance and quality evaluation, *reproducibility* [27] (a.k.a. *repeatability* [28]) is an important aspect because it is necessary to enable a fair comparison between (the evaluation results of) different algorithms especially if they are evaluated at different times by different parties. In this context, reproducibility means that another evaluation process (or at least its experimental setting) can be reproduced exactly. This includes the use of the same test data. Thus, test datasets that change over time pose a problem for reproducibility, especially if their size does not allow a separate storage of every intermediate version. To solve this problem, the datasets must be enriched by information that allows the user to reconstruct any of the old versions on request. It is important to note that such a reconstruction does not only apply to the actual records, but also all meta data (e.g., statistics and similarities) that are stored to describe them. We discuss how we ensure reproducibility for our test dataset in Section 5.1.

4 TEST DATA GENERATION

Since every snapshot of the voter register already contains outdated records and we wanted to reduce execution time as well as the number of exact duplicates as much as possible, we started to experiment with a single snapshot. Because we planned to use as much data as possible and the size of the snapshots grew monotonically over time, we used the most recent one. At the time of our analysis, this was the one created at 2021-01-01 and indeed, among all available snapshots, it contains the most records having the voter status *removed* (and thus are potentially outdated). The total number of records in this snapshot is 15,863,484 (8,308,925 *removed*) which corresponds to 3.04% of all voter records. However, the experiments showed that the amount of historical information stored in the individual snapshots is rather low compared to the whole history and thus only provides small clusters (see Figure 1a). Therefore, we also evaluated the entire voter history containing all snapshots available. By doing so, we examined a total of 522,463,029 records.

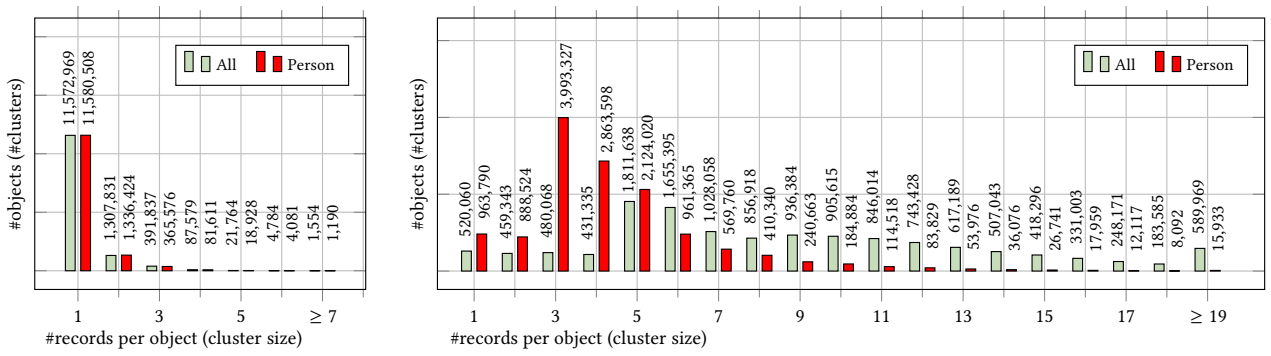
One of our goals was to analyze the amount of (near) exact duplicates within the resulting test data. Moreover, we think that most potential users are only interested in the personal data of the voters, since the election and district attributes are very case-specific. Therefore, we executed our approach four times: (i) one time without removing any duplicates, (ii) one time with removing all exact duplicates, (iii) one time with removing all duplicates that were exact after their values have been trimmed (i.e., leading and trailing whitespaces were deleted), and (iv) one time with removing all duplicates whose personal data were equivalent (after trimming attribute values). To check the equivalence of duplicate records efficiently, we used the *Message-Digest Algorithm 5* (short MD5) to calculate a hash value for each record. A record was then not imported into the test dataset when it already contained a record with the same hash value. Of course, collisions between non-exact records cannot be excluded for sure, but such a collision only means that the test dataset loses a duplicate record and thus does not have severe consequences if it happens a few times[7]. The input to the hash function is the concatenation of the values of all relevant attributes to a single large string. As mentioned in Section 3.1.3, some meta data and time-related attributes can reduce the number of near exact duplicates drastically and therefore were not included into the concatenation. These attributes are the different dates (snapshot, load, registration and cancellation) and the age[8].

The number of resulting objects (i.e., duplicate clusters), records, duplicate pairs, the average and maximal number of records per object (i.e., duplicate cluster size), as well as the number of removed records and duplicate pairs are listed in Table 2. The number of distinct duplicate clusters (i.e., objects) per cluster size (i.e., number of records per object) is presented in Figure 1b (one time for all attributes and one time for the personal data only). Using a single snapshot did not produce any exact duplicate which was even less than expected. In contrast, using all snapshots produced hundred of millions of exact duplicates. Obviously, the average number of records per voter decreased when these exact duplicates were removed (e.g., 8.90 without whitespaces) and decreased further on when we restricted the data to the personal attributes (4.33), but was still large compared to the single-snapshot approach (1.18). In total, the number of records that were removed because of being exact duplicates was up to 76.9% and the number of removed duplicate pairs was up to 94.6% when all attributes where taken into account and up to 88.8% and 98.9% if only person data was considered. These large amounts of exact duplicates illustrate the importance of their removal, because otherwise every evaluation of duplicate detection algorithms using these data would suffer from the effects described in Section 3.1.3.

To estimate the value of future snapshots, we counted the number of new clusters (i.e., the snapshot contains an NCID that

[7] MD5 produces 128 bit hashes, which means that it is relatively unlikely that the hash values of two different inputs collide.

[8] In the case of age values, the most obvious solution is to transform them into years of birth because the latter do not change. However, such a calculation would enclose a part of the dates of birth, which were originally removed from the data due to privacy reasons. We have therefore decided to use them only for internal calculations (e.g., plausibility) and not to store them in the resulting test data.



(a) Single Snapshot **(b) All Snapshots**

Figure 1: Distribution of the number of records per object (i.e., cluster size) after removing exact duplicates (trimming)

was never used before) and new records (i.e., the snapshot contains a record that was not part of any of the previous snapshots) per snapshot-year. These numbers are presented in Table 1 (note that the second includes the first). The last two columns show the percentage of rows that result in a new record (*new record rate*) and the percentage of new records that lead to a new cluster (*new object rate*). As expected, the number of new clusters and new records is the highest for the first snapshot. Surprisingly, the numbers of the following snapshots vary enormously (we expected an almost constant number). Investigations revealed that in some snapshots the formats of one or two attributes changed (e.g., from ‚64TH HOUSE' to ‚NC HOUSE DISTRICT 64') so that each of their records were considered to be ‚new' even if – apart from that – they were identical with one of the already existing ones. This again shows us the importance of providing the user with an instrument that allows her to filter out records based on their similarities (see Section 6.5). However, as one can see, even the last five snapshots contributed a significant amount of new clusters and records to the test data. Thus, we can expect the same for future snapshots.

5 TEST DATA STORAGE

The voter history is originally given as a set of TSV files. However, we want to store our test dataset by using a data model that is more suitable with respect to its later usage, i.e. to evaluate duplicate detection algorithms as well as potential extensions with data from new snapshots. As a consequence, the data model has to satisfy three essential requirements:

- To customize the test data, we need to select and reduce duplicate clusters based on user-defined specifications. Moreover, when we integrate additional snapshot data, we need to calculate statistics by comparing duplicate records (e.g., plausibility and heterogeneity). Both require fast and collective access to all records of the same cluster.
- Every record of the voter data has 90 attributes, but only a few records have values for district-related attributes. This means that millions of records have missing values in at least 38 attributes. Thus, we require the underlying data model to provide an efficient handling of sparse data.
- Working on hundreds of gigabytes requires scalable software solutions.

Schemaless NoSQL data models are much better suited to store sparse data than the relational model which requires the definition of a rigid schema. Moreover, many NoSQL data stores are designed to handle *aggregates* each of which is a collection of related data that we wish to treat as a unit [29]. Thus, they allow an easy and efficient way to access all the records of a certain person as we need it for customization and future extensions. Among all the available NoSQL data stores, we decided to use the document store MongoDB [22]. In contrast to the relational data model which is *aggregate-ignorant*, document stores are strongly *aggregate-oriented* [29] because they allow to (i) group records by storing them within the same document and (ii) nest different documents hierarchically. Furthermore, MongoDB is highly scalable. Besides its schemaless structure, MongoDB has three features that are especially helpful for this work [22]:

- *Indexes:* Since our test dataset contains millions of nested documents, indexes are very important to efficiently select those documents from the dataset.
- *Aggregation Pipeline:* Multi-stage pipelines can be used to transform documents into an aggregated result. Available pipeline stages provide tools for filtering, transformation, grouping and sorting. These pipelines enable users to extract relevant subsets of the data and thus to customize their own test datasets.
- *Compass:* MongoDB has a powerful GUI called *Compass*. It enables the user to easily interact with the stored data with full CRUD functionality. It is very helpful for exploring, generating, adjusting and using the test data. Moreover, it allows to monitor load jobs of new snapshots and helps to identify mistakes at an early stage.

In our case, we created one document for every person (i.e., duplicate cluster) that in turn contains a document for every record of this person (which are grouped into an array) and in addition a document containing some relevant meta data including the hash values of the stored records. Since most users will be interested in the personal data only, we split every record into four parts (person, district, election and meta) and stored them into different subdocuments.

5.1 Future Updates & Reproducibility

The NC State Board of Elections publishes a new snapshot at every election and every New Year's Day. Moreover, we have observed that they published some old snapshots belatedly (e.g., the snapshot from 2010-11-02 was first published in May 2019). To improve our test dataset both in size and heterogeneity, we will update it regularly.

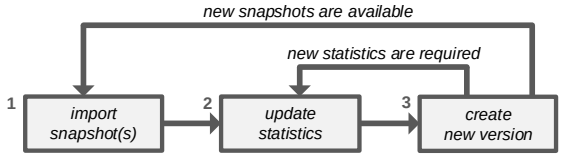


Figure 2: Update process for new snapshots and statistics

5.1.1 Update Process. The update process is depicted in Figure 2 and consists of three steps. The first step corresponds to a (parallel or sequential) import of one or more new snapshots. In the second step, current statistics are updated and (if required) new statistics are calculated. In the last step, a new version number is associated to the test data, versioning-related meta data are updated and the new version is published. As illustrated by this figure, the update process (and thus the creation of a new version) can be triggered by two reasons:

- new snapshots are available, or
- new statistics are required.

Logically, in the second case, the first step is skipped and the update process starts immediately with the second one.

5.1.2 Reproducibility. As described in Section 3.3, the import of new data poses some challenges to the repeatability of evaluation processes that were using previous versions of our test dataset. Since no record is ever removed from the test dataset, it grows monotonically, which means that the set of all records of the current version will always be a subset of all records of every future version. Thus, theoretically, it is sufficient to add a field to every record which is monotonically increasing with every new update. This field can be the date of import or the number of the first version containing this record (the snapshot date is not suitable because it is not monotonically increasing due to belatedly published snapshots). To reconstruct an earlier version, the user can use this field to filter out all records whose field value is greater than the value of the desired version.

However, we also want to allow users to limit their evaluation to an arbitrary subset of snapshots (e.g., a certain time interval). For doing this, we additionally store an array with the dates of all snapshots containing the corresponding record.

To reconstruct statistics, such as the number of records or snapshots per cluster, we enriched the meta data of every duplicate cluster by a map that counts how many new records were inserted per snapshot. The reconstruction of similarity scores is discussed in Section 5.2.

5.2 Storing Similarity Scores

To support users in customizing their data by (i) removing further near exact duplicates, (ii) repairing potentially unsound clusters, and (iii) restricting the data to a certain range of heterogeneity, we associate every record with three version-similarity maps (one for plausibility and two for heterogeneity). Every value of each of these maps corresponds to another map that assigns a similarity score to each of the previously existing records of the same cluster. Since the order of these records never change, this approach does not only avoid expensive recalculations, it also enables reproducibility because existing similarity scores are never updated or deleted. While the first heterogeneity map takes all attributes into account, the second is limited to the personal attributes in order to facilitate a customization of personal data[9]. In addition every cluster is associated with three version-similarity maps storing the aggregated values of their records.

Our understanding of plausibility and heterogeneity may change over time and/or we just may want to use other similarity measures to compute them. The versioning of the similarity scores protects reproducibility against such future changes, because we create a new version every time we use a new measure.

[9]Note, the plausibility is already limited to personal attributes (see Section 6.2) and thus does not need to be stored twice.

	NCID†	*last_name*	*first_name*	*midl_name*	*sex*	*age*	*year*◇
r_1	XX001	LARRELL	LEWIS	ANTWAN	MALE	17	2014

Figure 3: Examples of erroneous and unsound clusters

6 EXPERIMENTAL EVALUATION

When we explored the snapshots, we noticed several errors within the data. Some records contain typos, abbreviations, or have values confused between attributes. Moreover, some notations have changed over time (e.g., ‚1ST CONGRESSIONAL‘ vs. ‚CO. DISTRICT 1‘ or ‚66 AND ABOVE‘ vs. ‚Age Over 66‘). One example is presented in Figure 3. The first and last names of at least one record of voter XX001 got mixed up. In addition, either the middle name of r_1 or r_2 contains a typo (‚ANTWAN‘ vs. ‚ANTAWN‘) and the middle name of r_3 is abbreviated. Remember that a proper evaluation of duplicate detection algorithms requires errors of many different types and not just outdated values. Thus, such real-life data errors are very welcome in our test dataset, since they challenge the detection of duplicates, but do not corrupt the gold standard. However, we also detected some duplicate clusters that contain records that hardly refer to the same person. An excerpt of one of those examples is depicted in Figure 3 where the two records r_4 and r_5 share the same NCID, but obviously describe different persons. Such unsound clusters are a real threat to the quality of our test data because they spoil the gold standard and thus will negatively affect every future evaluation if they remain in the dataset.

In order to evaluate the quality and usability of our test dataset beyond these first impressions, we conducted a series of experiments, which are described in the rest of this section.

6.1 Evaluated Datasets

To better understand the results of the evaluation of our test dataset, we compare them with those of three manually labeled test datasets that are commonly used in the literature. We acquired all three datasets as TSV files[10] from the dataset repository of the Hasso Plattner Institute[11].

- *Cora*: This dataset contains bibliographical information on scientific papers including title, authors, publisher and year. The schema of the TSV file consists of 17 attributes including an artificial id. The file contains 1,878 records which form 182 clusters.
- *Census*: This dataset contains personal information including name values (first, middle and last), an address and a zip code per person (6 attributes in total). It contains 841 records which form 483 clusters.

[10]We used the non-prepared versions where special characters are not removed.
[11]http://hpi.de/naumann/projects/repeatability/datasets

Table 3: Characteristics of evaluated datasets

	Cora	Census	CDDB	NC1	NC2	NC3
#records	1,879	841	9,763	24,761	22,739	25,530
#attributes	17	6	7	38	38	38
#duplicate pairs	64,578	376	300	19,916	15,993	22,735
#clusters	182	483	9,508	10,000	10,000	10,000

avg. clustersize	10.32	1.74	1.03	2.45	2.27	2.55
max. heterog.†	0.63	0.46	0.65	0.25	0.43	0.72
avg. heterog.†	0.171	0.15	0.217	0.106	0.305	0.433

† The presented heterogeneity scores are pair-based.

- *CDDB*: This dataset includes information on 9,763 music CDs randomly extracted from freeDB[12]. In the TSV version of this dataset, all tracks of a CD are concatenated to a single string by using the pipe symbol as a delimiter. After doing so, the schema of this file consists of 7 attributes. The 9,763 records form 9,508 clusters.

For all three datasets the duplicate information is provided by a list of pairs. Several characteristics of these datasets are presented in Table 3. Interestingly, the duplicate distributions of these sets are quite different. Whereas the Cora dataset contains very large clusters (up to 238 records) and its average cluster size is 10.32, the maximal and average cluster sizes of the Census and CDDB datasets are quite small (1.74 or 1.03 respectively). The three datasets NC1 to NC3 are described in Section 6.5.

6.2 Plausibility Check

As we have explained in Section 3.1.1, it is very important that the gold standard of the test data is sound. However, as shown in Figure 3, we have also seen that this does not always seem to be the case. To keep the threat of an unsound gold standard to a minimum, we performed a quality check by calculating a plausibility score for every pair of duplicate records.

In this plausibility check, we have the basic assumption that all records of the same cluster are duplicates and the similarity scores should only reflect (significant) contradictions to this assumption. Consequently, the similarity measure should compensate simple errors and differences in data representation as we know it from duplicate detection algorithms. Due to our basic assumption, this compensation can be even stricter. Therefore, word confusions within an single attribute value or between different values as well as missing or abbreviated values should not reduce similarity at all, because they are more an indication of unknown or erroneous values than a clear sign of a non-duplicate. Moreover, to compensate outdated values we should only use attributes whose values rarely change and that are either very identifying (i.e., two records with the same value are likely duplicates) or discriminating (i.e., two records with different values are likely no duplicates). In our use case, we decided to use:

- the three name values (first, middle and last),
- the sex code,
- the year of birth (which we derived from the snapshot-date and the age value), and
- the place of birth.

It is not uncommon that values are confused between the three name attributes. Thus, we computed a single *name similarity* before combining it with the similarity scores of the other attributes.

[12] http://www.freedb.org/

To compensate errors in the name order, but also within the individual name values (e.g., typos), we computed the name similarity by using the hybrid Generalized Jaccard Measure [8] with an extended version of the Damerau-Levenshtein Similarity [4] as the internal token similarity measure, i.e.:

$$sim_{name}(o_i, o_j) = GenJacc_{DamLev}(names(o_i), names(o_j)) \quad (1)$$

where $names(o_i) = \{fname(o_i), mname(o_i), lname(o_i)\}$.

The Damerau-Levenshtein Similarity was extended to a proper handling of missing and abbreviated values. The comparison to a missing value results in a similarity of 1. The same holds true if one token is a prefix of the other because in both cases we do not have any evidence to mistrust the given data. In the case of the sex code, typos and different representations can almost be excluded for sure. Thus there are actually only four possibilities: The compared values agree (i.e., $sim_{sex} = 1$), disagree (i.e., $sim_{sex} = 0$), one of them is undesignated (i.e., it has the value ‚U') or missing. Since we do not have any contradiction in the later two cases, we set the similarity to $sim_{sex} = 1$, too.

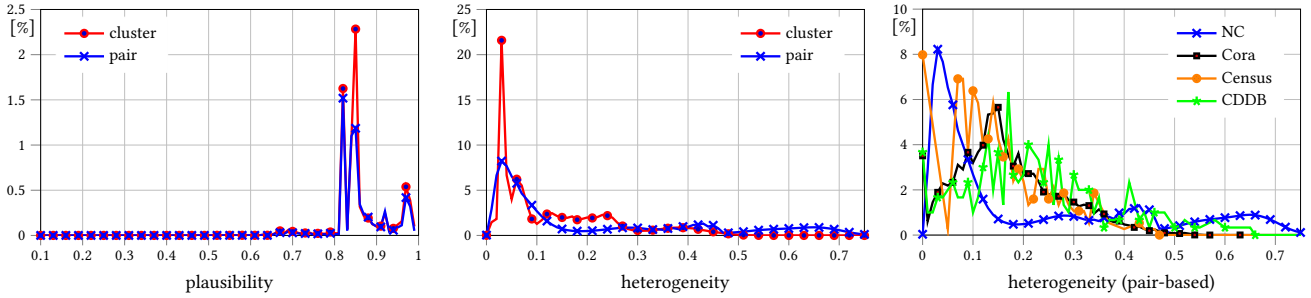
We computed the year of birth (short YoB) as *snapshot-date* − *age*. Since the actual YoB can be one year earlier if the person has not yet had birthday when the snapshot was made, we introduced a tolerance of 1. Moreover, we assumed a similarity of 0 if the age difference was 10 or greater. This led to the following formula:

$$sim_{YoB}(o_i, o_j) = 1 - min\left(1, \frac{max(0, |YoB(o_i) - YoB(o_j)| - 1)}{10}\right) \quad (2)$$

In the case of the place of birth we simply computed the extended Damerau-Levenshtein Similarity between the two values. The final similarity score was then calculated as the weighted average of the previously presented scores where we considered the name similarity to be more important (weight 0.55) than the others (each 0.15). A cluster is already unsound, if only one of its records refers to another voter regardless of how plausible the other records are actually duplicates. Thus, we computed the plausibility of a cluster as the minimal plausibility of its records.

We performed our plausibility check on the dataset with 120 million records (exact duplicates were removed after trimming). The results show that only a few clusters of this dataset are highly suspicious to be unsound. The average cluster plausibility is 0.988. 91.7% of all clusters (and 93.3% of all duplicate pairs) have the maximum possible value 1.0. The distribution of the remaining 8.3% (or 6.7% resp.) are presented in Figure 4a. The minimal plausibility of all clusters (and pairs) is 0.06. 6.4% of all clusters have a plausibility lower than 0.9, 0.47% (=61,548 clusters) lower than 0.8 and only 0.0049% (=641 clusters) lower than 0.5. The pair-based values are similar. As a comparison, the two clusters from Figure 3 have a plausibility of 0.82 (XX001) and 0.33 (ZZ002) respectively which matches our intuition that the differences in the first cluster are probably the result of data errors in the name values while the second cluster contains obvious non-duplicates.

An appropriate scoring of plausibility heavily depends on the domain of the data, since we should only use attributes that are less volatile and are either very identifying or discriminating. Moreover, it also depends on the quality of the data, since typical error patterns (e.g., an incorrect encoding of special symbols) are no significant evidence for an unsound cluster and should therefore be compensated in the scoring process. It is therefore difficult to make comparisons between the plausibility of datasets defined on different schemas without creating any noticeable bias. For this reason, we decided not to include such a plausibility calculation for the Cora, Census and CDDB datasets.



(a) Plausibility of NC test dataset **(b) Heterogeneity of NC test dataset** **(c) Heterogeneity of NC, Cora, Census and CDDB**

Figure 4: Plausibility and heterogeneity distributions of clusters and duplicate pairs for different datasets

6.3 Duplicate Heterogeneity

To score the heterogeneity between two duplicate records we want to take all their differences into account and thus do not actually want to apply measures that compensate them. At the same time, there are differences that should cause a larger heterogeneity than others. For example, difference in upper and lower case or confusions of tokens are less significant than replacing the original strings with completely different letters or tokens.

To address the problem resulting from uppercase letters, we decided to compare every two values one time with and one time without lowercasing them. To address the problem of token confusions, we decided to compare every two values one time with a sequential and one time with a hybrid similarity measure. Together this results in four comparisons for every two values. We used the average of the four resulting scores as final similarity. As the sequential similarity measure, we chose Damerau-Levenshtein. Since the Generalized Jaccard Measure is computationally too expensive when working on 90 attributes, we used the Monge-Elkan Similarity[13] [23] as the hybrid measure instead (using Damerau-Levenshtein as the internal token similarity measure)[14]. To calculate the heterogeneity between two records, we used the weighted average of their inverse value similarities (i.e., the records are the more heterogeneous, the less similar they are).

If the resulting heterogeneity scores should reflect any kind of difficulty to detect the corresponding fuzzy duplicates, identifying attributes, such as names, should be weighted higher than others. At the same time and in contrast to plausibility, we want to compare the heterogeneity (i.e., dirtiness) of different datasets in order to enable an evaluation of algorithms with respect to a varying dirtiness of the data. To ensure a fair comparison, no context knowledge and external expertise should be included into the scoring process and all necessary information should be taken from the dataset itself. To accomplish this, we used the same similarity measure for all attributes and weighted every attribute by its uniqueness[15], where we quantified this uniqueness by the attribute's entropy [19]. Since duplicate records distort these uniqueness scores (e.g., an otherwise unique id can occur multiple times), we initially created a canonical record[16] per duplicate cluster and used them to compute the weights. The heterogeneity of a cluster was then computed as the average heterogeneity of its records. Since a consideration of clusters of size one is pointless, we restricted our analyses to clusters with at least two records.

The results of our analysis are depicted in Figure 4b. They show that – despite of outdated values and other data errors – most of the duplicate records are very similar and the dataset as a whole is quite clean and homogeneous. However, since we removed exact duplicates, almost none of the clusters is completely homogeneous and most of them have a heterogeneity of around 0.03 (21.6%). In the case of the duplicate pairs, we do not have such a large peak, but also here you can see, that most values are in the range between 0.02 and 0.06. Considering this fact, the average heterogeneity (0.13 for clusters and 0.218 for pairs) is surprisingly large. The maximal heterogeneity (0.79 for clusters and 0.88 for pairs) is also very high. As a comparison, the two clusters from Figure 3 have a heterogeneity of 0.395 (XX001) and 0.366 (ZZ002) respectively. Interestingly, the less plausible cluster is more homogenous. That is because although cluster ZZ002 contains records referring to different persons, these records form two very homogenous groups (one with six records similar to r_4 and one with four records similar to r_5).

To score the heterogeneity of the Cora, Census and CDDB datasets, we used the same settings (i.e., the same similarity measures and all attributes are weighted based on their entropy). The pair-based distributions of all three datasets are depicted in Figure 4c. The heterogeneity scores of the Cora dataset are almost normally distributed. Most of them have a value of 0.15, the maximal value is 0.63 and the average is 0.171. The Census dataset has three peaks at 0, 0.07 and 0.1, a maximal heterogeneity of 0.46 and an average of around 0.15. In general, except of the large number of very homogenous pairs, its distribution has some similarity to this of the Cora dataset, but is less regular. The CDDB dataset is the dirtiest of them. Its maximal heterogeneity is 0.65 and its average is 0.217. The high heterogeneity results primarily from the fact that many language-specific symbols, such as accents, were incorrectly converted when the dataset was created. Thus, many duplicate records are very dissimilar if we do not compensate those irregularities in the matching process or repair it during preparation.

If we compare these distributions with the one from the NC dataset, we see that there is only little resemblance to our voter data although the average of the NC dataset is very close to that

[13] Since this measure is non-symmetric, we computed it in both directions and used the average as final score.

[14] There are millions of possible similarity measures (including various settings) and we had to choose one even though this could possibly generate a bias in the evaluation processes using this test data. However, as illustrated in Section 6.5, this bias was almost not existing in our experiments.

[15] To ensure reproducibility, these weights must not change although the dataset will grow with future updates. We therefore limited their computation to the first 5 million clusters and then hard-coded them into the source code.

[16] These records are built by using the most frequent value per attribute.

Table 4: Statistics of different irregularities within the NC, the Cora and the Census datasets

			NC (total 137 M pairs)			*Cora* (total 65 K pairs)			*Census* (total 376 pairs)		
			most frequent	*frequency*		*most frequent*	*frequency*		*most frequent*	*frequency*

[†]Selected from any attribute of the NC dataset.
[◇]Singletons are normalized using the total number of records (NC = 58.7 M, Cora = 1,879, Census = 841).
[★]Pair-based irregularities are normalized using the total number of duplicate pairs (NC = 136.7 M, Cora = 65 K, Census = 376).

of the CDDB dataset. Interestingly, the majority of pairs of the NC dataset is much cleaner than those of the other three datasets, but it has also a higher percentage in the range between 0.4 and 0.7. Thus, our dataset contains many homogenous records, which may need some additional pollution (see Section 8). However, as we will show in Section 6.5, its large dispersion allows us to easily achieve an average heterogeneity of 0.433 (which is significantly higher than this of the CDDB dataset) by adjusting the voter data based on the precalculated heterogeneity scores.

6.4 Diversity of Error Types

To allow an extensive evaluation of the capabilities of duplicate detection algorithms, we chose source data whose collection process promises many different types of errors. To test this assumption, we conducted a statistical analysis on the personal attributes of our test dataset by searching for several kinds of irregularities within these data (see Table 4). Here, we distinguished between irregularities that can be identified by analyzing single records (so-called *singletons*) and ones that can only be detected by comparing two duplicate records (so-called *pair-based* irregularities). In the first case, we evaluated every record individually leading to a frequency that can be normalized using the total number of records. In the second case, we compared every two duplicate records, counted the number of times the individual irregularities occur and normalized them using the total number of duplicate pairs. Moreover, we distinguished between irregularities that concern a single attribute and those that concern multiple attributes (record-level). We evaluated the following singletons:

- *outlier*: A value that is outside a predefined range (e.g., age > 110) or contains a character that is unusual for its associated domain (e.g., the first name ‚X ÆA-12‘)[17].
- *abbreviation*: A value that consists of a single letter, possibly followed by a punctuation mark.
- *missing*: A value that is null, an empty string or any other value indicating missing information (e.g., ‚-‘ or ‚unknown‘).

As pair-based irregularities, we analyzed:

- *typo*: Two values whose lowercase versions differ only in one character or contain a character transposition. These are exactly those values having a Damerau-Levenshtein distance of 1. In order not to interpret a complete replacement of one value by the other as a typing error, we only considered values longer than two characters.
- *OCR-error*: Two distinct string values which only differ at those positions where one of them has a digit. If both characters are digits, they need to be identical.
- *phonetic error*: Two values that are not identical after removing non-letter characters, are both longer than two and have the same Soundex code.
- *prefix/postfix*: Two values where one of them is a prefix/-postfix of the other after removing a potential punctuation mark from the end of the shorter value. Such pre- and postfix situations indicate abbreviations or forgotten token/characters.
- *different formatting*: Two values that only differ in non-alphanumerical characters (e.g., a hyphen, space or punctuation mark between tokens).
- *transposed tokens*: Two values whose token sets are identical, but their token order is different.
- *confused values*: Two records whose values are confused between two different attributes (e.g., the first and last name of one record are transposed).
- *integrated value*: Two records where in one of them the value of one attribute is integrated into another (e.g., a middle name stored as a second token in the first name).
- *scattered values*: Two records having the same set of tokens assigned differently to two attributes. To avoid possible overlaps with the previous two types, we only counted scattered values that are not integrated or confused.

Obviously some of these irregularities overlap (or sometimes even include each other) so that we counted some errors for more than one type. For example, some OCR-errors are also typos. Moreover, it is important to note that we consider these irregularities as indications of particular error types, but cannot always classify them with absolute confidence. For instance, not every two distinct values that have the same Soundex code are an actual phonetic error. This also applies to irregularities on record-level. Not every assignment of the same value to different

[17]Note that not every outlier corresponds to an actual data error.

attributes corresponds to a mistake. For example, in the U.S., it is not atypical to take the old last name as the middle name when getting married. Such a constellation can therefore also indicate an outdated record instead of a data entry error. Nevertheless, the errors are real even if their assignment to the individual types may be disputed. It should also be mentioned that our definitions of the individual error types do not cover them completely so that our analysis was not able to find every actual error. For example, OCR errors that do not contain digits (e.g., ‚Tim‘ vs. ‚Tirn‘) were not recognized as such. However, despite these minor inaccuracies, we think that our experiment provides a good overview of the wide variety of different error types contained in the voter data.

The results of this analysis are presented in Table 4 (grouped by singletons and pair-based irregularities), were we list the absolute values in combination with their percentages. To achieve greater comparability, we also evaluated the Census and the Cora datasets. We selected the Census dataset because it has a similar domain as our voter data and selected the Cora dataset because it has similarly large clusters. As we can see, the percentages of the Census and the Cora datasets are much higher than those of the NC dataset. For example, the percentage of typos in the attribute *last_name* of the Census dataset is 65%. This means that out of 376 duplicate pairs, 243 differed in this attribute by only one character or had two consecutive characters transposed. Although the percentages of the NC dataset are much smaller than those of the Cora and the Census datasets, the absolute numbers are many times larger. This shows the potential for customizing smaller datasets with higher error percentages, but still containing million of records. Moreover, the NC dataset contains irregularities that are (almost) not contained in the Cora and Census datasets. Examples are OCR-errors or errors that affect more than one attribute.

6.5 Usability

There are various ways to customize a test dataset by using the precalculated heterogeneity scores. In our experiments, we sketched a very simple approach and let the development of more sophisticated approaches to the user (or future research resp.). This approach consists of three steps. In the first step, we defined a lower and an upper bound $h_\perp$ and $h_\top$ for the heterogeneity scores. In the second step, we randomly selected 100,000 clusters from our whole dataset, scanned over all records of every cluster in their sorting order and removed every record whose heterogeneity to its preceding (not removed) records was not in the requested range $[h_\perp, h_\top]$. In the third step, we sorted the reduced clusters by their size and selected the 10,000 largest clusters as test input. We applied this approach for the three settings $(h_\perp, h_\top) \in \{(0.06, 0.2), (0.2, 0.4), (0.3, 0.7)\}$ while restricting the schema to the personal attributes. The result are the three test datasets NC1, NC2 and NC3. The characteristics of these datasets are depicted in Table 3. As these numbers show, even though we only used 0.07% of all clusters as input, these datasets are larger than the Cora, Census and CDDB datasets.

To evaluate the difficulty of detecting fuzzy duplicates within the individual datasets, we applied three duplicate detection algorithms each using another similarity measure[18] (the same for all attributes). The first measure (short *ME/DL*) was the same combination of the Monge-Elkan and the Damerau-Levenshtein Similarity as we used it to calculate the heterogeneity scores (see Section 6.3). The other two measures were the Jaro-Winkler Similarity (sequential) and the Jaccard Similarity using trigrams (token-based) [8]. The similarity of two records was always computed as the weighted average similarity of their values. Since we observed that the name values are sometimes confused between the individual attributes, we matched every combination of them and used the 1:1 matching with the highest similarity for aggregation. To weight the individual attributes we used again their entropy. In this case, however, we calculate it using all records (i.e., including the duplicates), since the user does not know these duplicates in advance. In addition, the entropy was calculated solely based on the records of the customized datasets. Thus, the resulting weights differed from the ones we used to calculate the heterogeneity scores (e.g., 0.66 vs. 0.48 for the first name). In the case of the larger datasets (CDDB and NC1-NC3), we reduced the initial search space by applying a multi pass of the Sorted Neighborhood Method [23] where we conducted one pass for each of the five most unique attributes and used a window of size $w = 20$. Since a few true duplicate pairs were lost through this reduction (always less than 1%), we added them back to the search space before starting the actual matching process.

The results of these duplicate detection algorithms applied to the different test datasets are depicted in Figure 5. As we can see in Figure 5a to 5c, the quality of the duplicate detection algorithms decreased when we increased the heterogeneity of the test data, since the more difficult it was to separate the duplicate from the non-duplicate pairs. In the first case, the test dataset was very clean and we could achieve almost a perfect F_1-score for all three measures. Moreover, for two out of three measures, this score was high for every threshold between 0.65 and 0.85, which made it easier to select an appropriate value for this threshold without knowing these numbers. In the case of the second dataset, the maximal F_1-score was still pretty solid (i.e., close to 0.8), but the threshold had to be set much more carefully and the quality of a setting already depended on the individual measures. For example, for Jaccard the best threshold was 0.57, but for Jaro-Winkler it was 0.75 and there was no threshold that worked well for all measures. Finally, in the case of the last dataset, the maximal F_1-score decreased significantly and even a score of 0.4 was hard to achieve. All this shows that the precalculated heterogeneity scores can be perfectly used to adjust the test data to increase the difficulty of detecting fuzzy duplicates. Moreover, as we can see, the ME/DL Similarity did not perform better than the Jaccard Similarity which shows that using this measure to calculate the test datas' heterogeneity scores has not produced any noticeable bias. Finally, when we compare the results of the three customized test datasets NC1 to NC3 with the results of the Cora, Census and CDDB datasets, we see that they show similar patterns as NC2 in terms of the maximally achieved F_1-score and the shapes and positions of the individual graphs. Only the Census dataset differs a little bit, because here Jaro-Winkler scored much better than for the other datasets and the single graphs correspond less to a bell shape. In summary, this shows that the sheer amount of data of our original test dataset enables us to create test data that are cleaner (NC1), equally clean (NC2) and dirtier (NC3) than these real-life use cases giving us the opportunity to design our test data in the way our evaluation goals require. We repeated this experiment with different parts of our original test dataset as input. Since the compositions of the generated datasets differ slightly, there were also slight differences in the resulting graphs, but the findings were always the same.

[18] Here, we tried to cover a wide range of measures by using a hybrid, a sequential, and a token-based measure.

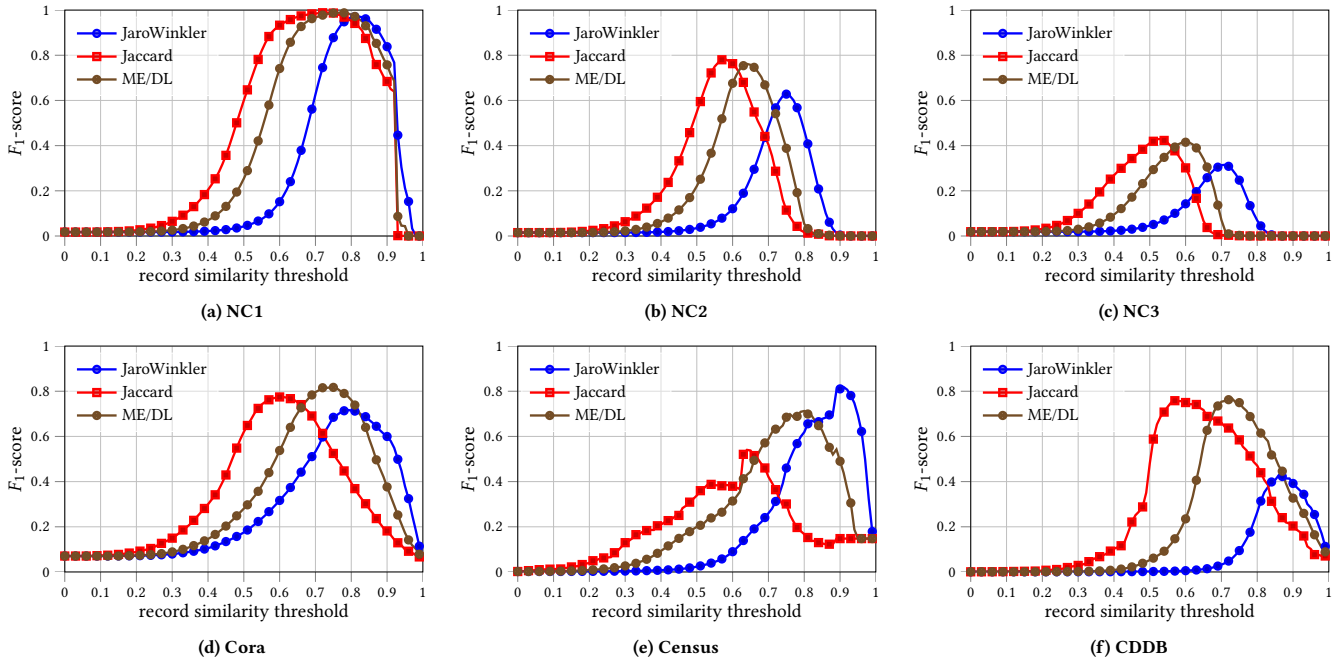

Figure 5: F_1-scores in relation to similarity thresholds for several similarity measures and test datasets

7 RELATED WORK

Almost all existing test datasets have been either artificially generated (e.g., by using an automatic generation tool) or been manually labeled. While artificial datasets have the obvious disadvantage of not containing actual real-life duplicates and errors (including outdated values), labeling duplicates manually is extremely expensive so that this approach is only an option for very small datasets. For example, the commonly used Cora, Census and CDDB datasets contain less than 10,000 records each (see Section 6.1). The essential shortcoming of an automatic labeling approach [32] is that the resulting gold standard is often not sound and biased towards the used algorithms, which can significantly distort evaluation results. One example of artificially created test data is the ERIQ dataset [31] which contains 100,000 records of customer data. Although this number is much larger than those of the manually labeled datasets, it is still small compared to typical big data applications. Further test datasets (manually labeled or artificially generated) can be found on the websites of the Hasso Plattner Institute[11], the University of Leipzig[19], and the Magellan project[20]. To the best of our knowledge, none of the existing test datasets provides precalculated similarity scores that help users to customize datasets on their basis.

Automatic test data generation tools can be divided into two classes: *Data synthetization* tools that generate all data values – including duplicates and errors – from scratch and *data pollution* tools that get a clean dataset as input and pollute it with duplicates, errors and inhomogeneities. Data synthetization tools, such as DBGen [14] or the Febrl Data Set Generator [3], are very efficient so that large datasets can be generated in short time [15]. However, since every data value is fictional, it is almost impossible to guarantee that the resulting values patterns are realistic. Data pollution tools, such as GeCo [6], TDGen [2], or DaPo [15], are the best option to generate test data with realistic value patterns because real-life data can be used as input. Moreover, if a broad spectrum of error types is supported they are nearly domain-independent. Except DaPo, however, existing pollution tools are strongly limited with respect to their scalability so that generating large datasets is either impossible or extremely time consuming [15]. A major problem that all these tools have in common is an appropriate simulation of outdated values and the complex error patterns that result from them.

Table 5: Previous usage of North Carolina voter data

	number of				cluster sizes†

†of non-singletons

Data of the NC voter register have been already used as test data in several works (see Table 5). Alas most of these uses are not fully documented and/or the provided links are outdated[21]. Thus, we cannot say exactly which data were used as input. The small size of the first dataset indicates that only a small portion of the voter register was used. The second dataset was created by Christen [5] in an earlier attempt to use the temporal changes of the voter data for generating test data with realistic outdated values. He regularly downloaded the current voter registration file on a bi-monthly basis over a time period of three years and combined these self-made snapshots after removing exact duplicates. However, instead of using the inherent gold standard

[19]https://dbs.uni-leipzig.de/en/research/projects/object_matching/benchmark_datasets_for_entity_resolution
[20]https://sites.google.com/site/anhaidgroup/useful-stuff/data
[21]ftp://www.app.sboe.state.nc.us [10, 11] and ftp://alt.ncsbe.gov/data/ [5]

provided by the NCID, he created it artificially by applying a rule-based duplicate detection approach. Thus, this gold standard is not guaranteed to be sound and biased towards algorithms using a similar detection approach.

Durham et al. [11] randomly selected 100,000 records from the voter register and generated polluted versions of these records by artificially introducing typos, semantic and phonetic errors. The last two datasets were created similarly by artificially polluting a randomly selected set of voter records with duplicates and errors using the GeCo tool [6]. Thus, these three datasets do not contain real-life errors and especially lack in realistic outdated values.

Except the last one, the sizes and duplicate distributions of these five datasets are nowhere near the numbers of the test dataset we generated in our study. Moreover, none of these authors enhanced their data with useful statistics, such as plausibility and heterogeneity scores, as we did in this study. Finally, to the best of our knowledge, we are the first who discuss the aspects of quality, usability and reproducibility in the context of test data for duplicate detection in such a depth.

8 CONCLUSION & FUTURE WORK

In this paper, we presented a large-scale dataset for evaluating duplicate detection algorithms and the approach behind its generation. Extracted from an historical voter register from North Carolina, our test dataset contains more than 120 million records and 640 million duplicate pairs making it uniquely suitable for evaluating duplicate detection at scale. Besides the dataset's size, our study focused on its quality, usability and reproducibility. The records' historical nature means that they contain many outdated values and – since data was often entered manually – also a large variety of other error types, such as typos, phonetic errors or confusions between attributes. While the data values themselves contain many errors, the underlying gold standard is largely error-free which is a mandatory requirement to ensure meaningful evaluation results. In general, its large size as well as its large number of different data errors makes the dataset perfectly suitable for users who want to customize their own datasets based on the requirements of their respective evaluation goals. To support such customizations, we equipped the individual records with similarity scores modeling their plausibility and heterogeneity. Finally, we integrated several mechanisms to ensure reproducibility when the dataset is growing with future updates. In summary, our approach enables generating large-scale test datasets with realistic errors including outdated values (which are hard to synthesize) and without the need for labeling duplicates manually (which is extremely labor-intensive).

Our plans for future work targets two different ways to extend our approach. First, we intend to generalize the procedure described here and apply it to historical corpora from other domains. This will provide the research community with large-scale test datasets beyond use cases that revolve around personal data. Second, we plan to combine our approach with a scalable data pollution tool, such as DaPo, to unite the strengths of having real outdated values and being able to inject additional errors at will. Our goal here is to increase the flexibility for customization and thereby facilitate generating test datasets geared for specific user demands. We think our presented work is useful to other researchers and we hope that our current line of research will pave the way for novel solutions that combine approaches using historical data with methods of data pollution in creative ways.

ABSTRACT

We investigate how a state of the art *path index* can be integrated into the Cypher query pipeline of the industrial Neo4j graph database. We identify the characteristics of practical use-cases where application of path indexes is beneficial to query evaluation and performance of index maintenance. Through in-depth empirical evaluation, we conclude that path indexes are most effective when used on *selective* patterns that allows the query planner to avoid high intermediate state cardinality and thus significantly accelerate query performance. As such patterns arise naturally in querying on real graphs, we can conclude that path indexes are a valuable method for improving the performance of graph database systems in practice.

1 INTRODUCTION

A common operation in graph databases is pattern query evaluation, i.e., looking for all matches of a query graph in a data graph [1]. This operation searches for sub-graphs in the data with a structure that is constrained by the query. A state of the art index on paths has been introduced in prior work [7, 17]. It has been shown that this index can be effective in accelerating query evaluation by multiple orders of magnitude and can be effectively maintained as the underlying data graph is updated [4, 12]. Current graph databases struggle with scalability, as graphs continue to grow in size and complexity [14]. Path indexes are a promising technique to help address query performance in practice.

In this short paper, we present experiences gained from the practical integration of a path index into the Cypher query pipeline of the Neo4j graph database management system. Cypher is a de facto industry standard query language for graph databases; Neo4j is one of the most popular and widely-deployed graph databases in industry [8]. We explore practical use-cases where path indexes can significantly improve query processing performance, and analyse scenarios when this query acceleration is achieved through an in-depth empirical evaluation. We conclude that path indexes are most effective when used on *selective* patterns that allow the query planner to avoid high intermediate state cardinality and thus significantly accelerate query performance. This result is not immediately obvious for contemporary graph database systems, and to our knowledge has not been observed before. As such patterns arise frequently in applications due to correlations in the structure of real world graphs, we can conclude that path indexes are indeed a valuable and practical method for scaling graph data management in industrial systems.

While our experiments were made using Neo4j, the results are immediately applicable to any graph database management system that implements Cypher or any other graph query language such as SPARQL or G-CORE that supports matching path patterns comprising a sequence of node and edge labels [1].

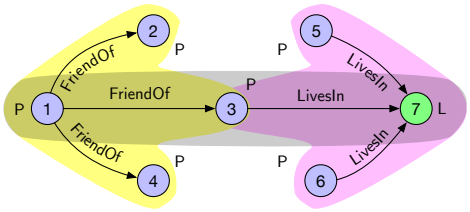

Figure 1: Example of a simple property graph. Nodes labeled *P* represent *Person* nodes. The node labeled *L* represents a *Location*. Shaded paths represent path indexes.

2 BACKGROUND

Property Graphs. Neo4j uses the *property graph* data model [1, 8]. A property graph is a graph where: every node can have an arbitrary number of labels; every relationship is directed between two nodes and has exactly one type; there may be multiple relationships of the same type between the same nodes, i.e. it is a multi-graph; and, every node and relationship can have an arbitrary number of associated attribute-value pairs. As an example, Figure 1 shows a property graph (suppressing attribute-value pairs) representing a small social network.

Cypher Query Language. Cypher is a declarative graph query language that is loosely based on SQL [8]. It contains familiar SQL keywords such as `WHERE` that function essentially the same by allowing users to apply predicates to filter the results of the query. However, in Cypher, the primary way to retrieve data is using the `MATCH`-clause. Such a clause contains one or more pattern expressions. A pattern expression is an alternating sequence of nodes and relationships, starting and ending with a node. Nodes are expressed using parentheses while relationships are expressed as arrows. Query variables are declared by their inclusion in one or more pattern expressions and can be used in other clauses. For example, `(x:Person)` matches all nodes `x` with label `Person` and `(p:Person)-[r:Lives_In]->(c:City)` matches all directed relationships `r` from nodes `p` to nodes `c`, with labels `Lives_In`, `Person`, and `City`, resp.

Path Patterns. A *path pattern* is a sequence of alternating node labels and relationship patterns starting and ending with a node label. A *relationship pattern* contains both a relationship type and its direction (either forward, $\rightarrow$, or reversed, $\leftarrow$). E.g., given the node labels $\{A, B\}$ and the relationship type R, the following notation describes a path pattern of length 2: $\langle A, (R, \rightarrow), B, (R, \leftarrow), B\rangle$, counting relationships to determine the length.

A path pattern describes a set of constraints that can be applied to paths of the same length. Given a k-length path pattern

$\langle N_0, (R_1, D_1), \ldots, (R_k, D_k), N_k \rangle$, then a path $\langle n_0, r_1, \ldots, r_k, n_k \rangle$ in the graph satisfies the pattern if and only if all nodes n_i have a N_i label for $0 \leq i \leq k$ and all relationships r_i are of type R_i and direction D_i for $1 \leq i \leq k$. As an example, the pattern $\langle P, (FriendOf, \rightarrow), P, (LivesIn, \rightarrow), L \rangle$ would yield one query result on the graph in Figure 1.

Prior Work on Path Indexing. Querying graph databases using indexes is a complex field of study. A detailed contemporary survey of existing techniques can be found in [1]. The *k-path index*, introduced by Fletcher et al. [7, 13, 16, 17], demonstrated that significant orders-of-magnitude query performance improvements are possible with path indexing. Here, the intuition is to index all, or a selected subset of all, paths of length up to k, where k is the count of relationships in the indexed paths. Fletcher et al. built the k-path index by concatenating edges in the graph and storing the resulting paths in a relational database [7]. The resulting table was indexed and used to speed up path queries.

Sumrall et al. [17] engineered a k-path index directly implemented using a B$^+$-tree and demonstrate the potential for accelerated query processing. Sumrall also studied how one could index paths with specific patterns (e.g., as given in a workload) rather than all paths of length k.

Persson [12] utilized the path index concept to speed up dense network data retrieval by indexing all paths of length 1. This index was called a *Shortcut Index*. Persson intentionally limited his work to indexes with a single relationship to avoid expensive maintenance computations on graph updates, which could not be afforded in the described use-case.

De Jong [4] demonstrated how indexes can be more efficiently maintained by maintaining sub-patterns as separate indexes. This allows for a significant speed-up of index maintenance, at the expense of increased storage overhead.

Boncz et al. [3] and Luo et al. [10] give a broader overview of graph query processing with indexes, both in contemporary systems and in research, as well as the role of query selectivity in effective graph query processing. To our knowledge, ours is the first study of path indexing in industrial systems.

Path Indexes. A *path index* is a data structure that indexes all paths in the data graph which satisfy a chosen path pattern. This path pattern is called the *indexed pattern*. The paths are not stored directly in the path index, instead a sequence of references is stored. For every indexed k-length path $\langle n_0, r_1, \ldots r_k, n_k \rangle$, the index stores references to the nodes and relationships of the matching paths as a sequence of identifiers: $\langle n_0^{id}, r_1^{id}, \ldots, r_k^{id}, n_k^{id} \rangle$, where n_i^{id} and r_i^{id} are the i-th identifiers of nodes and relationships in the path respectively.

These sequences of references are converted into a single key by concatenating the fixed-width identifiers (8 bytes each), which are stored in a B$^+$-tree. This allows logarithmic-time location, insertion and deletion of entries in the index. Since the identifiers are concatenated, the B$^+$-tree also supports prefix searches. Given the first m elements of a path, we can locate the first entry that starts with this prefix, and scan all paths that match the prefix in linear-time with respect to the number of results returned. The worst-case space complexity for the index is $O(E^k)$ where E is the number of edges in our graph and k the length of the path pattern that is indexed. While the size of the index is linear to the number of identifiers in the key, each index is defined for a fixed size key which keeps the size bounded. It is also worth noting that when indexes are chosen to represent selective patterns, the size of the index will naturally remain small.

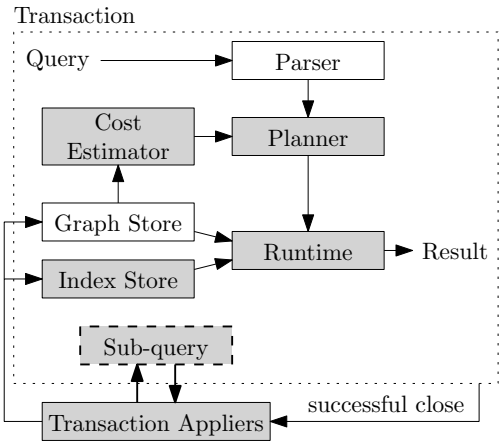

Figure 2: An overview of the query pipeline architecture. Shaded boxes represent our changes, while dashed outlines represent a new component.

The shaded parts on Figure 1 represent path indexes. An index on $\langle P, (FriendOf, \rightarrow), P, (LivesIn, \rightarrow), L \rangle$ (shaded grey) contains just the single path through nodes $\langle 1, 3, 7 \rangle$, an index on $\langle P, (FriendOf, \rightarrow), P \rangle$ (yellow) will contain the paths through nodes $\{\langle 1, 2 \rangle, \langle 1, 3 \rangle, \langle 1, 4 \rangle\}$ and an index on $\langle P, (LivesIn, \rightarrow), L \rangle$ (purple) will contain the paths through nodes $\{\langle 3, 7 \rangle, \langle 5, 7 \rangle, \langle 6, 7 \rangle\}$.

3 USING PATH INDEXES

Our Extensions. We next discuss the modifications and extensions to the query pipeline architecture necessary to support path indexes (Figure 2). Firstly, path index operators have been added to the *Planner* component which can scan or selectively read paths from path indexes. This also requires new costing heuristics in the *Cost Estimator* for these operators. The new operators are also implemented in the *Runtime* component as runtime-specific operators that perform the read operations on the path index store. Further the *Index Store* was modified to hold the new type of path index.

When a transaction is committed, the update commands are translated into paths that have to be added to or removed from the path indexes through sub-queries on the path patterns of those indexes. These sub-queries are inserted into the query pipeline as normal and might use other path indexes to resolve the query, depending on the context. Full details can be found in the extended report [9].

4 IMPLEMENTATION

We next discuss integrating the path index into the database code-base. We will start with an overview of all components that required modifications in Section 4.1. Section 4.1.1 describes query-based path index maintenance. Then Section 4.1.2 provides information on path index initialization.

4.1 Modified Pipeline Components

The implementation of our path index into the query pipeline required modifications in several components. Figure 2 shows an overview of the components, where a shaded background means the component required some modification. The dashed block "Sub-query" represents a new component.

The cost estimator is extended to estimate a cost for path index operators. We re-used the existing cardinality estimator

due to scoping constraints which assumes that all filtering and combining operations behave according to global data statistics.

4.1.1 Query-based path index Maintenance. De Jong [4] observed that, as a consequence of the policy in the Neo4j database to never allow the deletion of a connected node, we only ever need to look for relationship updates in the graph in order to update the path index. De Jong describes two methods for translating graph updates into path index updates.

(1) *Traversal-based translation:* starting from the updated relationship, traverse the indexed pattern on the data graph and make note of all the paths encountered. If the relationship was added, then add all these paths to the index. Otherwise, remove all these paths from the index.
(2) *Self-maintaining translation:* maintain a path index for all sub-patterns of the index pattern. Some of the sub-patterns need to be reversed in order to do prefix-scans on these indexes. Then, when handling an updated relationship, simply do a prefix search on the largest index that contains the changed relationship in both directions, and combine the two resulting sets created by these actions. Then add or remove these paths from the index.

The first method is a naive graph traversal. The second method requires all sub-patterns to be indexed. We introduce the following maintenance method, which uses the query pipeline itself to find the most effective way to search for updated paths:

(3) *Query-based translation:* query the index pattern with an additional predicate that the modified relationship must be part of the resulting paths. This query then returns all paths through the updated relationship. We can then add or remove these paths from the index.

The last approach is far more flexible in terms of which pattern indexes are allowed to exist, compared to self-maintaining translation. However, it requires executing new queries while processing transactions. This broke some assumptions about the way transactions are handled in Neo4j, namely one transaction per execution thread. As a result, our prototype does not support concurrent updates. Another issue was that we needed to by-pass the query cache, otherwise we had no control over which indexes would be used in the maintenance queries.

When a relationship is modified, added or removed in the graph, this could mean entries need to be added or removed from the path indexes. To find out which paths have been changed, a query is executed that contains the pattern of the index and an additional constraint that the relationship in the pattern must match the updated relationship from the transaction. This is described in Algorithm 1.

There are some important things to consider. Firstly, Neo4j 3.5[1] binds a transaction along with its transaction state to the thread that opened the transaction. That means that, while we are applying the outer transaction, the inner query we want to execute is filtered through the transaction state during maintenance. As a work-around to this behavior, we store the transaction state of the outer transaction and reset it for the maintenance queries. After processing the updates, we restore the old transaction state such that other Neo4j operations are not affected.

Further, since we are in the middle of applying a transaction, some of the path indexes might not be up-to-date while other path indexes may already have been updated. We introduce a sort order of path indexes by length, small-to-large, to ensure

[1]Transactions no longer bind to threads in Neo4j 4.0

Algorithm 1 Maintenance

Input Modified relationship r in graph G.
1: b := the label of the start node of r
2: e := the label of the end node of r
3: t := the type of r
4: I := a list of path indexes with patterns that contain `...(:b)-[:t]->(:e)...`
5: Sort I by pattern length, ascending.
6: T_{old} := the committed transaction state.
7: Reset the transaction state.
8: **if** r is a removed relationship **then**
9: **for** all *index* in I **do**
10: P := the pattern of *index* containing relationship r
11: R := Query(P, G)
12: Remove all entries R from *index*.
13: Process all other transaction appliers for r.
14: **if** r is an added relationship **then**
15: **for** all *index* in I **do**
16: P := the pattern of *index* containing relationship r
17: R := Query(P but avoid using *index*, G)
18: Add all entries R to *index*.
19: Set the transaction state to T_{old}.

Algorithm 2 Index initialization

Input index pattern P, data graph G
Output initialized index I
1: I := a new path index
2: *Result_Iterator* := Query(P, G)
3: **while** *Result* := *Result_Iterator.next* **do**
4: Add *Result* to I

that any maintenance query plan for a path of length k will itself only include path indexes of lengths smaller than k, which by then have already been updated. When we remove a relationship from the graph, we want the maintenance query results to still include it so we know which paths to remove from the index. That is why the query for removals is done before modifying the underlying data. For relationship additions, the reverse holds. We want to include it in the maintenance query results in order to add these paths to the index, therefore we must query these after the underlying data has been updated.

Similar maintenance steps can be applied for node label updates. Node additions and removals can be ignored, as those are only allowed for disconnected nodes, making it impossible to affect path index maintenance.

4.1.2 Initialisation. A small but important aspect is being able to create indexes on existing data: index initialization. This is done by querying the pattern on the existing data graph and adding the result set to the new index in a single transaction. Other indexes that have already been initialized may be used at this point. Index initialization thus follows the simple procedure described in Algorithm 2.

Sumrall [16] proposed constructing a B^+-tree directly from a sorted list of query results in order to speed up the B^+-tree construction, though this was not practical to achieve in our implementation since the B^+-tree memory layout is abstracted in the code base. As index initialization was not the primary focus of this study, we used our more naive approach, which increases the one-time construction cost of any path index.

5 EXPERIMENTAL SETUP

Baseline Planner Extension. The planning model used by Neo4j is node-centric. There exist a number of ways to selectively scan or seek nodes by their node labels and indexes exist on node properties, but there are few ways to selectively scan or seek based on relationship types. Our path index implementation will have these abilities. Therefore we apply an extension to the baseline planner which includes an operator that scans relationships by type. It is introduced with the same cost heuristics as the most similar node-based operator. Our path index query plans are compared with this extended baseline.

Hardware and Software. Our experiments were performed on a server with four Intel Xeon E5-4610 v2 CPUs running at 2.30GHz, 500GB of DDR3 RAM at 1600MHz. We used its 260GB NVMe SSD for data storage. The server ran Ubuntu 16.04.3 LTS and the Oracle Java (TM) SE Runtime Environment (version 1.8.0-151). We prototype on the Neo4j 3.5 community code base [11].

Methodology. Our experiments ran with a pre-allocated heap of 100GB. Each experiment ran until running time converges, which indicates that hot code paths were optimized by the JVM. Then we ran the experiment five times, triggering a garbage collection cycle between each run and flushing the data from memory without restarting the JVM as this would lose hot code path optimizations. We then discarded the highest and lowest running time and averaged the remaining three results. For data set sizes, we summed the total data file sizes on disk. Path index stores were measured separately and transaction logs were excluded.

Datasets. We use four data sets in our experiments: two synthetically generated and two real-world data sets. The first synthetic data set is referred to as the *correlated* data set, as it has high structural correlation. It has 125K nodes and 12.6M relationships and was created by interconnecting 25 000 copies of the same path, making it a highly selective pattern. The second synthetic data set is referred to as the *independent* data set as there are no structural correlations in the connections between nodes. It has 250K nodes and 5M relationships. The first real-world data set is the YAGO data set [15], containing 77M nodes and 100M relationships. The second real-world dataset is the GeoSpecies data set [5], containing 225K nodes and 1.5M relationships. Coming from distinct application domains, these graphs allow us to gain practical insights into the robustness of our methods.

6 RESULTS

Our hypothesis is that our path index is not suited for application on high-cardinality path patterns, since the worst-case space requirement is exponential in path length. Indeed, we observe that path indexes are especially useful for highly selective paths on correlated data, as the cost of the path index is very low compared to the computation of intermediate state that can be *skipped* by using the index.

To test this hypothesis, we first run two controlled scenarios of queries on highly correlated and uniformly distributed synthetic data sets. We generate our own data sets, rather than using a benchmark such as LDBC SNB [6], so as to finely control the structure of the data. This was sufficient for our goals here, but we note that off-the-shelf generators such as gMark could also have been used [2]. Then, we verify our findings by applying our path index to two real-world scenarios: a selective, correlated path query and a high-cardinality path query.

Finally, we show that path indexes can be applied to index maintenance in some cases, and the effect of selective, correlated index path patterns.

6.1 Synthetic Query Benchmarks

Our first experiments show that choosing the right path index can significantly improve query performance. The available indexes on this data set are described in Figure 3 (Correlated synthetic). The query pattern matches that of the full index. The result of this query when planned with different indexes can be seen in Figure 4 (Correlated synthetic). The full index is clearly the best as it essentially pre-computes the answer. However, sub-index S_1 has similar performance for a smaller index, which may offer more re-use capabilities.

The second experiment, illustrated in Figure 4 (Independent synthetic), shows the same technique applied to a uniformly distributed data set. The indexes available here are described in Figure 3 (Independent synthetic). Because there is no selective, structural correlation in this data set, the query produces many more results. Indexing these results, even in sub-indexes, provides no significant speed improvement.

Both of these experiments show dependency between the running time and the maximum intermediate cardinality. This indicates that indexing selective patterns can significantly reduce the maximum intermediate cardinality during query evaluation, and thus the running time of the query.

6.2 Real-world Query Benchmarks

After findings on synthetic datasets, we applied our technique to real-world data sets. Our first dataset, YAGO [15], has a file containing query workloads. We used the cardinality estimation model of the Neo4j planner that assumes independence between elements to find the query that was most mis-predicted, as our assumption was that this query would be highly correlated, since this is exactly the type of query that will yield mis-predictions by this cardinality estimation model.

We then applied path indexes that matched parts of the query to speed up query evaluation [9]. The heuristic cost estimator we used was built on the assumption of independence. For the YAGO experiments, the resulting query plans were of insufficient quality. We have manually created better query plans to show what an improved cost estimator could achieve with our indexes. The indexes are described in Figure 3 (YAGO dataset) and the benchmark results are shown in Figure 4 (YAGO).

The full index on the query pattern significantly speeds up query evaluation time compared to our manually optimized baseline. The plans using smaller sub-indexes further improve performance, even though it requires more steps to fully answer the query in these plans. This can be explained by the reduction of intermediate cardinality in later stages of the operator tree. The high cardinality of the S_2 and S_3 plans is caused by the first node scan operator which is reduced early on in the execution of the query plans, this explains the faster execution time despite the initially higher cardinality compared to the F plan. The path index efficiently produces the full path on this reduced state, achieving fast total execution times.

We have also applied this to another data set with a less selective query, expecting our path index would not be able to speed up query evaluation performance as much. And indeed, our experiment results (shown in Figure 3 and Figure 4 under

(b) Independent data

Figure 5: Results of the maintenance experiment on correlated (left) and independent (right) data. The rows show the amount of time required to update the index, given the presence of a sub-pattern index named in the left-most column.

GeoSpecies) show that, because the result cardinality is the highest cardinality in the query evaluation, our path index was not able to *skip over* large intermediate cardinalities, and thus no real performance gain was achieved.

6.3 Maintenance Using Sub-Indexes

Not only can sub-pattern indexes provide performance benefits during query execution. As De Jong [4] showed, sub-patterns can also be used to speed up the maintenance of the full index. Where the *self-maintaining translation* introduced by De Jong exhaustively provides all sub-patterns such that no data has to be read from the graph, our approach simply defers this decision to the query planner, as maintenance is performed using a specific query on the indexed pattern. This allows us to pick an arbitrary set of path indexes, which may then also be used to speed up maintenance when applicable.

In this experiment, we first look at the performance benefits on our synthetic correlated data set for index maintenance, as we provide one of the sub-pattern indexes from Table 3 alongside the *Full* index. The graph is updated to remove one of the Y-labeled relationships in a transaction, after which this same relationship is added again in a new transaction. Fig. 5 (a) shows the results of this experiment. The first row contains the maintenance performance of just the *Full* index and the subsequent rows contain the

performance of using a maintenance plan that includes the sub-pattern index. Further, the sub-pattern index itself may also need to be maintained, thus these measurements are also included. For this experiment, the query planner is forced to use a plan that uses the sub-pattern index for the *Full* index maintenance. This sometimes results in a slower maintenance plan as only some query plans are considered. We may assume that the planner would not use the sub-index for maintenance in that case, if given the choice, though the figures give an indication of the effect on maintenance of the sub-index. The average speed-up reported is the factor of performance increase of both maintenance operations for the removal and addition of a relationship.

Interestingly, both Sub_1 and Sub_4, the indexes that provided the most performance increase during query execution, do not speed up the maintenance operations of changes to this specific relationship. Sub_3 provides a moderate performance increase for maintenance computations, while it was the worst performing index in the previous query execution experiment.

We then perform the same set of transactions, by removing an Y-labeled relationship in a transaction and adding it in another transaction, leading to index maintenance on the synthetic independent data set. We observe that similar modest speed improvements can be achieved the sub-pattern indexes on the full index maintenance in Fig. 5 (b), while the forced plans for some sub-indexes perform considerably worse as well.

7 LESSONS LEARNED

Indexing paths in graphs often makes sense in practice. Since the number of (potential) paths in a graph grows exponentially with path length, it might seem too prohibitive (wrt. worst-case space complexity) to index path patterns in large graphs. In this work, on the contrary, we found out that, in practice, indexing *strategically-chosen* path patterns can, in fact, greatly improve query performance in both synthetic and real datasets at a *small* storage overhead. The practicality of this approach is underscored by our integration of our work in the Neo4j system.

Patterns with high structural correlation are most beneficial to index. Patterns where there is high correlation in the connections between the nodes in the data will result in a relatively low number of paths matching the pattern. The number of edges that have to be explored to match the same pattern through direct traversal of the graph would be substantially larger. In such situations the cardinality of the intermediate result is substantially larger than cardinality of matches to the whole pattern. Our experiments show that when correlated patterns are indexed, this high cost of computing these intermediate results of high cardinality is avoided. Furthermore the size of the index for such a highly selective pattern over correlated data is small as well. This turns out to be a sweet spot for path indexes, where the benefit of the index is high and the overhead of the index is low.

In contrast, for patterns matching uncorrelated data, the size of the index is proportional to the cardinality of the intermediate result, which in many cases grow exponentially in the size of the underlying graph. In these cases we experience not only a prohibitively large storage overhead for the index, but also no tangible performance benefit, since enumerating the paths from the index is proportional to enumerating the paths by direct traversal of the underlying graph.

Patterns to be indexed should be chosen with care. Hence, one should take advantage of structural correlations which naturally occur in graphs in order to choose path patterns that have (1) low cardinality and (2) help to cut down on the cardinality of intermediate results during the evaluation of queries in the workload. Finding path patterns that satisfy both (1) and (2) is not trivial and is ultimately a constrained optimization on the given workload and usable storage.

8 CONCLUSIONS

We have reported on our practical experiences integrating a state of the art path index into the query processing pipeline of Neo4j, a popular industrial graph database. Through extensive empirical study, we found that selective path indexes can greatly accelerate query evaluation performance. This is especially true in those cases where the query engine would otherwise require computations on large intermediate state to arrive at a relatively small result set. In these scenarios, which arise commonly in practice due to correlations in the structure of real world graphs, we have shown that even though path indexes in the worst case require exponential storage, these selective path indexes can be very small relative to the total graph size. These are optimal scenarios for path indexes since the path index is able to provide a significant performance improvement with a low space overhead. Our extended report [9] contains further details and results, such as technical aspects of the integration into Neo4j, the technical challenges encountered, and the engineering lessons learned.

Looking ahead, there are several interesting directions for further research. We close by indicating two of these: (1) investigate more deeply query planning in the presence of path indexes, including cardinality estimation and costing techniques for path indexes; and, (2) study methods for selecting which patterns to index, balancing space costs and performance benefit, e.g., with respect to a given query workload.

ABSTRACT

Personalized social media offer communication opportunities that mass media could not afford, yet also raise novel challenges. A prime challenge arising from this shift in digital communication is to detect topics and events of interest. In this paper, we propose and deploy a novel Deep Learning architecture that predicts if a *news topic* becomes viral by analyzing social media diffusion and audience interest in current *news events*. The proposed solution: (i) analyzes news articles, (ii) extracts associated topics and events, (iii) matches the topics and events to filter and extract developing topics, (iv) extracts current events from Twitter and matches them to the filtered news topics, and (v) predicts audience interest in news topics using Twitter likes and retweets. We employ several feature engineering techniques to improve prediction by integrating user metadata into the training set. In our experiments, we correlate two datasets collected over several months in the same time period. The first dataset contains news articles collected from different news venues, while the second one contains tweets regarding the news. The experimental results from our real-world deployment prove that the proposed system achieves high accuracy when integrating *influencers* metadata and the day of the week. Thus, proving that the *news topics* virality prediction is improved under the assumptions that spreaders and the day of the week play a huge role in information diffusion.

audience interest prediction, social media, news diffusion, topic modeling, event detection, neural networks

1 INTRODUCTION

The internet age has brought new ways of sharing information that changed the way the general public consumes media content. Physical newspapers moved to a digital form in a few years. With this migration to the virtual world, the number of news sources increased, and consumers gained a wide variety of options from where to choose their daily news using their preferred content.

Users have two methods at their disposal to stay up to date with current *news events*:

(1) buy a subscription to news publisher that provides in-app or email news content, or
(2) follow the content of news outlets or *influencers* on social media [30], where *influencers* are users that manage to sway a target audience.

An emerging and growing social media platform is Twitter. Twitter provides users a venue where they can share their thoughts, discuss, and forward various kinds of information [29]. The subjects are diverse, from daily local events to important global issues. The ever-growing number of users around the world tweeting makes Twitter a valuable source for real-time information. Thus, many consumers spend time on their news feeds to catch up with everything around them.

News outlets and publishers also embraced Twitter to update followers by regularly posting tweets that contain short news headlines and including direct links to full articles. Thus, news outlets reach large audiences and increase their reader base. Yet, to predict the audience's interest in a news topic, we should determine the underlying social structures and relationships between Twitter users [14], and utilize the network graph structure modelling the relationships between members of different social groups [18]. Nodes in a group's center are called *influencers* as they have a huge role in spreading the information. Nodes that like or retweet content are known as *spreaders*, as they propagate the information further in the network.

Our proposed solution is motivated by the recent negative impact viral Fake News has on society at large and the current need for systems that can help in stopping the viral spreading of such news. Knowing the veracity, determining the propagation patterns, and predicting the influence of news articles in social media, new strategies for mitigating harmful misinformation can be developed. Thus, the main objective of this paper is to determine if a news topic becomes viral on social media. We tackle this issue by predicting the audience in order to facilitate the development of new network immunization strategies.

The research questions we are trying to answer are:

(Q1) Do the current events presented in mass media also gain traction on social media?
(Q2) Does the diffusion of news articles on social media influence the trending topic of current events?

[*]Corresponding Author
[†]These authors contributed equally to the paper

(Q3) Can we predict the audience interest in a news topic by analysing the retweets and likes received by news articles belonging to the topic on social media?

(Q4) Does the network-related metadata improve the audience interest prediction?

To answer *(Q1)* and *(Q2)*, we first extract the *news topics* using Non-Negative Matrix Factorization (NMF) [2] and the *news events* using Mention-Anomaly-Based Event Detection (MABED) [15]. Second, we correlate the *news topics* and *news events* to extract *trending news topics* by employing the cosine similarity. Finally, we extract *Twitter events* also using MABED. For answering *(Q1)*, we analyze the correlation results of *trending news topics* → *Twitter events*. Whereas, for answering *(Q2)*, we analyse the reverse correlation results, i.e., *Twitter events* → *trending news topics*.

To answer *(Q3)*, we consider that the correlated < *trending news topics*, *Twitter events* > pair reveals insights in the audience interest through likes and retweets. Thus, we train two Deep Learning models on the *Twitter events* to predict their likes and retweets on Twitter. The high accuracy of the models proves that we can correctly predict the audience interest in *trending news topics* using social media information and determine if they become viral.

Finally, to answer *(Q4)*, we enhance the training dataset with metadata containing information regarding each tweet's author and its number of followers as well as the day of the week when the tweet was posted online. We base this approach on two assumptions. First, that *influencers* (users with a high number of followers) have a huge role in spreading the information and making news articles topics viral. Second, that user behaviour posting patterns, as well as media consumption, are influenced by the day of the week, as also empirically proven in [3]. We retrain our Deep Learning models and manage to obtain better accuracy results, thus showing that the assumptions stand for our use case.

We use Twitter's graph structure to extract events and to predict the audiences' interest by analyzing the textual and metadata content (e.g., retweets, likes, user followers, etc.) of each post. Thus, we propose and deploy a novel architecture that incorporates topic modeling, event detection, and Deep Learning classification. Our system:

(1) analyzes news articles,
(2) extracts their topics and associated events,
(3) matches these topics and events to filter and extract developing topics,
(4) extracts current events from Twitter and matches them with the filtered news topics, and
(5) predicts audience interest in the news topics using Twitter likes (formally known as favorites) and retweets by enhancing the dataset with metadata, i.e., the tweet author and its number of followers, as well as the day when the tweet was posted.

The novelty of our proposed architectures is threefold:

(1) we correlate and discover new insights between the relation of *trending news topics* and *Twitter events* in both directions, i.e., *trending news topics* → *Twitter events* and *Twitter events* → *trending news topics*;
(2) we manage to create accurate models that predict the audience interest in *trending news topics* on social media and determine if they become viral;
(3) we improve the model's performance by incorporating in our document embeddings and learning models the assumption that *influencers* play an important role in the spreading as well as the day when the tweet was posted, thus making *trending news topics* to become viral.

Experimental results show that all *trending news topics* are correlated to at least one *Twitter event*, whereas the reverse is not true. Furthermore, we obtain better audience interest prediction by enhancing the dataset with metadata.

The rest of this paper is structured as follows. Section 2 presents a survey of state-of-the-art-methods for analyzing news diffusion on social media. In Section 3, we discuss the models and techniques used in our deployed solution. Section 4 presents the architecture of our system and discusses each module in detail. Section 5 showcases and discusses the obtained results. Lastly, in Section 6 we conclude and we present several new directions and improvements for the proposed solution.

2 RELATED WORK

Online media content shapes people's perceptions regarding ongoing social, political, and economical changes around them. In the literature, the relevance of the story selection correlated to a specific audience, done by editors or by algorithms, has been analyzed to find better ways to get news online and explore the relationships that exist between individuals' characteristics and their interests. The results show that the audience's interest can be determined by context-specific characteristics [34]. Furthermore, the prediction of the audience's interest in a *news topic* can help publishers to create recommendation systems for social platforms that leverage tailor-made latent features [5].

One solution for building better recommendation systems for targeting the interested audience proposes to analyse the content of posts to detect bursty topics. The analysis predicts the emergence of current events that are of interest to multiple groups of people who discuss and share the content online [1, 15, 31]. Furthermore, community-based probabilistic algorithms can be used to model the spreading of *news events* on social networks [25]. Therefore in this paper, we use event detection techniques to match *news topics* with *news events* and extract *trending news topics*. Then, we correlate the *trending news topics* with *Twitter events* using the same time frame to determine the spread of current news topics on the social media platform and determine *viral topics*.

The visibility of news on social media also depends on the actions of a diverse set of actors, e.g., the users, their friends, content publishers such as news organizations, advertisers, and algorithms [33]. Thus, we propose a new feature construction method that incorporates metadata into the features of the training set.

Deep Learning architectures have been successfully used for predicting the trend of stocks [19], financial time series [28], marketing [26], etc. Deep Learning architectures have also been used to predict information diffusion in social media. Recurrent Neural Networks (RNN) architecture is a popular deep learning-based model used to model information diffusion, obtaining promising performance. In [36], the authors explore the advantages of using an RNN-based model enhanced with reinforcement learning in order to predict information diffusion in social media. In their work, they tackle diffusion prediction both at the user level (microscopic), i.e., the next influenced user, and at the network level (macroscopic). The

proposed solution, FOREST (reinFOrced REcurrent networks with STructural context), consists of two models: the microscopic and macroscopic cascade models. The microscopic model employs a Gated Recurrent Unit architecture and a structural context extraction algorithm based on neighborhood sampling. This model is fed to the macroscopic model that also applies a reinforcement learning based cascade simulation process. For experiments, they used three datasets, each from different social media platforms. FOREST is compared with other state of the art solutions that employ Long Short-Terms Memory, attention layers, and Convolutional or Recurrent Neural Nentwork architectures. The authors use the Mean-Square Log-Transformed Error (MSLE) metric for comparison. FOREST outperforms all the baseline solutions. In comparison with our work, FOREST does not detect news topics and does not analyze from this point of view the spread of information. Also, their models ignore the timestamp information. A similar solution to [36] that, in contrast, considers the temporal information, but which still does not address audience prediction on particular topics, is proposed in [6]. Their proposed method, called CasCN (Recurrent Cascades Convolutional Networks), is also based on an RNN architecture. CasCN predicts cascades through learning the latent representation of both structural and temporal information.

To the best of our knowledge, there are no current solutions that connect news articles and social media events in order to predict the spread of certain news topics in social media. To address this shortcoming, we analyze both news articles and tweets in order to correlate the events from the two type of sources and employ Deep Learning architectures together with our feature engineered training set for an accurate audience interest prediction on particular news topics.

3 METHODOLOGY

In this section, we discuss the core components of our solution.

3.1 Term Weighting Schemes

In Information Retrieval and Text Mining, a weighting scheme is a statistical measure to evaluate how important a term is to a document in a collection or corpus. Weighting schemes are the basis for many document vectorization techniques, such as the vector space model where each feature is a word (term), and the feature's value is a term weight.

For a corpus of documents $D = \{d_1, d_2, ..., d_n\}$, where $n = ||D||$ is the total number of documents in the dataset, a document d_i is defined as a sequence of terms t_{ij}, $d_i = \{t_{i1}, t_{i2}, ..., t_{im}\}$ where m is the length of the vocabulary. The vocabulary is the set of distinct words that appear in the corpus of documents. The term frequency $TF(t_{ij}, d_i)$ of a term t_{ij} is equal to the number of co-occurrences of that term in a document d_i (Equation (1)).

$$TF(t_{ij}, d_i) = f_{t_{ij}, d_i} \tag{1}$$

The inverse-document frequency $IDF(t_{ij}, D)$ is a statistical measure of the importance of a term in a text document collection (Equation (2)), where t_{ij} is the term, D is the corpus of documents, $n = ||D||$ is the number of documents in the corpus, and n_{ij} is the number of documents where term t_{ij} appears. Terms with a low document frequency add more information than terms with a high frequency. Thus, the more frequently the term appears in the collection, the less informative the term is.

$$IDF(t_{ij}, D) = \log_2 \frac{n}{n_{ij}} \tag{2}$$

Term frequency-inverse document frequency ($TFIDF(t_{ij}, d_i, D)$) is a statistical measure used to determine the importance of a word regarding its frequency in a document relative to the entire corpus. The term importance is proportional to the number of times a word appears in the document, although it is counterbalanced by the frequency of that word in the corpus (Equation (3)).

$$TFIDF(t_{ij}, d_i, D) = TF(t_{ij}, d_i) \cdot IDF(t_{ij}, D) \tag{3}$$

The normalized term frequency-inverse document frequency $TFIDF_N(t_{ij}, d_i, D)$ (Equation (4)) uses the ℓ^2-norm (Equation (5)) to normalize the values of $TFIDF(t_{ij}, d_i, D)$, for each term t_{ij} in each document d_i, in the $[0, 1]$ interval.

$$TFIDF_N(t_{ij}, d_i, D) = \frac{TFIDF(t_{ij}, d_i, D)}{\ell^2(d_i)} \tag{4}$$

$$\ell^2(d_i) = \sqrt{\sum_{t_{ij} \in d_i} \left(TFIDF(t_{ij}, d_i, D)\right)^2} \tag{5}$$

Using the weights, we construct document-term matrices $A \in \mathbb{R}^{n \times m}$ to describe the frequency of terms that occur in the dataset. By considering this representation, rows correspond to documents and terms to columns.

3.2 Topic Modeling

Topic modeling is a statistical unsupervised machine learning method used to extract hidden latent semantic patterns within a corpus of documents. Topic modeling algorithms use either statisical models, i.e., Probabilistic Latent Semantic Indexing (PLSI) [17], generative statistical models, i.e., Latent Dirichlet allocation (LDA) [4], or matrix factorization, e.g., Non-Negative Matrix Factorization (NMF) [2], Latent Semantic Analysis [9] (LSA). Experimental results prove that NMF is the best choice for extracting topics [7].

Non-Negative Matrix Factorization. NMF is an algorithm that factorizes a matrix $A \in \mathbb{R}^{n \times m}$ into two non-negative matrices $W \in \mathbb{R}^{n \times k}$ and $H \in \mathbb{R}^{k \times m}$. In the case of topic modeling, the matrices have the following signification:

(1) A is a document-term matrix constructed using weighted term frequencies for a corpus containing n documents and a vocabulary of size m terms;
(2) W is the document-topic matrix that assigns a document membership to each topic k;
(3) H is the topic-term matrix that assigns to each topic k the importance of a term.

To determine W and H, the objective function $F(W, H)$ must be minimized by respecting the constraint that all the elements of W and H are non-negative. Equation (6) presents the objective function, where $|| \cdot ||_F$ is the Frobenius norm.

$$F(W, H) = ||A - WH||_F^2 = \sum_{i=1}^{n} \sum_{j=1}^{m} (A_{ij} - (WH)_{ij})^2 \tag{6}$$

To minimize the objective function (Equation (7)), the values of W and H are updated iteratively (with t the index of the iteration) until they stabilize (Equation (8)).

$$\min_{W \geq 0, H \geq 0} F(W, H) = \min_{W \geq 0, H \geq 0} ||A - WH||_F^2 \tag{7}$$

$$H_{ij}^{t+1} \leftarrow H_{ij}^{t} \frac{((W^t)^T A)_{ij}}{((W^t)^T W^t H^t)_{ij}}$$
$$W_{ij}^{t+1} \leftarrow W_{ij}^{t} \frac{(A(H^{t+1})^T)_{ij}}{(W^t H^{t+1}(H^{t+1})^T)_{ij}} \quad (8)$$

3.3 Information Diffusion

Information diffusion in social media studies the data propagation to find events and forecast their spreading [13]. Event detection is a subdomain of information diffusion that aims to discover real-world events from the social media [38]. We choose Mention-Anomaly-Based Event Detection (MABED) [15] as the *Twitter event* detection algorithm. MABED is a statistical event detection on social media method immune to the topic bias added by the texts unrelated to the event.

Mention-Anomaly-Based Event Detection. MABED is an efficient method for event detection that filters irrelevant content and successfully removes spam messages with no actual intent, posted around certain hours.

To identify a bursty topic and detect an event for a period of time $I = [a; b]$ and a main word t (event label) with MABED, a weight $w_{t'_q}$ is computed for each candidate word t'_q (event keywords) in the time slice i (Equation (9)). The weight is computed using the affine function $\rho_{O_{t,t'_q}}$ (Equation (10)) that corresponds to the first order auto-correlation of the time-series for N_t^i (number of tweets in the time-slice i that contain the main word t) and $N_{t'_q}^i$ (number of tweets in the time-slice i that contain the candidate word t'_q) [12].

$$w_{t'_q} = \frac{\rho_{O_{t,t'_q}} + 1}{2} \quad (9)$$

$$\rho_{O_{t,t'_q}} = \frac{\sum_{i=a+1}^{b} A_{t,t'_q}}{(b-a-1)A_t A_{t'_q}} \quad (10)$$

Where:

(1) $A_{t,t'_q} = (N_t^i - N_t^{i-1})(N_{t'_q}^i - N_{t'_q}^{i-1})$;
(2) $A_t^2 = \frac{\sum_{i=a+1}^{b}(N_t^i - N_t^{i-1})^2}{(b-a-1)}$;
(3) $A_{t'_q}^2 = \frac{\sum_{i=a+1}^{b}(N_{t'_q}^i - N_{t'_q}^{i-1})^2}{(b-a-1)}$.

3.4 Text Representation using Embeddings

Before using machine learning models for classification, prediction, or clustering, the documents must be transformed from textual data to numerical data.

Word Embedding. The Word to Vector model (Word2Vec) is a shallow neural architecture that produces a vector space for a textual dataset using the values of the neural network hidden layer [27]. There are two approaches proposed in the literature:

(1) Continuous Bag-Of-Words model (CBOW) which accounts for the textual dataset vocabulary and represents documents as a set of continuous word-multiplicity pairs. The input to the hidden layer connections is replicated by the number of context words, and the context is preserved through the use of multiple words that target a given word.
(2) Skip-gram model which represents documents as sequences of words with gaps between them. The input to the neural network is the target word, and the output layer is replicated multiple times to accommodate the chosen number of context words. Thus, this model manages to embed in the word representation its linguistic context.

The two models mirror each other while both preserve context. The CBOW model uses multiple neighbouring words to preserve the context for a target word, while the Skip-gram model uses a word to preserve the context for multiple targeted neighbouring words.

Document Embedding.

The Document to Vector (Doc2Vec) model learns continuous distributed vector representations for textual data [23]. The text dimension may vary from phrases and sentences to large documents. The model is similar to the Word2Vec model which maps words into the vector space maintaining the semantic similarities by using a given word's context. There are two approaches in the literature [23]:

(1) The Paragraph Vectors Distributed Memory (PVDM) model [23] extends the CBOW architecture by mapping each document to a vector via an additional document-to-vector matrix and concatenating this vector to the word vectors in order to predict the central word.
(2) The Paragraph Vectors Distributed Bag of Words (PVDBOW) predicts the central word using the same mechanism as PVDM model but does not preserve the word order and ignores the context.

Similarity. Using word or document embeddings together with the cosine similarity [24], the semantic similarity between two words or documents can be computed [20]. This method assumes that two embeddings have a non-zero norm and measures their orientation instead of their magnitude, as in the case of the Euclidean distance. Equation (11) presents the cosine similarity for two p-dimensional vectors x and y.

$$cos(\theta) = \frac{\sum_{i=1}^{p} x_i \cdot y_i}{\sqrt{\sum_{i=1}^{p} x_i^2} \cdot \sqrt{\sum_{i=1}^{p} y_i^2}} \quad (11)$$

3.5 Deep Learning Architectures

Artificial neural networks (ANNs) use processing units to predict an output $y \in \mathbb{R}^{n \times k}$ for an input dataset $X \in \mathbb{R}^{n \times m}$. For the given input containing feature vectors $x_i \in X$, the processing unit will try to predict an output $\hat{y}_i = \delta(\sum_{j=1}^{m}(w_{ij} \cdot x_{ij}) + b)$ using a weight vector w_{ij}, the bias b, and the activation function $\delta(\cdot)$. The activation function has different forms depending on the processing unit (Table 1).

Table 1: Activation functions

Name	Function
Sigmoid	$\delta(z) = \sigma_g(z) = \frac{1}{1+e^{-z}}$
Hyperbolic	$\delta(z) = \tanh(z) = \frac{e^z - e^{-z}}{e^z + e^{-z}}$
ReLU	$\delta(z) = \max(0, z)$
Softmax	$\delta(z) = \frac{e^z}{\sum_{i=1}^{m} e^{z_i}}$ $(m = dim(z))$

To accurately predict the output y, the ANN models minimize the loss or cross entropy function (Equation (12)) by adjusting the weights after a specified finite number of iterations or when the function stabilizes.

$$L(\hat{y}, y) = -(y \log \hat{y} + (1-y)\log(1-\hat{y})) \quad (12)$$

Stochastic gradient descent (SGD) (Equation (13)) is used to update the weight vector at iteration t using the weights computed during the previous iteration. Equation (14) presents the weigths update function, where η is the global learning rate and $\alpha \in [0; 1]$ is the exponential decay factor.

$$\gamma_t = \nabla_{\boldsymbol{w}^{(t)}} L(\hat{y}, y) \tag{13}$$

$$\triangle \boldsymbol{w}^{(t)} = \alpha \triangle \boldsymbol{w}^{(t-1)} - \eta\gamma_t \tag{14}$$

ADAGRAD is a method used to improve SGD by increasing the learning rate when the $\boldsymbol{w}$ weight vectors are sparse [11]. Equation (15) presents update rule used by ADAGRAD, where $||\gamma||_2$ is the ℓ^2-norm of all previous gradients on a per-dimension basis.

$$\triangle \boldsymbol{w}^{(t)} = -\frac{\eta}{||\gamma||_2}\gamma_t \tag{15}$$

ADAGRAD has two problems :

(1) the continual decay of learning rates throughout training, and
(2) the need for a manually selected global learning rate.

ADADELTA [39] solves these two problems by using the Root Mean Square (*RMS*) to update the weights (Equation (16)).

$$\triangle \boldsymbol{w}^{(t)} = -\frac{RMS[\triangle \boldsymbol{w}]_{t-1}}{RMS[\gamma]_t}\gamma_t \tag{16}$$

Two Deep Learning Architectures used successfully in classification [21] are Multi-Layer Perceptron and Convolutional Neural Network.

Multi-Layer Perceptron. One of the basic processing units is the perceptron, which maps its input x_i to a single binary value $\hat{y}_i \in \{0, 1\}$. The perceptron can generalizes naturally to a multi-class perceptron to predict $\hat{y} = argmax_y f(x, y) \cdot \boldsymbol{w}$ by using a feature representation function $f(x, y)$ that maps each possible input/output pair to a finite-dimensional real-valued feature vector and multiplies it by a weight vector $\boldsymbol{w}$.

The Multi-Layer Perceptron (MLP) is a feed-forward ANN architecture that stacks perceptron units into three fully connected weighted directed layers:

(1) the input layer,
(2) the hidden layer, and
(3) the output layer.

The MLP becomes a Deep Feed-Forward Neural Network architecture by adding multiple hidden layers

Convolutional Neural Network. A Convolutional Neural Network (CNN) is an ANN architecture similar to the MLP, except it contains multiple hidden layers. These hidden layers consist of a series of convolutional layers that apply a filter to the activation function. They include the following types of layers: pooling, fully connected, and normalization layers. The pooling layer is used to reduce the dimensions of the data by combining the outputs of one layer into a single neuron in the next layer.

3.6 Evaluation Methods

Multi-class classification models assign a data point to one and only one non-overlapping class c_i ($i = \overline{1, k}$) [32]. To evaluate the quality of the model we can use the average accuracy (Equation (17)) where:

- TP_i (True Positive) is the number of data points correctly classified with class C_i;
- FN_i (False Negative) is the number of data points incorrectly classified with a class C_j ($j \neq i$);
- FP_i (False Positive) is the number of data points incorrectly classified with class C_i;
- TN_i (True Negative) is the number of data points correctly classified with a class C_j ($j \neq i$).

$$A = \frac{1}{k}\sum_{i=1}^{k}\frac{TP_i + TN_i}{TP_i + FN_i + FP_i + TN_i} \tag{17}$$

4 PROPOSED SOLUTION

Figure 1 presents the architecture of the proposed solution. The architecture is modular and each module is described in the following paragraphs. The code is publicly available on GitHub[1].

4.1 Data Collection and Storage Modules

To collect the News corpus we have used two APIs (Application Programming Interface): News River API[2] and NewAPI[3]. News River API returns the latest 100 news based on a given subject, e.g., politics, brexit, etc. NewAPI is a public and free API for news that contains news from many sources and can be configured to request the latest 100 news from the most popular news publisher, e.g., The New York Time, Reuters, The Washington Times, etc. Although, NewsAPI provides multiple metadata about each news article, e.g., title, description, online location, etc, the content is reduced to the first paragraph. We developed a scrapper to obtain the entire content of the article. To collect tweets, we used the Twitter API to request tweets with specific keywords and usernames. Besides the content of the tweet, we also store likes, retweets, and creation time for each tweet. The datasets are stored in a MongoDB[4] database.

4.2 Preprocessing Modules

Text preprocessing is done differently depending on the task, i.e., Topic Modeling or event detection, and type of corpus, i.e., News or Tweets. Thus, we create three preprocessed corpora:

(1) NewsTM with news articles for topic modeling,
(2) NewsED with news articles for event detection, and
(3) TwitterED with tweets for event detection.

To create the NewsTM corpus, we employ the following perprocessing steps:

(1) extract named entities to treat them as concepts and not as simple terms,
(2) extract lemmas to minimize the vocabulary and store only the base root, and
(3) remove punctuation and remove stop words because they do not add any information gain.

Both NewsED and TwitterED corpora are created using two preprocessing steps:

(1) removal of punctuation, and
(2) tokenization.

We choose this simple preprocessing pipeline to replicate the text preprocessing done originally for the MABED algorithm. The preprocessing pipeline is implemented in SpaCy[5]. The results are stored in the MongoDB database.

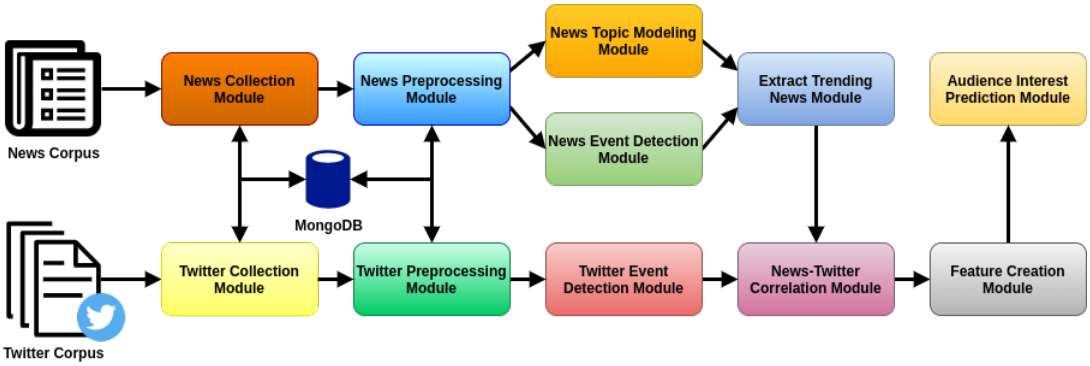

Figure 1: Architecture

4.3 Topic Modeling Module

Topic modeling is used to create an overview of the current and of interest subjects in the media. We use the NMF algorithm to extract the main topics from the NewsTM corpus. A document-term matrix is constructed from the NewsTM corpus after each document is vectorized using the $TFIDF_N$ weight. We use the Scikit-learn[6] implementations for $TFIDF_N$ and NMF.

4.4 Event Detection Modules

For both news articles and tweets, we use the MABED algorithm to detect trending topics. We enhance the NewsED and TwitterED datasets with the creation time of each record. MABED detects events defined by three characteristics:

(1) a set of main words,
(2) a set of related words, and
(3) the period of time when the topic is of interest.

We use the original implementaion of MABED[7].

4.5 Trending News Module

To correlate the news topics to the *news events*, we use the Doc2Vec model to encode the topic keywords (NewsTopic2Vec) and the *news events*' main and related terms (NewsEvent2Vec). Using the cosine similarity (Equation (11)) implemented in SpaCy, we score the match between each topic and each event. We extract the best matches for each topic, and with the help of each matching event, we determine how topics are diffused in mass media.

4.6 Correlation Module

The *news events* are correlated to the *Twitter events* to determine how current information is propagated on social media. As in the case of the *news event*, we use Doc2Vec to encode each *Twitter events*' main and related terms into one vector (TwitterEvent2Vec). We correlate the news and *Twitter events* that appear in the same time interval and extract candidate correlations. The cosine similarity implemented in SpaCy is used to find the best matches from the candidate correlations. Using this method we determine how news is propagated in social media.

[6]https://scikit-learn.org/stable/
[7]https://github.com/AdrienGuille/pyMABED

4.7 Feature Creation Module

Using the *Twitter events* detected by the Correlation Module, we extract the tweets that belong to each event. We consider that a tweet is part of an event if both of the following conditions are true:

(1) it was posted during the event's period of time, and
(2) its textual content contains at least one main word and 20% of the related words.

An event is considered of interest if there are at least 10 records associated to it. We constructed a new sub-dataset using this criteria. We encode each tweet belonging to an event using Word2Vec on the tweet's terms present in the vocabulary containing the main and related terms of that event. We use the Gensim[8] Word2Vec implementation. We then create three custom Doc2Vec embeddings for each tweet by averaging the Word2Vecs as follows:

(1) SW_Doc2Vec: only Word2Vecs found in the pre-trained model are considered in computing the document embedding;
(2) RND_Doc2Vec: random vectors with values in the range $[-1, 1]$ for terms that are not found in the pre-trained model are added before computing the document embedding;
(3) SWM_Doc2Vec: Word2Vecs found in the pre-trained model are multiplied by the word's magnitude in the context of the event before computing the document embedding.

Before creating the datasets for predictions, we also incorporate metadata into the representation of each record. The metadata vector incorporates a one-hot-encoder vector that embeds the author of each tweet, its number of followers, and the day of the week. We added these features because it was proven empirically that *i)* the number of followers influences the propagation of news in social media [16], and *ii)* the media consumption is influenced by the day of the week [3].

We also create a feature that represents the number of followers, during the period of the event, for each user. The likes and retweets classes used for predicting the events interest on social media are constructed similarly to the feature that encodes the user's number of followers. Table 2 presents the encoding for the number (#) of user followers, tweet likes, and retweets, respectively.

[8]https://radimrehurek.com/gensim/

Table 2: Features Encoding

Feature	# < 100	# ∈ [100, 1 000]	# > 1 000
followers	0	1	2
likes	0	1	2
retweets	0	1	2

4.8 Audience Interest Prediction Module

To predict the audience interest in a news topic, we analyze the retweets and likes received by the tweets that discuss the news articles belonging to that topic. We use two Deep Neural Networks architectures for our prediction module:

(1) a Multi Layer Perceptron (Figure 2), and
(2) a Convolutional Deep Learning architecture (Figure 3).

The first architecture uses only perceptron units that can easily generalize a wide variety of problems. The second architecture uses a convolution layer and a max pooling layer. We use accuracy to evaluate the networks' performance and classification's quality.

4.9 Design choices

We decided to fetch the latest tweets and news every 2 hours. Thus, we leave a large enough time window to manage to collect a representative number of new tweets and news articles. The algorithms are executed, from checkpoints or from scratch, after each dataset update, and the models are replaced with the new ones as soon as they finish. Thus, multiple instances of the same algorithm may run at the same time on different datasets. Also, we choose to use NMF instead of LDA [4] as it provides similar results on both small and large length texts in less time [35].

For training the word embeddings and then vectorizing the textual data to extract Doc2Vec, we choose a pretrained word2vec on the Google News corpus[9]. This dataset contains 3 million 300-dimension English word vectors. We made this design choice because this dataset is larger than the datasets we collected and manages to provide better word representations on which to construct our Doc2Vec embeddings. In contrast, the PVDM and PVDBOW models are not good for our study because they will not find good document representations since they can be trained by us only on the collected datasets. Thus, these models do not manage to generalize the document representation.

To alleviate the need to train the neural models each time the datasets are updated, we use checkpoints to continue the training as new data is added in real time. Furthermore, the most demanding networks are trained in less than 7 minutes. Thus, the models can be build again if all data is new.

5 EXPERIMENTAL RESULTS

We apply our method on a real-world data, aiming to eventually predict user interest.

5.1 Datasets

We have collected 261 052 news articles, and 80 569 tweets for a period of 5 months. Both datasets contain records from different news venues and are all written in English. For the Twitter corpus, we also collected statistics for both tweets, i.e., likes and retweets, and users, i.e., number of followers, the friends count, and the retweets count.

[9]https://code.google.com/archive/p/word2vec/

5.2 News Topics

The first set of experiments uses the NewsTM corpus together with NMF algorithm to extract the most relevant 100 topics from all the news articles. This process takes 19.01 minutes. Table 3 presents a subset of 10 *news topics* (NT) extracted for the entire period. These news topics are used to showcase the correlation with the corresponding *Twitter events*.

Table 3: News topics

#NT	Keywords

5.3 News Events

For our experiments, we extract the top 1 000 *news events* from the NewsED corpus, using the MABED algorithm. We use a time frame of 60 minutes. The extraction of *news events* takes 17.08 hours: 177.41 seconds to load the corpus, 1.3 hours to partition the news into time-slices, and 15.73 hours to extract events. Table 4 presents a subset of the *news events* (NE) detected by MABED. These *news events* are some of the *trending news articles* determined during the correlation with the *news topics*.

5.4 Twitter Events

Using MABED, we identified the top 5 000 events on the TwitterED corpus collected for a period of 5 months that have at least 10 tweets associated to it. We use a time window of 30 minutes. The extraction of *Twitter events* takes 11.74 hours: 1.61 seconds to load the corpus, 70.42 seconds to partition the news into time-slices, and 11.72 hours to extract events. Table 5 presents some of the detected *Twitter events* (TE) that we use to exemplify the correlation between *trending news topics* and *Twitter events*.

5.5 Correlation Results

We use cosine similarity to correlate the *news topics* (NT) with *news event* (NE) to extract *trending news topics*. Then, we correlate *trending news topics* with *Twitter events* (TE), i.e., *trending news topics* → *Twitter events* . First, we correlate each *news topics* with each *news event* and extract the ones with the highest similarity.

The pairs < *news topics*, *news event* > are the *trending news topics*. We extracted 83 *trending news topics* that have a similarity of over 0.7. Then, for each *trending news topics*, we extract the *Twitter events* in the same time window with the highest Doc2Vec similarity. Given the start date (S_{TT}) of a *trending news topics* (TT), the constraint of the *Twitter events* (TE) start date is $S_{TE} \in [S_{NE}; S_{NE} + 5day]$. We choose this start interval because a *Twitter event* can appear on social media as soon as the news appears in the mass media, but it can also be some delay between the appearance time on the two platforms. The end date is not significant as a *Twitter event* can be prolonged even though the mass media stops releasing new content. We determined a total of 421 < *trending news topics*, *Twitter events* > pairs that respect the time constraint and have a similarity of over 0.65. This process takes 31.2 minutes: 17.41 minutes to extract *trending news topics* and 13.79 minutes to determine the < *trending news topics*, *Twitter events* > pairs.

Table 6 showcases a subset of the correlation between the selected *news topics*, *news events*, and *Twitter events*, where the topic and event numbers can be found in Tables 3, 4, and 5. As we extract 1 000 *news events*, in Table 6 the *news events* also represent *trending news topics*. The presented correlations also include the best and the worst similarities.

Table 6: Correlation between topics and events

mass media are discussed in detail during their publication on social media. Although not all *news topics* are directly related to a *Twitter events*, e.g., NT #9 discussed Trump's impeachment, and TE #9 discusses the abortion law passed in Alabama, the correlation between *news topics* and *news events* is high. Thus, these topics are considered *trending news topics*. Furthermore, some *trending news topics* match generalized *Twitter events*, e.g., NT #10 is related to the Kentucky derby, where the winning horse named Maximum Security was disqualified, while TE #10 is related to Manchester football clubs, but both talk about sports. Other matches are quite specific, e.g., NT #1 and TE #1, which both are related to European politics and Brexit.

In conclusion, a similarity over 0.77 between *news topics* and *news events* shows that the topics and events are consistent, while a similarity over 0.69 between *news events* and *Twitter events* denotes a generalization tendency of events for *trending news topics*. Furthermore, we found that all the *trending news topics* have correlations with at least one *Twitter event* and that some *trending news topics* are correlated to the same *Twitter events*.

We also analyzed the reverse correlation, i.e., *Twitter events* → *trending news topics*, by applying the same steps as for *trending news topics* → *Twitter events* but in reverse. We observe that the set given by the correlation *Twitter events* → *trending news topics* is the same as the one given by *trending news topics* → *Twitter events*.

However, as Twitter is a social media platform for generic discussion, some events discovered by MABED within the tweets collected are not related to the current *news events*. Thus, we can conclude that some thread discussions present generic topics. They spam for longer periods of time and the keywords are more generic. These events are related to common discussions regarding food, social media in general, television shows, etc. Table 7 presents some of the tweeter events that are not related to any of the news articles topics and do not match any *trending news topics* using our matching condition.

5.6 Audience Interest Prediction

Using the correlation between *trending news topics* and *Twitter events* we want to predict the interest of twitter users in *news topics* on social media using metadata, i.e., the user and its number of followers, and determine if a *news topic* becomes viral. We employ the MLP and CNN architectures to predict the audience interest in the *trending news topic*. The interest is given by both the number of retweets and likes received by the *Twitter Events* correlated to the *trending news topics*. We train each network on a machine with a 3.5GHz quad-core processor and 16GB RAM, using the Keras[10] library with TensorFlow[11] as backend.

Each network is trained until it converges, using an Early Stopping mechanism that checks if there are any changes in the loss function from one epoch to the next. We used the optimizers SGD and ADADELTA and different leaning rates (lr). After hyperparameter tuning and cross validation, we obtain the following configurations which have the best results:

- MLP 1 uses the MLP architecture with the SGD optimizer and a $lr = 0.5$,
- MLP 2 uses the MLP architecture with the ADADELTA optimizer and a $lr = 2$,
- CNN 1 uses the CNN architecture with the SGD optimizer and a $lr = 0.5$, and
- CNN 2 uses the CNN architecture with the ADADELTA optimizer and a $lr = 2$.

The input of the networks contains the document embeddings (Doc2Vec) for each tweet belonging to a *Twitter event* determined by the correlation < *Twitter events*, *trending news topics* >. Thus, as some tweets can belong to multiple events, the size of the Twitter dataset increases. The label for a tweet is determined by the number of likes and retweets, respectively, as presented in Table 2. We create 8 datasets using the custom document embeddings and the metadata vector, as presented in Section 4 as follows:

- A1 uses the SW_Doc2Vec model;
- A2 uses the SW_Doc2Vec model concatenated with the metadata vector;
- B1 uses the RND_Doc2Vec model;
- B2 uses the RND_Doc2Vec model concatenated with the metadata vector;
- C1 uses the SWM_Doc2Vec model;
- C2 uses the SWM_Doc2Vec model concatenated with the metadata vector;
- D1 uses the SW_Doc2Vec model;
- D2 uses the SW_Doc2Vec model concatenated with the metadata vector and the tweet's author number of followers.

We set the document embedding size to 300. The metadata vector has a size 8 which includes an one-hot-encoding vector for the tweets' author, i.e., the *influencer* and the its number of followers, of length 7 and one element for the day of the week. Thus, we include two behaviour factors in our embedding:

(1) a temporal one given by the day which incorporate user behaviour patterns, i.e., the patterns users have to post online;
(2) a global one given by the author metadata which integrates the impact of *influencers* on the virality of *trending news topics*.

For each experiment, the behavior of the network is described by the reduction slope of the loss function and the increasing slope of the accuracy function over the training dataset. Table 8 presents the measured accuracy results over our *validation* sets on predicting *likes*, while Table 9 presents the accuracy for predicting *retweets*. We define accuracy in terms of correct

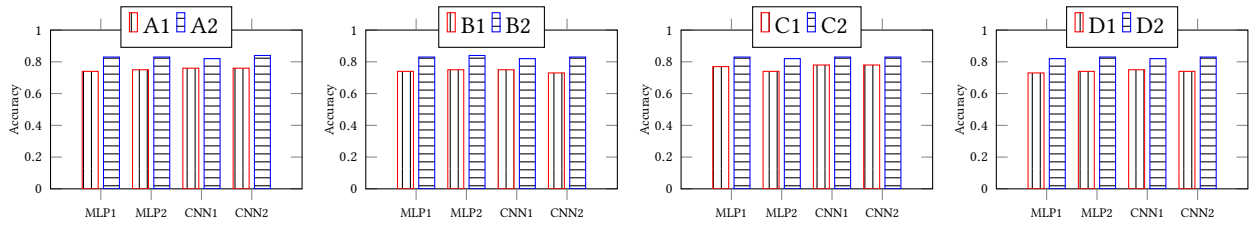

Figure 4: Likes accuracy comparison: without metadata (A1, B1, C1, and D1) vs. with metadata (A2, B2, C2, and D2)

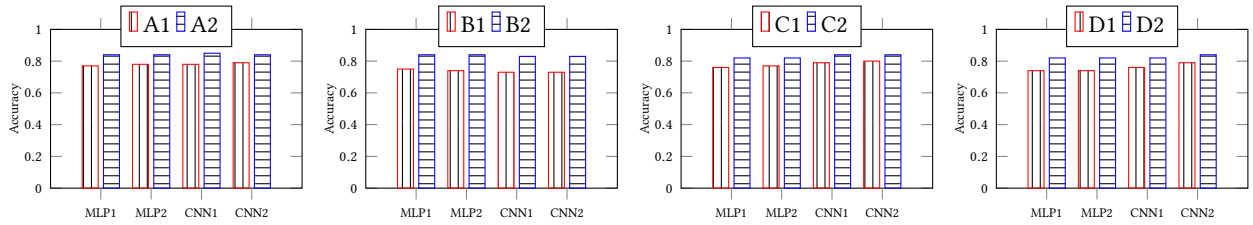

Figure 5: Retweets accuracy comparison: without metadata (A1, B1, C1, and D1) vs. with metadata (A2, B2, C2, and D2)

prediction in one of the 3 encoded classes for likes and retweets. Note that our accuracy results also reflect the error rate, since ErrorRate = 1 − Accuracy. As our results show, we successfully achieve low error rates by virtue of utilizing terms extracted using MABED and NMF; this success is based on the fact that similar topics/events have high similarity scores, while dissimilar ones have low similarity scores.

Table 8: Likes accuracy of correlated results

Dataset	MLP 1	MLP 2	CNN 1	CNN 2
A1	0.74	0.75	0.76	0.76
A2	0.83	0.83	0.82	0.84
B1	0.74	0.75	0.75	0.73
B2	0.83	0.84	0.82	0.83
C1	0.77	0.74	0.78	0.78
C2	0.83	0.82	0.83	0.83
D1	0.73	0.74	0.75	0.74
D2	0.82	0.83	0.82	0.83

Table 9: Retweets accuracy of correlated results

Dataset	MLP 1	MLP 2	CNN 1	CNN 2
A1	0.77	0.78	0.78	0.79
A2	0.84	0.84	0.85	0.84
B1	0.75	0.74	0.73	0.73
B2	0.84	0.84	0.83	0.83
C1	0.76	0.77	0.79	0.80
C2	0.82	0.82	0.84	0.84
D1	0.74	0.74	0.76	0.79
D2	0.82	0.82	0.82	0.84

We observe that both networks reach good results in terms of predicting the audience interest in specific *news topics* on social media, ranging from 0.73 to 0.85 accuracy, and accurately predict whether the *news topic* becomes viral. Furthermore, both architectures achieve similar accuracy scores regardless of the optimizer.

We conclude that these results are highly impacted by the MABED algorithm because by detecting the most trending topics and identifying the event for a tweet afterward, it basically extracts required features to predict a range of likes and retweets.

Interestingly, both architectures reach a prediction score of 0.75 after only a few epochs are finished. After these epochs, the learning process is slow and not very stable, exhibiting fluctuations between 0.78 and 0.90.

The high results are influenced by the metadata used to enhance the training corpus. We observe that the accuracy improves over the baseline with more 0.05 in some cases. This proves that the *influencer* role in spreading the news as well as the behaviour patterns of posting depending on the day have a huge impact on predicting the virality of a *trending news topic*.

The popularity of a person inside a group determines the spread of its messages, thus proving that the *influencers* assumption also holds for determining *trending news topics* on social media. In conclusion, a user that has many followers or tweets with many likes and retweets will maintain the ascending trend for future tweets with high probability. Also, we conclude that using the metadata vector improves the accuracy of prediction for all our experiments (Figures 4 and 5).

5.7 Scalability

To evaluate scalability, we extract 500, 2 500, and 5 000 *Twitter events*. We determine and encode using Doc2Vec the tweets for each event and train the networks. Table 10 presents the runtime evaluation for the networks using a batch size of 5 000 and 500 epochs. Early Stopping mechanism is used to stop the training. All the experiments are performed using the CPU. The training process for one epoch takes on average 1 second and 13/14 milliseconds for the MLP architectures (Figure 6), while the CNN architectures have a linear time increase from 1 second 71 millisecond to 6 seconds 83 milliseconds w.r.t. the number of events and the Doc2Vec size (Figure 7). This extra time is added by the complexity of the convolution layer and the number of kernel filters applied to the input vector. The CNN architectures maintain a much lower number of epochs than the MLP ones, regardless of the number of events or the Doc2Vec size. The difference between optimizers is not obvious at the batch level as

time performance and accuracy remains the same w.r.t. number of events and Doc2Vec size. We observe a difference in the number of batches, as the ADADELTA optimizer, on average, requires more batches until it converges than the SGD optimizer. We note that these results may vary, depending on the hardware used.

Table 10: Runtime evaluation

No. Twitter Events	Doc2Vec Size	Network	No. Epochs	Milliseconds Epoch	Runtime (Seconds)
500	300	MLP1	113	1013	119.51
		MLP2	119	1014	121.87
		CNN1	6	1071	6.67
		CNN2	7	1073	7.75
	308	MLP1	143	1013	154.53
		MLP2	162	1014	177.37
		CNN1	6	1073	7.16
		CNN2	8	1074	8.97
2 500	300	MLP1	316	1013	331.15
		MLP2	363	1014	381.52
		CNN1	6	3078	25.08
		CNN2	7	3079	26.95
	308	MLP1	319	1013	337.27
		MLP2	375	1014	392.24
		CNN1	6	4081	28.09

5.8 Discussion

Correlation between Trending News Topics and Twitter Events. To determine the *trending news topics*, we correlated the *news topics* with *news events*. Then, we correlated the *trending news topics* with the *Twitter events* that have a high cosine similarity and are in the same time window. We observe that for the same *trending news topics*, we can match multiple *Twitter events* using the imposed constraints. Thus, we can conclude that the events generated by posts on social media about *trending news topics* are intertwined. Therefore, we can conclude that some important *news topics* appear in multiple discussion and that users make connections between them in their discussion. Furthermore, all the *trending news topics* have at least one matching *Twitter event*.

We also applied the reverse correlation, by matching *Twitter events* to *trending news topics*. We discovered that we obtain the same set of pair for *Twitter events* → *trending news topics* as for *trending news topics* → *Twitter events*. During this analysis, we also discovered that multiple *Twitter events* have no correlated *trending news topics*. We attribute these results to the fact that Twitter is a generalized discussion forum. Thus, users do not address in their post only current *news events* but also discuss other events that impact their life but do not appear in mass media.

Audience interest prediction in Trending News Topics. We predict the audience interest in *trending news topics* by constructing two Deep Learning models to determine if they become viral. Thus, a *trending news topic* has a high probability of becoming viral if the posts that belong to the *Twitter event* correlated with it has a high number of likes and retweets.

For our experiments, we embedded the tweets by combining document embeddings with a metadata vector that contains the user's tweets and its number of followers as well as the day of the week. This enhanced tweet embedding feature adds two new dimension within the learning model: a temporal one given by the day and a global one given by the user metadata. The experimental results show that the two models determine with high accuracy if a *trending news topic* becomes viral for both the datasets constructed using only documents embeddings and the ones that also use the metadata vector.

Through the use of the metadata vector, we incorporate in our training set two assumptions. The first assumption is a global one and introduces the concept of *influencers* (users with a high number of followers) in the learning model. The *influencers* have a huge role in spreading the information and making *trending news topics* to become viral. The second assumption is a temporal one which introduces the user behavior based on the day of the week, as behaviour patterns can change from one day to another. Using the assumption, the neural networks learn to determine patterns in the way users post on social media and integrate them in the final prediction model. The experimental results prove that this assumption stands for our use case. Both Deep Learning models achieve an improved accuracy when the metadata vector is concatenated to the document embedding. Thus, we can conclude that the *influencers* metadata manages to create models that better generalize while improving the overall performance.

Fake news mitigation considerations. The spread of misinformation in social media has the effect of polarizing opinions and misleading readers by presenting alleged, imaginary facts about social, economic, and political subjects of interest [16]. Our method manages to predict the virality of news content and the interest the public at large has in different news topics. These findings can prove useful in designing new mitigation algorithms that take into account both textual content and network metadata. Thus, we consider that the presented system manages to determine what topics are important and can be a starting point to develop new strategies for network immunization in the fight against misinformation.

6 CONCLUSIONS

In this work, we introduce and deploy an architecture for predicting whether a *trending news topic* becomes viral on social media. We employ NMF topic modeling to extract *news topics* and MABED event detection to extract *news events* and *Twitter events*. We correlate *news topics* to *news events* by document embedding cosine similarity to extract *trending news topics*, match *trending news topics* to *Twitter events* in the same time window, and thereby extract likes, retweets, and user followers. We propose a new metadata-based document embedding for tweets associated to an event that encodes *influencers* information. Using the new document embeddings, we prepare a training corpus to predict audience interest in a *trending news topic*, using two Deep Learning architectures.

The similarity between *news topics* and *news events* in our data is over 0.77, while that between *trending news topics* and *Twitter events* is over 0.69. Our results show that the *trending news topics* and the *news events* are consistent, while the proposed architectures predict audience interest in a *news topic*, with accuracy over 0.82 in the metadata enhanced dataset.

In the future, we plan to use other matching techniques, e.g., Minimum Cost Flow, to correlate *news topics*, *news events*, and *Twitter events*, and use topic modeling [7] to see if we can extract more coherent topics from news. We also plan to employ word, sentence, and document level transformers (BERT [10], XLNet [37], ALBERT [22], ELECTRA [8]) as embeddings to take advantage of contextual information extracted using these models. Further, our solution can be included in larger solutions for fake news mitigation and misinformation immunization strategies for social media.

This work was done in collaboration with RoNews, a start-up offering news media content, which was interested in detecting article topics and verifying content veracity. Hootsuite and Sprinklr have also presented interest in this solution.

ABSTRACT

This work introduces and aim to overcome the potential challenges while deploying automated tuning of relational database as a service for a Platform as a Service (PaaS) provider. Some of the major challenges identified in this work include (i) automated detection of performance throttling (figure out when the performance of the system is affected due to incorrect configurations of knobs) of a database and identify potential points where a database requires a tuning, (ii) scalability and accuracy of tuning service and (iii) applying the recommendations obtained from tuning services wherein applying an obtained recommendation might require a database restart.

In this work, we present a generic tuning service architecture for PaaS providers. To deal with the above challenges, we introduce performance throttling engine which is responsible to detect potential points when a relational database actually needs a knob tuning, which helps in increasing the scalability and accuracy of the tuner deployments (responsible for tuning production landscapes). This work also proposes approaches that facilitate efficiently applying the recommendations without causing much disruption in Quality of Service (QoS) of the underlying database system. Lastly, the results are obtained by evaluation of the proposed methods and modules on multiple cloud native provisioners against various set of metrics.

1 INTRODUCTION

The PaaS customers do not have access to tune the configuration knobs of database/backing services as the service configurations are often abstracted. Tuning of the offered data services often requires DBAs to pitch in, observe/monitor and then, tune the service-instances. This often adds more complexity, as PaaS providers needs to have a DBA for each customer group, where each service offered has tens to hundreds of knobs to be tuned. In literature, there exists a set of various auto-tuners [1], [2] and [3] that aim to automate the tasks of a DBA. These tools are not holistic in nature and are limited to specific classes of parameters.

This work introduces challenges and requirements for introducing generic tuner as a service (AutoDBaaS), which can tune the configuration knobs of the relational data services as per requirement and thus, in-turn reduce the performance dependency on a DBA. In this work we evaluate already existing tuners and try to see how they can be used to tune live production systems. In literature there exists multiple style of tuners, broadly classified as search based [16] and learning based. This work specifically considers learning based tuners (as they can easily tune multiple types of databases and more suitable for PaaS service providers): bayesian optimization (BO) style tuners (like Ottertune [4]) and reinforcement learning (RL) tuners [18] and [17]. We discuss the pros and cons of both RL and BO style tuners for tuning live production systems in coming sections. Potentially, the challenges that drive the design and deployment of a tuning service as per PaaS architecture have been identified as follows:

- Scalability of Tuners
- High Quality Samples
- Metrics for Tuner Evaluation

Scalability of Tuners. As per the architecture of a BO style, it uses previously observed workloads to train a Gaussian Process (GP) regression (or a surrogate model), which recommends a new set of configs. The workload in Ottertune (any large scale machine learning tuner which tries to leverage previous experiences) is a collection of different knob values, obtained with respect to observed database metrics. The workload should contain enough data, where sufficient metric variations are observed across different variations in values of knobs. Or in another sense, a BO stlye tuner like Ottertune needs high volume of high quality samples. With the high volume samples, the Ottertune's workload size increases and causes a GPR training to take a time of around 100 to 120 seconds. Then if the underlying services, asks for recommendation with a high frequency of 5 mins (a typical monitoring time for a transactional data), one Ottertune deployment can be bound to a maximum of 3 to 4 service instances. This can also be inferred as a cost for a BO style tuners - 'recommendation-cost' to service-provider. In this aspect the RL style tuners do pretty well, as they do not need high volume of high quality samples. However, the pros and cons of BO style tuners and RL style tuners are discussed in comming sections.

High Quality Samples. Both RL and BO style tuners need to capture delta metrics (after execution of a workload) from the underlying database to be tuned. The quality of the captured metrics (or the quality of the samples) depends solely on the workload executed on the database. For example - when a client

*Produces the permission block, and copyright information
†The full version of the author's guide is available as `acmart.pdf` document

executes TPCC queries to a database, continuously for 10 minutes with 3000 requests per second, will generate a high quality sample. However, in production systems, the throughput of the executing workload is often low (or for most of the time, the production database does not needs a tuning), which cannot produce enough variations in the delta metrics (or often a low quality sample). In production systems, the spikes in throughput graph is seen at specific time-intervals only. In many cases, it is observed that even if there is high throughput, only a certain set of metrics show good variations and rest do not [4]. The quality of samples highly impacts the performance of both RL and BO style tuners. And, in production systems capturing high quality samples is very difficult (or atleast there exists no such way to do so in literature). In a nutshell, the main problem is that a production/live database tuner faces corruption of learning model when it trains over such samples (or collected metrics) which sometimes does not requires any tuning (and this is very much seen on production workloads). However, an offline tuner (which is expected to tune a staging, development, testing landscape database) does not face this issue. This is because in these database the all the queries are batched to form a workload and the workload gets executed for a time frame which generates a high quality sample.

Metrics for Tuner Evaluation. The tuner service the knobs, metrics and provides recommendations for performance improvements. As an end user, the expectations will be to get recommendations when the workload pattern changes in real time and the recommendation should actually improve performance. Currently there are ways in literature which can suggest changes in workload patterns [8], [19]. This works use templates (from queries) and cluster them. However, still there is no such information that with change in workload does the database actually needs a tuning. Secondly, just an increase in throughput cannot be a qualifier to suggest performance improvements. The reason for this is that in production systems, the workload pattern always changes i.e. say the throughput was measured when a query set was executed on a production database. Now after applying the recommendations, the next query set will get changed (or the workload gets changed) and the new throughput cannot be compared with the previous one. Hence, measuring performance based on recommendations on production system is also challenging.

A unifying theme to the above challenges is to identify the actual performance throttling on a database system. With respect to changing workload pattern of users SQL workload, performance throttling detection will help in predicting the incorrect knobs.

The paper makes the following novel contributions:

- **Identifying Performance throttling**: The performance throttling is responsible for identifying the database insufficiency to process SQL queries due to incorrectness of configured knobs. It classifies the knobs into different classes and then, for each class of knobs, it predicts throttling. This module increases the scalability of the tuner deployment by reducing the number of recommendation requests (when compared with the periodic nature of making tuning requests). The underlying services request for recommendation only when a performance throttling is detected. Thus, this module acts as a DBA and identifies when a database requires an actual tuning in real-time. This module identifies performance throttles from relational databases only.
- **Applying Recommendations in an effective way**: The tuning agent running on the database VM/Container as an plugin process, applies the recommendation on service-instance by re-loading the configs. The same plugin is also responsible for tuning of knobs that require a restart of the database.
- **Evaluation**: In production systems as the throughput varies, we need to identify new performance metrics to compare the effectiveness of obtained recommendations. To achieve this, we introduce the number of throttles triggered by the performance throttling module, as a metric.

2 SYSTEM DESIGN

This work presents a generic architecture, which can be easily integrated with any available cloud platform provisioners. As shown in Figure 1, the overall deployment of database tuning service, in an abstract form, is divided into two parts: (i) tuner instances - responsible for executing the ML pipeline to generate new config recommendations and (ii) config director instances - responsible for managing all available customer service-instances. The tuner instances can be spawned via either containers or VMs. There can be more than one tuner instances (also depends upon tuner scalability), where each tuner stores a workload W in a database, where a workload is combination of knob config parameters and metrics observed against those parameters (also called as training samples). Technically as described in [4], a tuner workload W is a set S of N matrices $S : \{X_0, X_1, X_2, ..., X_{N-1}\}$, where $X_{m,i,j}$ is the value of a metric m observed when executing a user SQL workload on database having configuration, j and the workload identifier, i. The tuner service uses the workload W for initial training of both BO and RL style tuners. These workloads are stored in database which is present on a different instance. This database acts as a common central data repository for all tuner instances. Tuning agent runs on the same database (and communicates to DB using Domain Sockets) which is responsible for identifying new workloads and uploads new workloads data periodically to the central data repository. The tuning services running on different IaaS'es, fetch the new workloads from the central data repository. This helps all tuning services to get the new unknown workloads, which might have been observed on a different IaaS, and create a better ML model.

The metric readings and recommendation request calls (we call it something like a tuning request) are event-based and triggered from the performance Throttling Detection Engine (TDE). The TDE gets periodically executed on the database master VM (like a plugin) and triggers recommendation requests to the config director. The TDE runs periodically on the master VM of the underlying database service and is responsible for figuring out performance throttling due to incorrect knob values with respect to current executing user workload. The config director receives the metric data (or queries in case of a RL based tuner) from service instances and triggers recommendation requests to tuner instances. The config director performs load balancing of recommendation request tasks across multiple tuner instances. The Service Orchestrator agent running on database services, is responsible for performing all life-cycle operations of service instances and maintains credentials. When the config director receives a new recommendation for a database service instance from a tuner, the config director passes the new configs synchronously to Data Federation agent (DFA) and Service-Orchestrator, while simultaneously storing it into the config data repository. The DFA

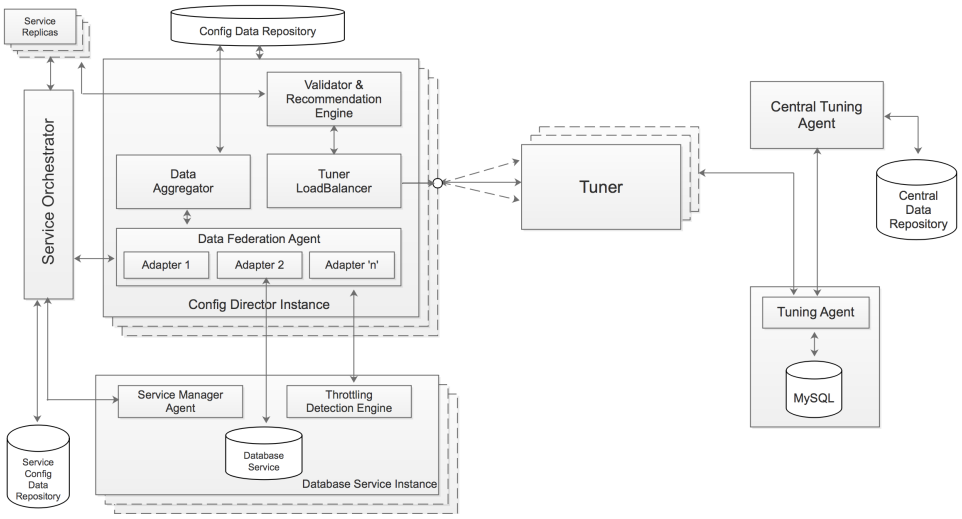

Figure 1: AutoDBaaS architecture.

fetches the credentials from Service Orchestrator layer and hits the APIs of TDE to apply configs to all nodes of the database service (such as all VMs/Containers of the service-instance). The DFA has multiple adapter implementations to get connected to various kinds of database services. As per the architecture, the tuner deployment is capable to tune multiple databases instances (one to many).

2.1 Tuner Instances

The tuner instances as shown in Fig. 1, can be any type BO or RL style tuners. Or can even be a hybrid combination. RL vs BO style tuners is offcourse a debatable topic as both have their pros and cons. BO style tuners when fully tuned with high volume of high quality samples can tune an underlying database in just two to three recommendations, where as RL style tuners need to experience large number of recommendations over the database (as per try-and-error strategy) to learn good configurations for the new workload pattern. At the same time, RL style tuners are highly sclable as they can quickly generate new configurations when properly trained (RL style tuners do not need high volume of high quality samples). Both BO and RL style tuners learning model relay on captured metrics when database actually needed tuning. And metrics/samples captured from database when database did not needed any throughput tuning (this is the often production system case), this corrupts the learning models of tuners. With such wrongly captured metrics BO style tuners face a cascading style corruption and RL style tuners face corrupting the current learning model. This problem of both RL and BO style tuner does not enable them to tune live production workloads, which are often characterized by low throughput or when the database does not needs any tuning. Well this is the major motivation for driving this work.

3 IDENTIFYING PERFORMANCE THROTTLES IN DATABASE

One of the crucial initial steps that the DBA performs before tuning is, monitoring the database to identify whether the database actually needs tuning or not. This module executes periodically as a part of TDE, gathers statistics based on the metrics/features collected using a rule-based approach and identifies potential points when a database needs a recommendation for tuning its configs. As per the proposed performance throttling approach, the config knobs of a relational database can be categorised, based on their properties, into three classes:

- Memory knobs
- Background writer knobs
- Async/Planner estimate knobs

The working of each sub-module is different and is explained as follows:

3.1 Memory Knobs

Memory knobs are the set of knobs which are dependent upon the resource (VM or container) hardware limits. The major portion of memory used by the database is utilised to keep the data in buffer. One of the approaches for identifying throttles could be to find out the actual working database size. To identify this, we use the algorithms proposed by authors in [5] where the authors use gauging techniques to identify the actual working page set. However, the major challenge with this knob is encountered while attempting to update this knob, since it requires a restart of the database. The TDE, collects this information and keeps on sending it to config director instances, where config-director collects the number of throttles and checks the size of the working page set and adjusts this knob value only during the scheduled maintenance downtime.

The other knobs belonging to this segment are related to working area of the database. The knobs related to the working area of memory depends upon the total number of active connections and if it is found to be in-sufficient, then database uses disk or system swap space to perform work operations like sorting, or maintenance operations like index-creation, storing temporary tables, table alter, etc. To get the memory usage details probes needs to be created in the codebase, which is arduous and dependent on freedom given from vendors. Alternatively, figuring out the disk usage while query execution, the query plans can be used as a potential source of information. We use query templating as described in [6], to reduce the total queries (to be examined in production systems), where the queries are converted to a template having a template-id. The queries collected from streaming logs are pre-processed and then converted

to generic templates (having no actual parameters/arguments). The final template selection takes place from the pool of queries by reservoir sampling (for capturing samples from streaming logs) [7]. The selected query templates undergoes execution plan evaluation by substituting the actual (most frequent) parameters to the template. From the plans/streaming logs, it can be easily inferred how much memory/disk the query is going to take. If any of the selected templates (from reservoir sampling) uses disk while execution, signifies that the memory is in-sufficient for execution of queries and now the TDE triggers a memory based throttle signal and asks for knob recommendation from a tuning service (raises a tuning request to the tuner).

However, there can be potential cases when the memory allocated for the buffer is maximum (which means the memory left for other processes becomes less), it is observed that TDE un-necessarily triggers throttle signals. This is a case, where the underlying instance configuration limit is in-sufficient (or the usage has reached the caps limit). When the size of the database is sufficiently higher than the actual memory allocated to database process, it is observed that the TDE frequently triggers throttle signals and is unable to understand that the throttles are being caused because of limited hardware resources. To deal with this cases, we need filtration approach, which identifies such situation and stops the un-necessary throttles (one potential case is the underlying VM hardware resource is in-sufficient and customer needs to upgrade to another plan or ask for more resources for the VM). We face the following challenges when designing such filters:

- There are a specific set of queries which trigger consecutive throttles from one memory knob (like use of aggregate queries triggers a throttle from working memory in PostgreSQL). Situations like this can cause increasing working memory continuously with each recommendation obtained and hence decreasing other knobs (to make room for increase of working memory). However, even after increasing the knob values to the maximum, throttles can get triggered. This situation can easily be captured by rule-based engine and throttles can be filtered.
- For a certain query, consecutive throttles are observed intermittently against different knobs. For example the first two throttles came from working memory and next two throttles came from *maintenance_work_mem*. This becomes very difficult to manage and identify with a rule based approach especially when number of knobs are high.
- There are a specific set of queries which triggers consecutive throttles from more than one set of knobs at a time (like use of aggregate queries, index creation queries, temp table creation queries, etc causes trigger of throttle from multiple knobs). Situations like this are difficult to be captured by rule based engine (becomes more complex when knob numbers increases or is already high) and needs a different approach.

We observed and collected such queries and table shown in Fig. 2 shows the same. In PostgreSQL, working memory is used by the execution engine to perform internal-sorting, joins, hash-tables, etc. We evaluated amount of working memory used by TPCC and CH-Bench, YCSB and Wikipedia bench in absence of indexes. We observed that Wikipedia and YCSB queries do not use working memory (due to absence of complex queries like aggregate, joins, and order-by). The table illustrates the actual working memory allocated and the amount of disk and memory used by queries.

Benchmark – Query Type	Work Mem (in MB)	Disk space utilized (in MB)	Memory utilized (in MB)	Execution Latency (in ms)
tpcc – Scan Query	0.5	3	0.5	8310
tpcc – Scan Query	1	0	0.64	3953
ch-bench – Scan Query	125	260	125	15413
ch-bench – Scan Query	150	0	137	6801
tpcc – Complex Aggregation Query	350	475	350	53013
tpcc – Complex Aggregation Query	375	0	367	19835

Figure 2: Queries and Memory statistics observed on PostgreSQL running on AWS VM, type-t3.x_large

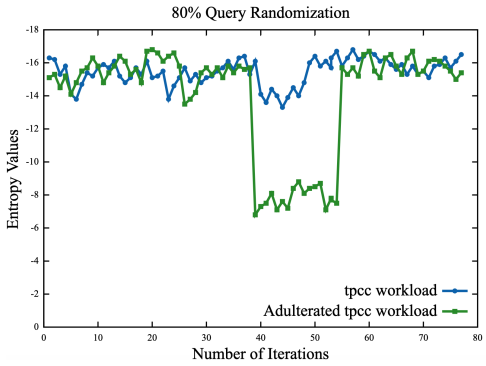

Figure 3: Entropy variation with 80% adulteration probability on Production SQL Workload

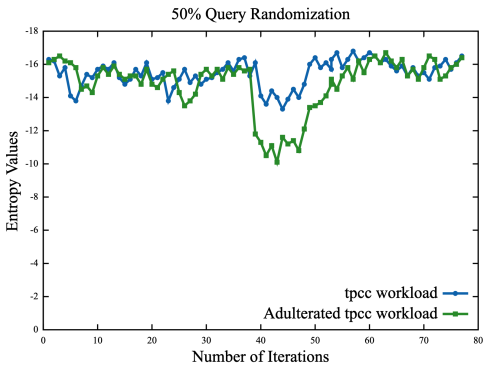

Figure 4: Entropy variation with 50% adulteration probability on Production SQL Workload

In this case, a probabilistic approach is needed to predict the pattern of SQL queries which can cause a potential throttle in performance. The queries which cause more use of working memory are mostly Join, aggregate queries, sorting queries (ORDER BY). On production systems, the frequency of rest queries like index creation or alter table is comparatively lesser. The worst-case scenarios could be all queries are fired with similar proportion. To deal with such cases, or to identify such randomness/query proportion, (to measure the probability distribution) entropy is

used. Entropy of a discreet variable $\mathcal{X}$ with possible outcomes $x_1, x_2, x_3, ..., x_n$ can be defined as:

$$H_n(\mathcal{X}) = -\sum_{i=1}^{n} p(x_i) log(p(x_i)) \quad (1)$$

where $p(x_i)$ is the probability of the i^{th} outcome of $\mathcal{X}$. With a more abstract approach, a generalized entropy can be defined as:

$$\eta(\mathcal{X}) = -\sum_{i=1}^{n} \frac{p(x_i) log(p(x_i))}{log(n)} \quad (2)$$

Value of $\eta(\mathcal{X})$ can range from 0 to 1 i.e. $\eta(\mathcal{X}) \in [0, 1]$. This helps in determining the threshold value of entropy, as for any number of classes the normalized entropy ranges between 0 and 1.

The queries are grouped into specific categories (grouping of obtained query templates), such as Join queries, Select queries, Alter-table queries, Update queries, etc and a hash table is built for each category. The classification of queries is done based on the trigger of throttle from knobs, for example - complex aggregation queries are grouped to one class which triggers throttles to working memory knob. Similarly, we create individual class for each given knob. From the generated logs, we create a hash table containing the class of queries and its frequency. Once the entropy value is evaluated, it can be inferred from multiple observations, that the entropy value is less when high randomness is present or all queries are fired with similar proportion (the query frequency from classes are evenly distributed). This, thus, indicates the SQL queries will, probably, again trigger a throttle (when underlying instance configuration is in-sufficient). However, if the entropy value is high, the degree of randomness is quite less or probability is quite evenly distributed. Thus, provided, if the query class, which is constrained by throttles, has less frequency, it can be concluded that in future, the throttles will not be triggered (as here the limits have not reached the caps and the underlying database depends on the tuner recommendation for knob optimization).

As part of the proposed flow, if more than 8 throttles are triggered consecutively, the entropy value is evaluated, and if the entropy value is higher along-with the memory-knobs reaching maximum cap value, the TDE triggers a plan update (increasing the hardware limits of instance) request to customer and recommendation requests are not sent to config director. Else, it is estimated that the throttles will soon reduce and the same job waits for next 8 throttles before calculating the next entropy value. The graphs shown in Fig. 3 and 4 shows the calculated entropy values while executing TPCC and an adulterated TPCC workload. The TPCC workload was adulterated with index creation, index drop, complex-joins, temp-table creation, order-by and aggregate queries.

In order to showcase the entropy variation, we loaded TPCC with a scale-factor of 18 (which loads around 21GB of data) to Postgresql. However the queries fired mostly hit the working memory and wal-memory knobs
(*sort_buffer_size* in MySQL). The amount of working memory used by TPCC as shown in Fig. 2 is around 0.5 MB, which is quite less to generate a throttle from memory based knobs. Hence now we add complex aggregation queries to TPCC (like queries having heavy sorts), which requires nearby 350 MB. Still we are able to trigger throttle for only working memory using TPCC. Now in order to design such a workload which triggers throttles from all defined classes/knobs, we started adding more queries and procedures, the following queries (analysing from production level performance bottlenecks faced earlier) were added to TPCC bucket:

- complex sorts/aggregation queries - To trigger throttle from Postgresql - *work_mem*, MySQL - *sort_buffer_size* and *join_buffer_size*
- create/delete indexes - To trigger throttle from Postgresql - *maintenance_work_mem*, MySQL - *key_buffer_size* and *sort_buffer_size*
- delete queries: To trigger throttle from Postgresql - *maintenance_work_mem*
- creating temporary tables and firing complex aggregation queries on it to trigger throttle from Postgresql - *temp_buffers* and MySQL - *temp_table_size*

Now the new queries are always added to the actual TPCC bucket based on probability as given in Fig. 3 and Fig. 4 (80% and 50%). With the adulterated TPCC workload, we were able to simulate throttles from all set of classes/knobs. The probably distribution with TPCC varies hugely with the probability distributions of adulterated TPCC due to absence of the new queries and results in entropy difference.

3.2 Background writer knobs

The background writer knobs control the writing of dirty pages from buffer, back to the disk. This write process is triggered by background writer processes or periodic checkpointing processes. However, if the checkpointing process is triggered too often and the amount of data written is high, then it leads to higher values in consumption of I/O throughput and disk latency resulting a decrease in throughput of the database. The other processes involved in writing dirty pages back to disk (background writer) helps in mitigating the same problem, with the aim to reduce the amount of data written by a checkpointing process. Usually the background process writes a fixed number of pages back to disk and the left pages are taken care by checkpointing process. In case of write heavy workloads, the background process writes fixed amount of data causing uncertain amount of data written by a checkpointing process. Given a discrete configuration for the set of knobs, for identifying throttles the following set of challenges needs to be overcome:

- To find out optimal value of checkpointing triggered per unit time. This parameter helps in understanding the overall period till which there can be a surge in disk latency, IO, etc.
- To find out optimal value of data written to disk with trigger of a checkpoint. This parameter helps in understanding the max surge the disk IO and latency parameters can go for write operations.
- There are various processes which write back to disk, for example - WAL writer, statistics writer, log writer, archiver, garbage collector, vacuum. This makes it difficult to figure out holistically the exact amount of data written by checkpointing process.

In order to figure out the exact amount of data written by a specific process requires use of user-level statically defined tracing probes (USDT probes). Where, any low-overhead tracing tool like ebpf or dtrace (Linux Foundation - IO Visor project) can use the probes to get information. The other option is to use kernel-probes (uprobes) for tracing, but this is also independent of the database process levels. Hence the safest way to get this data is to move writing of majority of processes to another

disk. In our experimentation, we changed the disk for storing of WAL, statistics, logs, etc. Now only background writer processes or checkpointing processes and vacuum/garbage-collector processes are responsible for writing on the current disk (where the production database files are located). This strategy also guarantees SLA for minimum IOPS for a disk which stores the actual database and at the same time increases cost of extra hardware and operations. Still the checkpointing process can be interpreted with the vacuum/garbage collector processes which is responsible for updating indexes for dead tuples and defragmenting pages on disk. The frequency of this process can easily be controlled and the left slots can be utilised for monitoring of checkpointing processes. During experimentations, we increased the frequency of vacuum/garbage collector to substantially a higher value and neglect the monitoring of checkpointing during the interval when vacuum/garbage collectors are triggered.

To predict/evaluate the values of optimal checkpointing and optimal amount of data written per checkpoint, the proposed approach uses the historic data of the workloads stored in the tuner's database or in short leverages the tuners experiences of tuning write oriented workloads. The workloads which are generated for tuner, are often pre-generated offline or it considers newer workloads as well (workloads from live database systems). The tuner service for recommending new knob values selects a target workload, and then uses the target workloads data to train the GPR. However, in all cases we monitor the disk latency from external monitoring agents such as Dynatrace. The throttling point for these knobs depends upon the disk latency as the performance degrades when the disk latency increases. In order to figure the optimal checkpoint per unit time with amount of data written to disk, the time difference between peaks in disk-latency is observed and averaged out for consecutive peaks. We define checkpointing per unit time based on the same observations. The checkpointing per unit time is calculated only for the highest observed throughout point in mapped workload.

Each database service in order to get the optimal parameters uses the best information seen/tried by tuner in past. Now, when a throttle is triggered, the tuner maps the current workload $'A'$ (workload representing a target underlying database service) to a target workload $'B'$ which had shown similar features in the past, with respect to the current workload. Now, for B, the timestamp value for the most optimal points observed (with respect to maximum throughput) are captured and passed on to the Dynatrace agent and the disk latency readings are collected. The points are the best recommended knob sets obtained using a trained GPR. From this data point, for the entire duration of workload execution on database, the checkpointing per unit time and respective disk latency is observed. Now on live/production systems, the checkpointing per unit time for A is calculated based on the baseline of disk-latency defined (obtained from tuner) earlier. If in $'A'$ the ratio of checkpointing per unit time and disk latency is more than the ratio of checkpointing per unit time and disk latency for B, then the throttle-detection scripts trigger a throttle signal. However, there could still be scenarios, when the workload A has very less data points (config values vs metrics) and for such a scenario, the mappings are initially incorrect for target workloads. Then for that scenario, the number of throttles could be either more or less, however, with each throttle signal that is triggered, the workload size increases and probability of getting mapped to an optimal workload increases. Thus, the proposed approach eventually improves in efficiency with passing time.

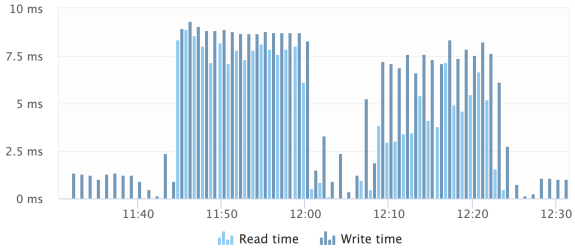

Figure 5: Disk Latency graph for TPCC execution.

The graph, as shown in Figure 5, represents the disk latency incurred when TPCC is executed on PostgreSQL with default knob config values and compared with when it is executed with optimal knob config values. The readings observed from 11:45 to 12:05, show the disk latency values for TPCC execution with default knob values and readings observed from 12:10 to 12:25, show the disk latency values for TPCC execution with optimal config values on PostgreSQL. Here, the TPCC execution on tuned PostgreSQL gives an average disk-write latency of around 6.5 ms and based on this the checkpointing per unit time is obtained. So, this becomes the base line for any workload on live systems which is mapped to the TPCC workload. Here, the major constraint is also that the underlying hardware (storage type as SSD or HDD) should be the same for all systems (databases used for training tuner and live systems).

3.3 Async/Planner estimate knobs

The async knobs are based on the ability of the database to parallelise the query execution, whereas the planner estimate knobs helps the query execution planner to estimate the best route. Most of the database recommends to statically set the planner estimate knobs (random page cost, effective cache size. etc) based on the underlying hardware capabilities. Still it is often seen that increasing/decreasing the values of such knobs (from the recommended values) improves the overall query execution. The async knobs are often defined by the number of parallel worker processes supported per relation by the database. During query execution, the parallel workers are taken from a pool of all defined workers. Often, it happens that the requested workers are not available or it could also happen that setting a higher value for these knobs affects the planner estimates. Thus, it always depends upon the nature of query and to what degree it can support parallel executions.

As this categories of knobs directly or indirectly impacts the planner estimates, it is often required to check the planners cost/benefit optimizations. The straight forward way to trigger a throttle would be to manually increase/decrease the knob values and check the overall cost/benefit optimizations. However, to automate this, the TDE needs to carefully take decision on whether to increase or decrease the value and by how much the value should be increased or decreased. Assuming at a given instance of time, for a given production workload, there exists an optimal values of this knobs. And the optimality does not depends on the underlying hardware (as per recommendations), making this a stochastic environment use case. Reinforcement learning is often seen as the best way for analysing the cost/benefit optimizations of query execution planner [8] [9] [10]. Hence, we model this problem as sequential decision problem and address it by using reinforcement learning.

Hence, we use a very basic Markov Decision Process (MDP) as a very basic RL model to solve the above sequential decision problem. In order tp minimise the uncertainty, the MDP starts with random set of actions and with course of time the action probabilities are adjusted, based on the response from the environment. The RL algorithm tries to optimize an agents returns when the episodes are restricted/limited. The RL engine captures all the queries in a time frame (typically a day or two based on the length of the workload). One episode comprises of atleast 350 to 400 steps (set of actions), where the knob values are changed as per policies (policies are random model initialization) and planner cost/benefit estimates are captured for all queries. The cost benefit estimates are then converted to rewards or penalties.

The TDE uses a MDP to trigger a throttle from this category of knobs. A MDP is represented by $\{Q, A, B, N, H\}$. For all given knob in this category, a MDP is given as follows:

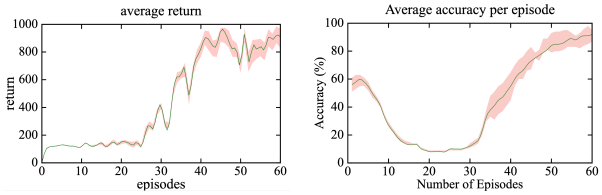
- Q is the finite set of internal states given by $Q = \{q_1, q_2, q_3, ..., q_n\}$, where q_n represents a specific knob value tried before or in current usage.
- $A = \{\alpha_1, \alpha 2, \alpha_3, ..., \alpha_n\}$ is the set of actions performed by the automata (increase/decrease the knob value) where each action has its own probability distribution.
- $B = \{\beta_1, \beta_2, \beta_3, ..., \beta_n\}$ is the response from the environment (cost/benefit calculated from query planner)
- N is a mapping function responsible to map current state and input to the next state and
- H is a mapping function responsible to current state and response to figure out the action to be performed.

The TDE triggers the MDP at interval of 2 to 4 minutes, where the MDP performs cost/benefit analysis by fetching all the queries from log, performing reservoir sampling as described above (in throttling detection for memory knobs). For a given knob value (represented by q_n), based on the action probability, the MDP increases/decreases the knob value by unit step (defined statically). Later the TDE calculates the loss/profit in execution time against the sampled queries with respect to the new knob value and old knob value. If there is a loss, which signifies the action is misleading and the MDP penalises the respective action (which adjusts the probability of the given action α_n) and vice-versa. However if a profit is seen with the change of the knob, the TDE triggers a throttle to get a recommendation from the tuner. The graphs in Fig. 6 presents the learning progress for a production workload as shown in Fig. 8. In the initial episodes, it is observed that the learning is less as the agent is suppose to do more and more exploration of knob configs. However, as the iterations continues, we observe more and more learning (as the episodic rewards increases). This draws a balance between exploration and exploitation.

One can argue that if with the course of time the MDP learns about the optimal/sub-optimal values of the knobs, is it really necessary to go and again ask the tuner to get recommendation. Yes, the tuner needs to be asked as the optimality changes with respect to change in workload pattern and secondly the tuners learning models predict best values for the given knobs by utilising the past seen experiences from set of other production systems.

4 APPLYING RECOMMENDATIONS

The potential challenges in this job could be designing the overall orchestration mechanism for applying these configs, considering the prevalent architecture of the database system like multi-node,



(a) Learning progress of proposed policy (b) Average accuracy of learning process

Figure 6: Measuring Reinforcement Learning accuracy on production workload

high-availability constraints, etc. The configs need to be persisted too such that a database reset or re-deployment doesn't overwrite the settings. Additionally, concerns like how to apply the recommendations without causing a downtime of the running database system, must also be addressed.

Generic Approach. An orchestration approach had to be formulated in-order to apply the recommendations, taking into consideration the above-mentioned challenges. As per the architecture explained in Figure 1, the service-orchestrator is responsible for spawning of database system instances for a customer. The config of the spawned database system is generated and applied initially to the database, by the service-orchestrator. If for any reason (like updating the system, applying security patch, etc.), the database system needs a re-deployment, then the service-orchestrator must re-deploy the system with the updated config of the database.

As per the architecture, the Data Federation Agent (DFA) hits API endpoints of TDE to apply the config recommendations. In case of multiple nodes maintaining high availability, the recommendations are first applied to the Slave node(s). If the process crashes in the Slave node, the config recommendations are rejected. Thus, it is ensured that the Master node is up and the process is still able to serve requests. After the config recommendations are applied to the Master node, the recommendations are stored in the persistence storage used by the service-orchestrator. Thus, whenever the service-orchestrator re-deploys the database system in the future, it retrieves the updated config from the persistence storage. An additional concern here could be the failure in one of the intermediate steps. Since, all of the operations are not atomic, but eventually are expected to yield consistent data (i.e., configs must be same for all master/slave nodes and persistence storage used by service-orchestrator), a reconciler process is defined. The reconciler keeps a watch on config of the database system running on the Master node. If the difference in config is observed for a threshold time-period (watcher timeout), the reconciliation occurs and the config stored in the persistence storage is applied to all nodes. Thus, this eventually leads to rejection of the config recommendation due to error in the intermediate process.

For changing the knobs values, one of the efficient methods is to use Socket Activation (using sockets via *systemd*). This also makes possible to restart the DB since the socket is up and keeps on accepting the incoming requests. However this method only caches the requests but causes a lot of jitter and performance degradation. Another method is to use linux reload signals, upon evaluating this method, we observe very minimal jitter in the performance of the database. A comparative analysis has been

presented in graphs in Figure 7 where the performance of the database is observed under identical load conditions.

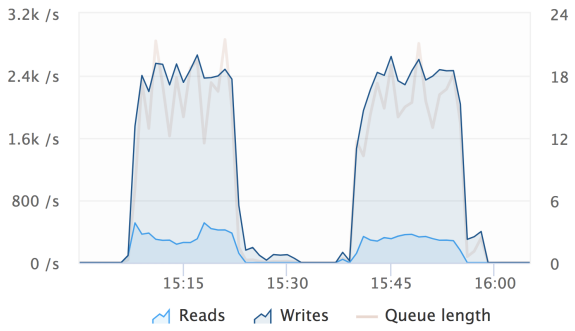


Figure 7: IOPS graph for TPCC execution.

The graphs shown in Figure 7, the TPCC workload is executed with tuned MySQL. Readings during 15:08 to 15:23, shows the TPCC execution without triggering any config reload signals, where as readings between 15:38 to 15:54, shows the TPCC execution which was accompanied by a config signal reload with a frequency of 20 seconds (even with this high frequency of reloads, the performance is not compromised).

Applying Non-tunable Knobs. 'Non-tunable knobs' has been used as a term to categorise such knobs that cannot be applied/tuned without causing a restart of the database process. Since, the restart of database can only be performed during scheduled downtime window (a pre-announced time-period where a re-deployment of database occurs), an approach had to defined for the tuning of such knobs. The design of the approach can be considered for memory-related knobs (as non-tunable knobs are majorly memory knobs). For a non-tunable memory related knob, like buffer-pool's size, the optimum value of this parameter can be obtained from the working set [5]. Once this optimum value is determined, the database system is initially set up with the same value. However, there could be other memory-related knobs that are dependent on such a non-tunable knob. The value of all such knobs must be within the total memory allocated to the database process. Let us consider the following equation. $A + B + C + D < X$ Here, A could be assumed to be a non-tunable knob like $buffer\_cache$ size. B, C, D could be other tunable memory knobs like $work\_mem$, $maintenance\_work\_mem$ and $temp\_buffers$, where X is the total memory allocated to DB process.

There is always an upper limit on buffer-pool knob out of the total memory pool. This knob is changed only during the scheduled downtimes. During the downtime, if the total working page set size is greater than the maximum limit, then we find out the 99^{th} percentile of this knob obtained during all last recommendations before the last scheduled downtime. If the new averaged value is lesser than the current value accompanied by at-least one entropy hit, then this knob value is reduced. The entropy hit indicates that the other tunable knobs have already raised many throttles and now it is mandatory to create more room for tunable knobs by reducing the buffer knob value.

Now when the memory for buffer value is reduced with respect to the current knob value, it increases more room for other memory related tunable knobs. So if the cost on throughput for tunable knobs is more, tuning services rotates around nearly same values for buffer knob, else in the next iteration it increases the value of buffer knob (average value of buffer knob obtained till last last scheduled downtime encountered.)

5 PERFORMANCE EVALUATION

The experiments were conducted on AWS instances, where cloud resources is provisioned by cloud-foundry managed by Bosh. The tuner deployment consists of 12 tuner instances with Ottertune and CDBTune (we do not go for QTune due to unavailability of its codebased in opensource) - m4.xlarge with 4vCPU and 16GB memory, 5 config-director instances - m4.xlarge. We connected a total of 80 live-database deployments (spawned through t2.small, t2.medium, m4.large, t2.large and m4.xlarge VM types) to the tuning. For evaluating the experiments, we used PostgreSQL (v9.6) and MySQL (v5.6). All the tuner instances collected data from one common data-repository (m4.xlarge VM plan) which is shared by all tuner instances. The bare-service-replicas were created: one for each plan and were used to test the recommendations obtained. A real-time customer workload (activity for 33 days) is captured for the purpose of some of the below experiments. The SQL workload has 132 tables, 42.13M queries per day (average), 71K Select queries, 41M Insert queries, 34K Update queries and 0.8K Delete queries with a DB size of 59GB. The query arrival rate is shown in Fig. 8

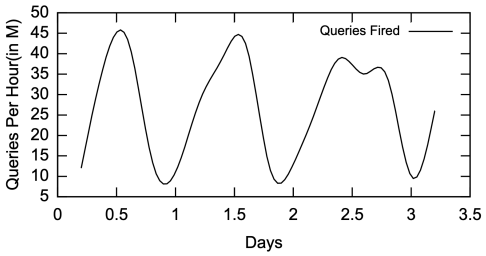

Figure 8: Production workload query arrival rate

Before evaluating the AutoDBaaS on live systems, we perform training of the tuners as per their standard ways [4] [18]. The first experiment we design is to measure the tuning requests per second on production landscape where both ottertune and CDBTune is being used for tuning. Figure 9 showcases one such outcome to illustrate the impact on scalability challenges of a BO style tuner. When comparing scalability of BO vs RL style tuners, a RL style tuner generates new configs very fast (but sometimes takes a long time to come around a good configuration). As per the BO approach, generating a new configuration takes around 200 seconds (which is assumed to be a good configuration). Both the RL or BO style tuners follow periodic approach (with a periodic length of nearly 5 to 10 minutes). In this case we bring in TDE which breaks down the periodic tuning approach. We measure the requests per second for live databases on production landscape where we compare requests per seconds generated when TDE checks in, periodic approach with a period of 5 min and periodic approach with a period of 10 mins. In both the cases it seems like the TDE approach gives a reduction and comes to peak when the workload pattern changes a lot like say morning 8AM to 11AM (when most of the microservice usages surge). The tuning requests per seconds when TDE checks in also directly gets impacted by the efficiency of tuner being used. If the tuner generates good configuration, in the next upcoming iterations, there are pretty less chances of a throttle getting detected.

As the proposed work largely reduces the tuning requests per minute, this evidence seems to directly impact the scalability of the tuning services and specifically the BO style tuners.

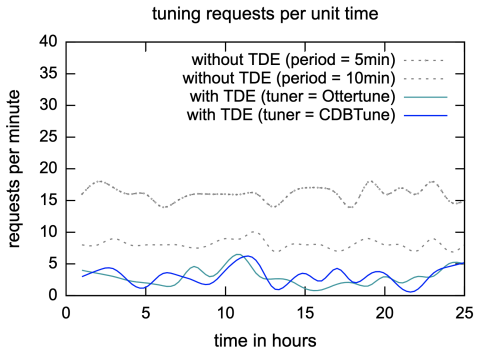

Figure 9: Requests per minute graph for 80 live connected databases

Next we measure the performance throttles due to incorrect knobs for some standard and production workloads. The parameters for the standard workloads was for (1) tpcc, 3300 requests per second with 26 GB of database size, (2) wikipedia, 1000 requests per second with 12 GB of database size (3) twitter, 10000 requests per second with 22 GB of database size and (4) ycsb, 5000 requests per second with a database size of 20 GB. We used oltpbench to do the benchmarking on postgresql (Fig. 10) and mysql (Fig. 11) on m4-large instances. In order to purely measure the performance throttles, we do not go for a tuning session. These throttles presents averaged score for nearly 20 to 25 iterations. However, for production systems (as described above), we do not run iterations, rather they are actually captured from live systems directly for the workload described above and measured at different timestamps. We observe that for both postgresql and mysql, the write heavy workloads raise more throttles for background writter knobs, read-heavy/mix workloads raise more throttles for memory and async/planner knobs and for production workload it seem like a mix of ratios.

The next crucial metric for evaluation is Performance. There could be two metrics for measuring the performance of the proposed approach: (i) the throughput of the database system and (ii) the number of throttles encountered by the database system.

In Fig. 12, we measure the average throughput on live database using (1) Ottertune and (2) Ottertune with TDE (i.e. Ottertune only captures high quality samples from TDE). Ottertune uses samples from both production-workloads and offline-workloads (like executing tpcc offline) to train GPR. As per the tuning pipeline of Ottertune, it bootstraps with offline-workloads and starts tuning live systems. It separately captures each experiences from each workload (i.e. eiter live or offline). There is no chances of training model corruption with offline workloads as samples from offline workloads are captured are always of high quality (i.e. there is no such point when a offline workload does not requires a tuning). So when new batches of production system are hooked with the same ottertune instances, ottertune's throughput is roughly the same as compared with Ottertune + TDE as initially Ottertune uses offline samples (i.e. samples taken from offline workloads) to train GPR. However, the samples captured from the first batch of productions systems causes corruption to GPR (with high probability). Hence, when such samples are

Experimental Setup			
Variable used in Fig. 14	workload	Metrics window length	knobs class
#1	YCSB to TPCC	5 min	background writter, async/planner
#2	TPCC to YCSB	5 min	memory, async/planner
#3	YCSB to Wiki	7 min	async/planner
#4	Wiki to YCSB	5 min	NA
#5	TPCC to twitter	6 min	memory, async/planner
#6	Twitter to TPCC	5 min	background writter

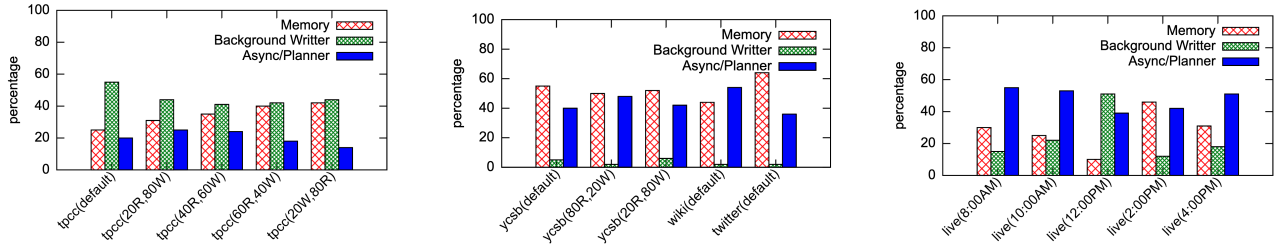
Table 1: Experimental parameters and values

utilized to tune other set of production systems, the accuracy of GPR recommendations is extremely low. Hence, in Fig. 12 we hook in the 40^{th} database instance and measure the throughput. As shown in the graphs the proposed approach seems to perform well and the main reason for that is there is no possible learning corruption in learning. For the workload executing in this database, we observed that Ottertune mapped the workload (with high mapping scores) to nearly 14 different workloads (to leverage tuning experiences) where only 4 of them were offline workloads. Similarly, we measure the same set of throughput when CDBTune is used as tuner. Here as CDBTune does not so much utilizes past learning experiences or atleast the way Ottertune does it. CDBTune minimally utilizes offline training but for sure does not uses learning from other production tuning experiences. Therefore in the case of CDBTune, this problem happens directly from the first hooked/subscribed database. The graph shown in Fig. 13 presents the throughput measured on the first database connected to CDBTune.

We also measure the effectiveness of performance throttling with changing of workload pattern by execution of standard workloads. The graph shown in Fig. 14 presents the same. This experiment is designed to measure how throttling detection helps to quickly capture workload change. In this experiment, we loaded 22GB of TPCC data, 24GB of TPCH data, 18.34 GB of YCSB data, 16 GB of twitter data and 20.2GB of wikipedia data on a m4-xlarge instance of postgresql. And we measure the throttles detected upon change of queries (i.e. from one workload to another). We present the details of experiment done here in the below table 1:

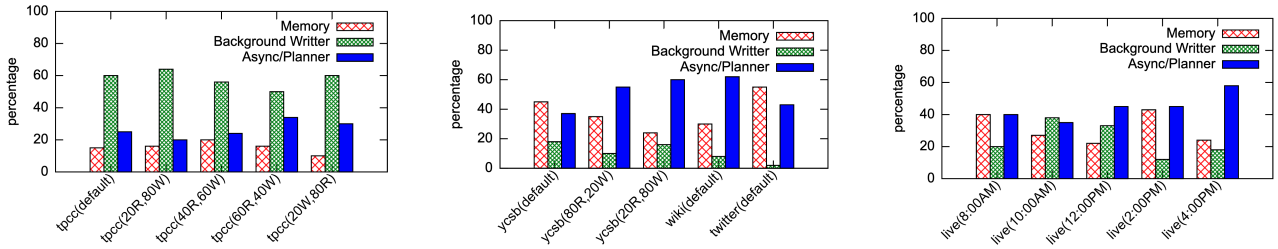
In this experiment we also observe and present the class of throttles. The tuner has a direct impact on the total number of throttles. This is because a single throttle triggers a tuning request and tuner recommends back a good configuration. Hence, in case of a very idealistic tuner the underlying database should not trigger more than one throttle as the idealistic tuner is expected to get the best config which would cause no throttles in the next iteration.

Lastly we tried measuring the accuracy of the throttling detection engine for all the classes of knobs what we presented. To evaluate the accuracy of throttles raised, either we could have used the human knowledge, where an administrator would have verified each throttles manually. But, this approach could have been time-consuming and could might result with a biased decision of the administrator. So another way to evaluate the throttles was to use the tuning of an already trained tuner. We trained Ottertune with offline workloads like TPCC, YCSB, Wikipedia and Twitter and then observed the throttles classes and configurations generated by Ottertune. If Ottertune recommends a majority of knob (say out of top 5 ranked knobs) whose class is



(a) write-heavy workload (b) mix/read-heavy workload (c) production workload

Figure 10: Performance Throttles detected on postgresql for varied set of workloads



(a) write-heavy workload (b) mix/read-heavy workload (c) production workload

Figure 11: Performance Throttles detected on mysql for varied set of workloads

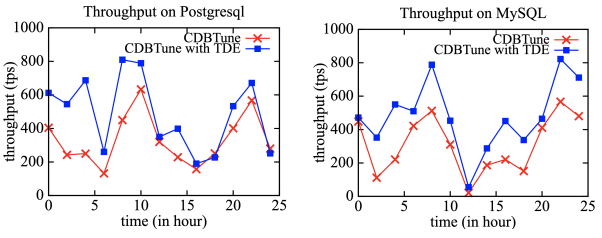
Figure 12: Throughput graph for live production database with Ottertune



(a) Average throughput per hour on Postgresql (b) Average throughput per hour on MySQL

Figure 13: Throughput graph for live production database with CDBTune

same as the class of throttle, then the throttle was accurate else we consider the throttle to be not accurate. This is specifically tested on the same workload with which Ottertune was trained i.e. TPCC, YCSB, Wikipedia and Twitter (as for the same trained

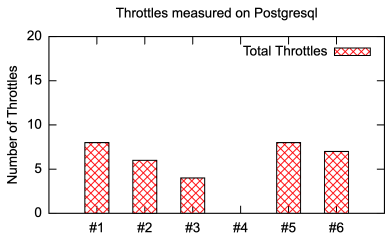


Figure 14: Throttles captured when tuner is Ottertune

data accuracy would be very high). Ottertune recommendations sometimes perform exploration for the Gaussian Models better training. We minimize this exploration by setting appropriate hyper parameters manually. With this settings, Ottertune's recommendation should least explore and only aim to maximize the throughput. We loaded similar amount of data on a Postgresql m4-xlarge instance as done in the previous experiment. The graph shown in Fig. 15 presents the same. We observed high accuracy for memory and background writter knobs and a lower accuracy for planner/async knobs. However, we are confident more for planner/async knobs as the throttle points clearly shows improvement as per cost-benefit analysis of planner estimates. However, we observed ottertune fails to understand such throttles mainly because of absence of planner estimates in the metric set that it captures for postgresql.

6 RELATED WORK

Facebook introduced Pressure Stall Information (PSI) [11] for evaluation and control of computational resources across large data centers. It is one of the first canonical ways of measuring resource pressure increase as it develops based on pressure metrics such as memory, CPU and I/O using *cgroup2* and *oomd*. There

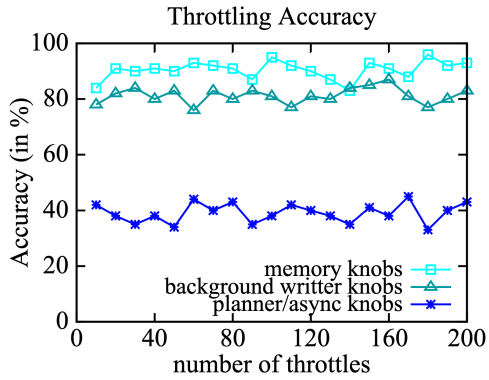

Figure 15: Accuracy of performance throttles on Postgresql

are many methods which exists in literature which try to capture similar pressure on computational resources. However in case of databases these approach seems to be in-efficient in figuring out pressure on individual database knobs. This is also because of the reasons that database knobs are mostly indirectly-non-linearly dependent on the computational resources.

Oracle came up with a database internal monitoring mechanisms [14] and [15] to identify the bottlenecks in performance due to misconfigurations in internal components or knobs. Here, authors propose 'database time' of query as a parameter to figure out performance bottlenecks. Later this information is given to DBA's for tuning of knobs. The system uses heuristics from performance measurements for tuning of memory knobs and however does not tunes all set of knobs.

In literature, there are many knob tuning approaches [12] and [13], which are either specific to specific databases or tune only a subset of knobs. Other PaaS providers like AWS RDS service, gives freedom to consumers to tune it based on the workload. The architecture of Ottertune seems to meet the requirements of PaaS tuning offerings to customers, based on its capabilities to tune multiple databases by leveraging the workloads seen by tuner in the past. Oracle came up with autonomous database, a similarly solution came from Microsoft, however the approaches does not tune more than one database (unable to leverage experience gained by another system) and is only coupled to tune one database at a time (and thus increasing cost of tuning).

Also there exists multiple works that have focused on tuning database knobs. However, there exists two main classes: (1) Search based methods like BestConfig [16] and (2) Learning based methods which includes BO style learning or RL style. We do not consider Search based methods for tuning production systems as it expects the user to execute the workload on staging landscapes and tries tuning it. However, it cannot tune live systems as it takes huge amount of time to get to a good configuration. This is because for every tuning from scratch they again start the searching process from scratch. This work mainly focuses to solve specific problems of learning based methods like Ottertune and CDBTune.

7 CONCLUSION

We presented a generic tuning architecture for tuning services to be provisioned by any PaaS model. In this work, we bring in the challenges and drive them to make the AutoDBaaS more robust for production environments. To take up all the challenges, this work presented (1) methods to monitor database and detect performance throttling, which helps the database to trigger recommendation requests only when potentially required and calculating the monitoring/observation time, (2) methods for applying and validating the obtained recommendations on production systems. Lastly we evaluate the proposed architecture on cloud-foundry managed by Bosh running on AWS. With our approach of detecting performance throttling, we were able to achieve better scalability. On Production systems, due to varying load - throughput, we measure the performance of tuning recommendations in terms of performance throttles hit on production systems. As the existing learning based method needs high quality samples from production system, proposed throttling detection engine enables it to do so. Hence, in this work we also achieve better throughput as throttling detection approach reduces corruption of learning methods.

In the coming future, we would like to explore more on using reinforcement learning methods to capture the performance throttles and making the current TDE free from static rules.

ABSTRACT

In this paper, we provide an in-depth study of the performance of spatio-temporal queries in document-oriented NoSQL stores. Existing NoSQL stores provide limited support for spatial data and (quite often) no native support for spatio-temporal data. As a result, the performance of query execution over large collections of spatio-temporal data is often suboptimal. We present an approach for indexing spatio-temporal data, which is applicable to *any* NoSQL store that provides key-based access to data *without modifications to its code*, and we show how to generate data partitions that preserve data locality. Moreover, we show the impact of indexing and partitioning on the number of cluster nodes that serve a query, and we discuss the advantages and disadvantages for different applications. We adopt a methodology for the evaluation of spatio-temporal range queries, which can serve as a benchmark. In our experiments, we focus on MongoDB (as a representative NoSQL store that provides spatial support) and we study the impact of indexing spatio-temporal data on performance, using both real-life and synthetic data sets in a medium-sized cluster.

1 INTRODUCTION

Big spatio-temporal data sets are collected every day at unprecedented rates [15, 17], due to emergent applications, such as fleet management solutions, surveillance systems in maritime and aviation, human and animal tracking, IoT sensor feeds, location-based web search, and social networks with geotagged content. These applications generate huge volumes of positional information represented as points, which require scalable storage and retrieval, so that data analysis techniques can be applied to discover hidden spatio-temporal patterns. As a result, scalable spatio-temporal data management is a challenging research topic, and efficient solutions are required for storage, indexing and querying.

NoSQL stores [4, 7] comprise the state-of-the-art in scalable storage to date. However, while support for spatial data is provided recently by an increasing number of NoSQL stores, this is seldom the case for spatio-temporal data. In fact, even spatial data access methods are not always optimized in today's mainstream NoSQL stores. While most relational DBMSs have adopted R-trees [11] (or its variants [2, 16]) for efficient spatial indexing, NoSQL stores with spatial support adopt GeoHashes to map spatial data to one-dimensional (1D) values, which is then indexed using traditional 1D indexes, such as B-trees [6] (see Table 1). Our conjecture is that this decision relates to the cost of building and maintaining a distributed R-tree. Consequently, the performance of existing solutions is suboptimal, when faced with the challenge of efficient and scalable retrieval of spatio-temporal data.

	Database	Spatial Indexing
RDBMS	PostgreSQL (PostGIS extension)	R-Tree
	MySQL	R-tree
	Oracle	R-tree
	MariaDB	R-tree
	SQL Server	B-tree
	SQLite (SpatiaLite extension)	B-tree
NoSQL	MongoDB	B-tree
	Redis (Geo API)	Sorted Set
	DynamoDB	B-tree
	Elasticsearch	BKD-tree
	Neo4J	B+Tree

Table 1: Spatial support in most popular relational and NoSQL data stores

Our work is motivated by real-life applications, revolving around fleet management operators in the urban domain, which collect large volumes of positional data from GPS-equipped vehicles daily. The specific use-cases that are supported by our work relate to exploratory analysis of historical routes, using multiple spatio-temporal queries of varying granularity. The retrieved trajectories are analyzed for fleet cost reduction (by analyzing the fuel consumption of historical routes), intelligent routing, as well as for discovering movement patterns. The challenge is to provide a scalable storage and spatio-temporal querying solution for large volumes of historical mobility data. Unfortunately, existing industrial solutions are not optimized for spatio-temporal querying at scale, thus fleet management operators apply data analysis techniques only on recent subsets of their historical database, while older data is kept in cold storage.

Motivated by these limitations, in this application paper, we provide an in-depth study of querying spatio-temporal data at scale, focusing on a document-oriented NoSQL store, namely MongoDB. The choice of MongoDB is justified due to its wide popularity among big data developers, and its maturity compared to other competitive technologies. We explain the internal details of indexing and sharding, focusing on how spatial data is supported, and eventually design a solution for spatio-temporal data using the built-in indexes of MongoDB. Then, we propose an alternative approach that uses the Hilbert space-filling curve (which has been shown to have nice clustering properties [14]) to generate one-dimensional (1D) keys, which facilitates indexing of spatio-temporal data, and allows to preserve data locality in the nodes of the MongoDB cluster. Moreover, this approach can be implemented *on top of* MongoDB (and other key-based NoSQL stores), thus being directly applicable for any application.

In particular, our approach has an effect on sharding, essentially creating spatio-temporal data partitions that preserve data locality. As we demonstrate in our empirical evaluation, this has a profound impact on performance.

Our contributions can be summarized as follows:

- We propose an approach for efficient storage and querying of spatio-temporal data based on Hilbert encoding, which can be applied to any NoSQL store that supports key-based access to data.
- We show that our approach achieves spatio-temporal data locality across the distributed data partitions, and we discuss the advantages and disadvantages for different applications.
- We present a methodology for evaluating the impact of spatio-temporal access to data at scale, which can also serve as a benchmark for spatio-temporal queries in NoSQL stores.
- We perform extensive experiments over a MongoDB installation on a public cloud, and we study the effect of different metrics (such as keys and documents accessed, nodes involved in query execution) on execution time using both real and synthetic data.

The remainder of this paper is structured as follows: In Section 2, we review related research efforts. Then, in Section 3, we present the internal mechanisms of MongoDB for indexing and handling spatial data. Section 4 outlines our approach for indexing spatio-temporal data. Section 5 presents the results of our empirical evaluation, and Section 6 concludes the paper.

2 RELATED WORK

Spatial data indexing is a long-studied topic, with R-tree [11] and its variants [2, 3, 16] being a prominent data structure in centralized databases. Even though approaches for distributed R-trees have been proposed [8], they have not been adopted by today's NoSQL stores, probably due to the high maintenance cost in distributed settings and due to the gradually diminishing performance after many inserts/updates.

2.1 One-dimensional Indexing of Spatial Data

Space-filling curves have extensively been used in spatial databases in order to map high-dimensional data to one-dimensional values, which can be indexed using standard data structures, such as the B-tree. Although many variants exist, notable examples include the z-order and the Hilbert curve (depicted in Fig. 1). In the context of data management and indexing, the objective of all space-filling curves is to preserve data locality in the one-dimensional space, so that spatial range queries can be transformed to one-dimensional intervals of small length, in order to reduce the number of false positives.

Even though the idea of GeoHashes was first proposed by G.Niemeyer in 2008, it bears similarities with space-filling curves (in particular with z-order), which have been known for decades. MongoDB uses GeoHashes to store spatial data efficiently. The idea of GeoHashing is to use a hierarchical subdivision of the 2D spatial domain, which uses multiple layers, with each layer divided in a set of cells (or buckets). At the top layer, four buckets exist which are derived by splitting each dimension in the middle. Then, each bucket at the top layer can be represented by 2 bits: 00, 01, 10, and 11. The hierarchical subdivision is performed recursively, so at the next layer sixteen buckets exist and four bits are used to address a bucket. As a result, any 2D spatial point

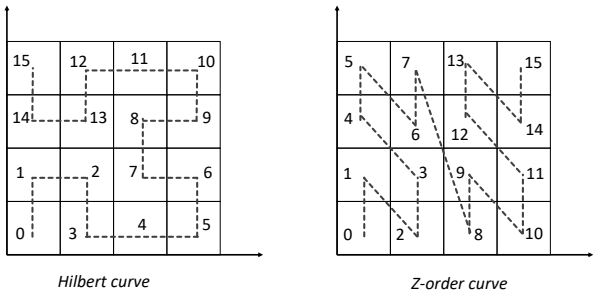

Figure 1: Illustration of the Hilbert and z-order space filling curves

is assigned into a lower-level bucket uniquely, and the bit representation of the bucket can be used as an indication about the location of the point in the 2D space. The more layers, the higher the precision of the respective location. Finally, GeoHashes use a *base32* String representation, instead of a bit representation, which uses a 32-character set comprising the twenty-six letters a–z, and the digits 2–7. As an example, Athens (Greece) has coordinates (37.983810, 23.727539) which is represented as a GeoHash of "swbb5ftzes" for precision of 10 characters. If we used lower precision, the corresponding prefix would be obtained. For instance, the GeoHash of Athens for precision of 5 characters is "swbb5".

2.2 Spatial and Spatio-temporal Queries in MongoDB

NoSQL systems are widely used by modern applications for scalability and high performance. For a recent survey on NoSQL stores, we refer to [7] and also to the early work of Cattell [4].

There exists some work on studying the performance of built-in mechanisms for spatial query support in MongoDB. Duan and Chen [9] compare MongoDB against ArcGIS, in order to assess the performance of the spatial extension of MongoDB against a well-established GIS. More recently, Bartoszewski et al. [1] compare MongoDB against PostGIS for spatial data. However, both studies evaluate the systems on a single machine, which is a limitation because it hides the impact of distributed storage on query execution.

In [13], an experimental evaluation of MongoDB against PostgreSQL is performed for spatio-temporal data. This is one of the few studies that try to evaluate MongoDB's capability in terms of querying spatio-temporal data. However, their study has some limitations, most notably the lack of data partitioning in evaluation. Instead, a small cluster is used and all machines contain replicas of the data set. In contrast, our work provides an in-depth investigation of different aspects of spatio-temporal data management, including indexing, data partitioning and load balancing, in a much larger deployment of MongoDB in a sharded cluster.

ST-Hash [10] follows an approach for spatio-temporal indexing on top of MongoDB. The main idea is to extend GeoHashes in a way that time is also incorporated in a string representation of a one-dimensional value. This value can be decomposed to obtain the corresponding spatial and temporal information. Hence, a one-dimensional index is built on this string value, in order to support efficient point and range searches. However, the resulting encoding uses the year as a prefix, which is not

effective for certain query types. For example, queries with high spatial selectivity but low temporal selectivity cannot exploit the encoding, in order to efficiently identify which data blocks need to be accessed.

SIFT [12] is an implementation of a distributed spatial index upon MongoDB. The study focuses on the ingestion, indexing and querying of highly-skewed spatial data. The basic data structure of SIFT is based on a tree where the spatial objects are represented by their minimal bounding boxes. The tree structure follows an approach so as to avoid any rebalancing, splitting and merging operations when spatial objects are inserted to the index. Nonetheless, the index is limited only to spatial queries.

3 BACKGROUND ON MONGODB

MongoDB [5] is a popular document-oriented NoSQL store that stores data in the form of *documents* in *collections*. *Documents* are binary JSON objects (BSON) that consist of a set of fields with associated values. Values can be simple or complex, e.g., an array or even a nested document. Each document is typically associated with a key that uniquely identifies it. *Collections* are containers for conceptually similar documents, however no restrictions are imposed to the schema of each document. In MongoDB, collections are stored in *databases* which are namespaces for physical grouping of collections.

3.1 Indexing in MongoDB

The main indexing structure used in MongoDB is the B-tree [6], which supports both point and range queries. Apart from *single field* indexes, which index documents based on a single field, a *compound* index can be used to combine multiple fields (up to 32 fields), thus supporting queries with predicates on multiple fields.

Compound indexes are organized hierarchically based on the *declared order* of the *index keys*. In the case of two fields A and B, the compound index first organizes the sorted values of A in buckets, and then these buckets keep references to buckets that hold the sorted values of B. An example is depicted in Fig. 2, where A=`hotelName` and B=`price`, denoted as `{hotelName:1, price:1}` in MongoDB. This indexing scheme has some important consequences on performance. First, only queries with a predicate on A can benefit from this index, since the value of the predicate is necessary to start the traversal of the index and locate buckets with relevant keys efficiently. Second, it is beneficial to use as first index key a field that has many distinct values, in order to effectively narrow down a search to few buckets only. As a result, the order of index keys in a compound index determines the performance of searches.

MongoDB holds by default a field for each document, called `_id`. The field represents the identifier of a document and is unique, acting as a primary key. The default type of its value is *ObjectId* with 12 bytes. Its length consists of 4-byte timestamp value based on ObjectId's generation, a 5-byte random value and a 3-byte incrementing counter which is initialized to a random value. For the `_id` field, MongoDB maintains a single-field index which cannot be dropped.

3.2 Indexing Spatial and Spatio-temporal Data

Two variants of spatial indexes are supported in MongoDB; a *2d* index, which manages data on a two-dimensional plane, and a *2dsphere*, which calculates geometries on the surface of the earth.

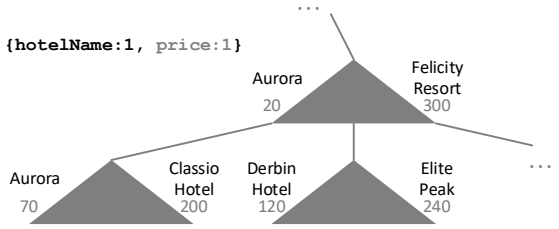

Figure 2: Example of a compound index on fields `hotelName` (string) and `price` (integer). The documents are organized based on `hotelName` and then based on `price`.

Both of them are applied on fields whose values hold spatial data. The values must be either *GeoJSON* objects or *legacy coordinate pairs* which is a representation of the longitude and latitude values either with the usage of two-sized array or by embedding the elements in a document. The spatial indexing mechanism in MongoDB is based on GeoHash[1], where a hierarchical subdivision of the 2D spatial domain using multiple layers takes place. The cells that result from the division of the space are represented by bits. The more bits that represent a space, the higher the precision of the respective location. The GeoHash values that are stored in the index consist of 26 bits by default. They can be set up to 32 bits, performing better for spatial queries, but at the expense of occupying more space in memory. A spatial index can be combined with another field by means of the compound index.

Unfortunately, indexing spatio-temporal data is not directly supported in MongoDB. As a result, our premise would be to build a compound index over the fields storing the spatial information and the temporal information respectively.

3.3 Sharding

Sharding refers to data partitioning and assigning the obtained partitions to MongoDB servers, also called *shards*. Specifically, when sharding a MongoDB collection, its documents are distributed across shards based on a *shard key*. When defining a shard key, MongoDB separates the range of shard key values into smaller non-overlapping ranges with continuous keys. Each of these ranges are associated with a *chunk* and contain a subset of the sharded collection. Also, a chunk has a configurable size which is 64MB by default, and if exceeded, it is split.

The configuration of small-sized chunks leads to a more even distribution of data. However, migrations become more frequent, adding overhead to the network and to the query routing layer (known as *mongos*). Large-sized chunks enforce fewer migrations at the expense of a less even distribution of data. MongoDB achieves load balancing through the (re-)distribution of chunks among shards. The *Balancer* runs in the background so as to migrate chunks across the shards, targeting to achieve an even distribution of chunks in the cluster.

Apart from the definition of the shard key, the sharding operation of a collection requires the strategy type which can be either *range* or *hashed*. With *range sharding*, it is highly probable that documents with similar shard keys will be in the same chunk or shard, as depicted in the example in Fig. 3. This enables

[1] https://docs.mongodb.com/manual/core/geospatial-indexes/

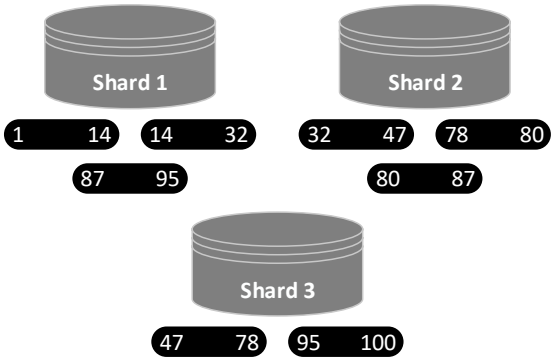

Figure 3: Instance of chunks' distribution that result from a range sharded collection, on a field that contains values from 1 to 99.

routing range queries to specific shards only. On the other hand, in *hashed sharding*, chunks or shards are unlikely to contain documents with similar shard key values. This may serve well for cases where broadcast operations are preferable.

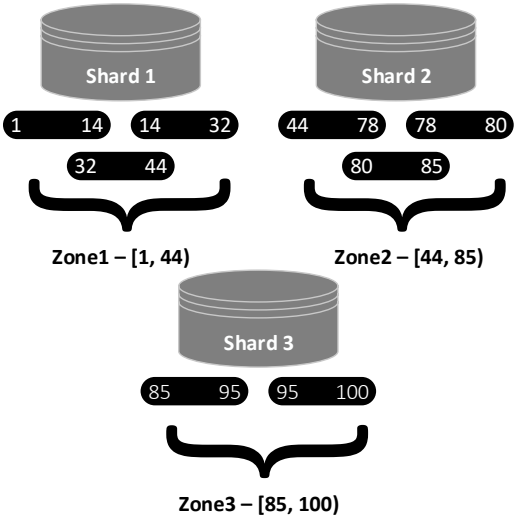

Figure 4: Instance of chunks' distribution that result from the definition and assignments of zones: $[1, 44)$**,** $[44, 85)$**, and** $[85, 100)$ **on the shard key.**

Sharding imposes the creation of a single or a compound index on each shard, based on the field/s of the shard key. MongoDB supports manual grouping of documents based on ranges of shard key values through the concept of *zones*. A zone can be associated with any shard. Similar to chunks, zones have lower inclusive and upper exclusive boundaries and their covering ranges do not overlap. By associating a zone with a shard or shards in an already sharded collection, the cluster migrates the affected data to the respective zones, if a collection is already sharded. Division of chunks may occur so as to follow the data distribution scheme determined from zone(s). If zones are set up before sharding a collection, chunks are created for the defined zone ranges (and additional chunks if necessary) to cover the entire range of the shard key values. Fig. 4 shows an instance of storing the data using zones. In the figure, each shard is assigned with one zone, thus shards maintain more contiguous key ranges.

4 INDEXING AND PARTITIONING SPATIO-TEMPORAL DATA

In this section, we present two alternative approaches for indexing spatio-temporal data, with different implications on partitioning and eventually on the performance of query execution. Our work focuses on point data, which covers many life real-applications, and we leave other data types (such as polylines and polygons) for future work. The first approach relies on the built-in features of the spatial extension of MongoDB for indexing and time-based sharding, therefore we consider it as a baseline solution. Then, we propose an alternative approach that adopts the Hilbert curve to map data to 1D values that will be stored and indexed as a single field, also enabling sharding based on spatio-temporal criteria.

4.1 Baseline Solution

4.1.1 Indexing. The baseline solution for efficient querying of spatio-temporal data stored in MongoDB is via the usage of a *compound* index that is built on the spatial and temporal fields of the documents. Consider the following document structure:

```
{
    "_id": 1,
    "location": {
        "type": Point,
        "coordinates": [37.983810, 23.727539]
    },
    "date": ISODate("2018-10-01T08:34:40.067Z"),
    ...
}
```

The spatial field (`location`) is supported by the built-in *2dSphere* index, and is combined under the *Compound* index with the `date` field. As a result, two possible solutions for spatio-temporal indexing can be designed by exploiting directly the built-in features of MongoDB, which differ on the order of fields: (`{location, date}` and `{date, location}`). The former approach favors the spatial dimension and organizes the buckets of the temporal dimension under the ranges encoded by GeoHash values. The latter approach favors the temporal dimension and organizes the buckets of the encoded GeoHash values under the ranges of the temporal values. As a result, the first approach works well for queries with high selectivity in the spatial dimension, whereas the second approach is more suitable for queries with high selectivity in the temporal dimension.

4.1.2 Sharding. In order to adapt the baseline solution to a distributed environment, a sharding key needs to be defined. We opt for setting as shard key the `date` field. In this way, the spatio-temporal queries are expected to access only specific shards based on the temporal constraint, thus avoiding broadcasting, i.e., routing the query to all shards. In MongoDB, broadcast operations occur if a query's field constraints are not found in the shard key[2]. It should be mentioned that the spatial field cannot participate in the definition of the shard key, since the current version (4.4) of MongoDB does not support a 2dsphere indexed field to be a shard key or part of it.

[2]Broadcast operations may occur also for queries that include the shard key, depending on factors such as the data distribution on nodes and the query selectivity.

By setting the date field as the shard key, it is very likely that the documents will be distributed evenly among the shards, thus resulting in a load-balanced cluster. Chunks are unlikely to become *jumbo* (i.e., this refers to chunks that cannot be split, despite becoming too large), because the values of the documents that represent the temporal information ordinarily are of high cardinality. However, it is still disturbing that the spatial dimension cannot be used for sharding, since this would benefit queries with spatial constraints. Instead, such queries will inevitably be routed to all nodes that contain data that overlap with the temporal constraint of the query.

It should also be noted that an index is automatically constructed on the shard key in MongoDB. Thus, the choice of the date field for shard key results in two indexes: an index on the temporal information and the compound index on space time. During query processing, the query optimizer is responsible for deciding which index is going to be used.

4.1.3 Data locality and zones usage. The baseline solution can only guarantee data locality at the temporal level. This means that documents associated with locations that exist near in space will only be stored on the same node if they have similar timestamps. Still, neighboring temporal intervals (corresponding to chunks) may be stored in different nodes, due to the allocation of chunks to nodes. To improve this shortcoming, we can define zones on the sharding key (date), which will force neighboring temporal intervals to be stored on the same node, thus improving data locality with respect the temporal dimension.

In summary, sharding on the date field has the following two drawbacks: (i) spatio-temporal queries may be routed to nodes that fulfill the temporal range constraint but do not contain any data that satisfy the spatial constraint, and (ii) queries that are selective in the spatial dimension but refer to a large temporal interval are forwarded to many of nodes of the cluster.

4.2 Solution based on Hilbert SFC

4.2.1 Indexing. Instead of relying on the built-in spatial indexes, our approach is based on the 1D mapping of data by means of the Hilbert space-filling curve. Specifically, for each document, the 1D Hilbert value is determined given its longitude and latitude value, and then it is included as a new field (hilbertIndex) that stores this value (of type long), as shown in the example below.

```
{
    "_id": 1,
    "hilbertIndex": NumberLong(2345),
    "location": {
        "type": Point,
        "coordinates": [37.983810, 23.727539]
    },
    "date": ISODate("2018-09-12T12:15:17.777Z"),
    ...
}
```

Even though any 1D mapping could be employed, we select the 1D mapping values based on the Hilbert space-filling curve, as it has been shown to exhibit nice clustering and locality properties [14]. This means that two documents with values of hilbertIndex that differ slightly correspond to objects that are spatially close to each other.

4.2.2 Sharding. Given this new spatial field (hilbertIndex) and the date field, we set the shard key as {hilbertIndex, date}, thus imposing spatio-temporal partitioning of data to nodes. Consequently, the formation of the chunks is based both on spatial and temporal information and each of them contains documents that exist in specific spatial cells (1D values) for a certain time period. In case of spatio-temporal skewness in the data, chunks are unlikely to become *jumbo* because of the cardinality of the temporal field. The hilbertIndex field is more prone to skewness, as it consists of finite long values and some of them may appear with high frequency (i.e., correspond to frequently visited locations). Thus, when a chunk surpasses its configured size due to a unique hilbertIndex value, it is split on the temporal dimension. The two new chunks will refer to the same 2D region, covering different and non-overlapping time spans. The definition of {hilbertIndex, date} as the shard key creates by default a compound index for these fields on each shard. The index constitutes a spatio-temporal index that uses the spatial field first and then the temporal.

When querying such an index, not only the expected spatial and temporal constraints are included in the query as in the baseline approach, but also a constraint is added on the hilbertIndex field. This constraint practically includes the set of spatial cells that need to be examined, because they intersect with the query. More concretely, such a query has the following document representation in MongoDB:

```
{ $and: [
    { location: { $geoWithin: { $geometry: { type : Polygon,
        coordinates: [ [ [23.7397867, 37.9698929],
         [23.7492228,37.9698929], [23.7492228, 37.9761557],
        [23.7397867,37.9761557 ], [23.7397867, 37.9698929] ] ]
    } } } },
    {date: { $gte: ISODate("2019-04-18T12:15:14.002Z") } },
    {date: { $lte: ISODate("2019-04-24T07:34:43.777Z") } },
    { $or: [
        { hilbertIndex: { $gte: 7865, $lte: 12869 } },
        { hilbertIndex: { $gte: 13192, $lte: 13210 } },
       { hilbertIndex: { $in : [7794, 7799, 7856, 12911] } }
    ] }
] }
```

Similarly to the baseline approach, the spatio-temporal query uses the MongoDB *$geoWithin* operator on the field that stores the location as GeoJSON object. Also, the query specifies a specific temporal range using the *$gte* and *$lte* operators on the temporal field. However, in the Hilbert-based approach, an additional constraint is posed on the specific spatial cells. Consecutive values of cells are expressed as ranges, whereas non-consecutive cell values are included as individual values. For this purpose, an additional disjunctive operator (*$or*) is used in the query that contains *$gte* and *$lte* operands to represent the ranges, and an *$in* operator to include the individual cells.

4.2.3 Data locality and zones usage. The exploitation of both spatial and the temporal information of documents for sharding leads to a distribution of data to nodes that preserves the *spatio-temporal* data locality. It is highly probable for the documents that are both spatially and temporally near to be stored on the same node. However, as already explained, this is not guaranteed for data that belong to different chunks. This is because MongoDB does not guarantee (by default) for each of the shards to store chunks with continuous ranges.

Thus, data locality can be improved by defining zones. With zones, documents with consecutive Hilbert values (disregarding the temporal dimension) are likely to be placed in the same shard; this is applied by defining and assigning zones to shards, handling documents with specific ranges of Hilbert values. The

fact that the zones are defined only on the spatial information of the documents cannot guarantee temporal locality, but only for documents with nearby spatial locations. In contrast to the baseline solution, in this approach, the spatial dimension affects the number of the nodes that are to be accessed during query processing.

4.2.4 Zones configuration. In order to assign a pre-defined range of key values to a shard, a zone is specified by means of a range of shard key values or a prefix of shard key values. Zones are then assigned to certain nodes. This enables manual partitioning of data in a controlled manner. In order to achieve data locality regarding the spatio-temporal information of the documents, we define as many zones as the number of available shards, and assign one zone per shard.

The configuration of zones for the Hilbert-based approach is performed on the `hilbertIndex` field (whereas the shard key consists of the spatial and temporal field). Specifically, by using the *$bucketAuto* aggregation pipeline stage of MongoDB, we get the ranges of n buckets, where n is the number of shards. The boundaries of buckets are formed with the goal of even distribution of documents to buckets. The ranges of the zones contain documents that have a specific Hilbert value, without taking account its temporal part. In other words, the zones contain documents that are located in specific cells for the whole timespan in which they belong to. The resulting zones may not contain exactly the same number of documents due to spatial data skew, but we manage to preserve spatial locality.

For the baseline approach, the configuration of zones is performed on the `date` field that constitutes the shard key, using again the *$bucketAuto* aggregation pipeline stage. Each of the buckets, contains the same number of documents. Based on these ranges, the respective zones are created, and each one is assigned to a single shard.

5 EXPERIMENTAL EVALUATION

In this section, the results of the experimental evaluation using both real-life and synthetic data are presented.

5.1 Experimental Setup

Platform. All experiments were performed in Okeanos-Knossos[3], an IaaS platform which is built and supported by GRNET[4] for research purposes. Okeanos-Knossos is a cloud service that provides virtual computing and storage services to the Greek research and academic community. We have engaged from the cloud service the following resources: 17 virtual machines, 68 CPUs, 136GB RAM, and 2.00 TB disk space.

MongoDB deployment. We deployed MongoDB (v 4.0.12) on 17 virtual machines. From this set of nodes, 12 of the VMs were used as (primary) shards, 3 of them as configuration servers and the remaining 2 as query routers. Replica shards were not used since the availability feature which mainly relates to node failures is beyond the scope of this experimental study.

Each VM is equipped with 8GB RAM, x4 CPU cores and 30GB system disk, running Ubuntu 16.04.6 LTS operating system. The VMs that serve as shards have a mounted disk drive of 102GB size. The VMs that serve as query routers have a mounted disk drive of 145GB size. The offered attachable disk of Okeanos-Knossos platform is based on the Ceph[5] storage system, which is a distributed block level storage.

By default, MongoDB uses the WiredTiger storage engine that integrates compression for collections and indexes. The compression on the collections is achieved through block compression, supported through the snappy library. At the level of indexes, prefix compression is used.

Data sets. Two types of data sets are used for the experimental evaluation; real-life (R) and synthetic (S). The R set used in the experimental evaluation is a subset of a proprietary data set that is provided from a fleet management provider in Greece. The subset used in our experiments is 13.7GB in the form of CSV files, containing $15,210,901$ records in total. The data set contains trajectories of vehicles within Greece for a period of five months (July to November 2018). Particularly, each record constitutes a GPS trace of a specific vehicle and is comprised of 75 values. The values represent information about the vehicle, its position in space and time, the prevailing weather conditions, the road network and the nearest points of interest. The coordinates of the minimum bounding rectangle of the data set are: [(19.632533, 34.929233), (28.245285, 41.757797)]. We also use larger portions of the same data set for our scalability study in Section 5.4, by including more vehicles in the same spatio-temporal bounding box.

The S set is a synthetic spatio-temporal data set, which contains twice as many records as the R data set. It consists of two CSV files where each one contains 4 columns (`id`, `longitude`, `latitude` and `date`). The values of each column are generated at random within predefined ranges and following the uniform distribution. Its size is 1.6GB. The timespan of the synthetic data set is the half of the covering time period of the R data set (i.e., it spans 2.5 months) and covers spatially a smaller area than R. Specifically, the minimum bounding rectangle of the synthetic data set is approximately 1.54% of the minimum bounding rectangle area of the R set. The lower and upper coordinates of this rectangle are: [(23.3, 37.6), (24.3, 38.5)].

Queries. In order to assess the performance of the approaches, two categories of spatio-temporal queries are specified; those with small and big spatial constraint, respectively. The categories will be stated henceforth as Q^s (small) and Q^b (big) correspondingly. Each category contains 4 queries with increasing temporal constraint: Q_1^x covers 1 hour, Q_2^x 1 day, Q_3^x 1 week and Q_4^x covers 1 month, where $x \in \{s, b\}$. The queries do not overlap on the temporal dimension; instead, each one pertains to a discrete time span.

The spatial constraint of the small queries category is defined as a rectangle with the following lower and upper bounds; [(23.757495, 37.987295), (23.766958, 37.992997)]. The spatial rectangle covers 526km^2. The spatial constraint of the big queries category is also defined as a rectangle, approximately $2,603$ times larger than the covering area of the small queries category. Its lower and upper bound coordinates are [(23.606039, 38.023982), (24.032754, 38.353926)], covering $1,369,107$km^2.

Tables 2 and 3 report the number of retrieved documents for each small and big queries, respectively. Clearly, small queries are selective and retrieve relatively few documents. This corresponds to queries for constrained space and time dimensions, aiming at retrieval of very specific records. Instead, big queries, return large result sets, and correspond to analytic queries that retrieve

Table 3: The results of big queries for the real and the synthetic data set

large portions of the data set in order to perform some large-scale data analysis task.

Metrics. The evaluation of the performance of the approaches is based on the following metrics;

- *Average execution time*: corresponds to the execution time required for processing the query and returning the query result (averaged over queries).
- *Documents examined*: corresponds to the maximum number of documents that were accessed on any node during query processing. This indicates the number of documents that need to be fetched from disk during query processing. We use the maximum as it corresponds to the highest cost induced on any node, so it affects the execution time.
- *Keys examined*: shows the maximum number of keys examined in the underlying index over all nodes, in order to find the necessary documents on disk. This indicates the cost paid during query processing induced by accessing the index.
- *Nodes*: reports the number of nodes that were accessed during the execution of a query. This corresponds the subset of nodes that participated in query processing.

Methodology. Based on the description of the subsections 4.1 and 4.2, we evaluate the following individual approaches which cover variants both for indexing and partitioning:

- *bslST*: sharding based on time, and local indexing on shards using compound index (`location`, `date`), where location is based on 2dsphere index.
- *bslTS*: sharding based on time, and local indexing on shards using compound index (`date`, `location`), where location is based on 2dsphere index.
- *hil*: range sharding based on Hilbert curve in 2D (with 13-bit precision) and on time. The applied Hilbert curve covers the entire globe. For local indexing on shards, a compound index (`hilbertIndex`, `date`) is used for each node.
- *hil**: range sharding based on Hilbert curve in 2D (with 13-bit precision) and on time. The applied Hilbert curve is limited to the spatial region of the data set. For local indexing on shards, a compound index (`hilbertIndex`, `date`) is used for each node.

With the *bsl* term we will refer to the sharding of the bslST and bslTS approaches which is common for both of them. These approaches differ only on their indexing part. Furthermore, the hil method competes on equal terms bslST and bslTS approaches, by taking account of the same spatial extent (whole world) and by using 26 bits for storing the geospatial information of each document on the respective indexes. We also tried hil* to investigate if the use of a curve with the same number of bits but on restricted spatial extent has any notable effect on performance.

The evaluation methodology followed in this experimental study is described as follows. Each of the queries of the two categories are executed 30 times, so as to ensure that the measurements of the performance time of queries are in warm state (where indexes have been already loaded in-memory). The execution time is calculated by averaging the last 10 executions of each query.

When switching from one approach to the other, MongoDB is re-installed from scratch so as to have a new deployment which will contain only one sharded collection. For each approach, data loading takes place. Both of the query routers are exploited for this purpose and perform bulk insertion.

The approaches are tested under range sharding with different settings: (i) with the default formation of the chunks, without intervening on the distribution of the data over the shards (Section 5.2, Figs. 5–8), and (ii) with the definition of zones where data is grouped to shards given some pre-determined ranges (Section 5.3, Figs. 9–12).

5.2 Evaluation of Approaches

***hil* vs. *bsl*.** For both of the baseline variants (bslST and bslTS), the number of nodes to which a query is routed increases when the temporal constraint of a spatio-temporal query is increasing, regardless of its spatial extent (Fig. 5c, 6c, 7c, 8c). This is not effective for big queries that cover a large spatial area and refer to a short time period (such as Q_1^b and Q_2^b in Fig. 6d and Fig. 8d). In that case, a small number of nodes are burdened with search operations, as a result of the multiple 1D mapping values that represent the area. This is reflected in Figs. 6a, 6b, 8a and 8b where the maximum number of examined keys and documents are many more than in hil. The same applies for the Q_3^b query, served by 2 and 6 nodes in the R and S set respectively, fewer than the exploited nodes of hil method. The query Q_4^b uses in the baseline approaches 3 nodes more than in hil for both sets, with more maximum examined keys and documents. In summary, hil outperforms the baseline methods in terms of execution time in the case of big queries.

Concerning the small queries, Q_1^s and Q_2^s perform better for hil in R set, since the maximum examined keys are fewer than in bslST and bslTS (Fig. 5a). The same applies for the S set in terms of the performance, but for the Q_2, a few more documents are examined in hil than bslST (Fig. 7a). Still, Q_2^s performs a little better in *hil* than bslST, as 1 node is used, thus without having the small overhead of merging the results from the shards. The opposite happens for the maximum examined documents (Fig. 5b and 7b) for the same queries on the two sets, but the differences are smaller than the respective cases of the examined keys. For queries Q_3^s and Q_4^s, bslST outperforms hil. This happens because more nodes contribute to the execution of the queries. Since the queries are spatially small, fewer nodes are used in the hil method.

hil* vs. *hil*.** The performance of hil and hil* methods differ in favor of hil for the big queries in both sets (Fig. 6d and 8d). The same does not apply for the small queries (Fig. 5d and 7d), excluding Q_1 for both sets and Q_2 for S set. In practice, hil* uses higher precision in the spatial domain than hil, having more

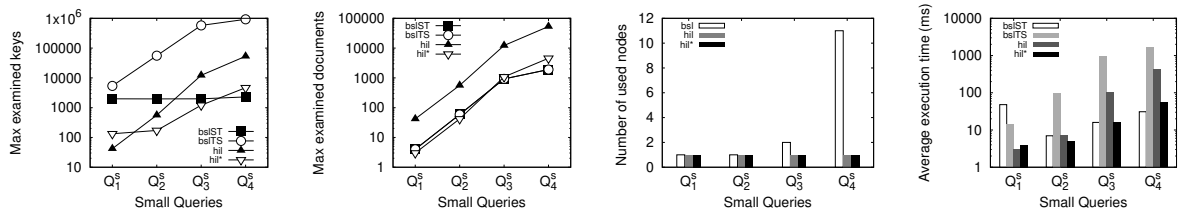

Figure 5: Default sharding ranges: Results for small queries and real (*R*) data

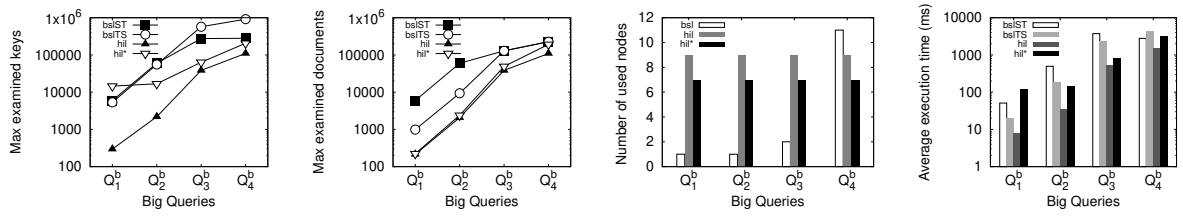

Figure 6: Default sharding ranges: Results for big queries and real (*R*) data

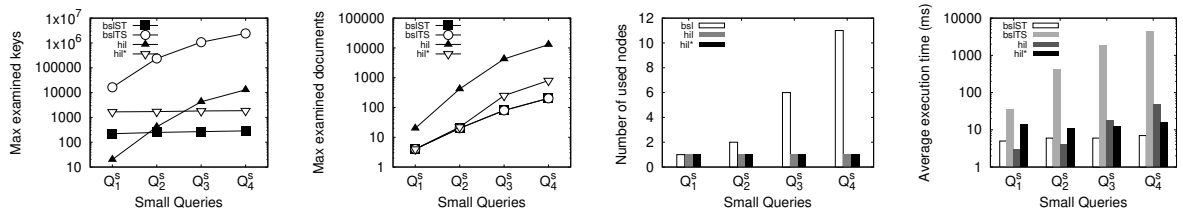

Figure 7: Default sharding ranges: Results for small queries and synthetic (*S*) data

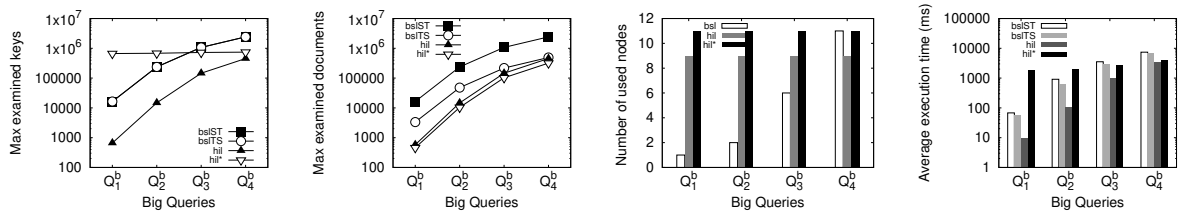

Figure 8: Default sharding ranges: Results for big queries and synthetic (*S*) data

indexed values on its spatial part. This results to a compound index with more buckets but with fewer elements on each bucket. It is expected, that such an index will perform better for spatio-temporal queries that cover a small area, than an index with fewer values on the spatial part. The difference in the performance is greater when the temporal dimension is increasing, since many of the buckets of the hil* that fulfill the spatial criteria will not be accessed, because of their temporal boundaries, thus resulting to fewer examined documents.

Discussion. In general terms, our experiments with the default distribution settings validate our intuition that the integration of the spatial information on the sharding offers performance gain. This is especially evident for big queries where hil outperforms bsl. In the case of small queries, bsl performs better but at the expense of using more nodes for query execution due to the lack of data locality. This is going to have a negative effect in a real system that processes thousands of queries at the same time, since it would require that all nodes need to participate in the execution of each query, which is not scalable.

5.3 Evaluation of Approaches with Zones

In this set of experiments, we only use hil (not hil*) since we did not observe significant performance improvements. Many of the experimental observations of Section 5.2 stand also for the case of grouping data via zones. For instance, for all of the big queries (Figs. 10d and 12d), hil outperforms both bslST and bslTS, because the maximum number of examined documents is smaller. Moreover, the required execution time of small queries

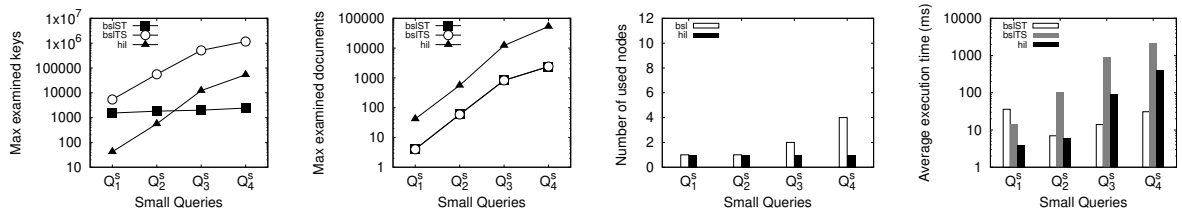

Figure 9: Zone ranges: Results for small queries and real (*R*) data

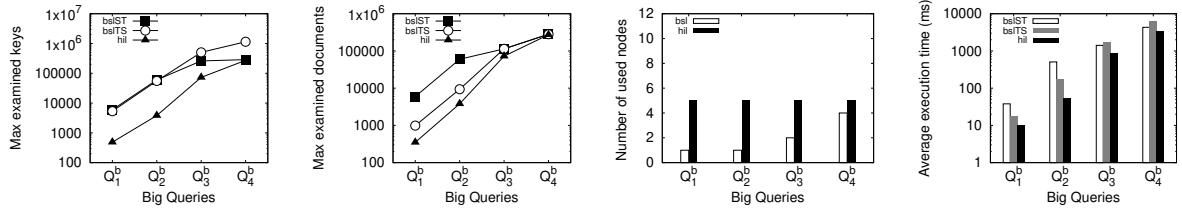

Figure 10: Zone ranges: Results for big queries and real (*R*) data

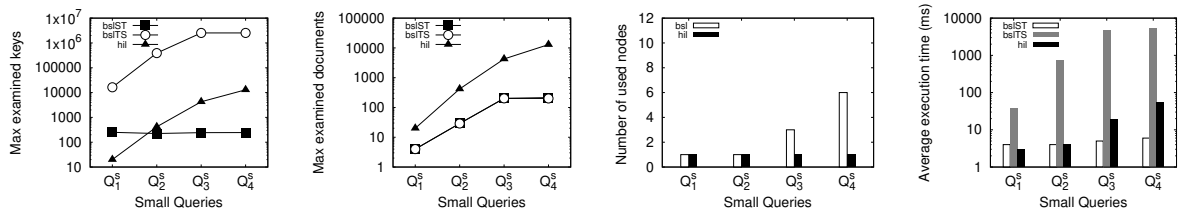

Figure 11: Zone ranges: Results for small queries and synthetic (*S*) data

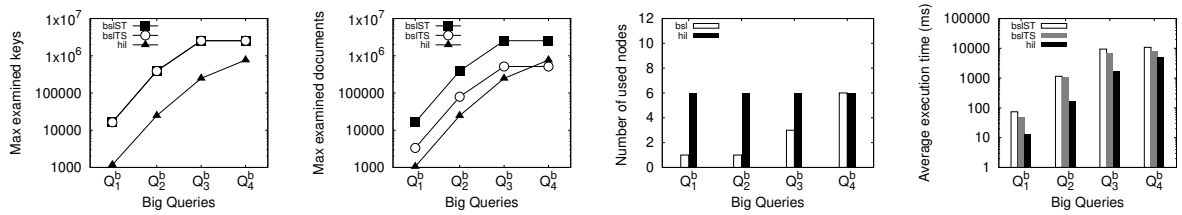

Figure 12: Zone ranges: Results for big queries and synthetic (*S*) data

with a large timespan (Q_3 and Q_4) is smaller for the bslST than hil, since more nodes are exploited, resulting to a smaller number of maximum examined keys and documents for both sets (Figs. 9a, 9b, 11a and 11b).

It should be underlined that in the cases in which more than two node were exploited for the performance of a query in the experiments of Section 5.2, their corresponding application over of the pre-defined zones use fewer nodes. This is expected because of the grouping of zones on shards. For those cases, the query performance drops to a small degree. Additionally, better data locality is offered via zones as data is moved to specific shards, adhering to the specified ranges.

Discussion. The usage of zones for each of the approaches confirms that data locality is better than in the case of default distribution of the documents among the shards. This is demonstrated by the fact that fewer (or, in some cases, the same number) of nodes take part in the processing compared to the case of no zones.

In the baseline approaches, the Q_4 big queries in both R and S data sets consume more time for their execution, as fewer nodes are involved in query processing. The performance degradation is also noticed for the Q_2^b and Q_3^b in the S set, whereas the respective queries gain performance in the R data set. Query Q_1^b gains slightly in performance in all cases. Regarding the small queries, in the bslST approach, query execution remains practically the same. In the bslTS approach, the performance of Q_4^s gets worse for both R and S data sets. The same applies for Q_3^s and Q_2^s, but in

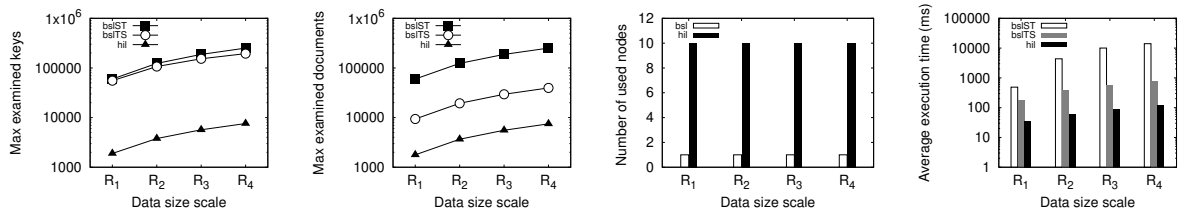

Figure 13: Scalability study for default sharding ranges: Results for Q_2^b query on real data

the S data set. The performance of the remaining queries remains the same.

For the Hilbert-based approach, the usage of zones affects only the execution of Q_2^b, Q_3^b and Q_4^b big queries, increasing their execution time as a smaller number of nodes are involved in query processing. An extra number of keys and documents have to be searched. This is validated in both R and S data sets. The remaining queries have similar performance, except for small queries Q_3^s and Q_4^s in the R data set. Their execution time is slightly decreased despite that the same number of nodes (namely one node) is still exploited with zones. These queries have been favored due to the change in the distribution of data by using zones.

5.4 Scalability Study

In this experiment, we study the scalability of our approach for larger data sets. For this purpose, we use larger portions of the real R data set. In particular, we use R_1 to denote the data set used so far, whereas R_2, R_3, and R_4 correspond to larger data sets, by a scale factor of x2, x3, and x4 respectively. Table 4 reports the size (in GB) and number of documents for each data set. Notice that we keep the same spatio-temporal bounding box for the data set, and we obtain larger instances of the data set by adding data from more vehicles. We select query Q_2^b in order to study its performance when the size of the data set is increased. Also, Table 5 reports the number of results for Q_2^b for the different data sets ($R_1 - R_4$), showing that the same query retrieves more results as the scale factor of the data set increases.

	Data sets with scale factor			
Data set info	R_1	R_2	R_3	R_4
Size (GB)	40.8	83.87	127.27	171.59
#documents (M)	15.2	31.4	47.7	63.9

Table 4: Information for instances $R_1 - R_4$ of the real data set for different scale factor

	Data sets with scale factor			
Query	R_1	R_2	R_3	R_4
Q_2^b	5,640	11,792	17,840	23,854

Table 5: Number of results for query Q_2^b per scale factor of the real data set

Fig. 13 demonstrates that our approach scales gracefully as the size of the data is increased. This is particularly evident when considering the execution time in Fig. 13d. Perhaps more importantly, the gain of hil over the baseline methods increases with the size of the data, which favors the performance of hil for larger data collections. Figs. 13a and 13b show that hil needs to access 1-2 orders of magnitude fewer documents and 2 orders of magnitude fewer keys respectively. When comparing the two baselines, bslTS performs better than bslST, since fewer documents are examined in the query's refinement phase. Recall that query Q_2^b is selective on its temporal dimension (covering only one day) and thus it is expected that bslTS will perform better than bslST.

Discussion. This experiment demonstrates that the proposed approach (hil) sustains its benefits over the baseline methods when the size of the underlying data set is increased. This indicates that our approach is scalable with data size.

6 CONCLUSIONS

In this paper, we provide an in-depth study of spatio-temporal query execution in NoSQL stores, focusing on MongoDB due to its popularity and support for spatial data. Our study indicates that existing NoSQL stores do not natively support spatio-temporal data, despite the ever-increasing number of applications that produce massive spatio-temporal data daily. We also show that a baseline approach based on built-in spatial indexes leads to suboptimal performance in several cases. More importantly, we investigate on the underlying reasons for this impact on performance, and we elaborate on indexing and sharding techniques. Furthermore, we propose an alternative approach which exploits the Hilbert curve to map data to 1D values, which are then: (a) indexed using a standard B-tree, and (b) used for partitioning the data in a way that preserves spatio-temporal data locality in shards. We conclude that this has an effect on the number of nodes storing data that participate in query execution. Our extensive experiments using both real-life and synthetic data in a cluster of nodes support our conclusions.

With respect to future work, we believe that big data developers that work on spatio-temporal data will find interest in our work, especially towards optimizing the performance of their applications. Also, we expect that future releases on NoSQL stores will provide support for spatio-temporal data, therefore our work is a small contribution in this direction. As a result, we intend to extend our approach and investigate other methods for indexing and partitioning spatio-temporal data in distributed NoSQL systems. Also, extending our work towards supporting more complex data types (polylines and polygons) is of interest. Last, but not least, we would like to expand our study using a workload of queries, and propose an adaptive, workload-aware mechanism for indexing and partitioning.

A ADDITIONAL EXPERIMENTAL RESULTS

We provide additional details on the empirical evaluation, including the bulk loading technique that we use, details on index usage, as well as information of query distribution to nodes and index size.

A.1 Data Loading

Data Loading. Both of the nodes that act as query routers, store half of the CSV files of the data sets on their disks. Data loading to the MongoDB store is carried out by accessing the CSV files record-by-record and converting them directly to documents (binary JSON - BSON format). The conversion process does include the formation of a GeoJSON object as a value of the `location` field based on the longitude and latitude columns of the CSV datasource files. It also includes the addition of the fields with its respective values for all of the rest columns of the CSV files, and the addition of the `_id` field which is handled automatically by the MongoDB client driver. Note that for the Hilbert-based approaches, a further action takes place, related to the calculation of the 1D value. When a document is formed, it is added to a list. The list is used for bulk insertion of documents for performance reasons. The insertion is triggered after a specific batch of elements has been placed in the list, and we use 15K documents as batch size in our experiments.

The size of the R and S set is a marginally smaller in the bsl method than hil and hil* (Table 6), since its documents do not integrate the `hilbertIndex` field, as hil and hil* do. Also, the sizes of the methods in R set are much larger than S set because they incorporate much more information due to the extra fields.

	Approach	
Data set	*bsl*	*hil(*)*
R	40.54	40.8
S	3.62	4.13

Table 6: Data size of real and synthetic data set in MongoDB (in GB)

A.2 Querying the Data

The bslST and the bslTS approaches use as a sharding key the `date` field which results to an additional index per node, apart from the compound index. As a result, there are some cases where the query optimizer chooses to process the spatio-temporal query at hand using the index on `date`, rather than using the compound index. This occurs only in the bslST approach, whereas in the bslTS approach all queries are processed using the compound index. Table 7 reports which index was used during query processing for the bslST approach for all queries and both data sets.

Querying under the hil and hil* approaches, requires the determination the cell of the indexes that cover the queries' spatial extent. Table 8 shows the average time execution of the Hilbert algorithm for the identification of the cell indexes. When applying the hil* methodology, it is reasonable that the algorithm requires more time than hil for specifying the 1D values, as the total searching space is limited to a smaller surface, resulting to increased precision. Furthermore, the execution time in the *S* data set is increased when comparing the respective approaches (except for Q^s for hil) to the *R* set, since the data exists in a smaller 2D space which increases the precision. This adds a burden to the algorithm's operation for identifying the 1D values. The figures that follow in the next subsections, showing query execution time, do not include the time for the determination of the 1D values through the space filling curve.

S	0.05	0.3	0.6	7.6

Table 8: Average time of Hilbert algorithm performance in ms, for finding which 1D values should be searched on the index

A.3 Index Size

The baseline methods have a few more main memory resources requirements than hil for maintaining the indexes among the shards. This is indicated in Figs 14a, 14b, 14c and 14d. Except for the spatio-temporal indexes, bslST and bslTS maintain additionally two indexes which are created by default; one for the *_id* field of every document, and the other for the *date* field, as it acts as the sharding key. Whereas, hil and hil* methods maintain as an additional index apart from the spatio-temporal, only the one that is used for the _id field. Their spatio-temporal indexes preexist by default due to the fact that its fields constitute the sharding key. This, favors especially the hil method, since in all cases, less memory is required for handling all the indexes than bslST and bslTS.

For each of the methods, both in R and S set, the total size of indexes among the shards increases when transiting from the default data distribution to zone ranges. The change in size is affected by the indexes' size that handle the _id field. The insertion of the documents in MongoDB database, takes place under the default distribution settings, and the documents with similar construction time have a larger common prefix part on the _id field. Documents created in similar timestamps that get inserted in the same shard contribute to the occupation of less main memory by the _id index, since MongoDB uses prefix compression. With the definition of zones, the documents that have been already stored in the shards, are shuffled around the cluster, resulting to shards with documents that have a smaller common part. This makes the compression less effective and thus the sizes of _id indexes are increased.

Moreover, the total size of the spatio-temporal indexes does not change significantly when shifting from the default data distribution state to zone ranges. The indexes have approximately the same size. The same applies for the date indexes that exist in bslST and bslTS methods; their size remains approximately the same for both default distribution and zone ranges.

Comparing the hil and hil* total size of indexes, it is noticed that in R set less main memory is required for hil* method (Fig. 14a), whereas the opposite is true for the S set (Fig. 14c). This is reasonable because for the S set, the cardinality of the 1D values for hil* is much greater than hil method when contrasting the same methods for the R set. In R set, many are the documents that have the same 1D value as they are spatially skewed. The values are grouped to buckets, covering each one a specific time period. This saves memory especially when having smaller buckets that still cover a specific time period; this is achieved through hil*. On the other side, in S set, hil* is less efficient in terms of memory occupation than hil because the 1D hilbert values that are handled, are many more as the data is distributed uniformly all over their minimum bound box. This makes the compression less effective either, thus increasing the size of the hil* index.

ABSTRACT

Massive data processing infrastructures are commonplace in modern data-driven enterprises. They facilitate data engineers in building scalable data pipelines over shared datasets. Unfortunately, data engineers often end up building pipelines that have portions of their computations common across other pipelines over the same set of shared datasets. Consolidating these data pipelines is therefore crucial for eliminating redundancies and improving production efficiency, thus saving significant operational costs. We had built CloudViews for automatic computation reuse in Cosmos big data workloads at Microsoft. CloudViews added a feedback loop in the SCOPE query engine to learn from past workloads and opportunistically materialize and reuse common computations as part of query processing in future SCOPE jobs — all completely automatic and transparent to the users.

In this paper, we describe our production experiences with CloudViews. We first describe the data preparation process in Cosmos and show how computation reuse naturally augments this process. This is because computation reuse prepares data further into more shareable datasets that can improve the performance and efficiency of subsequent processing. We then discuss the usage and impact of CloudViews on our production clusters and describe many of the operational challenges that we have faced so far. Results from our current production deployment over a two month window show that the cumulative latency of jobs improved by 34%, with a median improvement of 15%, and the total processing time reduced by 37%, indicating better customer experience and lower operational costs for these workloads.

1 INTRODUCTION

Modern data-driven enterprises rely on large-scale data processing infrastructures for deriving business insights. As a result, over the last decade, a plethora of tools have been developed that have democratized scalable data processing for data engineers and data scientists. Examples include MapReduce [14], Spark [5], Hive [4], Presto [34], BigQuery [19], Athena [6], and SCOPE [9, 47]. However, the large-scale data processing infrastructures also incur massive operational costs and therefore improving their efficiency becomes very important in production. Interestingly, easy access to large scale infrastructure often leads data engineers to quickly build data processing pipelines that later end up having portions of computations repeated across one another. Furthermore, these redundancies are hard to discover in large enterprises with thousands of developers spread across different business units. Thus, we need automated tools to consolidate these data pipelines and improve operational efficiency, without impeding the developer productivity in quickly going all the way from raw data to actionable insights.

We see two key challenges when considering approaches for automatic compute reuse. First, it is very tedious to automatically detect the common computations in large volumes of complex analytical queries that are declarative and often include custom user code. Our analysis over a large window of production workloads, consisting of 67 million jobs and 4.3 billion sub-computations (referred to as *query subexpressions*), show that more than 75% of the query subexpressions are repeated. However, not all of the common computations are going to be viable candidates for reuse, e.g., due to very large storage overheads. Therefore, carefully detecting and selecting the common computations for reuse is a challenge. And second, there is a shift towards serverless query processing infrastructures [6, 9, 19], also sometimes referred to as job services, where users simply submit their declarative SQL-like queries without provisioning any infrastructure. As a result, users do not have any spare offline cycles for materializing the common computations before running their actual data analysis. In fact, users want to get started with their analysis quickly and they would rather have any optimizations applied in an online and adaptive manner.

We also see two key opportunities. First, there is a presence of large volumes of shared datasets in enterprises. This is because raw logs and telemetry coming in from various products are extracted and preprocessed into a shape and form that could be easily consumed by thousands of downstream developers. The resulting shared datasets are written once and read many times. Furthermore, they get regenerated periodically without requiring any fine-grained updates. As a result, the shared computations also do not need to be maintained with updates. And second, computation reuse holds the promise of significantly improving both the job performance and the operational efficiency, which are crucial in speeding up the time to insights and to enable developers to do more with the same set of resources (that are likely to have longer procurement cycles).

To address the above computation reuse problem, we had built CloudViews for automatic computation reuse in big data workloads at Microsoft [26]. Specifically, CloudViews optimizes the SCOPE query workloads in Cosmos big data analytics platform, that is used in various business, such as Bing, Windows, Office, Xbox, etc., across the whole of Microsoft. CloudViews identifies the common computations (query subexpressions) across

different SCOPE jobs, selects the ones that could lead to more efficiency, materializes them as part of query processing with minimal overhead, reuses them in future jobs — all completely automatic and transparent for the users. In contrast to prior works on materialized views [20] and multi query optimizations [37], CloudViews materializes common query subexpressions as part of query processing, i.e., does not require any offline cycles, and automatically replaces older materialized views with newer ones when the shared datasets are bulk updated, i.e., no update maintenance. Production experiences with Cosmos showed that bulk updates are a significant part of the workload, incremental updates if required can be handled using techniques proposed by Wang, et al.[42]. CloudViews considers only the same logical query subexpressions (with some normalization) for reuse, i.e., it does not consider view containment [21]. Although this is helpful in getting more accurate statistics for estimating the utility and cost of reusing different candidate subexpressions. CloudViews uses these estimates to select the set of subexpressions to materialize such that they provide the maximize reuse within a given storage budget [24]. We plan to add query containment to CloudViews as part of future work.

In this paper, we describe our production experiences with CloudViews. We delve deeper into the data preparation process in Cosmos, referred to as *data cooking*, and discuss how computation reuse naturally augments data cooking by creating more shareable datasets that can boost the performance and efficiency of further downstream processing. While we previously showed the impact of CloudViews on TPC-DS workloads and a small set of production queries in pre-production environment, we now analyze the usage of CloudViews in production and compare the impact along several performance metrics. Apart from performance improvements, CloudViews also introduced an automated feedback loop in the SCOPE query engine, i.e., moving towards a self-tuning model [25, 26]. As a result, there were several operational challenges that we have faced and valuable lessons learned along the way. We discuss these challenges and also reflect back on our journey from research to product.

In summary, we make the following key contributions in this paper:

(1) We provide a detailed description and analysis of data cooking in Cosmos and reason about how compute reuse with CloudViews helps augment the data cooking process. We also discuss the impact of various design decisions that were made in CloudViews. (Section 2)
(2) We present an analysis of the usage and impact of CloudViews on our production workloads. Results from our production deployment show that over a two month window the cumulative latency of jobs improved by 34%, the total processing time reduced by 37%, and the total number of containers used for processing dropped by 36%. We also highlight some of the other non-obvious implications, including smaller inputs (by 36%), less data read (by 39%), and shorter queue lengths (by 13%). (Section 3)
(3) We discuss several operations challenges faced, including challenges in view selection when considering job scheduling, correctness guarantees, dependencies with other components, customer on-boarding, customer expectations, and quantifying the impact over constantly changing workloads. (Section 4)
(4) Finally, we reflect back on the journey from taking a research prototype to production, describe how the ability to create derived data as part of query processing is a powerful mechanism in general, and present insights for many of the open opportunities that we see going forward (Section 5).

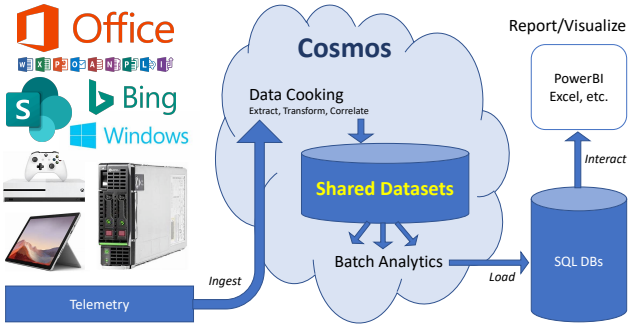

Figure 1: Illustrating typical data cooking in Cosmos.

2 DATA COOKING

Cosmos powers the internal big data analytics at Microsoft, with a massive infrastructure consisting of multiple 50k+ node analytics clusters [35], and processing declarative analytical queries using the SCOPE query engine. Cosmos runs hundreds of thousands of batch SCOPE jobs per day, consuming millions of containers and crunching over several petabytes of data generated per day. Almost 80% of the SCOPE workloads are recurring in nature [28], i.e., similar jobs templates are executed periodically at regular intervals over new data sets and parameters. Furthermore, SCOPE jobs have dependencies across each other. In fact, 80% of the jobs depend on at least one other job, while 68% have dependencies in a recurring fashion [12]. This is because of the presence of large volumes of shared data sets in Cosmos. Below we describe this enterprise pattern in more detail.

2.1 An Enterprise Pattern

Figure 1 illustrates the typical data cooking pipeline in Cosmos, where the raw telemetry data from different Microsoft products and services are ingested into the Cosmos store. Thereafter, the data cooking process extracts the structured data, transforms it into better representation, and correlates across multiple sources. The resulting shared datasets are generated periodically and consumed in multiple downstream batch-oriented analytics. Aggregated data is then loaded into interactive query processing systems like SQL databases for interactive analysis, reporting, and visualization using tools such as PowerBI or Excel. We can see that data cooking and the ability to collect and process large volumes of shared datasets across various developers and even business units is at the core of the above pipeline.

Figure 2 shows cumulative distributions of shared data sets and their consumers in five of our production clusters over a one-week window. We can see that more than half of the datasets are shared across multiple distinct consumers. Furthermore, several datasets are consumed tens to hundreds of times, with few getting reused thousands of times as well. Cluster1 in particular sees more shared data sets since that feeds into the Asimov platform that *implements a new mechanism for user feedback, allow for the testing of new features to gauge user acceptance, track bugs, and easily roll out new functionality and fixes* [33]. In fact, 10% of the inputs on this cluster get reused by more than 16 downstream consumers. For other clusters, 10% of the inputs are consumed

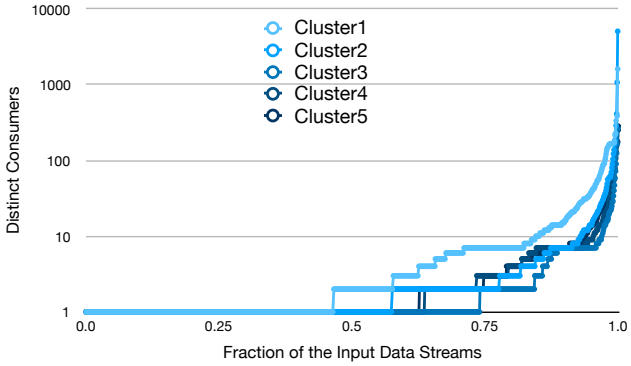

Figure 2: Shared data sets in five production clusters.

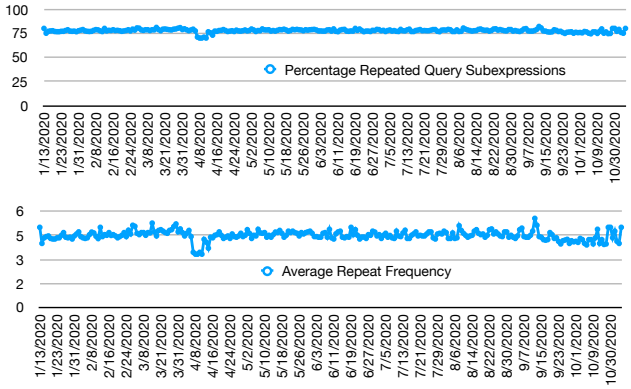

Figure 3: Overlaps in production clusters.

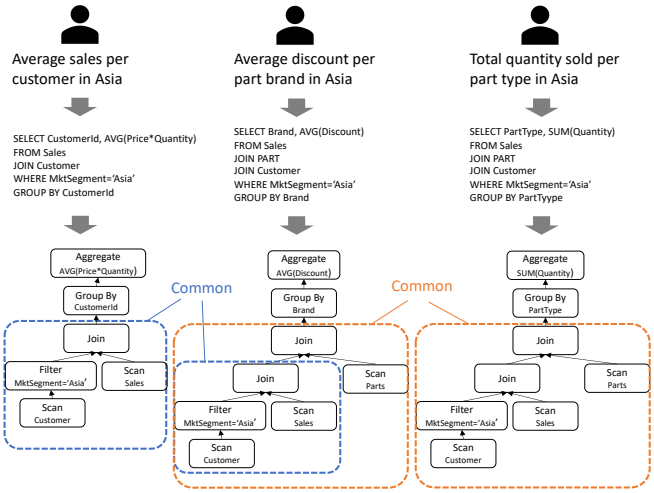
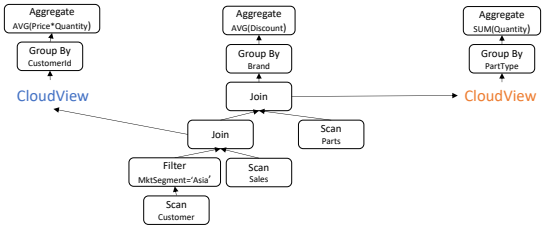


(a) Query plans with common computations across different users.



(b) Modified query plans with computation reuse across users.

Figure 4: Illustrating computation reuse across three analysts working on the same datasets.

by 7 or more downstream consumers. Thus, we see that shared data sets are prevalent in Cosmos.

2.2 Augmented Data Cooking

We saw that enterprise data analytics involves cooking massive volumes of data into a form that is consumable by several users. The shared datasets are therefore also a natural habitat for shared data analytics. Furthermore, it turns out that computation reuse is a natural problem in shared data analytics since often there are same sets of transformations that are applied repeatedly by analysts over the same shared datasets. Ideally, these shared computations could be captured in the cooking process itself. However, that is hard practically due to the lack of visibility into the downstream analytics (e.g., by different teams or business units consuming the shared datasets), complexity of SCOPE queries where it is non-trivial to identify the shared computations (portions of declarative large queries, including user defined functions, that may end up getting compiled to the same query sub-plan), or even due to the evolving nature of the analytics (new reports or dashboards being created). In a way, computation reuse can *augment* the handcrafted data cooking process by further fine-tuning the shared datasets with reusable views that are automatically identified, adapted, and created just in time, based on the workloads. Thus, we argue for computation reuse to be a first-class citizen in conjunction with data cooking for shared data analytics.

We analyzed the overlaps in our workloads in five of our production clusters over a 10-month window (January–October, 2020). Overall, there were 67 million jobs consisting of 4.3 billion query subexpressions from 2.5K users and 776 virtual clusters[1]. Figure 3 shows that more than 75% of query subexpressions are consistently overlapping over the 10-month window. Furthermore, the average repeat frequency consistently hovers around 5, indicating that materializing and reusing could be helpful for many of these overlapping computations. We refer interested readers to [26] for more fine-grained analysis of overlaps over a single day window.

In summary, computation reuse can fill the gaps in data cooking, and we see significant opportunities for computation reuse in our production workloads.

2.3 CloudViews Overview

Figure 4 illustrates an example scenario of computation reuse across three different users who are analyzing the same shared datasets (which include Customer, Sales, and Parts tables) and analyzing the sales behavior in the same Asia region. We can see how the insights that they are looking for is expressed as SQL queries that get compiled into query plans, and even though the user queries might appear very different, their query plans turn out to have significant portions in common (shown in orange and blue boxes). The analysts may identify that they are all analyzing the same market segment, i.e., the plain sentence version of the insights they are looking for has "In Asia" in common. This may lead them to create indexes or vertical partitions on the customer table. However, the query plans in the bottom of Figure 4a

[1]A virtual cluster represents a sub-cluster that is dedicated for one particular customer or business unit.

shows much large computations, called *query subexpressions*, are shared across them. Furthermore, different sets of computations are shared across different sets of users. To really discover these opportunities, the analysts would have to understand their analytics more deeply and then coordinate amongst themselves to manually share the common computations, requiring a lot of manual effort that is simply not possible at enterprise scale.

CloudViews addresses the above challenges by introducing automatic computation reuse in an online fashion. Figure 5 shows the overall system architecture of CloudViews and the various steps involved. We briefly summarize them below. CloudViews leverages the presence of large workloads in modern clouds [25]. It extracts the query workload into a denormalized subexpressions table that pre-joins the logical query subexpressions with their runtime metrics as seen in the history. Thereafter, we identify the common subexpressions across queries using a strict subexpression hash, known as *signature*, that uniquely captures a subexpression instance including its inputs used. From the set of all common subexpressions, we select the useful set of expressions to materialize and reuse. Some of the considerations for reuse include storage cost for materialization, processing time saved when reused, saving opportunities per customer, and the presence of concurrent queries that may not benefit from materialization-based reuse. Users can provide storage and other constraints (e.g., maximum number of views to create) for view selection. The view selection output is also made available to customers for insights and expected overall benefits. For the selected views, we collect their corresponding *recurring signatures* that discard time varying attributes like parameter values and input GUIDs, and are likely to remain the same in future instances of the recurring workloads. For easier lookup and control, we generate tags for each of the signatures that help fetch relevant signatures for a given SCOPE job and could also be used for access control. These tagged signatures are then polled by insights service and stored using Azure SQL databases. We also generate a query annotations file with the selected signatures that could be used for quickly debugging any job. For instance, in case of a customer incident, we can reproduce the compute reuse behavior by compiling a job with the annotations file.

At query time, for an incoming SCOPE job, the compiler extracts its tags and fetches the annotations from the insights service. These annotations are then parsed and stored in the optimizer context. During core search, the optimizer tries to match top down (match larger subexpressions first) whether any of the query subexpressions is already materialized. If yes, then it modifies the query plan to reuse the common subexpression with scan over previously materialized subexpression, updates more accurate statistics, and inserts the modified plan into the memo for overall costing. The plan using a materialized subexpression is chosen only if its cost is lower than the plan without the materialized subexpression. In either case, there is a follow-up optimization phase to check (in bottom-up manner) if any of the subexpressions are candidates for materialization. If yes, then an exclusive lock is obtained from the insights service and a spool operator with two consumers is added to that subexpression: one feeds into the rest of the query processing while the other materializes the common subexpression to stable storage. During execution, the job manager makes the view available even before the query finishes (referred to as early sealing in Cosmos), and notifies the insight service to release the view creation lock and start reusing it wherever possible. The modified query plans are surfaced to the users in the query monitoring tool and also logged into the telemetry for future analyses.

We refer interested readers to [26] for more details on each of the components in the above architecture.

2.4 Design Decisions and Limitations

We now highlight some of the key decisions that have served our workloads well while discussing some of the key limitations of our approach. The key things that worked well include:

- **Preserving query boundaries.** One way to reuse computation could be to combine query plans of overlapping SCOPE jobs into merged query plans. However, this is inconvenient since it requires changes to submission system and hard to explain the cost of merge query to different users. Also, fault tolerance becomes more intertwined due to the hard dependency between multiple jobs. CloudViews keeps job boundaries intact while opportunistically reusing computations wherever possible.
- **Online materialization.** CloudViews materializes common computations in an online manner as part of query processing, i.e., it does not require any offline cycles for materialization. As a result, CloudViews is easier to manage operationally without requiring uses to submit additional queries while also hiding the materialization latencies in large complex query DAGs.
- **Just-in-time views.** CloudViews are also materialized just-in-time when the first query hits a particular query subexpression instance. This means that: (i) the storage space for materialized views is consumed only when the views are about to be reused, and (ii) if the workload changes and a selected subexpression is no longer found in the workload then it will automatically stop being materialized.
- **Accurate cost estimates.** Traditional view selection approaches suffer from poor cardinality and cost estimates in query optimizers [40, 43] since they explore alternate query plan expressions that may not have been executed in the past. However, by considering only the same logical subexpressions for reuse, CloudViews is able to leverage the actual runtime statistics seen in the past instances of those subexpressions. As a result, it can make better decisions about the views that could improve performance when reused and the storage costs associated with them.
- **Scalable view selection.** View selection over large workloads is non-trivial since it explodes the search space exponentially. This is because traditional view selection algorithms consider more generalized sets of views, ones that may not have appeared in past query executions, and select the most useful ones from them. However, by restricting to common subexpressions, CloudViews can run subexpressions selection to Cosmos scale by running it as a label propagation problem in a distributed manner [24].
- **Lightweight view matching.** Traditional view matching require expensive containment checks during query optimization to determine whether a query could be answered from a view or not. CloudViews replaces that with lightweight hash equality checks that only require to recursively compute a signature for each subexpression and then match them with the signatures of one or more available views.

Some of the limitations of our approach are as follows:

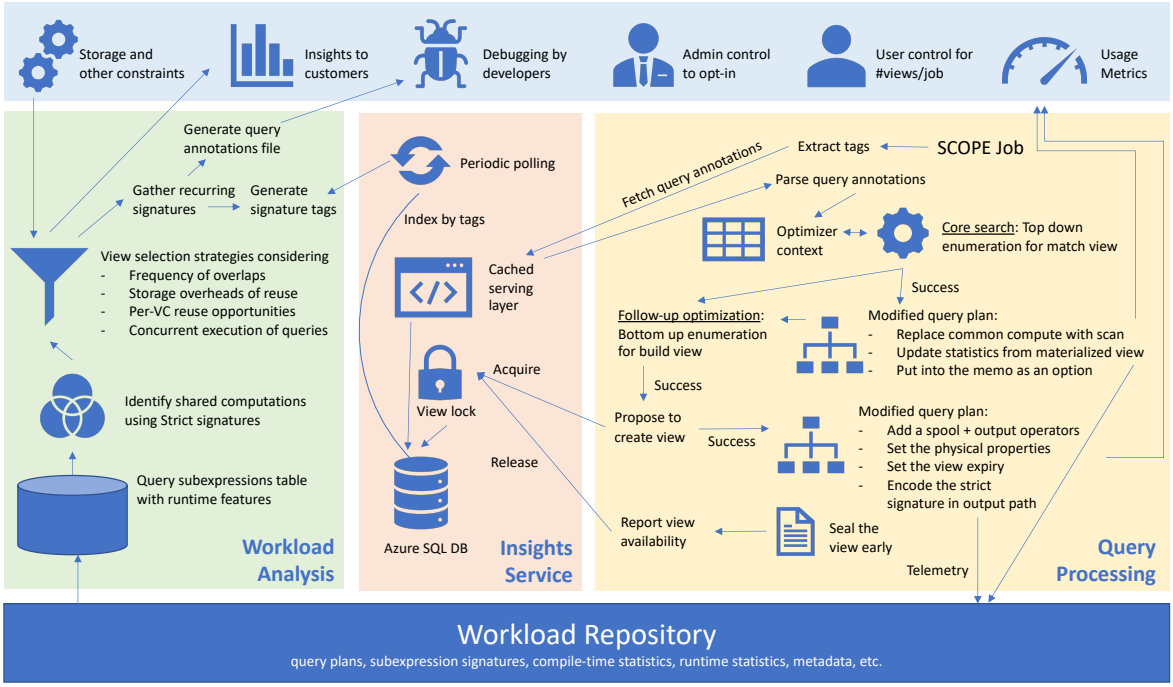


Figure 5: The CloudViews architecture for computation reuse in Cosmos.

- **Exact logical subexpression match.** The most obvious limitation of CloudViews is that it can only reuse the exact same logical query subexpressions, although they can have different physical implementations. While there are numerous opportunities for such reuse, there is even more potential for creating more generalized views and reusing them in queries that are contained in those views. We discuss this further in Section 5.
- **Concurrent queries.** CloudViews requires materializing common subexpressions before they can be reused in subsequent queries. Although the materialized views are made available as soon as the subexpression portion of the first query finishes (early sealing), still CloudViews cannot help queries that are submitted concurrently unless their submission schedule is altered, which is typically harder in production environments.
- **Not maintained.** CloudViews are treated as cheap throw-away views that are recreated whenever the inputs change. While this eradicates the need for view maintenance strategies, it also results in recreating views over sets of inputs where most have remained unchanged. This is particularly true for recurring queries with a sliding window, e.g., last seven days, where all except the most recent input in the window might remain same.
- **No DDL for user visibility or tuning.** CloudViews are created transparently to the users without registering them as any DDL statements. As a result, users do not have direct visibility into the catalog of available views at any given point nor can they reason about them. They can, however, see the CloudViews-generated files, given that they are stored in user-specified location, and even purge views whenever necessary.
- **User expectations.** CloudViews causes the first query hitting a common subexpression to slow down due to additional materialization overhead. Therefore, the users need to be informed about some queries getting impacted for overall workload efficiency.

Jobs	257,068
Pipelines	619
Virtual Clusters	21
Runtime Versions	12
Views Created	58,060
Views Used	344,966
Latency Improvement	33.97%
Processing Time Improvement	38.96%
Bonus Processing Time Improvement	45.01%
Containers Count Improvement	35.76%
Input Size Improvement	36.38%
Data Read Improvement	38.84%
Queuing Length Improvement	12.87%

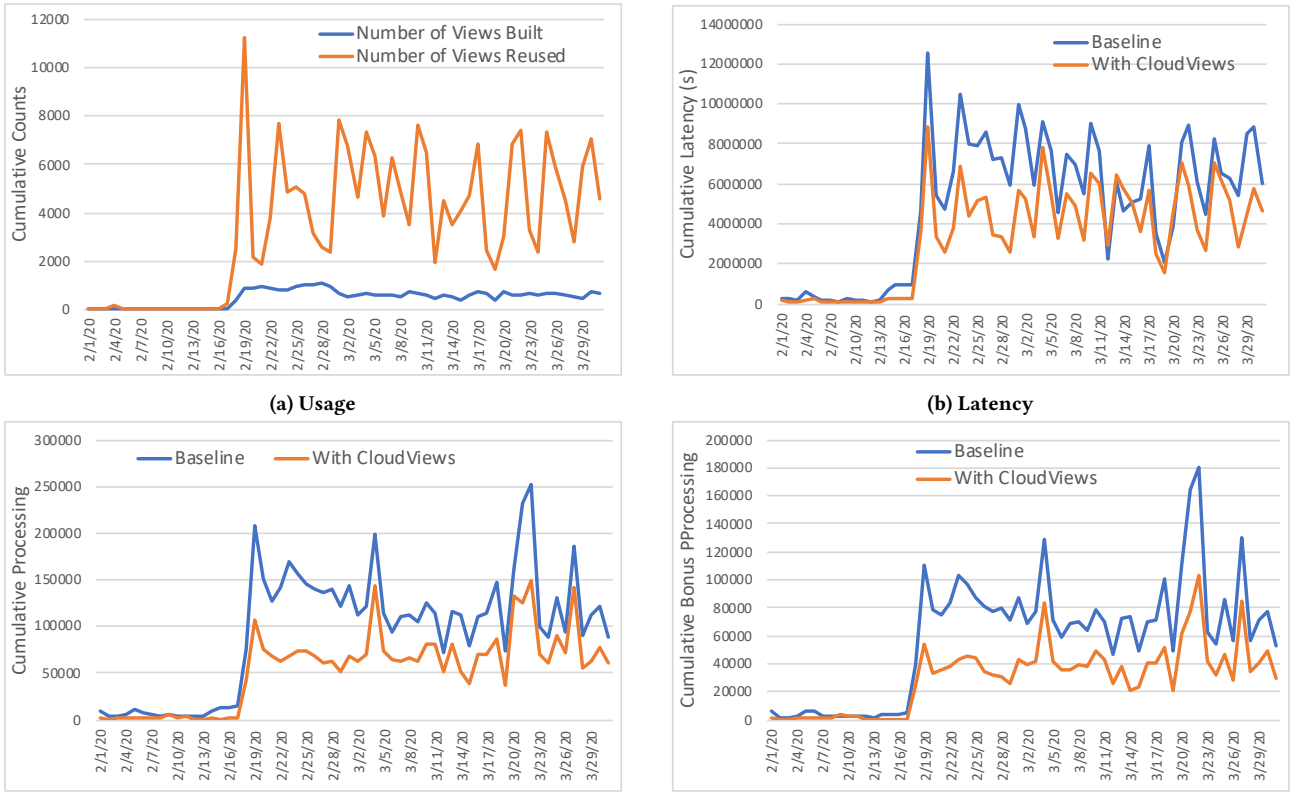
Table 1: Production Impact Summary

3 PRODUCTION IMPACT

In this section, we describe the impact of CloudViews when deployed for several customers over a two-month window (February–March 2020). Table 1 shows the summary of workload and the performance impact. Below we discuss them in more detail.

3.1 Usage

Let us first look at the usage numbers. Our current deployment strategy was *opt-in*, i.e., the feature was made available for customers and they can choose to enable it on their virtual clusters. Overall, we see more than 250k analytical SCOPE jobs across 21 virtual clusters using CloudViews. These jobs were from 619 unique data pipelines and ran over 12 different SCOPE runtime versions. Figure 6a shows the number of views materialized and



(a) Usage

(b) Latency

(c) Processing Time

(d) Bonus Processing Time

Figure 6: The usage and impact of CloudViews on production workloads.

reused over a two-month window. After an initial customer onboarding period, we see a periodic view creation and reuse pattern. Naturally, much more views are reused than created every day. Overall, approximately 58k views were created and they were reused 350k times, each view being reused almost 6 times on average. Our current eviction policies expire each of the views after one week of creation, thus consuming a fixed amount of storage (that is configured by the customers and affects the number of views selected for reuse) in the stable state.

3.2 Latency

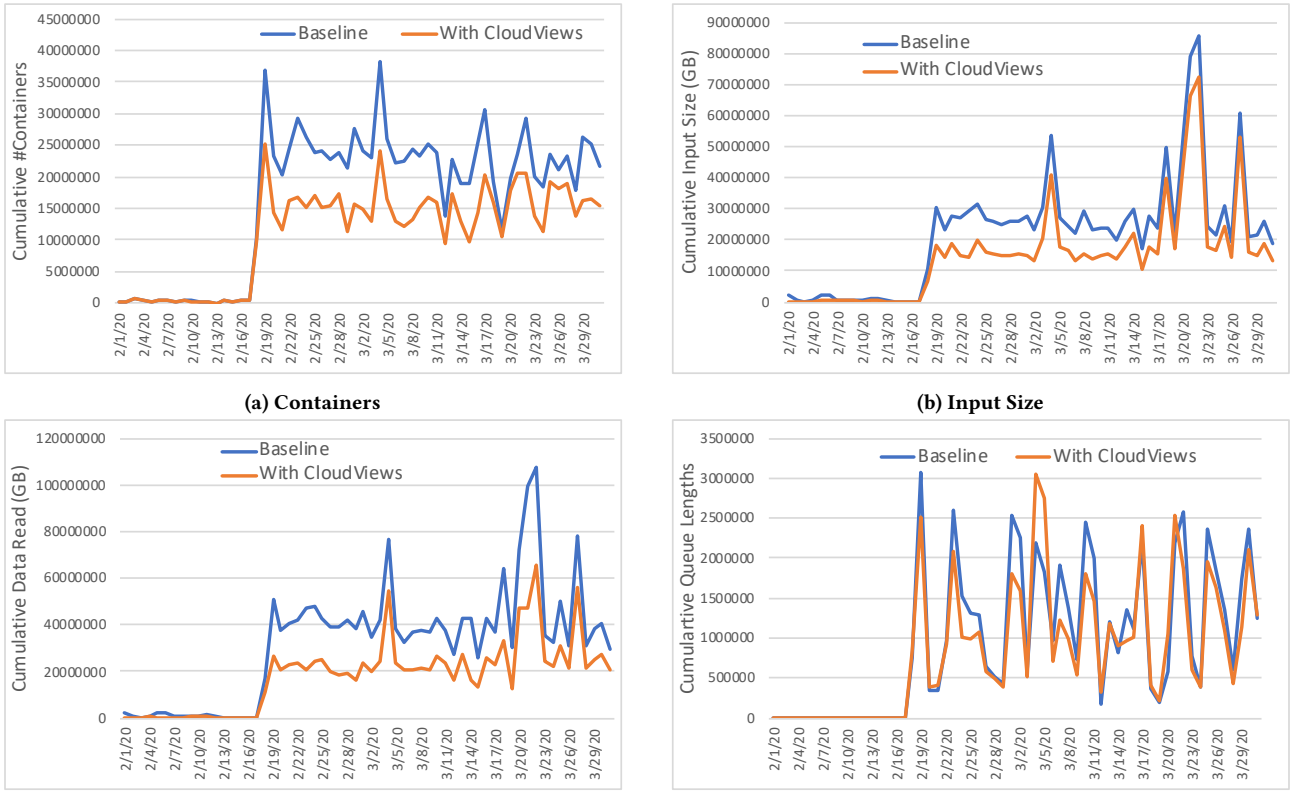
Latency is a crucial metric for customers and so we next explore the impact of CloudViews on job latencies. Figure 6b shows the daily cumulative latencies of jobs when CloudViews was enabled, compared to if it was not enabled, over the same two-month window. We can see that even though view materialization incurs an overhead, overall there is a gain in cumulative latencies of the jobs. This is because we materialize CloudViews in an online fashion in a separate stage that runs in parallel and hence the impact of latency is typically less. At the same time, we also see that the latency improvements are staggered and minimal on several days. This is because computation reuse could only improve latency if the portions of the query graph that was reused lies on the critical path of the job. Given that our view selection strategies do not optimize for that (since the objective function is to maximize for total compute), latency improvements are not guaranteed, especially with large query DAGs where overlapping computations may not be on the critical path. Still, we see a median per-job latency improvement of 15% and a cumulative overall improvement of close to 34%, that is significant for improving the customer experience in production workloads.

3.3 Processing Time

We now look at the impact on total processing time (i.e., the sum of processing time of all the containers used in the jobs) which is often considered a better measure of compute efficiency. Figure 6c shows the cumulative processing costs per day when CloudViews was enabled compared to if it was not enabled. Indeed, in contrast to latency, we can see more distinct change in processing time, with close to 39% improvement overall. This is because processing time savings do not depend on the critical path and any reuse in the query graph contributes to some savings, modulo the time spent in reading the materialized shared computation. Strictly speaking we also need to discount the extra processing time spent in writing the shared computation in the first job. Since we look at the observed processing times in the cluster all of these overheads automatically get accounted for. The processing time savings validate the utility of CloudViews to improve cluster efficiency and to free up spare resources that will let developers do more with the same set of resources.

3.4 Bonus Processing Time

Cosmos employs an opportunistic resource allocation policy to improve cluster utilization [8]. The idea is to allocate unused resources opportunistically to jobs in case they could use them, e.g., one or more stages in a job has more partitions than the number of containers available to the job or stages that could start making



(a) Containers **(b) Input Size**

(c) Data Read **(d) Queuing Lengths**

Figure 7: Other non-obvious impact of CloudViews on production workloads.

progress in parallel. We record the processing time using opportunistic resources as bonus processing time, and this is helpful to not only improve the utilization but to also improve SCOPE job performance by dynamically leveraging unused cluster capacity. Unfortunately, bonus processing also leads to unpredictability in performance, i.e., the job runtimes may vary a lot based on the unused capacity at any given time in the cluster. Therefore, reducing the reliance on bonus processing is desirable for more predictable job behavior. Interestingly, it turns out that by sharing common computations and not re-executing them with a lot of variance each time, CloudViews can reduce the reliance on bonus processing and hence improve job predictability. Figure 6d shows the reduction in bonus processing time with CloudViews. We can see a significant change in bonus processing time with an overall reduction of 45%, which is important for improving the overall system reliability.

3.5 Containers

While latency and processing are expected to be impacted by computation reuse in CloudViews, we also discover other rather unexpected implications. In particular, the total number of containers used in each SCOPE job is an important measure of resource consumption and computation reuse can also help improve that. Figure 7a shows the change in the cumulative number of containers used with CloudViews. We can see that similar to the total processing time, total number of containers also show significant improvement both for each day (and also for each job) and also overall (36% fewer containers used). This is because eliminating re-computation of large expensive chunks of query DAGs also eliminates the corresponding set of resources used to process those computations. Furthermore, due to the challenges in estimating cardinality over big data workloads, SCOPE query engine often ends up overestimating cardinalities and thus over-partitioning the intermediate outputs, leading to many more containers getting instantiated and each processing relatively smaller amounts of data [43]. Computation reuse automatically circumvents this issue by avoiding re-execution of such common computations in the first place and thus saving resources that would been otherwise be consumed due to mis-estimation. In fact, computation reuse further helps feed more accurate statistics from the previously materialized subexpressions to the rest of the query plan.

3.6 Input

Another less anticipated effect of computation reuse is the size of the input read. Figure 7b shows a sizeable reduction in the total inputs sizes read by all queries in that workload. This is because quite often the inputs datasets are filtered, selectively joined, or aggregated before they are materialized as common subexpressions, which end up being much smaller than the initial input sizes. Smaller input sizes not only reduce IO but also improve the container efficiency since SCOPE jobs are widest at the beginning (due to very large input sizes) and then their width drops significantly, causing lots of allocated containers remaining unused in a large portion of the query [7]. Smaller input sizes avoid such extreme container usage over the course of a job execution. Furthermore, it also eases the pressure on the storage layer, which is increasingly disaggregated from the compute in modern clouds [35], and thereby helps in reducing the throttling during peak load conditions.

3.7 Data Read

Apart from the input data read, let us also look at the total data read. Figure 7c shows the change in the overall data read and it is very similar to the trend of input read, although overall, data read improves by 39%, which is more than the improvements in input read. Reducing data reads eases the overall IO pressure including both the persistent store and also the local temporary store that is used to write intermediate outputs for each of the SCOPE jobs. This is significant because there could be hotspots with significant intermediate IO for large SCOPE DAGs and fewer data read can alleviate some of these hotspots.

3.8 Queue Lengths

SCOPE jobs are processed in a job service form factor, where users submit their jobs and they are queued until there are enough resources available for them to be scheduled. Interestingly, computation reuse can even help reduce the queue length due to less computations being done by each job which causes them to finish faster. Figure 7d shows the cumulative queue lengths seen by all jobs for each day in the workload, with a reduction in queue lengths on several days and an overall reduction of 13%. Shorter queue lengths improve the user experience and reduces their time to insights, enabling tighter SLAs in many cases. It also helps execute queries with more recently optimized query plans, e.g., leveraging more recently generated CloudViews, that would otherwise be missed by jobs sitting in longer queues.

4 OPERATIONAL CHALLENGES

In this section, we describe some of the operational challenges that we have faced. Note that these exclude the multiple rounds of customer feedback and feature improvements we did before deploying CloudViews in production.

- **Schedule-aware views.** Cosmos customers have built several workflow tools to schedule and monitor SCOPE jobs periodically. In some cases, these tools trigger all jobs at the start of every period, with the goal of finishing them before the period ends and to avoid missing their SLAs. Given that CloudViews requires materializing the common computation before it can be reused, jobs that get scheduled (and thus compiled) at the same time cannot benefit from such reuse. One option could be to alter the job submission and add a little lag to jobs that could reuse common computations. However, it turned out to be very hard to convince customers to change their job submission schedules. Instead, we modified our view selection algorithms to account for concurrent job submissions; specifically, we only consider subexpressions that could finish materializing before the start of other consuming jobs.
- **Per-customer view selection.** The data cooking process could create shared datasets across multiple customer virtual clusters (VCs), leading to computation reuse opportunities across multiple VCs as well. However, customers often care about the reuse and performance improvements in each of their individual VCs. This is because they want to benefit from better SLAs and do more processing on a per-VC basis. Furthermore, the cost of storing the common computations could be significant (depending on how much reuse is done) and customers often want to keep it separate for each VC. This means that selecting the views to materialize globally is not enough but rather we need to select them for each virtual cluster. Given that there are thousands of virtual clusters in Cosmos, it is not possible to run view selection separately for each of them. At the same time, a single view selection script that partitions workloads by virtual clusters needs to also consider the constraints per VC (see top left in Figure 5). It also makes it hard to maintain the single script with evolving requirements for different customers.
- **Signature correctness.** The core of CloudViews relies on a signature (i.e., a hash) to identify logical subexpressions. While this is trivial for native operators in the SCOPE engine, things can get murky with the user defined operators (UDOs) and the libraries used in it. In particular, it could be very difficult to compute the signatures in user code that involves recursively dependent libraries (there are extreme cases in Cosmos with very deep dependency chains). Traversing these long chains could slow down the entire compilation process. Furthermore, in some extreme cases, the UDOs may even contain non-determinism by design, e.g., `DateTime.Now`, `UTCNow`, `Guid.NewGuid()`, or `new Random().Next()`. It is not clear what the correct semantics are when computing signatures over such UDOs. Our approach is to exclude such extreme cases to avoid failures or incorrect results, i.e., we skip any computation reuse if the dependency chain is too long or if a UDO is found to contain non-determinism.
- **Impact of changed signatures.** While it is understood that the signatures will change with the workloads, sometimes they also evolve with new SCOPE runtime (due to changes in compilation, optimizer representation, or other code changes). As a result, all existing materialized views get invalidated. Thus, evolving signatures is very tricky since we need to keep track of changes that can affect signatures and re-run any prior workload analysis.
- **Other dependencies.** From Figure 5, we can see that CloudViews depends on other components, such as the offline workload analysis, insights service, the job manager to seal the view early, and the various customer interactions. However, these components often evolve independently and so they need to be kept in sync. For instance, the early sealing had to be ported to new job manager versions, the view storage locations need to be migrated to ADLS [13], and the insights service had to be scaled.
- **Handling GDPR requirements.** The emergence of new privacy regulations, such as [16], mean that we cannot simply look at the input paths but need to also keep track of when the inputs have changed due to *forget* requests and automatically stop consuming them henceforth. When inputs change, Cosmos handles updates as incremental files or delta updates. We handled input changes by ensuring that the input GUIDs are updated both with recurring updates and with GDPR related updates, which are handled separately in our storage layer.
- **Opt-in vs opt-out.** Given that CloudViews trades computation reuse for storage costs (and some latency overheads in the first job that hits the common computation), we need to make customers aware of the expected costs and benefits. As a result, we adopted an *opt-in* model of deployment where only the customers who bought in were onboarded. This also helped us address bug fixes and other deployment issues more gradually. However, *opt-in* also requires significant customer interaction eating up a lot

of program manager time. As a result, it is not scalable to large number of customers. Therefore, after sufficient hardening of the CloudViews feature in production, we have now started enabling it using an *opt-out* model, where virtual clusters are grouped into tiers (based on business importance) and they are automatically onboarded tier by tier, starting with the lowest tier.

- **Multi-level control.** We ended up placing several levels of control to enable or disable CloudViews. These include job-level control for individual developers to toggle CloudViews in their jobs, VC-level control for enabling or disabling specific VCs once they decide to onboard or opt-out, cluster-level to make the feature enabled or disabled across the board for the entire cluster instead of doing it for each of the thousands of VCs on each cluster, and insight service level control as the uber control for gate keeping and toggling during customer incidents.
- **Measuring impact.** Finally, while it is easy to measure performance improvements in a pre-production environment by re-running both the baseline and the modified version, it is less simple to measure performance once a feature is deployed in production. This is because it is very difficult to draw the baseline in a constantly changing production environment, e.g., when input sizes in recurring jobs change significantly [40]. It is also not possible to re-run all production jobs with CloudViews disabled to establish a baseline. Therefore, we took the following approach to identify baseline performance: we took previous instances of the queries that qualified for CloudView optimization and collected four weeks' worth of observations before enabling CloudViews on them. Thereafter, we took the 75^{th} percentile value of each of the performance metrics, such as latency and processing time, and compared them with each of the newer instance of that query once CloudViews was enabled.

5 LOOKING BACK AND FORTH

We now reflect back on our journey from research to production and discuss many of the next set of problems we see in the area of computation reuse.

5.1 From Research to Production

CloudViews has come a long way from research to production, starting from our initial research ideas in 2015 and then us spending the next five years for prototyping in the SCOPE codebase, rallying product team support around it, getting valuable customer feedback, fixing many of the bugs that were discovered, onboarding customers first by opt-in and later by opt-out approach, and finally addressing many of the operational challenges. More significantly, however, CloudViews introduced a self-tuning feedback loop to the SCOPE query engine, a significant departure from using just the compile-time estimates to leveraging how things went in the past for query optimization. Along the way, we also learned valuable lessons for doing applied research within a product group setting [23]. A key amongst them is the realization that productization of research ideas is often a much longer and sometimes even a painful journey, that requires perseverance and willingness to adapt. This is because production features need to consider a lot of corner cases. The new DevOps model where there is no dedicated testing team anymore, combined with the cloud service form factor of modern software, acts as a forcing function for product teams to put all requisite safeguards for a consistent user experience and lower maintenance overhead. Finally, applied research turns out to be a highly collaborative endeavor, right in the trenches of product teams, and therefore it needs to be appreciated as such.

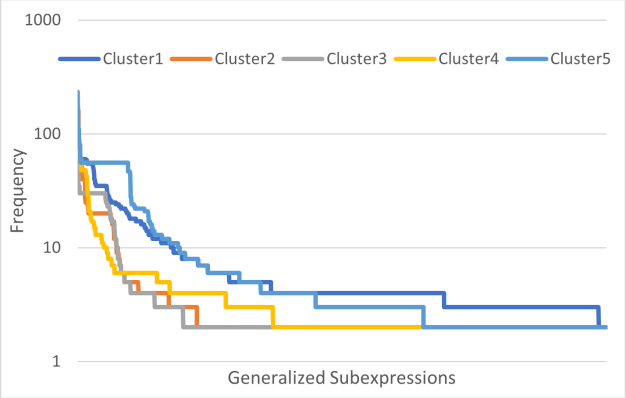


Figure 8: Opportunities for more generalized views: the x-axis shows the subexpressions that join the same sets of inputs, and the y-axis shows their corresponding frequency.

5.2 Towards Broader Workload Optimization

CloudViews helped open up the area of workload optimization for cloud query engines, leveraging the large workload telemetry that are visible, with appropriate anonymizations, in modern cloud environments [25]. This resulted in a mindset change from optimizing just a query at a time to also consider optimizing the entire workload, something which customers care a lot in order to manage their total cost of ownership (TCO). Specifically, the notion of signatures to uniquely identify query subexpressions turned out to be very helpful not just for computation reuse, but also for applications such as discovering interesting query patterns in the workload, learning high accuracy micro-models for specific portions of the workload [27], compressing workloads into a representative set for pre-production evaluation, and surfacing data and job dependencies for interesting pipeline optimizations. Likewise, the insights service evolved into an independent component that could serve many different kinds of insights, e.g., cardinality [43], cost [40], or resources [39]. The insights could be scaled and bulk loaded upfront to the SCOPE optimizer, with an end to round trip latency of around 15 milliseconds. All of the above resulted in common pieces of infrastructure that could be leveraged across several new optimizations in SCOPE, and even for other query engines like Spark.

5.3 Generalized Reuse

CloudViews identifies view candidates using per-operator signature matching, which establishes syntactic equivalence but does not consider views that differ syntactically but are otherwise logically equivalent (e.g., `SELECT * FROM Sales WHERE CustomerId > 5` and `SELECT * FROM Sales WHERE 2 * CustomerId > 10`). However, while relaxing this constraint may offer additional performance improvements by enabling the reuse of more views, computing logical equivalence is expensive and in general undecidable. Nonetheless, recent work has pushed down this cost to the point where exploiting these opportunities may be feasible for many

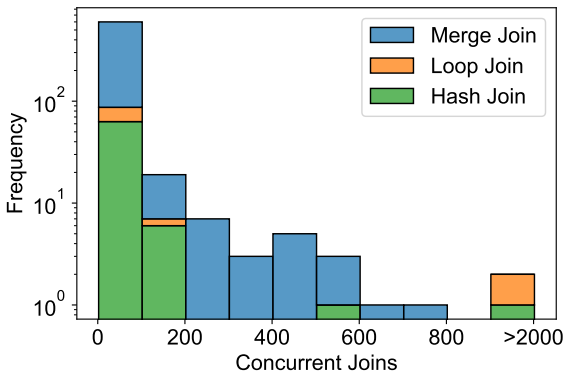

Figure 9: Concurrently executing joins on a Cosmos cluster occurring in a single day. This workload contained two outliers that were concurrently executed 2016 and 23,040 times.

queries [10, 11, 38, 48, 49]. Evaluating this precise trade-off, and quantifying the number of materialized views that more general logical equivalence would allow, remains a ripe avenue for future research.

Similarly, equivalence itself (logical or otherwise) is more restrictive than necessary for view reuse, and in many cases containment may offer similar opportunities for reusing computation (e.g., materializing `SELECT * FROM Sales WHERE CustomerId > 5` and using it to answer the query `SELECT * FROM Sales WHERE CustomerId > 6`). Like logical equivalence, containment is a hard problem (in general NP-complete, although polynomial-time algorithms exist for some subproblems), has been extensively explored in the literature, and is expensive to compute. Nonetheless, some recent work has used machine learning to evaluate containment rates [22], and many techniques used to efficiently compute logical equivalence may be applicable to containment as well.

Figure 8 shows the reuse opportunity when considering one kind of generalization: subexpressions that join the same sets of inputs. These subexpressions could still have different projections, selections, or group by operations, which could be merged to create more general materialized views and then later query could be rewritten using containment checks. Figure 8 shows the opportunity over the same five clusters as in Figures 2 and 3, and we see lots of generalized subexpressions with frequencies on the order of 10s to 100s.

5.4 Reuse in Concurrent Queries

CloudViews materializes views for reuse in subsequent queries, which is necessary for queries that are temporally non-overlapping. However, opportunities for reuse exist for *concurrent* queries, which does not require pre-materialization since intermediate results may be directly pipelined. While at first this might seem like an infrequent occurrence, we observed thousands of such opportunities per day in our production workloads. Figure 9 illustrates these opportunities for concurrently-executing joins within a single Cosmos cluster over a single day. We see that several join instances that are found to be concurrent hundreds to thousands of times.

Extending CloudViews to support concurrently executing queries and extending its feedback loop to efficiently learn the trade-offs between immediate reuse and materialization remains a ripe direction for future exploration.

5.5 Reuse in Other Engines

The idea of computation reuse goes beyond the SCOPE query engine. In fact, we adapted the computation reuse ideas to the Spark query engine as part of the SparkCruise project [36]. SparkCruise selects high utility common computations and performs automatic materialization and reuse for Spark SQL queries. Like CloudViews, SparkCruise analyzes past application workload logs to select common subexpressions for reuse. The list of common subexpressions is provided to the Spark query optimizer for future materialization and reuse. All these actions are performed automatically without any active involvement from the customer. On TPC-DS benchmarks, SparkCruise can reduce the running time by approximately 30% [36].

Even though both CloudViews and SparkCruise share the same ideas, there are differences in the target systems and the deployment environments. SCOPE query engine is developed by Microsoft and we added the signatures and optimizer rules deep inside the query optimizer. However, Spark is an open-source project and making any code changes in Spark will tie us to a specific version and delay the upgrade process in the future. Therefore, we use the optimizer extensions API in Spark to add two additional rules to the query optimizer — first for online materialization, and second for computation reuse. We also implemented an event listener for Spark SQL that can log query plans and compute signature annotations on the logical query plan object. The user simply needs to add SparkCruise library and set a couple of configuration parameters. With these changes, we can provide computation reuse in Spark without modifying its code.

Currently, SparkCruise is deployed on Azure HDInsight [32]. Azure HDInsight offers Spark cluster-as-a-service. Users can spin up ephemeral Spark clusters, run their query workloads, and delete the cluster after the job has finished. This scenario requires a fast workload-based feedback loop. To enable this fast feedback loop, we gave the control of the workflow to the end users or the data engineers. The users can schedule the workload analysis and view selection job periodically, or as often as the changes in the query workload. To help users understand their query workloads and decide whether SparkCruise will benefit their workload or not, we provide an interactive Workload Insights Notebook in Python [31]. The Workload Insight Notebook shows the workload statistics in aggregate as well as the redundancies in the workload. The results from the notebook can convince the users to enable the computation reuse feature on their workloads.

CloudViews and SparkCruise show that the benefits of computation reuse are not limited to a specific query engine. We believe that computation reuse should be a fundamental principle, like data locality and fault tolerance, when designing big data processing systems.

5.6 Other Applications of Reuse

The CloudViews mechanism of producing artifacts as part of query execution is useful in many other related applications:

- **Checkpointing.** Computation reuse can be applied for automatic checkpoint and restart in large analytical queries. The idea is to select intermediate subexpressions in a job's query plan to materialize and reuse them in case the job is

restarted after a failure. Job failures are common in production clusters, with a small fraction failing every day. There are many reasons for failures including but not limited to storage errors, lack of compute capacity, missing input files, and network timeouts [46]. These transient errors are especially problematic for long running jobs that run for hours and fail towards the end. Typically, the failed jobs are resubmitted after a short delay. However, these jobs execute from the start all over again, thus wasting valuable compute resources and also delaying the final results. CloudViews can be used in this scenario to recover quickly from failures. During the compilation phase, we use query history to find which operators are more likely to fail and add a checkpoint just before them [50]. Then, during the resubmission, CloudViews can load the last available checkpoint thereby avoiding re-computation. Going forward, it would be interesting to select views that increase cluster utilization by maximizing the reuse across queries and minimizing the recovery time at the same time.

- **Pipeline Optimization.** Enterprise data analytics consists of data pipelines where analytical queries are interconnected by their outputs and inputs. Furthermore, the output of each producer query in the pipeline is typically consumed by multiple downstream queries. Unfortunately, the producers are not aware of the right data representations, or physical designs, required by their consumers. As a result, downstream queries need to prepare the data before they can run the actual processing. Therefore, it is crucial to leverage the data dependencies for creating the right physical designs tailored to the downstream queries. This can be done by producing the right physical design as part of query execution of producer job, i.e., a CloudViews that captures the required physical designs needed by downstream jobs.
- **Sampling.** Sampling is a powerful technique used for approximate query execution. Approximate query execution helps lower the latency and cost of running complex analytical queries on large datasets [29]. CloudViews style computation reuse can be applied for reducing the cost of approximate query execution even further. This can be achieved by sampling the views created by CloudViews. Sampled views will particularly help reduce query latency and cost in queries where substantial work happens after the sampler. Likewise, we could create statistics on the common subexpressions to provide insights to data scientists and analysts.
- **Bit-vector Filtering.** Bit-vector filters such as bitmap filters, Bloom filters and similar variants have been proposed by both industry and academia to perform semi-join reductions [15]. Semi-join reductions help filter rows which do not qualify join condition early-on in the query execution plan. Bit-vector filters have a low storage and compute overhead. They are commonly used in hash joins during query processing. CloudViews style computation reuse can be applied for generating bit-vectors during query execution as well. During query execution, a spool operator could be used for generating the bit-vector filter from right child of hash join and reuse it in subsequent queries.

6 OTHER RELATED WORK

Compute reuse is a hot topic in industry and we discuss some of the trends in other major companies below.

Snowflake is a cloud-based data warehouse company. The Snowflake design caches results of every query executed in the past 24 hours [41]. Users can then postprocess the cached result for further analysis. However, caching only the final results has limited applicability. CloudViews on the other hand reuses computation at any point in the query plan and is thus a superset of result set caching performed by Snowflake.

Google BigQuery is an interactive big data system that supports different kinds of caching and computation reuse. In particular, similar to Snowflake, it also supports caching arbitrary query results [18]. However, same as Snowflake, users have to manually rewrite their queries against the cached query results. BigQuery also supports materialized views that are maintained and support automatic query rewriting [17]. However, it only supports queries with aggregate function to simply the query rewriting problem.

Amazon Redshift is cloud data warehouse product from Amazon. Redshift enables materialized views to be automatically refreshed with automatic query rewrites [3]. However, the materialized views are still created manually and unlike online materialization in CloudViews, the responsibility of creating materialized views in Redshift lies with the user.

Alibaba [2] allows users to create materialized views. Once created, the materialized views could be used in queries. However, Alibaba's data warehouse engine requires manual re-writes to reuse materialized views. Again, unlike the automatic materialization and reuse in CloudViews.

Oracle deploys an algorithm called extended covering subexpressions (ECSE) to select materialized views for reuse [1]. It performs pairwise selection of 'join sets' and deploys other heuristics to reduce the search space to polynomial size. The authors test ECSE against a two-node configuration against a small number of queries, and intend to deploy the technique to their cloud in the future. By contrast, CloudViews is not restricted to this smaller class of candidate materialized views and has been continuously executing at extreme scale over hundreds of thousands of queries per day.

Finally, there are several other works that apply computation reuse in other settings. Yuan et al. [45] apply computation reuse on query workloads from Alibaba. Inspired by BigSubs algorithm [24] of CloudViews, they formulate the subexpression selection problem as ILP (Integer Linear Programming) and use deep reinforcement learning to solve the ILP. AStream [30] is a shared computation reuse framework for streaming queries. AStream can dynamically adapt to changing streaming query workloads without affecting the query execution topology. Computation reuse was also applied on Machine Learning workloads by Helix [44]. Helix finds common intermediate computation between iterations and automatically materializes some of them for future iterations.

7 CONCLUSION

Large-scale data processing infrastructures are key to data-driven decisions in modern enterprises. Unfortunately, the scale and complexity of these infrastructures could also make them unwieldy and highly inefficient. In this paper, we describe how large scale data preparation, also referred to as data cooking, in the Cosmos big data infrastructure at Microsoft often leads to

redundant computations across different data pipelines and how computation reuse naturally augments the data cooking processing by fine-tuning the cooked datasets with more shareable ones. We show the impact of CloudViews, an automatic computation reuse infrastructure that we had build in the SCOPE query engine, over large production workloads and discuss many of the operational challenges that we faced. CloudViews has not only helped improve operational efficiency (37% less aggregated processing time) and customer experience (34% less aggregated latency), but it has also opened up new avenues and reusable infrastructure for a broad range of feedback-driven workload optimizations — the stepping stones towards a self-tuning intelligent cloud.

ABSTRACT

Major news media frequently uses the method of *news timeline summarization* to summarize important daily news over major events across the timeline. While various sophisticated methods have been proposed to generate both concise and complete news timelines, in practice, generating timelines from a large number of news articles not only faces quality issues but also encounters the challenge of generation speed, which all existing methods have neglected. To mitigate these issues, in this work, we propose to speed up timeline generation by dividing the whole summarization task into sub-summarization tasks, adopting the "divide and conquer" philosophy: (1) date selection and (2) text summarization.

Furthermore, since existing methods in news timeline summarization pay less attention to the date selection than text summarization, in this paper, we re-examine the role of date selection in news timeline summarization and demonstrate that accurate date selection "alone" can significantly contribute to the task of news timeline summarization. Leveraging on the explicit date selection, then, we propose a simple yet fast and effective news timeline summarization method, named WILSON (neWs tImeLine SummarizatiON). Experimented on two widely used timeline summarization benchmark datasets, *timeline17* and *crisis*, empirical evaluation shows that WILSON outperforms state-of-the-art approaches in both speed and ROUGE scores, significantly improving ROUGE-2 F1 scores by 9.5%~17.7% and reducing generation time by two orders of magnitude. A further user study with professional journalists also validates the superiority of WILSON. Finally, we build a real-time news timeline summarization system and achieve encouraging results on an industrial-level corpus.

1 INTRODUCTION

Along with the rapid development of web services, an increasing number of news articles are published daily, describing both major and minor events worldwide. Due to the tremendous amount of news articles being produced every day, readers easily get lost in this information flood. Fortunately, *news timeline*, which summarizes each event with primary messages in a chronological order, makes it easy for readers to gain key insights and understand the evolution of news events. As such, many major news media has adopted the idea and have frequently produced news timelines of major news events. For example, Table 1 describes how 2018 North Korea-United States Singapore summit finally became a reality. Note that as the example illustrates, creating a news timeline requires the resolution of two sub-problems: (1) choosing of an ideal number of days among hundreds or thousands of candidate days, and (2) generating succinct text summaries per days.

Feb. 25, 2018 North Korea is "willing to have talks" with the United States, South Korea says, as the PyeongChang Winter Olympics close in a burst of fireworks and diplomacy.
Mar. 8, 2018 Trump agrees to meet Kim for talks, an extraordinary development after months of heightened tension. Kim commits to stopping nuclear and missile testing.
Mar. 27, 2018 Kim makes a clandestine visit to Beijing to discuss the negotiations with South Korea and the United States.
...
Jun. 1, 2018 Trump says the summit will take place June 12 as planned. During a visit to the White House, a North Korean hands Trump a large letter from Kim.

Table 1: An example timeline by The Washington Post about the summit between United States and North Korea.[1]

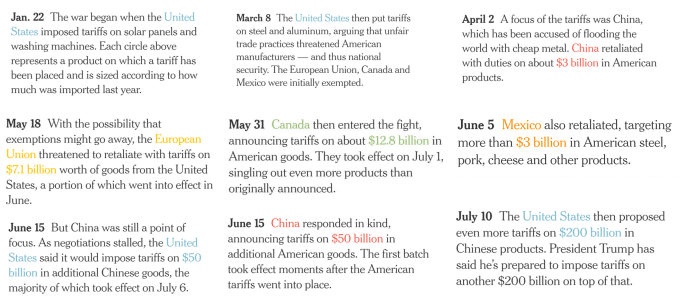
1.1 Industrial Use Case

Combined with visual or interactive interfaces, news timelines can provide a convenient way to compress overloaded news to audience. Figure 1 illustrates two real timeline example on two major US newspapers. Figure 1 (a) is an interactive timeline summarization about Trump-Russia investigation from The Washington Post, while Figure 1 (b) is a text-based timeline summarization about China-US Trade War from The New York Times. To help readers better understand the evolution of each news event, journalists take time to collect and organize related news articles, figure out major events and story lines, and "manually" summarize them in a chronological order. As events such as natural disasters and political issues can span from several months to multiple years and involve thousands of news articles, such a manual process cannot scale well. As this process is both time-consuming and labor-intensive, currently, despite the popularity of the concept, not all newspapers are able to quickly produce such news timelines.

To address this challenge, several automatic news timeline summarization methods have emerged in recent years [4, 12, 21, 22, 25, 27, 29]. By and large, there are mainly two categories of news timeline generation methods. One is aimed at separating

[1] https://www.washingtonpost.com/graphics/2018/national/trump-kim-jong-un-timeline/

(a) Trump-Russia investigation (The Washington Post)



(b) China-US Trade War (The New York Times)

Figure 1: News timeline summarization examples on major news media

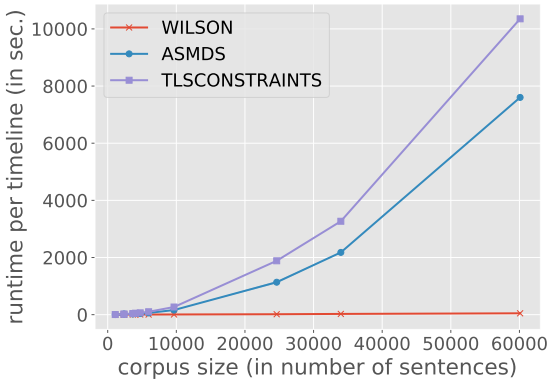


Figure 2: Running times over varying corpus sizes using *Timeline*17 and *Crisis*. ASMDS and TLSCONSTRAINTS are the two state-of-the-art methods that use submodular framework. Note that, as both of them are not sufficiently scalable to the large corpus, we followed [12] to use a reduced corpus here.

different stories from a whole news corpus, such as using variants of topic modeling [8, 31] and neural networks [30]. Another category focuses on generating a series of chronological summaries for one specific event from only relevant news articles [12, 22, 28], where the first categories can serve as pre-processing to find relevant news articles for each event. In this paper, our focus is on the latter category in an unsupervised manner.

However, majority of existing methods focus only on the quality of generated timelines and neglect the generation speed. For example, the state-of-the-art unsupervised approach adopts submodular framework [12] and requires the pairwise similarities for all tokenized sentences, which could be over 100,000 per timeline. This yields extremely slow running time, as clearly demonstrated in the comparison of running times in Figure 2. As the compression rates of timeline summarization vary with events and journalists may not know the exact value beforehand, iterative trials with different values are necessary, which makes faster timeline generation even more important. Therefore, in this work, we are greatly motivated by real industrial use cases to speed up the timeline generation by dividing the whole summarization tasks into multiple small summarization tasks by date separation.

News timelines are composed of both salient dates and daily summaries, but previous studies mainly focus on modeling relationships among article contexts while paying less attention to date selection. For example, some models [14, 24, 26, 27] just treat date information the same as text information and include it as one of the features, while others [4, 19] simply use date frequency to resolve events. Although simply modeling text correlation shows good performance on both timeline summarization and date selection [12], it is not clear how date selection will contribute to news timeline summarization. In addition, existing state-of-the-art unsupervised approaches mostly include global optimization, which helps daily summaries to be relevant to the topic. However, using global optimization also makes daily summaries less specific per each day and very time-intensive to generate timelines. Therefore, considering both the quality and speed of news timeline summarization, this paper makes the following main contributions:

(1) We re-examine the role of date selection in timeline summarization and show that, even without considering contextual correlation across different dates, accurate date selection is sufficient to generate high-quality news timelines. More importantly, although ignoring contextual correlation across dates leads to a lower empirical upper bound than other models, all of the previous approaches still fail to reach this lower upper bound, and they are not even close.
(2) Leveraging the explicit date selection, we propose a simple but fast and effective unsupervised news timeline summarization method, named WILSON. Experimented on two widely used timeline summarization datasets, WILSON outperforms state-of-the-art approaches in both speed and ROUGE scores, significantly improving ROUGE-2 F1 score by 9.5%~17.7% and reducing generation time by two orders of magnitude.
(3) To our best knowledge, WILSON is the first work to include an evaluation by professional journalists in news timeline summarization. Through manually comparing the machine-generated news timelines with corresponding human-generated ones, journalists confirm that our approach produces better timelines than competing methods.
(4) Based on the proposed WILSON, we build a real-time news timeline summarization system on an industrial-level news corpus.

2 THE PROPOSED METHOD: WILSON

In this section, we introduce our proposed method, named WILSON (neWs tImeLine SummarizatiON), also illustrated in Figure 3. Besides the pre-processing modules such as temporal tagging

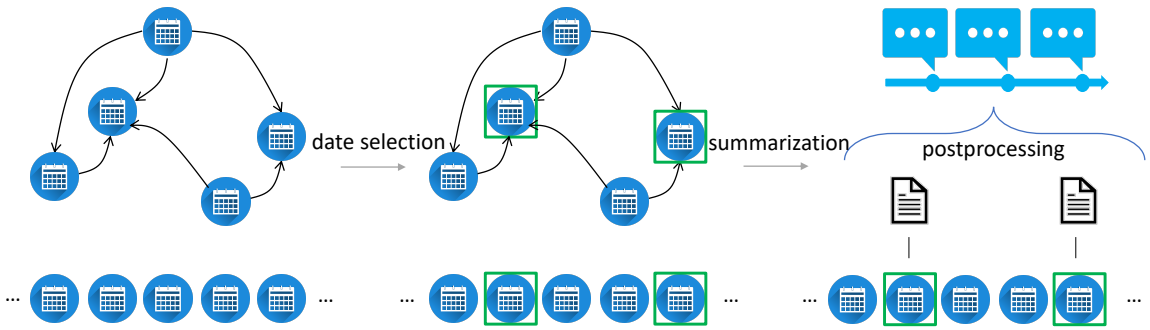

Figure 3: Workflow of our proposed method–WILSON.

and search engine indexing, WILSON mainly consists of two components – explicit date selection and text summarization for each selected date.

2.1 Problem Formulation

A news timeline can be viewed as a series of chronologically ordered daily summaries over main events, denoted by (d_i, S_i), where d_i and S_i stand for i_{th} date and i_{th} summary. Thus, news timeline summarization can be formulated as:

Definition 1 (News Timeline Summarization). *Given a corpus of articles C_q, which is associated with a topic query q and a time window $[t1, t2]$, the process of automatic timeline generation is to produce a series of daily summaries $(d_1, S_1), ..., (d_T, S_T)$, where $t1 \leq d_i \leq t2$.*

For both readability and reliability of generated news timelines, we follow existing works and utilize extractive summarization, which directly selects sentences from the corpus as summaries. More specifically,

Definition 2 (Extractive News Timeline Summarization). *Given a corpus of articles C_q, which is associated with a topic query q and a time window $[t1, t2]$, the corpus is first tokenized to dated sentences $\{(date_i, sentence_i) | date_i \in [t1, t2], sentence_i \in C_q\}$ by a date expression in the sentence and/or by the publication date, then the timeline generation is to produce a series of daily summaries $(d_1, S_1), ..., (d_T, S_T)$, where $t1 \leq d_i \leq t2$ and $S_i = (sentence_{i1}, ..., sentence_{iN})$.*

The number of selected dates T and sentences N are hyper-parameters and chosen by users to control the compression rate of the generated timelines. Date selection is evaluated by f1 scores and summaries are evaluated by ROUGE [10].

2.2 Date Selection

We use HeidelTime [20] to tag temporal expressions in sentences during pre-processing stage and start with an unsupervised date selection algorithm [23] to select the most salient dates: (1) we build a date reference graph with dates as nodes and reference relationships as edges; (2) then, we run the PageRank algorithm [16] on the graph and select the top T ranked nodes as the most salient dates. Date references refer to the sentences s_{ij} that are published on $date_i$ while mentioning $date_j$. We experiment with 4 types of edge weights as follows:

- W1: the number of reference sentences $|s_{ij}|$
- W2: temporal distance $|date_j - date_i|$ in days
- W3: W1 $*$ W2, which considers both frequency and temporal distance.
- W4: We adopt BM25 [18] to estimate the relevance of sentences to the query, and use max $BM25(s_{ij}, q)$ as edge weight for each reference.

Edge Weight	Date F1	Rouge-1 F1	Rouge-2 F1
timeline17			
W1	0.5512	0.3905	0.0969
W2	0.5528	0.4029	0.1002
W3	0.5628	0.4009	0.0995
W4	0.5068	0.3934	0.0934
crisis			
W1	0.3022	0.3476	0.0715
W2	0.2838	0.3604	0.0715
W3	0.2710	0.3575	0.0738
W4	0.2925	0.3509	0.0726

Table 2: Performance of different edge weights

For example, considering $date_i$=2018-06-01, $date_j$=2018-06-12, and s_{ij} composed of only two sentences, i.e. *Trump says summit with North Korea will take place on June 12* and *The summit will take place on June 12.* Then, W1 is the number of sentences and equals 2, while W2 is the difference between 2018-06-01 and 2018-06-12 in days and equals 11. Accordingly, W3 equals W1 $*$ W2 and is 22. For W4, we treat each sentence as a document, use topic query q to score each document with BM25, and take the maximum BM25 score as W4.

As Table 2 shows that all four edge weights yield comparable results, date reference relationship alone can extract as accurate date selections as topical information. Since constructing topical relationships across dates takes extra time, we finally adopt W3 as the edge weight to select the most salient dates in the rest of this paper. Note that, for completeness, we also generate daily summaries to obtain a complete news timeline per each date selection and evaluate the summaries by ROUGE scores in Table 2. The details about daily summarization is introduced in the next subsection.

Although the occurrence of an event signals its importance within the news timeline [4] and is well leveraged in existing timeline summarization algorithms, we note that the occurrence of events is also correlated with the recency of events, where past events occur earlier and are more heavily reported than recent events. Consequently, existing approaches may suffer from this issue. For example, approaches that optimize the summaries to

Date Selection	Date Coverage (±3)	Date F1	ROUGE-1	ROUGE-2	ROUGE-S*
Timeline17					
Uniform	0.8398	0.4475	0.3896	0.0917	0.1598
W3	0.7828	0.5668	0.4000	0.0995	0.1676
W3 + Recency	0.8111	0.5542	0.4036	0.1005	0.1702
Crisis					
Uniform	0.5932	0.1325	0.3387	0.0570	0.1138
W3	0.5459	0.2726	0.3573	0.0738	0.1246
W3 + Recency	0.5885	0.2748	0.3597	0.0760	0.1270

Table 3: Performance on date coverage

recover the whole corpus, such as ETS [29] and TILSE [12], will generate more summaries on past events.

In addition, as most references in articles refer to past events, the current date selection algorithm tends to give too much weight on old dates and will also result in timelines that lack recent dates. For a better illustration, we present the Cumulative Distribution Function (CDF) of the date duration between selected dates and the start date in Figure 4. As expected, both TILSE (Submodular) and date selection via PageRank (Tran et al.) tends to select more old dates, while the date distribution of ground-truth timelines is generally more uniform. Thus, we use the standard deviation of differences between consecutive dates to measure the uniformity of date distribution:

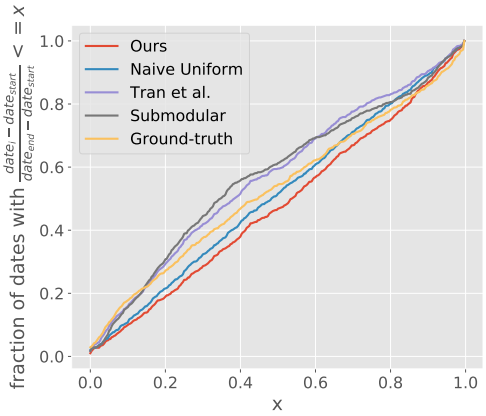
Definition 3 (Uniformity of Date Selection). *Given a series of selected dates $\{d_1, d_2, ..., d_T\}$ in chronological order, we regard the differences between consecutive dates as $\{diff_i = d_{i+1} - d_i\}$, then define its standard deviation $\sigma = \sqrt{\frac{1}{T}\sum_{i=1}^{T}(diff_i - \bar{diff})^2}$, as the uniformity of date selection.*

2.2.1 Recency Adjustment. To add more weights on recent dates, we leverage the Personalized PageRank algorithm [1], where the restart distribution is not uniform. More specifically, we weight each date node $date_i$ by $W_i = \alpha^{-d_i}$, where $d_i = |date_i - date_{start}|$. α ranges from 0 to 1 and is used to control the restart distribution. In practice, we use a grid search to find the α that gives the most uniform distribution in the date selection, then use the chosen dates for news timeline generation.

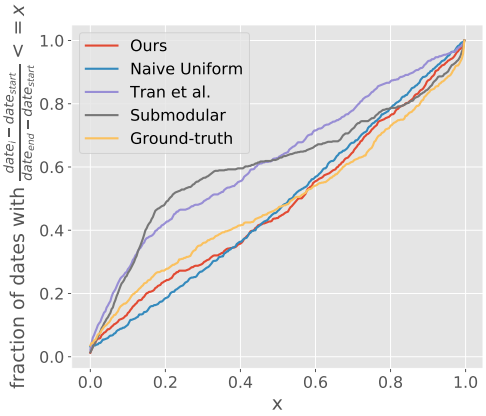
2.2.2 Date Coverage. To better check the coverage of generated timelines, besides f1 score on date selection, we also measure the date coverage, e.g., if any day of ground-truth date $g_i \pm 3$ days lies in the generated timeline, g_i will be considered to be covered and we will measure what percentage of ground-truth dates are covered per timeline. For comparison, we also generate news timelines on truly uniformly distributed dates and present the results in Table 3. As we can see, although truly uniformly distributed dates cover the most ground-truth dates, due to the low accuracy in the date selection, the generated daily summaries are poor. However, adding recency adjustment with uniformity contributes to date selection in coverage, thus yields better timeline summarization.

2.3 Daily Summarization

Having selected the most salient dates, next, we divide timeline summarization into sub-summarization tasks. Although daily summarization tasks can be accomplished by any supervised or unsupervised document summarization algorithms, we intend to use a simple daily summarization method to validate the effectiveness of our explicit date selection, as complicated summarization techniques may introduce extra improvements in the performance. Specifically, we utilize the classic TextRank



(a) Timeline17



(b) Crisis

Figure 4: Distribution of selected dates among different approaches.

[13] to generate daily summaries. Similar to the task of date selection, TextRank constructs a sentence graph with sentences as nodes and similarity scores as edge weights. In particular, we use BM25 [18] to compute edge weights [2] and run PageRank on this directed graph to select the most important sentences as daily summaries.

2.3.1 Post-processing. Dividing large text summarization tasks into smaller ones greatly speeds up timeline generation, and these sub-tasks can naturally be further accelerated through parallel processing. Conducting text summarization on a daily basis rather than on the whole corpus, however, ignores temporal correlation and thus introduces redundancy in summarization. To remove redundancy across dates, therefore, we incorporate post-processing to re-rank daily summaries based on the whole summarization. Similar to MMR [3], instead of directly using daily summaries, we add sentences into timeline summarization by their daily ranks and only accept sentences whose maximum cosine similarity with selected ones is smaller than a threshold (e.g., < 0.5).

2.4 News Timeline Generation Algorithm

The generation algorithm of WILSON is summarized in Algorithm 1. First, we build a date reference graph based on the date

Algorithm 1: Algorithm for WILSON

Input : temporally tagged sentences $C = \{(date_i, sent_i)\}$
preset number of dates T
preset number of daily sentences N

Output : a series of daily summaries $(d_1, S_1), ..., (d_T, S_T)$

Build a date reference graph based on date co-occurrence $\{(date_i, date_j) | (date_i, sent_k) \in C \ \& \ (date_j, sent_k) \in C\}$;
Compute edge weight according to W3 in Section 2.2 ;
selected_dates $\leftarrow \emptyset$;
for *Grid search* $\alpha \in (0, 1)$ **do**
    Compute personalized node weight for each date $date_i$ *using* $W_i = \alpha^{-|date_i - \min_k(date_k)|}$;
    Run personalized PageRank to select the top T *ranked dates as a date selection candidate ;*
    Based on Definition 3, compute the uniformity score of this date selection candidate ;
    selected_dates $\leftarrow$ *save the date selection with the best uniformity score as* $(d_1, d_2, ..., d_T)$;
end for
for $d_i \in$ *selected_dates* **do**
    Find all sentences on d_i
    $C_i \leftarrow \{sent_k | (date_k, sent_k) \in C \ \& \ date_k = d_i\}$;
    Run TextRank on C_i *to rank all sentences by importance score in a max heap* H_i ;
    Initialize selected sentences $S_i \leftarrow \emptyset$;
end for
repeat
    Currently selected sentences $S \leftarrow \bigcup_{i=1}^{T} S_i$;
    Top ranked sentence per day $H \leftarrow \bigcup_{i=1}^{T} H_i[0]$;
    Remove top sentences: heap_pop(H_i*) for* $i \in$ *[1, T];*
    Remove sentences from H *that have maximum similarity > 0.5 with existing sentences in* S ;
    Add remaining sentences in H *to the corresponding daily summary* S_i *only if* $|S_i| < N$;
until *(all* $|S_i| = N$*) or (all* $|H_i| = 0$*);*
return $(d_1, S_1), ..., (d_T, S_T)$

pairs that appear in the same sentences. Second, we extract features to compute weights for the graph edges and run personalized PageRank to pick the most salient T dates. More specifically, we include the recency adjustment strategy to improve the date coverage of selected dates. Then, we use TextRank to rank all sentences on each selected date. According to the sentence ranks per selected date, we post-process the sentences in batch and remove sentences that could introduce redundant information on existing selections. Finally, our algorithm produces a series of compact daily briefs as the summarized news timeline to help people better understand the evolution of the corresponding news event.

2.5 Complexity Analysis

In this section, we briefly provide a time complexity analysis of our approach with a comparison to the submodular framework. Denote T as the total number of dates, N as the average number of sentences per date, t as the desired number of dates and n as the desired number of sentences per date in the summarized timeline. According to PageRank on the dense graph, date selection takes $O(T^2)$ while t daily summarization tasks take $O(t * N^2)$. Thus the total time complexity of WILSON is $O(T^2 + t * N^2)$.

For submodular framework [12], which conducts global summarization, it takes $O((TN)^2)$ to obtain pair-wise similarities for all sentences and takes $O(t * n * T * N)$ to iterate $t * n$ times to select each individual sentence in a greedy manner. Therefore, the total time complexity is $O((TN)^2 + t * n * N * T)$. In Figure 2, the corpus size is defined as the total number of sentences (i.e. $T * N$). As expected, the submodular frameworks show quadratic growth with a time complexity $O((TN)^2)$, while our approach is almost linear to the corpus size with a time complexity $O(T^2 + t * N^2)$.

Given the approximation that T and N are in the same order of magnitude (based on Table 4), WILSON runs faster than the submodular framework by a factor of $O(\frac{T^2}{t})$. Given around 10% date compression rate ($\frac{t}{T}$) and T in hundred level, theoretically, our approach could gain over three orders of magnitude improvement in generation speed. Note that, due to the scalability issue of the submodular framework, [12] filtered sentences with predefined keywords to reduce N by over one order of magnitude, reducing the time complexity in practice. Given ~10% filtering rate, our approach could still gain about two orders of magnitude in generation speed, which is consistent with experiments in Table 7.

Dataset	# of topics	# of timelines	average per timeline		
			# of doc	# of sents	duration days
Timeline17	9	19	739	36,915	242
Crisis	4	22	5,130	173,761	388

Table 4: Dataset overview

3 EMPIRICAL VALIDATION

3.1 Set-Up

3.1.1 Datasets. We run experiments on *timeline17* [24, 25] and *crisis* [22]. Both datasets[2] consist of journalist generated timelines from major news media such as CNN, BBC and Reuters, and a corresponding corpus of articles per topic (e.g. H1N1 flu and Egypt war). More specifically, *timeline17* contains 19 timelines from 9 topics, while *crisis* involves 22 timelines from 4 topics. An overview of the two datasets is shown at Table 4.

3.1.2 Competing methods.

- **Random**: The system generates daily summaries by randomly selecting sentences from the corpus.
- **MEAD** [17]: a classic centroid-based multi-document summarization system.
- **Chieu et al.** [4]: a multi-document summarization system that uses date related TFIDF scores to measure sentence importance among corpus.
- **ETS** [29]: an unsupervised timeline summarization algorithm via simultaneously optimizing multiple heuristic metrics, including relevance, coverage, coherence, and diversity.
- **Tran et al.** [25]: a supervised timeline summarization algorithm, which extracts various features from sentences and leverages learning to rank techniques.
- **Regression** [26]: a supervised approach that formulates sentence selection as a linear regression problem.
- **Wang et al.** [27]: a supervised approach that formulates sentence selection as a matrix factorization problem.

Table 5: Results on Timeline17

- **Liang et al.** [9]: a dynamic evolutionary framework leveraging distributed representation for timeline summarization.
- **ASMDS (TILSE)** [12]: TILSE is a state-of-the-art unsupervised timeline summarization approach, which incorporates submodularity-based multi-document summarization framework with temporal criteria.
- **TLSCONSTRAINTS (TILSE)** [12]: as a variant of TILSE, this method uses the same objective funtion as ASMDS but adopt different temporal constraints.

3.1.3 Measurement. Among all the baselines, TILSE is the only one with source code available. Consequently, for all the other baselines, we follow the existing works [9, 25, 27], which conduct experiments on *timeline*17 with settings mentioned at the beginning of Section 5.2 in [25] and directly report the baseline results from previous papers. More specifically, in the generated timeline, the number of selected dates T is set to the number of dates in each ground-truth timeline, while the number of sentences per day N is forced to be the rounded value of the average number of sentences per date from the ground-truth timeline.

To fairly compare with TILSE, we re-run the their code, follow all their pre-processing, including text cleaning and keywords filtering, and conduct experiments on exactly the same sentence corpus per timeline generation. Note that, [12] used a slightly different setting from previous papers: 1) for Timeline17 dataset, they mixed articles of the same topic from different news agencies together, which yields a bit higher ROUGE scores in timeline generation; 2) it suffers from the scalability issue and thereby uses filtered sentence corpus for both datasets. Thus, we followed their settings for a fair comparison with TILSE in Table 7. Wall time is measured on a 24-core 128GB machine.

3.1.4 Evaluation Metrics. The commonly used summarization metrics, ROUGE scores [10], including ROUGE-1, ROUGE-2 and ROUGE-S* F1 scores, are adopted to evaluate the agreement between machine-generated and journalist generated timelines. Moreover, to be consistent with TILSE comparison, we also include time-sensitive ROUGE scores as additional measurements [11]. More specifically, *concat* ROUGE scores totally ignore the time information by directly concatenating all texts together, while *agreement* ROUGE scores only consider the generated daily summaries on the groundtruth dates, and *align* ROUGE scores discount the quality of generated daily summaries by their distance to the corresponding groundtruth date. Last but not least, we test for significant improvements using an approximate randomization test [15] with a p-value of 0.05.

Liang et al.	0.268	0.057	0.054
WILSON **(Ours)**	**0.352**	**0.074**	**0.123**

Table 6: Results on Crisis

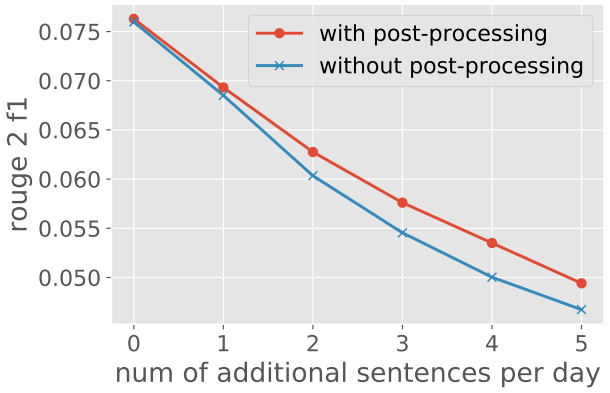

Figure 5: Concat Rouge 2 f1 scores when adding more sentences on each date on Crisis.

3.2 Performance Comparison

Table 5 and 6 shows that our unsupervised approach WILSON outperforms all baselines in ROUGE-1 and ROUGE-S* f1 scores by a significant margin, and is only second to [27], a supervised approach, and [9] in ROUGE-2 f1 score on Timeline17 dataset.

In addition, Table 7 illustrates that WILSON outperforms the state-of-the-art unsupervised framework TILSE in all ROUGE metrics. Averagely, our method outperforms the submodular approaches by 12.9% in concatenate ROUGE-2 scores, by 58.3% in agreement ROUGE-2 scores, and by 40.1% in alignment ROUGE-2 scores. More importantly, our method also gains two orders of magnitude improvement in generation speed, making it possible to generate news timelines in a real-time manner.

In Table 7, We also include multiple variants of WILSON for ablation analysis. WILSON-uniform simply adopts uniform date selection, while WILSON-Tran directly uses W3 as edge weight without recency adjustment. As expected, selecting uniformly distributed dates results in the worst summarization, while including recency adjustment improves time-sensitive ROUGE-2 scores by 9.0%~21.6%.

Overall, comparing with all competing approaches, the performance improvement of our method is higher in *Crisis* dataset. One explanation is that *Crisis* dataset contains more articles and spans a longer period, making it difficult for those competing approaches to correctly identify the long-term event dependencies, while our method mainly focuses on local dependencies.

3.2.1 Effectiveness of Post-processing. In Table 7, we observed that considering correlation across different dates and reducing redundant daily summaries are seemingly minor, especially on *Crisis* datasets. Different from *Timeline17* datasets, *Crisis* datasets consist of more compact daily summaries, where more than 90% dates contain only 1 sentence. Although reducing redundancy across dates is not necessary for timelines with compact daily summaries, we intend to verify the effectiveness of

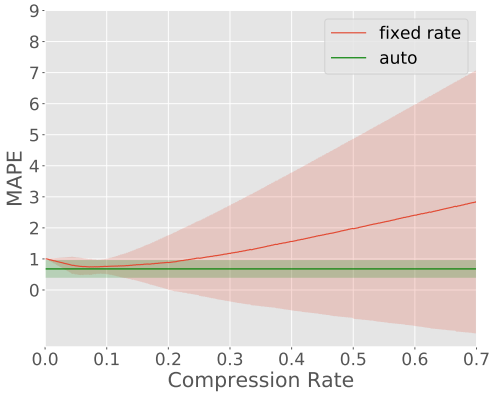
timeline17		
Submodularity framework [12]	0.50	0.18
Ground-truth date + Daily summary	0.41	0.11
Crisis		
Submodularity framework [12]	0.49	0.16
Ground-truth date + Daily summary	0.42	0.10

Table 8: Empirical upper bound of submodularity framework and our two-stage method

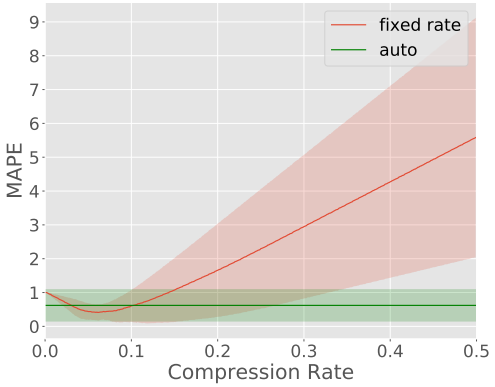
post-processing for timelines with abundant daily summaries. Instead of using the exact number of sentences per date in the ground-truth timelines, we generate timelines with more sentences per date, which is more practical as the true numbers are unknown. As demonstrated in Figure 5, simply adding daily summaries together suffers from the redundancy issue and using post-processing indeed helps. Note that we use the ROUGE-2 f1 score, so the overall scores going down with more sentences is because more generated texts lead to lower ROUGE accuracy.

3.2.2 Empirical Bounds. Empirical bounds of our two-stage method are given in Table 8, where we use ground-truth dates as date selections for daily summarization. Note that, besides using ground-truth dates, the upper bounds of the submodularity framework [12] also employ ground-truth summaries and are obtained by directly optimizing ROUGE f1 scores in a supervised way, but we only use ground-truth dates and never touch ground-truth summaries, making us aware of how date selection will contribute to news timeline summarization. As demonstrated, even without considering contextual correlation across different dates in text summarization, it is still possible to generate reasonable news timelines with accurate date selection. Although the upper bound of our two-stage framework is much lower than that of the submodular framework, it is worth mentioning that all existing approaches fail to reach our upper bound, not even close on the *Crisis* dataset.

3.2.3 Automatic Date Compression. As defined in Section 2.1, existing news timeline summarization works only use a preset number of dates and length of daily summaries to generate news timelines. Unlike the length of daily summaries, which only implies the compression rate for a single day and is usually set



(a) Timeline17



(b) Crisis

Figure 6: Mean Absolute Percentage Error (MAPE) of predicted number of date selection

to 2 or 3 sentences, determining the number of dates requires understanding for the whole corpus, making it difficult to select. To solve this issue, we aim at automatically detecting the number of dates for news timelines. Motivated by the fact that news timelines consist of major events within the duration, we propose to consider major event coverage to determine the number of dates. Specifically, we use the daily summarization to generate major events for each date and encode daily summaries with BERT

Method	rank 1st	2nd	3rd	MRR	DCG
ASMDS	4	3	3	0.72	7.39
TLSCONSTRINTS	1	6	3	0.56	6.29
WILSON (Ours)	**5**	1	4	**0.76**	**7.63**

Table 9: Results of journalist evaluation on the quality of machine-generated timelines. Best and second best scores are highlighted by bold and underscore respectively.

[5] into embedding vectors. Then, we use Affinity Propagation [6] to cluster encoded daily summaries into event clusters, and adopt the detected cluster number as date selection number. We compared our methods with fixed compression rates for date selection and presented the results in Figure 6. As shown, our automatic date compression method generally performs well on both datasets.

3.3 Evaluation by Journalists

In addition to ROUGE scores, we also consult two professional journalists at *the Washington Post*, which is one of the leading daily American newspapers, to manually evaluate the quality of machine-generated news timelines. Among 41 timelines from the two datasets, we sample 10 timelines (20%) from 6 topics, including H1N1 flu, BP oil spill, Egypt crisis, Libya war, Yemen war, and Syria war. For each sampled timeline, we present the human-generated ground-truth timeline and three machine-generated timelines from ASMDS, TLSCONSTRINTS, and WILSON (Ours) to journalists. The ground-truth timeline is labeled as a reference, while the other three are given in random order and the order is independent for each evaluation. The evaluation is based on the comprehensiveness and readability of the generated timelines compared with the ground-truth timelines.

For each evaluation, the two journalists are asked to review ~ 80 daily summaries from ~ 50 distinct dates, which adds up to ~ 800 daily summaries from ~ 500 distinct dates in total, and collaborate to provide one final ranking of the three machine-generated timelines. To measure the ranking performance of each method, we adopt two common rank-aware measurements, Mean Reciprocal Rank (MRR) and Discounted Cumulative Gain (DCG), and present the results in Table 9. As shown, when evaluated by professional journalists, our method outperforms the state-of-the-art unsupervised framework TLSCONSTRAINS and achieves slightly better or comparable results with ASMDS. Considering our method gains two orders of magnitude improvement in generation speed, the results are very encouraging. More interestingly, although TLSCONSTRAINS generally achieves higher ROUGE scores than ASMDS in table 7, TLSCONSTRAINS receives unexpectedly lower rank scores than ASMDS in this evaluation by journalists. This may imply a warning that automated measures may not be enough for news timeline summarization and human evaluation could be beneficial at times.

4 A CASE STUDY

In this section, we perform a qualitative analysis of the generated timelines of our approach. Since TILSE [12] is the only baseline with source code available, we also include its output in comparison. Table 10 presents a subset of timelines about the lawsuit of Michael Jackson's death in the *Timeline17* dataset, where the manually generated timeline was collected from BBC[3]. As different approaches generate timelines with different date selections, we only consider the dates that appear in all 4 timelines and show the first a few dates and their summaries in chronological order. We highlight the overlaps between manually generated and automatic generated timelines in colors and observe that the output of our approach is aligned better with the handcrafted one.

Interestingly, more summaries of our outputs are closer to the main events on each date than those of TILSE's, though they are all relevant to this topic. We think it may be because more important daily events are reported more heavily on each date, while existing models try but fail to effectively capture the evolution clues across dates, thus simple daily summarization can work well. Apparently, how to balance local and global summarization and effectively capture event evolution could be one potential direction for news timeline summarization.

5 REAL-TIME SYSTEM FRAMEWORK

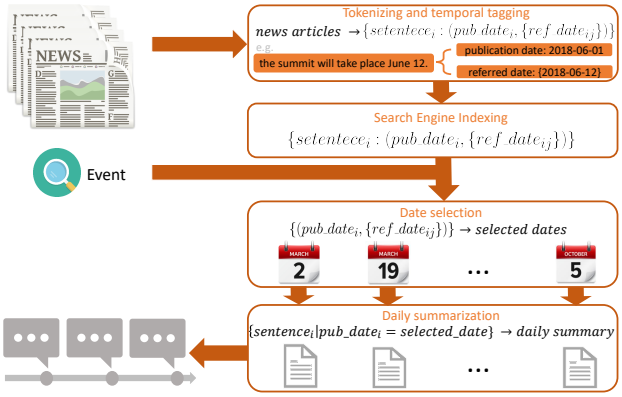


Figure 7: Framework for Real-Time News Timeline Summarization

The framework of our real-time news timeline generation system is shown in Figure 7. This framework applies our proposed method WILSON on a 4-year news corpus of over 1 million news articles[4] from the Washington Post and can generate timelines by event keywords in seconds. Firstly, we tokenize all the news articles into sentences and conduct temporal tagging to label each sentence. Then, to query relevant news content in real-time, we build a search engine on tagged sentences and index both date and content information. Specifically, we use ElasticSearch [7] as our backend search engine. Note that, we can easily include newly published news articles into our system by inserting them into the existing search engine. Finally, given both the keywords and duration time of a query event, our system will fetch related news sentences and run WILSON to generate a complete news timeline.

For example, we can generate a timeline about how the United States and North Korea reached the summit in seconds by setting query keywords to "trump, north korea, kim, summit, united states" and time duration between 2018-01-02 to 2018-06-12. We set the timeline length to 10 and present the output in Table 11. Taking journalist generated timeline[5] as a reference, we highlight

[3]https://www.bbc.com/news/entertainment-arts-15060651
[4]We excluded all news articles containing the keyword "timeline".

Donald Trump cast his Tuesday summit with North Korea 's Kim Jong Un as a " one - time shot " for the autocratic leader to ditch his nuclear weapons and enter the community of nations ...	2018-06-12 President Trump said the U.S. will end its " war games " with South Korea after the historic summit with North Korean leader Kim Jong Un on June 12 .

Table 11: WILSON **generated output of the timeline about how the U.S. and North Korea finally had the summit. Main coverage with journalist generated timeline is color-coded blue, and some trivial contexts are omitted by ellipsis for space.**

the coverage between our generated news timeline with the journalist-generated timeline in blue color and demonstrate that our output is aligned well with the journalist-generated timeline, showing the effectiveness of WILSON in practice.

6 RELATED WORK

Existing works in summarizing timelines for a specific topic from relevant news articles include both supervised and unsupervised approaches. As representatives of supervised approaches, [25] leverages learning to rank techniques based on sentence features, while [27] proposes a matrix factorization framework to predict importance scores of sentences. Unsupervised approaches usually optimize task-specific heuristic object functions, which measure relevance, coverage and diversity of daily summaries. For example, [28] solves the optimization problem by iteratively substituting sentences in summaries, while the state-of-the-art framework TILSE adapts the sub-modularity framework from multi-document summarization domains to optimize timeline summarization [12].

In addition to extractive methods, some recent works also utilize abstractive summarization methods to generate more compact sentences as daily summaries [19]. Although the generated sentences are empirically proved to be readable, the reliability of generated summaries are not guaranteed, probably leading to false information. Extractive summarization methods, however, directly borrow sentences from original news articles and do not encounter reliability issue. Thus, in this paper, we utilize extractive summarization for both readability and reliability of generated timelines.

Besides ROUGE scores, [19] is the only existing work to include human in the evaluation, but they just assess the readability of daily summaries as they utilize the abstractive summarization. Since none of the previous studies utilize user study to measure the generation quality of the whole news timelines, we are the first work to include user study in timeline evaluation and consult journalists to assess the generation quality of the entire news timelines.

7 CONCLUSION

This paper shows that, with accurate date selection, we can generate high-quality news timelines without considering the temporal correlation of text summarization. Leveraging the explicit date selection, we propose a fast and effective unsupervised timeline summarization method named WILSON. Specifically, WILSON outperforms state-of-the-art approaches in both ROUGE scores and speed, significantly improving concatenate ROUGE-2 F1 scores by 9.5%~17.7%, time-sensitive ROUGE-2 F1 scores by 17.1%~123.1% and reducing generation time by two orders of magnitude, which allows us to develop a real-time news timeline generation system for the news room. More importantly, a user study with professional journalists also confirms that the outputs of WILSON are closer to human-generated ones than outputs of other methods. Last but not least, this work also suggests two potential directions for future works, i.e. considering both occurrence and recency of events for better salient date selection and reducing contextual correlation across dates by balancing local and global summarization to improve daily summarization.

ACKNOWLEDGMENTS

The authors would like to thank the anonymous referees for their valuable comments and helpful suggestions. This work was in part supported by NSF awards #1742702, #1820609, #1909702, #1915801, and #1934782. Any opinions, findings and conclusions or recommendations expressed in this material are the author(s) and do not necessarily reflect those of the sponsors. Last but not least, we truly appreciate Everdeen Mason, Sophie Ho and their journalist team at the Washington Post for the valuable feedback and support.

A REPRODUCTION

We present the experiment details to reproduce our results.

Datasets and pre-processing. Both *timeline17* and *crisis* are available at http://l3s.de/~gtran/timeline/. We use spaCy [6] to tokenize news articles into sentences. For temporal tagging, we use HeidelTime [7] to detect all temporal expressions in each sentence. If one sentence contain multiple date expressions, we consider all distinct date-sentence pairs in generating dated sentences $\{(date_i, sentence_i)\}$. Besides, each sentence is also paired with the publication date of the article it appears in.

Evaluation. As suggested at the beginning of Section 5.2 in [25], we set the number of selected dates T to the number of dates in each ground-truth timeline, and the number of sentences per day N to the rounded value of the average number of sentences per date from the corresponding ground-truth timeline. In Table 4 and Table 5, we follow existing works and use ROUGE-1.5.5 to get concatenate ROUGE scores, including ROUGE-1, ROUGE-2 and ROUGE-S*, which ignores date selection in the generated summarization and concatenate all daily summaries together. For comparison with TILSE, we use the evaluation library from the authors [8] for time-sensitive ROUGE scores in Table 6. But different from previous papers, for *Timeline17* dataset, TILSE [11] mixed articles of the same topic from different news agencies together and uses filtered sentence corpus for both datasets. Thus, for a fair comparison, we dump their sentence candidate pool through TILSE code and run our daily summarization on the same sentence candidate pool for each timeline. In speed evaluation, we do not consider the temporal tagging in the pre-processing, and only measure the speed of generation on the tagged sentences for both TILSE and WILSON. The wall time is measured on a 24-core machine.

Implementation details of WILSON. For daily summarization, we group dated sentences $\{(date_i, sentence_i)\}$ by the date to obtain the sentence candidates for each date. Since one sentence can have multiple paired dates, it may appear in multiple daily summaries. When utilizing TextRank [13] to generate daily summaries, we use BM25 [18] scores as edge weight. More specifically, when calculating the edge weight of one sentence to other sentences, we treat the source sentence as query and other sentences as documents, and use its BM25 relevance scores as edge weights. BM25 weights are unsymmetrical, so we build a directed graph for each date and then run the PageRank algorithm to select top sentences as daily summaries. For PageRank algorithm in both date selection and daily summarization, we use the implementation of NetworkX [9] with default damping parameter $\alpha = 0.85$. Code is available at https://github.com/wilson-nts/WILSON.

Implementation details of baselines. Among all the baselines, TILSE is the only one with source code available. Therefore, for all the other baselines, we follow the existing works [9, 25, 27], adopt the conventional experiment setting and directly report the results from previous papers. For the news timeline outputs of TILSE [12] (both TLSCONSTRAINTS and ASMDS), we use the author implementation [10] and their provided configurations [11]. Note that, the TILSE implementation uses the same processing (e.g. caches sentence similarity calculation) to generate multiple timelines that use the same news corpus, therefore, we add the processing time back in measuring the generation time per timeline.

ABSTRACT

The democratization of data access and the adoption of OLAP in scenarios requiring hand-free interfaces push towards the creation of smart OLAP interfaces. In this demonstration we present COOL, a tool supporting natural language *COnversational OLap* sessions. COOL interprets and translates a natural language dialogue into an OLAP session that starts with a GPSJ (Generalized Projection, Selection and Join) query. The interpretation relies on a formal grammar and a knowledge base storing metadata from a multidimensional cube. COOL is portable, robust, and requires minimal user intervention. It adopts an n-gram based model and a string similarity function to match known entities in the natural language description. In case of incomplete text description, COOL can obtain the correct query either through automatic inference or through interactions with the user to disambiguate the text. The goal of the demonstration is to let the audience evaluate the usability of COOL and its capabilities in assisting query formulation and ambiguity/error resolution.

1 INTRODUCTION

Following the spreading of analytic tools, a heterogeneous plethora of data scientists is accessing data. However, the gap between data scientists and analytic skills is growing since different types of data require to learn specialized metaphors and formal tools (e.g., SQL language to query relational data). Natural language interfaces are a promising bridge towards the democratization of data access [13]. Rather than demanding vertical skills in computer science and data architectures, natural language is a native "tool" to organize and provide meaningful questions/answers. Interfacing natural language processing (either written or spoken) to database systems opens to new opportunities for data exploration and querying [9]. Actually, in the area of data warehouse, OLAP (On-Line Analytical Processing) is an *"ante litteram"* smart interface, since it supports the users with a "point-and-click" metaphor to avoid writing well-formed SQL queries. Nonetheless, the possibility of having a conversation with a smart assistant to run an OLAP session (i.e., a set of related OLAP queries) opens to new scenarios and applications. It is not just a matter of further reducing the complexity of posing a query: a conversational OLAP system must also provide feedback to refine and correct wrong queries, and it must have memory to relate subsequent requests. A reference application scenario is augmented business intelligence [6], where hand-free interfaces are mandatory.

In this demo paper, we propose COOL to convert natural language into *COnversational OLap* sessions composed of GPSJ queries and analytic operators. GPSJ [8] is the main class of queries used in OLAP since it enables Generalized Projection, Selection and Join operations over a set of tables. Although some natural language interfaces to databases have already been proposed [3], this is the first proposal addressing a full-fledged implementation for OLAP analytical sessions that is:

- *Automated and portable*: by reading metadata (e.g., hierarchy structures, measures, attributes, and aggregation operators) from a ROLAP engine, COOL automatically builds the minimal lexicon involved in the translation.
- *Robust* to user inaccuracies in syntax, OLAP terms, and attribute values, by exploiting metadata and implicit information.
- *Extendable* and easily configurable on a data warehouse (DW) without a heavy manual definition of the lexicon. The minimal lexicon is extendable by importing known ontologies in the Knowledge Base.

COOL's initial proposal in [4] has been now extended by (1) implementing a full-fledged application that supports a complete OLAP session rather than a single query; and (2) providing a visual metaphor based on the Dimensional Fact Model (DFM) [7] to guide user interaction (Figure 2 conceptualizes a multidimensional cube with the DFM formalism). Noticeably, the user interface's effectiveness has been assessed with 40 users, including data scientists and master students with varying skill levels.

The goal of the demonstration is to let the audience evaluate the usability of COOL and its capabilities in assisting query formulation and ambiguity/error resolution. The system is publicly available at https://big.csr.unibo.it/cool.

2 SYSTEM OVERVIEW

Figure 1 sketches a functional view of the architecture. Given a set of multidimensional cubes (DW), we distinguish between an offline phase (to initialize and configure the system) and an online phase (to enable the user interaction). We refer the user to [7] for an explanation of the DW terminology.

2.1 The offline phase

The *offline* phase automatically extracts the set of entities $\mathcal{E}$, i.e., the DW-specific terms used to express the queries. Such information is stored in the knowledge base (KB), which relies on the DFM expressiveness [7]. This phase runs *only* when the DW undergoes modification (e.g., cube schemas or data instances) and extracts all multidimensional metadata. A cube modeled as a *star schema* in a ROLAP engine consists of dimension tables (DTs: the cube hierarchies) and a fact table (FT: the cube). The `Automatic KB feeding` extracts measures (FT columns not included in the primary key), attributes (DT columns), values (distinct instances of the DT columns), and hierarchies (either coded in a specific table or inferred [10]). These elements represent the lexicon necessary to translate natural language into conversational sessions. COOL supports lexicon extension with external synonyms that can be automatically imported from open data ontologies (e.g., Wordnet [11]) to widen the understood language. Besides the domain-specific terminology, the KB also includes the set of standard terms that are domain independent and that do not require any feeding (e.g., group by, where, select). Further enrichment can be optionally carried out manually when the application domain involves a non-standard vocabulary (e.g., the physical names of tables and columns do not match a standard vocabulary).

2.2 The online phase

The *online* phase runs every time a natural language query is issued. In a hand-free scenario (e.g., [5]), the spoken query is initially translated to text by the `Speech-to-text` software module. Since this task is out of our research scope, we exploited the public Web Speech API (https://wicg.github.io/speech-api/). The uninterpreted text is then analyzed by the `Interpretation` step, refined in the `Disambiguation & Enhancement` step, translated by the `SQL generation` step, and finally executed and visualized by the `Execution & Visualization` step.

2.2.1 Interpretation. `Interpretation` consists of two alternative steps. `Full query` interprets the texts describing full queries (which happens when an analytic session starts). `OLAP operator` modifies the latest query when the user states an OLAP operator along a session (i.e., roll-up, drill-down, and slice&dice). The switch between the two steps to manage the conversation (i.e., a dialog between the user and COOL) is modeled by two states: *engage* and *navigate*.

- *Engage*: this is the initial state, in which the system expects a full query to be issued and whose interpretation is demanded to `Full query`. When COOL achieves a successful interpretation (i.e., it is able to run the query) it switches to the *navigate* state.
- *Navigate*: the dialogue evolves by iteratively applying OLAP operators that refine the query (e.g., by aggregating by different levels or narrowing the query selectivity). The management of these steps is demanded to `OLAP operator` until the user resets the session, making COOL return to the *engage* state.

`Full query` and `OLAP operator` follow these steps: (i) `Tokenization & Mapping`, (ii) `Parsing`, and (iii) `Checking & Annotation`.

Tokenization & Mapping. A raw text T is a sequence of single words $T = \langle t_1, ..., t_z \rangle$. The goal of this step is to identify the entities in T, i.e., the only elements that will be involved in the `Parsing` step. Turning a text into a sequence of entities means finding a *mapping* between words in T and $\mathcal{E}$.

Definition 2.1 (Mapping & Mapping function). A mapping function $M(T)$ is a partial function that associates sub-sequences (or *n-grams*)[1] from T to entities in $\mathcal{E}$ such that:

- sub-sequences of T have length n at most;
- the mapping function determines a partitioning of T;
- a sub-sequence $T' = \langle t_i, ..., t_l \rangle \in T$ (with $|T'| \leq n$) is associated to an entity E if and only if $Sim(T', E) > \alpha$ (where $Sim()$ is a similarity function, later defined) and $E \in TopN(\mathcal{E}, T')$ (where $TopN(\mathcal{E}, T')$ is the set of N entities in $\mathcal{E}$ that are the most similar to T' according to $Sim(T', E)$).

The output of a mapping function is a sequence $M = \langle E_1, ..., E_l \rangle$ on $\mathcal{E}$ that we call a *mapping*.

The similarity function $Sim()$ is based on the Levenshtein distance and keeps token permutation into account to make similarity robust to token permutations (e.g., sub-sequences $\langle P., Edgar \rangle$ and $\langle Edgar, Allan, Poe \rangle$ must result similar).

Several mappings might exist between T and $\mathcal{E}$ since Definition 2.1 admits sub-sequences of variable lengths (corresponding to different partitionings of T) and associates the top similar entities to each sub-sequence. This increases the interpretation robustness since COOL chooses the best mapping through a scoring function. Given a mapping $M = \langle E_1, ..., E_m \rangle$, its score $Score(M)$ (i.e., the sum of entity similarities) is higher when M includes several entities with high similarity values. Intuitively, the higher the mapping score, the higher the probability to determine an optimal interpretation.

Parsing. Parsing validates the syntactical structure of a mapping against a formal grammar and outputs a data structure called *parse tree* that is later used to translate a mapping into SQL.

In `Full query`, `Parsing` is responsible for the interpretation of a complete GPSJ query stated in natural language. A GPSJ query contains a measure clause (MC) and optional group-by (GC) and selection (SC) clauses. Parsing a full query means searching in a mapping the complex syntax structures (i.e., clauses) that build-up the query. Given a mapping M, the output of the parser is a parse tree PT_M, i.e., an ordered tree that represents the syntactic structure of a mapping according to the grammar from Figure 3. To the aim of parsing, entities are terminal elements in the grammar.

In `OLAP operator`, `Parsing` is responsible for searching the syntactic structures of the OLAP operators that build-up the conversation. The grammar is described in Figure 4. Our conversation steps are inspired to well-known OLAP visual interfaces (e.g., Tableau[2]). To apply an OLAP operator, COOL must be in the state *navigate*, i.e., a full GPSJ query has been already successfully interpreted and translated into a parse tree PT_C that acts as a context for the operator. The output of the parser is a parse tree PT_M that is used to update PT_C (see Section 2.2.3).

Both GPSJ grammars are LL(1)[3] [2], not ambiguous (i.e., each mapping admits, at most, a single parse tree PT_M), and can be parsed by an LL(1) parser with linear complexity [2]. If the input mapping M is fully parsed, PT_M includes all the entities as leaves. Conversely, if only a portion of the input belongs to the grammar, an LL(1) parser produces a partial parsing, meaning that it returns a parse tree including the portion of the input mapping

[1] The term *n*-gram is used as a synonym of sub-sequence in the area of text mining.
[2] https://www.tableau.com/
[3] The rules presented in Figure 3 do not satisfy LL(1) constraints for readability reasons. It is easy to turn such rules in an LL(1) complaint version, but the resulting rules are much more complex to be read and understood.

⟨GPSJ⟩ ::= ⟨MC⟩⟨GC⟩⟨SC⟩ | ⟨MC⟩⟨SC⟩⟨GC⟩ | ⟨SC⟩⟨GC⟩⟨MC⟩ | ⟨SC⟩⟨MC⟩⟨GC⟩

⟨DROP⟩ ::= "*drop*" (⟨MC⟩ | ⟨Attr⟩ | ⟨SSC⟩)

⟨REPLACE⟩ ::= "*replace*" (⟨MC⟩$_{old}$ "*with*" ⟨MC⟩$_{new}$ | ⟨Attr⟩$_{old}$ "*with*" ⟨Attr⟩$_{new}$
| ⟨SSC⟩$_{old}$ "*with*" ⟨SSC⟩$_{new}$)

Figure 4: Backus-Naur representation of the `OLAP operator` grammar. We omit ⟨MC⟩, ⟨Attr⟩, ⟨SSC⟩ in common with Figure 3.

that belongs to the grammar (i.e., the *PT* rooted in ⟨GPSJ⟩). The remaining entities can be either singleton or complex clauses that could not be connected to the main parse tree. We will call *parse forest* PF_M the union of the parse tree with residual clauses. Obviously, if all the entities are parsed, it is $PF_M = PT_M$. Considering the whole forest rather than the simple parse tree enables disambiguation and errors to be recovered in the `Disambiguation & Enhancement` step. Henceforth, we refer to the parser's output as a parse forest independently of the presence of residual clauses.

2.2.2 Disambiguation & enhancement. Due to natural language ambiguities, speech-to-text inaccuracies, and wrong query formulations, parts of the text can be misunderstood. The reasons behind the misunderstandings are manifold, including (but not limited to) a wrong usage of aggregation operators (e.g., summing non-additive measures), inconsistencies between attributes and values in selection predicates (e.g., filtering on product *"New York"*), or grouping by a descriptive attribute. Such parts of the parse forest are annotated as ambiguities. The `Disambiguation & Enhancement` step solves ambiguities (if any) automatically whenever possible (by exploiting implicit information) or by asking appropriate questions to the user. Through disambiguation, the parse forest PF_M is reduced to a single parse tree PT_M.

2.2.3 SQL generation. `SQL generation` translates a full-query parse tree into an executable SQL query. If an OLAP operator has been submitted, the context parse tree PT_C must be updated according to the OLAP operator parse tree PT_M. All the OLAP operators can be implemented atop the addition/removal of new/existing nodes in PT_C. We apply a depth-first search algorithm to retrieve the clauses interested by the OLAP operator. We recall that adding a new clause to ⟨GPSJ⟩ (e.g., "add city" requires to add the attribute City) requires to append the new clause to the existing ⟨MC⟩/⟨GC⟩/⟨SC⟩ (and to create it if it does not exist in ⟨GPSJ⟩). Given a full query parse tree PT_M, the generation of its corresponding SQL requires to fill in the `SELECT`, `WHERE`, `GROUP BY` and `FROM` statements. The SQL generation applies to both star and snowflake schemas [7] and is done as follows:

- `SELECT`: measures and aggregation operators from ⟨MC⟩ and attributes in the group by clause ⟨GC⟩;
- `WHERE`: predicates from the selection clause ⟨SC⟩;
- `GROUP BY`: attributes from the group by clause ⟨GC⟩;
- `FROM`: measures, attributes, and values identify fact and dimension tables. The join path is identified by following the referential integrity constraints.

3 VISUALIZATION METAPHOR

The obtained query is run on the `DW` and the results are reported to the user by the `Execution & Visualization` software module. The visual interaction relies on the DFM [7] (Figures 5 and 6), which natively provides a graphical representation for multidimensional cubes and queries: such representation is conceptual and user-oriented, and its effectiveness is confirmed by its adoption in commercial tools (e.g., https://www.indyco.com/) for both modeling and descriptive purposes. With reference to Figure 2, the DFM explicitly represents the cube as a rectangle (i.e., Sales) including the measure names (e.g., StoreSales) surrounded by hierarchies organized in many-to-one acyclic graphs (e.g., Products are grouped in Types). This representation includes all the elements necessary to formulate a GPSJ query, namely measure clauses, group-by clauses, and selection clauses on both measures and dimensional attributes.

At first, users are asked to submit the natural language description of a full query (e.g., *"return the medium costs for Beer and Wine by gender"*). Once COOL interprets the natural language query, it shows in green the entities that are fully-understood (`product_category=Beer and Wine`, `store_cost(avg)`, and `gender` in Figure 5) and, if no ambiguities exist, it also returns the query result. If some ambiguities exist, COOL shows in yellow the ambiguous elements on the DFM one by one. For instance, when users ask for *"average costs in the USA"* (Figure 6), COOL shows that `store_cost(avg)` is correctly understood, while `USA` is ambiguous since it belongs to both attributes `store_country` and `country`. In the case of ambiguities, besides color codes, COOL notifies the user of the encountered ambiguity and enables multiple resolutions (e.g., either picking the correct attribute or dropping the clause). COOL also shows the parse tree on request, enabling more skilled users to understand how natural language is interpreted. After issuing a full query, the conversational session proceeds by describing further analytic steps (e.g., *"generalize product subcategory to category"* or more briefly *"generalize product subcategory"*).

We tested COOL against the Foodmart [1] cube with 40 users, mainly master students in data science, with basic or advanced knowledge of business intelligence and data warehousing. On a scale from 1 (very poor) to 5 (very high), on average, users scored 3.60 ± 0.7 their familiarity with the English language, and 3.28 ± 1.1 their familiarity with the OLAP paradigm. Users evaluated the responsiveness and user-friendliness of COOL as 4.09 ± 0.85, and the overall user experience (e.g., the perceived translation accuracy) as 3.82 ± 0.91, confirming a good — or even

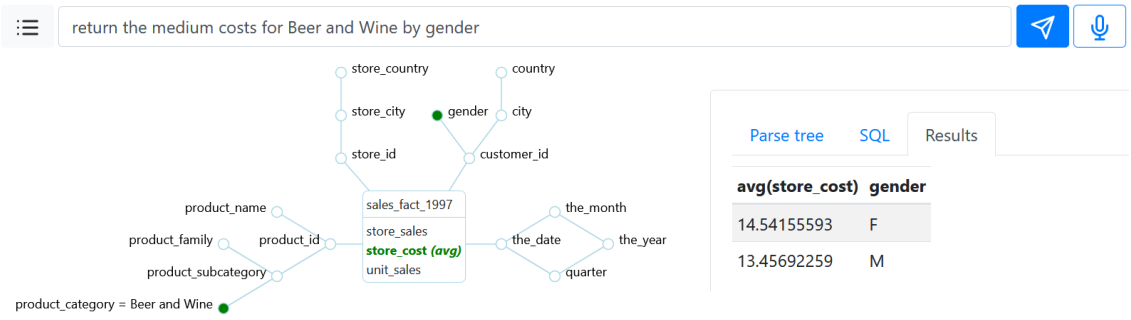

Figure 5: COOL returns the results for a fully-interpreted query.

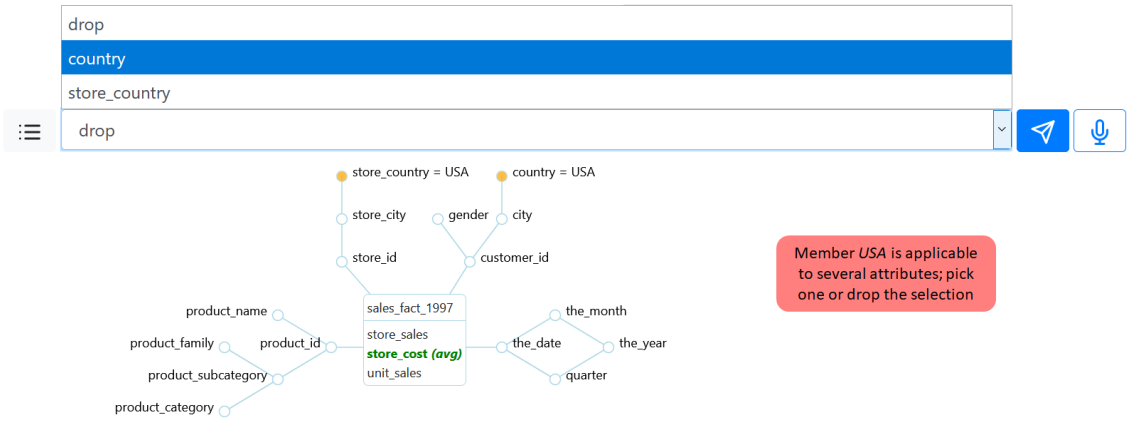

Figure 6: COOL shows a hint to disambiguate the *member* "USA".

optimal — experience. Finally, the average response time is less than 1 second for mappings including up to 9 entities.

4 DEMO PROPOSAL

In the demonstration, we develop an experience to showcase the translation of natural language dialogues into analytical sessions. In particular, we consider the usability criteria of a visual interface from [12]. Usability is assessed by *learnability* (how easily novel users accomplish basic tasks), *efficiency* (how quickly users can perform tasks), *error recovery* (how many errors users make and how easily can they recover from these errors), and *satisfaction* (how pleasant it is to use the interface). Two distinct scenarios are proposed to assess these functionalities.

In the *guided* scenario, we drive the formulation of analytic sessions on the Sales cube. In particular, we provide users with three formal definitions of GPSJ queries in the format $GPSJ = \{\{GC\}, \{SC\}, \{MC\}\}$; users interact with the system by formulating such queries in natural language. Once the query description is submitted (spoken or written), COOL drives users in the resolutions of ambiguities, if any, through a question-answer approach. Then, further analytics steps are shown to the user, who is required to abstract and describe the operators necessary to accomplish such steps. In such a way, we address *learnability* and *efficiency*, allowing users to approach COOL in a user-friendly manner.

In the following *unguided* scenario, users are to freely interact with COOL starting only with a generic analytic task (e.g., *"Investigate sales drop. This might depend on examining products sales over time"*). This requires to formulate custom analytic goals and sessions toward such goals (e.g., sales drop for the category "Beer and Wine" might be caused by a drop in "Wine" sales). As we expect users to encounter ambiguities while freely navigating the cube (e.g., in case of homonyms and synonyms), we address the robustness of COOL through its *error recovery* capability. Also, we assess user *satisfaction* by understanding how easy it is for the user to accomplish their analytic goal (i.e., how many steps it takes).

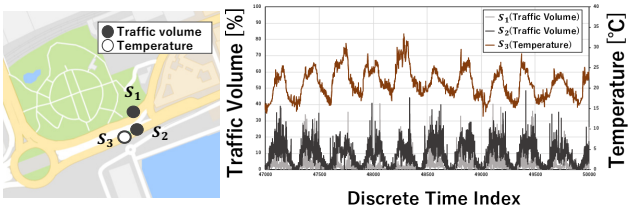
ABSTRACT

Urban conditions are monitored by a wide variety of sensors that measure several attributes, such as temperature and traffic volume. The correlations of sensors help to analyze and understand the urban conditions accurately. The correlated attribute pattern (CAP) mining discovers correlations among multiple attributes from the sets of sensors spatially close to each other and temporally correlated in their measurements. In this paper, we develop a visualization system for CAP mining and demonstrate analysis of smart city data. Our visualization system supports an intuitive understanding of mining results via sensor locations on maps and temporal changes of their measurements. In our demonstration scenarios, we provide four smart city datasets collected from China and Santander, Spain. We demonstrate that our system helps interactive analysis of smart city data.

1 INTRODUCTION

Many cities have started smart city initiatives and installed a wide variety of sensors that measure several attributes, such as traffic volume and temperature. The collected data from smart cities is used for continuously and cooperatively monitoring urban conditions, such as the distribution of air pollution, the transition of traffic volume, and the change of citizen activity. Researchers and municipalities analyze smart city data and make a decision for urban planning. For example, environmental researchers in Shanghai Jiao Tong university analyze the relationships between traffic and air pollution [5, 7]. Santander, Spain monitors the traffic volumes within the city and informs people of the real-time traffic information [6]. They work on obtaining useful patterns in cities by using database and data mining techniques.

Smart city data has spatial and temporal information. For analysing spatio-temporal data, we proposed *correlated attribute pattern (CAP) mining* [2, 3]. CAP mining aims to find correlated attributes of sensors that are spatially close to each other and whose measurements temporally co-evolve. We developed an efficient algorithm for CAP mining, called Miscela and presented that the correlated attribute patterns can discover useful knowledge from smart city data. We show an example that illustrates the effectiveness of CAP mining.



(a) Sensor location (b) Correlation

Figure 1: The correlation between traffic volume and temperature in Santander [2]

Example 1.1. Figure 1 shows locations of three sensors s_1, s_2, and s_3 in Santander and these measured values. s_1 and s_2 measure traffic volume and s_3 measures temperature. These sensors are spatially close to each other, and the measurements of them co-evolve frequently (i.e., change the values simultaneously). The CAP mining can discover correlated patterns among traffic volume and temperature measured by the three sensors. Municipalities can understand that traffic behavior in the area is correlated to temperature from the CAP.

Contribution: In this paper, we develop a visualization system for CAP mining, called Miscela-V, to support an intuitive analysis of smart city data. Miscela-V has the following characteristics:

- Miscela-V natively supports CAP mining with user-specified parameters.
- Miscela-V visualizes sensor locations on a map and temporal changes of sensor measurements.
- Miscela-V caches results of CAP mining and reuses the cached results for efficient interactive analysis.

Our system supports intuitive understanding of analytic results via visualization. We demonstrate an analysis of smart city data by using our system. We use two different scale datasets: Santander (i.e., city size) and China (i.e., country size). Our system is effective for any space and time scales such as daily city-scale and minutely country-scale datasets. For further investigation, we open our source codes[1].

This work is a collaborated work with researchers in database, environmental, and urban science fields, so we validated that Miscela-V is effective for environmental and urban science studies. Through the demonstration of Miscela-V, we expect that Miscela-V helps researchers in more other fields for accelerating their analysis.

[1]https://github.com/OnizukaLab/MISCELA-v

* These authors contributed equally. Yuya Sasaki is the corresponding author.

Related systems: There are several systems for visualizing spatio-temporal data (e.g., [1, 4, 8]). Some systems support spatial-temporal pattern mining but no systems support CAP mining. The novelty of our system is that it focuses on CAP mining with efficient interactive analysis.

Organization: The rest of this paper is organized as follows. We explain the CAP mining and the CAP mining method Miscela in Section 2 as preliminaries. Then, we present a visualization system Miscela-V in Section 3. After that, we show our demonstration plan in Section 4, followed by the conclusion in Section 5.

2 PRELIMINARIES

We explain CAP mining and Miscela as preliminaries.

2.1 CAP mining

We consider a sensor set in a geographical region. Each sensor has longitude and latitude as spatial information. It measures a specific attribute, such as temperature, traffic volume, and PM2.5. Each sensor is synchronized, that is, it measures its sensor value at a certain interval. We define that measurements are co-evolved if they increase/decrease at the same timestamp.

The CAP mining aims for discovering spatially and temporally correlated environmental properties such that multiple sensors measure those attributes that satisfy the following conditions: (1) the set of sensors are located at spatially close locations to each other, (2) the measurements of the sensors co-evolve frequently, and (3) the set of attributes measured by the sensors includes multiple attributes. The CAP mining restricts the correlation between different attributes to support diversified analysis of smart cities. This restriction can be easily removed.

CAP mining has several parameters for obtaining CAPs that users want. We here summarize parameters and their impacts on the number of CAPs to be discovered.

- Evolving rate ε: The CAP mining removes slight changes of measurements by specifying ε. If the amount of changes from the previous timestamp is smaller than ε, the timestamps are evaluated as that the measurements do not change. If ε is large, sensors likely co-evolve, so the number of CAPs likely becomes large.
- Distance threshold η: η gives a criterion of close sensors. If a distance between the two sensors is less than η, we define that they are close. If η is large, many sensors are spatially close to each other.
- The maximum number of CAP attributes μ: μ restricts the number of attributes in CAPs. The CAP mining discovers correlations among not larger than μ attributes.
- The minimum support ψ: ψ is the minimum support. If measurements of two sensors co-evolve at more than ψ timestamps, they are co-evolving sensors. If ψ is small, many sensors become co-evolving sensors, and thus the number of CAPs likely becomes large.

Since the sensitivity of parameters depends on datasets, it is necessary to support interactive analysis. Please see more detailed definitions in [2].

2.2 MISCELA: an efficient algorithm for CAP mining

Miscela supports efficient computation for CAP mining, which comprises the following four steps.

(1) **Linear segmentation**: We filter uninteresting data fluctuation by applying a linear segmentation algorithm to time series data.
(2) **Extracting evolving timestamps**: We extract evolving timestamps in the measurements of all sensors by using the given evolving rate ε.
(3) **Discovering spatially connected sets of sensors**: Since CAPs are discovered only from spatially connected sets, we divide a given sensor set into spatially close sensors to restrict the search space.
(4) **CAP search**: For each set of spatially close sensors, we search for CAPs. We recursively conduct the CAP search with gradually expanding spatially close sensors according to a tree structure for CAP mining.

Please see more detailed and precise procedures in [2].

3 MISCELA-V: VISUALIZING SYSTEM

We present our visualization system, which we call Miscela-V. The purposes of Miscela-V is (1) to easily find CAPs in users' datasets, (2) to visually understand the CAPs, and (3) to efficiently support interactive analysis. First, Miscela-V natively supports CAP mining. It visualizes locations of sensors and changes of their measurements to understands reasons why these attributes are correlated. In addition, since Miscela may take a large execution depending on their parameters, it has a caching mechanism for efficient interactive CAP mining.

3.1 System overview

Figure 2 shows an overview of Miscela-V. Miscela-V has three main processes to visualize CAP mining results. First, we upload datasets to the system. Then, we input parameters of CAP mining for obtaining appropriate results. Finally, we can see the CAP results on a map and the temporal behaviors of their measurements. Since our system supports interactive analysis, data and CAPs are stored in databases. Users can easily change parameters to check CAPs in different parameters. If users specify the parameters of CAPs stored in databases, we can immediately see CAPs without processing Miscela.

Figure 3 shows a visualization of sensor locations and temporal measurements. Figures (A) and (B) show sensor locations, and three sensors are highlighted. When we click a sensor in the map, sensors are highlighted if their measurements are correlated to measurements of the clicked sensor. In addition, we can see the attributes of correlated sensors. Figures (C) and (D) show temporal behaviors of measurements, which we can zoom in and zoom out. In (D), you can see that three measurements frequently increase/decrease together. Our visualization helps to intuitively understand correlations among sensors.

3.2 Data upload

We can easily upload our datasets via a user interface that provides two ways of data upload: drag-and-drop and selecting files from finder. For uploading datasets, we need to prepare three files; data.csv, location.csv, and attribute.csv. data.csv lists the set of measurements at all timestamps. We note that timestamps must be the same time intervals, and sensor values are null if the sensors do not have the sensor values at timestamps. location.csv lists the sensor information; identifier, attribute, and location. attribute.csv lists all attributes in the datasets. Each file should have the following formats:

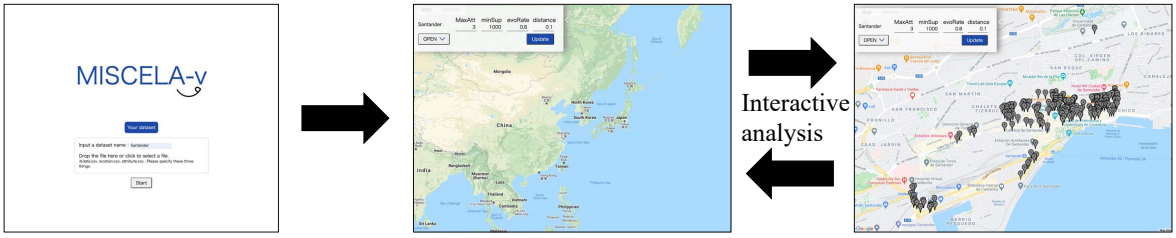


Figure 2: An overview of MISCELA-V

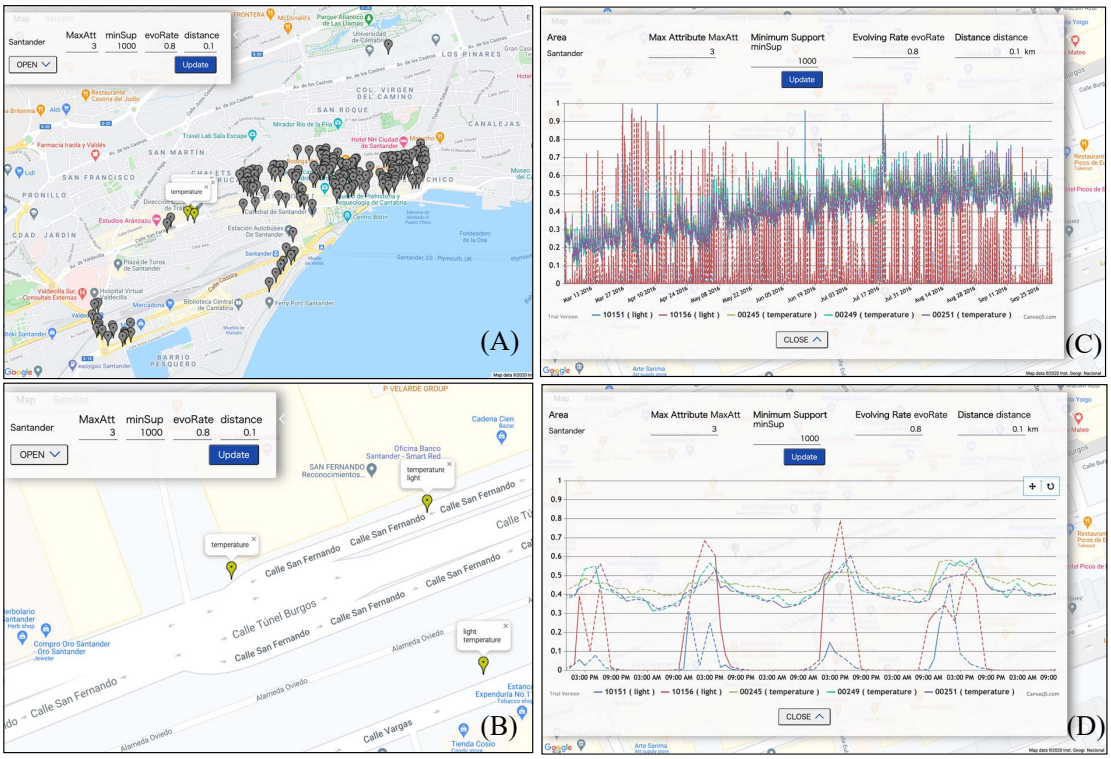

Figure 3: Visualization of CAP mining results

data.csv

```
id,attribute,time,data
00000,temperature,2016-03-01 00:00:00,null
00000,temperature,2016-03-01 01:00:00,9.87
...
```

location.csv

```
id,attribute,lat,lon
00000,temperature,43.46192,-3.80176
00001,temperature,43.46212,-3.79979
...
```

attribute.csv

```
temperature
light
...
```

The data.csv might be very large. For scalably uploading large datasets, we divide the file into 10,000 lines and send each divided set to our system. Each dataset is stored in databases, and thus we can use the dataset without re-uploading by specifying the dataset name.

3.3 Caching mechanism

MISCELA may take a long time for finding CAPs depending on data and user-specified parameters. For efficient interactive analysis, MISCELA-V caches CAP mining results and reuses the cached results if users specify the same parameter setting. This caching mechanism accelerates the analytic process and reduces the computational costs when the front end receives multiple requests at the same time.

We store the name of the dataset, parameters, and CAPs (i.e., a set of sets of sensors) to the database. Before computing CAPs by MISCELA, our system searches for CAPs with the same parameters and the name of the dataset from the database. Since interactive analysis could input the same parameters to compare results repeatedly, the caching mechanism supports more efficient data analysis.

3.4 Implementation

We use MongoDB as database management systems and django as API servers. Miscela is implemented by Python, and a map visualization is implemented by JavaScript, jQuery, and Google Map API. Miscela returns a set of sets of sensors as CAPs that might include many sensors (or empty), and its format is JSON. Since RDBMS is not suitable for Miscela outputs, we select MongoDB to store datasets and CAP results. Since we design that these components are connected by APIs, we can modify each component individually.

4 DEMONSTRATION PLAN

For Miscela-V demonstrations, we use smart city data in Santander and China, as a case study. We will introduce the system architecture, the analytic process, and how to use our system to find knowledge. Attendees can interact with our system to perform analysis using the data. For example, since Miscela-V can show temporal changes of sensors' measurements, we can analyze the difference of measurements before/after COVID-19. The attendees will interactively discover CAPs of smart city data.

The attendees can use the following datasets[2]:

- **Santander** includes 552 sensors in Stantander, Spain from 2016 March 1st to September 30th. The number of records is 2,329,936. Attributes are temperature, light, sound, traffic volume, and humidity.
- **China6** includes 9,438 sensors in China from 2016 September 1st to 2018 October 31st. The number of records is 6,889,740. Attributes are PM2.5, SO2, NO2, CO, and O3.
- **China13** includes 4,810 sensors. The period is the same as China6. The number of records is 3,511,300. Attributes are additionally included in temperature, humidity, air pressure, daylight, rainfall percentage, rain volume, and wind speed.
- **COVID-19** includes 12 sensors in Shanghai and Guangzhou, China from 2020 January 1st to June 30th. The number of records is 52,261. Attributes are PM2.5, PM10, SO2, NO2, CO, and O3. This data includes the period after and before spreading COVID-19.

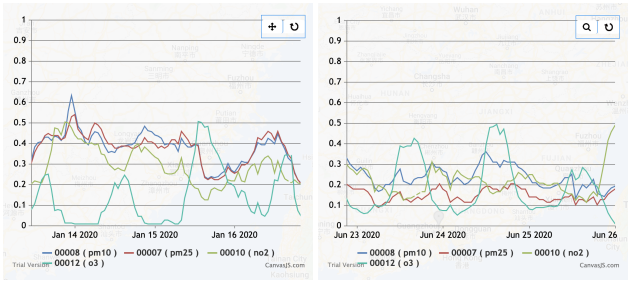
We plan to demonstrate the following case studies.

Interactive analysis: In this demonstration, we first provide interactive analysis to upload datasets, input parameters, and view CAP results. Attendees can freely use our system and try to find interesting patterns in our datasets. First, attendees set the parameters for finding CAPs and see the visualization of the results. Second, the attendees can investigate why the CAPs are discovered by visualizing the temporal behavior of measurements of sensors. Since our system highlights sensors that are correlated, they can understand what sensors are correlated intuitively.

Santander dataset: a single city data analysis: This scenario aims to find interesting knowledge within Santander. Attendees will find interesting CAPs from Santander datasets and investigate the results via visualization. For example, we can find correlated patterns among temperatures and traffic volumes and among light and temperature.

China dataset: multiple cities data analysis: This scenario aims to find interesting knowledge among many cities in China. In particular, attendees can intuitively understand that two sensors are correlated even if they are distant from each other. Furthermore, sensors are not correlated if two sensors are vertically (north and south) close to each other, but if sensors are horizontally (east and west) close, they are correlated. These are often caused by wind directions. We can understand that wind directions affect to air quality from the CAPs. Our system supports for understanding reasons why sensors are correlated and not correlated.

[2]We consider sensors with different attributes as different sensors even if they are located at the same location.



(a) Before (b) After

Figure 4: An example of correlation pattern changes before/after spreading COVID19

COVID-19 analysis: COVID-19 dataset includes the period before and after spreading COVID-19. Attendees can know that levels of air pollution change due to spreading COVID-19. Figure 4 shows the correlation patterns before and after COVID-19. From these results, we can visually understand that our activity changes affect not only the amounts of air pollutants but also their correlation patterns.

5 CONCLUSION

In this paper, we introduced a visualization system Miscela-V for CAP mining and demonstrated the data analysis of smart city via Miscela-V. We plan to continuously extend our system to improve usability and add additional data mining techniques, based on user feedback. We hope that our system accelerates data analysis in many research fields.

ABSTRACT

Heterogeneous Information Networks (HINs) provide a natural way to represent various relationships between entities of different types, thus they are valuable in many domains. Extracting knowledge from HINs typically relies on the concept of metapaths, which are paths in the network schema denoting relations of different semantics among entities. Moreover, real-world HINs are often extremely large, containing millions of nodes and edges. Thus, exploring HINs not only requires interdisciplinary expertise, being able both to interpret and select appropriate metapaths in the network, but also to run the analysis in an efficient and scalable manner. Since there is a lack of tools to facilitate this task, we present SciNeM, an open source, publicly available, scalable analysis tool for metapath-based knowledge discovery in HINs.

1 INTRODUCTION

Many modern applications rely on analysing large amounts of data that comprise multiple types of entities and relationships between them. For instance, *data-driven science*, which has become a very popular and effective paradigm for scientific research, is based on computationally exploring large heterogeneous datasets. Also, the foundations of the *Fourth Industrial Revolution* heavily rely on *data science* techniques for data-driven decision making based on large heterogeneous datasets from multiple sources.

Heterogeneous Information Networks (HINs) provide a way to represent such complex information. They are graphs comprising multiple types of nodes and relationships between them [7]. An example HIN is illustrated in Figure 1, representing the interactions of genes (G) with a class of biomolecules called miRNAs (M) and their relationship with particular biological processes (P) and diseases (D)[1]. It contains 4 distinct node types (G, M, P, D) and 3 distinct types of (bidirectional) relationships (GM, GP, GD).

Various data science methods to analyse HINs and facilitate knowledge discovery from them have been proposed [6, 8, 11]. These typically rely on the concept of *metapaths*: paths in the HIN schema that represent types of entity relationships with particular semantics. For instance, two interesting metapaths in the HIN of Figure 1 are GPG and $MGDGM$. The former connects genes based on the processes they are involved in (i.e., strongly connected genes based on it may share common functionalities).

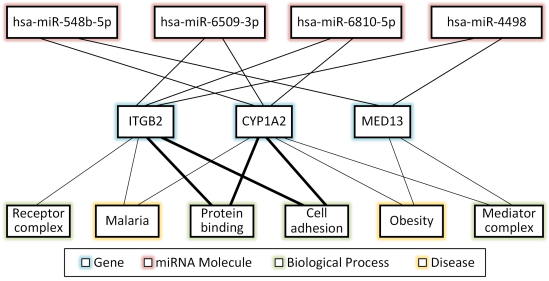

Figure 1: An example HIN.

The latter links miRNAs based on the diseases which relate to the genes with which they interact.

Many HIN analysis algorithms use metapaths as input; the metapath-based connectivity can be used to define a measure for node *similarity search* [8] or *similarity join* [11] or to rank nodes based on their centrality in a metapath-defined network [6]. In the previous example, using the metapath GPG for similarity join could reveal that genes *ITGB2* and *CYP1A2* are similar since they are involved in two common processes. Moreover, to further elaborate the analysis, it is often useful to apply constraints to a given metapath (e.g., in the previous example, to consider only metapath instances involving Cell adhesion).

Despite the wide applicability of HINs and the plethora of proposed algorithms in the literature, there is still a lack of (a) open-source, scalable implementations of these methods, and (b) tools to facilitate their use by non-experts. Also, implementing metapath-based analysis of HINs on top of a graph database, such as Neo4j, requires significant programming skills and familiarity with the system's native query language; also, certain important features of Neo4j, including distributed execution, are only available in the Enterprise Edition. As a first attempt to fill this gap, we have recently developed SPHINX [2]; however, SPHINX is mainly tailored to similarity search and does not offer parallel and distributed execution that is required to scale to larger HINs.

In this work, we introduce SciNeM[2] (Data Science tool for heterogeneous Network Mining), an open-source[3] tool that offers a wide range of functionalities for exploring and analysing HINs and utilises Apache Spark for scaling out through parallel and distributed computation. SciNeM provides an intuitive, Web-based user interface to build and execute complex constrained metapath-based queries and to explore and visualise the corresponding results. Under the hood, all the supported state-of-the-art HIN analysis types have been implemented in a scalable

[1] Note that some edges have been added for presentation purposes and may not reflect real relationships.

[2] http://scinem.imsi.athenarc.gr
[3] https://github.com/schatzopoulos/SciNeM

manner supporting the distributed execution of analysis tasks on computational clusters. SciNeM has a modular architecture making it easy to extend it with additional algorithms and functionalities. Currently, it supports the following operations, given a user-specified metapath: ranking entities using a random walk mode, retrieving the top-k most similar pairs of entities, finding the most similar entities to a query entity, and discovering entity communities.

2 SYSTEM OVERVIEW

2.1 Architecture & Functionalities

Figure 2 illustrates the key components of SciNeM's architecture, as well as the data flow between them. All (back-end) components have been implemented on top of Apache Spark to allow scalable execution on computational clusters. In the following paragraphs, we elaborate on their functionality and implementation.

2.1.1 Distributed HIN Storage. This is SciNeM's main storage layer. It is responsible for the storage of all HIN data and it is based on a Hadoop Distributed File System (HDFS) hosted on the storage media of the underlying computational cluster. Each HIN consists of a set of files including (a) a *schema file*, that describes the HIN node types and the types of relationships between them (compatible with Cytoscape's Elements JSON format[4]), (b) *node files* in TSV format containing data attributes for the nodes of each type, and (c) *relationship files* that define the edges of the network. User-created HINs can be uploaded to this storage layer via the Web front-end.

2.1.2 HIN Transformation. Most metapath-based analysis types, like those discussed in Section 2.1.3, require a common preprocessing step that transforms the initial heterogeneous network to a homogeneous (or bipartite) one. This network is essentially a *view* of the HIN containing only the nodes of the first (or the first and last, respectively) entity type in the metapath and having one edge for each metapath instance connecting these entities. Further analysis is performed on the aforementioned HIN view.

The HIN Transformation component implements this preprocessing step. It takes as input a user-defined metapath and a set of constraints and identifies all pairs of nodes that are connected based on this constrained metapath. For each pair, it also captures the number of metapath instances that connect the corresponding nodes.

Since the calculation of the metapath-based view is a computationally intensive task, special care was taken for the efficient implementation of this component. The core of transformation is calculated using matrix multiplication between the adjacency matrices defined by the relations of the given metapath. Specifically, our approach is based on the work in [6] but extends it by utilising sparse matrix representations. Since the order of multiplications significantly affects the performance of the whole processing, we adopt a dynamic programming approach that estimates the optimal ordering taking into consideration the computational cost of sparse matrix multiplications introduced in [4]. This modification offers significant speedups in many cases. In addition, the implementation of this component utilises Apache Spark, thus taking advantage of parallel and distributed computing.

2.1.3 Metapath-based analysis. This component implements a range of metapath-based mining tasks for HINs. In particular, state-of-the-art methods for entity ranking, similarity join, similarity search, and community detection are implemented, as explained below.

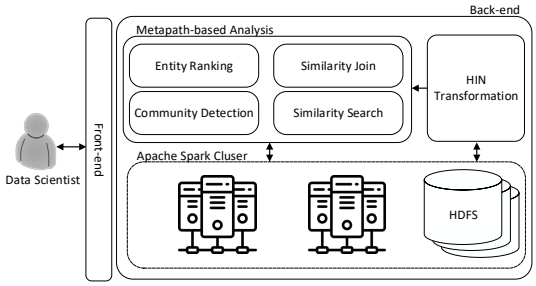

Figure 2: Architecture of SciNeM.

Given a particular constrained metapath, the *Entity Ranking* component estimates the significance of entities according to a random walk model applied to the corresponding HIN view [6]. In particular, the PageRank score of each node in the HIN view is calculated, and the corresponding entities are ranked based on these scores. The intuition is that this procedure brings as top-ranked results nodes which are well-connected inside the metapath-based view, i.e., nodes that correspond to entities which are important according to the semantics of the selected constrained metapath (this is why so many other nodes connect to them). To guarantee scalability, a high-performance Spark-based ranking component has been developed, allowing the analysis of very large HINs.

The *Similarity Join* component identifies the most similar pairs of nodes based on the way they are linked with other nodes when considering a particular (possibly constrained) metapath. As this type of analysis is computationally intensive, SciNeM leverages Locality Sensitive Hashing [3] (LSH) using Bucketed Random Projection to prune expensive similarity calculations. For each node, a feature vector is constructed based on its connectivity on the metapath-based HIN view. These vectors are then hashed into buckets, so that vectors that are similar end up in the same bucket with high probability. A similar approach is also followed by other relevant works (e.g., [11]).

The *Similarity Search* component detects nodes that are similar to a given query node. The notion of similarity used is the same as the one used by the Similarity Join component. In more details, SciNeM performs an approximate nearest neighbors search using the Euclidean Distance to determine (dis)similarity between nodes. Moreover, the same hashing technique as in Similarity Join is used to effectively prune the search space. Furthermore, it should be noted that, to improve scalability of the performed analyses, the Similarity Search and Join components have been implemented based on Apache Spark.

Finally, the *Community Detection* component identifies communities (i.e., clusters) of interacting nodes/entities based solely on the structural properties of the selected metapath-based HIN view, that is produced by the HIN Transformation component (see Section 2.1.2). The analysis is based on the Label Propagation Algorithm (LPA) [5], which is a popular community detection approach that requires no a priori knowledge about the network's structure. It is based on propagating labels throughout the network and forming the communities following the intuition that labels will be trapped and become dominant in clusters of densely connected nodes. Although this type of analysis is less intensive

Figure 4: Screenshots from the results of the analysis of Figure 3.

than other approaches (e.g., Fast-Greedy, Infomap), for large networks it requires significant computational power and has a very large memory footprint. This is why the corresponding component of SciNeM takes advantage of a Spark-based, distributed implementation of the algorithm.

2.1.4 Web front-end. SciNeM's Web UI supports determining and executing metapath-based analysis tasks. These can be executed on already available HINs or new ones uploaded by the user. A *visual wizard* used to determine the details of the desired analysis tasks lies at the core of this component (see also Section 2.2). The front-end was implemented using React[5] JS library assisted with Redux[6] state container for efficient state management. Graph visualisations (e.g., HIN schema visualisation for the query builder) were implemented using the Cytoscape JS library.

2.2 User Interface

Figure 3a presents a screenshot of SciNeM's analysis task submission form. To perform a new analysis, the user first selects an existing HIN from the corresponding drop-down menu or uploads a new one. The latter requires uploading a single compressed file that contains the files described in Section 2.1.1[7].

After selecting the input HIN, the user specifies the metapath to be used for the analysis and the desired constraints. To assist the user in selecting metapaths, an interactive version of the schema of the HIN is displayed in the submission form. The user can either click on the entity types (nodes) of the schema to incrementally build the desired metapath, or add extra entity types by selecting them from a drop-down list after clicking on the green button located at the end of the currently selected sequence. To select the desired constraints, the user can click on the filter icon located below the involved entity type. A pop-up window will appear on the screen (see Figure 3b). The user selects the desired constraints and then hits the 'Save' button.

Finally, the user selects the types of analysis to be performed (multiple can be selected simultaneously) and clicks on the 'Execute analysis' button[8]. A progress bar appears in the screen (see at the bottom of Figure 3a) to monitor the status of the execution. Moreover, a unique identifier is assigned to each analysis so that the user can return to the analysis using the option 'Reattach to analysis' from SciNeM's navigation bar.

After the analysis is completed, the results appear in a tabular form (see Figure 4a). The user can browse them or select to download all or part of them. She also has the option to select some of them to create a condition file, i.e. a special file in JSON format that encodes them into a set of constraints that can be used in a later analysis. In particular, after creating a condition file the user can provide it as input in a later analysis by clicking on the 'Load from file' button of the constraints pop-up window (see Figure 3b). Essentially this creates a mechanism to use the results of an analysis as input to a subsequent one.

Finally, apart from the tabular results, SciNeM also provides a set of visualisations. The user can click on the 'Visualize' button, located above the list of results, and select the visualization type to display (for the cases for which more than one visualization type is provided). Figure 4b displays examples of such visualisations, in particular a bar chart showing the distribution of ranking scores in the top ranking results of Figure 4a and a graph showing the part of the corresponding metapath-based HIN view that contains the top-10 results (the node sizes are based on the corresponding ranking scores).

[5]https://reactjs.org/
[6]https://redux.js.org/
[7]Details can also be found in SciNeM's dataset upload page.

[8]It should be noted that for all similarity search analysis tasks the user should also determine the search entity before starting the execution.

3 DEMONSTRATION

During the demonstration, the audience will have the opportunity to become familiar with the concepts of metapath-based analysis in HINs and to interact with SciNeM's user interface exploring its functionalities. The members of the audience will be able to execute their own analysis tasks and, if needed, to upload their own HINs. However, to facilitate examining SciNeM's capabilities, three datasets have been already prepared and made available:

- *BIO.* It contains data about the involvement of genes in biological processes and diseases (based on GeneOntology [1, 10] and DisGeNET[9], respectively). It also contains data about the suppression of genes by miRNAs (provided by MR-microT[10]). It includes 4 entity types (see Figure 5a), containing a total of 61, 177 nodes and 4, 190, 808 edges.
- *GDELT.* It contains data for news articles and associated entities collected by the GDELT project[11]. In particular, we have collected articles published in 2019 from BBC and CNN. GDELT consists of 5 entity types (see Figure 5c) totaling 245, 950 nodes and 6, 523, 924 relationships.
- *DBLP-Ext.* This HIN contains bibliographic data from the DBLP Citation Dataset of AMiner [9] enriched with european project data from the Cordis project[12]. It contains 6 entity types with 12, 152, 816 nodes and 190, 998, 307 relationships. DBLP-Ext's schema is presented in Figure 5b.

Based on these HINs, four indicative scenarios have been prepared for demonstration. Short descriptions of them follow:

Scenario 1: Important miRNAs for a disease (Ranking). Although the involvement of genes in biological processes and diseases is relatively well-studied, this is not the case for the role of miRNAs. Yet, it is possible to reveal a miRNA's role based on the list of genes it suppresses. Using SciNeM on the BIO dataset, a member of the audience can reveal miRNAs having important role in 'Colorectal Cancer' by selecting to rank miRNAs based on the *MGDGM* metapath using the *D.name = 'Colorectal Cancer'* condition. Highly ranked entities have large centrality in the corresponding HIN view, thus they are highly connected through metapath instances that satisfy the determined condition about the disease of interest. A search in PubMed reveals that there are various articles mentioning in their abstract and/or title both the top retrieved miRNA ('miR-548c') and disease of interest.

Scenario 2: Similar venues to a given one based on the topics of their published papers (Similarity Search). A member of the audience is interested in finding similar venues to the "Very Large Data Bases" (VDLB) conference, according to the topics of their recent papers. As a result, she selects to perform a similarity search on the DBLP-Ext dataset using the *VPTPV* metapath and the constraint $P.year > 2000$. The top results include very relevant venues like the "Int'l Conference on Data Engineering" (ICDE) in the first position and the "Int'l Conference on Management of Data" (SIGMOD) in the second position.

Scenario 3: Communities of organizations based on article mentions (Community Detection). A member of the audience is interested in revealing clusters of related organizations (e.g., governmental institutions, companies) based on their mentions in the news articles of an international network source like CNN. To do so, she chooses to perform community detection on the GDELT dataset using the *OAO* metapath with the *A.source* ="cnn" constraint. The results contain various interesting communities; e.g., the one with $id = 111$ consists of 3 institutions having an agenda related to climate change ("UN Intergovernmental Panel on Climate", "European Union Copernicus Climate Change Programme", "World Meteorological Organization"), whereas the one with $id = 394$ includes 7 institutions involved in politics in India.

4 CONCLUSION

We demonstrated SciNeM, an open source, high-performance and scalable online data science tool that facilitates metapath-based analysis of HINs. Its intuitive user interface aids non-experts to perform a variety of HIN analysis tasks such as metapath-based ranking, similarity join, similarity search, and community detection. Finally, SciNeM's users may upload their own HIN datasets to analyse, however the tool also provides pre-loaded datasets for demonstration reasons.

ABSTRACT

In this demonstration paper, we present an innovative *IoT Meta-Control Firewall* (*IMCF*), which allows users to schedule their IoT devices in smart buildings (e.g., heating, cooling, lights) in order to reach some long-term energy consumption objective (e.g., consume less than 400 kWh in December) while, at the same time, retaining high levels of user convenience (comfort). IMCF internally deploys an AI-inspired Energy-Planner (EP) algorithm that exploits domain-specific operators to balance the trade-off between convenience and energy consumption. Our framework then filters the rules of users in a way that these do not conflict with the long-term objectives (i.e., like a network firewall). We demonstrate IMCF using a prototype system we have developed in the Laravel PHP web framework using the open Home Automation Bus (OpenHAB), the Linux crontab daemon and Anyplace for building modeling. In our demonstration scenario, attendees will be able to observe the execution and benefits of IMCF on a graphical dashboard using pre-configured or custom-made Meta-Rule-Table profiles.

1 INTRODUCTION

Internet of Things (IoT) refers to a large number of physical devices being connected to the Internet that are able to "see", "hear", "think", "react", perform tasks, as well as communicate with each other using open protocols [8]. According to Gartner[1], it is expected that the number of IoT devices per house will increase to more than 500 smart devices by 2022. Many IoT devices also enable the execution of *Rule Automation Workflows (RAW)*, which span from simple predicate statements to procedural workflows capturing a smart actuation pipeline in tools like IFTTT [5], controlling Philips Hue lights, BMW i3 EVs or Daikin A/Cs [7][4], Apilio.io, or Apple Automation.

RAW aim to meet the convenience level of users under specific conditions (e.g., *"warm house to 22°C if cold or preheat Electric Vehicle when approaching"*). In the simplest case, a user expresses preferences manually through a vendor-specific smartphone app / integrated app (e.g., see Fig. 1). This process requires continuous attention by custodians, making it a cumbersome process that generates erroneous executions and that clearly calls for more automated (i.e., *"smarter"*) approaches.

[1]Gartner Inc., URL: https://tinyurl.com/ycrxsmy6

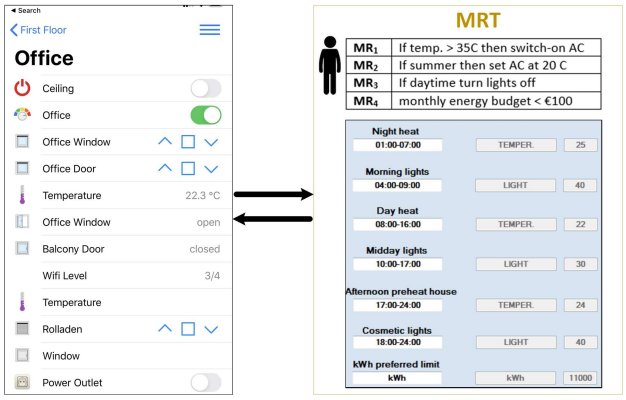

Figure 1: The openHAB bridge gives the privilege to users to adapt a Meta-Rule-Table (MRT) profile as necessary

One of the most straightforward approaches to achieve a smarter RAW is to utilize the so-called *trigger-action* model. Users control the behavior of an IoT by specifying triggers (e.g., *"if it is sunny outside"*) and their resultant actions (e.g., *"turn off the lights"*). Because of its conceptual simplicity, the trigger-action model (a.k.a. Event-Condition-Action) has attracted significant attention with ifttt.com (*"If This Then That"*) becoming one of the first large-scale deployments. Services like Apilio expanded the expressiveness of the RAW with Boolean predicates (e.g., conjunctions) and Apple Automation [3] even introduced procedural programming constructs, like variables, while loops, if statements and functions to advance RAW actuations.

However, none of the above RAW technologies enables individuals or group of users to express their convenience (comfort) preferences while achieving some long-term objective. Similarly, prior research [6] was mainly concerned with improving comfort levels of HVAC system but not long-term energy planning targets. In our scenario, the long-term objective relates to *energy consumption* (e.g., in kWh), which is motivated by European's Commission calls for a climate-neutral Europe by 2050[2]. Particularly, we aim to consume energy more intelligently and within margins we define as persons or group of users.

In this demo we present an innovative system, coined the *IoT Meta-Control Firewall (IMCF)* [2], which aims to fill the gap of manual RAW tuning to reach the energy consumption targets. The user (or group of users) start out by defining a vector of RAW rules, dubbed *MRT*, and an *Energy Consumption Profile*, dubbed *ECP*. The high-level objective is to identify among all MRT rules

[2]EU 2050 long-term strategy, `https://tiny.cc/9wu8iz`

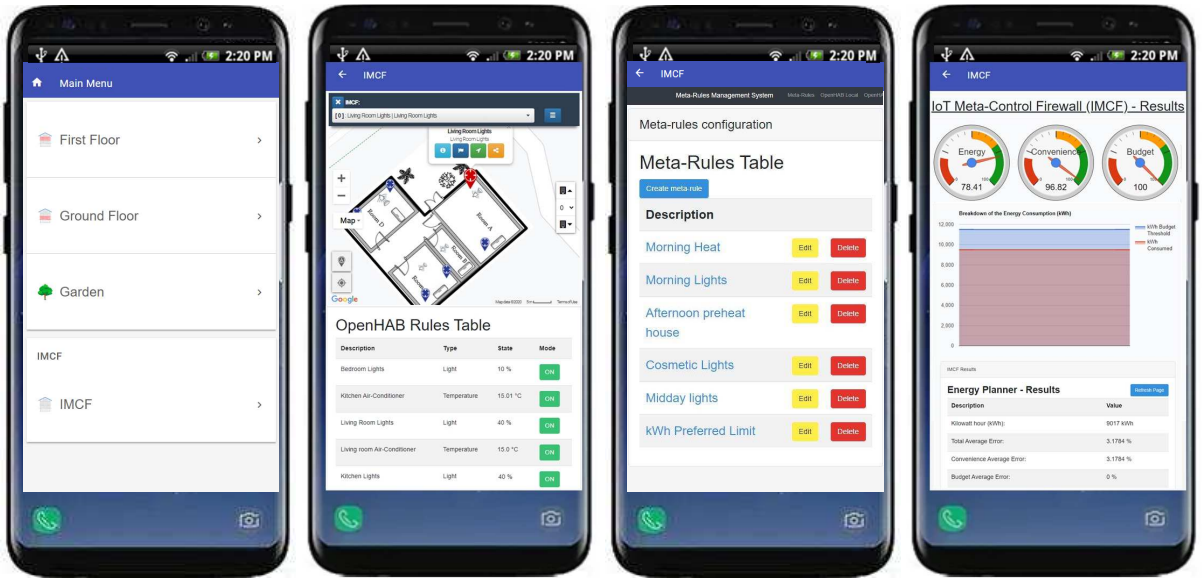

Figure 2: IMCF Graphical User Interface: Integration of the IMCF Software Library in the openHAB Home Automation Stack. the ones that must be dropped so that the user stays within the desired energy budget according to the *ECP* history (e.g., consume less than 400 kWh in December). For this purpose, it utilizes an intelligent search algorithm, coined *EP (Energy Planner)*, which goes over the exponentially large search space of $\sum_{r \leq n} r$-combinations (where $n = |MRT|$), yielding quickly the rules to be dropped. Particularly, IMCF is composed of an intelligent energy amortization process and an AI algorithm for balancing the trade-off between convenience and energy consumption, and satisfying the RAW pipelines of users in a way that these do not conflict with the long-term objectives.

Considering several system implications, IMCF can be implemented in various ways such as the following: (i) a *cloud meta-service*, which guides the IFTTT *cloud service* that in turn controls a *local controller* (e.g., Linux, as in the case of OpenHab), which controls the sensors/actuators (e.g., A/C unit); or (ii) a *local controller* (filtering rules out at the network level on the local controller).

2 THE IOT META-CONTROL FIREWALL (IMCF) OVERVIEW

In this section, we describe a prototype system we have developed for IMCF using the open Home Automation Bus (OpenHAB)[3], the Linux crontab daemon, Anyplace for building modeling [1], as well as the Laravel PHP web framework following the model–view–controller architectural pattern.

We start out with a discussion of the system architecture, followed by the IMCF algorithm, and then describe the Graphical User Interface (GUI) we have developed. The GUI integrates directly into OpenHAB's mobile and web Panel view for both interactive management of IoT and automated management of Energy-aware MRT pipelines using the EP described below.

[3]OpenHAB, `https://openhab.org`

2.1 System Architecture

Our system architecture comprises of the following components: (i) a full-fledge local controller implemented inside the openHAB stack, which is a smart home management software; and (ii) IMCF, which is the software system that encapsulates the complete application logic of the energy management stack we propose along with the respective user interfaces.

Local Controller (LC): is a java-based system that can be installed on a micro device, like a Linux Raspberry PI, running on the local network of a user. The LC will be in direct communication with the IoT devices (i.e., *Things (TG)*) to instruct them based on the preferences registered by a user. A user will typically download the openHAB smartphone *application (APP)*, for iOS or Android, and interact with TG through LC. For the implementation of LC we decided to extend the openHAB stack, which is a vendor and technology-agnostic open source automation software for smart home that provides a rich ecosystem of bridges through which a user can interact directly with IoT devices (e.g., Daikin Smart A/C, Phillips HUE lights) both locally and remotely. This gives us the benefit to achieve maximum IoT market compatibility as the integration of IoT is always an immense challenge.

To realize the operation of LC consider, for example, a user inside his smart space that uses an APP to increase the temperature of an A/C from 21 to 25 degrees Celsius (see Figure 2a-b). This manual interaction goes directly to LC that eventually communicates with TG (on older units this is typically refers to unencrypted http communication channels, either http querystring or in some cases JSON web 2.0 interactions). When a user's APP is outside a smart space, the network firewall and Network Address Translation (NAT) will obviously not let this user interact with LC. As such, the user's APP connects to the *Cloud Controller (CC)*, which is a server on the public Internet that communicates and controls LC remotely. The complete picture can tentatively be complemented by a *Cloud Meta-Controller (CMC)*, like IFTTT, which can enable the user to configure and run various custom rules. CMC would in this case interact with CC that

Table 1: Evaluating our system prototype with respect to Energy Consumption (F_E) and Convenience Error (F_{CE})

Time Duration	Energy Consumption (F_E)	Convenience Error (F_{CE})
Week	130.64 kWh	2.35%

Table 2: Individual Resident Convenience Error (F_{CE})

Users	Convenience Error (F_{CE})
Father	0.8006%
Mother	0.7899%
Daughter	0.7595%

would in turn interact with LC that would eventually interact with TG, all under the *manual* control of the user APP.

The IMCF Component: is a software extension to LC we have implemented to enable the adaptation of convenience preferences to meet the long-term energy planning targets of individuals or group of individuals. It has been developed in a way that encapsulates the implementation of the EP algorithm but also the GUI and storage necessary to allow the user to interact with the system. EP is implemented as a JAVA library, which takes the user configurations from a local MariaDB persistency layer. The storage layer is populated by the user using the APP, which has been configured in a way to integrate seamlessly the *MRT* rule definition process through a web-based GUI (see Figure 2c,d). The GUI code is written in the Laravel PHP web framework, as well as JavaScript and HTML. The GUI code execution relies on a webserver supporting PHP while for the IMCF EP library a cron job daemon is assumed (available on Linux) that reliably invokes the Energy Planning in fixed time intervals (e.g., every few minutes). In case devices have to be turned on or off, the IMCF system has the following options in our system:

- *Binding-mode*, where IMCF exploits the rich ecosystem of bridges available on the openHAB open source project to interact with local devices. We use this as the default mode, as it allows our platform to scale up to a wide spectrum of IoT devices.
- *Extended mode*, where IMCF implements locally the custom instructions for enabling and disabling the various TG devices in the smart space of a user.
  Given that many of the IoT communications are unencrypted, this can be easily captured by deep packet analyzers like Wireshark. Moreover, to avoid any additional CMC, CC or LC interactions with TG, we also configure the LC network firewall with the `iptables` command to disable TCP flows to designated TG devices on the local network. In this case, IMCF works actually as a real network firewall by blocking all outgoing traffic from LC to TG.

Case scenario: We have deployed an instance of our real prototype system for a family of three persons for one week. Particularly, we allowed each person to configure their personal preferences using the Mobile APP that interacts with an IMCF-LC node on a Linux VM on our datacenter described earlier. Particularly, each individual resident entered approximately three different meta-rules according to their personal preferences. One of them have set the weekly energy consumption (kWh) limit to 165kWh. This results in configuration data of approximately 65 bytes / user stored in the MariaDB persistency layer. In order to measure the environmental parameters (i.e., temperature, light) we use data from the open weather forecast API. We measure the performance of the proposed EP framework in regards to Energy Consumption (F_E) and Convenience Error (F_{CE}). The F_E and F_{CE} results for our evaluation are summarized in Table 1. In respect to F_{CE} our observation is that EP is indeed an efficient approach for retrieving great user satisfaction, as it performs in 4 seconds on average with $F_{CE} \approx 2.35\%$. Table 2 demonstrates for each individual resident their own Average Convenience Error values in respect with their configured meta-rules, showing both a consistent and high satisfaction close to 99.2% for all residents. Another observation is that $F_E \approx 130.64$ kWh is within the preferred budget limit as pre-configured by the user, and the system behaves correspondingly to what we observed in the simulations. Please note, this particular framework can be equally utilized in various cases such as CO_2 emission deduction, or any other scenario type that requires a planning to conserve some kind of resources.

2.2 The *IMCF* algorithm

The *IMCF* algorithm is composed of two subroutines: (i) the *Amortization Plan (AP)*; and the (ii) the *Energy Plan (EP)*. The amortization plan is responsible for calculating the maximum energy budget constraint (coined E_p) through a pre-selected amortization formula. Then an artificial intelligence approach is executed every t seconds (e.g., hourly, daily, monthly, yearly preference) over a time period p (i.e., the complete duration of the execution) for generating an energy plan solution s^* for optimizing the Convenience Error

$$\min F_{CE} = \sum_{k=1}^{t} \left(\frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{D} ce_j(MR_i)\right), \tag{1}$$

where ce_j is the difference between the desired output value $\Omega_i^j \in \mathfrak{R}$ of a rule set by a user (temperature or light intensity level) and the actual value $O_i^j \in \mathfrak{R}$ set by the controller, given by: $ce = |\Omega_i^j| - |O_i^j|$.
Subject to satisfying the Energy Consumption $F_E(s^*) \leq E_p$, where:

$$F_E = \sum_{k=1}^{t} \left(\frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{D} e_j(MR_i)\right), \tag{2}$$

E_p is total available energy budget for the complete period p during which the execution of our algorithm takes place, N is the total number of meta-rules, D the set of all IoT devices and e_j is the energy consumption of device j given the action defined by output O_i^j of meta-rule MR_i, given by:

$$E = \begin{cases} e_j, & \text{if } O_i^j \text{ is executed} \\ 0, & \text{otherwise} \end{cases},$$

where e_j is the energy cost of device j for MR_i.

Amortization Plan (AP) Algorithm. The $AP()$ subroutine is initially executed for calculating the energy budget constraint E_p, subject to a monthly residence *Energy Consumption Profile ECP*. There are several amortization strategies that can be used, such as Linear Amortization Formula, Balloon Linear Amortization Formula, and ECP-based Amortization Formula. Given that our approach requires no training data and only a primitive MRT preference profile, this can be easily integrated in smart actuations platforms.

Energy Plan (EP) Algorithm. An energy plan solution is a vector $s =< s_1, \ldots, s_N >$. A vector component s_i represents a

meta-rule in the meta-rule-table MRT, where $s_i = 0$ means ignoring meta-rule at position i of table MRT and $s_i = 1$ means adopting meta-rule at position i. We have adopted a hill-climbing algorithm, an iterative local search heuristic, which doesn't require a learning history (like respective Machine Learning techniques), doesn't require a target function (e.g., like A*) and is straightforward to be implemented in a resource-constraint setting like local smart controllers (e.g., Raspberry). At the beginning of the local search heuristic an initial solution s^* is developed that will specify the initial state of the algorithm either randomly or deterministically. For the optimization step, a hill-climbing local search heuristic is utilized for local optimization with neighborhoods that involve changing up to k components of the solution, which is often referred to as k-opt. Each solution s is evaluated using the performance metrics F_E and F_{CE}. A solution s is considered better and replaces the current best solution s^* if $(F_E(s) \leq E_p)$ && $(F_{CE}(s) < F_{CE}(s^*))$. The energy planner stops when τ_{max} iterations are completed. Alternatively, the algorithm can iterate until $\nexists s | F_{CE}(s) < F_{CE}(s^*)$.

2.3 Graphical User Interface (GUI)

Our prototype GUI provides all the functionalities for a user participating in IMCF. The GUI is divided into a Meta-Rule-Table interface and the OpenHAB Rules Table, respectively as shown in Figure 2b-c. The Meta-Rules interface prompts users to define kWh preferred limit, temperature and light values for any configured time slots. The OpenHAB Rules Table records are retrieved through the OpenHAB Rest API system consisted of smart device sensor measurements installed and pre-configured in a building. These rule combinations are used by the AI Energy Planner algorithm to satisfy the user needs, while keeping the balance between convenience and energy consumption.

At a high level, our GUI enables the following functions: (i) record OpenHAB item measurements/values on local storage and present those on a table; (ii) configure various meta-rules in regards of kWh limit, temperature and light values; (iii) operate IMCF framework and get an efficient execution considering user satisfaction along with balanced F_{CE} and F_E.

3 DEMONSTRATION SCENARIO

During the demonstration, the attendees will be able to appreciate the key components in IMCF, as well as the adaptability and the performance of our propositions (see Figure 2).

3.1 Demo Artifact

We have implemented a prototype of IMCF as a standalone program that is loaded on a Linux-based local controller. Particularly, we implemented a graphical user interface in the Laravel PHP web framework, following the MVC architectural pattern where a user has the privilege to upload a MRT profile that is stored on the filesystem of the Linux device. A cron job has been programmed in order to initiate our energy planner every few seconds. Every time our program runs, it decides whether certain local IPs have to be banned to satisfy user's profile by interacting with the Linux firewall using the iptables commands.

3.2 Demo Plan

The conference attendees will have the opportunity to interactively engage with the OpenHAB and MRT user profile website by setting up configurations through a smartphone. We will preload a variety of synthetic and web-accessible rules to the MRT user profile website back-end. The loaded rules will capture the structure and needs of real residential data and will be very useful to visually demonstrate how the IMCF algorithm works in real time through the OpenHAB application.

The main objective of our intelligent algorithm is to identify among an exponentially large search space of MRT rule combinations the ones that must be dropped so that the user stays within the desired energy budget. In order to present the benefits of our propositions to the attendees, we will provide visual cues that will enable the audience to understand the performance benefits (i.e., CPU time) and the negligible reduction in energy consumption and convenience error we have observed during the experiments.

We will also provide conference attendees the opportunity to create custom MRT profiles through the website. Our hypothesis is that many data engineering researchers and practitioners would feel more comfortable to formulate MRT profile predicates, as opposed to be limited within the boundaries of well-defined MRT templates provided. We will provide participants the possibility to upload an actual building plot through Anyplace. The *OpenHAB* interface will allow the attendees to rapidly visualize the result-sets on a smartphone, using fancy charts (pie, bar, etc.) when the rules get enabled or disabled by the proposed firewall, respectively. Our particular aim here will be to describe how the IMCF structure, residing on the OpenHAB, will be accessible to enable/disable rule services.

4 FUTURE WORK

In the future, we plan to further investigate multiple energy planners with conflicting interests but also to investigate the so-called IMCF-Cloud extensions that will enable IMCF to operate as a CMC controller in the cloud. We also aim to look at CO2 reductions methods with algorithms geared towards the environment. Finally, we aim to investigate power workload identification methods for power-hungry devices (e.g., white devices, electric vehicles, heating) and how to reschedule those workloads in a environmental friendly manner.

ABSTRACT

BBoxDB Streams is an extension of the key-bounding-box-value store BBoxDB. The extension allows the handling of multi-dimensional data streams. Multi-dimensional streams consist of *n*-dimensional elements, such as position data (e.g., two-dimensional positions of cars or three-dimensional positions of aircraft). In this demonstration, we show how BBoxDB Streams can be used to process data streams of position data in a distributed manner. The software allows the user to capture data streams and process continuous queries. Continuous range queries or continuous spatial joins are supported. The GUI of BBoxDB Streams shows the query results interactively as an overlay over a map. For the demonstration, public real-world data streams with positions of aircraft and transport data are processed. Continuous range queries such as *which aircraft is currently in the area of Berlin?* or continuous spatial join queries such as *which bus drives currently through a forest?* are executed, and the results can be observed in real-time. The spatial joins are executed between the stream data and previously stored static geographical information (e.g., the polygons of roads or forests), which are fetched from the OpenStreetMap Project.

1 INTRODUCTION

Data streams consisting of position data are ubiquitous. For example, aircraft periodically broadcast their positions via *ADS-B messages* (*Automatic Dependent Surveillance–Broadcast*), and the positions of buses, trains, or ferries of public transport companies are available in real-time via the internet in GTFS format (*General Transit Feed Specification*). Processing streams containing position data is an essential topic in location-aware applications. The ability to capture data streams and the near real-time execution of queries is required to deal with the information of the stream. Data streams can contain a lot of elements, and queries can be expensive to evaluate. Therefore, a scalable solution is required to process data streams.

BBoxDB Streams is an extension of *BBoxDB* [15], which allows the efficient handling of *n*-dimensional data streams. BBoxDB streams implements a novel way to execute efficient continuous joins between dynamic elements from a data stream and static already stored *n*-dimensional big data. This capability is shown for the first time in this demonstration. Besides, the GUI of BBoxDB was enhanced to execute queries on data streams and show the results interactively. This new enhancement is shown in this demonstration for the first time. BBoxDB streams is included in BBoxDB since version 0.9.5 and licensed under the Apache 2.0 license. The software can be freely downloaded from the website of the project [3].

In this demonstration, we show two types of queries with BBoxDB Streams: (1) *continuous range queries*, and (2) *continuous spatial joins*. Continuous range queries can answer questions such as *which aircraft are inside of a specific region of the airspace?*. Continuous spatial joins can be used to join the dynamic position data of the stream with static data (e.g., geographical information). With a continuous spatial join, queries such as *which buses are closer than 10 miles to a forest?* or *which bus drives on a particular street?* can be answered.

The rest of the paper is organized as follows: Section 2 describes the key-features of BBoxDB and BBoxDB Streams. Section 3 describes our demonstration. Section 4 describes the related work. Section 5 concludes the paper.

2 BBOXDB AND BBOXDB STREAMS

The amount of data is increasingly growing. NoSQL databases like *distributed key-value stores* (DKVS) are often used to handle large amounts of data. In a DKVS, the data are assigned to the nodes of a cluster. Each node stores only a part of the whole dataset. A value is stored under a given key. Using this key, the value can be retrieved. The key is the access path to the data. A key for a one-dimensional value can be easily chosen. For data with a higher dimensionality, a key is hard to choose. Which key should be used for the geographic information about a road? Using the name of the road as the key does not help to access the data when a spatial range query is performed; the name does not contain the information where the road is located. To answer such range queries, a full data scan has to be performed; all stored tuples have to be loaded and it needs to be tested whether or not the stored value intersects with the given query rectangle. This is an expensive operation that is performed on all nodes of the distributed system.

BBoxDB was designed to solve this problem. BBoxDB is a distributed *key-bounding-box-value store* (KBVS) which supports the efficient storage and retrieval of *n*-dimensional data.

2.1 Basic Concepts of BBoxDB

BBoxDB is a distributed generic datastore optimized for the handling of *n*-dimensional big data. Values are stored as byte arrays together with a key and an *n*-dimensional bounding box as tuples. The bounding box describes the location of the *tuple* in the *n*-dimensional space. Point and non-point data are supported by BBoxDB. Tuples are grouped together in *tables* and multiple tables of the same dimensionality can be stored together in a *distribution group*. The space is split automatically to ensure almost equal-sized partitions; the data of these partitions (called *distribution regions*) are assigned to the nodes of a cluster. The tables of the same distribution group are distributed in the same way; this means the tables are stored co-partitioned, which enables the execution of efficient spatial joins. No data need to be transferred through the network; all join partners are stored on

the same node. The complete system is highly available, data can be replicated and failing nodes are handled automatically.

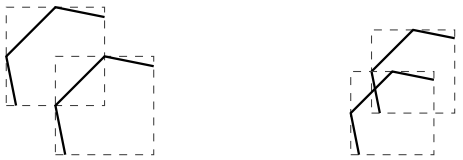
Operations: Data are stored in BBoxDB with the `put(table, key, hrect, value)` operation. As `hrect` parameter, an *n*-dimensional bounding box (a hyperrectangle) has to be specified. One-dimensional point data (as used in DKVS) can also be stored in BBoxDB. In this case, the bounding box degenerates to a point in the one-dimensional space.

Data are retrieved by the `queryByRect(table, hrect)` operation, which retrieves all tuples whose bounding box intersects with the query bounding box. The operation `join(table1, table2, hrect)` executes a spatial join between the two tables in the specified region in space.

Indexing: BBoxDB uses a two-level indexing structure that enables the efficient execution of range queries. The *global index* is used to map the distribution regions to the nodes of the cluster ($distribution\ region \rightarrow \mathcal{P}(nodes)$)[1]. The space is partitioned (split and merged) by a *space partitioner* automatically, based on the stored data [13]. Splitting and merging the space is done transparently in the background without interrupting the access to the data. BBoxDB provides multiple algorithms for the global index. The used algorithm can be specified (KD-Trees [4] or Quad-Trees [5]) when the distribution group is created. The *local index* is stored on the nodes and maps from the space to the stored tuples ($space \rightarrow tuples$). This index is implemented by an R-Tree [7] which is stored on the nodes.

User-defined filters: BBoxDB is a generic data store; the stored values are a plain array of bytes. BBoxDB does not understand the semantics of the stored data. Therefore, operations are executed primarily on the bounding boxes of the tuples. *User-defined filters* [14] (UDFs) can be used to decode the bytes of a value (e.g., GeoJSON encoded data) and to refine the bounding box based operations of the query processor. UDFs are developed by the user of the system. Only the user who has stored the data knows how to interpret the values of the data. Besides, BBoxDB ships with a collection of UDFs for common data formats. UDFs are written in Java and can use existing libraries.

One of the UDFs that have been included is capable of decoding GeoJSON data. Using this UDF, a bounding box based spatial join is refined to a spatial join on the real geometries of the values. Intersecting bounding boxes is a necessary but not sufficient criterion for a spatial join (see Figure 1).



(a) Two non-intersecting spatial objects. (b) Two intersecting spatial objects.

Figure 1: Two spatial objects (solid line) with intersecting bounding boxes (dashed line). In (a), the spatial objects do not intersect, while in (b), the spatial objects do intersect.

This UDF is used in the demonstration to refine the continuous spatial joins. The property map of GeoJSON encoded objects (see Listing 1) can also be taken into consideration in the UDF. For example, this can be used to filter streets of a specific name like *Elizabeth Street*. Queries such as *find all buses which are on a street named Elizabeth Street* become possible.

[1]When replication is used, one distribution region is mapped to multiple nodes.

2.2 BBoxDB Streams

BBoxDB is an extension of BBoxDB that allows the handling of data streams. With the extension, data streams can be captured and continuous queries can be executed. Figure 2 shows the architecture of the extension. The upper part of the figure shows the stream capturing part, the lower part the query processing part.

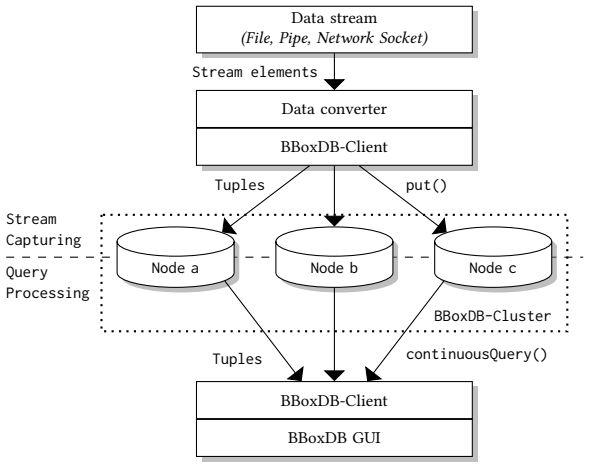


Figure 2: Handling a data stream with BBoxDB. The data stream is captured, converted into tuples, and written to the BBoxDB cluster. Afterward, the continuous queries are executed and the result can be consumed.

Stream Capturing: BBoxDB Streams captures data continuously from an input source like a *file*, a *pipe*, or a *network socket*. After a stream element is read, the element is converted into a BBoxDB tuple and sent to the BBoxDB nodes of the cluster[2]. To communicate with the BBoxDB nodes, the regular BBoxDB-Client library is used. The library manages the connection to the nodes, observes the global index, and executes the operations on the necessary nodes. Changes of the global index or the available nodes are handled. The converted stream elements are written to the BBoxDB cluster by executing the `put()` operation. The bounding box of these tuples is compared with the global index; the tuple is written to all nodes that are responsible for the region is space. On these nodes, the potential join partners are stored for a spatial join; the stream elements become co-partitioned to the already stored data, and efficient spatial joins become possible. After a node receives a tuple, the registered continuous queries are executed. The highly-available architecture is also used for the processing of the streams. Distribution groups can be stored replicated, in this case the continuous queries are also registered on multiple nodes. As the stream is written to a table, BBoxDB splits the space, updates the global index, and re-distributes uneven distributed tables automatically as described in [15, p. 20].

Query Processing: BBoxDB Streams enhances BBoxDB by two operations for the handling of continuous queries: (1) `continuousQuery(queryPlan)` and (2) `cancelQuery(id)`. The first operation registers a new query while the second operation cancels a previously registered query. The existing BBoxDB-Client

[2]BBoxDB ships with some data converter for common data formats like GTFS or ADS-B. The converter decodes the input data, calculates the bounding box and creates a tuple. Further data converters can be added easily by a user. For certain stream types, multiple elements from the stream are combined into one BBoxDB tuple. For example, the ADS-B format defines multiple message types. Three different message types have to be read to get the current data of an aircraft.

was enhanced by BBoxDB Streams to register continuous queries. The BBoxDB-Client automatically registers the queries on the required nodes of the cluster; this part of the client library was re-used. In this demonstration, the GUI of BBoxDB uses the BBoxDB-Client to register the queries and to obtain the results. These tuples are consumed by the GUI and shown as an overlay of a map. The stream handling functionality is now integrated into the regular client library. Any application can create queries on data streams and consume the results.

The query plan defines the operations of the continuous query. In the query plan, (1) the *type* of the query (range query or spatial join), (2) *transformations*, and (3) *filters* are defined. Technically, the query plan is a JSON document that is sent to the BBoxDB nodes. A helper class is available, which allows the easy and syntactically correct creation of these query plans.

Transformations allow the modification of the stream elements and the potential join partners. For example, the bounding box of an aircraft can be extended and joined with the obstacles in the airspace. Due to the enhancement of the bounding box, a possible collision is detected and reported before the aircraft and the obstacle actually collide. Also the potential collision of two aircraft can be detected. This is done by storing the data stream in a table and performing a continuous spatial join between the new stream elements and the materialized stream elements from the table.

Filters allow removing elements from the stream or from the list of potential join partners. For example, process only the aircraft with a call sign starting with `LH`. In addition, UDFs can also be used as a filter.

The complete architecture of BBoxDB and BBoxDB streams is horizontally scalable. When more static data have to be stored, the existing distribution regions can be split, and these new regions can be assigned to further BBoxDB nodes. This can also be done to process a larger stream or more continuous queries. The use of more distribution regions splits up the stream into more parts. Each part is handled by an individual node that has its own resources to capture the stream and execute the registered queries.

3 DEMONSTRATION

A cluster of five nodes is used in our demonstration, which is located at our university. Each node contains an Intel Xeon E5-2630 CPU, 32 GB of memory and four 1 TB hard disks. All the nodes are connected via a 1 Gbit/s network and running Java 8 on a 64 bit Ubuntu Linux. A notebook is used to run the GUI and to perform the demonstration.

3.1 Data Streams for the Demonstration

In this demonstration, two real-world data streams are used: (1) *The ADS-B aircraft data stream* and (2) *the Sydney transport data stream.*

An aircraft continuously broadcasts its position periodically via radio as ADS-B transmissions. The transmissions contain the position of the aircraft, the height, the call sign, and some more information. However, an ADS-B receiver captures only the transmissions in a radius of some miles around the antenna. Websites such as adsbhub.org [19] provide a service to aggregate the feeds of several individual stations into a global feed, containing the flight data of the whole world.

The government of the state of New South Wales in Australia operates the *NSW open data portal* [17]. On this portal, real-time data about buses, ferries, metros, and trains of the region are published. A GTFS encoded real-time feed of the data can be subscribed.

For our demonstration, the elements of both data streams are used and converted into GeoJSON objects. GeoJSON is a format that can be read and understand by a human (in contrast to binary-encoded GTFS data), which makes it suitable for demonstration purposes. Listing 1 contains one element from the public transport data steam after it is converted into GeoJSON. In addition to the position of the bus, further *properties* are contained which contain additional information such as the route or the speed of the vehicle.

Listing 1: Bus trip data converted into GeoJSON

```
{
 "geometry":{
  "coordinates":[151.17762756347, -33.92598342895],
  "type":"Point"
 },
 "type":"Feature",
 "properties":{
  "Speed":"19.2",
  "TripStartDate":"20200121",
  "TripScheduleRelationship":"SCHEDULED",
  "OccupancyStatus":"MANY_SEATS_AVAILABLE",
  "TripStartTime":"02:00:00",
  "RouteID":"2437_N20",
  "Timestamp":"1579530867",
  "TripID":"883447",
  "Bearing":"77.0",
 }
}
```

For executing spatial joins, we fetched the *planet* data set from the *OpenStreetMap Project* [18], converted this data set into GeoJSON, and stored it in the BBoxDB cluster. The dataset contains the geographical information of the whole world. We imported the *roads* (146 060 493 elements - 67 GB) and the *forests* (5 187 592 elements - 5.4 GB) in our BBoxDB cluster for the demonstration.

3.2 The GUI of BBoxDB

The GUI of BBoxDB shows information about the BBoxDB cluster, the data distribution, and can be used to perform queries. BBoxDB Streams enhances the GUI in such a way that continuous queries are supported. The GUI is optimized for the handling of GeoJSON encoded data. On the main screen, a map of the world (fetched dynamically from the OpenStreetMap Project) is shown. The mouse can be used to create a query rectangle, and a window that is automatically opened allows one to specify the desired query. Continuous range and continuous spatial joins can be executed, and user-defined filters can be applied.

The geometries of the result tuples are shown as an overlay over the map. In addition to the location, the stream elements contain further information. Placing the mouse cursor over an element opens a tooltip. The tooltip contains all the additional information that is contained in the GeoJSON object (e.g., the height of an aircraft or the trip id of a bus). The area of the GUI below the map shows details about the used cluster (i.e., IP, software version, available disks, disk space, CPUs).

Different practical queries can be formulated and observed in the GUI. Figure 3 shows the visualization of an ADS-B data stream of aircraft in the region of Berlin, Germany. Another example (see Figure 4) shows the visualization of a GTFS data stream of metro buses in Sydney, Australia. Additional operations, such as spatial joins between forests and buses (*Which bus drives currently through a forest*?) or roads and buses (*Which buses are driving on the Elizabeth Street in Sydney?*) can be performed and displayed in the GUI.

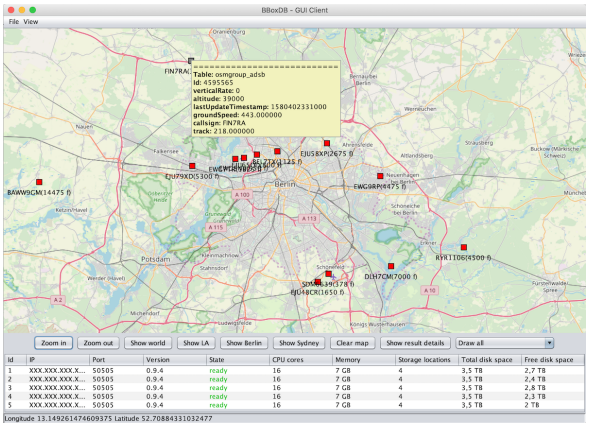

Figure 3: Observing aircraft traffic over Berlin, Germany.

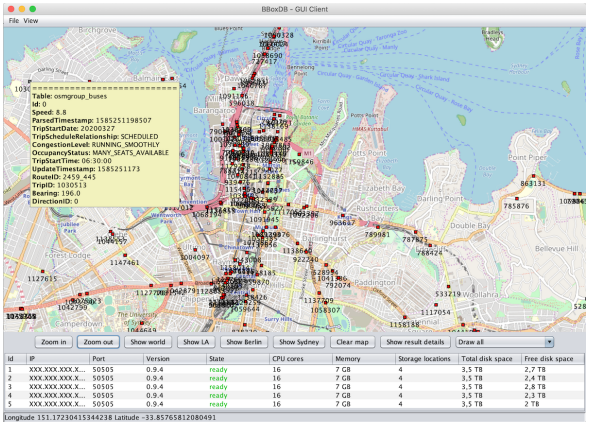

Figure 4: Observing bus traffic in Sydney, Australia.

4 RELATED WORK

BBoxDB and BBoxDB streams have related work in the area of key-value stores and stream processing systems.

Key-Value Stores: During the last decade, NoSQL databases have become popular. They omit features from RDBMS, such as transactions and permanent consistency. This allows NoSQL systems to scale better horizontally. Distributed key-value stores such as *Cassandra* [9] or *HBase* [1] provide simple methods to manage large amounts of key-value pairs. These are optimized for one-dimensional data, since handling n-dimensional data is a laborious task in such systems (see Section 2).

KVS with support for n-dimensional data: *MD-HBase* [16] is a multi-dimensional extension of HBase that allows the efficient storage and retrieval of multi-dimensional data. MD-HBase employs *Quad-Trees* and *K-D Trees* together with a Z-Curve to build an index. Systems such as *EDMI - Efficient Distributed Multi-dimensional Index* [21], *Pyro* [10], and *HGrid* [8] are also enhancements of HBase which use an additional index layer to store multi-dimensional data in HBase. However, operations such as spatial joins or continuous queries are not supported by these systems, and these systems only support point data.

Stream Processing Systems: *Apache Flink* [6], *Apache Spark Streams* [11], *Apache Storm* [2], and *Apache Kafka* [12] are widespread stream processing systems. These systems are not optimized to compare the stream data with larger previously-stored datasets. Operations like geometric indexing or spatial joins are not supported by these systems. In [20] an extension of Apache Storm for the handling of spatial data streams is proposed. However, the paper focuses only on 2-dimensional point data; BBoxDB streams can handle n-dimensional point and non-point data.

5 CONCLUSION

In this demonstration, we have shown the capabilities of BBoxDB Streams for the first time. Two real-world data streams are captured and processed. Queries such as continuous range queries and continuous spatial joins are performed on these streams. The spatial joins are executed between the dynamic data from the data stream and static stored data fetched from the OpenStreetMap Project. The results of the queries are visualized using an enhanced version of the GUI of BBoxDB and user-defined filters are used to refine the bounding box based operations of the query processor. In this demonstration, many aspects of the architecture of the system are only superficially addressed. Topics such as the integration with BBoxDB, the scalability, the filters, and transformations have to be described more precisely. We plan to discuss these topics in detail together with an experimental evaluation of BBoxDB Streams in a full research paper.

Correlation graph analytics for stock time series data

Tong Liu, Paolo Coletti, Anton Dignös, Johann Gamper and Maurizio Murgia
Free University of Bozen/Bolzano, Bozen/Bolzano, Italy
{name.surname}@unibz.it

ABSTRACT

Stock market events are hard to model. In recent years, one approach that has been receiving increasing attention is to analyze graphs induced by price correlations of different stock companies. By analyzing the structure of such graphs, it is possible to identify critical events, e.g., market crises. To the best of our knowledge, there are no tools available that offer comprehensive support for such analyses. This paper introduces a novel tool that offers in-depth analysis with the ability of fine tuning parameters with an intuitive user interface. With a proposed workflow to handle time series data, the tool becomes versatile and it can analyze correlation graphs of different semantics: minimum spanning tree, graphs with edge thresholds, and evolving graphs. It also provides a rich set of functions that enable users to explore easily, interactively and systematically the correlation graphs starting from a file of raw time series data. With real-world stock data, we demonstrate how straightforward yet effective it is to accomplish various analytical tasks with the proposed tool.

1 INTRODUCTION

Time series systems are pervasively used in many domains for different tasks such as monitoring and recording data gathered over time, with which analysts can discover meaningful and valuable information to understand the observed system and to avoid risks. The examples of applying time-series technologies to real-world problems are numerous, e.g., fault detection [18], seasonal trend analysis [21], financial data [11], etc.

For the analysis of financial data, Mantegna [14] proposed to compute all correlations between the time signals and to visualize them in a graph. This is illustrated in Fig. 1. First, the pairwise correlations between the five input signals are computed and stored in a matrix. Then, the correlation matrix is transformed into a graph, where nodes represent signals and edges are labeled with the correlation coefficient between the two nodes. Instead of visualizing a complete graph, the minimum spanning tree (MST) is often used as a compact overview of the signal correlations.

In recent years, a significant number of works have shown that by observing changes in the structure of a MST, it is possible to deduce important events in stock markets, such as market crises and volatility [5, 6, 16]. Many studies about stock market analysis adopted this approach and investigated the structure and topologies of the induced network or MST [4, 6, 9, 19]. The study of correlation graph analysis also raised the attention of the computer science community. Marti et al. [15] studied the best window length to calculate time series correlations. Azzalini et al. [2] proposed a technique to detect significant changes in financial time series clusters expressed with hierarchical correlation trees. Luo et al. [12] used correlation graphs to spot cheating behaviors with business data. In the database community, research focused on efficient methods for correlation graph

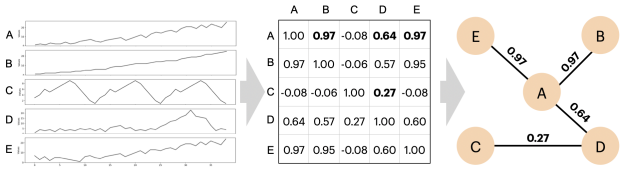

Figure 1: Correlation analysis of time series using MST.

analyses. Petrov et al. [17] proposed different approaches for exploring correlated time signals interactively. Aghasadeghi et al. [1] presented techniques to visualize evolving graphs at different resolutions. Likewise, Mamun et al. [13] studied efficient solutions for computing MSTs.

When it comes to correlation graph analytics for financial data, analysts have to tackle several challenges: identifying appropriate parameter values such that the computed correlation graph is meaningful and presents visible characteristics; investigating whether patterns exist for graphs under different representational semantics, such as MST, graphs with specific thresholds, graphs of signal classes; assessing the robustness of graph features (e.g., radius, degree distribution), and determining if they are reliable to capture special events. Existing tools in the finance literature [4, 6, 9, 19] suffer at least from the following two limitations: (i) they offer only a few of the above mentioned aspects and (ii) they were implemented ad hoc for specific case studies and are not designed to be easily integrated with other tools or analyses.

In this demo paper, we present a versatile and user-friendly tool for analyzing time series data based on the pairwise correlations that are visualized in a graph. We propose a workflow in which the parameters are considered logically, and it allows a high level of flexibility to visualize and analyze the graphs: the comparison of two graphs representing subsequences of the data selected by two different windows; the evolution and changes of a graph over time by applying a moving window; and a compact heatmap representation of crucial graph parameters for all possible windows over the data. Throughout the paper, we use the financial domain to illustrate the key features of the system. However, the analysis tool can also be applied in other domains, as we will illustrate in one of the demonstration scenarios. The tool is online at https://dbs.inf.unibz.it/projects/ismard/, and people can use it with their data at hand. In four demo scenarios we discuss how to use the tool and what can be learned by a data analyst.

2 SYSTEM OVERVIEW

2.1 Architecture

The system is implemented as a web App based on a client-server architecture (cf. Fig. 2). On the client side, a user can upload time series data, set parameters for data pre-processing and graph computations, and inspect the resulting graphs. By tuning the parameters in the client side, the web page will perform AJAX calls and trigger the processing of the data in the server. The computed graph data is then returned to the client and interpreted by visualization components. On the client side, two Javascript

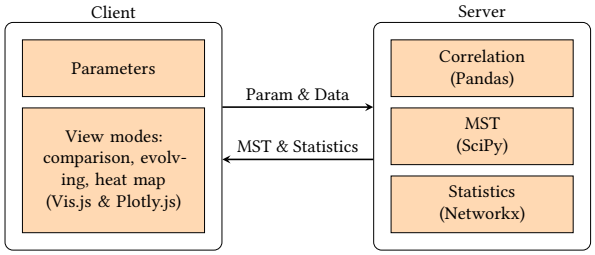

Figure 2: System Architecture

libraries are used for the visualization: VIS.js for graph views and Plotly.js for data reports. On the server side, three Python libraries are employed: Pandas for correlation computation, SciPy for MST computation, and Networkx for graph statistics.

2.2 Data and Parameters

The system accepts time series data in CSV format. The first row specifies the signal names. Each subsequent row stores a time point followed by the signal values for that time point. Missing values are marked with `NaN`. Optionally, a second CSV file containing ⟨signal name, class name⟩-pairs can be uploaded in order to group the time signals into classes.

There are a number of parameters that can be controlled by the user and make the tool flexible for data analytics. For the preparation of the input data, the user can, among others, specify a time granularity (e.g., daily, weekly, or monthly) for the analysis and whether to use the raw data values or the variation of the value w.r.t. the previous time point. The computation of the correlations and the construction of the MST/graph can be controlled by several parameters, including a time range for the analysis, the required minimum number of values for each signal for a meaningful analysis, a minimum overlap between two signals, and a correlation threshold for an edge to be included in the graph visualization. Finally, for the visualization of the analysis results three different views are offered.

2.3 Analysis Workflow

The first step in the analysis workflow is to load the raw data file, store it on the server, and then to optionally apply two *preprocessing* operations. First, the user can specify a time granularity for the analysis which is different from the granularity of the raw data. For instance, in the financial sector the raw data typically contain the daily closing prices, but financial analysts often prefer to use weekly or monthly price values in order to reduce noise. Instead of computing the average, the closing price of Thursday is used as the weekly price, and the price of the last trading day of each month as the monthly price. To support the analysis of data from other domains, the tool also offers the use of the average value in combination with different granularities. Second, the analysis of stock data usually investigates the variation of the price rather than the price itself. Two different variations are frequently used: the return rate, which is the relative price difference to the previous time point, i.e., $r_i = (p_i - p_{i-1})/p_{i-1}$ with p_i being the closing price at time point t_i; and the log return $r_i = (\log p_i - \log p_{i-1})$. The result of the pre-processing phase is stored in the so-called working file on the server.

The next step is to compute the *pairwise correlations* matrix using the Pearson Correlation coefficient. For this, the subsequences of the signals that correspond to the specified window are loaded from the working file into a so-called DataFrame — an efficient two-dimensional main memory data structure of the Pandas library, which natively supports the computation of the Pearson correlation. To obtain robust and reliable results, time series that contain an excessive number of missing values are omitted from the computation of the correlation. Similarly, we do not compute the correlation between two time series if they do not sufficiently overlap in time. Both parameters can be controlled by the user. For the time series that pass these filters, the Pearson Correlation coefficient is computed, which for two time signals x and y with average value $\bar{x}$ and $\bar{y}$, respectively, is defined as $r = \frac{\sum_{i=1}^{n}(x_i-\bar{x})(y_i-\bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i-\bar{x})^2}\sqrt{\sum_{i=1}^{n}(y_i-\bar{y})^2}}$ with $-1 \leq r \leq 1$. A value of 1 indicates total positive linear correlation, a value of -1 total negative linear correlation, and a value of 0 no linear correlation. Instead of analyzing the correlation between individual stock signals, the user can decide to investigate the stock sectors (classes), which allows them to gain insights into entire sectors rather than individual stocks. The signal of a class is computed as the average of all stock signals belonging to that class. More advanced aggregation methods are known in the literature, e.g., the free-float adjusted market-capitalization weighting method [10], which computes a weighted average based on the stock shares.

Next, we compute the *minimum spanning tree (MST)* from the correlation matrix using the classical algorithm by Kruskal [7]. Each node represents a stock signal, and the edges are labeled with the correlation coefficient between the connected nodes. As an alternative to the MST, a correlation graph can be used for the visualization. Since a complete graph would not be very useful for analysis purposes, the user can prune weak edges by introducing a threshold for the correlation.

The last step is to compute several *statistics* for the MST/graph. A very important measure for the analysis is the degree distribution of the graph nodes. This measure reflects structural information of a graph and can be used to detect stock market events [3, 6]. Other useful statistics include the range of the actual correlation values and the radius of the MST/graph. Additionally, we also compute the modularity score [8, 20], which allows us to measure whether the stock connections in a MST correlate with the stock sectors. This score is defined as $\sum_{i=1}^{k}(e_{ii} - a_i^2)$, where k is the number of sectors, e_{ii} is the percentage of edges connecting two nodes of the same sector i, and a_i is the percentage of edges for which at least one node belongs to sector i.

2.4 Interaction and Result Visualization

For the visualization of the analysis results, our tool offers three principal viewing modes: comparison mode, evolving graphs mode, and heatmap mode.

The goal of the *comparison mode* is to analyze the data over two different time periods in order to spot similarities and differences, e.g., comparing a normal period with a crisis period. Figure 3 shows a screenshot of this mode, which contains two panels for the two graphs. A scroll bar allows users to select a time window for the analysis. The graphs report the node names (either signal name or class name), and edges are labeled with the correlation coefficients. By clicking on a node, additional information is shown such as the node's eccentricity and class. A color coding is used for the graphs. The node color indicates the class of the represented stock. For the edges, the colors distinguish different levels of correlation: red for high correlations above 0.7, orange for medium correlations between 0.4 and 0.7, and gray for low correlations below 0.4. At the bottom of the screen, the computed statistics are summarized.

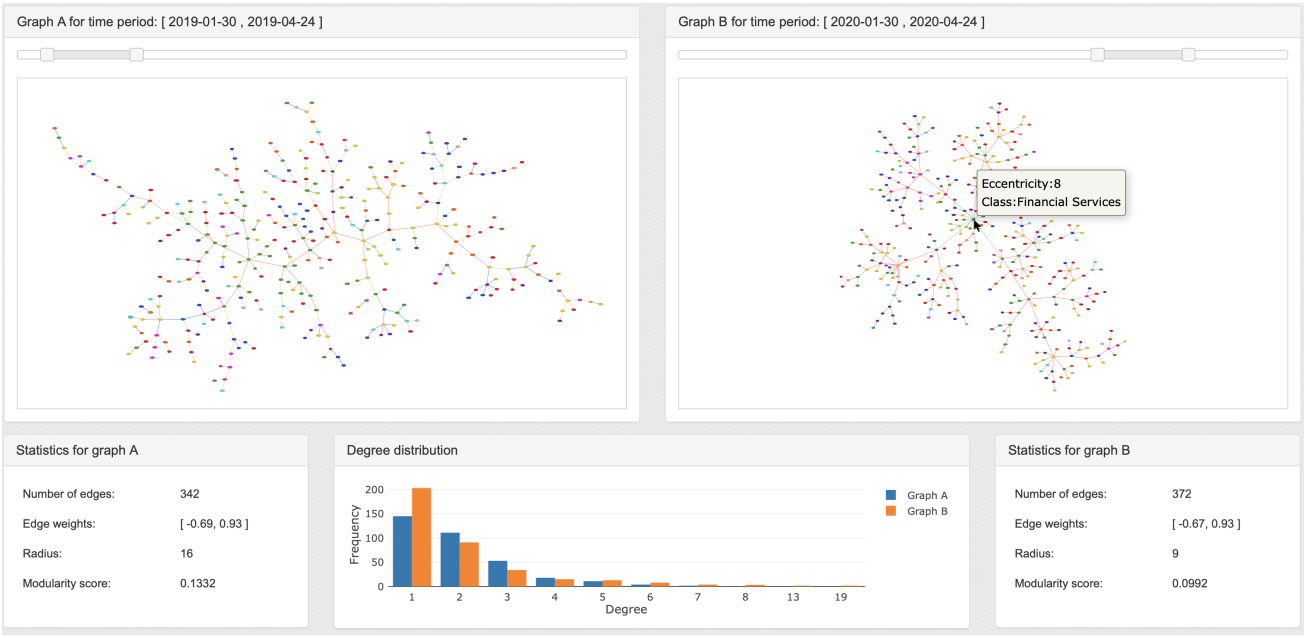

Figure 3: Compare MSTs in ordinary period with COVID crisis period.

The *evolving graph* mode shows the evolution of a graph along the time axis, which helps to understand the subtle changes of graph components over time. For this, a sliding window is used, where the user can specify the window length and the step size. For each window a graph is computed. To highlight the changes between consecutive windows, the new edges w.r.t. the previous graph are shown by dashed lines (cf. Fig. 4).

The *heatmap* mode helps to understand the stability and reliability of a MST metric w.r.t. the values of the selected time window. For this, we compute a heatmap for three important graph metrics: first degree score defined as the number of nodes with degree one divided by the total number of nodes; the modularity score; and the radius. Each heatmap shows the metric for all possible windows over the data (cf. Fig. 5). The x-axis represents all possible starting points of time windows, and the y-axis all possible window lengths. Heatmaps allow users to investigate whether the metric value changes drastically with different time windows, as well as discern whether a metric's values are similar with time windows that cover special events in the timeline. The heatmaps are interactive. By clicking on the heatmap, the system computes the MST over the corresponding window. This allows us to inspect the MST in detail. Since the computation of the heatmaps in real time is a computational bottleneck, this feature is currently only activated for the demo dataset. An efficient computation of the heatmaps for large datasets is part of our future work.

3 DEMONSTRATION SCENARIOS

The following four scenarios provide a glimpse of how our tool can be used to systematically investigate behaviors and properties of time series data. We use the Italian stock market data collected from Yahoo Finance. This dataset contains the daily stock prices of 407 companies which traded from January 2019 to June 2020 and includes the COVID stock crash. The companies are classified into 12 market sectors, such as financial service, real estate, energy, etc. In addition, we use a dataset that contains signals from industrial devices provided by a local company.

Comparing Normal and Crisis Periods. In the first demo scenario, an analyst is interested in investigating how stock correlations were affected by the COVID crash. This can be observed by graph shapes and indicators in the comparison mode shown in Fig. 3. The left-hand side shows the MST over a normal period (Jan 2019 – Apr 2019), while the right-hand side shows the MST during the COVID crisis (Jan 2020 – Apr 2020). From the graph shapes, analysts can observe that the crisis led to the formation of many star-like hubs and red-color edges, indicating that a large number of companies were strongly correlated. From the indicators, analysts find that during the COVID crisis the MST had a much smaller radius and a steeper degree distribution compared to the normal period. In particular, significantly more nodes had a degree of 1 during the crisis period. Similar analyses can be performed for other market events. More details on shapes and indicators are described in [6]. Moreover, different parameter values and time windows can be chosen to examine the stability of the above features.

Changes over Time. In this scenario, an analyst wants to investigate whether the correlation between different sectors has changed in proximity to the COVID crash. This type of analysis is supported in the evolution mode. Figure 4 shows the MST computed over three consecutive windows over the aggregated stock signals. The length of the sliding window is three months, and the step size one month. A dashed line indicates a new edge compared to the MST over the previous window. It can be observed that the Industrials sector (red node) tends to be at the center of the tree. Presumably, sectors in Fig. 4c that are connected with Industrials are the most negatively affected sectors by the COVID crash. In contrast, Healthcare (purple) switched its connection from Technology to Consumer Cyclical and Utilities. They could be the positively influenced sectors, since with the medical research and "stay at home" order, these sectors either received more investments or increased consumption.

Figure 4: Evolving graphs.

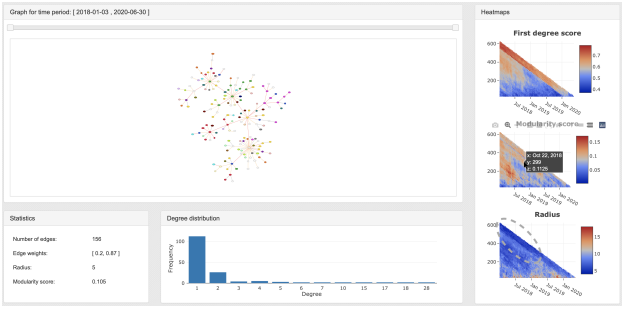

Figure 5: Heatmap view.

Concise Overview of All Windows. A critical aspect for time series analysis is to choose an appropriate window length, owing to the fact that real-world data are often noisy and contain missing values. The heatmap mode helps in this regard as it provides a concise overview of important MST metrics over all possible windows. An example is shown in Fig. 5 with three heatmaps for the first degree score, the modularity score, and the radius of the MST, respectively. It can be observed that for long time windows (i.e., more than 300 time points) the radius is more reliable to signal the crisis period. This is explained by a dark strip at the top border of the heatmap (gray circle in Fig. 5). It appears that for all long time windows that cover the crisis period, the radius of the corresponding MST is significantly lower than the MSTs in normal periods. A similar pattern can be observed for the heatmap of the first degree score. In this scenario, a user learns which are sound indicators for detecting crises and the conditions to use them, e.g., the appropriate window length.

Beyond Stock Data. To show the generality of our tool, we also provide a demonstration scenario for the analysis of data from the industrial sector. The time series come from sensors monitoring components of large industrial printers, such as the temperature of internal CPUs, ink speed, or belt velocity. In this scenario, we show how our tool can be used to understand the interaction of different components, similar to stock sectors, based on their correlation over different time periods.

4 CONCLUSIONS AND FUTURE WORK

In this demo paper, we presented a new web App to investigate stock time series data. The key idea is to compute the pairwise correlations between the data and – in order to facilitate the analysis – to visualize them in a minimum spanning tree, where nodes represent the trading companies and edges show their correlation. With Italian stock market data we demonstrated the effectiveness and versatility of our tool.

Future work points in two directions. First, we will investigate more efficient algorithms for the computation of heatmaps in order to make the tool scalable for larger datasets. The other direction concerns the use of machine learning techniques to detect useful parameter configurations for the analysis automatically.

ABSTRACT

The Python programming language has become very popular among data scientists because of its easy-to-learn syntax and rich ecosystem of libraries. Especially the Pandas framework is widely used for various data processing and analytics tasks. However, due to its memory management and eager evaluation Pandas does not scale and workstations quickly come to their limits even for moderate data set sizes. With Grizzly, we introduce a framework that produces SQL queries for operations on `DataFrames`, moving complexity from workstations to database servers. Grizzly allows to not only access data already stored in a database, but also to combine it with external data from files. Furthermore, users can use their own user-defined functions or use Grizzly's model join feature to easily apply machine learning models to data, both being executed inside the database server. This allows for fast and scalable data analytics operations, even with a small workstation.

1 INTRODUCTION

Data Science and Machine Learning are hot topics, not only in research but also in industrial and commercial applications. Although the terms *Data Analysis* and *Data Science* date back to the early 1960s and 1970s, respectively, with the rise of *Big Data* in the early 2000s more and more companies started to collect and analyze every piece of information they could generate about their, e.g., sales and customers with the goal to gain insights that help to improve the companies productivity and business. One of the standard languages for data science tasks is Python (besides Julia and R). Python has become very popular because of its easy to learn syntax that allows to quickly build prototypical data processing pipelines. One of the most popular libraries for Python in the field of data analytics is Pandas. It allows to easily load data from various sources and represents it in `DataFrames`– a table-like abstraction with column names, types and more meta information. Using Pandas, one can load data in various formats from local or remote locations into `DataFrames` and apply operations such as projection, filter, grouping, join – all well known from the relational algebra. In Pandas, these operations are executed on the local machine of the data scientist and create copies of the data in the local RAM. Since this is slow and means larger-than-RAM data sets cannot be processed easily, data scientists who should actually focus on their data analytics tasks, started to build their custom solutions for parallel processing or buffer management. However, the database community has built fast, robust, and scalable systems to perform exactly this kind of operations efficiently, even if the complete data set does not fit into RAM. Often the data to analyze is already stored in such reliable database systems. Thus, instead of moving the data from the large DBMS server into the potentially small data scientist's laptop for processing, the operations defined in the Python script should be transferred to the DBMS and be translated into a language it understands, i.e. SQL.

During recent years, a few systems have been developed to address these needs, such as RIOT-DB [12], AIDA [3], Modin [9], AFrame [10], and IBIS[1]. IBIS was initiated by the creators of Pandas and tries to overcome the scalability issues of Pandas by using lazy evaluation and converting operations on `DataFrames` into a (sequence of) SQL queries. However, it is not possible to join data from different database systems and UDFs can only be executed using the Pandas backend (i.e. local execution) or on Google Big Query. The `DataFrame` concept has also been adopted by other frameworks like Apache Spark [11], Koalas[2], and Nvidia Rapids[3]. Internally, these systems use optimizers to tune the query and produce good execution plans. The idea of providing a `DataFrame` API over graph data has been studied for example in [2] and [8].

In this paper, we demonstrate our Grizzly[4] framework for transpiling Python code to SQL queries, with the following features:

- Grizzly uses query-shipping and lazy evaluation to achieve high scalability.
- It supports relational operations in standard SQL syntax and uses configurable templates for DBMS-specific dialects without changing the underlying execution system.
- External data can be combined with in-DBMS data.
- Users can define their own functions (UDFs) in Python to apply within the generated query.
- Grizzly uses the UDF mechanism to load and execute pre-trained machine learning models inside the database.

In our demonstration, we show how easy it is to exchange Pandas with Grizzly as the execution engine for `DataFrame` programs. Using a web application, users can compare Pandas and Grizzly scripts, either using our provided examples for various scenarios or writing own code, side-by-side and run them on prepared datasets. Our demo system automatically generates comparison charts for query performance and memory consumption. As these charts are maintained over multiple runs, users can built their own evaluations by varying parameters like the dataset size.

2 REQUIREMENTS

Companies typically store their valuable data in some durable and integer database. This database consists of various tables,

[1] http://ibis-project.org/
[2] https://www.github.com/databricks/koalas
[3] https://developer.nvidia.com/rapids
[4] https://github.com/dbis-ilm/grizzly

containing, e.g., the customer information, the products the company sells, and of course the orders the customers have made over time. This basically resembles the well-known TPC-H [1] benchmark and for larger companies this database can quickly store several GBs. Below we briefly describe use case scenarios from which the requirements for a system that shifts the processing into the DBMS can be derived.

Basic Data Processing. As an example use case, a data scientist may be interested in the names of the customers, who ordered a specific product most often. Using Pandas, the scientist would load the tables `customer`, `orders`, and `products` onto her local workstation and then filter the products by the product name she is interested in, join the remaining products with orders and then with customers. Finally, the join result may be grouped by the customer and aggregated to count how often they have ordered the specific product.

At this point we would like to emphasize that with Pandas, all these processing steps take place in the scientists workstation and not on the actual database server that stores this data. Though, Pandas is able to send a SQL query to a database server in order to fetch proprocessed data. However, we argue that many data scientists often don't know or use SQL and prefer their higher level languages. Thus, to improve the query performance and often make the evaluation possible at all, the computational part should be shifted into the database server while letting the users still express their analysis tasks in Python.

Accessing External Data. After getting these top customers, the data scientist needs to find out how these products are perceived in social media platforms. The company may track social media posts using some additional systems and collects the product reviews in a text file. However, these posts are not critical to the company and are not ingested into the DB. Thus, the data scientist needs to join the data in the DB with the data in files. Currently, this operation would typically also be executed on the workstation, but should optimally be executed by the DBMS. In order to do so, the DBMS must import the file as a (temporary) table. This import should be transparent to the user so that she only needs to specify a file path, but does not have to bother with DBMS specific import code.

UDFs & Model Join. The well-known data processing libraries all provide a vast variety of algorithm implementations and operators for various tasks. However, these may not be enough for every problem to solve and users fall back to implement their own logic in user-defined functions which they want to apply. Such functions could either be applied to every record individually or to one table/data set as a whole. Again, the function could be applied on the workstation using Pandas, but then subsequent operations which could be handled in the DBMS are not possible anymore. Thus, the function's code should also be shipped to the database server transparently for convenient execution.

A special case is the application of some existing machine learning model. An existing model like RoBERTa [6] may be trained to detect the sentiment of some text, i.e. if it is positive or negative. After the data scientist joined the top customers and products with the product reviews from a text file, she needs to classify how the reviews rate the corresponding product. Thus, she needs to join the model with the data (intermediate query result) in the database. For this, it must be possible to select and load an existing model and join it with the data in the database, i.e. apply it to every tuple of a table/intermediate result. In further discussion we name this concept model join.

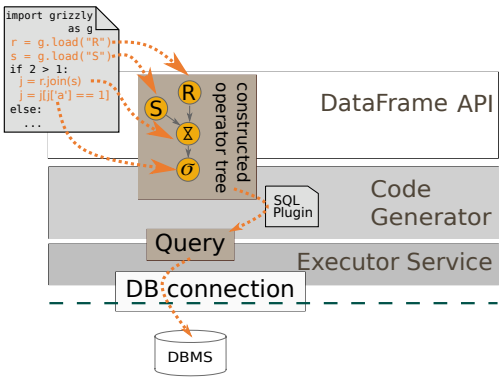

Figure 1: Overview of Grizzly's architecture.

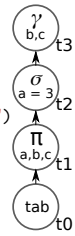
```
# load table (t0)
df = grizzly.read_table("tab")
# projection to a,b,c (t1)
df = df[['a','b','c']]
# selection (t2)
df = df[df.a == 3]
# group by b,c (t3)
df = df.groupby(['b','c'])
```

(a) Source Python code.



(b) Operator tree.

```
SELECT t3.b, t3.c FROM (
  SELECT * FROM (
    SELECT t1.a, t1.b, t1.c
    FROM (
      SELECT * FROM tab t0
    ) t1
  ) t2 WHERE t2.a = 3
) t3 GROUP BY t3.b, t3.c
```

(c) Produced SQL query.

Figure 2: Steps for transpiling Python code to a SQL query: The operations on `DataFrames` (a) are collected in an intermediate operator tree (b) which is traversed to produce a nested SQL query (c).

3 GRIZZLY ARCHITECTURE

The scalability issues of the Pandas framework are a consequence of two major bottlenecks:

- Pandas operations are executed eagerly, producing numerous intermediate results that increase the memory consumption of a Pandas program.
- Pandas uses the data-shipping paradigm, which means that data is transferred to the place where the program is executed. Despite being easy to use, the data-shipping paradigm limits scalability as potentially large amounts of data are transferred. Operators are executed on the client-side, which usually consists of weaker hardware compared to (cloud) servers.

The design of the Grizzly framework focuses on solving these two problems. First, Grizzly replaces the eager operator execution approach with a lazy approach by collecting operators and generating a query when the result is needed. Second, Grizzly combines the convenience of the data-shipping paradigm with the scalability of the query-shipping paradigm by abstracting from data access and pushing query execution to the DBMS.

An overview of the Grizzly architecture is given in Figure 1. Grizzly provides a Pandas-like `DataFrame` API for compatibility with existing Pandas programs. In order to achieve the lazy execution paradigm, Grizzly collects operators and builds a lineage graph as an internal query representation, following a similar approach as RDDs in Apache Spark [11]. Operators are classified as transformations (e.g. projections, filters, joins) or actions (e.g. show, count, sum). While transformations are collected in the lineage graph, actions trigger code generation and execution. In order to meet the second design goal of using the query-shipping

paradigm, Grizzly transpiles the lineage graph of `DataFrame` to standard SQL, compatible with a broad range of DBMSs. The transpilation is achieved by traversing the lineage graph and using a mapping between `DataFrame` operators and SQL query constructs, which is described in detail in [4]. There are two options for incrementally constructing a SQL query:

(1) Incrementally extend `SELECT`, `FROM` and `WHERE` blocks of a (single) SQL query, or
(2) generate a separate query for each operator and nest the existing query in the `FROM` clause.

While producing more compact and easier-to-read queries, option (1) has the drawback that nesting is still required in some cases, e.g. for a filter on a computed column. These cases require special handling in the code generation as well as a careful naming. We observed that modern query optimizers of existing DBMSs have excellent capabilities for unnesting queries, and thus decided to follow option (2) and apply a generic naming schema for sub-queries. Queries are send to the DBMS using a standard connection object as specified by PEP 249[5]. Additionally, Grizzly uses a template file in order to match vendor-specific SQL dialects. An example workflow for transpiling a Pandas program into a nested SQL query is shown in Figure 2.

4 API EXTENSIONS

Modern data analytics tasks not only use traditional operators, but also include the use of external data sources, user-defined functions (UDFs) or machine learning models for prediction or classification as we argued in the use case discussion in Section 2. In order to address these challenges, we extended the `DataFrame` API of Pandas with a set of operators. All additional operators are designed with the goal of hiding complexity and providing an easy-to-use interface for complex operations.

The basic approach of supporting the described features is the generation of additional queries to create functions or define external data sources. Such queries are required to be run before the actual analysis starts. Grizzly maintains a list of pre-queries and whenever the lineage graph traversal reaches an operator that requires a pre-query, it is generated and appended to the list. Finally, all pre-queries are automatically executed before the actual generated query.

External Data Sources. Various database systems offer support for external data sources by creating a table over a file, e.g. using foreign data wrappers in PostgreSQL or external tables in Actian Vector. Similar to ordinary database tables using `read_table`, external tables can be used as leaf nodes in the lineage graph. Grizzly offers the `read_external_table` function for this, which takes the path to the external source as well as the schema as parameters and returns a `DataFrame` for further usage. During code generation, the external table is generated using a pre-query and given a temporary name to be referenced in the actual query.

UDF Support. In Pandas, users can apply custom functions to `DataFrames` using the `apply` function in an elementwise fashion (scalar UDFs) or as a reduce function (table UDFs). Modelling the apply operator as an action, and therefore executing the subquery and applying the UDF at the client side, has the major drawback that further operators also need to be executed at the client side. In order to avoid this, we model UDFs as transformations in Grizzly by exploiting the recent upcome of Python UDF support in database systems. The source code of the UDF is accessed via reflection and transferred to the database system using a UDF creation as a pre-query. The function is created with a generic name and is then applied in the actual query in the projection list. Note that many database systems currently only support scalar UDFs and only offer this feature as a beta version due to security concerns. Consequently, Grizzly is currently also limited to scalar UDFs and requires the vendor-specific activation of the UDF feature in order to support UDFs. As a result of modelling UDFs as transformations, UDF computation can also be pushed to the database, enabling efficient subsequent operations on the UDF result.

```python
# Define conversion functions
def input_to_model(a: str):
        ...
def model_to_output(a) -> str:
        ...

# Use external file
df = grizzly.read_external_table("path/to/file", schema, options)
# Apply onnx classification model using conversion functions
df['class'] = df['text'].apply_model("/path/to/model",
↪  input_to_model, model_to_output)
# Count elements per classification
df = df.groupby('class').count()
# Trigger execution and show result
df.show()
```

Listing 1: Example for external file usage and model join

Machine Learning Model Join. Database systems are a non-optimal environment for training complex machine learning models, as this task is mainly performed on massively parallel engines like GPUs and involve a hybrid workload of intensive computations as well as large updates of e.g. weights in the model. However, there are various pre-trained models available that can be easily used for data analytics, e.g. in the Model Zoo on Github[6]. Applying machine learning models to data is a special case of UDFs and can also be applied to Pandas `DataFrames` using the `apply` function and handcrafted code for model execution. Grizzly offers a family of specialized `apply` functions for the most popular model formats and execution engines PyTorch[7], Tensorflow[8] and ONNX[9]. Similar to UDFs, these operators are modelled as transformations and designed for comfortable usage, demanding only necessary, model type specific parameters from the user. The generated code for model execution (application) is handled like a UDF: it is defined in the database system using a pre-query and used in the projection list of the generated SQL query. For a more detailed discussion of challenges that come with this features and their solutions in Grizzly, we kindly refer to [5].

For the discussion of the presented features we assume that necessary files like data sources or machine learning models are accessible from the database server and that required Python modules are installed. We argue that using cloud file systems or NAS storage this is not a limitation and that root access or contacting the database administrator is currently necessary anyway in order to use the UDF feature.

As an example, Listing 1 shows a program that loads an external file, applies a classification model in the ONNX format on column *text* and then counts the number of entries per class. ONNX models are typically provided with conversion functions to convert an input to a tensor and convert the output tensor

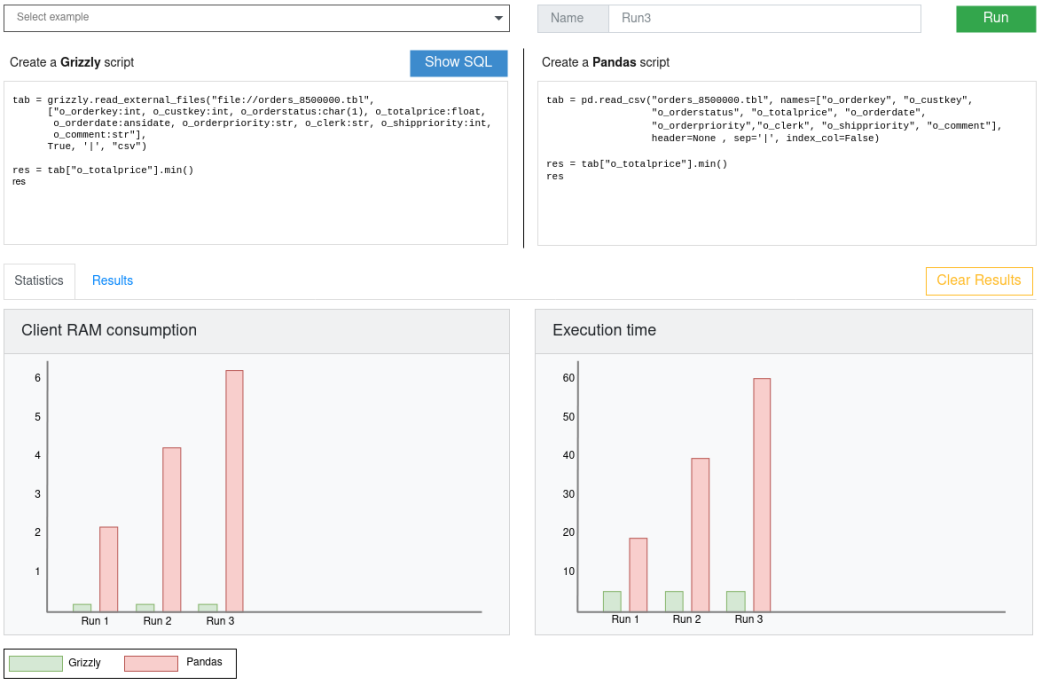

Figure 3: Screenshot of the Grizzly Web Application.

back. The type hints in the signature of these functions are used to determine the type of the overall UDF. The types are required to define the functions in SQL. Grizzly generates pre-queries for the external table and the UDF, ultimately executing three SQL statements.

5 OBSERVING THE BEARS IN THE WILD

The demonstration highlights the benefits users can expect when using Grizzly over Pandas. It invites visitors to interact with the system over a web application and Jupyter notebooks.

The application lets users choose between prepared scenarios, but also allows to run own scripts. For both cases we provide a pre-loaded collection of data sets (from TPC-H [1] and IMDB [7]) with varying sizes. The scenarios range from simple queries to more complex tasks that make use of the features we explained in the previous sections: executing UDFs, combining existing tables with external files, and performing the model join. For every scenario, a prepared Grizzly and Pandas script can be selected and executed. The side-by-side code editors demonstrate how similar the Grizzly and Pandas APIs are, but especially for the model join this will also highlight how much work Grizzly saves developers compared to Pandas. Using the "Show SQL" button, one can inspect the SQL query Grizzly transparently generates for an entered Python program. As an example, the model join scenario offers different models available in ONNX, PyTorch, and Tensorflow format to classify entries in the tables. It follows the use case described in Section 2: We connect to a movie database and join this data with reviews from a text file and classify every movie using a pre-trained model into the categories *positive* and *negative*. The final result is grouped in order to count the number of positive and negative reviews per movie. The Grizzly code is as easy as shown in Listing 1, being significantly smaller than the respective Pandas implementation. Additionally, the application shows the effort to handcraft the SQL code, which is transparently generated by Grizzly. Users can also compare the external table feature of Grizzly to the respective `read_csv` feature of Pandas as sketched in Figure 3 and observe a significant performance gain when using Grizzly. The web application tracks the execution time as well as the memory consumption during the execution of a program over multiple runs and visualizes both metrics for comparison. Through the collected result graphs and by using our input data sets of different sizes, users can build their own evaluation and investigate the scalability of the systems.

A second part of the demonstration uses Jupyter notebooks to demonstrate the easy integration of Grizzly in such environments and how it can be used to process and visualize data and query results interactively.

DocDesign 2.0: Automated Database Design for Document Stores with Multi-criteria Optimization

Moditha Hewasinghage, Sergi Nadal, Alberto Abelló
Universitat Politècnica de Catalunya
Barcelona, Spain
moditha|snadal|aabello@essi.upc.edu

ABSTRACT

We present DocDesign 2.0, a novel system that supports database design for document stores. DocDesign 2.0 automatically generates a document store design driven by a query workload and a set of optimization objectives. In the presence of a massive search space, DocDesign 2.0 adopts multi-objective optimization techniques that, with high probability, guarantee to yield the optimal design based on the preferences (i.e., weights) provided by the end-user. In this paper, we demonstrate how DocDesign 2.0 improves the productivity on the task of designing a document store, as well as how the quality of the results is improved with respect to those obtained by manually generating the design.

1 INTRODUCTION

The plethora of current NoSQL systems introduces alternative data storage methods to the traditional relational database management systems (RDBMSs) [2]. Among these, document stores have gained popularity due to the semi-structured data storage model. In contrast to the RDBMS normalization, document stores favor embedding, trying to keep the data related to a single instance together instead of spreading it across different tables. This increases the complexity of database design for document stores as opposed to RDBMS, where reaching 3NF or BCNF guarantees an optimal database design in the majority of the use-cases. Database design for document stores is, in general, given low precedence, and mostly carried out in a rule-based ad-hoc manner. For instance, MongoDB, the leading document store, provides a set of design patterns[1] that provide certain guidelines on how to structure documents. However, it has been shown that the choice of design has a major impact on performance, specially in the NOSQL realm [1]. Thus, it is advantageous to have a better design by exploiting any prior knowledge on the requirements rather than a purely random one.

Let us take an example of implementing an online auction system based on the RUBiS benchmark [3] in a document store. Fig. 1 shows the 5 entities and 6 relationships composing the RUBiS framework. We can have a normalized solution, similar to that in a RDBMS, an embedded single-document solution, or the solution suggested by a purely workload-based schema recommender, such as DBSR [11], which denormalizes certain entities. To show the complexity of finding the optimal database design in a document store, let us define a running example use case consisting of two single entities from RUBiS, namely Product and Comments, and an equiprobable hypothetical workload defined as follows:

- Given a Comment ID, find its text.
- Given a Product ID, find its name.
- Given a Comment ID, find the Product name.
- Given a Product ID, find all of its Comments.

In this scenario, we have two entities and one relationship. If we assume that all attributes for an entity are kept together within a document, we are left with the decision on where the relationship must be stored in the final design. Thus, database designs can be enumerated based on the alternatives to store the relationship, which depend on three independent choices: direction, representing, and structuring as shown in Fig. 2, together with two examples. **Direction** determines which entity keeps the information about the relationship. It can be one of the two entities, or both. **Representation** affects how this relationship is stored either by keeping a reference or embedding the object. Finally, **Structuring** determines how we structure the relationship, either as a nested list or flattened. For example, if keep the references to the comments in the product, they can

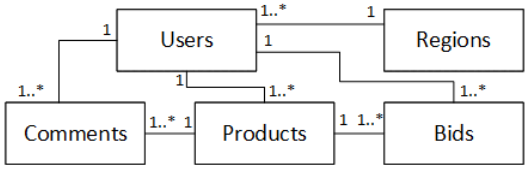

Figure 1: ER diagram of RUBiS Benchmark

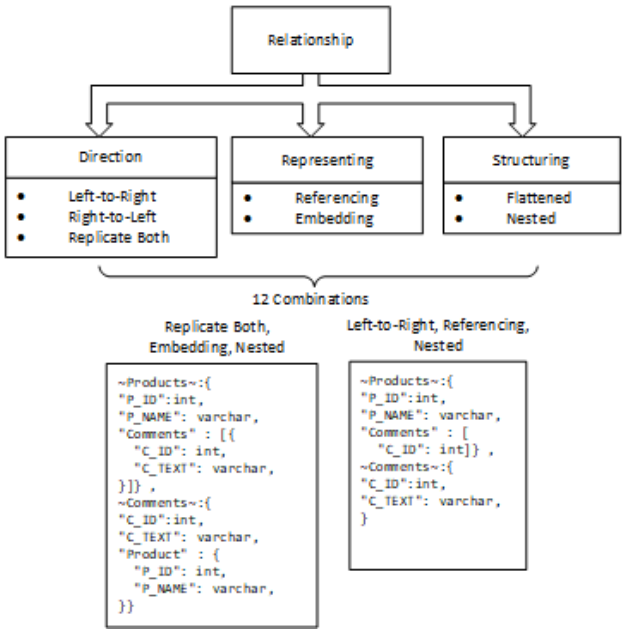

Figure 2: Relationship design choices, and two examples

[1] https://www.mongodb.com/blog/post/building-with-patterns-a-summary

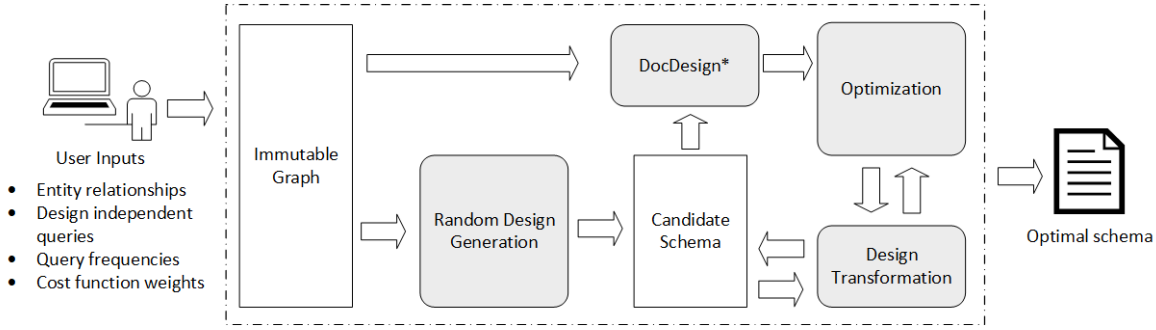

Figure 3: Overview of the DocDesign 2.0 Architecture

be stored as a list of references (*comment:..*) or in a flattened manner (*comment_1:.., comment_2:..*). Hence, we end up with 12 possible designs for our running example. Each of these could potentially be the optimal solution for an end-user depending on their preferences. For example, the design where products and comments nest their counterparts redundantly (i.e., both directions are stored by embedding the objects) will benefit query performance, as all queries can be answered with a single random access. However, this is at the expense of storage space due to redundancy. What if we only have a single reference on the product for its comments? Does the reduction of storage space justify the impact on performance? This trade-off between alternatives makes the process of finding the optimal design a complex one.

The number of relationships of the use-case (r) determines the number of candidate designs, which is exponential (12^r), as the storage option of each relationship is independent of others. Note, however, that here we did not consider allowing heterogeneous collections/lists, which is possible in the context of schemaless databases, leading to a complexity increase. For example, collections at the top level could potentially contain different kinds of documents. In our running example, user and region documents could be stored in a single heterogeneous collection mixing both. Precisely, for a design with c top-level collections, the total number of combinations will be $\sum_{i=1}^{c} \left\{ {c \atop i} \right\}$ where $\left\{ {n \atop k} \right\}$ is the Stirling number of the second kind, used to calculate the number of ways to partition n distinct elements into k non-empty subsets [5]. Overall, such exponential growth makes impossible to enumerate and evaluate all candidate designs. Hence, existing solutions, such as DBSR [11], NoSE [10] and Mortadelo [4], mainly rely on the query workload to propose a database design.

Contributions. Considering the above observations it is clear that the problem of storage design for document stores has a large search space. Moreover, each candidate solution potentially performs differently among the considered cost functions. It is, hence, obvious that exhaustively exploring the search space is prohibitively expensive. To overcome this issues, in this paper, we present DocDesign 2.0, a novel solution that addresses the complex problem of database design for document stores. DocDesign 2.0's contributions involve *automatically generating potential designs*, as well as *evaluating the performance of a design on four objectives: storage size, query performance, degree of heterogeneity, and average depth of documents*. Finally, DocDesign 2.0 *presents the end-user with the near-optimal database design specific to his/her preference of the objective* for a given use-case and query workload. Precisely, in this paper, we consider read-only query workloads. DocDesign 2.0 embeds and extends our former solution DocDesign [7], which aids on evaluating database designs based on storage size and query performance, requiring however to provide a concrete schema as input. Contrarily, DocDesign 2.0 automatically generates such designs yielding, with a high probability, the near-optimal one with respect to a set of objectives.

Outline. In the rest of the paper we introduce DocDesign 2.0's demonstrable features to resolve the motivational example and other database design for document stores scenarios. We first provide an overview of DocDesign 2.0and its core features. Lastly, we outline our on-site demonstration, involving the motivational scenario as well as other more complex real-world use cases.

2 DOCDESIGN 2.0 IN A NUTSHELL

DocDesign 2.0 adopts multi-objective optimization techniques, which have shown to be effective on obtaining near-optimal solutions out of a large search space in the presence of contradicting objectives [9]. In these scenarios, one can only aim to obtain a Pareto solution (a solution that, in the presence of multiple objectives, cannot improve one objective without worsening another).

Search algorithm. Local search algorithms consist of the systematic modification of a given state, by means of action functions, in order to derive an improved state. The intricacy of these algorithms consists of their parametrization, which is at the same time their key performance aspect. Due to the genericity of different use cases DocDesign 2.0 can tackle, we decided to choose *hill-climbing*, a non-parametrized search algorithm which can be seen as a local search, always following the path that yields higher utility values. Nevertheless, the cost functions we use are highly variable and non-monotonic, which can cause hill-climbing to provide different outputs depending on the initial state. To overcome this problem, we adopt a variant named *shotgun hill-climbing*, which consists of a hill-climbing with restarts using random initial states.

An overview of DocDesign 2.0 is shown in Fig. 3 and we present the modules and components of DocDesign 2.0 in the following subsections.

2.1 User Inputs

There are three inputs the end-user must provide, namely the equivalent to an Entity-Relationship diagram of the domain, query workload, and the weights of the cost functions.

Entity-Relationship. Refers to the use case-specific entities, their attributes, and the relationships between them. To accurately measure the different cost functions, DocDesign 2.0 requires the number of instances of each entity, the size of its

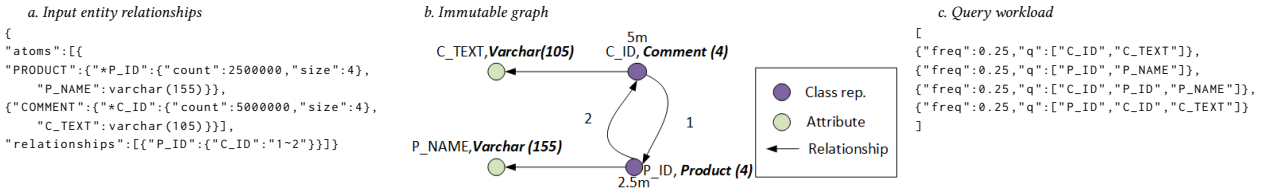

Figure 4: Input entity relationships, its internal graph representation, and query workload

attributes, and the relationship multiplicities (Fig. 4.a). This information is considered immutable, and the database design is carried out on top of it. We use a hypergraph-based canonical model internally to represent them [8]. (shown in Fig. 4.b). Furthermore, the entities are atomic, meaning that attributes related to an entity cannot be split.

Query workload. Consists of a set of queries together with their frequencies to be executed in the use case. These queries are independent of the database design and are represented as subsets of the immutable information (Fig. 4.c).

Cost function weights. Allows the end-user to include his/her preference in the database design. Currently, DocDesign 2.0 supports tuning four cost functions corresponding to the objectives: query cost, storage size, degree of heterogeneity within collections and sets, and average depth of the documents. The end-user can decide how important each of these costs are and resolve trade-offs between them. For instance, forcing higher importance to query cost and lowering the one of storage size would lead to a schema with higher redundancy and better performance.

2.2 Design Operations

Information about entities, their attributes, and the relationships are considered immutable, and the database design is built from it. Indeed, with regard to our running example, the final design must have information on all the warehouses, districts, and the relationships between them. A hypergraph-based representation enables DocDesign 2.0 to guarantee this property (we refer the reader to [7, 8] for further details). We introduce two methods to fit the shotgun hill climbing approach: generation of a random design, and evolution of a design using valid transformations.

Random design generation. The random schema generator relies on identifying subsets of entities and relationships that will be made into a collection (referred to as connected components) and the structure of the documents inside the collection in a document store database design. Based on the 12 possible designs that a relationship can be stored, we make the following decisions randomly in the schema generation process.

- **Root of the connected component** is chosen at random from the available entities. This choice determines the root document of the document store collection that this component represents. In our running example, this is either picking the warehouse or the district as the root of the collection. Let us assume we picked the warehouse in this case.
- **Choosing the next path to explore** expands the connected component and determines it's structure. Potentially multiple relationships connect an entity to others in a connected component. Thus, for a given entity of a connected component, a random subset of these relationships is picked to further expand, determining the depth and the related documents of the final design. This, together with the root of the document determines the choice of the direction in Fig. 2 except for replicating both. In the running example, we choose the relationship to the district from the warehouse (already inside the component).
- **Embedding or Reference** determines possible ways to represent the relationship between two entities of a component. If embedding is chosen, the entire document is embedded in the parent and referencing only keeps the reference of the related document on the parent. In the running example, if the embedding option is chosen, the final collection will be warehouses with embedded districts. We also make the decision of replicating both based on a given probability.

The above choices are carried out until all the entities and relationships belong to at least one of the connected components. Finally, each of the components is represented as a document store collection. These initial designs do not contain heterogeneous collections or lists, yet, since we initially ignore the choice of flattening and only use the nested option for structuring with regard to the options in Fig. 2. This decision reduces the complexity of the random generation and the number of starting schemas. However, we introduce this through design transformations to ensure that we do not lose certain designs in the process.

Design transformations. Even though it is possible to generate most of the potential designs through the random generator, it is very unlikely to reach an optimal state randomly. Moreover, we omitted the heterogeneous collections/lists and flattened ones in the random process. Thus, we introduce seven design transformation operations and use five of them to generate the neighbors of a particular design. These transformations are inspired by the rule-based design patterns proposed by MongoDB.We have validated them by recreating the MongoDB design patterns as sequences of transformations[2].

- **Union** - merges two collections/lists at the same level and creates a heterogeneous one.
- **Segregate** - separates a homogeneous collection/list out of a heterogeneous one.
- **Embed** - embeds a related document inside another.
- **Flatten** - flattens an embedded document or a list inside it's parent.
- **Group** - creates an embedded list of related documents inside another (opposite of flattening a list).

We also identify two other operations, namely, **Nest** and **Split**. Nest operation creates a nested document inside another and is unnecessary as we already cover it through the random generation. Split is similar to vertical partitioning a document. However, adhering to the atomic entity rule, we decided not to include this operation as it would also expand the search space uncontrollably.

2.3 Optimization

Candidate designs obtained through random generation or transformation need to be evaluated in order to assess their optimality.

[2]More details at https://www.essi.upc.edu/~moditha/transformations

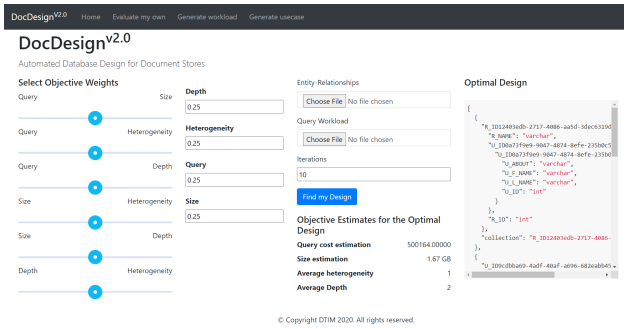

Figure 5: DocDesign 2.0 user interface

Cost functions. We introduce four cost functions to be measured and optimized in DocDesign 2.0: query cost, storage cost, degree of heterogeneity, and average depth of the documents. These are defined as follows:

- **Query cost** (CF_Q), is the sum of the relative query performance values calculated from the schema using a cost model for document stores [6].
- **Storage size** (CF_S), is the total storage size required by the collections and indexes, calculated using the canonical model.
- **Degree of heterogeneity** (CF_H), is the number of different types of documents in a collection/list. We use the average over all the collections and lists of the schema. Each heterogeneity is given a weight depending on which level the list/collection lies in the document. The higher the level, the higher the assigned weight, penalizing heterogeneities at higher levels of the document structure.
- **Depth of the documents** (CF_D), is the average depth of the documents of the design.

Utility function. Guiding the local search algorithm requires the definition of a utility function taking into account the end-user's preferences. Here, this is a function to be minimized. Hence, the end-user can assign weights to each of the cost functions according to their importance in the use-case. Then, for a given design C, we define the utility as the normalized weighted sum of each cost function $u(C) = \sum_{i=1}^{n} w_i \frac{CF_i(C) - CF_i^o}{CF_i^{max} - CF_i^o}$. The expression considers the weight w of each cost function, which is used on the transformed utility function for C. This is a normalized value that considers the *utopia* (i.e., the expected minimal) and the maximal design costs, yielding values between zero and one.

3 DEMONSTRATION OVERVIEW

DocDesign 2.0 has a web interface as shown in Fig. 5. In the on-site demonstration, we will showcase DocDesign 2.0 using the RUBiS usecase as a real-world example The manual database design process is expensive as RuBiS contains five entities and six relationships, leading to a large solution space. Moreover, we use the 11 queries with their access frequencies as the workload. First, for the ease of explanation, we will use the paper's running example (i.e., Products and Comments) and the four queries to showcase the ease of using DocDesign 2.0, initially with equal weights and then higher weight to query cost. In the first scenario with equal weights, the optimal schema is products having references to their comments. When optimizing only for the query performance, DocDesign 2.0 suggests redundantly nesting comments inside the product and product inside the comment. This approach reduces the actual runtime almost by half at the expense of double the storage space. This establishes the functionality and the efficiency of DocDesign 2.0.

Then, we will import the full RUBiS E/R to DocDesign 2.0 together with the queries and showing the ability of DocDesign 2.0 to solve more complex use-cases. The results presented by DocDesign 2.0 have a higher throughput once implemented compared to the best solution suggested by DBSR [11]. Moreover, the suggestion by DocDesign 2.0 has far less redundancy compared to the ones by DBSR. The participants are also allowed to interact with the DocDesign 2.0 demonstration with the ability to choose between different queries and objective function weights as well as generate their own. The resulting updates made to the design can be discussed by means of changes introduced (e.g.: giving more importance to query cost will result data redundancy). We also present the actual runtimes (calculated by a benchmarking suite) and storage sizes for the usecases and the designs that we demonstrate. This allows the users to validate the effectiveness of the solutions generated by DocDesign 2.0.

Since the JSON input format is specific to DocDesign 2.0, we also include a functionality to create them through an intuitive UI. Moreover, the users can suggest their own design to compare against the one suggested in terms of the four objective functions. The designs suggested by DocDesign 2.0 rely on pre-defined queries. If the queries are unknown the end users have to rely on the other three cost functions to obtain a "good enough" design. Through this hands-on experience, we are able to show the ability of DocDesign 2.0 to address the complex problem of document store database design improving the quality and productivity as opposed to a manual design process.[3]

ABSTRACT

The extended use of the RDF model has made available many datasets from heterogeneous sources that are of interest to a wide audience. Their exploration, however, is a highly demanding task requiring extensive training and knowledge of the SPARQL language. In this demo, we present an innovative system, which supports the exploration of large RDF datasets without requiring any knowledge about the RDF or SPARQL. The system is based on a novel algorithm that detects semantically similar communities capitalizing on hyperbolic network embedding and a weighted similarity metric. The detected communities are visualized in a user-friendly way and presented to the user through a two level abstraction interface with a toolbox of exploration functionalities.

1 INTRODUCTION

Many organisations and scientists use the RDF model to share their data. There is currently high availability of linked datasets, that cover a wide range of topics and have a high degree of diversity regarding their size and characteristics [1]. Exploring and visualizing these datasets is a complex task that requires extensive knowledge about RDF and the SPARQL language. Because of their volume and update rate, they require expensive infrastructure for their processing. Therefore, even though the information is of interest to a wide audience, the datasets are, in practice, accessible only to a few data scientists.

In order to allow the exploration of linked datasets by people with no experience with the RDF and the SPARQL language, as well as no access to expensive infrastructure, we need an approach that enables: (a) accessible visualization that is scalable even for very large datasets, (b) exploration that is user-friendly and intuitive. In the following, we discuss these challenges.

Scalable visualization. RDF follows the graph structure, since the entities can be represented as nodes, and the relationships between them as edges of a graph. Systems visualizing datasets compliant with RDF, should use a graph model to represent the data, presenting each entity as a distinct node and their relationships as respective edges. Such systems should be easily accessible through commodity infrastructure and scale efficiently for very large graphs. Actually there is a requirement for efficient and scalable rendering for many devices, such as laptops, tablets and smartphones, and for a high number of simultaneous users.

User-friendly and intuitive exploration. Exploration of the dataset and extraction of relevant information should be user-friendly for users with no knowledge of the RDF model. To this end, the system should offer an easy-to-use toolbox that provides a set of exploration functionalities, such as keyword search, semantic filtering based on labels, path navigation and neighbor retrieval. Also, the system should allow interactive navigation towards the sought information. Finally, the dataset should be explorable through different abstraction levels, allowing the user to determine the degree of detail in the visualized information. Furthermore, exploration should be intuitive for users with little knowledge regarding the information that the specific dataset represents or about what can be of interest to explore.

To this end, many systems use summarization methods [6]. These can be divided in three basic categories: pattern mining, statistical and structural. Pattern mining methods employ aggregations and graph structures to identify trends in the datasets. Due to the strictness of these trends, such methods are ideal for schema identification. Statistical methods provide quantitative results over the data based on targeted queries and available semantic information. Such methods are used for the selection of the proper dataset for the user needs. The structural methods create the summaries based on the graph structure and can be further divided in quotient, which aim to identify equivalent nodes based on an equivalence relation over them, and non-quotient that use other structural measures, such as centrality, to create the summaries. Quotient summaries target indexing and querying, while non-quotient summaries are better suited for visualization and data understanding. Thus, we focus further on them.

The Grouping Nodes on Attributes and Pairwise Relationships (SNAP) [12] method is the most well-known among them. It focuses on the construction of a graph visualization that uses supernodes, nodes that contain multiple nodes of the input graph, to create summarizations based on user input and structural information such as edge values and node connections. The main drawback of this solution is the requirement for the user to select the summarization properties, in order to produce the visualized graph. Such a limitation is hindering for inexperienced users or users that want to explore datasets they are unfamiliar with.

An alternative to summarization, and a promising solution for intuitive exploration of RDF datasets, is community detection. As discussed in [7], community detection has a key role in the analysis of complex networks and the inference of useful insights regarding graph topology. However, although traditional community detection methods are very useful when applied to small networks, they cannot scale for networks of modern size as they rely on heavy computations and require a significant size of main memory. Therefore, they can process networks of up to only a few thousand nodes and edges. Hence, in order to apply community detection to RDF datasets, we need new scalable and efficient algorithms that use persistent memory and data management models to process larger graphs.

Contributions. We propose the demonstration of a robust system that implements a novel visualization technique over a novel community detection algorithm to detect communities that include semantically similar content in large RDF datasets. The system takes as input a semantically annotated dataset, divides it into semantically similar communities using a novel algorithm, stores the communities and their interconnections in a graph database and visualizes the results with respect to the graph structure. The dataset is then presented to the user through a user-friendly interface that offers two abstraction layers, allowing the user to explore both the detected communities and the subgraphs within. The system has strong advantages related to:

Semantic community detection. We have designed and implemented a novel algorithm that detects semantically similar communities [9], by first transforming the RDF dataset into a weighted graph and then employing embedding of the graph in the hyperbolic space. This is a proven "natural" space for embedding large graphs, with a semantic similarity metric aiming to detect semantically similar communities.

Community visualization. The system implements a novel two-level visualization approach: first, the nodes and edges within a community are visualized as an independent two-dimensional graph; second, the connections between communities are visualized to provide a high-level overview.

Scalability. We ensure the scalability of our technique in two ways. First, our algorithm for community detection is the first of its kind to employ a DBMS. We have selected a graph DBMS for indexing and storage of the RDF dataset to facilitate the storage of node coordinates in the hyperbolic space and the computation of the distance for all node pairs. Second, we employ a graph DBMS for storage and indexing of the inner and intra communities graphs, a design decision so that the system can support the retrieval of the information using a client-server architecture. In practice, this ensures that the system can work efficiently on any web browser and device.

Exploration functionalities. We provide an easy-to-use toolbox of functionalities that allows the users to explore the dataset using multiple filtering criteria, and navigation through panning and zooming capabilities [10].

2 SEMANTIC COMMUNITY DETECTION

We propose a new algorithm for semantic community detection. The algorithm takes as input a RDF dataset and pre-processes it in order to map it in a three dimensional (3D) space and store it as a weighted graph. In order to introduce the semantics in the detected communities we need to calculate a weight for pairs of RDF triplets that represents their semantic relation. This is based on a novel metric that encapsulates semantic and lexical similarities. Finally, the new graph is processed by the algorithm we have proposed in [9], which employs hyperbolic space concepts for semantic community detection. Algorithm 1 shows the pseudocode, and in the following we give more details for every step of the algorithm.

Step 1: RDF dataset pre-processing. Each RDF triplet of the input dataset is mapped to one node in a custom 3D space, where each one of the three dimensions correspond to *(subject, predicate, object)*. The nodes of the 3D space are connected with edges, to create a complete graph. This is the representation of the input dataset to the custom 3D space. Next, to ensure the efficiency and scalability of the algorithm for very large datasets, the information is stored and indexed in a graph database where each node has three properties.

Step 2: Weighted graph creation. In order to calculate semantically accurate weights for the graph, we follow a three-step method. First, all the words of the dataset are mapped to semantically similar groups and given a popularity score. Each node has three labels: subject, predicate and object. For each label of the node a semantic metric is calculated. Finally, the metric is used to calculate the weight between two nodes.

Initially, we aim to create groups of semantically similar words. In order to achieve this, each word is examined against all already formed groups in case it exists in one of them. In this case, the word is added to the group. In any other case, the word is examined for lexical similarity with all the words already in each group. If none is found, then the word is placed in the group that contains a semantically similar word. If no such group exists, then the word is placed in a new group.

As 'lexically similar' we consider two words that share the same lemma. For example, the words 'playing' and 'player' are lexically similar to one other, as well as to the word 'play'. As 'semantically similar' we consider two terms that have common semantic content, based on the likeness of the meaning between them, as defined in dictionaries. Two entities are semantically similar when they are associated with what is commonly refer to as 'is a' semantic relationships which are synonymy, hyponymy and hypernymy [11]. For each group i that has been formed, a score is calculated by dividing the count of words within the group with the total number of words in the dataset.

Definition 2.1. **Popularity Score.** Let $\mathbf{G} = \{\mathcal{G}_1, \mathcal{G}_2, ..., \mathcal{G}_k\}$ be the set of semantic groups, where $\mathcal{G}_i$ for $i = 1, 2, ..., k$ corresponds to the i-th group of words and includes the words $\mathbf{W}_i = \{\mathcal{W}_{i,1}, \mathcal{W}_{i,2}, ..., \mathcal{W}_{i,m}\}$ where each $\mathcal{W}_{i,l}$ for $l = 1, 2, ..., m$ corresponds to the l-th word in the i-th group. Let $\mathbf{C}_i = \{C_{i,1}, C_{i,2}, ..., C_{i,m}\}$ where each $C_{i,l}$ corresponds to the number of times the l-th word of the i-th group is found in the dataset. Then the popularity score for the i-th group is calculated as:

$$popularityScore(G_i) = \frac{\sum_{l=1}^{m} C_{i,l}}{\sum_{i=1}^{k} \sum_{l=1}^{m} C_{i,l}} \quad (1)$$

□

Definition 2.2. **Semantic Similarity.** Each label of the node is split into m words and each word $W_{i,l}$, where $l = 1, 2, ..., m$, is replaced by the popularity score of the group it belongs to, G_i. The sum of the popularity scores divided by the number of words in the label is the semantic metric:

$$semanticMetric(label) = \frac{\sum_{n=1}^{m} popularityScore(G_n)}{m} \quad (2)$$

□

Then, for each pair of nodes the distance between them for each dimension is calculated as well as a total distance between them, the weighted average of the three distance values. The calculated distance is used as the graph weights.

Step 3: Community Detection. The community detection starts with pruning the edges of the complete weighted graph by applying the DMST method [5] to obtain a graph that is dense enough to represent the relationships between nodes and sparse enough to highlight the underlying community structure. This graph is then embedded in the hyperbolic space using Rigel Embedding [15]. In the embedding process, each node is assigned coordinates in the hyperbolic space and these are stored in the database. Based on these coordinates the computation of Hyperbolic Edge Betweenness Centrality (HEBC) follows. The HEBC

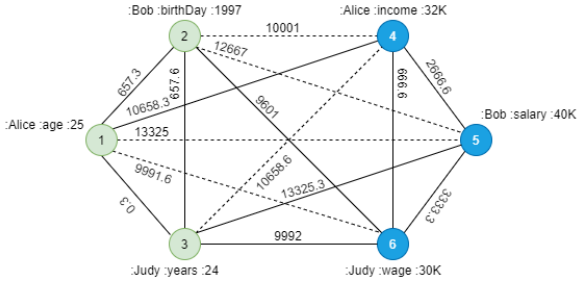

Figure 1: Semantic Community Detection

metric can be considered as the "hyperbolic" analog of the traditional Edge Betweenness Centrality (EBC) metric. The HEBC quantifies for each edge, the amount of shortest paths in the graph that pass through it. In its computations it uses the hyperbolic distance between nodes. Even though the HEBC values do not always match the nominal EBC values, the ordering of the edges is very similar. The edges of the graph are ranked in descending order and in that order edges are removed in batches, until one of the following occurs. Either the graph becomes disconnected, meaning a new community is discovered, or the maximum number of edges to remove in a single round is reached. Then, if a pre-specified number of communities is reached the algorithm terminates, otherwise the previous process is repeated for the current largest connected component of the graph. The details of the basic version of the hyperbolic-embedding can be found in our previous work[9]. In [13], we have enhanced this work for efficient and scalable processing of very large graphs.

Example. In Figure 1 we present how the proposed algorithm detects the communities on a small RDF dataset. The figure shows six nodes that relate to the ages and salaries of three people, as well as the complete graph created from the first and second step of the algorithm. The distances for each node pair are calculated as follows: the Euclidean distance is used for the numerical properties and the distance based on the semantic metric is used for the rest. This dataset is split into three semantic groups, $G_1 = (Alice, Bob, Judy)$, $G_2 = (age, years, birthDay)$, $G_3 = (salary, income, wage)$, with scores $(0.167, 0.25, 0.25)$. For example, the distance between the triplets (:Alice, :age, :25) and (:Judy, :years, :24) is computed as follows. First, the distance $d('Alice','Judy') = 0$, then $d('age','years') = 0$ and finally the distance $d(25, 24) = 1$. From that it follows that the distance between these two triplets is $\frac{0+0+1}{3} = 0.3$. In the third step, the algorithm performs the DMST, removing edges shown as dashed lines, and then we proceed to the core part of community detection, which results in two communities denoted by the two different node colors. The algorithm discovers a community that corresponds to the ages of the people and a community that contains information about their salaries. It is important to note that a different averaging technique could result in a different clustering as more importance could be given to one attribute over another. As an example, if we wanted the analysis to focus more on people's names, and thus possibly discover clusters containing information about the attributes of a person, we could use an average with larger weight on the distance between names.

Experimental results. For the Facebook network provided by SNAP library [2], our community detection algorithm obtains a modularity score of 0.59. The Girvan-Newman method resulted in a score of 0.7 but it required almost double the time necessary for our approach. As discussed in detail in [9], this result proves the benefits of our algorithm when applied to real life networks and its the ability of finding high quality clusters.

Algorithm 1: Semantic Community Detection

Input: RDF dataset, distance metric, # communities cm, # spanning trees to join k, embedding parameters $params$, maximum # edges to remove per round $batch$
Output: clusters stored as communities in a Graph DB

```
D ← distances between RDF triplets
D is stored in DB
G ← DMST(D, k)
comm_found ← 0
while comm_found < cm do
    coords ← embed(G, params)
    top_edges ← HEBC(G, coords)
    i ← 0
    while i < batch & isconnected(G) do
        G remove top_edge[i]
    if not isconnected(G) then
        comm_found ← comm_found + 1
        store newly found community in Graph DB
```

3 ARCHITECTURE & FUNCTIONALITIES

As shown in Figure 2, we have developed a server-client architecture that takes as input a RDF dataset, process it using the proposed *Semantic Community Detection Algorithm*, stores the communities to a *Graph Database* and further processes the information through two dedicated modules, the *Inner Community Visualization* and the *Intra Community Visualization*. The processed information is presented to the user through the *Visualization Interface* that it is based on a novel visualization technique [10].

Graph Database Due to the structure of the RDF model and the needs of the *Visualization Interface*, the Neo4j[14] graph database is used for the storage of the dataset. For the *Semantic Community Detection Algorithm* the custom 3D graph is stored in the graph database, but now the dataset has been restored to its initial structure and stored here. Each entity has as properties its unique identifier, the community id it belongs to, the ground truth community, if available, and its coordinates within the 2D graphical representation of the community.

Intra-Community Visualization The *Intra-Community Visualization* uses the Scalable Force Directed Placement algorithm [8] for the graphical representation of the entities and their relationships that belong in each community in the 2D space. This algorithm was selected as it allows the parameterization of many attributes of the output graph including the overlapping percentage and the size of the nodes.

Inter-Community Visualization The *Inter-Community Visualization* creates an overview of the dataset by connecting the communities in a super-graph. Two communities, i and j are super-nodes that are connected with super-edges that contain information about the real edges that connect pairs of nodes (n_i, n_j), where n_i belongs to i and n_j to j. In addition, each super-node contains information about the content of the respective community. It includes the three most prevalent nodes and edges as they are calculated based on a popularity score, calculated as follows: first, the frequency of appearances of each label in the super-node is calculated; the counter is then converted to the percentage of the label appearances in the overall dataset. As an example, if the label 'happiness' appears in the dataset 1000 times and the label 'hate' just once, then for a super-node that includes the label 'hate' once and the label 'happiness' 700 times, the score for the first would be 1 and for the second 0.7.

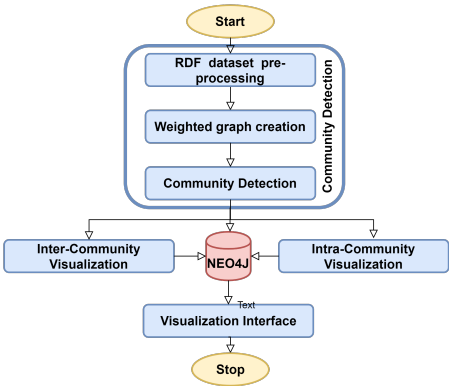

Figure 2: System Overview

This way, nodes and edges that are important to the communities but also contribute to their differentiation from the others, are included. Similarly, each super-edge has a list with the three most important edges connecting the two super-nodes.

Visualization Interface The information is presented visually through a user interface in two abstraction levels. The high level presents the interconnections between communities, as well as a brief summary regarding the context of each community. The second layer presents as a graph all the triplets of information of the community and as meta-information connections with other communities. In order to allow the user to explore the input dataset and the detected communities a series of functionalities are provided through the interface. Employing the indexing and querying capabilities of the graph database, the functionalities are provided in real-time. One key functionality is the zoom support, where the user can use the mouse wheel or the buttons at the functionality panel to visualize the graph in different levels of detail. In addition, dedicated controls allow the user to navigate between the two abstraction layers, focusing either on the overview of the communities or visualizing its information. Also, the visualization panels for the two abstraction layers are interactive and responsive to user requests. The user can browse information within them using panning and scrolling actions. The system, also, enables the user to view the information within the communities using multiple filtering and aggregation criteria either independently or at the same time. For example the user can isolate a specific edge type as well as nodes with a given node degree. To further support the exploration of the dataset, the user can locate information through keyword search. A term is matched against node and edge labels, and the result is presented as an interactive list. Last but not least, the user can select a node and focus on paths within its community, originating from it. Figure 3 shows the interface of the system, which includes the dataset selector, the functionality toolkit and the graph visualization. The graph panel depicts two of the communities based on the user selections.

4 DEMONSTRATION

We will demonstrate the prototype system that implements the proposed technique using three datasets. The audience will be able to explore the datasets through the visualization of semantic communities and compare our results with the ground truth.

Scenarios A: Semantic communities overview. The first scenario will be based on the Wikidata[3], which is a free and open knowledge base, mainly the central storage for the structured data of Wikipedia. The dataset contains a plethora of diverse information that can be used for multiple analysis based on topic, source or category. Initially, the users will be able to access multiple visualized overviews of semantic communities focusing on different attributes of the RDF entities. The overviews will focus on popular topics such as persons and places. Next, the users will delve into the fine exploration of a community graph. Given the volume and diversity of the information available in this dataset, examples of the customizable filtering and aggregation functions will allow the users to focus on specific information. The users may discover for example, based on their interests collaborations between scientists, artists or countries. Finally, the users will be encouraged to follow paths between entities aiming to identify patterns and information exchanges.

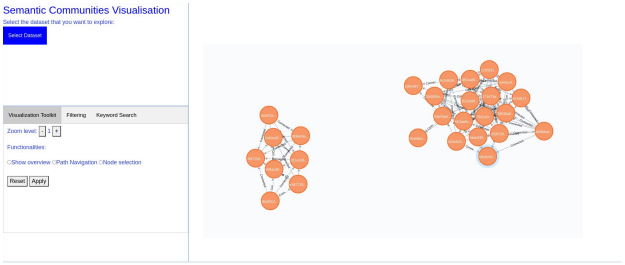

Figure 3: User interface

Scenarios B: Ground truth comparison. For the third scenario the DBLP and Amazon datasets will be used, which are offered with ground-truth by SNAP [4]. The DBLP dataset provides open bibliographic information on major computer science journals and proceedings. The RDF dataset extracted includes information about co-authors and the semantic communities are formed based on the journal or conference that a paper was published. The Amazon dataset contains a product co-purchasing network. The users will be also provided with statistics and detailed analysis of the comparison of the detected semantic communities through the proposed technique with the ground truth.

ABSTRACT

We demonstrate the *Temporal Graph Explorer*, a distributed open-source framework that enables time-dependent graph exploration and analysis on large real-world networks using a rich temporal property graph model and dynamic graph operators. In this demonstration we show how the evolution of a graph plays an essential role in many analytical questions. Besides retrieving a snapshot from a past graph state or calculating the difference between two graph snapshots, users can use our application to summarize the graph to reduce its complexity and to obtain deeper insights into its evolution. Visitors of the demo can visually experience these advanced temporal operators and their results or build and manipulate analytical programs in a declarative way without extended programming skills and run them on a distributed local or remote environment. We provide real-world temporal graph data from bicycle rentals of New York City with millions of rentals per month, also demonstrating horizontal scalability of the system.

1 INTRODUCTION

Graphs are an intuitive way to model and analyze complex relationships between entities representing real-world scenarios. Since most entities and interconnections evolve in the real-world, graphs also change over time in terms of their structure and content. For example, Figure 1 shows a toy example of bicycle rentals (represented as directed edges) between fixed stations (vertices) over time. Such temporal property graphs [1] additionally allow tracking changes in the graph over time. In the example of Figure 1 both vertices and edges store temporal information (marked by a clock symbol) as attributes (valid times) and, thus, the graph reveals that the bike with id 2115 was moved from station [1] to [2] by three consecutive rentals over time.

In this paper, we demonstrate the *Temporal Graph Explorer*, a tool for user-friendly exploration, analysis, and visualization of large temporal property graphs. The core of this application is Gradoop[1], an open-source framework for distributed graph analysis. Its *Temporal Property Graph Model (TPGM)* [8] enables modeling and analysis of graphs with bitemporal time semantics. The TPGM also comes with a set of composable temporal graph operators (including snapshot retrieval, graph evolution, and time-dependent grouping and aggregation) that can be visually configured through the user interface or programmatically

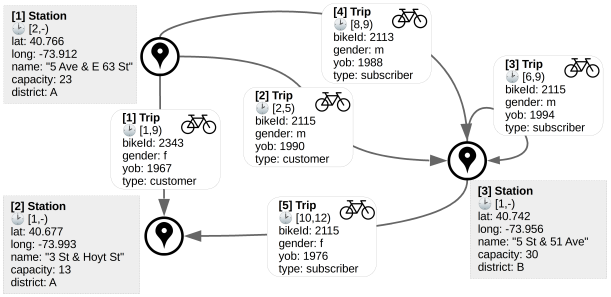

Figure 1: Example temporal property graph representing bicycle rentals between rental stations. The validity period of an edge is marked with a clock symbol and simplified with numbers instead of timestamps.

combined with the help of the declarative language GrALa [5] to build distributed analysis workflows.

The *Temporal Graph Explorer* thus enables the analysis of the evolution of graphs, i.e., to figure out *when* something happened or changed, rather than a static view representing something that happened at some time [9]. To this end, it provides temporal graph operators (including **snapshot** retrieval and graph **difference**) to compute and visualize changes, including additions and deletions, that have been occurred. This can be used in the given bicycle example to find, for a given week in the past, all rentals that have been added, removed, or remained the same.

Our *Temporal Graph Explorer* can also be employed for the analysis of large graphs by using **time-related grouping and aggregation**. This allows for a profound exploration of a graph's structure, semantics, and development over time, which is a significant part of knowledge discovery for temporal graphs. Such a graph grouping mechanism helps to find out *how* different types of vertices and edges are connected as well as *when* and *how long* they were connected. In addition, the graph can be grouped on different dimensions, e.g., by rental time or by station location, as well as on different dimension levels, e.g., per year or month for the time dimension. The grouped vertices and edges can further be aggregated in any conceivable way, from a simple count to the minimum, maximum and average duration of a specific relationship type.

2 TEMPORAL GRAPH ANALYSIS AND EXPLORATION

The *Temporal Graph Explorer* is an application to explore, analyze and visualize temporal property graphs. An intuitive web-based user interface enables the configuration of selected temporal

[1] https://github.com/dbs-leipzig/gradoop

graph operators and their application on a predefined graph dataset of the user's choice. The whole processing is then executed in a distributed environment by using Gradoop as a backend framework. The resulting graph is again temporal and sent back to the user interface for visualization. Frontend and backend application communicate through a RESTful webservice. The visual representation is adjusted to the temporal characteristics of the graph, as later explained. An architectural overview of the system is given in Figure 2.

In the following, we will dive into the single parts of the application including the used bitemporal graph data model, three selected operators, and graph visualization techniques focused on understanding the graph's evolution.

Graph model and distributed processing. The heart of our *Temporal Graph Explorer* is Gradoop [4, 5], which offers many generic operators on graphs (for pattern matching, global aggregations, etc.) that can be used within workflows for graph analysis. Workflows representing graph analytical programs can be expressed in GrALa for distributed execution. All operators are closed over the model, i.e., they take graphs as input and produce graphs. Since Gradoop is built on top of Apache Flink's Dataset-API, each operator is based on a subset of Flink's transformations (map, flatmap, join, etc.) to achieve a parallel execution and scalability to large graphs. Thus, it combines and extends features of graph analytical systems with the benefits of distributed graph processing.

To maintain the full history of a graph, including any insertion, deletion, or update of a vertex, edge, or its properties, Gradoop was extended by the recently introduced TPGM [7, 8] as a graph data model. It supports labeled, directed, multi-graphs where the vertices and edges are characterized by a unique identifier, a type label, and a set of properties, modeled as key-value pairs. In addition, each vertex and edge is extended by two time intervals I_v and I_{tx} that define a lifespan regarding to valid-[2] and transaction time dimension, which ensures a bitemporal data modeling [3]. Each close-open interval is represented by two first-order attributes t_{from} and t_{to} defining the start and end timestamp of the respective time interval. Thus, a graph of this model contains all historical and rollback information and therefore allows the exploration of its evolution and retrieving valid snapshots from the past, present or future for the valid time dimension or past and present states from the transaction time domain. To provide maximum flexibility, I_v can also be empty if no time information is available or just hold a single timestamp t_{from} if the duration of the element is not available or can be neglected, e.g., the time at which a bike station was newly built. A more detailed description and scalability evaluation of the TPGM and its operators is given in [8].

Graph snapshot and difference. To enable temporal and evolutionary queries and analysis, one data management challenge for large historical graphs is the retrieval of graph snapshots as of any time-point in the considered time domain [6]. To achieve this, we developed the *snapshot* operator that can be applied on a temporal graph instance and allows to retrieve a valid state of the graph either at a specific point in time or a subgraph that is valid during a time range. The user can configure the operator by pre-defined time-dependent predicates such as *asOf()*, *overlaps()* or *precedes()*. Furthermore, user-defined predicates, as well as helper functions to extract certain time dimensions, can be used.

[2]Valid-time is also known as application time.

An important part of the analysis of graphs is the examination of changes that have occurred between two points in time. Changes, i.e. additions, deletions, and edits, represent the evolution of a temporal graph and can be selected or aggregated in subsequent analysis steps. Therefore, we demonstrate the *difference* operator that computes a graph $\triangle G$ between two graph snapshots G_1 and G_2 by determining the union $G_1 \cup G_2$ and extending each element by a property that expresses the addition, deletion, or persistence of this element respectively. The user configures both snapshots by using time-dependent predicate functions, as described before. In addition, the desired time-dimension can be selected.

Time-specific grouping and aggregation. The maintenance of the entire history of a real-world graph entails a huge amount of graph elements. A structural grouping of the graph (also denoted as summarization) will help to reduce the overall complexity and offers deeper insights into the graph's structure, distribution, and evolution. For example, a graph with billions of vertices and edges can be first grouped by the element's label to explore the schema that reveals how the heterogeneous types are connected. In addition, temporal and content information of the grouped vertices and edges can be aggregated in many ways to get knowledge about the respective groups.

The temporal grouping operator goes further and offers a flexible mechanism to group a temporal property graph by *all* available information of the vertices and edges, especially their temporal characteristics. This is achieved by the possibility of defining a function $f(v) \mapsto k$, denoted as *key function*, that maps a vertex v (or edge) to a key k on which to group. All elements mapped to the same key are grouped together and form a new super-vertex or -edge, respectively. To simplify the specification for users, Gradoop offers predefined key functions, e.g. label() to group elements by their label, as well as helper functions, e.g., functions for extracting time-related information to summarize the graph at different temporal resolutions. Since real-world graphs are usually very heterogeneous, the application of the key functions can also be restricted to nodes or edges of a certain label (*label-specific grouping*), e.g., to group *Station* vertices by district and *Trip* edges by *gender*.

Besides the grouping itself, one main feature is to enrich the grouped elements by summarized information about the group, which can be achieved by applying pre- and user-defined aggregate functions. Not only properties but also information from the additional time dimensions can be aggregated. For example, the earliest or latest beginning of an edges validity can be calculated by using *minTime()* or *maxTime()* aggregate functions.

Analysis specification and result visualization. As already mentioned, Gradoop workflows are described in the declarative language GrALa. Besides the possibility for users to write programs directly in GrALa (see programmatic demonstration) the Temporal Graph Explorer allows the creation of simple workflows with the help of an adaptive user interface. Users can select operator(s) and the user interface allows easy parameterization by displaying suitable graphical elements, e.g. drop-down lists for selecting a snapshot predicate.

The resulting temporal graph is visualized by the Temporal Graph Explorer using Apache ECharts[3] and the JavaScript library of Cytoscape[4], an open-source software platform for visualizing

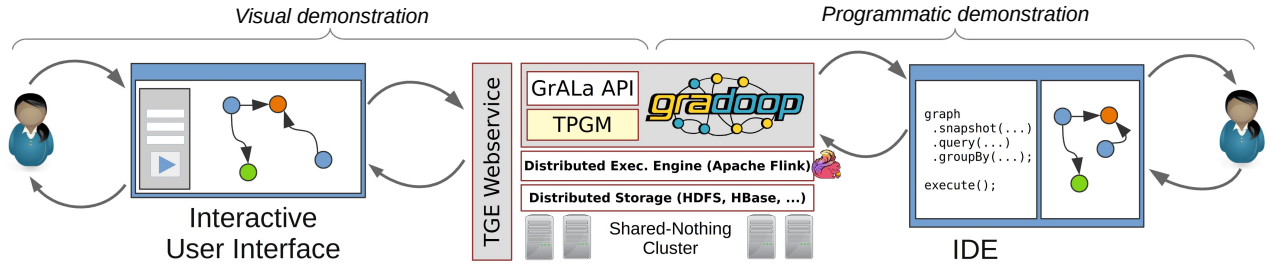

Figure 2: System architecture overview of Temporal Graph Explorer and user interaction workflow for both demonstration scenarios.

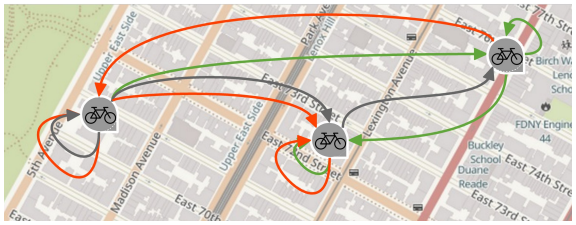

Figure 3: Example visualization of a difference graph.

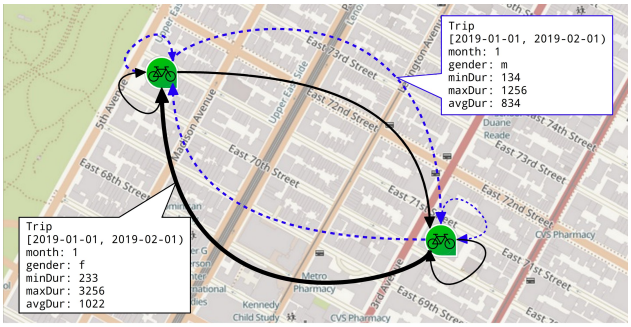

Figure 4: Visualization of two grouped stations each placed in the grid center and their aggregated trips distinguished by gender (blue dotted = male; black solid = female).

complex attributed networks. By default, the coloration of vertices and edges is based on the respective label, i.e., elements with the same label are equally colored. Further, identifiers, properties, and temporal attributes are displayed in a tooltip after selecting a vertex or an edge.

Besides this default graph visualization, we provide two additional graph representations: a difference graph view and a grouped graph view. Figure 3 shows a cutout of a difference graph's visualization. It colorizes the vertices and edges depending on the annotation with which the elements are expanded by the difference operator. A vertex or edge is colored red if the elements have been deleted in the time between both snapshots, grey if the elements were not changed at all, or green if the elements were created.

For the visualized result of the grouping operator, aggregated properties (e.g., `count`, `minDuration`, `maxTimestamp`) can be used to adjust the radius of vertices and width of edges to the corresponding property value. For example, the width of a super-edge depends on the average duration of the grouped edges. Besides, if the graph data set contains geographic coordinates as properties of vertices, these can be mapped onto an interactive map using a geo-layout (see the example in Section 3).

Further, the graph can be exported to the graph description language *DOT*, which can be easily rendered by *Graphviz* library or *Gephi*, an external visualization and exploration tool.

3 DEMONSTRATION DESCRIPTION

Our demonstration of the *Temporal Graph Explorer* is separated into two parts as shown in Figure 2. First, we demonstrate our web-based toolbox and user-interface for Gradoop. There, different analytical operators can be selected and configured in many ways, whereas the resulting graph is presented to the user by graph visualization to present the analytical value of the operators. We provide real-world graph data based on the open-source New York CitiBike[5] database which captures bicycle rentals since the year 2013. The structure of the graph is analogous to the example graph of Figure 1. The dataset consists of around 1,000 vertices (ascending over time) representing the rental stations and more than 2,000 trip edges per hour, which results in about 17 million trips per year. Further, we also integrated other temporal networks such as a heterogeneous social network synthetically generated by the LDBC data generator [2]. In the second part of the demonstration, we give visitors the opportunity to inspect and manipulate existing example temporal programs written in GrALa. All our examples can be executed on demonstration data locally, but also remotely on our research cluster.

Visual demonstration. To give more insight about results of frequently used single temporal operators, such as *snapshot*, *difference* and *temporal grouping*, we demonstrate their usage by the *Temporal Graph Explorer*. The explorer offers each visitor the possibility to parameterize the operators by using a dynamic user interface. Each operator is then executed by a Gradoop instance from where resulting temporal graphs are pushed back to the web application for visualization. The visualized graph is interactive, i.e., visitors can zoom in and out, drag vertices and edges to other positions or click on them to show their properties and temporal attributes.

To demonstrate the *snapshot* operator, a user is able to choose between supported time predicates, e.g., *asOf*, *fromTo* or *overlaps*, a time dimension (valid- or transaction time) and a respective timestamp or interval. Through the visualization, the user receives instant feedback on the changes made and thus can explore and compare various states of different times.

For the *difference* operator, a user can compare two temporal graph snapshots by exploring a difference graph. To define the

29    new MaxDuration("maxDur", VALID_TIME),
30    new AverageDuration("avgDur", VALID_TIME)
31   ]
32  )
```

Figure 5: Analytical application defined in GrALa.

snapshots, we are using the same implemented time predicates. For the visualization, graph elements are colorized to provide more information about their temporal evolution as described in Section 2. Using this kind of visualization a user gains insights about how and how frequently the graph evolves between two graph states.

Temporal grouping, the last operator we demonstrate, offers a large variety of possibilities to explore the temporal graph by summarizing it. The configuration options of this operator are very extensive and depend on the characteristics of the selected graph dataset and the objectives of the corresponding analysis. The *Temporal Graph Explorer* supports the user in the configuration of the operator by a flexible selection of the predefined key functions for vertices and edges, as well as aggregate functions. Appropriate arguments are offered for parameterized key functions. For example, a list of property names is offered for the function `property(<name>)`. Timestamps which appear to be useful for the selected temporal graph are also suggested for use with temporal key functions. Besides, the user can choose from pre-defined aggregate functions to additionally configure the grouping and thus to enrich the grouped elements with detailed information about the grouped element, which can be accessed in the graph visualization. The user can thus interactively add key and aggregate functions to the configuration step by step until the grouped graph and its aggregated values provide information about a specific analysis question. Figure 4 shows a cutout of a grouping result in the *Temporal Graph Explorer*. The used configuration is equal to the later-described analytical application. Since the grouped vertices have geographic properties, they can be placed on a map-view. Edges can also be colored according to a certain property, as one can see in the figure. The properties created by the aggregates are displayed after selecting a vertex or an edge.

Programmatic demonstration. For a better understanding of the API of our temporal operators, we prepared a set of example programs[6] that show basic functionality and usage. Advanced examples, like the one in Figure 5, demonstrate the composition of multiple (temporal-) operators to answer specific analytical questions.

In an example scenario, we want to answer the following question: *In 2019, how did the minimum, maximum and average trip duration change per month for male and female users born after 1990 between stations located in different areas?*

We first use the *snapshot* operator (line 3) to retrieve all information about trips, users, and stations of the whole year of 2019. Since *snapshot* can produce dangling edges, we make sure to remove them by calling the *verify* operator (line 8). We further apply a *subgraph* operator with specific predicates (line 10) to filter for users born after 1990. At the end of our pipeline, we want to summarize our graph by calling the *grouping* operator with specific grouping key functions for vertices (lines 15-16) and edges (lines 22-24). Besides the predefined *label()* function, we also show the usage of a user-defined grouping key function (line 16). It calculates a map grid using latitude and longitude properties of our vertices. We further group the edges for each month of the year, separated by the two genders of the users. During this step, we also apply multiple aggregation functions to calculate the minimum, maximum, and average duration of trips (lines 28-30). Figure 4 shows the results of this GrALa program for two randomly picked stations.

The example illustrates the level of abstraction using our operators. A user does not have to care about the underlying graph data structure, operator implementation, or distributed execution details. Gradoop offers a variety of *DataSources* and *DataSinks* to read and write different kinds of data such as *.csv* files for data exchange or *.dot* files for graph visualization.

A visitor of this demonstration has the possibility to freely manipulate the provided GrALa programs. For example, it is possible to use *asOf* instead of *overlaps* at the *snapshot* operator (line 3) to specify a different time period. Further a user is able to use *pattern matching* instead of *subgraph* (line 10) to detect important graph patterns. Also the *grouping* operator can be parameterized by different pre- or user-defined functions to summarize different aspects of the data.

ACKNOWLEDGEMENT

This work is partially funded by the German Federal Ministry of Education and Research under grant `BMBF 01IS18026B`.

ABSTRACT

Motivated by the global unrest related to the COVID-19 pandemic, this demo paper presents a system for acquisition of COVID-related data from different, public sources, and interlinking under a common semantic data model at a fine level of granularity. The integrated data set contains data from several European countries, which come in different schemata, formats, granularity, and data integration acts as a facilitator towards querying data from different sources, joint data analysis, and identifying correlations at varying geographical level. Moreover, our work shows how such an integrated data set can be exploited to answer complex questions for the pandemic, also in combination with other data sets via federated queries.

1 INTRODUCTION

The COVID-19 virus outbreak presents major problems worldwide, as it affects every country in the world, both economically and socially. Governments publish COVID-related data daily, and it is commonly accepted that analyzing this data may unveil hidden patterns and aid in developing a better understanding of the pandemic. However, published data comes in different schemata, formats, granularity, which prevents data analysts from applying advanced spatio-temporal analysis methods for monitoring the evolution in space-time, due to the well-known problem of big data integration from disparate sources [7]. This motivates our work for building an extensible system based on linked data principles that allows integration of data that combines reports regarding COVID-19 cases from various countries with other public data sources.

To the best of our knowledge, the public data sets related to COVID-19 that are currently available, either report the total number of cases per country or per administrative region within a specific country. Typical examples of the first category are the World Health Organization (WHO) Coronavirus Disease Dashboard [6], the WorldOmeter [1] and the Johns Hopkins University dashboard [2], built mainly for monitoring the situation at a coarse level of detail, rather than for supporting any kind of analysis, as epidemiologists do with elaborated models. On the other hand, several countries report details about the confirmed cases in their administration regions [3]. Nevertheless, it is hard to extract the time series of reported cases for each country from the unstructured text. Also, summaries of reports provided per region through online repositories by individual countries, such as [4] and [5], do not share a common schema and use different data formats (JSON, CSV or ESRI shapefiles), which hinders joint data exploration and analysis. However, data integration needs to solve several problems at a technical level, such as different languages, text encodings and region identification systems used. For example, Germany uses "landkreis" codes, whereas Austria uses "Gemeindekennziffer" (GKZ) codes. As a result, it is necessary to convert this spatial data to a level of granularity that allows correlation analysis.

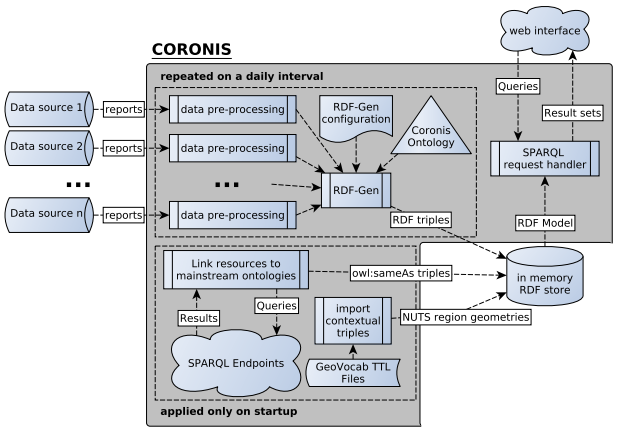

Figure 1: The overall workflow for retrieving, transforming updating and publishing data as RDF triples.

This work contributes a system, called *Coronis*[1], for gathering and linking COVID-related data from different sources under a common ontology, at a fine level of granularity and as five-star Open Data[8], enabling the correlated analysis of such data via queries that can extract useful knowledge and insights. Currently, our prototype automatically retrieves data from daily reports regarding COVID cases from 7 European countries, populating a single ontology, at a specific level of spatial and temporal granularity. Moreover, the administrative regions reported in the data set, are related to data regarding population density per region and per various age groups[2], as well as to external Open Data portals. Data exploration is enabled by a SPARQL[11] endpoint that supports federated queries. The result set is visualized using a variety of options including tables, charts and a map-based interface.

2 SYSTEM ARCHITECTURE

Figure 1 illustrates the overall system architecture as well as the workflow for data integration. Our system for COVID-19 data acquisition, integration and querying comprises the following main components:

- *Data connectors*: enabling data acquisition from different data sources.
- *Data transformation*: converts incoming data into a common semantic representation (RDF triples) according to a given ontology.

[1] In greek mythology, Coronis is a Thessalian princess and a lover of Apollo, also the mother of Asclepius, the Greek god of medicine.
[2] Data retrieved from: https://ec.europa.eu/eurostat/

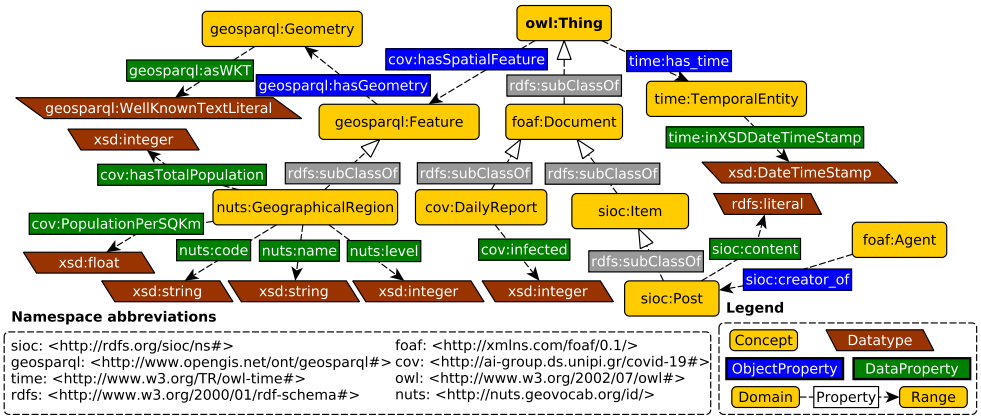

Figure 2: Core concepts (rectangles) and properties (labeled edges) of the ontology.

- *Data storage*: using an in-memory RDF store for efficient SPARQL query processing.
- *Query handler*: a SPARQL request handler that validates SPARQL queries and directs them to the RDF store.
- *User interface*: the web-based, graphical user interface that renders query results in different formats.

2.1 Data Connectors

We separate data acquisition from the remaining components, by implementing a set of data connectors, one for each data source. A data connector is responsible for establishing the connection to a remote data source, parse data, and perform data preparation tasks, such as conversion of spatial and textual encoding, build population groups, etc. The separation of data acquisition and parsing from data transformation to RDF, makes the system extensible, flexible and robust to data source modifications, or even failures of individual connectors.

The data sources accessed daily for confirmed cases per region include: Austria[3], Belgium[4], France[5], Germany[6], Greece[7], Italy[8], and Sweden[9]. Regions referenced in the data of these sources are converted to the corresponding level of *Nomenclature of Territorial Units for Statistics* (NUTS) regions. This conversion allows the correlation of regions of different countries, and also enables data integration with population data per region and age group, provided by Eurostat[10].

2.2 Data Transformation to RDF

The transformation of data into RDF triples is performed using RDF-Gen [10], our tool for efficient and flexible data transformation to RDF. RDF-Gen transforms input data using a *template* of triples that allows the use of variables or predefined functions on any of the constituent parts (subject, predicate, object) of a triple. The connector to a COVID-19 data source is initialized with contextual data related to the source, such as Administrative Regions and population (total and groups per age). The data are then automatically converted to RDF triples by RDF-Gen, and the whole process is repeated on a daily interval.

The transformation process also computes `owl:sameAs` triples between resources referring to regions in our data set and resources referring to the same regions on Open Data, such as the EU Open Data Portal, wikiData[11] and FactForge[12].

2.3 Triple Store and Query Handler

The generated RDF triples are preserved in an in-memory RDF store (Jena 3.14), which enables efficient evaluation of federated SPARQL queries over the integrated data set. In federated queries, a portion of the query is directed to a particular remote SPARQL endpoint and results returned to the federated query processor are combined with results from the rest of the query. The RDF store is initialized with static data (GeoVocab TTL files) that describe the geometries of NUTS regions and their topological relations.

The Query Handler implements SPARQL 1.1 protocol and enables our endpoint to participate in federated queries. Queries to the RDF store are supported by means of YASGUI [9], which features a user-friendly SPARQL query editor and allows rendering the result set in a wide range of formats, varying from plain CSV tables to 2D-3D maps, enriched with HTML formatted pop-ups.

2.4 The Coronis Ontology

To support the process of data integration, we build an ontology that describes the domain. Figure 2 illustrates the core concepts and properties of the ontology, where the rounded rectangles represent concepts, while edges and skewed parallelograms illustrate properties and datatypes respectively. Our ontology imports at the conceptual level:

SIOC (Semantically-Interlinked Online Communities) Core Ontology[13], OGC GeoSPARQL standard[14], OWL-Time ontology[15], and RAMON geographic ontology[16]. The integration of COVID-19 reports from different countries with EU NUTS/RAMON introduces the spatial dimension to the data, and allows the detection of topological relations between regions.

We use `cov:`, `geosparql:`, `nuts:`, as prefix abbreviations for the namespaces of our ontology, GeoSPARQL and EU NUTS RDF ontologies, respectively. The concept `cov:DailyReport`

[15]https://www.w3.org/TR/owl-time/
[16]https://ec.europa.eu/eurostat/ramon/ontologies/geographic.rdf

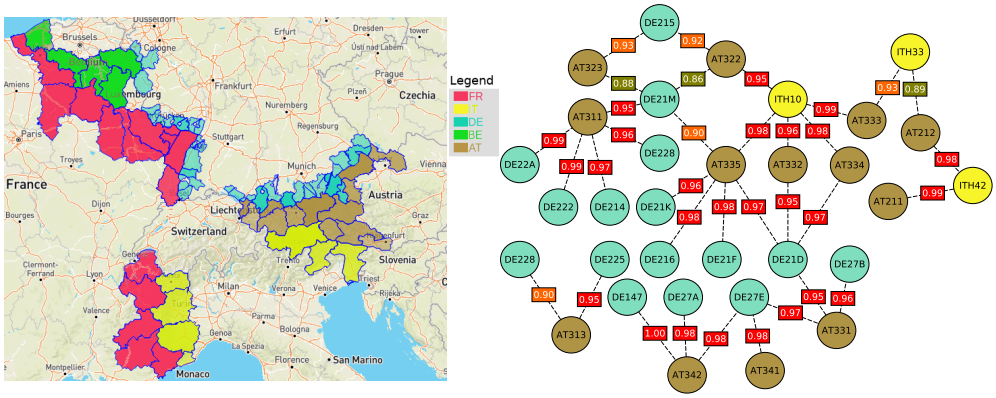

Figure 3: Adjacent regions (left) and correlations between German, Austrian and Italian regions (right).

represents the set of reports of confirmed cases. A daily report has both spatial and temporal constituents: it is associated to a resource representing a region in the EU NUTS RDF vocabulary by the property `cov:hasSpatialFeature`, and it is also related to exactly one temporal resource via the property `time:has_time`. We also define `nuts:GeographicalRegion` as a subclass of `geosparql:Feature`.

In addition, we specify a set of data properties related to the population profile of any region. Specifically, the total population, the population density, and the population per age group, with domain `nuts:GeographicalRegion`. Finally, the properties `cov:infected` and `cov:deceased` specify the number of infected and deceased cases for a region, respectively.

2.5 Queries

The Coronis ontology enables the retrieval of interlinked data with simple SPARQL queries. For example, the reported cases for a specific region (e.g., Ravensburg), sorted by date, can be obtained with the query:

```
PREFIX : <http://ai-group.ds.unipi.gr/covid-19#>
PREFIX nuts: <http://nuts.geovocab.org/id/>
PREFIX time: <http://www.w3.org/2006/time#>
SELECT ?report ?date ?population ?infected ?deceased
WHERE {
   ?report :hasSpatialFeature ?region ;
      :infected ?infected ; :deceased ?deceased ;
      time:has_time/time:inXSDDateTimeStamp ?date .
   ?region :totalPopulation ?population ;
      nuts:name "Ravensburg" .
}order by ?date
```

Figure 3 depicts an example of exploiting interlinked data from European regions, in order to investigate whether the number of infections reported in adjacent regions (of different countries) show a linear correlation. Figure 3 (left) illustrates the 67 pairs of regions returned for this query. Interestingly, the results show high correlation (0.86–1.00) between Austrian and German regions, depicted in Figure 3 (right). Lower correlation (0.25–0.46) is observed between French and Belgian regions, while negative values (-0.04 – -0.48) between French and Italian regions (probably a result of measures in Italy, when the reported number of infections dramatically increased).

To identify the adjacent regions $g1, g2$ in queries, we use the spatial predicate $touches(g1, g2)$. The Pearson R coefficient in Figure 3 (right) is computed from the results of the query:

```
PREFIX : <http://ai-group.ds.unipi.gr/covid-19#>
PREFIX nuts: <http://nuts.geovocab.org/id/>
PREFIX geosparql: <http://www.opengis.net/ont/geosparql#>
PREFIX f: <java:SPARQL_functions.>
SELECT ?r1 ?r2 ?inf1 ?inf2 ?date WHERE {
   ?r1 nuts:name ?name ;
      geosparql:hasGeometry/geosparql:asWKT ?wkt ;
      nuts:level ?l1 .
   ?r2 nuts:name ?name2 ;
      geosparql:hasGeometry/geosparql:asWKT ?wkt2 ;
      nuts:level ?l2 .
   ?c1 :hasPart ?r1 ; nuts:level "0" .
   ?c2 :hasPart ?r2 ; nuts:level "0" .
   ?rp1 :hasSpatialFeature ?r1 ; :infected ?inf1 ;
      time:has_time/time:inXSDDateTimeStamp ?date.
   ?rp2 :hasSpatialFeature ?r2 ; :infected ?inf2 ;
      time:has_time/time:inXSDDateTimeStamp ?date.
   FILTER(f:touches(?wkt,?wkt2)&&(?c1!=?c2) &&
      ((?l1="2")||(?l1="3"))&&((?l2="2")||(?l2="3")))
} ORDER BY ?date
```

3 SYSTEM DEMONSTRATION

Coronis provides a wide range of options for query building and rendering the result set, by supporting federated queries and a user-friendly web interface based on YASGUI. In this section, we provide the demonstration scenario briefly[17]. The system prototype uses a SPARQL editor to query the integrated data set.

Illustrate results in tabular format: In this option, the result set is presented as a table where each column corresponds to the projected variables, and each row corresponds to the combination of values that match the query pattern. The web interface enables sorting the results by values of specific columns or filtering the results by value. A table reporting the total number of confirmed cases for a specific date is shown in Figure 4.

Illustrate results in a grid: The result set of queries are rendered in a grid, where the cells are HTML formatted blocks dynamically constructed from the result set. For example, Figure 5 illustrates the result set of a federated query, combining number of hospitals (from wikidata) and confirmed cases (from the locally stored RDF triples) per region.

Illustrate results in a chart: In this option, a result sets that contain numerical values is presented in one of various chart types. The user can select the type of chart (and customize) by clicking on "configure". The chart can be also downloaded as an SVG file for offline use. Figure 6 depicts the number confirmed cases in Bayern per day.

[17]The queries presented in this paper and additional examples are publicly available at the endpoint's URL address: http://83.212.169.101/datasets/yasgui.html

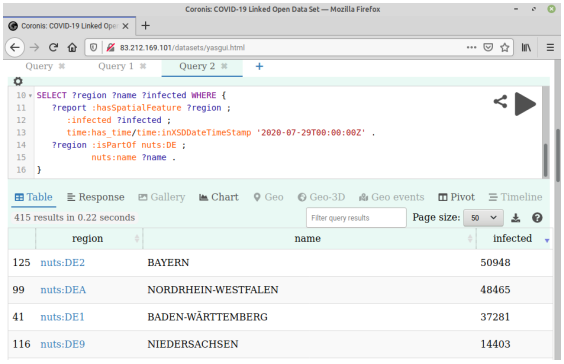

Figure 4: Result set rendered as a table.

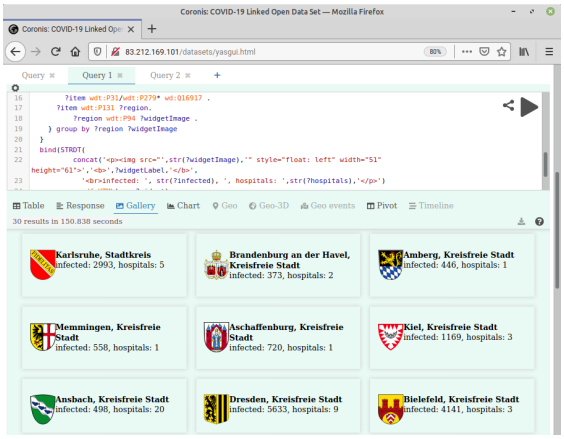

Figure 5: Result set rendered as a gallery.

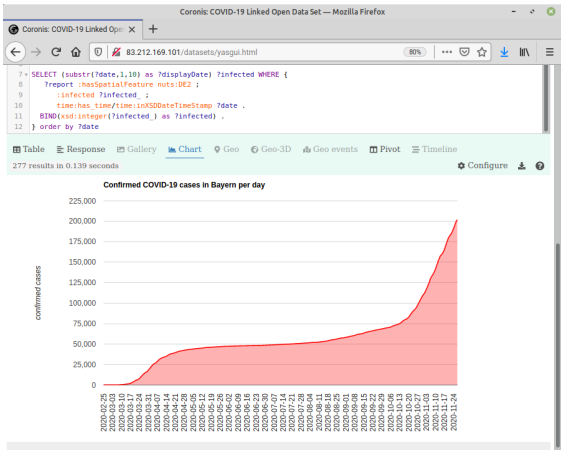

Figure 6: Example of a result set as a chart.

Illustrate results in a map: This option can be applied on results sets with spatial dimension. It renders each spatial object in the result set as a point or polygon on a 2D or a 3D map, on top of OpenStreetMap layer. The 2D map of Figure 3 and 3D map of Figure 7 are examples of this option.

4 CONCLUSIONS

This work presents Coronis, a prototype for data collection and integration of an Open Data set about COVID-19 confirmed cases

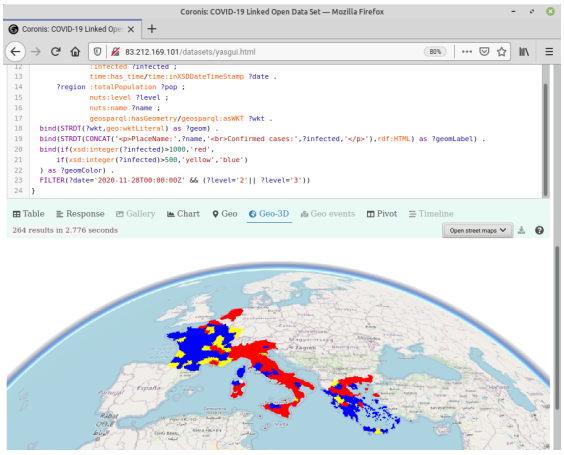

Figure 7: Result set rendered as a 3D map.

that enables cross-country, spatio-temporal analysis at different levels of granularity. Our work facilitates querying and analyzing data from different data sources, which would otherwise be a tedious and time-consuming task. The integrated data set is transformed into RDF triples to populate an ontology built on top of well-known ontologies, and resources are linked to external Open Data repositories. In turn, this enables the formulation of complex queries over interlinked COVID data with external sources, thus offering the opportunity for advanced data analysis. In our future work, we plan to expand our data set with more countries and link the data with more portals that provide information about social events, news feeds and human activities that possibly affect the spreading of the virus.

Effective and Scalable Data Discovery with Nextia$_{JD}$

Javier Flores, Sergi Nadal, Oscar Romero
Universitat Politècnica de Catalunya
Barcelona, Spain
jflores|snadal|oromero@essi.upc.edu

ABSTRACT

We present Nextia$_{JD}$, a data discovery system with high predictive performance and computational efficiency. Nextia$_{JD}$ aids data scientists in the discovery of datasets that can be crossed. To that end, it proposes a ranking of candidate pairs according to their join quality, which is based on a novel similarity measure that considers both containment and cardinality proportions between candidate attributes. To do so, Nextia$_{JD}$ adopts a learning approach relying on profiles. These are succinct and informative representations of the schemata and data values of datasets that capture their underlying characteristics. Nextia$_{JD}$'s features are fully integrated into Apache Spark and benefits from it to parallelize the profiling and discovery processes. The on-site demonstration will showcase how Nextia$_{JD}$ can effectively support large-scale data discovery tasks with a large set of datasets the audience will be able to play with.

1 INTRODUCTION

Data-driven organizations are nowadays generating valuable insights by crossing their core data with external third party data, such as data from open data catalogs [6]. This has led to the creation of massive data repositories, or data lakes [8], of heterogeneous datasets without a proper structure or organization [7]. Yet, it is reported that data scientists spend up to 80% of their time in the process of discovering and integrating such datasets [9]. The lack of efficient strategies to automate such discovery process has a large impact on productivity. We exemplify this fact with the following scenario:

Example 1.1. *Emma is a data scientist employed by a marketing agency, hired to launch a campaign in the northern region of Spain. The objective is to find the best way to upsell a new product. To that end, Emma is provided with a reference dataset, such as that depicted in Table 1, containing the store locations and marketing channels that will be used to advertise the new product. She knows that the best strategy for this task is to use demographic data to define consumer segments, ultimately driving the kind of promotion and budget devoted to it. Thus, Emma plans to search for datasets in the agency's data lake, requiring to manually explore each dataset to find interesting ones to be crossed.*

Table 1: Stores in Spain's northern region (D_{ref})

The previous example is a commonplace *data discovery* scenario. This is the process of automatically identifying and crossing relevant datasets to enable informed data analysis [1]. We put the focus on the task of discovering joinable attributes among datasets in a data lake. The problem is commonly tackled by measuring the similarities among pairs of attributes, aiming to provide the user with higher similarity pairs. We distinguish exact and approximate approaches, where there is a trade-off between their search accuracy and algorithmic complexity. Massive data lake environments, containing hundreds of datasets with thousands of attributes, require solutions with the ability to scale-up, and thus rule out exact methods. The state-of-the-art on approximate approaches to data discovery is those adopting *comparison by hash* techniques, such as MinHash [2] or LSH Ensemble [11]. These compare and predict similarities among pairs of attributes using techniques that, with high probability, hash similar elements to the same bucket (e.g., locality-sensitive hashing or locality-preserving hashing). This process is optimized by building index structures for a particular threshold, such that they allow to efficiently look up the predicted similarity. We next elaborate on applying hash-based techniques on Example 1.2.

Example 1.2. *Table 2 depicts a sample of Emma's agency data lake. She aims to automatically find datasets that will yield the best join with D_{ref}. To do so, as an indicator of a high quality join, she builds a threshold index to discern pairs of attributes with a containment similarity larger than 0.75. Then, Emma uses this index to find promising joinable pairs. Examples of the proposed pairs are D_{ref}.1st Admin Level = D_1.Area, D_{ref}.1st Admin Level = D_2.Region and D_{ref}.1st Admin Level = D_3.Product. Note, however, that the last pair is clearly a false positive, since many regions have a matching product name. Indeed, the values from D_{ref}.1stAdminLevel can also be found in datasets related to ship names, people names, places that are not from Spain, etc. This is a usual scenario in heterogeneous data lakes (i.e., files in different formats and covering different semantic topics) that tend to generate a significant amount of false positives pairs when only considering containment. The number of false positives generated by current approaches is overwhelming when working at scale.*

State of the art hash-based data discovery systems tend to optimistically propose too many candidate pairs at scale. Moreover, the arrival of new datasets requires to reconstruct the threshold indexes for efficient lookup. Such factors can overwhelm data scientists when dealing with large data lakes. Alternatively, another kind of approximate method to data discovery is the *comparison by profile* approach. These approaches extract summaries of datasets and their attributes to build a profile. Profiles are then compared to predict whether a given pair of attributes will join. Such succinct representations can be efficiently generated in a distributed fashion, and their comparison is much more efficient than comparing data values from a complexity point of view. Nevertheless, state of the art profile-based solutions, such as FlexMatcher [3] and Aurum [4], have a low quality prediction rate with respect to other approaches. This is mainly due to either the

usage of a predictive binary class (i.e., joinable or non-joinable) that generate too many false positives in practice; or to the adoption of rather basic profiles that do not accurately describe the underlying data.

In order to overcome the previous issues, we present Nextia$_{JD}$[1], a novel data discovery system with high predictive performance and computational efficiency. Nextia$_{JD}$ aims to fill the gap generated by the low predictive performance of current profile-based methods, as well as the limited precision and scalability of hash-based ones on data lakes. Nextia$_{JD}$ adopts a novel learning-based method based on data profiles. Importantly, the steps related to profiling and classification can be efficiently run in parallel. Our experiments (see [5] for more details) have shown that the predictive performance of Nextia$_{JD}$ is comparatively better than that obtained using state-of-the-art profile-based solutions, and the rate of false positives (i.e., precision) is improved w.r.t. hash-based ones. Additionally, Nextia$_{JD}$ also outperforms these systems in terms of scalability. This is achieved by integrating Nextia$_{JD}$ into the Apache Spark[2] ecosystem for distributed data processing, providing a competitive advantage with respect to the state of the art on scalability. Nextia$_{JD}$'s predictive model is based on random forest classifiers, a highly expressive model robust to outliers and noise. These models, unlike current approaches, predict a categorical quality for a candidate join based on both the containment and cardinality proportion of the involved attributes, and provide a join quality ranking that facilitates to disregard false positives.

Our demonstration will let EDBT participants impersonate Emma on her data discovery tasks. These involve exploring a data lake, generating a ranking based on the join quality of attribute pairs, as well as generating data processing pipelines from them. Similarly to other contemporary data discovery solutions (e.g., [10]), Nextia$_{JD}$ is accessible via a friendly notebook interface, nowadays the customary tool to develop and visualize data science tasks. Nevertheless, NextiaJD is able to scale-up and manage more and larger datasets. Additionally, the audience will be encouraged to try Nextia$_{JD}$ on datasets of their interest.

This will demonstrate how Nextia$_{JD}$ facilitates data discovery by reducing the time on high quality data exploration and discovery, and thus increasing the productivity of data scientists.

Outline. We next introduce Nextia$_{JD}$'s demonstrable features to resolve the motivational example and other data discovery scenarios. We first provide an overview of Nextia$_{JD}$, followed by a presentation of its core features. Lastly, we outline our on-site demonstration, involving the motivational scenario as well as other more complex real-world use cases.

2 Nextia$_{JD}$ IN A NUTSHELL

Apache Spark has emerged as the leading framework for Big Data processing due to its scalability and performance. It has been extended with modules to enable structured data processing and machine learning, namely SparkSQL and MLlib. Nextia$_{JD}$ extends Spark's source code with new operators to discover joinable datasets: `attributeProfile` and `discovery`. Figure 1, depicts a high-level overview of the stages involved in these operators.

2.1 Attribute profiling

The profiling operator implements the computation of a dataset's profile, which is composed of attribute meta-features. These represent the underlying distribution and characteristics of attributes. Hence, the method `attributeProfile` lazily computes the attribute profiles from a `DataFrame` object once and stores them for later reuse. This process can be triggered at ingestion time, or later in the discovery phase. Nextia$_{JD}$ takes full advantage of the Spark's Catalyst Optimizer to efficiently distribute the workload on very large datasets.

Kinds of profiles. Nextia$_{JD}$ collects extensive meta-features about the structure and content of String attributes in a `DataFrame`. We consider three kinds of meta-features: cardinalities, value distribution, and syntax. Cardinalities provide a broad view of an attribute via meta-features like the number of distinct values, uniqueness, or incompleteness. The value distribution builds a histogram by collecting the number of occurrences and aggregating it to compute meta-features such as the mean, standard deviation, or quantiles. Finally, syntax meta-features aim to describe the shape of data and their patterns. Nextia$_{JD}$ collects meta-features such as the length of values, numbers, or alphabetic values. Here, Nextia$_{JD}$ also exploits several regular expressions to identify specific data types such as telephones, IPs, or emails.

Overall, Nextia$_{JD}$ computes 48 meta-features that compose an attribute's profile. Figure 2, depicts the Scala code used to compute attribute profiles for D_{ref}, as well as an excerpt of its

output. Additionally, prior to the discovery process, Nextia$_{JD}$ also computes binary meta-features, which denote the characteristics of the relationship between pairs of attributes. Precisely, we measure the degree of similarity and dissimilarity between attribute names by computing the Levenshtein distance. Nextia$_{JD}$ also estimates a best-case containment scenario, assuming all unique values are covered in both attributes. The current set of meta-features used result from a principal component analysis and therefore, all of them are guaranteed to contribute with relevant information to make the decision. Indeed, Nextia$_{JD}$ computes richer profiles compared to other profile-based approaches.

2.2 Data discovery

The data discovery operator exposes the functionality to discover joinable attributes by using the profiles. We distinguish two scenarios: discovery-by-attribute and discovery-by-dataset. The former focuses on the discovery from a reference attribute, while the latter exhaustively searches all attributes in a reference dataset. Both settings require a reference dataset and a list of candidate datasets. Additionally, discovery-by-attribute requires a reference attribute name. This operator encapsulates and hides from the analyst the complexity required to implement the different stages in the discovery pipeline: profile normalization, comparison, classification, and ranking. Thus, Nextia$_{JD}$ does not require to parameterize or process the input data.

Normalization. Meta-features in a profile are represented in different magnitudes, therefore normalization plays an important role to guarantee a meaningful comparison between profiles. Nextia$_{JD}$ adopts the Z-score normalization method for all meta-features in a profile. To do so, a UDF function computes the mean and standard deviation for a given meta-feature using the respective SparkSQL aggregation functions.

Comparison. Comparing profiles requires computing distances among meta-features corresponding to a pair of attributes. Once pairs are created, we merge the profiles subtracting the normalized meta-features from the reference attribute and the to-be-compared attribute by using Spark SQL.

Classification. Nextia$_{JD}$ adopts a learning approach that allows us to classify pairs of attributes producing high quality joins. Precisely, Nextia$_{JD}$ aims to predict the join quality, which is an asymmetric rule-based measure combining both containment similarity and cardinality proportion. In [5] we introduced the concept and role of the cardinality proportion, which complements the containment metric to remove a substantial amount of the false positives generated by it. In short, the cardinality proportion contextualizes containment, and as such, different cardinalities tend to identify different semantics or granularity levels for heterogeneous data lakes. Such metric yields a quality class from a totally-ordered set $S = \{\texttt{None}, \texttt{Poor}, \texttt{Moderate}, \texttt{Good}, \texttt{High}\}$. Hence, the definition of join quality is as follows:

Definition 2.1. Let A, B be sets of values, respectively the *reference* and *candidate* attributes. The join quality among A and B is defined by the expression

$$Quality(A,B) = \begin{cases} (4)\ \texttt{High}, & C(A,B) \geq C_H \wedge \frac{|A|}{|B|} \geq K_H \\ (3)\ \texttt{Good}, & C(A,B) \geq C_G \wedge \frac{|A|}{|B|} \geq K_G \\ (2)\ \texttt{Moderate}, & C(A,B) \geq C_M \wedge \frac{|A|}{|B|} \geq K_M \\ (1)\ \texttt{Poor}, & C(A,B) \geq C_P \\ (0)\ \texttt{None}, & \text{otherwise} \end{cases}$$

Nextia$_{JD}$ embeds a set of general purpose models, one per quality label in the previous definition, trained with Random Forest classifiers from Spark MLlib. These models were trained by transforming a multi-class classification problem into a binary one per class. Each of these models takes as input the normalized unary and binary meta-features of the pair of attributes for which we aim to predict their join quality. These models were trained following good practices in model learning and the ground truth (including labeling), data preparation, and validation processes are thoroughly presented in a reproducible manner at: https://www.essi.upc.edu/dtim/nextiajd/. As part of this process, we empirically determined the values $C_H = 3/4 = 0.75, C_G = 2/4 = 0.5, C_M = 1/4 = 0.25, C_P = 0.1$ for containment, and $K_H = 1/4 = 0.25, K_G = 1/8 = 0.125, K_M = 1/12 = 0.083$ for cardinality proportion on our training dataset composed of 138 real datasets. The models validation was conducted with 139 real datasets from different topics and file sizes and yielding a high predictive performance [5]. As a result, for each candidate join pair the discovery operator associates a join quality label (i.e., from `None` to `High`) and five probability scores, one per model.

A key distinguishing factor of Nextia$_{JD}$ with regard to other profile-based approaches (e.g., FlexMatcher [3]), is that it relies on general purpose models that can be used for any data discovery process with heterogeneous datasets.

```

"1st␣Admin.␣Level")
```

Dataset	Attribute	Quality	Probability
D_2	Region	High	0.95
D_1	Area	High	0.93

Figure 3: Code to trigger a discovery process, and the two first elements of the ranking it generates

Ranking. Finally, an evaluation is performed in the probabilities of a candidate join pair to assign a single probability. In short, the highest probability wins, except for cases where several probabilities are close to each other. In those cases, we follow a rule-based strategy to avoid misclassifications due to the fact that the probability for the `None` class is the only one predicting no join. We identified two main cases generating the most misclassifications: (i) when the no join probability (i.e., the probability for `None`) is above 50% and (ii) when the join-related labels (i.e., from `Poor` to `High`) are all below 50% and the `None` probability is close to them (measured by an empirical threshold). In these cases, the final decision is modified to the second highest probability (which in practice, given these rules, mostly means to that of `None`). Then, Nextia$_{JD}$ generates a partial order by considering, first,

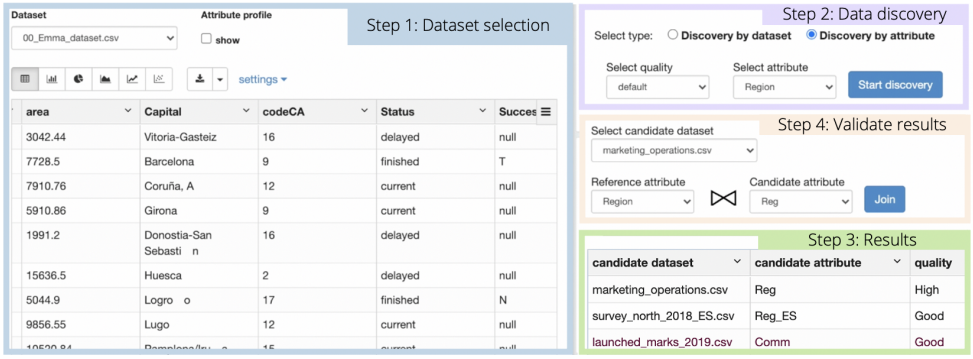

Figure 4: Nextia$_{JD}$ GUI in a Zeppelin notebook

the predicted quality label (and the totally-ordered set related to them). For pairs yielding the same quality label, we rank them considering the probability yielded by the model (i.e., that of the model of the quality labeled finally assigned). An example of the ranking produced for Emma's use case is presented in Fig. 3. By default, Nextia$_{JD}$ only shows High and Good qualities. However, other qualities can be requested on-demand.

3 DEMONSTRATION OVERVIEW

Computational notebooks have become the de-facto tool for data science projects. In our experience in several Data Science projects, data scientists like to explore datasets with their usual analytical tools. Using a third party tool to perform data discovery is disruptive for their day-by-day tasks, and they tend to avoid it. For this reason, we created Nextia$_{JD}$, which fills a current gap to bring data discovery closer to data scientists. We argue that embedding data discovery into notebooks and taking advantage of their interactive capabilities will improve data scientists' productivity. Therefore, for our demonstration, we will use a Zeppelin notebook to present the main functionalities: profiling and data discovery, and how they can be used in the day-by-day of data scientists. We have also created an informative companion website[3] where the notebooks[4], source code and experiments are publicly available. It is worthy to say that Nextia$_{JD}$ is not tied to this demonstration platform and can be integrated into any technology that supports Spark in Java or Scala clients.

We encourage attendees to impersonate Emma and follow the workflow she would have to execute using Nextia$_{JD}$. Note that we assume for this demonstration that datasets were profiled when ingested into a repository to be ready for use in further discoveries. However, new datasets can be processed and profiled on demand if required during the demo. Figure 4 shows Nextia$_{JD}$'s GUI in a Zeppelin notebook:

(1) **Dataset selection.** First, attendees can select and preview datasets available in our heterogeneous data lake containing Emma's dataset and datasets from different topics such as movies, territories, finance, etc. Through this step, attendees can also preview the profiling computed to have a better perspective of what kind of meta-features Nextia$_{JD}$ collects.
(2) **Data Discovery.** Once a dataset is selected, we proceed to the data discovery task. Users can perform two types of setting: discovery-by-dataset or discovery-by-attribute. Through this step, it is possible to select the desired quality. Nextia$_{JD}$ will execute the data discovery operator and will handle all steps: normalization, comparison, classification, and ranking.
(3) **Explore results.** After data discovery, results are visualized in a table where we show the attributes pairs found, the source of the datasets, the quality predicted, and the probability.
(4) **Validate results.** Once the attendees find an interesting pair proposed by Nextia$_{JD}$, they can validate the result by executing the join operation. This operation will update the dataset preview with the result of the join. Additionally, the similarity and cardinality proportion obtained by the join operation is also computed and shown.

Last, but not least, we are aware that some data scientists are advanced users. In these cases, they do not need to use Nextia$_{JD}$'s GUI but directly use the new it offers as an extension of Spark. These are compiled and ready in the Spark fork available from our website. This is shown in the live demo on our website. Overall, this demonstration will offer a comprehensive dive into Nextia$_{JD}$.

ABSTRACT

JSON Schema is an evolving standard for the description of JSON documents. It is an extremely powerful language endowed with boolean operators and recursive definitions. Hence, classical problems like schema *consistency* and *equivalence* may be challenging without well-principled tools. Based on our recent effort for laying down an algebraic formal semantics of JSON Schema, we demonstrate an approach for generating valid *witnesses* of a user-defined schema. Our goal is not only to allow programmers to design schemas that meet their intentions, but also to guide them in their journey to understanding the semantics of existing schemas, in an interactive fashion. We thus aim to contribute to the adoption of the JSON Schema language by facilitating its use.

1 INTRODUCTION

In recent years, JSON has become the *de facto* standard data interchange format, and is now widely used for exchanging data between web applications and remote servers, for exporting and importing data, as well as inside complex ML pipelines for combining different stages, as in Google TFX [11].

Despite its great popularity, there is no consensus about a *standard* schema language for JSON yet. Indeed, in many cases, JSON datasets come without a schema, and the end user or application has the duty to infer or guess a new schema, if required. In many other cases, however, several and vastly different schema languages are used for describing the structure of JSON data, ranging from Apache Avro [3], to the MongoDB internal schema language [6], and to JSON Schema [12].

Differently from what happened with XML, whose standard schema languages (DTDs and XML Schema) reached quickly a wide diffusion, JSON Schema is not being adopted at the same pace. Many reasons are slowing down its adoption, but, according to our observations, a major obstacle is the fact that, while extremely powerful, JSON Schema is – frankly – hard to use. Indeed, a schema is a logical combination of implicative assertions, and some of them may produce side effects on previous ones.

As a consequence, leaving the realm of plain vanilla schemas may expose the programmer to many risks, such as the definition of a schema with unintended semantics, or one that is even empty.

Example 1.1. Consider the following schema.

```
{
    "type": "object",
    "properties": {
        "x": { "type": "integer" }
    },
    "required": [ "x" ]
}
```

This schema declares that all instances are JSON objects, and that each object has a mandatory *member* whose name is x and whose type is *integer*. This schema, however, does not impose further constraints on object values; therefore, an object may also have supplementary and unconstrained members.

Example 1.2. Consider now the following schema, differing only in the next-to-last line.

```
{
    "type": "object",
    "properties": {
        "x": { "type": "integer" }
    },
    "not": { "required": [ "x" ] }
}
```

One may assume that this specifies that x is "not required", hence is optional. However, given the semantics of JSON Schema, negating a required member does not make it optional: indeed, the final effect is to actually forbid the presence of the member, hence excluding any JSON object having a member whose name is x (this example is inspired by a discussion on Stack Overflow [1], where the confusing effect of this schema is testified).

Given the complex and non-trivial interplay between schema assertions, designing a rich yet sound schema is challenging, especially when other powerful mechanisms of JSON Schema are involved, such as negation, mutual exclusion, recursion, union and conjunction, as well as array constraints controlling array length and content, possibly requiring uniqueness of elements.

Motivating Witness Generation. The state-of-the-art approach for exploring JSON Schema semantics is ultimately a manual trial and error: using a JSON Schema validator, a schema designer can test whether a JSON document is valid w.r.t. the schema. That is, the designer must come up with suitable *witness* documents.

Yet, in this demo, we present a tool capable of automatic witness generation. For instance, for the schema from Example 1.1, our tool generates the witness `{"x": 0}`, as any valid instance

must be an object, where member x is mandatory and integer-typed. For Example 1.2, our tool generates the witness `{}`, since the empty object is valid. For the schema designer, this valuable feedback may well increase the overall productivity.

Moreover, upon the push of a button, the designer can generate further witnesses. In the example just discussed, the designer would be provided with `{"0": null}`. Thus, by interactive iteration, the designer ensures that he or she "gets it right".

Moreover, our tool allows the comparison of two schemas: for a witness that is valid w.r.t. the schema from Example 1.2, but not w.r.t. the schema from Example 1.1, the tool returns the JSON document `{}`. For the other way round, a witness is `{"x": 0}`. Again, the designer can request further witnesses, as needed.

Contributions. The goal of this demonstration is to showcase a tool allowing the schema designer to investigate the formal properties of a schema, and even to compare schemas. Our tool is based on our earlier contributions on algebraic manipulations of JSON Schema [7]. With our tool, the designer can:

- obtain an algebraic representation of the input schema;
- generate a witness for the schema, to verify whether the schema is empty or not, and to gain insights into the actual semantics of a given schema;
- exploit witness generation for checking whether a schema S_1 is a subtype of a schema S_2, and hence, whether it represents a conservative and not disruptive evolution.

This combination of features is currently not supported by any existing commercial or academic tool: while tools for JSON Schema containment checking are available (e.g., [9]), they merely produce boolean answers. Ours is the first tool capable of generating actual witnesses in containment checking.

2 JSON AND JSON SCHEMA

In the following, we introduce the JSON data model and provide some intuition for JSON Schema. We refer to [7, 10] for details.

2.1 JSON data model

The grammar below captures the syntax of JSON values, which are either basic values, objects, or arrays. Basic values B include the null value, booleans, numbers n, and strings s. Objects O represent sets of members, each member being a name-value pair, and arrays A.

$J ::=$	$B \mid O \mid A$		**JSON expressions**
$B ::=$	null $\mid$ true $\mid$ false $\mid n \mid s$		**Basic values**
	$n \in \mathsf{Num}, s \in \mathsf{Str}$		
$O ::=$	$\{l_1 : J_1, \ldots, l_n : J_n\}$		**Objects**
	$n \geq 0, \quad i \neq j \Rightarrow l_i \neq l_j$		
$A ::=$	$[J_1, \ldots, J_n]$	$n \geq 0$	**Arrays**

2.2 JSON Schema

JSON Schema is a language for defining the structure of JSON documents, maintained by the Internet Engineering Task Force [4].

JSON Schema uses the JSON syntax. Each construct is defined using a JSON object with a set of fields describing assertions relevant for the values being described. Some assertions can be applied to any JSON value type (e.g., *type*), while others are more specific (e.g., *multipleOf* applies to numeric values only). The syntax and semantics of JSON Schema have been formalized in [10] following the specification of Draft-04. We limit ourself to an informal discussion about the possible constraints associated to each type:

- when defining a *string*, it is possible to restrict its length by specifying *minLength* and *maxLength* constraints, and to define the *pattern* that the string should match;
- when defining a *number*, it is possible to define its range of values (by any combination of *minimum* / *exclusiveMinimum* and *maximum* / *exclusiveMaximum*), and to define whether it should be *multipleOf* a given number;
- when defining an *object*, it is possible to define its *properties*, the type of its *additionalProperties* and the type of the properties matching a given pattern (i.e., *patternProperties*). It is also possible to restrict the minimum and maximum number of properties using *minProperties* and *maxProperties*, and to indicate which properties are *required*;
- when defining an *array*, it is possible to define the type of its *items* and the type of the *additionalItems* which were not already defined by *items*, and to restrict the minimum and maximum size of the array; moreover, it is also possible to enforce uniqueness of the items using *uniqueItems*.

JSON Schema allows the combination of assertions using standard boolean connectives: *not* for negation, *allOf* for conjunction, *anyOf* for disjunction, and *oneOf* for exclusive disjunction. A finite set of accepted values can be indicated through the *enum* constraint. Please note that hereafter, as well as in our formal development [7], we will use in some examples the usual notation for boolean operators (e.g., $\vee/\neg/\wedge$ for disjunction/negation/conjunction) and the symbols S/S_i to indicate schema fragments.

3 WITNESS GENERATION

Witness generation is challenging for JSON Schema, in particular due to the non-algebraic nature of JSON Schema (the meaning of certain assertions depends on the surrounding context), and because of the presence of negation and conjunctive schemas. We elaborate on these facts, and describe some main aspects of the formal systems and algorithms we devised. We will provide the full details in a future publication.

In a nutshell, our approach proceeds as follows. Assume that you have an algorithm to generate a witness for any schema assertion S of size up to n. In order to generate a witness for a schema of size $n + 1$ describing objects having a field of label l and value of type S, one will generate a witness w for S and use it to build an object with a field label l whose value is w.

For disjunction $S_1 \vee S_2$, we recursively generate witnesses of S_1 and of S_2. Yet negation and conjunction are problematic, as there is no way to generate a witness for $\neg S$ starting from a witness for S, and, given a witness for S_1, if this is not a witness for $S_1 \wedge S_2$, we may need to try infinitely many others before finding one that satisfies S_2. As we will see, since conjunction is used for object and array schemas, dealing with conjunction is particularly important for generating these two kinds of values.

Dealing with these challenges requires schema manipulations that can be rather complex. In order to devise the necessary schema transformation rules, as well as to study their properties and optimization techniques, we designed an algebra which is at the same time minimal and fully compliant to JSON Schema.

Details can be found in [7], but just to have a glimpse, consider the following JSON Schema fragment describing properties of label-value members of object values. In this fragment, we have a conjunction of assertions satisfied by a JSON value J if the following holds: if J is an object then i) if a k_i label is present,

then its associated value meets S_i, ii) if a label k' is present, satisfying a pattern (regular expression) r_i, then its associated value satisfies PS_i, iii) for all other labels in J not satisfying the previous conditions, the associated value satisfies S, iv) a member with label k_1 is required.

$$\begin{array}{l}\texttt{"properties"} : \{\texttt{"}k_1\texttt{"} : S_1, \ldots, \texttt{"}k_n\texttt{"} : S_n\},\\ \texttt{"patternProperties"} : \{\texttt{"}r_1\texttt{"} : PS_1, \ldots, \texttt{"}r_m\texttt{"} : PS_m\},\\ \texttt{"required"} : [\texttt{"}k_1\texttt{"}],\\ \texttt{"additionalProperties"} : S\end{array}$$

In this example, we can see the non-algebraic nature of JSON Schema: the semantics of one assertion (`additionalProperties`) depends on a co-occurring assertion (`properties`).

Our algebra encapsulates possibly interacting assertions into one, as shown below.

$$\begin{array}{l}\mathsf{props}(\underline{k_1} : \langle S_1\rangle, \ldots, \underline{k_n} : \langle S_n\rangle, r_1 : \langle PS_1\rangle, \ldots, r_m : \langle PS_m\rangle; \langle S\rangle)\\ \qquad \wedge\ \mathsf{req}(k_1)\end{array}$$

In the above algebra expression, we use $\underline{k}$ to indicate the JSON pattern "^$k$$" that only matches k, and $\langle S'\rangle$ to indicate our algebra expression corresponding to a schema S'.

By relying on this algebra, in order to deal with schemas $\neg S$ for enabling witness generation, we follow a traditional approach: we push negation inside S by playing with standard boolean laws, in order to obtain an equivalent, not-free schema that we use for witness generation. Unfortunately, JSON Schema does not enjoy negation closure: there are JSON schemas for which not-elimination is not possible. So we have extended our algebra with several new basic operators ensuring negation closure (that can be produced by not-elimination), and for which witness generation is possible in an inductive fashion, after further rewritings that we are going to exemplify. One of such operators is

$$\mathsf{pattReq}(r_1 : S_1, \ldots, r_n : S_n)$$

In order for a value to be an instance of the schema above, if the instance is an object, then, for each $i \in \{1..n\}$, it must possess a member whose name matches r_i and whose value satisfies S_i. (It is worth observing, that it is strictly more expressive than `required` since it allows one to require a name that belongs to an infinite set $L(r_i)$, and it associates a schema S_i to each required pattern r_i.)

A second challenging aspect is related to conjunction. In order to deal with conjunctive schemas we rely on standard rewritings, enabling the transformation into equivalent schemas in Disjoint Normal Form, which is more amenable for witness generation.

Unfortunately, DNF rewriting is not sufficient, because some mutual dependencies still remain among factors of conjunctions after DNF transformations. This means that we need to effectively push DNF transformation (as well as other operators) a step further in an unconventional fashion. The approach we have devised can be illustrated by the following example, where we focus on object schemas.

We use here JSON regular expressions (patterns), where $\hat{}$ matches the beginning of a string, $[\hat{}abc]$ matches any one character different from a, b and c, a dot . matches any character, \$ matches the end of the string, so that "$\hat{}\,a[\hat{}b]$." matches *acccccc* and *acc* but does not match *ac*, because the dot after the "$\hat{}\,a[\hat{}b]$" requires a third letter (carefully consider the dots in the patterns).

The expression below is a conjunction that we obtain by means of DNF transformations. We use the notation $\{\mathsf{Obj}, S_1, \ldots, S_n\}$ to denote a *group* of statements whose conjunction $\mathsf{Obj} \wedge S_1, \wedge \ldots \wedge S_n$ describes object values (we can also have array groups, etc.). Also note that $\mathbf{t}$ stands for the schema accepting any value.

$$\begin{array}{c}\{\mathsf{Obj}, \mathsf{props}(\hat{}\,a : S_1), \mathsf{props}(\hat{}\,.b : S_2),\\ \mathsf{pattReq}(\hat{}\,.d : \mathbf{t}), \mathsf{pattReq}(\hat{}\,a : S_3)\}\end{array}$$

A possible plausible witness generation strategy for this group would start considering pattReq constraints, but we need to keep into consideration possible interactions with other patterns in the object type, so we should first generate a witness for pattReq constraints, then checking whether props() are satisfied by the candidate witness, and if it is not the case, go back to pattReq and so on, by possibly infinite loops. To avoid this we rather manipulate the object group in order to be able to focus on subexpressions of the newly obtained object schema where, in some sense, all possible interactions are finitely enumerated, so that they can be dealt with separately.

Rather than providing the step-by-step process that produces this expansion, we show below the final result.

$$\begin{array}{l}\mathsf{props}(\hat{}\,a : S_1), \mathsf{props}(\hat{}\,.b : S_2) \rightarrow\\ \qquad \hat{}\,a[\hat{}b] : S_1, \hat{}\,ab : S_1 \wedge S_2, \hat{}\,[\hat{}a]b : S_2, \hat{}\,[\hat{}a][\hat{}b] : \mathbf{t}\\ \mathsf{pattReq}(\hat{}\,.d : \mathbf{t}) \rightarrow\\ \qquad \mathsf{orPattReq}(\hat{}\,ad : S_1 \wedge S_3, \hat{}\,ad : S_1 \wedge \neg S_3, \hat{}\,[\hat{}a]d : \mathbf{t})\\ \mathsf{pattReq}(\hat{}\,a : S_3) \rightarrow\\ \qquad \mathsf{orPattReq}(\hat{}\,ad : S_1 \wedge S_3, \hat{}\,a[\hat{}bd] : S_1 \wedge S_3,\\ \qquad\qquad\qquad\qquad \hat{}\,ab : S_1 \wedge S_2 \wedge S_3),\end{array}$$

In the props()-part the set $\{\hat{}\,a, \hat{}\,.b\}$ has been divided into three disjoint parts $\{\hat{}\,a[\hat{}b], \hat{}\,ab, \hat{}\,[\hat{}a]b\}$ by separating the intersection $\hat{}\,ab$ from the two original patterns, and the set is completed with $\hat{}\,[\hat{}a][\hat{}b] : \mathbf{t}$. Note that these new patterns can be obtained by means of standard techniques, thanks to the well-known closure properties of regular expressions.

The first request $\mathsf{pattReq}(\hat{}\,.d : \mathbf{t})$ is split into three different cases. The first $\hat{}\,ad : S_1 \wedge S_3$ is in common with the other orPattReq (an internal operator introduced to decompose pattReq into disjoint components), while the case $\hat{}\,ad : S_1 \wedge \neg S_3$ is internally and externally split, thanks to the $\neg S_3$ factor in the schema, and $\hat{}\,[\hat{}a]d$ is pattern-disjoint thanks to the initial $[\hat{}a]$. You can also observe that $\hat{}\,ad : S_1 \wedge S_3$ *internalizes* the requirement $\hat{}\,a : S_1$, the same holds for $\hat{}\,ad : S_1 \wedge \neg S_3$, while $\hat{}\,[\hat{}a]d$ only matches the trivial requirement, hence maintains its $\mathbf{t}$ schema.[1]

The second pattReq is split into three cases as well, in order to bring into view the intersection with the first pattReq, and in order to internalize the constraints of the props()-part.

This splitting effort is needed in order to be able to enumerate and try all the possible ways of satisfying a set of requests. For example, in this case the two orPattReq requests share the first component $\hat{}\,ad : S_1 \wedge S_3$, and contain two more components each, all of them mutually incompatible, hence having a structure $\mathsf{orPattReq}(a, b1, b2), \mathsf{orPattReq}(a, c1, c2)$. Hence, we know that there are exactly 5 ways of satisfying both: either by generating a single member that satisfies a, or by generating two members that satisfy, respectively, $(b1, c1)$, $(b1, c2)$, $(b2, c1)$, $(b2, c2)$, and our witness generation algorithm will try to pursue all, and only, these five approaches.

Even array groups obtained by DNF rewriting need preparation, by a different approach, which we cannot detail here, for

[1] As we have introduced not-schemas, notably $\neg S_3$, we re-apply not-elimination. For space reasons we do not delve into these aspects.

space reasons. Also, we have omitted how we deal with recursive definitions, both in not-elimination and witness generation.

This algorithm has an overall exponential complexity. However, we have designed techniques that make the problems tractable for many real-world schemas, and we are currently measuring their effectiveness.

4 DEMONSTRATION OVERVIEW

Our demo setup includes these datasets: we explore schemas from the JSON Schema Test Suite [2], a collection of small schemas that serve as unit tests for JSON Schema validators (and explore different operators), and real-world schemas from SchemaStore.org [5]. Naturally, our attendees may also formulate their own schemas.

We next describe the analysis for single schemas in more detail, and then remark on how attendees may also compare schemas.

Witness generation. Our tool is implemented as a Spring web application, with a Java backend. Our prototype does not yet support the operators `uniqueItems` and repeatedItems. Figure 1 shows a screenshot of the analysis of a single schema.

Typically, the user will first enter a JSON Schema document (or load one of the provided schemas), and then convert the schema (shown in the midsection of our screenshot) into our algebra (shown in the bottom section). Our algebra has been designed to be close to the original language, to be intuitive for practitioners. Yet different from the JSON Schema language, our algebra enjoys substitutability, that is, the semantics of an operator does not depend on its context, which eases manipulation.

The user may then choose to generate a first JSON witness. If the system finds no witness, it will alert the user that the schema is empty, otherwise, a witness is generated.

If there is a witness, the user can generate a further ("yet another") witness, that is different from all those previously seen. Alternatively, the user can edit the original JSON Schema, or directly the algebraic expression, and request that a new first witness is generated (disregarding witnesses already seen).

The schema designer can choose to convert back from the algebra to JSON Schema. Thus, the schema designer can interactively explore the semantics of a given schema, switch between the JSON Schema representation and the (often more compact) representation in our algebra, and iteratively revise the schema.

To allow interested demo attendees to inspect the internals of witness generation, as outlined in the previous section, our tool can also perform negation elimination on algebraic expressions. This feature would not be included in a tool targeted at end users.

Comparing schemas. Our tool offers a second screen (not shown here) where two schemas may be compared. Rather than computing a boolean answer to the question whether one schema subsumes the other, as done in state-of-the-art tools today [8], our tool can generate a witness that exemplifies a JSON document which is valid w.r.t. the one schema, but not the other.

Target audience. Our demo targets both the EDBT and the ICDT community. Attendees will become sensitive to the intricacies of working with the JSON Schema language, which caters to the ICDT community. Moreover, we point out original research questions that are of interest to the EDBT community, such as efficiency and scalability issues in dealing with real-world schemas, either due to the conditional semantics of the JSON Schema language, the interplay between negation and recursion (known to be difficult also in other areas of database research), and the sheer size of some real-world schemas (especially generated schemas, which can even take up hundreds of thousands of lines [8]).

ABSTRACT

This demo presents covRew, a Python toolkit for rewriting slicing operations in pre-processing pipelines (i.e., pipelines to be executed before further tasks, such as data analytics and machine learning) so that the pipeline execution ensures that protected groups are adequately represented (i.e., *covered*) in the result. The toolkit includes: (i) an analyzer, which identifies candidate operations for rewriting; (ii) a rewriter, which transforms operations for ensuring coverage satisfaction with respect to user specified constraints; (iii) an impact evaluator, allowing the user to assess the impact of the rewriting on the obtained results.

1 INTRODUCTION

One of the main current challenges in data processing is the development of technological solutions satisfying non-discriminating requirements. Themes such as diversity, non-discrimination, fairness, protection of minorities, and transparency are increasingly crucial when processing and analyzing data.

Analytical pipelines processing real data are often very complex and various systems have been designed for supporting the user in the design and the execution of processing pipelines in a non-discriminating way. Among them, we recall: Fair-DAGs [11], an open-source library aiming at representing data processing pipelines in terms of a directed acyclic graph (DAG) and identifying distortions with respect to protected groups as the data flows through the pipeline; FairPrep [10], an environment for investigating the impact of fairness-enhancing interventions inside data processing pipelines; AI Fairness 360 [5], an open-source Python toolkit for algorithmic fairness, aimed at facilitating the transition of fairness-aware research algorithms to usage in an industrial setting and at providing a common framework to share and evaluate algorithms.

The complexity of data processing pipelines does not only depend on the used analytical or learning tasks but also on the types of pre-processing operations applied to input datasets for filtering, projecting (thus slicing), or merging together input objects. Indeed, it has been recognized that data pre-processing tasks can introduce bias at different levels [10]. As an example, classical data transformation operations, often defined in terms of Selection-Projection-Join (SPJ) operations over tabular data, can reduce the number of records related to some protected or disadvantaged groups, defined in terms of some sensitive attributes, even if such attributes are not directly used in the specification of the data transformation operation. As a consequence, some protected or disadvantaged categories can be under-represented in (*uncovered by*) the result of a transformation, possibly introducing bias in the following analytical steps.

As already recognized [3, 11], we believe that it is important to support the user in the design of non-discriminating data pre-processing tasks, with a special reference to data transformations defined in terms of slicing and merge operations. Additionally, following what stated in [9], we believe that such design can be improved by the usage of specific diversity or fairness-aware data transformations, where the idea is to *minimally* rewrite the transformation operation so that certain non-discrimination constraints are guaranteed to be satisfied in the transformation result. Through minimal rewriting, the revised process takes into account the original transformation goals and is traced for further processing, thus guaranteeing *transparency*.

Starting from these considerations, in our recent work [2], we designed an approach for minimally rewriting slicing and merge operations with the aim of satisfying specific *coverage constraints* [4, 6], guaranteeing that there are enough entries related to specific protected groups of interest in the result obtained by applying a given transformation, thus increasing diversity with the aim of limiting the introduction of bias during the next analytical steps. The problem we address is closely related to [3], where a constraint-based optimization approach is proposed for identifying a filter-based transformation generating a dataset satisfying a given input set of soft constraints. However, differently from [3], we consider the rewriting of transformations corresponding to SPJ queries with the aim of satisfying (hard) coverage constraints through a rewriting approach that can be easily integrated inside a pre-processing pipeline.

The aim of this demonstration is to showcase the techniques proposed in our recent work [2] by presenting covRew, a Python toolkit for rewriting data transformations specified inside pipelines described in Pandas [7], ensuring the satisfaction of a set of coverage constraints provided in input. The toolkit includes: (i) a *pipeline analyzer*, which identifies candidate operations for rewriting, (ii) a *pipeline rewriter*, which transforms operations that are selected by the user according to the input coverage constraints, and (iii) an *impact evaluator*, assessing the impact of the rewriting of the selected operations by comparing the result of the execution of the rewritten pipeline with that of the original one, according to the solution-based accuracy measures proposed in [1]. We showcase our toolkit in action with various scenarios on real-world datasets, demonstrating its usability in coverage constraint enforcing and the provided support for analyzing the impact of coverage-based rewriting. Notice that, though the approach supports merge operations and works on multiple datasets, in the demonstration, for the sake of simplicity, we will rely on a single dataset and will not consider merge operations. This way, indeed, the analysis of the impact of the proposed rewriting on the obtained results is clearer.

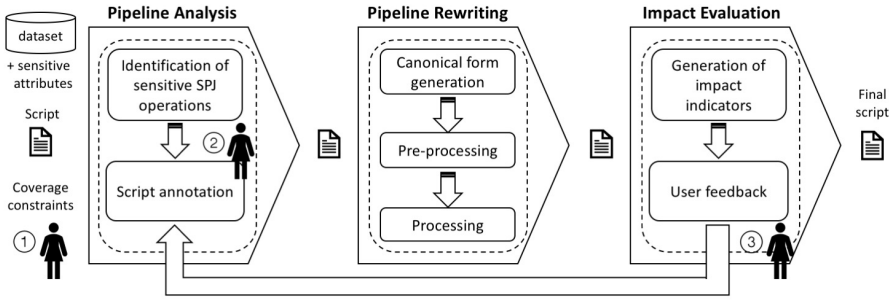

Figure 1: covRew flow

The remainder of the paper is structured as follows. In Section 2, we present the covRew architecture, illustrating the techniques underlying each step. In Section 3, we present the demonstration scenarios, with a special reference to the user interaction. Section 4 concludes and outlines some future work directions.

2 OVERVIEW

covRew is a Python toolkit focusing on the rewriting of data preprocessing pipelines, with the aim of satisfying specific coverage constraints on the results of slicing operations. In the following, we describe the characteristics of input data, processing pipelines, and the main covRew tasks. The covRew logical architecture is illustrated in Figure 1.

2.1 Input specification

Input data for covRew are: a dataset, with the related sensitive attribute specification, for the identification of protected groups; a processing pipeline represented as a Pandas script; a set of coverage constraints.

Dataset. covRew takes as input a tabular dataset I, represented as a Pandas Data Frame. We assume that some discrete valued attributes $S_1, ..., S_n$ of the input dataset are of particular concern since they allow the identification of protected groups and we call them *sensitive attributes*. Examples of sensitive attributes are the `gender` (with values in $\{female, male\}$) and the `race` (with values in, e.g., $\{asian, black, hispanic, white\}$).

Pipelines. covRew focuses on pre-processing pipelines represented in Pandas and in particular on Pandas data preparation tasks corresponding to *data slicing* operations.[1] The slicing operations we are interested in correspond to monotonic Select-Project (SP) queries over input tabular data that might alter the representation (i.e., the coverage) of specific groups of interests, defined in terms of sensitive attribute values. To this aim, we focus on SP queries that return, among the others, at least one sensitive attribute (called *sensitive SP operations or queries*). The sensitive attributes returned by an SP query Q are called *reference sensitive attributes* for Q. We further assume the user is satisfied by the specified transformations and she does not want to lose the obtained results through rewriting.

In the following, when needed, we denote Q by $Q\langle v_1, ..., v_d\rangle$ or $Q\langle\overline{v}\rangle$, $\overline{v} \equiv (v_1, ..., v_d)$, where $v_1, ..., v_d$ are the constant values appearing in the selection conditions contained in Q that, for the sake of simplicity, we assume to be numeric.[2]

Coverage constraints. Conditions over the number of entries belonging to a given protected group of interest returned as result by the execution of SP queries can be specified in terms of *coverage constraints* [4, 6]. Given an SP query Q with reference sensitive attributes $S_1, ..., S_n$, given a value s_i belonging to the domain of S_i, $i \in \{1, ..., n\}$, a coverage constraint with respect to S_i and s_i is denoted by $|Q \downarrow_{s_i}^{S_i}| \geq k_i$ and it is satisfied by Q over the input dataset I when $|\sigma_{S_i=s_i}(Q(I))| \geq k_i$ holds.

2.2 Pipeline analysis

In the first step, given the dataset, the list of sensitive attributes, the Pandas script, and the coverage constraints, covRew analyzes the script for identifying the sensitive SP queries and pre-annotates the script by highlighting them.

The user can then select, among the sensitive SP queries, those that, from her point of view, should be used for guaranteeing input coverage constraint satisfaction and, if needed for experimental purposes and for increasing system flexibility, she can change input coverage constraints. The output of this phase is a script annotated with information about the operations to be rewritten and related coverage constraints, if changed. By selecting different selective SP operations, during different covRew executions, the user can examine the impact of different coverage-based rewritings on the generation of the final result.

As an example, Figure 2 shows a Pandas script to be run on the US *Adult* Census database[3] containing information about 48,842 individuals from the 1994 U.S. census, taking `sex` as sensitive attribute and $|Q \downarrow_{female}^{sex}| \geq 100$ as coverage constraint, thus requesting that at least 100 females are returned by the selected SP operations. The pipeline analysis returns lines 7 and 17 as sensitive SP operations and the user can select one or both lines for the rewriting. In the following, we suppose line 17 is selected.

2.3 Pipeline rewriting

In the second step, covRew rewrites each selected sensitive SP query Q into another query Q', according to what presented in [2], so that Q' is the minimal query relaxing Q guaranteeing coverage constraint satisfaction when evaluated over the input dataset. More precisely, according to what stated in Section 2.1: (i) $Q' \equiv Q\langle\overline{u}\rangle$, thus it is obtained from Q without changing the original transformation goal; (ii) $Q \subseteq Q'$, thus the result of the original transformation is kept by the rewriting;[4] (iii) all coverage

[1] https://pandas.pydata.org/pandas-docs/stable/getting_started/intro_tutorials/03_subset_data.html

[2] We remark that the proposed approach can however be easily extended to deal with any other ordered domain.

[3] https://archive.ics.uci.edu/ml/datasets/census+income

[4] We remark that covRew can be easily extended by relaxing assumption (ii), in case query relaxation is not mandatory.

```
1  data = pd.read_csv('DEMO/dataset/adult.csv')
2
3  # projection
4  data  =  data[['capital_gain','age','education_num','sex',
   'capital_loss','hours_per_week','marital_status','label']]
5
6  # filtering
7  data = data.loc[(data['hours_per_week'] <= 70) &
   (data['capital_gain'] > 200)]
8
9  # OneHotEncoder considering marital_status
10 data = pd.concat([data[['age','education_num',
   'sex','capital_gain','capital_loss','hours_per_week'
   'label']],pd.get_dummies(data['marital_status'])], axis=1)
11
12 new_columns = list(data.columns)
13 new_columns.remove('label')
14 new_columns.remove('sex')
15
16 # filtering
17 data = data.loc[(data['education_num'] >= 15) &
   (data['hours_per_week'] > 40)]
18
19 # model
20 model = SVC()
21 model.fit(data[new_columns], data['label'])
```

Figure 2: Pandas script over the *Adult* dataset

constraints associated with Q are satisfied by $Q'(I)$. The coverage-based rewriting should be *optimal*, i.e.: (iv) there is no other query Q'' satisfying conditions (i), (ii), and (iii) such that $Q''(I) \subset Q'(I)$ (thus, Q' is the minimal query satisfying (i), (ii), and (iii)); (v) $Q' \equiv Q\langle\overline{u}\rangle$ is the closest query to $Q\langle\overline{v}\rangle$ according to the Euclidean distance between $\overline{v}$ and $\overline{u}$, satisfying (i), (ii), (iii), and (iv), in a normalized space in which the values for each dataset attribute are between 0 and 1, potentially increasing user satisfaction.

In order to compute the optimal coverage-based rewriting of an SP query $Q\langle\overline{v}\rangle$, given a set of coverage constraints CC and an instance I, we follow the approach presented in [2].

Canonical form generation. We first translate the selected SP queries into a *canonical form*, in which each selection condition containing operators ($>$, $\geq$, $=$) is translated into one or more equivalent conditions defined in terms of operator $<$. For example, any predicate of the form $A_i > v_i$ can be transformed into the predicate $-A_i < -v_i$. An optimal coverage-based rewriting of a canonical query is obtained from the original one by replacing one or more selection predicates $sel_i \equiv A_i < v_i$ with a *relaxed* predicate $sel'_i \equiv A_i < v'_i$ with $v'_i \geq v_i$. Relaxed queries generated through coverage-based rewriting starting from $Q\langle\overline{v}\rangle$, I, and CC have the form $Q\langle\overline{u}\rangle$, with $\overline{u} \geq \overline{v}$, and can be represented as points $\overline{u}$ in the d-dimensional space defined over the selection attributes, thus satisfying conditions (i) and (ii) of the reference problem.

Pre-processing. During the *pre-processing step*, we organize the reference space for the detection of a coverage-based rewriting of $Q\langle\overline{v}\rangle$ as a multi-dimensional grid. The grid has d axes, one for each selection attribute in $Q\langle\overline{v}\rangle$, and each axis is discretized into a fixed set of bins, by using the equi-depth binning approach, typical of histogram generation. Each cell in the resulting grid corresponds to a sensitive SP query containing $Q\langle\overline{v}\rangle$, in line with condition (ii) of the reference problem. The grid represents the search space for identifying the optimal coverage-based rewriting. The approach is *approximate* because a smaller coverage-based rewriting of the input query might exist but, if lying inside one grid cell, it cannot be discovered by the algorithm. Notice that the grid is computed starting from I and Q (CC is not used).

Processing. During the *processing step*, the multi-dimensional grid is visited starting from the cell corresponding to the input query, one cell after the other, at increasing distance from Q. For each cell ($\overline{u}$), we check whether the associated query $Q\langle\overline{u}\rangle$ is a coverage-based rewriting of $Q\langle\overline{v}\rangle$ by estimating the cardinality of $|Q(I)|$ and one cardinality for each coverage constraint. The properties of the grid and of the canonical form are considered for pruning cells that cannot contain the solution and for further improving the efficiency and the scalability of the process [2].

The processing step requires fast and accurate cardinality estimates. To make the processing more efficient and scalable, similarly to [8], we rely on estimators based on (uniform, independent, and without replacement) samples of the input dataset, dynamically constructed during the rewriting phase. covRew then allows the user to select two different rewriting modalities: *fast*, but potentially inaccurate, execution due to the usage of sample-based approaches for cardinality estimation (as a consequence, some constraints might not be satisfied when evaluated over the real dataset); *accurate*, but potentially slower execution, by detecting cardinalities in a precise way through query execution over the real dataset.

As a result of the pipeline rewriting step, covRew generates a rewritten script whose impact is evaluated in the final phase. In our example, line 17 of the original script is rewritten into: `data = data.loc[(data['education_num'] >= 14) & data['hours_per_week'] > 37)]`.

2.4 Impact evaluation

In the last phase, for each rewritten sensitive SP query, covRew shows many statistics useful for evaluating the impact of rewriting. In case the user is not satisfied by the rewriting, she can discard the changes and go back to the pipeline analysis pane, for changing her selections. More precisely, for each rewritten query, covRew returns (see Figure 3):

- the result of the rewriting of each original selection condition (in the example `data['education_num'] >= 14` and `data['hours_per_week'] > 37`), with information about the data distribution related to the selected attributes, before and after the rewriting;
- the maximum and the minimum approximation error due to the pre-processing, defined as the maximum and the minimum diagonal length of grid cells, normalized between 0 and 1, and the approximation error of the detected solution, corresponding to the grid-based accuracy proposed in [1] (0.04, 0.28, and 0.07 in Figure 3);
- the percentage of additional tuples returned, due to the rewriting, corresponding to the relaxation degree proposed in [1, 2] (66% in Figure 3);
- the Euclidean distance, in the normalized space, between the rewritten solution and the original one, corresponding to the proximity measure proposed in [1] (0.08 in Figure 3);
- the absolute and percentage distribution of protected groups in the result of the original query and of the rewritten one, (121 wrt to 22, 19.3 wrt 10.5 in Figure 3);
- information about the satisfaction of the coverage constraints on the result of the original query when evaluated on the input dataset (satisfied, in Figure 3).

The impact evaluation pane gives the user the opportunity to revise the annotation, if the accuracy is not satisfactory, and select the accurate execution if, due to the estimation error of the fast approach, some coverage constraints are not satisfied by the result of the rewritten queries over the input dataset. After this revision, the final script is returned to the user.

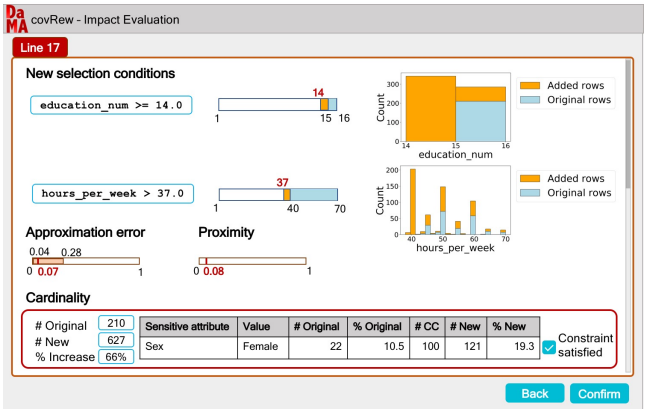

Figure 3: Impact evaluation pane

3 DEMONSTRATION SCENARIOS

In the demonstration of covRew we pursue three goals: (i) to ascertain the feasibility of rewriting slicing operators to ensure adequate protected group representation by means of coverage constraints; (ii) to explore the effects of such rewriting with respect to protected group membership on result accuracy; (iii) to compare executions of alternative rewritten pipelines sharing the same goal in terms of coverage, but using different rewriting approaches (efficiency vs accuracy). In the following, we discuss the foreseen user interactions and how these interactions realize the most relevant scenarios for our demonstration goals.

Datasets and sensitive attributes. As first operation, the user can select one dataset to work on ((1) in Figure 1). Two datasets are available: the already mentioned US *Adult* Census database. and the *Diabetes US*[5] dataset representing 10 years (1999-2008) of clinical care at 130 US hospitals and integrated delivery networks (100,000 instances). For each dataset, a short description of the dataset and the list of attributes is shown. The user is asked to select the sensitive attributes from this list for the task at hand and to define coverage constraints over them ((1) in Figure 1). For example pipelines, we select the `sex`/`gender` and `race` attributes for both datasets.

Input scripts. For each dataset, three different scripts are already available and will be proposed as a starting point. The user is allowed to freely modify the code as well as to enter her own code ((1) in Figure 1). A sample script is shown in Figure 2 and has been discussed in Section 2. The other scripts allow us to demonstrate different combinations of projection and filtering operations, with multiple conditions on different attributes, allowing to obtain a different ratio among different groups for sensitive attributes.

Script annotation and impact evaluation. In addition to selecting the input dataset and sensitive attributes, among those available, the user interacts with the toolkit in the pipeline analysis phase ((2) in Figure 1), when she can select the operations to rewrite, choose for each of them the execution type (fast rather than accurate) and, if needed, modify the input coverage constraints. The user can also provide a feedback after impact evaluation ((3) in Figure 1) when, by looking at the statistics about execution, she might want to reconsider some of the choices made in script annotation with reference to one or more slicing operations, thus producing a new annotated script.

[5]https://archive.ics.uci.edu/ml/datasets/Diabetes+130-US+hospitals+for+years+1999-2008

In the online demonstration, active user involvement for several simultaneous demonstration attendees will be fostered by using clickers/instant polling tools to select the input to provide to the system in the various steps.

Realized scenarios. The demonstration will be conducted in such a way to show, with reference to cases in which one or more operations are rewritten and one ore more coverage constraints are specified, different possible scenarios of interest, namely:

- the coverage constraints are satisfied and the user is fine with the rewriting;
- the coverage constraints are not satisfied on the input dataset and the user changes the type from fast to accurate;
- the user is not satisfied by the results, either because she deems the pre-processing approximation too high or because the rewriting has a too high impact on result accuracy, and decides to revise the choices she made, going back to the pipeline analysis pane.

In addition to the prefigured scenarios, the user will be given the opportunity to suggest modifications to the pipelines and even to submit her own script, on one of the reference datasets.

4 CONCLUSIONS

We have presented covRew, a user-friendly Python system for rewriting sensitive slicing operations that can lead to the violation of coverage constraints with respect to the protected groups of interests. In the demonstration, we illustrated the main covRew functionalities over predefined and user-specified pipelines. As future work, we plan to extend covRew with functionalities for automatically identifying sensitive operations to be rewritten with the highest accuracy. Further extensions concern the relaxation of the containment property between the original query and the rewritten one, a comparison of covRew with the approach proposed in [3], the integration with different types of fairness constraints, a graph-based representation of input scripts, similarly to [11], for simplifying pipeline analysis.

ABSTRACT

The large volume of currently available data creates several opportunities for sciences and industry, especially with the application of data analytics. But also raises challenges that make unfeasible the use of batch-based ETL processes. Indeed, near real-time data analytics is a requirement in several domains as an alternative to traditional data warehouses. In the last years, big data platforms have been developed to enable query execution over distributed data sources. However, they do not deal with subject-oriented analysis, do not provide data distribution transparency, or do not assist with schema mapping and integration.

In this demonstration, we present EasyBDI. It's a near real-time big data analytics prototype that enables users to run queries over heterogeneous data sources based on global logical abstractions created by the system and provides some usual concepts of data warehouse systems, like facts and dimensions. We use two motivating scenarios, one based on three years of real data on photovoltaic energy production and consumption, and the other based on the SSB+ benchmark. We will also present implementation challenges, issues, solutions, and insights.

KEYWORDS

Distribution transparency, data analytics, near real-time data warehousing

1 INTRODUCTION

For several years, data analytics has been based on large data warehouses. Such warehouses are mostly centralized databases whose data is periodically extracted from OLTP databases and load into the warehouse as part of an ETL (extract, transform, and load) process [10]. This traditional warehouse structure is not suitable for most of the current big data analytics environments. On the other hand, near real-time operations have become a requirement in several current IT contexts, like in IoT, where several sensors generate data streams and users need to process and analyze the most recent data [10].

This demonstration presents EasyBDI (*Easy Big Data Integration*), a prototype for logical integration of distributed and heterogeneous data sources (including NoSQL ones, like MongoDB, Kafka, and Redis) into a global database and global star schemas. The integration is logical, i.e., there is no materialized global database, and data source autonomy is maintained. Analytical queries specified over global star schemas are transformed and executed by the distributed and heterogeneous sources.

Building a global schema requires finding and matching syntactic and semantic similarities between the data structures of distinct local sources. This can be achieved either by looking at the structural organization of data (i.e., schema-based matching) or to the contents and meaning of data (i.e., instance-based matching) [7]. Also, each local element should be mapped into a global element. For instance, local structures identified as semantically identical in the schema matching process should be mapped into a single global entity. Partitioning of (logical) global structures across distinct databases should also be handled [6]. Creating a global schema over distributed databases is challenging, particularly in the context of NoSQL and heterogeneous databases. EasyBDI gets the data organization on participating sources and uses a combination of techniques to automatically propose a global schema, which can be fine-tuned by the users.

EasyBDI runs over a distributed query execution engine (Trino, formerly PrestoSQL [4, 8]) and adds some levels of abstraction, namely data location and fragmentation transparency, and specialized subject-oriented analysis. The system uses schema matching and integration techniques to automatically design a global model and allows users to build subject-oriented cubes over such model. Non-expert users may use drag-and-drop to submit analytical queries over global cubes, but advanced features (e.g. based on SQL language) are also available for experts.

Big data frameworks and polystore systems (e.g. Apache Drill [5], Presto [8], BigDAWG [3]) provide a unified query language that can be used to access distributed data. But big data frameworks commonly lack providing distribution transparency, while polystores are tightly integrated, managing all sources together, including in terms of data location and data replication [9]. Our system maintains source autonomy, uses a global schema to provide distribution transparency (location, replication, and fragmentation), is extensible, and supports a wide range of data sources.

In the demonstration, two scenarios will be made available for participants. The first one is based on more than 3 years of real data on photovoltaic panel production/consumption in Sydney, Australia, and nearby areas. The second uses the SSB+ benchmark [2], which contains persistent and streaming data on retail store's sales, deliveries and popularity in social media.

Participants will understand how EasyBDI deals with some key challenges, like how to (i) explore the local data models to identify entities of the global model that are partitioned across multiple data sources, (ii) implement the automatic schema matching, mapping, and integration procedures to support the users in designing global models for a large number objects and data sources, and (iii) execute queries on a high-level star schema model abstracting several distributed, heterogeneous and autonomous data sources. They will also see the global SQL queries generated by EasyBDI and their translation into queries to the local sources. Implementation challenges and issues, adopted solutions and insights will be discussed, making this demonstration helpful to researchers and practitioners.

2 EASYBDI PROTOTYPE

EasyBDI is a framework for near real-time analytics that provides logical integration of multiple data sources while also enabling the creation of star schemas over global (logical) entities. Local databases are assumed to be autonomous (operate independently) and heterogeneous (in terms of data models and query languages, e.g., relational, graph and document databases, or semi-structured and unstructured data sources).

Data sources are accessible through a distributed query engine (Trino). The role of EasyBDI is to add additional levels of transparency, namely, location and fragmentation transparency, to allow building global schemas providing unified and high-level representations of the data sources, and to enable the execution of analytical queries by subject-experts. The architecture and the main components of EasyBDI are depicted in Figure 1.

API communication handler This component handles the interaction with the external systems: Trino and SQLite.

The *Distributed Query Execution Engine Interface* uses Java and JDBC, and implements all the logic regarding the integration of EasyBDI with Trino. Even though Trino provides a single representation of the underlying data, queries to Trino must contain the data source identifier for each data fragment. Thus, this component must also convert the queries specified using a global schema (see Database Integration below) into queries supported by Trino. This requires adding data source identifiers, as well as union and join operators, according to the mapping used between the global and local schemas.

The *Schema Metadata Storage* is responsible for the storage and management of the metadata of all schemas: local schema view, global schema, and star schema. Currently, these (meta)data are stored in an SQLite database.

Configuration Manager This component is responsible for generating the configuration files that allow Trino to communicate with the data sources (e.g., data source type, data source URL, username, password, and other parameters that depend on the data source type). It also creates local schema views. The procedure consists of iterating each data source and retrieving (meta)data about their schemas, namely, tables and columns information (or the equivalent concepts depending on the data source), using Trino commands. These (meta)data are stored in an SQLite database through the *Metadata Storage Interface*.

Database integration This layer deals with the creation of the global schema. A global schema contains a set of global tables, each containing a mapping to logically related data fragments. The integration is logical, i.e., the global schema is entirely virtual and not materialized. The main tasks to build a global schema are *schema matching*, *schema integration* and *schema mapping*.

The *schema matching* defines a mapping of concepts in a schema with concepts in another schema. EasyBDI uses a schema-based method with linguistic and constraint-based criteria [6]. The algorithm starts by finding tables with similar names using the Levenshtein distance. For each pair of matching tables, EasyBDI does columns matching using the Levenshtein distance to compare names and a similarity measure to compare data types.

The *schema integration* defines the global tables and their columns, using the correspondences found in the schema matching. EasyBDI uses the stepwise binary integration method [6].

The *schema mapping* defines how to combine data from one or more local data sources (data fragments) into a single global table while keeping consistency and semantic coherence. EasyBDI

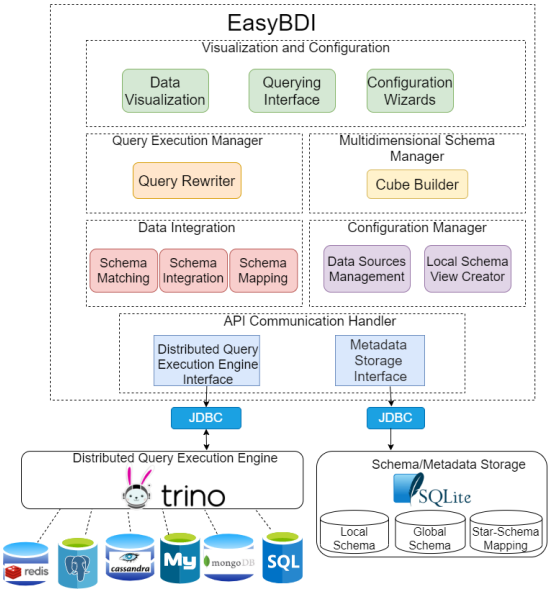

Figure 1: Main Components of EasyBDI architecture

analyzes the matching between global and local entities, and identifies the type of partitioning (horizontal, vertical, or none) used. If a global table corresponds to only one local entity, then there is no partitioning. If a global table has a correspondence with several local tables, and the number of matching columns and their data types in all tables are the same, then the local tables are considered horizontally partitioned. The current implementation of EasyBDI uses foreign key-primary key relationships to find whether two or more tables are vertically partitioned, but this is only feasible when it is possible to get constraint information from the catalog of the data sources.

The methods presented above are automatic and may lead to incomplete or semantically incorrect results. Thus, EasyBDI allows users to review and edit the global schema generated automatically (e.g., removing replicated data sources) using an intuitive GUI interface.

Multidimensional Schema Manager This component allows the design of data cubes (star schemas) and the use of abstractions like facts and dimensions to perform analytical queries so that users focus on data analysis rather than technical details regarding data organization. Data cubes are built over the global schema,i.e., fact and dimensions tables are based on global entities. A start query is basically a join between a fact table and some dimensions, possibly with filters and aggregations.

Query Execution Manager This component rewrites the queries on the global schema into the queries submitted to Trino to get data from the local data sources. It handles vertical and horizontal data partitioning. Queries on global tables are automatically translated into queries on local tables using union and join operations of data fragments. The framework can handle multiple aggregations and joins at the same time. The queries that merge partitioned data are written as nested queries. An outer query contains the operators specified by the user (e.g., filters and aggregations) and other implicit joins needed between the facts table and dimensions. It is also possible to deal with complex operations such as pivoting and unpivoting data.

Figure 2 exemplifies the query submission process, which starts with a user interacting with the interface and issuing a

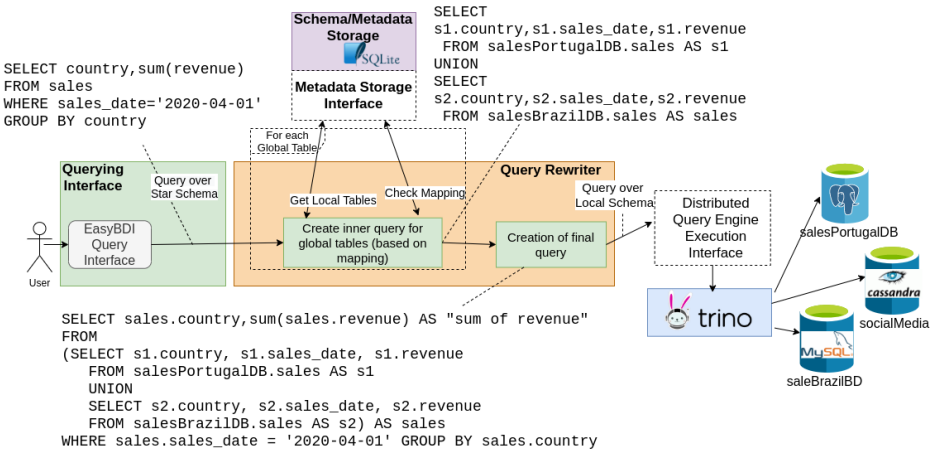

Figure 2: Query transformation - from an initial query over global schema to a query over local schemas

query over the star schema. Then the system generates an SQL query based on the global schema, which is translated into a query on the local schema and submitted to Trino. Notice that users do not need to know any query language: EasyBDI provides an intuitive interface and analytical queries are specified using drag-and-drop. Finally, Trino prepares and sends the queries that must be executed by the local data sources. Thus, users can create queries using global names and cubes and do not need to know about the format, organization and distribution of the data, nor a query language.

The *Query Execution Manager* also transforms the results provided by Trino according to the global schema and sends them to the visualization layer.

Visualization and Configuration This layer comprises several tools related to querying and configuration, including wizards to provide guided operations to users, like the cube builder, query builder, global schema editor, and data source configuration.

3 DEMONSTRATION

This demonstration has two case studies to highlight different features of EasyBDI. It will cover the selection of data sources, automatic generation of a global schema, creation of a star schema and execution of drag-and-drop (and user-edited) analytic queries.

Case study 1 uses data on energy production and consumption of 300 homes equipped with photovoltaic panels in Sydney over the span of 3 years. The data are available in three CSV files. The lines represent the customers, generator capacity, dates and type of consumption or production (GC, CL, and GG), and the columns represent the values recorded every 30 minutes (Figure 3). This case is interesting because the organization of the data is far from a typical data organization in relational databases.

We consider that the data on the customers' location (postal codes related data) are in a PostgreSQL database and the temporal data are in a MySQL database, just for experimentation purposes.

Customer	Generator Capacity	Postcode	Consumption Category	date	00:30	01:00	01:30	...	23:30	00:00
1	3.78	2076	GC	01/jul/10	0.303	0.471	0.083	...	0.078	0.125
1	3.78	2076	CL	01/jul/10	1.25	1,244	1.256	...	0	1.075
1	3.78	2076	GG	01/jul/10	0	0	0	...	0	0
1	3.78	2076	GC	02/jul/10	0.116	0.346	0.122	...	0.12	0.111

Figure 3: Sample of a CSV file with photovoltaic data

After the automatic generation of the global schema, we will manually edit it to show some advanced features. In particular, we will show how to use virtual tables and user-defined commands to unpivot the data in the CSV files, how to specify constraints and change the data types of global schema columns, and how to create a mapping between the global schema and the data sources using virtual tables (Figure 4).

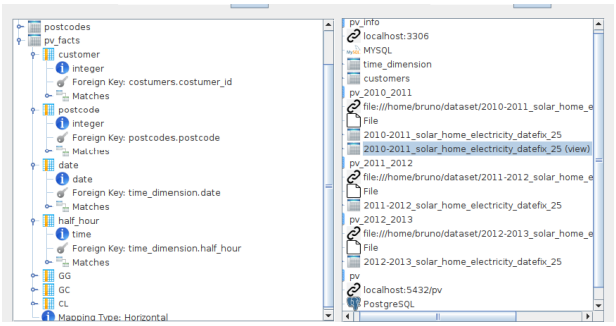

Figure 4: Global schema (left panel) and local schema views (right panel) for the photovoltaic datasets

Then, a star schema will be created with a fact table (pv_facts), three measures (GC, CL and GG) and three dimensions (customer_dim, time_dim and postalcodes_dim). We will show how to run queries on the global schema using only drag-and-drop how to edit the commands manually (Figure 5). We will also illustrate the transformation of queries on a global schema (Listing 1) into queries on the local schema views that must be executed by Trino (Listing 2). The "<user query>" in Listing 2 denotes the query used to transform the data structure depicted in Figure 3 into a virtual table and is omitted because of its size.

Listing 1: Code generated for the global query depicted in Figure 5 (top) (datatype casting operators were removed).

```
SELECT    c.customer_id, t.year,
          SUM(pv.GG) AS "SUM_of_GG"
FROM      customers c, time_dimension t, pv
WHERE     ( t.half_hour = pv.half_hour
AND         c.customer_id = pv.customer
AND         t.date = pv.date )
GROUP BY ( t.year, c.customer_id)
```

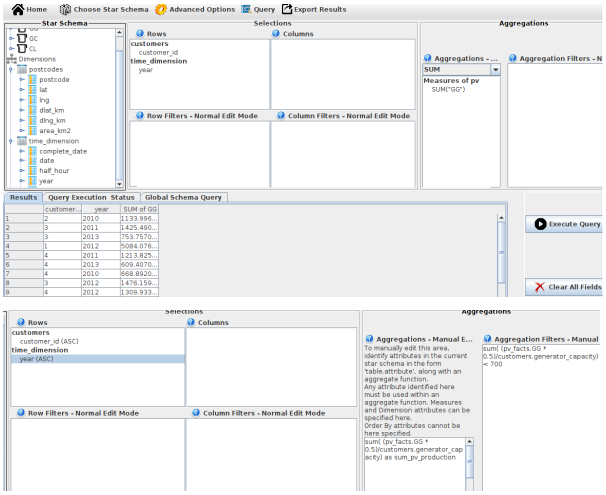

Figure 5: A global query made with drag-and-drop (top) and a global query edited manually (bottom)

Listing 2: Translation of the code in Listing 1 into a query over the local schema views (the name of the data source "mysql_localhost_3306_time" is abbreviated to "mysql").

```
SELECT customers.customer_id, time_dimension.year,
       SUM(GG) AS "SUM_of_GG"
FROM
  (SELECT mysql.pv_schema.customers.customer_id
   FROM mysql.pv_schema.customers) AS customers,
  (SELECT mysql.pv_schema.time_dimension.half_hour,
   mysql.pv_schema.time_dimension.year,
   mysql.pv_schema.time_dimension.date
   FROM mysql.pv_schema.time_dimension) AS
   time_dimension,
SELECT customer, date, half_hour, GG FROM
   (<user query> UNION <user query>
   UNION <user query>) AS pv
WHERE (time_dimension.half_hour = pv.half_hour
   AND customers.customer_id = pv.customer
   AND time_dimension.dated = pv.date)
GROUP BY(time_dimension.year, customers.customer_id)
```

Case study 2 uses the SBB+ benchmark [2] and represents a more conventional scenario in a big data environment. The SSB+ data model has two star schemas, one for batch Online Analytical Processing (OLAP) and the other for streaming OLAP. The batch OLAP is an adaptation of the schema proposed in TPC-H. The streaming OLAP is based on social media data and represents the popularity of retail stores (and their sales and deliveries).The data for OLAP batch storage are stored in Hive, while the facts data for streaming OLAP are stored in Cassandra (a NoSQL database that uses a wide-column store model), and conceptual relationships exist between data stored in both systems, as represented in Figure 6. We use the code available in [1] to populate the data sources.

In this case, EasyBDI's automatic matching, integration and mapping was mostly correct. Only a few manual edits are needed and no user-defined commands are necessary. We also show how to create the star schemas for batch OLAP and streaming OLAP and how to execute queries. SSB+ has a listing of analytical queries that we used to test the functionality of EasyBDI and we also use some of these queries in this demonstration. Regarding EasyBDI's performance, the overhead associated with query

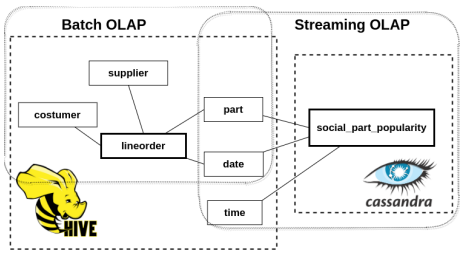

Figure 6: Case study 2: batch and streaming OLAP – overview of local schemas

generation is small (≈ 1% of query execution time). Query execution time depends mostly on query complexity, data sources' efficiency, and on the resources available for Trino.

4 SUMMARY

In this work, we present EasyBDI, a framework for near real-time data analytics that uses logical data integration to provide a high-level abstraction of data distribution and heterogeneity, while keeping the autonomy of the data sources. Automatic schema matching and configuration wizards are used to support the addition of new data sources. Multidimensional data organization is used to enable query analytics by subject-experts. We present two scenarios, one based on real data and the other on the use of a benchmark that simulates sales data and social media data. We also present several implementation issues, discussing adopted solutions that may be helpful to researchers and practitioners. EasyBDI is publicly available on Github *https://github.com/bsilva3/EasyBDI*.

Very Short Primer on Blockchain Technology for Database Researchers

Zsolt István
IT University of Copenhagen, Denmark
zsis@itu.dk

ABSTRACT

Blockchain is an emerging technology, considered increasingly often beyond the cryptocurrency world for business-to-business use-cases. In contrast to public blockchains such as Bitcoin, that are open systems in which anyone can participate, in business-to-business scenarios the membership of the service is controlled (permissioned blockchain). This permits the use of Byzantine fault tolerant (BFT) consensus protocols at the core of the service to establish a total order of transactions, instead of the more expensive Proof-of-Work-based consensus protocols. Permissioned blockchains typically set out to solve problems in the space where databases have traditionally resided, with the main difference being that the former decentralizes trust. There are numerous research proposals in the intersection of databases and blockchains. Sadly, there are still many misconceptions about this technology which leads to confusion in the community. The main goal of this primer is to give an overview of the relevant topics and provide pointers for further reading.

1 BLOCKCHAIN BASICS

Blockchains have entered the "spotlight" after the seminal Bitcoin paper published by Nakamoto [11] more than a decade ago. Even though many think of Blockchains as being part of the data management field, the Nakamoto paper was addressing a financial issue: its goal was to provide a decentralized currency that does not require trust in a central authority for its functioning. It has been only later that discussions emerged about "transaction processing", that is, smart contracts on top of blockchains, perhaps most notably, in the Ethereum White Paper [4].

In the years since their proposal, Blockchains have lived through a hype and this resulted in a dizzying number of different systems. At their core, however, all blockchains are quite similar. They aim to *decentralize trust* and are composed of two parts: *1) a verifiable data structure* that allows participants to determine whether the data in the blockchain has been tampered with and *2) a consensus algorithm* that defines how participants can add new data to the data structure. The choice for data structure is typically an append-only log with cryptographic hashes linking entries (i.e., blocks, see Figure 1). Nonetheless, there are also blockchains, such as IOTA, that order data into a directed acyclic graph (DAG) [10] instead. Put in database terms, we can think of the former as establishing global total order on all transactions and keeping a single logical shard of the data, and the latter as data sharding with total order within a shard and infrequent cross-shard transactions.

The choice of the consensus algorithm is determined by the assumptions the blockchain makes on the trustworthiness of third parties and the participation model. We can split blockchains into two categories based on who is allowed to participate in the consensus algorithm and, as a result, add data to the data structure: First, *permissionless blockchains* where anyone is allowed to participate and, second, *permissioned blockchains* where only selected entities can participate (this also assumes that the nodes in the system have verifiable identities, which is not the case in permissionless blockchains).

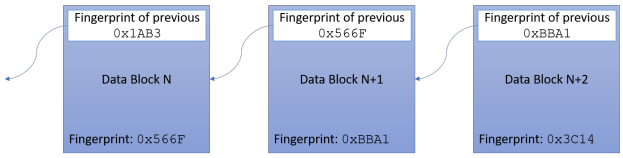

Figure 1: At the core of all blockchains is a verifiable data structure, typically in the form of an append-only log. Cryptographic hashes (fingerprints) included in blocks recursively tie them to the previous blocks.

Permissionless blockchains are, by definition, *public*, since anyone can access the data structure and read all previous transactions. Permissioned blockchains can be either *private*, in which case the governing consortium or members of the blockchain restrict access based on internal rules (e.g., business partners in specific areas), or they can be *public*, in which case anyone fulfilling some non-restrictive condition can join (e.g., Alastria[1] implements a country-wide blockchain network that relies on national tax register numbers as a pre-condition to joining). It is important to note that, while permissionless blockchains are typically used for dealing with fully virtual assets, permissioned blockchains are more similar to databases, in that the data they store typically represents real-world assets and events.

What is there for database researchers to explore? In the permissionless blockchain space most current and future challenges are related to scalability of the network, to economic incentives, as well as, to consensus algorithms with better guarantees for tolerating malicious actors. In terms of data management and transaction processing, there is no clear need for inventing new approaches because these systems can benefit from already existing best practices. In contrast, permissioned blockchains are considered for use-cases which are much closer to the database community, such as supply-chain management, banking or notaries, and therefore face challenges closer in nature to the database community. As we will discuss in the last section, there is significant overlap in database and blockchain research, with many database ideas/techniques being well applicable in the blockchain space. The fundamental difference, however, between permissioned blockchains and traditional distributed databases is the decentralization of trust in the former, that is, the assumption that not all nodes belong to the same enterprise and the ability to function even if not all members of a consortium are trusting each other. From a database research perspective, hence, most

[1] https://alastria.io/en/

of the interesting future work is in understanding how the performance of transaction processing (and perhaps analytics) can be increased while benefiting from the trust decentralization of blockchains. Additionally, the standardization of smart contracts and data models, as well as their integration with traditional databases is an open challenge.

2 PERMISSIONLESS BLOCKCHAINS

In permissionless blockchains there are no node identities and, as a result, a consensus mechanism is required that cannot be subverted by creating a large number of "fake" nodes to achieve majority in the system (Sybill attack). Therefore, Bitcoin and many other cryptocurrencies use *Proof of Work* (PoW) consensus, that requires participants to the consensus to solve a cryptographic puzzle before they can add to the log. The puzzle consists of finding a hash value that fulfills a specific condition, for instance, a number of leading zeros. The input to the hashing is the block that the participant would like to record on the blockchain. Inside the block are 1) transactions collected from clients of the system and other participants, 2) the cryptographic hash (signature) of the previous block in the blockchain and 3) a field holding a random number. The randomness is added to the block before being hashed, and unless the resulting hash fulfills the condition, the last step is repeated (this is the process of *mining*). Finally, when a miner discovers a combination for which the condition holds, it appends it to the blockchain by broadcasting it to all other participants. These can *validate* whether the added block is legitimate simply by computing its cryptographic hash and checking whether this hash fulfills the condition[2]. Hence, even though mining is very expensive, clearly limiting the throughput of the system, validation itself is cheap. In exchange for "finding" the next block of the blockchain, the miner will receive a payment in the underlying cryptocurrency, typically deducted as fees from the transactions in the just-appended block.

While PoW consensus has benefits in that it limits participants' power in the blockchain to their relative compute power (which is much more costly to increase than creating new IP addresses for instance), it has also many drawbacks. Apart from the obvious energy efficiency concerns resulting from the repeated hashing computations and the issue that all miners are fundamentally competing with each other for the next block, it has an important implication on *transaction finality*. In systems relying on PoW, competing miners could create forks in the log, working towards two "alternate realities". In practice, blocks are considered committed once enough additional blocks (e.g., 5) have been added after them. The expectation is that, at that point, the economic incentives are driving all participants to continue building on the longest subchain of the system. Nonetheless, transactions never reach *finality* because there is a small probability that any block, no matter how old, could have been forked and it does not, in fact, lie on the longest subchain.

It has to be noted that the common practice of composing *blocks* from a large number of transactions is rooted in the space of PoW blockchains in an effort to amortize the exuberant cost of mining, as well as, to simplify global broadcasts. Overall, the idea of a blockchain and its underlying mechanisms could just as well work for appending single transactions into a tamper-proof log, albeit, with much less efficiency for PoW consensus-based blockchains, such as Bitcoin.

To overcome the fundamental efficiency issues of PoW, other forms of consensus are becoming wide-spread, most notably, variations of Proof of Stake (PoS), e.g., in Tezos, Peercoin, and in newer iterations of Ethereum. PoS consensus is, at its core, a majority-based consensus algorithm that requires the voting participants to stake part of their cryptocurrency holding behind each consensus round. In case irregularities happen, e.g., forks, or conflicts, they are liable to lose their stake. This creates a strong economic incentive for participants to adhere to the rules.

In addition to PoS, there are other exciting proposals, such as Proof of Storage, Proof of Elapsed Time and Proof of Personhood, to name only a few (see more in this survey [14]). In addition to consensus protocols that provide a "proof" of owning some information or property, there are other proposals that embrace stochastic behavior and can even tolerate 51% attacks temporarily [13].

Even though non-PoW consensus solves many of the efficiency issues of PoW blockchains and, in principle, allows for lower latencies, these blockchains still typically suffer from the lack of finality in transactions: their throughput and latency are not determined only by the choice of underlying consensus protocol but also by the economic assumptions the blockchain makes.

3 PERMISSIONED BLOCKCHAINS

Permissioned Blockchains, such as Hyperledger Fabric [2], Corda R3 [3] and IOTA [12], introduce the requirement for a mechanism to associate identities with participants of the blockchain. Identities could be either issued by a trusted third party or by a consortium of the blockchain nodes themselves. Identities allow the use of more traditional, and significantly cheaper, forms of consensus algorithms, typically those from the family of Byzantine Fault Tolerant (BFT) algorithms (e.g., PBFT [5]), to append to the shared data structure. Using BFT consensus has the important benefit that transactions can be committed with *finality*. As a result, these permissioned systems can reach latencies and throughputs more similar to those of traditional databases. It has to be noted, however, that many of these systems run in widely geodistributed setups without the availability of dedicated, high bandwidth, networking, resulting in lower performance than what we typically see in RDBMSs.

In addition to the limitations imposed by networking bottlenecks, many permissioned blockchains inherit other limitations from the PoW blockchain space. They often rely, for instance, on batching a large number of transactions into blocks, which unsurprisingly results in artificially high latencies. These limitations, however, are not fundamental. We have demonstrated, as an example, that by rethinking the block-based processing of Hyperledger Fabric [9], its latency can be lowered from the hundreds of milliseconds to the millisecond range without negatively impacting its throughput or requiring significant changes to its code base. Therefore, it is reasonable to assume that permissioned blockchains that are being deployed in production systems will eventually "shed" the most obvious inefficiencies.

Given the decades-long of research in distributed consensus and fault tolerant systems, it is reasonable to predict that the work of database researchers will not necessarily be most useful in improving consensus but, instead, in enhancing the data management and data processing aspects of these systems. For instance it is an open challenge how to make Smart Contract

[2]Depending on the nature of the transactions in a block, of course, additional checks might be required that ensure that the underlying state remains consistent at all times.

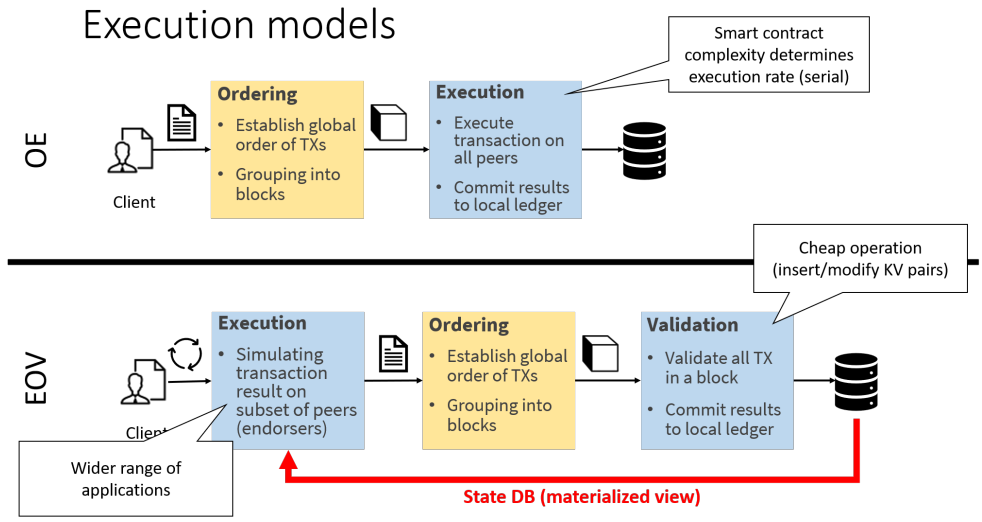

Figure 2: Blockchains can be classified into two groups depending on their smart contract execution model (nomenclature might differ across systems)

execution more efficient and integrated with RDBMs, which, in some cases, might have different schemas at different companies.

4 SMART CONTRACT EXECUTION

Most practical solutions for Smart Contracts (e.g., in Ethereum, Tezos, Fabric, etc.) treat the "contents" of the blockchain as a multi-versioned key-value store. As such, it is possible to think of smart contracts as small programs that can only interact with a key-value interface.

Blockchains adopt one of two execution models: *Order-Execute* (OE), which is similar to active replication in database terminology, and *Execute-Order-Validate* (EOV), which can be thought of as passive replication. As shown in Figure 2, the OE model first establishes the total order of transactions (that is, the order of smart contract invocations), then broadcasts these to all participants, each participant executing the transactions locally, typically in a serial manner. For this approach to work, smart contracts cannot include non-deterministic operations, otherwise the results could diverge. Blockchains using the OE model ensure this by relying on carefully designed DSLs for writing smart contracts.

Systems implementing the EOV model start by simulating (also called executing or endorsing) smart contracts on a subset of the nodes, chosen by a user-defined policy. The results of these executions are recorded in a terms of read/write modifications they would perform on the key-value store (state DB). Once the client receives enough simulation results, and these are all identical, it can submit the transaction for ordering (that is, the R/W modifications and proofs of execution). Once the order of transactions has been established, all participants will receive the list of transactions to record in their ledgers. At this point, the smart contracts are not re-executed but instead their read/write modifications are made directly on the ledger. The benefit of this solution is that it allows executing a large number of smart contracts in parallel but, since all simulations happen on a "view" of the ledger state that can change by the time validation happens, transactions can fail in the validation phase due to data staleness in the state DB in the first phase. In the EOV model it is feasible to use general purpose programming languages, such as Go or Java, to write smart contracts since (most) non-deterministic behavior will be detected in the simulation phase.

5 RECENT RELATED WORK IN DATABASES

In the following, we present a handful of related works published within the database community targeting shortcomings of permissioned blockchains mentioned above (the list is not exhaustive and is intended as a sample of the space).

In an effort to increase transaction processing throughput in the EOV model, Sharma et al. [16], show that by relying on database techniques for concurrency control, it is possible to reorder transactions within a block during the ordering step (i.e., when establishing their total order) in a way that minimizes the number of failing transactions due to R/W conflicts. They implemented their prototype on Fabric and it is one example of how ideas from the database world can be used to improve existing blockchain platforms without fundamental redesigns. Other examples include FastFabric [7], that brings various optimizations, inspired by databases, to Fabric which result in an unprecedented 20,000 ops/s throughput.

There are also proposals which aim to increase throughput and lower latencies by implementing sharding at different levels in permissioned blockchains. CAPER [1], for instance, allows multiple applications to share one blockchain and leverages the fact that they operate on disjoint parts of the dataset to increase the overall throughput. This is achieved by separating the ordering of operations inside an application from that of ordering across applications. In a similar vein, ResilientDB [8] proposes a permissioned blockchain that incorporates a hierarchical consensus protocol design that relies on locality, both in terms of dataset and physical proximity of the nodes, to boost performance.

Other lines of work treat blockchains as a fault-tolerant and highly available storage layer and build traditional database capabilities on top, e.g., as in BlockchainDB [6]. This direction of research provides one possible answer the question of how to bridge the gap between SQL-based processing (and the amassed expertise in this space by developers) and the fairly exotic field of smart contracts. Other work, e.g., ChainifyDB [15], explores a similar

question and provides a different possible answer. Instead of replacing the storage engines of databases, ChainifyDB re-designs the distributed transaction processing protocol and utilizes a blockchain for BFT fault tolerance and transparency/auditing for both local and distributed transactions.

ABSTRACT

To bridge the gap between users and data, numerous text-to-SQL systems have been developed that allow users to pose natural language questions over relational databases. Recently, novel text-to-SQL systems are adopting deep learning methods with very promising results. At the same time, several challenges remain open making this area an active and flourishing field of research and development. To make real progress in building text-to-SQL systems, we need to de-mystify what has been done, understand how and when each approach can be used, and, finally, identify the research challenges ahead of us. The purpose of this tutorial is to present recent advances of deep learning techniques for text-to-SQL translation, and to highlight open problems and new research opportunities for researchers and practitioners in the fields of database systems, natural language processing and deep learning.

1 INTRODUCTION

Data is a prevalent part of every business and scientific domain, but its explosive volume and increasing complexity make data querying and exploration challenging even for experts. In an attempt to bridge the gap between users and data, numerous *text-to-SQL systems* have been implemented, both from industry and academia, that enable users to pose *unstructured queries* (using keywords or free-form text) over relational databases [1, 4, 26]. The recent advances on deep neural networks and the creation of two large datasets for training text-to-SQL systems, have led to the emergence of several, novel, text-to-SQL systems that leverage deep learning techniques. These efforts show very promising results. At the same time, several open challenges make this area an active and flourishing field of research and development. It is high time for a systematic study of these solutions.

In this work, we aim at presenting the recent advances in the field of text-to-SQL systems with the adoption of deep learning techniques. We follow a systematic and structured approach. First, we introduce the text-to-SQL problem, explain and categorize its challenges. Then, we present available benchmarks and explain their advantages and shortcomings. We zoom in on the recent advances of deep learning techniques for text-to-SQL translation. We explain the problems they address and their limitations, and we highlight research opportunities on the intersection of database systems, natural language processing and deep learning.

2 THE TEXT-TO-SQL PROBLEM

The text-to-SQL (also known as NL2SQL) problem can be described as follows: *Given a Natural Language Query (NLQ) on a Relational Database (RDB), produce a SQL query equivalent to the NLQ, which is valid for the said RDB.* Several challenges arise, including: ambiguity, schema linking, vocabulary gap and user mistakes.

Ambiguity of natural language queries is one of the most difficult challenges a text-to-SQL system has to cope with. There are several types of ambiguity [3, 27]. For instance, *lexical ambiguity* refers to the case of a single word with multiple meanings (e.g., *"Paris"* can be a city or a person).

On the other hand, *schema linking* is the problem of understanding which parts of the NLQ refer to which parts of the database schema. *Vocabulary gap* refers to the differences between the vocabulary used by the database and the one used by the user. *User mistakes*, such as syntactical or grammatical errors, make the problem even more challenging.

3 TEXT-TO-SQL LANDSCAPE

The problem of translating user queries to SQL has been a holy grail for the database community for over 30 years [4]. In this section, we will give a very brief overview of the earlier approaches, especially those proposed by the database community.

Early database approaches use (a) inverted indexes (like search engines do) to map query keywords to database elements (relations, attributes and values) and (b) the database schema to find how relations in a query should be joined [18]. These approaches use either a schema graph that represents the database relations as nodes and the joins between them as edges [2, 6, 14, 21, 22, 30, 38] or a tuple graph where the nodes are the database tuples [5, 9, 13, 16]. Answers to a query are defined as sub-graphs over the complete graph, comprising a subset of the relations and tuples that contain the query keywords and are connected by the joins between them. NALIR [17] is the first to use a syntactic parse tree to represent a query and map it to the database schema graph. ATHENA [29] employs an ontology to represent a real-world domain (such as finance) and an ontology-to-database mapping, which describes how the ontology elements are mapped to the database objects. DBPal [33] aims at generating join queries based on the information learnt from domain-specific training data, and requires many training examples with different join paths.

4 AVAILABLE BENCHMARKS

Training a deep learning system is a very data-intensive procedure; large amounts of data are required in order to train an accurate model. For this reason, the availability of datasets is the main fuel for the development of deep learning solutions and the text-to-SQL task is no exception. In this section, we will introduce the two major large-scale benchmarks, explain their characteristics as well as highlight their shortcomings.

WikiSQL [39] is *a large crowd-sourced dataset for developing natural language interfaces for relational databases* released along with the Seq2SQL text-to-SQL system. It contains over 25,000 tables gathered from Wikipedia pages and over 80,000 natural language and SQL question pairs, which were created by crowdsourcing. Note that each of WikiSQL's questions is directed to a single table and not to a relational database. This means that the

proposed task is much simpler than the ultimate goal of creating a natural language interface for relational databases. Additionally, the complexity of the queries is very low. There are no JOIN, GROUP BY, UNION, INTERSECTION or other complex SQL elements. We must also note that that WikiSQL contains multiple errors and ambiguities, which might hinder the performance of any model trained on it.

Spider [37] *is a large-scale complex and cross-domain semantic parsing and text-to-SQL dataset* annotated by 11 Yale students. It contains 200 relational databases from 138 different domains along with over 10,000 natural language questions and over 5,000 complex SQL queries. Its queries range from very simple to very hard, using all the common SQL elements, including nested queries. All the above, along with the fact that it was hand-crafted and re-checked are an indicator of its higher quality, compared to WikiSQL, and has led to the development of very promising systems.

5 NL REPRESENTATION

We will now provide an overview of the state-of-the-art techniques for natural language representation in neural networks. The use of neural networks, which can only handle numerical inputs and not raw text, has led to the adoption of word embeddings for numerical word representation. Additionally, in the past few years, the use of language models is blooming, following their rise as an efficient solution for increased performance in NL tasks.

Word embeddings assume that every unique word has a numerical representation that can be different from all other words and at the same time incorporate useful information about the word, and aim at mapping each word to a multidimensional vector. Besides the brute-force creation of one-hot embeddings, researchers have provided highly efficient techniques to create representations that carry the word's meaning and its relationships with other words. Word2Vec [25], GloVe [28] and WordPiece embeddings [34], to name a few, are some famous word embedding techniques that are used in most, if not all, text-to-sql systems.

Language models are a novel and emerging type of pre-trained neural networks for processing NL, that has been shown to excel in NL tasks during the past few years. Note that language models are not a replacement for word embeddings, given that they are neural networks and they still need a way of transforming words to vectors. The way this type of models are created, is that a very large network (10^8 order of magnitude of parameters) is created and is pre-trained on a very large NL dataset (10^9 order of magnitude of words). The pre-trained model is made available for researchers who can then adapt its inputs and outputs to the specific task they aim to solve, and train it for an additional number of epochs on their task-specific dataset. The result is a much stronger model that can reach state-of-the-art performance even without the need of complex architectures [8]. These models have been able to reach such performances due to the use of a neural network architecture that was recently proposed, called the Transformer [31], which excels at handling NL sequences. Some of the most used language models for the text-to-SQL task are BERT [8] and MT-DNN [20].

6 TEXT-TO-SQL DEEP LEARNING APPROACHES

Deep learning systems following the encoder-decoder architecture can be distinguished in three categories, based on the output of their decoder [7]: (a) sequence-to-sequence approaches, (b) grammar-based approaches, and (c) sketch-based slot-filling approaches. In order to better understand the proposed systems, we will now give a taxonomy of deep learning approaches for text-to-SQL, and highlight the main characteristics as well as the advantages and shortcomings of each neural network architecture. Additionally, we will provide an overview of some key systems in each category.

6.1 Sequence-to-sequence approaches

This category includes systems (e.g. [19, 39]) that produce a sequence of SQL tokens and schema elements as their output, with the resulting sequence being the final SQL query prediction, or a major part of it. Essentially, they attempt to transform an input NLQ sequence to an output SQL sequence. This approach is the simplest, but is also very prone to errors. It was adopted by one of the first deep-learning systems for the task at hand, Seq2SQL [39], but later systems steered away from such approaches. The main drawback of sequence-to-sequence architectures is that they do not take the strict grammatical rules of SQL into account when generating a query. The system attempts to learn how a SQL sequence is generated, but at prediction time there are no measures to safeguard from producing syntactically incorrect queries.

Seq2SQL [39] was one of the first neural networks created specifically for the text-to-SQL task and was based on a previous work focusing on generating logical forms using neural networks [10]. Its authors released the WikiSQL dataset along with it, which signified a new era for deep learning research on the text-to-SQL problem. The system predicts an aggregation function and the column for the SELECT clause as classification tasks and generates the WHERE condition clause using a seq-to-seq network. The latter part of the system is burdened with generating parts of the query that can lead to syntactic errors, which is its major drawback. The network architecture combines LSTM and linear layers, and the GloVe embeddings are used to represent the inputs.

6.2 Grammar-based approaches

Grammar-based approaches (e.g., [7, 11, 12, 32]) are an evolution of sequence-to-sequence approaches, and produce a sequence of grammar rules instead of simple tokens as their output. These grammar rules are instructions that, when applied, can create a SQL query. The advantage over sequence-to-sequence approaches is that the possibility for generating an out-of-place token or a syntactically incorrect query is dramatically reduced. This is the most used approach for generating complex SQL queries.

RAT-SQL [32] is a grammar-based text-to-SQL system focusing on the Spider dataset. It is capable of generating complex SQL queries by incorporating three note-worthy features. First, it creates a *question-contextualized schema graph*, i.e. a graph representing the database schema, its tables and columns, as well as the words of the user's question as nodes and the connections between them as edges. The edges between DB elements are created based on the DB schema and the edges between NLQ words and DB elements are created by performing text matching, which is a form of schema linking. Furthermore, it uses a modified Transformer network for *relation aware self-attention*, that is specifically designed to leverage the information of the created graph and its edges. Finally, it follows a method for SQL

generation as an abstract syntax tree, by generating a sequence of actions for building the tree, as proposed in [36].

IRNet [12] is another grammar-based system capable of generating complex SQL queries. It uses text-matching techniques to address the schema linking challenge similarly but in a simpler form than RAT-SQL. It uses a complex architecture of linear and recurrent neural networks to process the input, in addition to BERT. After processing the input, it creates an SQL query using the same method as RAT-SQL for generating an abstract syntax tree, with the main difference that the output it produces is in an intermediate language called SemQL designed specifically for this system. Its authors argue that it is easier to generate queries in this language and then transform them to SQL.

6.3 Sketch-based slot-filling approaches

Systems following this approach (e.g., [15, 23, 24, 35]) aim at simplifying the difficult task of generating a SQL query, to the easier task of predicting certain parts of the query (e.g. which of the table columns will appear in the SELECT clause), transforming in this way the SQL generation task to a classification task. In this case, we consider a query sketch with a number of empty slots that must be filled and develop neural networks that predict which element is most probable to fill each slot. A basic prerequisite for such approaches is to have a query sketch that, when filled, will be able to capture the NLQ's intention. As a result, this category of systems is rarely able to produce complex SQL queries.

SQLNet [35] was one of the first sketch-based approaches. It was based on the observation that the way Seq2SQL chose to generate the WHERE clause was prone to errors that could be avoided. For this reason, a query sketch, which could cover every SQL query in the WikiSQL dataset, was developed and separate neural networks were created to fill each slot. All slots are filled by considering a classification task (e.g., which of the six possible aggregation functions is appropriate for the given NLQ) except for the condition value slot which was generated by a seq-to-seq network. Note that in this case the aforementioned seq-to-seq network only generates a value and does not handle SQL tokens, meaning that it is not possible to generate syntactically incorrect queries. Another improvement is the introduction of a *column attention* neural mechanism to the network.

HydraNet [23] focuses on the WikiSQL task and follows a sketch-based approach, using the same sketch as SQLNet, but takes advantage of the BERT language model and achieves much better results.

SQLova [15] is another sketch-based approach focusing on the WikiSQL dataset and leveraging the BERT language model, just as the HydraNet system. Their main difference is that while HydraNet aims to use a very simple network after receiving BERT's output, SQLova employs a large and complex network similar to the one used by SQLNet, while also incorporating BERT into the system. What must be noted is that even though SQLova employs a larger and more complex network than HydraNet, it achieves lower accuracy scores on the WikiSQL dataset.

7 CHALLENGES AND RESEARCH OPPORTUNITIES

While a lot of progress has been made on the text-to-SQL problem, several important issues need to be tackled. Here, we outline some of the most challenging ones.

The need for new benchmarks and in-depth system evaluations is pressing and the database community can help complement the work done by benchmarks such as Spider. New benchmarks are needed that can test the query expressivity (i.e., what types of queries a system can answer) as well as the efficiency and scalability of text-to-SQL systems to bigger and more complex data sets.

Furthermore, there is a need for further research on answer validation. Since in many cases users are not familiar with SQL, the question is how they can confirm that the obtained results match the intention of the NLQ. Another challenge is the universality of the solution, i.e. the system's ability to perform equally well for different databases. It is also important to enable natural language queries in languages other than English, which is the main focus of current efforts. Due to the problem's multidisciplinarity, database, ML, and NLP approaches can join forces to push the barrier further.

8 PRESENTERS

George Katsogiannis-Meimarakis is a research assistant at Athena Research Center in Athens, Greece, where he works on the INODE (Intelligent Open Data Exploration) project, focusing on the text-to-SQL problem. He is a graduate of the Department of Informatics and Telecommunications of the National and Kapodistrian University of Athens, where he completed his thesis with the title "Translating Natural Language to SQL using Deep Learning". Currently, he is attending a MSc programme on Data Science and Information Technologies with a specialisation on Artificial Intelligence and Big Data.

Georgia Koutrika is a Research Director at Athena Research Center in Greece. She has more than 15 years of experience in multiple roles at HP Labs, IBM Almaden, and Stanford. Her work focuses on data exploration, recommendations, and data analytics, and has been incorporated in commercial products, described in 14 granted patents and 26 patent applications in the US and worldwide, and published in more than 90 papers in top-tier conferences and journals. She is Editor-in-chief for VLDB Journal, PC chair for VLDB 2023, associate editor for TKDE, and an ACM Distinguished Speaker. *Prior tutorials:* Fairness in Rankings and Recommenders [EDBT20], Recommender Systems [SIGMOD'18, EDBT'18, ICDE'15], Personalization [ICDE'10, ICDE'07, VLDB'05].

ABSTRACT

Data series are a prevalent data type that has attracted lots of interest in recent years. Specifically, there has been an explosive interest towards the analysis of large volumes of data series in many different domains. This is both in businesses (e.g., in mobile applications) and in sciences (e.g., in biology). In this tutorial, we focus on applications that produce massive collections of data series, and we provide the necessary background on data series storage, retrieval and analytics. We look at systems historically used to handle and mine data in the form of data series, as well as at the state of the art data series management systems that were recently proposed. Moreover, we discuss the need for fast similarity search for supporting data mining applications, and describe efficient similarity search techniques, indexes and query processing algorithms. Finally, we look at the gap of modern data series management systems in regards to support for efficient complex analytics, and we argue in favor of the integration of summarizations and indexes in modern data series management systems. We conclude with the challenges and open research problems in this domain.

1 INTRODUCTION

In various scientific and industrial domains analysts are required to measure quantities as they fluctuate over a dimension; these values are commonly called *data series* or *sequences*. The dimension over which data series are ordered depends on the application domain and can have various diverse physical meanings. By far, the most common dimension over which data are ordered is time. In this case, we specifically talk about *time series*. Other applications though, produce series ordered over position (DNA sequences), mass (mass spectrometry) or angle (shapes). In all cases, data have to be captured, stored and analyzed as series rather than individual values.

Applications range from forecasting methods to correlation analysis, summarization, representation methods, sampling, outlier detection and more [6–8, 35, 41]. Moreover, it is not unusual for applications to involve numbers of sequences in the order of hundreds of millions to billions [1, 3]. As a result, analysts are more frequently than ever deluged by the vast amounts of data series that they have to filter, process and understand. Consider for instance, that for several of their analysis tasks, neuroscientists are currently reducing each of their 3,000 point long sequences to a single number (the global average) in order to be able to analyze their huge datasets [1]. In astronomy, there are currently available more than 70TB of spectroscopic sequence data from 200 million sky objects, collected by the Sloan Digital Sky Survey [3], allowing scientists to study the universe. These data have to be processed and analyzed, in order to identify patterns, gain insights, and detect abnormalities.

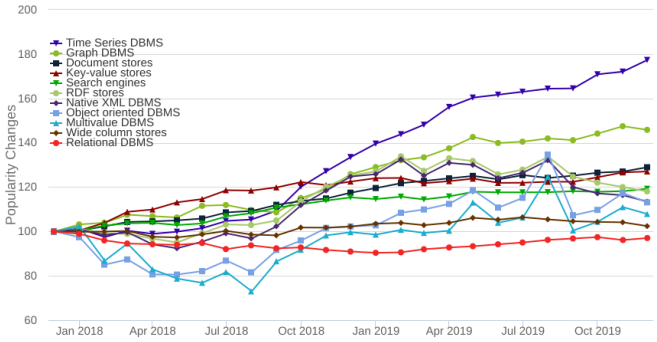

Figure 1: DBMS category popularity change trend [2]

Recent advances in domains such as cloud computing and data centers, IoT and smart cities, self-driving cars and communications, generated a tremendous interest in developing specialized systems able to manage and mine data series. This is evident both by industrial [42] [17] and academic interest [5, 28], as well as through popularity studies [2], where time series management systems gather the most intense interest change over the last two years, as shown in Figure 1.

Our goal is to describe the current state in data series management, including applications, query types and data types, complex analytic algorithms, their components and their implementation in modern data systems. Further on we will explore how modern techniques can be leveraged to speed up complex analytical pipelines, and take a glimpse on how these techniques can be improved by applying machine learning.

2 SEQUENCE MANAGEMENT OVERVIEW

We take a holistic look at the problem of managing and analyzing very large collections of data series, discuss the state-of-the-art and pinpoint the opportunities for optimizing complex query execution.

[Introduction and Foundations] We will start by looking at some foundational aspects of data series management. Those include the *data characteristics*, the query workloads, and the *specialized data structures* used to index sequential data. Data series can be categorized under many dimensions: i.e., the way that data arrive: streaming vs static, the lengths of data series: fixed vs variable length per series, the way that points are sampled: fixed intervals vs variable sampling intervals, and the presence of uncertainty in their values.

In terms of workloads, we will then look at various applications and query patterns that recur in each one of those. Specifically, we will discussing both simple Selection-Projection-Transformation (SPT) queries, where analysts filter based on data properties (e.g.,

*The author is currently at Snowflake Computing

thresholds) or meta-data values, as well as complex data mining (DM) analytics, like clustering, outlier detection and more [39]. We will look at the core component of advanced analytics, which is similarity search, and look at the different flavors of this problem. Those include whole matching vs sub-sequence matching, exact vs approximate similarity search, as well as various distance measures that are commonly used in practice. Finally, we will briefly talk about the different data structure categories that exist, and how they are used to organize and retrieve data in each one of the aforementioned query patterns.

[Complex Analytics] We will dive in analytics like outlier detection [12, 16], frequent pattern mining [51], clustering [29, 52, 54, 63], and classification [13]. Such analytics involve a series of operations that are performed in a pre-processing step (e.g., sliding windows, normalization, interpolation, etc.), as well as operations that are repeated in the context of an iterative algorithm (e.g., similarity search). We will discuss these operations, and pinpoint the ones that can be optimized at the database kernel level. Such operations include sliding windows, normalization, interpolation, and various transformations such as dft that are specific to each algorithm. During the iterative part of these analytics, multiple similarity search operations need to be performed. This is useful for finding series within a given radius from a centroid in clustering, or for identifying distances from a given model in anomaly detection and classification, but also for retrieving patterns in frequent pattern mining. All of these operations can be implemented externally, in the application side. However, since some of them are data-intensive, pruning or incremental computation can significantly improve their performance. For this reason, performing them at the database level can provide large improvements in terms of execution time. We will focus on similarity search as such an example, being a crucial and expensive component of most mining algorithms, and motivate a deep-dive at its characteristics and scalable implementations.

[Systems for Data Series Management] We will then look at current state-of-the-art systems, describing their storage layers and data structures, as well as how they implement the aforementioned data manipulation operations. In particular, we will both look at systems that have been specifically designed to support sequential data, as well as systems that have been adapted to support them.

Specialized systems either utilize custom storage layers, or existing solutions. Common off-the-shelf storage systems are log-structure merge tree (LSM) based engines like RocksDB and LevelDB, and distributed systems such as HBase. Custom engines utilize domain-specific compression, indexing and data partitioning to increase efficiency. They support both simple and complex analytical queries and some of the systems offer encryption and distributed query processing.

Beringei [42] is developed by Facebook, it has a custom in-memory storage engine. It compresses and organizes data in a series per series scheme. CrateDB [15] partitions data in chunks, stores them in a distributed file system, and indexes them using Apache Lucene. InfluxDB [27] uses Time-Structured Merge Trees (LSM tree variant), logging data on disk as they arrive, and periodically merge-sorting overlapping time-stamps. Prometheus [48] is based on the Beringei ideas. QuasarDB [49] utilizes either RocksDB or Hellium [26]. Riak TS [53] supports both LevelDB or Bitcask, which is a custom log structured hash table. Timescale [59] is a Postgres extension. It partitions time series both in groups of series as well as in distinct time segments. It then provides an abstraction of a single table. Finally, various systems such as OpenTSDB [38], Timely [58] (concentrated on security) and Warp10 [62] are developed on top of HBase.

All the aforementioned systems support range scans in the positions, aggregation functions and filtering. Beringei additionally supports correlation queries through a brute force implementation. Crate supports geospatial queries. InfluxDB supports queries like moving averages, prediction, transformations, etc, and Timescale supports gap filling.

[Advanced Techniques for Optimizing Analytics] We will present techniques for speeding up similarity search, which plays a central role in several algorithms related to complex data series analytics, and discuss opportunities for integrating such techniques in modern data series management systems. Previous work on similarity search has proposed the use of spatial indexes such as R-Trees with DFT [4, 50] and DHWT [11]. Specialized indexes are based on domain specific summarizations. Examples include DS-Tree [61], *i*SAX [40, 56], *i*SAX 2.0 [9], *i*SAX2+ [10], ADS+ [68, 68], SFA [55], Coconut [31, 32], and ULISSE [33, 34].

In addition, we will pay particular attention to parallel and distributed solutions for similarity search. These include methods that support both exact and approximate similarity search query answering, and make use of modern hardware (e.g., SIMD, multi-core, multi-socket, GPU) such as ParIS+ [43, 45], Delta-Top-Index [47], MESSI [44], and SING [46], as well as distributed computation (e.g., Spark) such as DPiSAX [65, 66], TARDIS [67], KV-match [64], MVS-match [23], and L-match [22]. These methods are in a much better position than traditional single-node techniques to address the scalability challenges of modern data series analytics applications that have to deal with very large data collections.

Apart from exact indexes, there are also various approximate index structures proposed in the literature. Those include methods based on hashing [30, 57], sketches and grid indexes [14], and kNN-Graphs [36, 37]. Recent studies [20, 21] have compared several data series and high-dimensional similarity search methods under a common framework, revealing multiple promising future research directions, which we will analyze.

[Challenges and Conclusions] Massive data series collections are becoming a reality for virtually every scientific and social domain. This leads to the need of designing and developing general-purpose Data Series Management Systems, able to cope with big data series, that is, very large and fast-changing collections of data series, which can be heterogeneous (i.e., originate from disparate domains and thus exhibit very different characteristics), and which can have uncertainty in their values (e.g., due to inherent errors in the measurements). These systems should have data series indexes and summarizations integrated into their engines, so as to speedup the time-intensive operations of complex analytics pipelines, and support interactive exploration of big data series. To this end, progressive analytics operators would also be very useful [24, 25, 60]. At the same time, the role that deep learning techniques can play should be studied in more detail, especially with regards to similarity search [18, 19] and query optimization. Finally, there is a pressing need for developing data series specific benchmarks [69, 70] able to stress test index structures in a principled way.

Karima Echihabi is an Assistant Professor at Mohammed VI Polytechnic University (UM6P) in Morocco. She is interested in scalable data analytics and data series management and has performed an extensive analysis of data series indexes. She holds a PhD degree from Mohammed V University (Morocco) and the University of Paris (France) and a Masters Degree in Computer Science from the University of Toronto. She has worked as a software engineer in the Windows team at Microsoft, Redmond (USA), and the Query Optimizer team at the IBM Toronto Lab (Canada).

Kostas Zoumpatianos is a Software Engineer at Snowflake Computing. He has been a Marie Curie Fellow at the University of Paris and a postdoctoral researcher at Harvard University. He got his PhD from the University of Trento in topics related to indexing and managing large collections of data series. He also holds a M.Sc. in Information Management and a Dipl.Eng. in Information and Communication Systems Engineering from the University of the Aegean in Greece.

Themis Palpanas is Senior Member of the French University Institute (IUF), a distinction that recognizes excellence across all academic disciplines, and professor of computer science at the University of Paris (France), where he is director of the Data Intelligence Institute of Paris (diiP), and director of the data management group, diNo. He received the BS degree from the National Technical University of Athens, Greece, and the MSc and PhD degrees from the University of Toronto, Canada. His interests include problems related to data science (big data analytics and machine learning applications). He is the author of 9 US patents and 2 French patents. He is the recipient of 3 Best Paper awards, and the IBM Shared University Research (SUR) Award. He is currently serving on the VLDB Endowment Board of Trustees, and as an Editor in Chief for the BDR Journal. He has served as General Chair for VLDB 2013, and in the program committees of all major conferences in the areas of data management and analysis.
